The most pressing need of patients with PSC is for effective medical therapy for the underlying disease. Until this therapy is found, liver transplantation is the only option for patients with advanced PSC. The results of liver transplantation for patients with PSC have steadily improved: the 1- and 5-year survival rates are now reported to be 90–97% and 85–88%, respectively [80,87]. Nevertheless, PSC can recur after liver transplantation, and as the follow-up period lengthens the risk of recurrence seems to increase, although the recurrent disease is typically mild [88,89]. Patients with PSC and CUC who have undergone liver transplantation seem to be at particularly high risk of colon cancer if they have an intact colon. These patients need screening with annual colonoscopy and surveillance biopsies [90].

Conclusions

Primary sclerosing cholangitis is a progressive, chronic cholestatic liver disease of unknown cause. A number of complications can occur and should be considered in the treatment of these patients, the most important being the development of cholangiocarcinoma. Unfortunately, no medical therapy has been of proven benefit for the underlying liver disease. Currently, liver transplantation is the only effective, life-extending option for patients with advanced PSC. Additional basic and clinical research studies are necessary to understand the pathogenesis of PSC in order to develop better medical therapies for this devastating disease.

Multiple choice questions

20.1 There is a strong association between inflammatory bowel disease (IBD) and primary sclerosing cholangitis (PSC). According to the current knowledge, which of the following statements about IBD in PSC patients is true?

a Crohn disease is the predominant form of IBD in PSC patients.
b Approximately 20% of patients with PSC will have concomittant IBD.
c Treatment for underlying IBD will improve the natural history of liver disease.
d Generally, IBD is diagnosed prior to liver disease.
e Patients with PSC and concomittant IBD are at lower risk for developing colon cancer than patients with IBD alone.

20.2 Which of the following therapies have been consistently shown to improve outcomes in patients with PSC?

a Ursodeoxycholic acid at 13–15 mg/kg/day.
b Ursodeoxycholic acid at 20–30 mg/kg/day.
c Liver transplantation.
d Pentoxifylline.
e Corticosteroids.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 21
Primary Biliary Cirrhosis

Stephen P. James

Division of Digestive Diseases and Nutrition, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD, USA

Key concepts

- Primary biliary cirrhosis (PBC) is an uncommon condition that primarily affects middle-aged women throughout the world.
- Most patients are identified in an asymptomatic phase, but they gradually develop symptoms of pruritus, fatigue, and symptoms of associated syndromes or end-stage liver disease.
- Typical laboratory findings are elevations of alkaline phosphatase levels, modest elevations of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels, increases in total cholesterol level, and positive antimitochondrial antibody test results.
- The characteristic pathologic features of PBC are destruction and dropout of intrahepatic bile ducts, chronic portal tract inflammation, cholestasis, and progressive fibrosis, cirrhosis, and portal hypertension.
- About one half of patients have associated autoimmune syndromes, most commonly sicca syndrome, thyroid disease, arthritis, and scleroderma or CREST syndrome (calcinosis, Raynaud phenomenon, esophageal motility disorders, sclerodactyly, and telangiectasia).
- Treatment options include ursodeoxycholic acid (UDCA), cholestyramine, replacement of fat-soluble vitamins, management of complications of portal hypertension, and liver transplantation for end-stage disease.

Primary biliary cirrhosis (PBC) is a chronic, progressive disease of unknown etiology characterized by necrosis of the intrahepatic bile ducts that leads to chronic cholestasis, portal fibrosis, and cirrhosis. The disease is characterized by female predominance, characteristic antimitochondrial antibodies (AMAs), associated autoimmune syndromes, and chronic inflammatory histologic features that have led to its classification as an autoimmune syndrome. Although the first descriptions of PBC appeared in the 19th century [1], wider recognition of the disease did not occur until the publication of reviews in the 20th century that clarified the clinical characteristics of this distinct syndrome [2,3]. Other important developments were the discovery of AMAs [4], which led not only to an important diagnostic test but also to research into the pathogenesis of PBC that continues to the present time. Another advance was the introduction of cholestyramine to treat intractable pruritus and, more recently, ursodeoxycholic acid (UDCA) treatment to improve the biochemical features and to retard the progression of disease. PBC is now frequently recognized in asymptomatic patients, who may have a slow and insidious disease course. Nonetheless, most patients ultimately develop symptoms and have progressive disease. For those who develop end-stage liver disease, liver transplantation is the only therapeutic option.

Epidemiology

Primary biliary cirrhosis appears to occur throughout the world and in all races; however, there is uneven geographic distribution (Box 21.1). Studies of the epidemiology of PBC are hampered by methodologic problems, including variation in case definition and ascertainment and absence of noninvasive markers of high sensitivity and specificity. The estimates of incidence and prevalence vary widely, from 2 to 24 per million and 19 to 240 per million population, respectively, with the highest incidence and prevalence reported in northern Europe [5–8]. Here the prevalence appears to be increasing, although the relative contributions of methodologic differences, increased awareness, or a true increase in prevalence are uncertain. The median age of diagnosis is approximately 50 years, with a broad range of diagnosis from approximately 20 to 90 years, and 90% of patients are women. Within regions of high prevalence, clustering of cases has been observed, suggesting a contribution of environmental factors to the

Box 21.1 Epidemiology and genetics of primary biliary cirrhosis.

• Incidence:	2–24/1,000,000
• Prevalence:	19–240/1,000,000
• Median age (range):	50 years (20–90 years)
• Female:	90%
• Environmental risk factors:	Smoking, environmental toxins?
• Associated autoimmune syndromes:	50%
• Familial clustering:	1–2%
• Twin concordance rate:	Monozygotic 0.63/dizygotic 0.0
• Genome-wide association study:	HLA class II, IL12A, IL12RB2

HLA, human leucocyte antigen.

pathogenesis [7]. Clustering of cases near superfund toxic waste sites in the United States suggests a role for environmental toxins [9]. Case–control studies have searched for risk factors with inconsistent results: In the United Kingdom, an association with smoking was found, while in the United States an association with non-PBC autoimmune disease, genitourinary tract infections, and previous tonsillectomy was identified [10].

Genetics

There are multiple lines of evidence indicating that genetic susceptibility plays a role in the pathogenesis of PBC (Box 24.1). This evidence includes striking female predominance, familial clustering, association with other autoimmune syndromes, concordance in twin studies, and the results of genome-wide association studies [11–13]. The striking female predominance of PBC obviously links the pathogenesis of the disease to the genetic basis of sex determination, as for many other autoimmune diseases. However, the specific causal mechanisms are currently unclear. Among candidate mechanisms are direct effects of female hormones, immunologic differences between males and females, and increased monosomy X in women with PBC. A commonly recognized feature of diseases that are thought to have an autoimmune basis is that different autoimmune diseases tend to occur with increased frequency within families, which forms the basis for the hypothesis that the tendency to autoimmunity is based in part on shared genetic traits. PBC has long been associated with a variety of autoimmune syndromes both in individual patients and within families of patients with PBC (see subsequent text). One recent population-based study confirmed that autoimmune conditions are found in approximately one half of patients and that the prevalence of autoimmune disease in first-degree family members is 14% [14], consistent with the thesis that PBC shares common genetic susceptibility traits with other autoimmune conditions. Many case series and epidemiologic studies have noted the familial tendency of PBC, which although uncommon, appears to be increased compared to the general population. The estimates of familial prevalence have ranged from approximately 1% to a high of 6.4%, with estimates in the largest studies being in the 1–2% range. These estimates are similar in different geographic regions, including England, the United States, Sweden, Italy, and Japan. The familial occurrence of PBC also supports a genetic basis, although, of course, environmental etiologies also cause familial clustering.

One of the important traditional methods to evaluate the heritability of disease is to determine concordance rates in twins. In two older reports of single twin pairs, one was reported to be concordant and the other discordant. More recently, an international study evaluated 16 twin pairs with PBC, of whom eight were confirmed to be monozygotic [13]. The concordance rate was 0.63 in monozygotic twins and 0.0 in dizygotic twins. The concordance rates were potentially subject to bias because cases were collected from referral centers and the internet, which differs from traditional population-based twin registry studies. Nonetheless, the high concordance rate for monozygotic twins suggests an important contribution of genetic susceptibility to PBC.

The first genome-wide association study of PBC performed in 536 Canadian and US subjects using a 373,400 single nucleotide polymorphism (SNP) platform identified significant associations in loci in the human leucocyte antigen (HLA) class II region and the interleukin 12A (IL12A) and IL12RB2 regions, as well as lower statistical significance for an association with two other loci implicated in immunologic processes, STAT4 and CTLA4 [12]. The association of PBC with HLA class II alleles confirms and clarifies earlier candidate gene studies, and is consistent with the general association of autoimmune diseases with the HLA class II region. The unexpected association with IL12A and IL12RB2 suggests that abnormal signaling through the IL12 cytokine pathway may play a role in pathogenesis. These observations are particularly intriguing because other lines of evidence implicate the IL12 pathway in autoimmunity and host defense. IL12 represents a potential pathway that could be a target of therapy.

Symptoms

In the past, patients were frequently diagnosed with initial symptoms of fatigue, pruritus, and jaundice, and

Box 21.2 Symptoms and physical findings in primary biliary cirrhosis.

Symptoms
- Asymptomatic (most common)
- Fatigue
- Pruritus
- Symptoms of associated syndromes (e.g., sicca, arthritis, Raynaud disease)

Physical findings
- Hepatomegaly
- Splenomegaly
- Jaundice
- Xanthoma
- Increased skin pigmentation, excoriations
- End stage: ascites, edema, wasting, encephalopathy

physical findings such as hepatomegaly. However, currently, most patients are diagnosed with PBC at an early stage of disease before the onset of any specific symptoms or physical findings (Box 21.2). The reasons for the shift to early, asymptomatic diagnosis include the widespread use of screening laboratory studies including serum alkaline phosphatase, increased physician awareness of the features of the disease, the ready availability of AMA tests, and, finally, recognition that the disease does in fact have a long, presymptomatic phase in which a specific diagnosis is readily accomplished [15,16]. Most patients, if followed up long enough, eventually develop symptoms that are attributed to the disease.

In order of frequency, the most common symptoms of PBC are fatigue, pruritus, and jaundice. Occasionally, patients have right upper quadrant abdominal pain. Many other symptoms may be present, including that of associated syndromes, such as dry mouth and eyes, Raynaud phenomenon, and arthralgias. Occasionally, patients are brought to attention because of xanthoma, xanthelasma, increasing skin pigmentation, or fracture. Much less commonly, the presenting symptoms may be due to decompensated liver disease, including ascites, edema, bleeding, or encephalopathy.

Fatigue may have an insidious onset and is often the dominant symptom, significantly diminishing the quality of life of patients [17]. It is not uncommon for patients to be initially misdiagnosed with other conditions in which fatigue is prominent, including depression, chronic fatigue syndrome, fibromyalgia, or thyroid disease, which may be associated with PBC. The cause of fatigue in PBC is unclear, but it has been suggested to have a central etiology [18], although other causes might exist, such as mechanisms related to chronic inflammation. Pruritus is also a significant, sometimes debilitating, symptom in PBC, occurring much earlier in the course of the disease than in other more common forms of liver disease, in which it is commonly associated with hepatic decompensation. As in other cholestatic liver diseases, the pathogenic mechanisms of pruritus are unknown [19].

Physical findings

Early in the course of the disease, physical abnormalities are often completely absent. As the disease progresses, the most common physical findings are hepatomegaly, splenomegaly, excoriations, skin hyperpigmentation, jaundice, and xanthelasma [20]. Late in the course of the disease, physical findings of decompensated liver disease may be present, including ascites, edema, palmar erythema, spider nevi, muscle wasting, and signs of encephalopathy. Uncommonly, patients have physical findings of associated syndromes such as xerophthalmia and xerostomia. Very rarely, patients have Kayser–Fleischer rings because of copper retention.

Routine laboratory tests

The routine laboratory abnormalities in PBC are typical of chronic cholestatic syndromes and chronic liver disease (Box 21.3). Almost invariably, the serum alkaline phosphatase and γ-glutamyltransferase levels are elevated, typically approximately 2–2.5 times the upper limit of normal at the time of diagnosis [21]. Serum alkaline phosphatase levels often remain relatively stable and do not closely correlate with the stage or progression of disease. Rarely, patients have been identified with normal alkaline

Box 21.3 Characteristic laboratory abnormalities in primary biliary cirrhosis.

• Alkaline phosphatase:	2–2.5 times upper limit of normal
• AST, ALT:	<5 times upper limit of normal
• Bilirubin:	Normal in early phase, progressive rise late phase
• Cholesterol, HDL cholesterol:	Elevated
• Serum IgM:	Elevated
• Antimitochondrial antibodies:	Present titer >1 : 40 in 95% of patients
• Other autoantibodies:	ANA, RF, SMA, and others commonly found

ALT, alanine aminotransferase; ANA, antinuclear antibody; AST, aspartate aminotransferase; HDL, high-density lipoprotein; IgM, immunoglobulin M; RF, rheumatoid factor; SMA, smooth muscle antibody.

phosphatase levels on the basis of positive serum AMAs and typical liver histologic abnormalities, presumably at a very early stage of disease [22]. Serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels are only modestly elevated, usually less than five times the upper limit of normal, and their levels also do not correlate with stage of disease. Serum bilirubin levels are typically normal early in disease and rise with disease progression. Serum bilirubin is a major component of the prognostic indices for end-stage PBC [23]. In common with other cholestatic syndromes, serum lipid levels are abnormal in PBC. Patients occasionally have striking hypercholesterolemia, which correlates with the physical finding of xanthomas. However, there is a corresponding increase in high-density lipoprotein cholesterol, which may explain why patients with PBC seem to have only an average risk for cardiovascular complications [24]. In addition, although low-density lipoprotein (LDL) levels are also increased, a subfraction, lipoprotein X, is present that may inhibit the atherogenic properties of LDL lipoproteins [25]. Late in the course of disease serum cholesterol levels may decline along with other synthetic functions during end-stage liver failure, including a fall in serum albumin level and rise in prothrombin time, which may be exacerbated by malabsorption of fat-soluble vitamins such as vitamin K. Because of the overwhelming fatigue experienced by some patients, concern may arise because of anemia in patients with PBC, which is similar to the anemia of chronic disease. Rarely patients are identified with autoimmune Coombs-positive hemolytic anemia [26], which may confound the interpretation of serum bilirubin levels, or pernicious anemia [27]. Thrombocytopenia, if present, is usually a manifestation of portal hypertension, although rare cases of idiopathic thrombocytopenic purpura have been associated with PBC. PBC, like other cholestatic syndromes, leads to copper retention, resulting in raised urinary copper and serum ceruloplasmin levels [28]. Other laboratory abnormalities may be present as a result of associated autoimmune syndromes. Patients with PBC typically have elevated serum immunoglobulin M (IgM), sometimes to striking levels [3], some of which may be monomeric rather than pentameric [29].

Autoantibodies

The presence of autoantibodies, particularly AMAs, is a clinical hallmark and important diagnostic feature of PBC, first reported as a distinguishing characteristic compared with other forms of chronic cholestasis by Doniach et al. in 1966 [4]. Since that time, extensive studies have refined diagnostic testing for AMAs, which are found in up to 95% of patients [30]. Furthermore, AMAs have been a major theme in research on the pathogenesis of PBC. Initial studies defined AMAs by indirect tissue immunofluorescence. Subsequent studies showed that serum autoantibodies react with trypsin-sensitive components of the inner mitochondrial membrane, the so-called M2 antigen, in a nontissue-specific manner with broad cross-reactivity to antigens present in many species, including both eukaryotes and prokaryotes such as *Escherichia coli* [31,32]. Other mitochondrial antigens, arbitrarily designated M1 to M9 [33], have been previously described as the target of PBC autoantibodies. Some, such as M1, represent anticardiolipin of syphilis and are unrelated to PBC. Others, such as M4, M8, and M9, were previously described as being PBC specific; however, the specificity of these antigens has been questioned and they are not routinely used for diagnosis [34].

Cloning and characterization of the M2 autoantigens recognized by PBC sera has led to the identification of four major components of a family of mitochondrial antigens that contain lipoic acid and are members of the 2-oxoacid dehydrogenase (2-OAD) multimeric enzyme complexes [35,36]. These include the pyruvate dehydrogenase complex (PDC), 2-oxoglutarate dehydrogenase complex (OGDC), and branched-chain 2-oxoacid dehydrogenase complex (BCOADC). All the members of this family play important roles in cellular metabolism. Approximately 95% of sera of patients with PBC react with both the PDC core dihydrolipoamide acetyl transferase (E2) structure and the E3-binding protein (E3BP) by immunoblot or enzyme-linked immunosorbent assay (ELISA), these two subunits being completely cross-reactive. PBC sera also react, at a much lower frequency, with other components of PDC, including the E1α and E1β subunits. Sera also react with the E2 subunits of OGDC and BCOADC with a frequency of 90% and 50%, respectively. Considerable information is available on the B-cell epitopes, and they all appear to be defined by conformational structures contained within the lipoic acid-binding domains. AMAs block the enzymatic activity of 2-OAD complexes in vitro [37,38]; however, it is not known whether PBC autoantibodies have in vivo activity against these enzymes.

Even though serum IgM may be elevated to striking levels, AMAs are present in all three immunoglobulin classes, including secretory IgA, and no consistent clinical correlations have been reported with different immunoglobulin classes of reactivity.

Although there has been considerable progress in the definition of AMAs in PBC, the literature consistently contains patients who are negative for AMAs but otherwise have the same typical clinical, biochemical, and liver histologic features of the disease [39,40]. Some patients are found to be positive for AMAs when the more sensitive and specific tests available in research

laboratories are used [41]. Some studies have reported a high frequency of antinuclear antibodies (ANAs) in this group of patients and have referred to this condition as autoimmune cholangiopathy [39,42]. However, because the clinical features of the two conditions overlap considerably [43], it is unclear whether these are separate conditions or variants of the same condition with differing autoantibody patterns. The views on these conditions are more than semantic. The absence of AMAs in patients with PBC-like syndromes has been used as an argument that AMAs are only an epiphenomenon, rather than pathogenic. However, this argument would be dismissed if future research on "autoimmune cholangiopathy" identifies a different etiologic basis compared to AMA-positive PBC.

Other autoantibodies are frequently found in patients with PBC. Approximately 25% of patients have ANAs with a "nuclear rim" and "multiple nuclear dots," which correlate with autoantibodies recognizing gp210, nucleoporin 62, and nuclear body protein sp100. These ANAs are relatively specific for PBC [44]. Other autoantibodies that have been reported in patients with PBC include those connected with associated autoimmune syndromes (see below) such as antithyroid autoantibodies, rheumatoid factor, and antibodies found in Sjögren syndrome, as well as a long list of other antibodies of unknown significance, including antilymphocytotoxic antibodies, anti-acetylcholine receptor antibodies, antiplatelet antibodies, antihistone antibodies, anticentromere antibodies, and antibodies against carbonic anhydrase II, α-enolase, lactoferrin, and smooth muscles.

Historically, AMA has been detected by indirect immunofluorescence on rat tissue sections showing a cytoplasmic granular pattern of the mitochondria. False-positive reactions may occur because of the presence of other serologic cross-reactions, such as those with anticardiolipin [45]. AMAs may be detected by immunoblot of submitochondrial particle preparations such as antigens or by ELISA using recombinant antigens for PDC-E2, BCOADC-E2, and OADC-E2. It appears that immunoblot and ELISA methods have higher sensitivity and specificity for PBC than immunofluorescence tests. Currently, clinical AMA testing is usually performed by ELISA directed against E2 antigens. AMAs may be found in patients with other syndromes, particularly overlap syndromes and autoimmune hepatitis (AIH), but also occasionally in primary sclerosing cholangitis (PSC) and drug-induced liver disease.

Pathology

The gross pathologic features of PBC are not specific for the disease and include bile staining of the liver, enlargement, fine nodularity, and, eventually, a grossly cirrhotic appearance. The extrahepatic biliary system is normal, with the exception of an increased prevalence of gallstones. Enlarged lymph nodes may be found in the porta hepatis, along with other intra-abdominal sites, and these do not have any characteristic features other than the occasional appearance of granulomas. Enlargement of the spleen, along with other pathologic features of portal hypertension, appear later in the course of the disease.

Characteristic microscopic hepatic abnormalities include portal inflammation with the destruction and disappearance of intrahepatic bile ducts, abnormal bile duct proliferation, fibrosis, and cirrhosis (Fig. 21.1). Although, overall, the disease is characterized by progressive destruction and loss of bile ducts with portal fibrosis progressing to cirrhosis, in the early and intermediate stages of the disease the process is not uniformly distributed throughout the liver. There is therefore potential for significant sampling error when performing needle biopsy of the liver. Two similar staging systems, as proposed by Ludwig et al. [46] and Scheuer [47], have been widely adopted to describe the liver histologic lesions. Because of the focal nature of the lesions, multiple stages – sometimes all four histologic stages – of lesions have occasionally been identified in the same liver.

In stage 1, which is thought to represent the earliest pathologic lesions of the disease, there is destruction of the intrahepatic septal and interlobular bile ducts, which can range in size up to 100 μm in diameter. This stage has been called the *portal stage* in the Ludwig system and the *florid duct lesion stage* in the Scheuer system. Portal lesions are characterized by damage to the bile ducts, which may be associated with vacuolated or pyknotic biliary epithelial cells and even frank rupture or disappearance of portions of the duct. The duct is typically surrounded by a dense lymphocytic infiltrate, which may also include histiocytes, plasma cells, eosinophils, and, occasionally, true epithelioid giant cells. Neutrophils are absent or infrequent, and periductular fibrosis, as found in PSC and biliary obstruction, is absent. Inflammation does not extend beyond the portal tracts, and hepatocyte injury is minimal.

The second stage of the disease is characterized by the appearance of abnormal proliferating bile ductules without duct lumens, the disappearance of normal bile ducts, and extension of the portal inflammation into the hepatic parenchyma. Typically, there is limited piecemeal necrosis of periportal hepatocytes with surrounding foamy macrophages and limited fibrosis confined to the portal tract.

In stage 3, there is a substantial increase in fibrosis, and fibrous septa may link portal tracts. Lymphocytic infiltrates remain in the portal tracts, but bile ducts may be difficult to identify or completely absent.

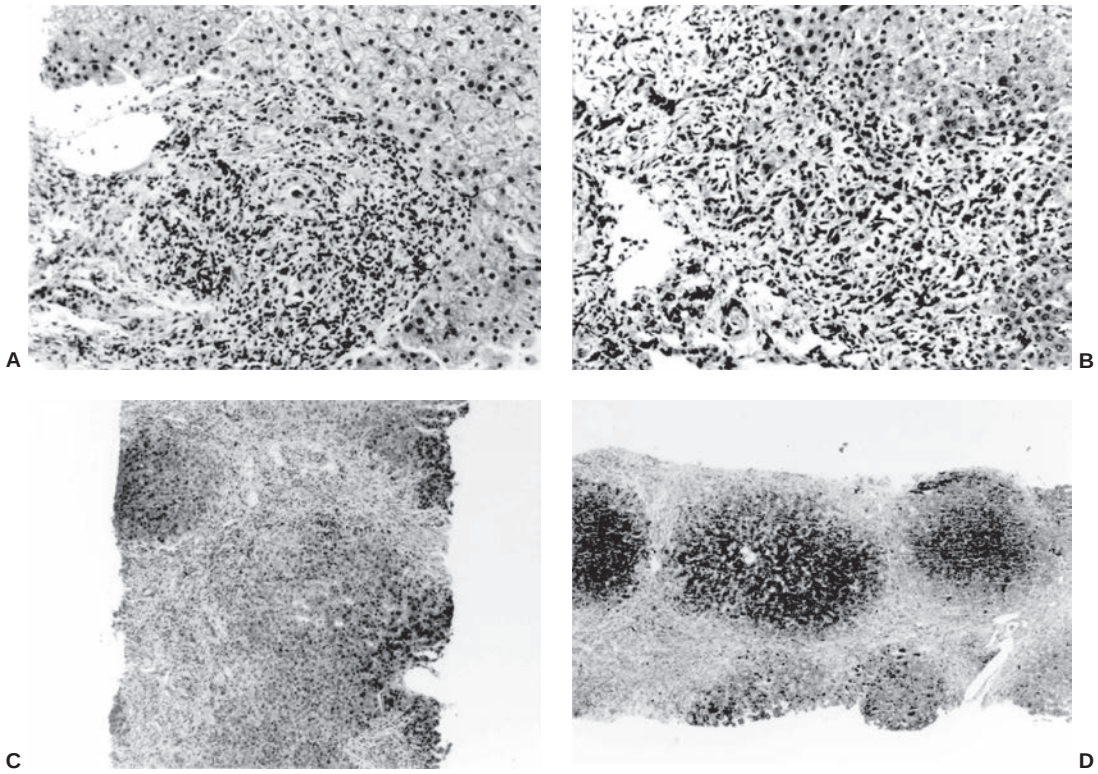

Figure 21.1 Liver histologic abnormalities in primary biliary cirrhosis. (A) Stage 1: a damaged bile duct is surrounded by chronic inflammatory cells. (B) Stage 2: proliferation of abnormal bile ductules and chronic inflammation of portal tract. (C) Stage 3: portal fibrosis. (D) Stage 4: cirrhosis.

Stage 4 is characterized by frank cirrhosis with regenerative nodules.

Other histologic abnormalities may be found that are not specific for PBC, including Mallory bodies and deposition of copper, which are found in other cholestatic liver diseases.

Immunologic techniques have been used to further define the histologic lesions of PBC [35,48,49]. The lymphocytic portal infiltrates primarily contain CD4+ T cells, although CD8+ T cells predominate in areas of piecemeal necrosis, and their levels may be increased in early stages of the disease. The infiltrating CD4+ T cells have a CD45RO high phenotype characteristic of memory T cells. The bile duct epithelium contains small numbers of intraepithelial lymphocytes, potentially analogous to those found in the intestinal epithelium, that are predominantly CD8+ T cells and are found in PBC bile duct lesions. Natural killer T (NKT) cells represent only approximately 5% of lymphoid cells in liver infiltrates. Infiltrates also contain B cells, plasma cells, eosinophils, macrophages, and dendritic cells. The cytokine profile of PBC tissue is predominantly characterized by expression of interferon-γ, but interleukins IL2, IL5, IL6, and transforming growth factor-β (TGF-β) are also expressed, so that PBC does not have a clear T_H1 or T_H2 profile.

A number of bile duct abnormalities have been defined using immunologic techniques. Bile ducts in patients with PBC have aberrant expression of the AMA antigen PDC-E2 on the cell surface [50]. In addition, major histocompatibility complex (MHC) class II antigens, which are usually not expressed on normal bile ducts, have increased expression on bile ducts in PBC. Other molecules have also been noted to have increased expression on bile duct cells in PBC, including intercellular adhesion molecule 1 (ICAM-1), vascular cell adhesion molecule 1 (VCAM-1), the cytokines IL6 and tumor necrosis factor-α (TNF-α), and the chemotactic molecule fractalkine [51].

Associated syndromes

Numerous case reports and descriptions of patient cohorts have noted the association of PBC with other diseases, particularly autoimmune syndromes (Box 21.4). There are no extensive epidemiologic studies with case–controls to evaluate the true prevalence of autoimmune syndromes in PBC, and many of the reports are likely subject to referral and reporting bias. In one study of a geographically based PBC cohort, the most commonly identified associated conditions were Sjögren syndrome (25%), Raynaud phenomenon (24%), autoimmune

thyroid disease (23%), rheumatoid arthritis (17%), CREST syndrome (scleroderma and calcinosis, Raynaud phenomenon, esophageal motility disorders, sclerodactyly, and telangiectasia) (8%), and pernicious anemia (4%) [52]. The overall prevalence of autoimmune conditions in patients with PBC was 53% in this study. The association with Sjögren syndrome, arthritis, Raynaud phenomenon, and autoimmune thyroid disease is the most commonly reported associated syndrome in other reports on autoimmunity in PBC [53–56]. The most common thyroid disease is Hashimoto thyroiditis, but rarely Graves disease or hyperthyroidism is found. Antithyroid antibodies are frequently found in patients with PBC without clinical evidence of thyroid dysfunction. Sicca symptoms are relatively common in PBC, but only a minority of patients have anti-Ro or anti-La antibodies typical of primary Sjögren syndrome. Similarly, although arthralgia is common in PBC patients, only a minority fulfill American Rheumatism Association criteria for definite or probable rheumatoid arthritis. Patients having manifestations of scleroderma most often have the limited CREST variant of this disease. Among patients with PBC who have one autoimmune condition, most also have a second one.

Overlap syndromes

Patients with PBC may have features that overlap significantly with those of AIH [57,58]. Positive AMAs, high serum alkaline phosphatase levels, and histologic bile duct lesions are sometimes found in patients with otherwise typical features of AIH. Conversely, patients with PBC may have significant hepatocyte injury and high titer positive ANAs. Additional heterogeneity is represented by patients with typical clinical features of PBC except for the absence of AMAs, and some of these patients have high ANA levels. This latter syndrome has been called *autoimmune cholangiopathy* and is otherwise indistinguishable from PBC. Individual reports have indicated the presence of features of AIH in 2–19% of patients with PBC. Overlap features may be present at the time of initial diagnosis or appear subsequently. Different scoring systems have been proposed for the diagnosis of overlap, but further definition of overlap syndromes will depend on new specific information on the etiopathogenesis of these various conditions to differentiate whether overlap represents a spectrum of one disease or the simultaneous presence of two different conditions. The diagnosis of overlap syndrome is not purely academic because there are different treatment recommendations for AIH and PBC. In patients with significant features of AIH in addition to PBC, a treatment trial with corticosteroids and/or azathioprine should be entertained in addition to treatment with UDCA [59] (see below).

Complications

The early course of most patients with PBC who are not asymptomatic is marked by fatigue, pruritus, and, occasionally, symptoms or complications of associated conditions; however, patients often continue to have a good functional status. Sometimes, the symptoms of pruritus and fatigue may be quite disabling and emotionally disturbing to patients. Interestingly, depression does not seem to be a common diagnosis in PBC because there are alternative explanations for mood alterations. One small trial of an antidepressant in patients with fatigue found no benefit [60].

Late in the course of the disease, the major complications are related to chronic cholestasis, portal hypertension, and cirrhosis (Box 21.5). Chronic cholestasis is

Box 21.5 Complications of primary biliary cirrhosis.

- Emotional disturbance: debilitating pruritus and fatigue
- Metabolic bone disease
- Portal hypertension: ascites, edema, encephalopathy, varices
- Malabsorption: fat-soluble vitamins
- Hyperlipidemia
- Hepatocellular carcinoma
- Asymptomatic urinary tract infection
- Distal renal tubular acidosis

associated with metabolic bone disease [61], which may cause painful fractures. The etiology of bone disease appears to be primarily the direct effects of cholestasis on bone, rather than malabsorption of vitamin D. The full spectrum of complications of portal hypertension is found in patients with PBC, often before the appearance of stage IV cirrhosis on liver biopsy specimens [62]. Historically, complications due to portal hypertension were common either as presenting symptoms or shortly after diagnosis, but these are now uncommon. There do not seem to be any unique features related to variceal bleeding, ascites, edema, encephalopathy, or wasting due to end-stage liver disease, with the possible exception of the additional contribution of malabsorption due to chronic cholestasis. Hyperlipidemia is a manifestation of chronic cholestasis, although the specific lipid abnormalities do not provide independent additional risk factors for cardiovascular disease. Although hepatocellular carcinoma has been reported in PBC, it may not be as common as other forms of cirrhosis [63,64]. There have been reports of an increase in breast cancer in women with PBC, but this has not been confirmed by others. An increased frequency of asymptomatic urinary tract infection has been reported in PBC, however the significance of this finding is unclear. Distal renal tubular acidosis has been reported in 30–60% of patients with PBC.

Pathogenesis

The etiology and pathogenesis of PBC are unknown. A variety of etiologies have been postulated, including infectious causes; however, the most common view is that the disease falls within the category of autoimmune diseases [35]. The rationale for this thesis is that multiple features of PBC support a primary autoimmune pathogenesis, including: (i) the histologic features of bile duct lesions; (ii) characteristic autoantibodies; (iii) strong female predominance; (iv) an association, although weak, with MHC class II genes; (v) the frequent association with other autoimmune syndromes; and (vi) the presence of similar bile duct lesions in other immunologically mediated diseases, namely, graft-versus-host disease (GVHD), both in humans and animal models, and the recurrence of PBC in liver allografts. One feature that unfortunately sets PBC apart from other autoimmune diseases is the apparent lack of benefit of immunosuppressive therapies. Until recently, the lack of robust animal models for the disease has impaired rapid exploration of novel hypotheses, and patient-based research is hindered by the indolent and slowly progressive nature of the disease. Much current research into the pathogenesis of PBC parallels that of other autoimmune diseases, including a search for environmental triggers, a genetic basis of susceptibility, and details about the effector mechanisms responsible for the primary bile duct lesions. This will hopefully lead to the identification of new therapeutic targets.

AMAs are the most distinctive specific immunologic characteristic of PBC and, not surprisingly, have been the focus of numerous studies. As noted in the preceding text, AMAs can inhibit the enzymatic activity of their target antigens in vitro, but it is not known whether this occurs in vivo. Autoantibodies may potentially cause tissue injury, regardless of whether they alter the function of their target antigen; therefore, this particular issue does not resolve the question of the pathogenicity of AMAs. AMAs fix complement, although remarkably little attention has been directed at determining whether there is specific deposition of AMAs at sites of tissue injury in the liver. An intriguing piece of evidence suggesting a potential pathogenic role for AMAs in liver disease is the association of neonatal hepatitis in two cases with the presence of AMAs of maternal origin, which resolved on disappearance of the AMAs [65]. Another observation is that patients with GVHD have histologic lesions of chronic nonsuppurative destructive cholangitis [66] that has features similar to those of PBC. This disease is mediated by the recognition of alloantigens by T cells, and the disease can be recapitulated in animal models, including the production of bile duct lesions [67]. Although this model is useful in elucidating the specific immunologic mechanisms present in GVHD, it is as yet unknown whether the lessons learned extend to PBC. PBC may recur [68] in approximately 20–30% of patients within 10 years of orthotopic liver transplantation, characterized by typical bile duct lesions and persistence of AMAs. Recurrent PBC following liver transplantation potentially affords an opportunity to study pathogenic mechanisms in the liver prospectively from the onset of disease. However, the mechanisms of recurrence per se are no less complicated to dissect than the primary disease itself, and as yet no new insights into pathogenesis have emerged from studies of recurrent PBC.

Considerable information has emerged to define the nature of both the B-cell and T-cell responses to the autoantigens recognized by AMAs. There is overlap between epitopes recognized by B cells and both CD4+ T cells and CD8+ T cells, and there is enrichment for specific antigen-reactive clones within the liver [69]. Cytokines produced in liver infiltrates are dominated by T_H1 cytokines but also contain T_H2 cytokines, providing a mixed picture. Furthermore, the expression of adhesion molecules and chemokines, such as fractalkine, by biliary epithelial cells provides further details on potential mediators involved in the formation of inflammatory lesions within the liver. However, the precise sequence of events and specific effector mechanisms contributing to bile duct injury are as yet undefined, and the possibility that the

inflammatory lesions are entirely secondary in nature has not been eliminated.

Recently there has been progress in developing animal models to study the pathogenesis of PBC. These models include completely unrelated, genetically modified strains with systemic diseases that were created for other purposes, which spontaneously developed liver injury, and animals that have been immunized with PBC relevant antigens with the intent of inducing liver injury. Among the former models, mice with modified TGF-β signaling [70], specific modified strains of the nonobese diabetic (NOD) mouse [71], the Scurfy mouse, and $Ae2_{a,b}$-deficient mice lacking the $CL^-/HCO3^-$ anion exchanger [72] have all been observed to have a number of features of PBC. These features include serum AMA, portal lymphoid infiltrates, and bile duct injury. Some of these animals have widespread systemic immunologically mediated injury and autoimmunity, including injury to the gut. By analogy with animal research in the field of inflammatory bowel disease, although animals with spontaneous PBC-like abnormalities may or may not provide insight into the genetic or environmental causes of PBC, they may be extremely useful in studying detailed pathologic pathways and mechanisms in PBC that could lead to new targets for diagnosis and treatment. In contrast to the spontaneous models, there have been many previous attempts to purposefully immunize animals to produce specific liver diseases, including PBC. Recently, immunization approaches using lipoic acid, the cofactor of PDC-E2, have produced histologic lesions and AMA [73], lending support to the hypothesis that specific xenobiotics could trigger PBC.

The mechanisms that trigger the immunologic abnormalities observed in PBC remain a matter of speculation. The highly conserved sequences in antigens are recognized by AMAs across species, including prokaryotes, suggesting that molecular mimicry could play a role in triggering autoimmune responses. Multiple microbes have been identified with sequence homology, including *E. coli*, *Neurospora crassa*, *Pseudomonas putida*, *Novosphingobium aromaticivorans*, and others [74]. It has also suggested that xenobiotics might trigger immune recognition of self-antigens; however, other than lipoic acid, no specific candidates have emerged in PBC.

Another theory for the pathogenesis of PBC is that it is the direct result of an infection. In the search for a transmissible agent, filtrates of lymph nodes from patients with PBC were shown to induce the expression of PDC-E2 in biliary epithelial cell cultures [75]. Further studies identified viral particles in biliary epithelial cultures and tissues from patients with PBC, and were able to clone exogenous retroviral sequences from cultured biliary cells, which were identified as a β-retrovirus related to murine mammary tumor virus (MMTV) [76]. However, others have not been able to verify the presence of MMTV-related retrovirus in PBC [77]. In an uncontrolled pilot study, combination therapy using lamivudine and zidovudine in a small number of patients showed improvement in liver histology and biochemical abnormalities. This suggests the possibility that antiviral therapy might be of benefit, but validation of this approach would require further controlled trials [78].

Diagnosis

The diagnosis of PBC is based on the presence of typical clinical features, routine laboratory tests, AMAs, liver biopsy specimen abnormalities, and the absence of other conditions that could resemble PBC [20,79]. PBC should be suspected in patients with symptoms such as profound fatigue, pruritus, abdominal pain, or hepatomegaly and with routine laboratory test results consistent with cholestasis – that is, an elevated alkaline phosphatase level with minimal or modest elevation of serum transaminase levels (less than five times the upper limit of normal). Other typical features are hypercholesterolemia and a high serum IgM level. As noted in the preceding text, most patients are now diagnosed because of abnormal liver biochemical test results obtained on screening examinations in the absence of any symptoms. Occasionally, patients are diagnosed during the evaluation of symptoms of an associated syndrome, such as sicca syndrome, thyroid disease, or arthritis. The most important confirmatory laboratory test is the detection of serum AMA. The sensitivity and specificity of AMAs are both approximately 95%, but there is variation in the literature, depending on case definition and the test used [80]. Approximately 0.5% of the general population is AMA-positive, but the great majority of these individuals do not develop PBC. Approximately 5% of patients are AMA-negative, and some of these patients have other autoantibodies, particularly ANAs. These latter patients are sometimes referred to as having autoimmune cholangitis; however, their clinical syndrome is not clearly distinguishable from PBC. Rarely, patients have been identified with normal serum alkaline phosphatase levels and positive AMAs, with typical liver biopsy findings.

Although, historically, a liver biopsy was considered mandatory to make a specific diagnosis of PBC and to provide prognostic information on the basis of histologic stage, a recent study has suggested that most patients do not need a liver biopsy for diagnosis [81]. On the basis of a retrospective analysis of a large sample of patients who had undergone liver biopsy, AMA level determination, and serum biochemical tests, the combination of positive AMAs, alkaline phosphatase levels greater than 1.5 times the upper limit of normal, and AST levels less

than five times the upper limit of normal (found in 112 of 131 patients; 85% of patients reviewed) had a positive predictive value of 98.2% for the diagnosis of PBC. Although other studies confirming this analysis have not been done, patients falling within this profile probably do not need a liver biopsy unless other clinical features raise the possibility of a different diagnosis. A liver biopsy to confirm the diagnosis should certainly be entertained in the approximately 15% of patients who do not meet the above criteria. An additional rationale for restricting the use of liver biopsy in patients suspected of having PBC is that valid prognostic information can be obtained from indices based on noninvasive testing, and that histologic stage as determined by liver biopsy is not needed for clinical decisions.

Imaging studies are important in the evaluation of patients with cholestatic liver disease. In patients with typical clinical features of PBC, imaging studies may not be necessary. However, as the differential diagnosis of PBC includes other hepatobiliary diseases with overlapping clinical features, cholangiography may be indicated to exclude stones, strictures, tumors, PSC, or other uncommon conditions affecting the biliary system. The imaging procedure of choice is magnetic resonance cholangiography; endoscopic retrograde cholangiopancreatography (ERCP) is generally indicated only when therapeutic intervention is required. Magnetic resonance imaging may be indicated in the detection of advanced fibrosis, cirrhosis, or hepatocellular carcinoma, but is generally not indicated for interval evaluation. The utility of other noninvasive methods, such as elastography, has not been conclusively established for PBC [82].

The differential diagnosis of cholestatic syndromes includes: extrahepatic biliary obstruction due to stones, strictures, or tumors; PSC; drug-induced cholestasis; cholestatic viral hepatitis; sarcoidosis; idiopathic granulomatous hepatitis; AIH; and idiopathic adulthood ductopenia (Box 21.6). Other conditions that cause injury to bile ducts should be straightforward to differentiate and include GVHD, hepatic allograft rejection, ischemic cholangitis, and infectious cholangitis in immunosuppressed patients. Finally, clinical features of PBC may coexist with features of AIH in an overlap syndrome. PSC should be suspected in patients with inflammatory bowel disease. AMAs are only occasionally positive in patients with PSC. The diagnostic procedure of choice for PSC is cholangiography because the specific liver biopsy specimen lesions of PBC and PSC are each found in only a minority of their respective conditions, and nonspecific liver biopsy specimen features may be similar. The use of drugs known to cause chronic cholestasis could cause difficulty in diagnosis, particularly because some drugs also induce autoantibody production. Patients with viral hepatitis occasionally have a chronic cholestatic syndrome and bile duct lesions on liver biopsy specimens; however, AMAs are negative and serologic tests for viral hepatitis are positive. Occasionally, differentiation of PBC from hepatic sarcoidosis presents a difficult diagnostic problem [83]. AMAs are typically negative in sarcoidosis, and the presence of typical extrahepatic manifestations is necessary to make the diagnosis of sarcoidosis. In about one fourth of patients with AIH, AMAs are positive, usually in low titer, and bile duct lesions may be found on liver biopsy specimens. Idiopathic adulthood ductopenia is a somewhat recently described condition in adults characterized by paucity of bile ducts, chronic cholestasis, and, by definition, the absence of any defining characteristics of other ductopenic diseases, including inflammatory liver histologic lesions, autoantibodies, or associated conditions such as IBD [84].

Box 21.6 Differential diagnosis of primary biliary cirrhosis.

- Extrahepatic biliary obstruction (e.g., stone, stricture, tumor)
- Primary sclerosing cholangitis
- Drug-induced cholestasis
- Cholestatic viral hepatitis
- Sarcoidosis
- Idiopathic granulomatous hepatitis
- Autoimmune hepatitis
- Idiopathic adulthood ductopenia
- Special situations with bile duct injury: graft-versus-host disease, liver allograft rejection, ischemic cholangitis, infectious cholangitis in immunocompromised host

Treatment

Medical treatments of PBC have included primary therapies aimed at the underlying disease processes and at preventing or delaying progression, therapies for symptoms such as fatigue and pruritus to improve quality of life, and therapies directed at complications, including osteoporosis, fat-soluble vitamin deficiency, and complications of portal hypertension (such as ascites, edema, variceal bleeding, and hepatic encephalopathy) (Table 21.1). Comprehensive practice guidelines have been published, representing a consensus of expert opinion for the management of PBC [85]. There are no specific treatments for complications related to portal hypertension in PBC that differ from other causes of end-stage liver disease, and they will not be discussed here. Therapy may also be needed for associated syndromes, such as thyroid disease, arthritis, or Sjögren syndrome, and they will also not be discussed here. In evaluating treatment trials for PBC, it should be kept in mind that this is a difficult disease to

Table 21.1 Treatment therapies for primary biliary cirrhosis.

Therapy	Drug	Dose
Primary therapy	Ursodeoxycholic acid	13–15 mg/kg/day
Therapies for pruritus	Cholestyramine or colestipol Alternatives: rifampin, phenobarbital, opioid antagonists, plasmapheresis	Up to 16 g/day in divided doses[a]
Therapies for complications:		
Metabolic bone disease	Calcium, vitamin D	
Malabsorption	Water-soluble forms of vitamins A, D, E, and K	
Sicca	Artificial tears, dental hygiene	
Portal hypertension complications	As indicated	
Other associated syndromes	As indicated	

[a]May interfere with drug absorption; do not administer with other drugs.

study because of many factors, including the indolent and variable natural history of the disease, sampling error in liver biopsy, and the absence of robust biomarkers for the early stages of the disease, in which therapeutic interventions might be expected to have the greatest benefit.

Ursodeoxycholic acid, the only US Food and Drug Administration (FDA)-approved medical therapy for PBC, is generally agreed to ameliorate serum biochemical abnormalities and to potentially delay progression of disease to death or need for transplantation [86]. A number of mechanisms have been proposed by which UDCA is therapeutic in PBC, including anticholestatic effects and antiapoptotic actions. However, the precise mechanisms are unclear and may not involve the primary abnormalities that lead to autoimmune destruction of the bile ducts. Numerous treatment trials of PBC with UDCA alone, or in combination with other agents, have been conducted using varying numbers of patients and trial designs, and these are summarized in detail elsewhere [87,88]. In the largest reported trial – a Canadian multicenter double-blinded, placebo-controlled study of 222 patients – treatment with UDCA at a dosage of 13–15 mg/kg/day resulted in improvement in transaminases, alkaline phosphatase, total cholesterol, and IgM levels and prevention of a rise in serum bilirubin level. However, no improvement in symptoms, liver biopsy results, or need for liver transplantation was noted. In a subsequent meta-analysis of 11 randomized trials involving 1,272 patients, improvements in biochemical studies were found, but no difference between placebo and UDCA was found for progression of liver histology or the need for liver transplantation [89]. In contrast, a meta-analysis of the five studies [90–94] that included data obtained from open-label long-term follow-up periods reached a different conclusion, showing a significant reduction in risk of death or liver transplantation (odds ratio, 0.68 (95% CI, 0.48 to 0.95)) equivalent to a 32% reduction in patients treated with UDCA [95]. Because UDCA consistently ameliorates serum biochemistry abnormalities, concern has been raised that predictive models for PBC might underestimate progression of disease. However, models such as the Mayo risk score still accurately predict the clinical course in patients with PBC who are receiving UDCA [96]. Studies have also reported a delay in progression of liver fibrosis [97]. A subsequent analysis of histologic data from four large placebo-controlled trials demonstrated that UDCA therapy had a beneficial effect in stage 1 or 2 disease, reducing periportal inflammation and ductular proliferation [98]. Continuing analyses of open-label follow-up of patients have provided conflicting interpretations of the benefits of UDCA. In one randomized study in which patients received UDCA or placebo for 2 years, followed by open-label treatment in 112 patients for a subsequent 2 years, no differences were found in death or the need for liver transplantation [99]. In another study of long-term UDCA treatment comparing treated and nontreated patients for a mean of 5.8 years, there was amelioration of serum biochemical abnormalities in treated patients; however, there was no significant difference in death, need for transplantation, symptoms, or complications. It should be noted that this study did not evolve from a randomized trial, and required data analyses taking into account baseline differences and prognostic models [100]. Another analysis of 262 treated patients followed up for a mean of 8 years, using a Markov model and the updated Mayo model for control predictions, found that treatment with UDCA normalized survival rate (for death or transplantation) for patients with stage 1 or 2 disease who were treated, whereas those with more advanced stages had significantly worse survival [101]. A more recent long-term follow-up study demonstrated that patients with early PBC who were treated with UDCA have a prognosis

similar to that of the general population, and those with advanced PBC who had a biochemical response to UDCA had a better prognosis than nonresponders [102]. In summary the weight of evidence supports the use of UCDA as primary therapy for PBC at all stages of disease.

Fortunately, UDCA is relatively well tolerated, the main side effect being diarrhea, and therapy appears to have no significant long-term complications. The currently recommended dosage is 13–15 mg/kg/day, although higher dosage regimens have been investigated. If cholestyramine is used concurrently to treat pruritus, there should be a 4-hour delay between the administration of cholestyramine and UDCA. Multiple other agents have been tested as therapies for PBC, including azathioprine [103], methotrexate [104,105], prednisolone [106], chlorambucil [107], cyclosporin A [108], and D-penicillamine [109]. There is no clear overall benefit of most of these therapies, and some, such as systemic corticosteroids, are associated with significant bone complications [3]. Although one prospective double-blind trial of colchicine showed improved survival after 4 years in one study, subsequent studies have shown much less benefit and no improvement in survival [20].

UDCA has also been used in combination with other drugs, including prednisolone, budesonide, azathioprine, methotrexate, and colchicines – drugs that individually have not shown consistent benefit for the disease in multiple trials. The results of these trials can be summarized as showing benefits no different from UDCA alone, and sometimes with more side effects [110]. Small pilot studies have been undertaken with other agents, including mycophenolate mofetil, silymarin, and bezafibrate, but results of these studies are at best preliminary. At present, there is no strong evidence for any combination therapy using UDCA [85,110].

Pruritus is a distressing, and sometimes disabling, symptom of PBC. Although antihistamines are frequently used because they are well tolerated, most patients do not show an adequate response. UDCA treatment is associated with a reduction of this symptom in some patients, but overall results of randomized trials do not demonstrate a significant improvement. Cholestyramine has been the mainstay of therapy for decades [111]. There are no randomized controlled trials of the anion exchange resins cholestyramine and colestipol, although there is extensive clinical experience supporting their efficacy. Most patients have improvement in response to symptoms within about 2 weeks of initiating therapy. Typically, the drug is administered as 4 g doses, up to four times per day. These drugs are typically not well tolerated because of unpleasant taste, abdominal discomfort, and constipation. Anion exchange resins may contribute to malabsorption and may interfere with the absorption of other medications, including UDCA, thyroxin, digoxin, and oral contraceptives. Phenobarbital has been used occasionally and may be helpful. Rifampin has been used to treat pruritus at a dosage of 300–600 mg/day in divided doses [112,113]. Although well tolerated, its use has occasionally been associated with hepatotoxicity and bone marrow aplasia. On the basis of the theory that pruritus occurs because of endogenous opioids, opioid antagonists have been used to treat PBC [114]. Two randomized controlled trials of intravenous naloxone demonstrated benefit for intractable pruritus [115,116], and subsequent studies with oral naltrexone and oral nalmefene have also shown benefit [117,118]. Symptoms of opioid withdrawal may occur as a side effect during the initiation of opioid antagonist therapy. It has been suggested that the serotonin system may also be involved in pruritus [114], and drugs such as ondansetron and sertraline have been shown to beneficial in patients with PBC in small trials [119]. Plasmapheresis has been used as a therapy in intractable patients.

Metabolic bone disease, osteopenia, and osteoporosis may present a significant problem in patients with PBC. The pathogenesis is complex and may involve, among other factors, malabsorption of fat-soluble vitamins and, more importantly, direct effects of cholestasis on bone metabolism. Although their efficacy is uncertain, calcium and vitamin D supplementation are routinely provided for patients with PBC [120,121], calcium at 1.5 g/day and vitamin D at 800 IU/day. Two studies of etidronate provided mixed results on the benefits for patients with PBC [122,123]; however, a more recent study with alendronate demonstrated favorable effects on bone mass [124]. The role of hormone replacement therapy in women with PBC is unclear, given recent results in other conditions that question its efficacy in relation to the increased risk of cancer and vascular disease. Insufficient data are available to recommend calcitonin or sodium fluoride as therapy for bone disease in PBC.

Fat-soluble vitamin deficiencies may secondarily contribute to morbidity in PBC, including night blindness, bone disease, bleeding disorders or, rarely, neurologic symptoms of vitamin E deficiency. Deficiencies have been documented for vitamins A, D, K, and E, in decreasing order of frequency, with approximately one third of patients being deficient in vitamin A [125,126]. Deficiencies correlate with advanced-stage disease and higher risk scores. Vitamin A supplementation should be based on serum retinol levels because excessive vitamin A may be hepatotoxic. Since zinc is necessary for the function of retinols, zinc repletion may be necessary for the correction of vitamin A deficiency in patients with concurrent zinc deficiency. Although the evidence base for the effectiveness of therapy is limited, it has been recommended that patients with hyperbilirubinemia be treated with water-soluble forms of vitamins A, D, E, and K, and patients

with prolonged prothrombin times can be treated with parenteral vitamin K with a 10 mg/month dosage [84].

Hyperlipidemia and xanthomas are common manifestations of PBC and cholestasis, although patients with PBC may be relatively protected from the adverse effects of hyperlipidemia [24]. Cholestyramine or colestipol (Colestid®) is used to treat pruritus and UDCA because primary therapy may improve hypercholesterolemia. Nonetheless, additional therapy may be warranted in patients with other risk factors for cardiovascular disease. Clofibrate has been found to cause a paradoxical elevation of serum cholesterol level in two small studies [127,128]. In other studies, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) have been shown to improve lipid levels without causing evident hepatotoxicity [129].

Additional medical therapy considerations should include treatment for sicca syndrome, with artificial tears, dental hygiene, antireflux measures, and vaginal lubricants, and treatment of thyroid disease when present.

Liver transplantation

Liver transplantation is the only option for patients with PBC with life-threatening end-stage liver disease and its complications or severe intractable symptoms. PBC is a relatively common indication for liver transplantation, representing 12% of patients in the European Liver Transplant Registry, which includes results for 3,357 patients with PBC undergoing transplantation between 1988 and 2003 [130]. However, recently there has been a decline in the number of transplants performed yearly for PBC. In general, patients with PBC are good candidates for transplantation and have a better long-term prognosis compared with those with other common indications for transplantation such as viral hepatitis or alcoholic liver disease, with 1-, 5-, and 10-year survival of 84%, 78%, and 69%, respectively [130]; similar results have been obtained in the United States. Most experience is based on cadaveric transplantation, but living related donor transplantation has also been performed successfully for PBC. The indications for liver transplantation in PBC include symptoms and signs of end-stage liver disease and its complications. In addition, patients have been considered for transplantation because of intractable severe pruritus, profound fatigue, and severe bone disease. Patients are typically considered for transplantation when their predicted survival is 1 year or less. The Mayo risk score has been validated as a reliable prognostic index for patients with PBC. This index was derived from analyses of large datasets, and is calculated from easily obtained clinical information: age, serum bilirubin, albumin, prothrombin time, and presence of edema. The prognostic value of the Mayo risk score has been validated for patients treated with UDCA, which improves serum biochemical values in many patients. More recently, the allocation of cadaveric organs in the United States is based on the model for end-stage liver disease (MELD) score [131]. Both the Mayo risk score and the MELD score contain multiple factors, with serum bilirubin level being the major component of both. A serum bilirubin level greater than 8.5 mg/dL generally correlates with Mayo and MELD scores that are indicative of a need for liver transplantation.

PBC recurs in approximately 20–30% of patients 10 years after orthotopic liver transplantation [78,132], characterized by typical bile duct lesions and the persistence of AMAs. The diagnosis is based on liver biopsy and cannot be made on clinical features alone because of the overlap with features of transplant rejection and drug toxicity. There has been interest in the possibility that transplantation immunosuppressive regimens may alter the natural history of the recurrent disease and, in particular, that some regimens may retard progression better than others. However, the recurrent disease does not appear to be of major clinical consequence in most patients, and there is too little information available to select transplantation regimens on the basis of disease recurrence [133]. There have only been rare cases of retransplantation for recurrent PBC [78].

Natural history and prognosis

The initial descriptions of PBC were based on observations in patients diagnosed at a relatively late symptomatic stage of disease, with relatively rapid progression to liver failure and death in approximately 6 years [2,3]. The full clinical spectrum of PBC and its natural history are now much better defined. The disease has a variable spectrum but appears to be invariably progressive, whether presenting in asymptomatic or symptomatic patients. Multiple publications (with data largely from the pre-UDCA treatment era) have indicated that overall survival to death or transplantation is better in asymptomatic patients, approximately 10–15 years [134–136], although significantly worse than in control populations. One large study of 770 patients found that the symptom status had little effect on overall mortality from all causes, with a median survival of 9.6 versus 8.0 years in asymptomatic versus symptomatic patients, respectively [21]. However, in the latter study, less than one third of deaths among asymptomatic patients with PBC were attributable to liver disease. In asymptomatic patients with a recent diagnosis (i.e., patients presumably in the early stages of the disease), it is difficult to predict the ultimate course on the basis of serum biochemical or

AMA titer, or liver histology. In considering the limited medical therapies currently available that may change the underlying disease (e.g., UDCA), management decisions should not depend on a precise definition of where the patient may be along the course of the natural history of the disease. Considerably more is known about defining the late stages of the disease, which is important in considering the optimal timing for liver transplantation. A rising serum bilirubin level is an ominous prognostic sign in PBC [137]. Multivariate analysis of survival in PBC as a function of multiple different parameters has resulted in the Mayo index, which has been validated in many subsequent analyses [138]. More recently, the timing of transplantation has been supplanted by the use of the MELD score for prioritization for organ allocation. The MELD score is based on serum bilirubin level, creatinine level, international normalized ratio (INR) for prothrombin time, and etiology of liver disease, and it has been validated for prediction of death within 3 months for patients with PBC [139]. Further progress in developing better treatment approaches will depend on the identification of better biomarkers and surrogate markers, particularly for patients with early stages of PBC, as suggested by approaches using multiple serum biochemical measurements [140].

Multiple choice questions

21.1 What is the most specific diagnostic test for primary biliary cirrhosis?

a Magnetic resonance (MR) image of the liver.
b MR cholangiography.
c Serum antimitochondrial antibody.
d Percutaneous liver biopsy.

21.2 Which therapy for primary biliary cirrhosis improves the natural history compared with an age-matched general population?

a Oral budesonide.
b Colchicine.
c Ursodeoxycholic acid.
d Azathioprine.
e Liver transplantation.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 22

Autoimmune Hepatitis

Edward L. Krawitt

Department of Medicine, University of Vermont, Burlington, VT, USA

Key concepts

- Autoimmune hepatitis is a chronic hepatitis characterized by immune and autoimmune features.
- The pathogenesis of autoimmune hepatitis involves a loss of tolerance to self-antigens, but the tolerogenic mechanisms are incompletely understood.
- The predominant genetic factor in autoimmune hepatitis is a human leukocyte antigen (HLA) association, with variable expression in different ethnic groups.
- An autoantibody classification of types 1 and 2 is commonly applied.
- Other autoimmune diseases are frequently seen in patients with autoimmune hepatitis and/or their family members.
- The histologic severity in autoimmune hepatitis extends from mild chronic hepatitis to active cirrhosis.
- The biopsy finding of interface hepatitis with an abundance of plasma cells in the infiltrate is characteristic of autoimmune hepatitis
- Because of asymptomatic periods and a fluctuating course, cirrhosis is often present at the time of the initial biopsy.
- Despite the disappearance of symptoms and normalization of laboratory abnormalities once treatment has been instituted, continuing activity may be evident histologically.
- Circulating hyperglobulinemia, in particular hypergammaglobulinemia, and circulating autoantibodies occur frequently in autoimmune hepatitis but their presence is not unique to, nor specific to, autoimmune hepatitis.
- Patients usually respond to anti-inflammatory/immunosuppressive therapy, but life-long treatment may be required, particularly in children and in adults who present with cirrhosis.
- Liver transplantation has been successful in patients who do not respond to medical treatment, but post-transplantation hepatitis may occur.

Pathogenesis

Autoimmune hepatitis is a chronic hepatitis characterized by immunologic and autoimmunologic features that generally responds to immunospuppresive therapy [1,2]. One paradigm for the pathogenesis of autoimmune hepatitis embraces the concept that an environmental agent triggers an autoimmune process in a genetically predisposed individual, resulting in a dimunition or loss of tolerance to self-antigens. However, the precise relationships between the genes and the autoimmune process remain largely undefined and speculative [3]. Infectious agents, immunizations, herbs, and drugs have been suggested as triggering agents, but in most cases no specific inducer of autoimmunity is identified when autoimmune hepatitis appears. Potential mechanisms of induction include molecular mimicry, exposure of a sequestered antigen, alterations of a self-antigen, or the formation of a neoantigen by the combination of a foreign determinant and a self-antigen [4]. There is some evidence implicating hepatitis viruses, herpes simplex virus, varicella zoster virus, cytomegalovirus, Epstein–Barr virus, and measles virus as initiators of disease, perhaps involving a long latency period after infection. Immunizations for hepatitis A and B, among others, as well as a variety of herbs and drugs, have been proposed as triggers.

Drug-induced hepatocellular injury that resembles autoimmune hepatitis has been recognized over many years from drugs including oxyphenisatin, methyldopa, nitrofurantoin, diclofenac, and minocycline [5]. Although circulating autoantibodies and hyperglobulinemia occur in so-called drug-induced autoimmune hepatitis, there is no unequivocal evidence that a self-perpetuating injury exists after discontinuation of the drug, nor has there been evidence of a drug or metabolite producing a relevant neoantigen for autoimmune hepatitis. The administration of interferon may unmask or induce a variety of autoimmune diseases, including autoimmune hepatitis.

The search for genetic predisposing factors has for many years been largely directed at genes of the

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.

immunoglobulin superfamily, which includes those encoding human leukocyte antigens (HLA) located in the major histocompatibility complex (MHC), immunoglobulins, and T-cell receptor molecules [2,3,6]. It is likely that multiple genes are involved but that MHC genes account for much of the susceptibility.

In Caucasians, type 1 disease is strongly associated with the HLA-DR3 serotype (which is found in linkage disequilibrium with HLA-B8 and HLA-A1) and with HLA-DR4. DRB1*0301 and DRB3*0101 are common genotypes in North America; in South America DRB1*1301 is common. Additional associations have been found in Mexico, Brazil, and Argentina where mixed ethnicity is common. In Japan, where HLA-DR3 is rare, there is a primary association with the HLA-DR4 serotype, genotype DRB1*0405, and genotype DQB1*0401. Type 2 disease is associated with HLA-DRB1*07, HLA-DRB1*03, and DQB1*0201 alleles.

How the HLA alleles confer susceptibility to autoimmune hepatitis is not well understood. One theory designates a common susceptibility determinant in the HLA class II-binding groove crucial to antigen recognition that is carried by the DRBl*0301, DRB3*0101, and DRB1*0401 alleles in Caucasians [3,6]. There may be weaker associations with HLA class I MICA genes, the promoter region of tumor necrosis factor α (TNF-α), and complement genes (class III). Associations with TNF promoter polymorphisms appear to reflect an extended DRB1*0301 haplotype.

A genome-wide association study in 81 Japanese patients looking for weaker associations than those that occur at HLA loci found 26 candidate susceptibility regions in DR4-positive patients [7]. Understanding the weaker associations in autoimmune hepatitis will require genome-wide association analysis of large numbers of patients and/or other advanced modalities to insure statistical validity.

Based upon the character of the hepatic inflammatory infiltrate from patients with autoimmune hepatitis, and experimental findings from patients and animal models, the ongoing necroinflammatory process in autoimmune hepatitis appears to be mediated by CD4+ T cells. Clonal analyses of the T-cell receptor (TCR) chain variable region repertoires in liver-infiltrating lymphocytes have demonstrated oligoclonality for CDR region 3. Polyclonal T-cell responses to CYP2D6 appear to be involved in type 2 autoimmune hepatitis [8]. Despite the abundance of circulating autoantibodies found in autoimmune hepatitis, there is little evidence for direct antibody-induced liver damage, although abnormalities in B-cell function may yet prove to be important in the pathogenic process.

Implicit in the hypothesis of an immunoregulatory effect is an escape from tolerogenic mechanisms, probably involving suppression of self-reactive T cells. Early studies of immune regulation, based primarily upon in vitro observations, supported the hypothesis of a defect in the downregulation of the immune response, presumably mediated by CD8 suppressor T cells; the defect was reversed in autoimmune hepatitis patients with corticosteroid treatment [9–11]. The concept of suppressor T-cell function specifically mediated by CD8+ lymphocytes, came into question but the hypothesis of escape from suppressive mechanisms remains viable and is supported by studies of CD4+, CD25+ regulatory T cells (Tregs) that express CTLA-4, and the forkhead transcription factor Foxp3. Defects in expansion, generation, and function of Tregs have been discovered [3,12,13].The precise roles of CTLA-4 and Foxp3 and their relationship to Th 17 cells and CTLA-4 polymorphisms awaits further experimentation.

Histopathology and differential diagnosis

The histologic appearance of autoimmune hepatitis is that of chronic hepatitis, and is crucial to the diagnosis of autoimmune hepatitis. Although certain changes are characteristic, there are no findings specific to the disease [14]. The histologic differential diagnosis of chronic hepatitis is provided in Box 22.1. Based on advances in virologic studies and refinements of cholangiographic methods to exclude other entities, diagnosis has become easier.

The inflammatory component is characterized by a mononuclear cell infiltrate, which invades the sharply

Box 22.1 Histologic differential diagnosis of chronic hepatitis.

- Autoimmune liver disease:
  - Autoimmune hepatitis
  - Primary biliary cirrhosis
  - Primary sclerosing cholangitis
  - Variant syndromes
- Chronic viral hepatitis:
  - Chronic hepatitis B
  - Chronic hepatitis C
  - Chronic hepatitis delta
  - Chronic hepatitis due to other viruses
- Chronic drug-induced hepatitis
- Alpha$_1$-antitrypsin deficiency
- Wilson disease
- Granulomatous hepatitis
- Systemic lupus erythematosus
- Graft-versus-host disease
- Alcoholic steatohepatitis
- Nonalcoholic steatohepatitis

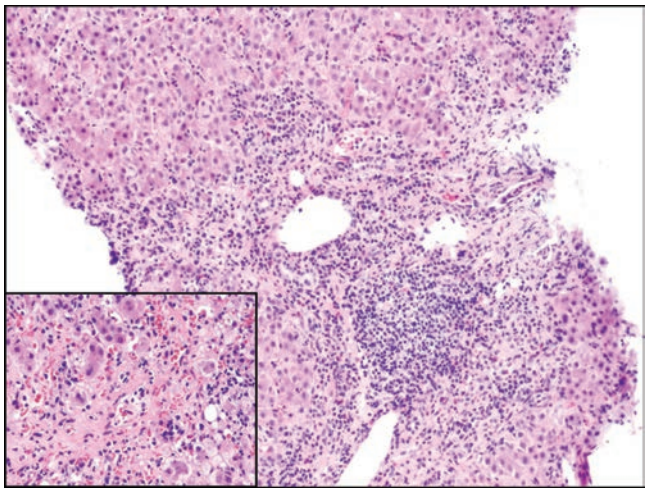

Figure 22.1 Interface and lobular hepatitis with a mixed inflammatory infiltrate composed of plasma cells, lymphocytes, and eosinophils, accompanied by ballooning degeneration and stage 2 fibrosis in a biopsy from a 56-year-old woman who presented with acute onset autoimmune hepatitis. Hematoxylin and eosin (H&E).

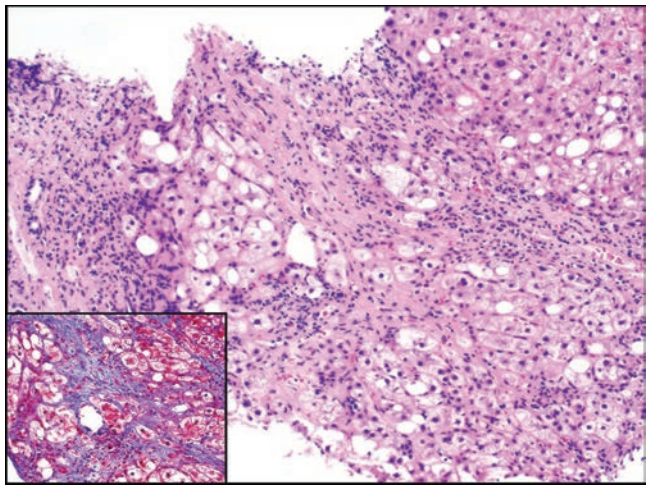

Figure 22.3 Significant lymphoplasmacytic inflammatory infiltrate accompanied by bridging fibrosis, regenerative nodules, ballooning degeneration, steatosis, and perisinusoidal and pericentral fibrosis characteristic of autoimmune hepatitis with nonalcoholic steatohepatitis in a biopsy obtained from a 53-year-old woman with diabetes mellitus. H&E; insert trichrome.

demarcated hepatocyte boundary (limiting plate) surrounding the portal triad and permeates the surrounding parenchyma (periportal infiltrate, piecemeal necrosis, and interface hepatitis) and beyond (lobular hepatitis). It may include an abundance of plasma cells and/or eosinophils, but the portal lesion generally spares the biliary tree. A dense plasma cell infiltrate is characteristic; in the past this led to the use of the term "plasma cell hepatitis" (Figs 22.1–22.3). In all but the mildest forms, fibrosis is present. In advanced disease fibrosis is extensive (bridging fibrosis) and, with distortion of the hepatic lobule and appearance of regenerative nodules, cirrhosis occurs [14]. On occasion, pericentral necrosis may be present [15].

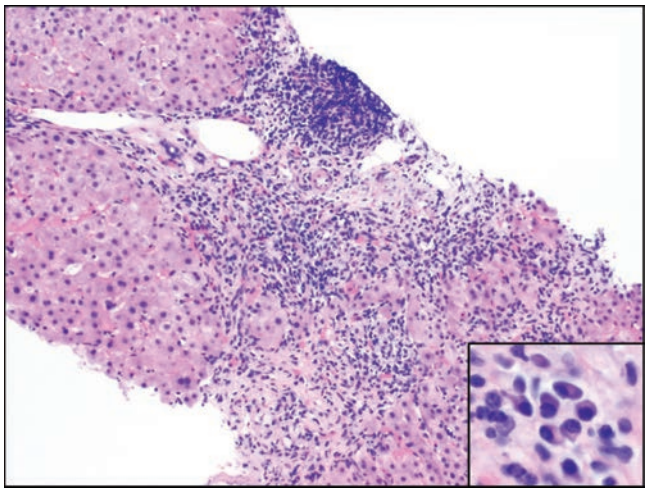

Figure 22.2 Marked interface and lobular activity with an abundance of plasma cells accompanied by bridging fibrosis and early regenerative nodules in a biopsy from a 64-year-old asymptomatic man. H&E.

Steatosis in autoimmune hepatitis patients not treated with corticosteroids has been thought to be uncommon, but given the increasing prevalence of diabetes, dyslipidemia, and obesity in many parts of the world, nonalcoholic fatty liver disease (NAFLD) may be seen more often accompanying autoimmune hepatitis (Fig. 22.3). Whether the co-morbidity of steatosis and steatohepatitis accelerate the progression of disease in autoimmune hepatitis is unknown. The discovery of portal inflammatory changes in NAFLD [16], particularly in children, and the prevalence of autoantibodies in NAFLD, however, emphasizes the diagnostic difficulties of differentiating these disorders.

The prevalence of cirrhosis in patients ≥60 years at presentation was found to be higher than that in patients ≤30 years; when comparing groups of patients ≥60 years with those <60 years, however, no differences were found [17,18]. In patients with a spontaneous or pharmacologically induced remission, histologic findings may revert to normal; inflammation may be confined to portal areas; cirrhosis may become inactive; and fibrosis may regress or disappear [19] (Fig. 22.4).

The histologic findings differ somewhat when comparing patients with acute-onset autoimmune hepatitis to those with an insidious presentation. Patients presenting with fulminant hepatic failure have more interface and lobular hepatitis, lobular disarray, hepatocyte necrosis, central necrosis, and submassive necrosis, but less fibrosis and cirrhosis compared with patients presenting with a more chronic course [17].

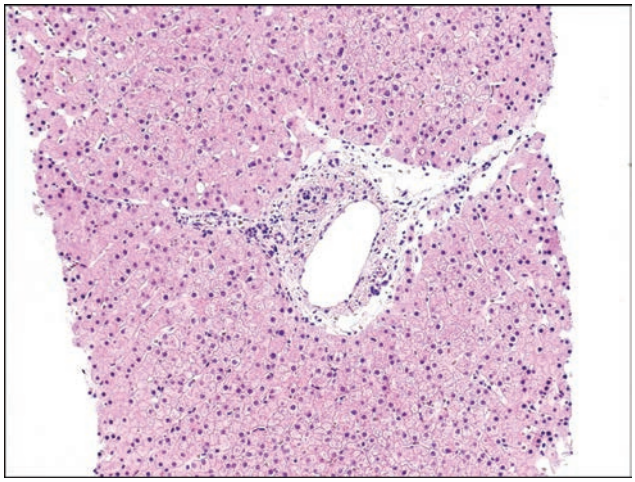

Figure 22.4 No histologic abnormalities were present in a follow-up biopsy obtained 3 years later when the patient described in Fig. 22.1 was in clinical remission on maintenance therapy. H&E.

Box 22.2 Autoantibody classification of autoimmune hepatitis.

Type 1 (classic)
- Antinuclear antibody (ANA)
- Smooth muscle antibody (SMA)
- Anti-F actin antibody (AAA)
- Antisoluable liver/liver–pancreas antigen (SLA, SLA/LP, SEPSECS)
- Atypical perinuclear antineutrophil cytoplasmic antibody (pANCA, pANNA)
- Antimitochondrial antibody (AMA)[a]

Type 2
- Antiliver–kidney microsome-1 (ALKM-1)
- Antiliver cytosol-1 (ALC-1)
- UDP–glucuronosyl transferases (UGT1A, ALKM-3)[b]

[a] Occurs infrequently in association with other characteristic autoantibodies. It may be the sole antibody present in AMA-negative autoimmune hepatitis.
[b] Occurs rarely.
pANCA, p-antineutrophil cytoplasmic antibody; pANNA, peripheral antineutrophil nuclear antibody; UDP, uridine diphosphate.

Although the histologic appearance of autoimmune hepatitis is characteristic, it is not specific to the disease. Fulminant Wilson disease is difficult to distinguish from severe autoimmune hepatitis. Many of the features seen in autoimmune hepatitis are common to chronic viral hepatitis. Cholestatic autoimmune diseases may at times be indistinguishable from autoimmune hepatitis but are commonly characterized by a paucity of bile ducts and/or bile duct inflammation, fibrosis, and damage [14].

Autoantibody classification

Since the first descriptions of autoimmune hepatitis in the twentieth century, it has been known by a variety of terms; autoimmune hepatitis is now accepted as the most appropriate and least redundant term. Its heterogeneity is underscored by a variety of clinical manifestations, histologic findings, immunogenetic phenotypes, and serologic abnormalities. Thus, classification can be based on a number of features. Since 1987, when Jean-Claude Homberg and his colleagues described a second type of autoimmune hepatitis [20], an autoantibody-based classification has been in common usage with type 1 and type 2 designations based on differing circulating autoantibody patterns (Box 22.2).

In type 1 autoimmune hepatitis, the main circulating autoantibodies, although not specific for the disease, are antinuclear antibody (ANA), smooth muscle antibody (SMA), and anti-F actin antibody (AAA) (Box 22.2). Although AAAs may be more specific for type 1 autoimmune hepatitis, until recently they have not generally been measured in clinical laboratories. Antiactin antibodies (immunoglobulin G (IgG) anti-F actin) measured by enzyme-linked immunosorbent assay (ELISA) [21] have now become more readily available, and in some laboratories have replaced SMA in autoantibody profiles. This may require using equivalence of levels when utilizing the recently published, simplified criteria [22] for the diagnosis of autoimmune hepatitis (see below).

Soluble liver antigen antibodies (anti-SLAs) have been found in approximately 10–30% of adult patients with type 1 autoimmune hepatitis but are more common in children with type 1 and type 2 disease. Anti-SLA was found to be identical to an antibody to a liver–pancreas (LP) antigen, which had been described in a subset of patients with autoimmune hepatitis, accounting for the term anti-SLA/LP. SLA is also known as SEPSECS (Sep (O-phosphoserine) tRNA synthase), a selenocysteine synthase. Sometimes anti-SLA may be the only circulating antibody found in autoimmune hepatitis patients [1].

Atypical p-antineutrophil cytoplasmic antibody (pANCA), sometimes referred to as peripheral antineutrophil nuclear antibody (pANNA), recognizes neutrophil nuclear lamina proteins and is frequently present in type 1 autoimmune hepatitis. It is also common in primary sclerosing cholangitis and in inflammatory bowel disease.

Although not frequently sought, antibodies to double-stranded DNA, which are most commonly associated with systemic lupus erythematosus, and single-stranded DNA can occur in autoimmune hepatitis. Antimitochondrial antibodies (AMAs), although more specific and sensitive for primary biliary cirrhosis, can also be seen

in type 1 autoimmune hepatitis, generally with ANA and/or SMA and rarely as the only autoantibody [23]. The frequency of these autoantibodies in autoimmune hepatitis varies significantly in different reports but is generally in the 5–20% range. Variations are probably in part due to the definitions of variant/overlap syndromes used [24,25].

In type 2 autoimmune hepatitis, a disease that occurs predominantly in girls and young women, antiliver–kidney microsome-1 (ALKM-1) antibodies and anti-cytosol-1 (ALC-1) antibodies are the major circulating autoantibodies (see Box 22.2). ALKM-1 antibodies, which are directed at the cytochrome P450 enzyme CYP2D6, are also found in approximately 5% of patients with chronic hepatitis C and 25% of those with halothane-induced hepatitis. ACL-1 antibody, which recognizes formiminotransferase cyclodeaminase (FTCD), a liver-specific 58 kDa metabolic enzyme, generally occurs in conjunction with ALKM-1 antibody, but may be the sole circulating autoantibody [26]. Antibodies to ALKM-3 rarely occur in type 2 disease [1].

Variant syndromes

Autoimmune hepatitis–primary biliary cirrhosis overlap patients have characteristic clinical, histologic, and immunologic findings of both diseases [25,27,28]. Patients with autoimmune hepatitis–primary sclerosing cholangitis overlaps (referred to in children as autoimmune sclerosing cholangitis) have serologic and histologic features of autoimmune hepatitis with cholangiographic abnormalities characteristic of primary sclerosing cholangitis (Table 22.1) [25,29].

Table 22.1 Autoimmune hepatitis variant syndromes.

	AIH-PBC	AIH-PSC
Antinuclear antibody	Often present	Often present
Smooth muscle antibody	Often present	Often present
Antimitochondrial antibody	Present	Absent
Biochemical cholestasis	Present	Present
Histologic evidence of bile duct abnormalities	Present	Sometimes present
Cholangiographic abnormalities	Absent	Present
Responsiveness to immunosupression	Variable	Variable

AIH-PBC, autoimmune hepatitis–primary biliary cirrhosis; AIH-PSC, autoimmune hepatitis–primary sclerosing cholangitis

Some authors recognize additional overlap syndromes including "autoimmune hepatitis–cryptogenic hepatitis," "autoimmune hepatitis–sarcoidosis," and "autoimmune hepatitis–chronic hepatitis C." However, the existence of these disorders as distinct overlap syndromes is less clear.

The list of recognized IgG4-associated diseases continues to grow, and IgG4-associated pancreatitis and IgG4-associated cholangitis are now well-established entities. Whether or not IgG4-associated autoimmune hepatitis is a distinct entity is not clear [30,31]. Documentation of its existence awaits a more extensive description of clinical and immune-histologic features.

Clinical features

Although there is a female predominance, autoimmune hepatitis occurs in children and adults of both sexes in diverse ethnic groups. Type 2 disease, which is seen predominantly in children and young women, is rare in North America. Although autoimmune hepatitis was previously thought to be a disease of the young or middle aged, it is now clear that it also occurs in the elderly, generally defined as $\geq$60 years of age [17,18].

The heterogeneous, sometimes fluctuating, nature of autoimmune hepatitis leads to marked variability in clinical manifestations. Presentation may be asymptomatic or insidious, with mild nonspecific symptoms only, or may mimic acute viral hepatitis, sometimes presenting as fulminant hepatic failure [17,18,24]. Patients with occult disease may have undetected cirrhosis. The group of patients now labeled as cryptogenic cirrhosis, includes some patients without detectable standard autoantibodies. Measurement of other autoantibodies may be helpful in clarifying a diagnosis of autoimmune liver disease (Fig. 22.5).

Many patients with an acute presentation have histologic evidence of chronic disease indicating that they have had antecedent subclinical disease, although the duration of the subclinical anicteric course is generally difficult to ascertain. In retrospect, a fluctuating course, which had been thought to reflect some other disease, can be identified. Long periods of subclinical disease may also ensue after presentation. Surveys of pregnancy in autoimmune hepatitis indicate that the initial presentations may occur not only during pregnancy but in the early postpartum period. A variety of putative autoimmune diseases, including the gastrointestinal immune-mediated disorders of inflammatory bowel disease and celiac disease, occur in conjunction with both type 1 and 2 disease. Arthralgia, commonly involving small joints, is common; inflammatory arthritis may be particularly troublesome even after immune suppression has been successful in quietening the hepatitis.

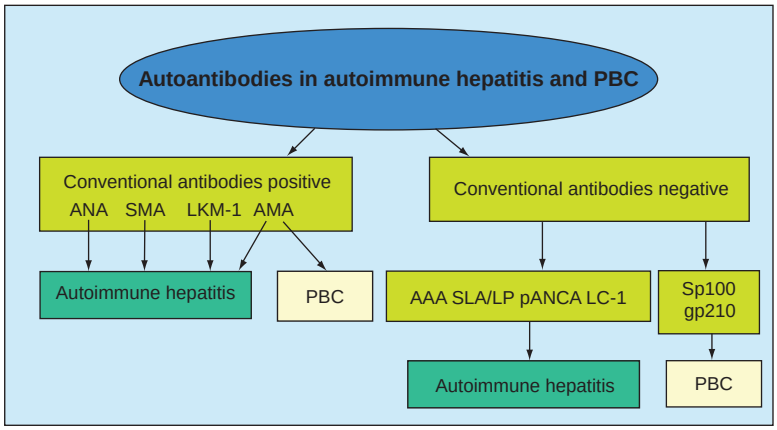

Figure 22.5 The use of conventional and other serum antibodies as an aid in diagnosing autoimmune hepatitis. AAA, anti-F actin antibody; ALC-1, anticytosol-1; ALKM-1, antiliver–kidney microsome-1; AMA, antimitochondrial antibody; ANA, antinuclear antibody; anti-SLA/LP, soluble liver antigen/liver–pancreas antigen antibody; SMA, smooth muscle antibody; pANCA, p-antineutrophil cytoplasmic antibody; Sp 100 and gp 210, multinuclear dot ANAs.

Complications of autoimmune hepatitis are those seen in any progressive liver disease and primary hepatocellular carcinoma is an expected, although uncommon, consequence [32,33]. There are no established guidelines for hepatocellular carcinoma screening in cirrhosis, but a reasonable approach is surveillance with abdominal ultrasonography and α-fetoprotein every 6–12 months.

Diagnosis

In the presence of a compatible histologic picture, the diagnosis of autoimmune hepatitis is based on characteristic clinical and biochemical findings, circulating autoantibodies, and abnormalities of serum globulins. A scoring system, proposed and subsequently revised by the International Autoimmune Hepatitis Group [34], to standardize diagnosis for clinical trials and population studies, has been adapted by clinicians but found to be problematic when applied to individual patients, especially children. The International Autoimmune Hepatitis Group has devised a less complicated system [22] for application in individual patients, which uses serum autoantibodies measured by immunofluorescence, serum IgG levels, histologic findings, and the absence of viral hepatitis (Table 22.2) as follows:

- *Autoantibodies*: assign 1 point if the ANA or SMA are 1 : 40 *or* assign 2 points if the ANA or SMA are ≥1 : 80 (*or* if the ALKM-1 is ≥1 : 40 *or* if the anti-SLA is positive).
- *IgG*: assign 1 point if the IgG is greater than the upper limit of normal (ULN) *or* assign 2 points if the IgG is >1.1 times the ULN.
- *Liver histology* (evidence of hepatitis is a mandatory condition): assign 1 point if the histologic features are compatible with autoimmune hepatitis *or* 2 points if the histologic features are typical of autoimmune hepatitis.
- *Absence of viral hepatitis*: assign 2 points if viral hepatitis has been excluded. In the validation study, patients were mainly tested for hepatitis B and C.

A probable diagnosis of autoimmune hepatitis is made if the total is 6 points, while a definite diagnosis is made if the total points are ≥7 (Table 22.2).

A scoring system for a "strictly" defined autoimmune hepatitis–primary biliary cirrhosis variant has been devised by Chazouilleres et al. [27,28], requiring at least two of three accepted criteria for each disease. Primary biliary cirrhosis criteria are: (i) alkaline phosphatase levels at least two times the ULN or γ-glutamyl transpeptidase levels five times the ULN; (ii) a positive AMA; and (iii) a liver biopsy specimen showing florid duct lesions. Autoimmune hepatitis criteria are: (i) serum alanine aminotransferase levels more than five times the ULN; (ii) serum IgG levels at least two times the ULN or a positive SMA; and (iii) a liver biopsy specimen showing moderate or severe periportal hepatitis.

Autoimmune sclerosing cholangitis should be suspected in all children being evaluated for autoimmune

Table 22.2 Simplified diagnostic criteria for autoimmune hepatitis.[a]

Variable	1 point	2 points
ANA or SMA ≥1 : 40	1	–
ANA or SMA ≥1 : 80	–	2
or LKM ≥1 : 40	–	2
or SLA-positive	–	2
IgG > upper normal limit	1	–
IgG > 1.1 times upper normal limit	–	2
Liver histology compatible with AIH[b]	1	–
Liver histology typical AIH[b]	–	2
Absence of viral hepatitis	–	2

[a]Points achieved for autoantibodies: maximum 2 points. Probable autoimmune hepatitis: 6 points. Definite autoimmune hepatitis: ≥7 points.
[b]Evidence of hepatitis is a necessary condition.
ANA, antinuclear antibody; IgG, immunoglobulin G; LKM, liver–kidney microsome; SLA, soluble liver antigen; SMA, smooth muscle antibody.

liver disease. It should also be suspected in adults who have clinical and serologic features of autoimmune hepatitis as well as: pruritus, chronic ulcerative colitis, bile duct abnormalities by biopsy, serum cholestatic biochemical changes of an elevated alkaline phosphatase and/or γ-glutamyl transpeptidase, poor response to corticosteroid therapy, and/or an abnormal cholangiogram. The overlap should also be suspected in patients diagnosed with primary sclerosing cholangitis who have high levels of IgG, circulating ANAs or SMAs, and moderate to severe interface hepatitis on liver biopsy.

Treatment

Despite the striking heterogeneity and our incomplete understanding of its pathogenesis, autoimmune hepatitis is in general a "steroid-responsive" condition. Appropriate management can improve quality of life, mitigate inflammation and fibrosis, prolong survival, and delay the need for liver transplantation. The life expectancy of treated patients is similar to age- and gender-matched controls in patients who have been followed for up to 20 years [35].

Standard medications for initial and maintenance regimens are still considered to be prednisone (or prednisolone) alone or in combination with azathioprine (or 6-mercaptopurine) (Table 22.3) [1,36].

Progress in nonstandard treatment for patients with inadequate responses or intolerance to therapy with glucocorticosteroids alone or in combination with azathioprine or 6-mercaptopurine has been slow [1,36]. In view of the paucity of trials with nonstandard forms of therapy most decisions must be based on data obtained from case reports and series of small numbers of patients. Cyclosporine, which has been used successfully in children to induce remission [36], and tacrolimus are used on occasion to treat adults. Off-label use of mycophenolate mofetil has become more frequently employed in intolerant or nonresponsive adults [37–40] and is considered a promising agent [1]. In children it has proved to be effective in autoimmune hepatitis but not in autoimmune cholangitis [40].

The role of budesonide in treating autoimmune hepatitis has not been extensively studied. A recent investigation suggests that it may be as effective in noncirrhotic patients and may serve as an alternative to prednisone or prednisolone [41].

One issue of concern is toxicity and/or intolerance to 6-mercaptopurine and its prodrug azathioprine. The methylation of 6-mercaptopurine and 6-thioguanosine 5′-monophosphate is catalyzed by thiopurine methyltransferase (TPMT). The genes encoding TPMT are highly polymorphic. Homozygosity and heterozygosity for mutations in TPMT genes occur in Caucasian and other populations, and these patients may accumulate high levels of thioguanine nucleotides in bone marrow cells. Patients who are homozygous for a mutation of TPMT are at high risk for severe toxicity, including death. Patients who are heterozygous for the TMPT mutation probably have an intermediate risk of toxicity. These findings have led to the suggestion that prior to placing patients on azathioprine or 6-mercaptopurine, TPMT genotyping may be appropriate. Despite reliable methods

Table 22.3 Suggested regimens for the treatment of autoimmune hepatitis.

Regimen	Single-drug therapy	Combination therapy
Adults		
Initial	Prednisone 20–40 mg daily[a]	Prednisone 10–30 mg daily *and* azathioprine 50–100 mg daily *or* 6-mercaptopurine 25–50 mg daily
Maintenance	Prednisone 5–15 mg daily *or* azathioprine 100–200 mg daily *or* 6-mercaptopurine 50–100 mg daily	Prednisone 5-10 mg daily *and* azathioprine, 50–150 mg daily *or* 6-mercaptopurine 25–75 mg daily
Children		
Initial	Prednisone 1–2 mg/kg of body weight daily (up to 60 mg/day)	Prednisone 1–2 mg/kg of body weight daily (up to 60 mg/day) *and* azathioprine 1–2 mg/kg of body weight daily
Maintenance	Prednisone 0.1–0.2 mg/kg of body weight daily *or* 5 mg daily *or* azathioprine 1–2 mg/kg of body weight daily	Prednisone 0.1–0.2 mg/kg of body weight daily *or* 5 mg daily *and* azathioprine 1 mg/kg of body weight daily

[a]Prednisolone may be used as well.

for TMPT genotyping and measurement of levels of 6-mercaptopurine metabolites, their assessment in the clinical management of autoimmune hepatitis is not established and must be evaluated in the context of severity of disease, as advanced fibrosis has been shown to predict azathioprine toxicity [42].

Glucocorticoid-related side effects must be considered in treatment and may influence the decision or timing of treatment and the choice of medications, particularly in patients with brittle diabetes, osteoporosis, emotional lability or a history of psychosis, or poorly controlled hypertension. These conditions are not necessarily contraindications for the use of glucocorticoids, but their presence may require special precautions and monitoring. Budesonide may have an impact on decisions regarding the treatment of patients with these conditions. A recent retrospective analysis of corticosteroid treatment in patients with severe and fulminant autoimmune hepatitis, suggested that steroids did not obviate the need for transplantation and may have promoted septic complications [43].

A subset of patients with cirrhosis with inactive disease, characterized by the absence of inflammatory cells on liver biopsy and normal or near-normal serum aminotransferases, were included in a group of patients considered to have cryptogenic cirrhosis. This group is now presumed to have autoimmune hepatitis based upon the clinical setting, the presence of serologic markers, and the absence of other causes of liver disease. They may be at increased risk for the development of glucocorticoid-related side effects, while the benefit of treatment is uncertain.

Cessation of therapy during pregnancy has been associated with the relapse of autoimmune hepatitis and such patients need to be monitored carefully during pregnancy and several months postpartum because of the risk of flares in disease activity.

In the rare instances in which autoimmune hepatitis is accompanied by chronic hepatitis C virus infection, treatment should first be directed toward autoimmune hepatitis because of the danger of exacerbating autoimmune hepatitis with interferon. Although this approach may result in raising circulating levels of hepatitis C virus, it is the safer initial strategy.

The initial approach to therapy in autoimmune hepatitis depends in part upon histologic findings. The decision to treat patients with only mild hepatitis is often based on symptoms. Asymptomatic patients with mild inflammation may be observed without institution of treatment, but their clinical status should be monitored carefully, including performance of repeat liver biopsies at appropriate intervals for evidence of disease progression, so that therapy can be instituted if indicated. Treatment should not be withheld from patients with decompensated cirrhosis who have active disease. The response may be excellent even in those who have already experienced bleeding from esophageal varices or who have significant ascites.

Since autoimmune hepatitis tends to be more severe in children compared to adults, possibly because of a delay in diagnosis, treatment is generally recommended in children at the time of diagnosis, except in those with inactive cirrhosis (Table 22.3) [1,36].

There are no trials on which to base the treatment of autoimmune hepatitis variant/overlap syndromes. Patients who have AMA-positive autoimmune hepatitis should be treated and followed as for patients with type 1 autoimmune hepatitis as they are generally steroid-responsive [23]. In the overlap syndrome defined by Chazouilleres and colleagues, a combination of glucocorticosteroids and ursodeoxycholate is recommended [27,28]. Reports of therapy for the autoimmune hepatitis–primary sclerosing cholangitis overlap syndrome have been limited to small case series using a variety of regimens, often combining ursodeoxycholic acid with immunosupression [25,44]. For children with autoimmune sclerosing cholangitis, ursodeoxycholic acid is usually added to corticosteroids and azathioprine [1,36].

Although some patients will remain in remission when drug treatment is withdrawn, the majority require long-term maintenance therapy. In general, the response is better with milder disease. Adults with active cirrhosis at the time of initial biopsy and children, particularly those with type 2 disease, rarely stay in remission when treatment is withdrawn and almost always require life-long maintenance therapy.

No firm guidelines exist for decisions regarding the withdrawal of medications because histologic changes may lag behind biochemical responses. A quiescent histologic appearance and normal biochemical findings while patients are still receiving therapy are not necessarily predictive of continued remission once therapy is withdrawn. Although, in the past, aminotransferase levels less than two times normal were proposed as a guideline to reducing medication, relapse has been shown to be less likely in patients who achieve normal transaminase and γ-globulin (or IgG) levels [45]. The utilization of transaminase levels also should include consideration of gender-based differences, which may not be reflected in a laboratory's normal values, and variability in ULN levels among different laboratories.

A reasonable approach following a relapse is to resume drug therapy at initial induction doses and then to attempt drug withdrawal once clinical remission is achieved again. Patients who continue to relapse can be treated with the lowest dose of either azathioprine, 6-mercaptopurine, or prednisone that controls symptoms and laboratory test results. These strategies are effective

in controlling the disease in the majority of patients. The decision involves weighing the long-term side effects of the medications used.

Patients who are refractory to or intolerant of therapy may develop decompensated cirrhosis and require liver transplantation. Five-year patient survival rates are in the 70–90% range [46,47]. As in other autoimmune liver diseases, recurrence of chronic hepatitis may occur after transplantation and mandate modifications of the post-transplant immunosuppressive regimens [48]. So-called de novo autoimmune hepatitis, also referred to as post-transplant immune hepatitis, plasma cell hepatitis, or graft dysfunction mimicking autoimmune hepatitis, occurs after liver transplantation for diseases other than autoimmune hepatitis in both adults and children, and may require changes in post-transplant therapy as well [49,50].

Acknowledgments

I am indebted to Ms Margo Mertz for editorial assistance, to Ms Laura Krawitt for preparing Fig. 22.5, and to Dr Rebecca Wilcox for her advice and expertise preparing the histologic images.

PART V

Viral Hepatitis

Overview

Eugene R. Schiff

We are entering an era when the prevention and successful treatment of viral hepatitis is rapidly escalating. Universal vaccination against hepatitis A in 1–2-year-old babies is highly effective in controlling transmission to children but also through herd immunity to adults as well. Hepatitis A vaccine is effective in postexposure settings within 14 days of exposure and may be preferable to immunoglobulin since active immunization provides long-term immunity. Hepatitis B vaccine prevents infection and hepatocellular carcinoma. Universal hepatitis B vaccination is actively progressing, particularly in endemic areas in Southeast Asia. Inability to prevent intrauterine infection leads to vaccine failure in some newborns of hepatitis B virus (HBV) infected mothers, particularly in those mothers with high HBV DNA levels. Nucleos(t)ide analogs are safe during the third trimester and have been known to reduce the rate of perinatal transmission in mothers with HBV DNA levels $>10^8$ IU/mL. An effective hepatitis E vaccine has been developed but is not widely available.

Treatment of hepatitis B patients with nucleos(t)ide analogs that have high genetic barriers to resistance (i.e., entecavir and tenofovir) is becoming the norm. These first-line antivirals have proven to be effective in safely sustaining HBV DNA negativity, the normalization of aminotransferases, and the amelioration of hepatic necroinflammation and fibrosis. However, long-term therapy is the rule, with the exception of those undergoing hepatitis B surface antigen (HBsAg) seroconversion. HBeAg seroconversion and long-term HBV DNA suppression is not sufficient to confidently predict the durability of disease remission. Treatment of immunotolerant patients is controversial and requires research in clinical trials. These relatively young patients with very high HBV DNA levels and relatively little or no histologic injury often will become inactive carriers over time and if treated will require long-term indefinite treatment. Nevertheless, a subgroup will be undergoing malignant transformation at a molecular level and if identified would certainly be candidates for early treatment. It has become apparent in recent years that prior to treatment with cancer chemotherapy patients should be screened for HBsAg and anti-hepatitis B core (HBc). This is done to identify those patients to be treated prophylactically with antiviral therapy to prevent the reactivation of hepatitis B that can evolve into severe hepatic failure.

Protease inhibitors of hepatitis C virus (HCV) will be licensed and a spectrum of other direct antiviral agents (DAAs) targeting NS3/4A protease, NS5B polymerase, NS5A, NS5B, and NS4B should be forthcoming over the next 3–5 years. The ultimate goal is an interferon-free regimen with a high sustained virologic response (SVR) rate and with a relatively low side effect profile. SVR rates have proven to be durable and equate with a cure. Response-guided therapy should permit shorter durations of treatment in those achieving HCV RNA negativity by 4 weeks (rapid virologic response (RVR)). Individualized therapy will undoubtedly relate to the earliest time point of HCV RNA negativity. Rapid escape from host responses by resistant mutants will have to be monitored to develop antiviral strategies. HCV resistance is likely to become an important issue in clinical practice. Interleukin 28B (IL28B) polymorphism, a gene on chromosome 19, is the most powerful host factor in determining interferon responsiveness. How useful this parameter will be with the use of DAAs is being studied. Hepatic steatosis and insulin resistance are common in patients infected with HCV and are associated with disease progression and reduced response to antiviral therapy. Low serum levels of vitamin D are related to low responsiveness to interferon-based therapy, and vitamin D supplementation has been associated with higher SVR rates but the mechanism for this phenomenon is unknown. One of the biggest unmet needs is successful treatment in transplant recipients with recurrent hepatitis C. Drug–drug interaction will undoubtedly modify

antiviral regimens. Treatment of coinfected patients with human immunodeficiency virus (HIV) presents a similar challenge.

Studies with therapeutic vaccines are designed to improve SVR rates by enhancing cellular immune response.

Interferon is the only effective therapy for hepatitis D. It has become apparent that hepatitis E may evolve into chronic hepatitis among solid organ transplant patients and interferon may also be effective in clearing hepatitis E virus (HEV) in chronic hepatitis.

These major advances in the management of viral hepatitis will eventually change the spectrum of candidates for liver transplantation. However, the aging cohort of hepatitis C patients are increasingly at advanced stages of liver disease where successful antiviral therapy will have little impact on decompensated cirrhosis and the risk for hepatocellular carcinoma.

CHAPTER 23

Hepatitis A and E

Joshua Watson & Maria H. Sjogren

Gastroenterology Service, Department of Medicine, Walter Reed Army Medical Center, Washington, DC, USA

Key concepts

- Hepatitis A and E viruses (HAV and HEV) are worldwide infections that cause outbreaks or sporadic, self-contained infections.
- The precise mechanism of hepatic uptake in human liver is unknown for both viruses, but once infection occurs HAV or HEV is distributed throughout the liver.
- Infection with HAV or HEV does not result in chronic disease in immunocompetent hosts. HAV rarely can have a prolonged course or a relapsing course, and profound cholestasis can occasionally occur. Mortality rate is low in previously healthy persons; however, HEV has a reported mortality of 15–25% in pregnant women.
- Acute hepatitis A and hepatitis E are clinically indistinguishable from other forms of viral hepatitis. A diagnosis requires serologic confirmation.
- Hepatitis A vaccine is widely available and is approved for subjects over the age of 1 year. An HEV vaccine has successfully completed a phase III trial, but it is not commercially available.

Experimental work in humans led to the clinical recognition that viruses were etiologic agents of hepatitis A (infectious hepatitis) and hepatitis B (serum hepatitis) [1,2]. Later, the existence of two distinct hepatitis viruses was demonstrated: hepatitis A virus (HAV) and hepatitis B virus (HBV) [3]. HAV was first characterized in 1973 when scientists detected the virus in stools from human volunteers who were infected with HAV [4]. The ensuing development of sensitive and specific serologic assays for the diagnosis of HAV infection and the isolation of HAV in cell culture [5] were important advances that permitted the understanding of the epidemiology of HAV infection and, ultimately, control of the disease.

With the accurate diagnosis of hepatitis A and hepatitis B, it became apparent that at least two non-A, non-B infectious agents existed. One was similar to hepatitis B, mainly transmitted parenterally, and another was similar to hepatitis A, transmitted by the fecal–oral route. In the 1980s, two seminal discoveries correctly identified the first one as hepatitis C [6], and the second one became known as hepatitis E [7].

Since then, hepatitis E virus (HEV) has been recognized as the agent responsible for enterically transmitted non-A, non-B hepatitis. Research to understand the epidemiology, viral characteristics, and immunity against this viral agent was propelled by the work of Balayan et al. [7] and subsequently by cloning the virus [8], which allowed the development of diagnostic assays, better understanding of its epidemiology, and development of vaccine candidates.

Virology

Hepatitis A virus

In 1982, HAV was classified as an enterovirus type 72 belonging to the Picornaviridae family. Subsequent determination of the sequence of HAV nucleotides and amino acids led to questioning of this classification, and a new genus, hepatovirus, was created for HAV [9]. HAV has an icosahedral shape and is a nonenveloped virus. It measures 27–28 nm in diameter, has a buoyant density of 1.33–1.34 g/cm [3] in cesium chloride, and has a sedimentation coefficient of 156–160S by ultracentrifugation. HAV survives exposure to ether and an acid environment at pH 3. It also survives heat exposure at 60°C for 60 minutes but is inactivated at 85°C for 1 minute. HAV is capable of surviving in seawater (4% survival rate), dried feces at room temperature for 4 weeks (17% survival), or live oysters for 5 days (12% survival) [10].

Only one serotype of HAV is known, and there is no antigenic cross-reactivity with the hepatitis B, C, D, E, or G agents. The HAV genome consists of a positive-sense RNA that is 7.48 kb long, single stranded, and linear. HAV RNA has a sedimentation coefficient of 32–33S and a molecular weight of 2.8×10^4 daltons. The HAV RNA

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.

has a long open reading frame (ORF) of 6,681 nucleotides and is covalently linked to a 5′ terminal protein and a 3′ terminal polyadenosine tract.

The onset of HAV replication in cell culture systems takes from weeks to months. Primate cells, including African green monkey kidney cells, primary human fibroblasts, human diploid cells (MRC-5), and fetal rhesus kidney cells, are favored for the cultivation of HAV in vitro. The virus is not cytopathic, and persistent infection in the cell cultures is the rule. Two conditions control the outcome of HAV replication in cell culture [11]. First, the genetic make-up of the virus is important; HAV strains mutate in distinct regions of the viral genome as they become cell culture adapted. The second condition is the metabolic activity of the host cell at the time of infection. Cells in culture, although infected simultaneously, initiate HAV replication in an asynchronous manner. This asynchronicity may be caused by differences in the metabolic activity of individual cells, but there is no definitive evidence of cell-cycle dependence of HAV replication [12].

An initial step in the life cycle of a virus is its attachment to a cell surface receptor. The location and function of these receptors determines tissue tropism. Little is known about the mechanism of entry of HAV into cells. Some work has suggested that HAV could infect cells by a surrogate receptor-binding mechanism (by a nonspecified serum protein). HAV infectivity in tissue culture has been shown to require calcium and to be inhibited by the treatment of the cells with trypsin, phospholipases, and β-galactosidase [13]. A surface glycoprotein (HAVcr-1) on African green monkey kidney cells has been identified as a receptor for HAV. Blocking of HAVcr-1 with specific monoclonal antibodies prevents infection of otherwise susceptible cells. Experimental data suggest that HAVcr-1 not only serves as an attachment receptor, but may also facilitate the uncoating of HAV and its entry into hepatocytes [14].

Whatever the entry mechanism, once HAV enters a cell, the viral RNA is uncoated, cell host ribosomes bind to viral RNA, and polysomes are formed. HAV is translated into a large polyprotein of 2,227 amino acids. This polyprotein is organized into three regions: P1, P2, and P3. The P1 region encodes the structural proteins VP1, VP2, VP3, and a putative VP4. The P2 and P3 regions encode nonstructural proteins associated with viral replication.

The HAV RNA polymerase copies the plus RNA strand. The RNA transcript, in turn, is used for translation into proteins, which are used for assembly into mature virions. It appears that downregulation of HAV RNA synthesis occurs as defective HAV particles appear [15]. In addition, a group of specific RNA-binding proteins have been observed during persistent infection [16]. The origin and nature of these proteins is unknown, but they exert activity on the RNA template and are believed to play a regulatory role in the replication of HAV [17].

Numerous strains of HAV exist with considerable nucleotide sequence variability (15–25% difference within the P1 region of the genome). Human HAV strains can be grouped into four different genotypes (I, II, III, and VII), whereas simian strains of HAV belong to genotypes IV, V, and VI [18]. Despite the nucleotide sequence heterogeneity, the antigenic structure of human HAV is highly conserved among strains.

The HAV VP1/2A and 2C genes are thought to be responsible for viral virulence on the basis of experiments in which recombinant HAV caused acute hepatitis in animals following the construction of 14 chimeric virus genomes from two infectious complementary DNA clones that encoded a virulent and an attenuated HAV isolate (HM175 strain). Using this method, the genotype and phenotype of each virus were then compared [19].

Among the many strains of HAV, the HM175 and CR326 human HAV strains were used for the production of commercially available vaccines. Strain HM175 was isolated in 1978 from the human feces of Australian patients in a small outbreak of hepatitis A. CR326 was isolated from Costa Rican patients infected with HAV. The nucleotide and amino acid sequences showed 95% identity between the two strains. Vaccines prepared from these strains are thought to provide protection against all relevant human strains of HAV.

Variations in the HAV genome are thought to play a role in the development of acute liver failure (ALF) during acute HAV infection. The 5′ untranslated region of the HAV genome was sequenced in serum samples from 84 patients with HAV infection, including 12 with ALF [20]. The investigators observed relatively fewer nucleotide substitutions in the HAV genome of patients with ALF than in those without ALF ($P < 0.001$). The differences were most prominent between nucleotides 200 and 500, suggesting that nucleotide variation in the central portion of the 5′ untranslated region influences the clinical severity of HAV infection.

Hepatitis E virus

Hepatitis E virus was first visualized in 1983 when it was transmitted to a human volunteer and subsequently to an experimental animal model, thereby establishing its role as the etiologic agent of hepatitis E [7]. HEV is a spherical nonenveloped virus 32–34 nm in size with spikes and indentations on its surface. It was recently classified into the separate genus *Hepevirus*, which is the only member of the family Hepeviridae [21]. The genome of the virus is a positive single-stranded polyadenylated RNA of approximately 7.5 kb. It consists of three overlapping ORFs and short untranslated regions at the 5′ and

Table 23.1 Geographic distribution of hepatitis E virus genotypes [22,23].

Genotypes	Isolates
Genotype 1	Throughout Asia North Africa
Genotype 2	Mexico Central and western Africa (e.g., Chad, Nigeria)
Genotype 3 (found in humans and swine)	North America South America Europe (e.g., United Kingdom, France, Netherlands, Spain, Austria, Greece, Italy) Japan Australia New Zealand
Genotype 4	East and Southeast Asia (e.g., China, Japan, Taiwan, Vietnam)
Genotype 5	Avian isolates (appears to be a separate genus)
Heterogeneous	Europe Argentina

3′ termini. ORF1 is located at the 5′ end and consists of the nonstructural genes, while the 3′ end ORF2 represents one or more structural or capsid proteins. ORF2 contains important epitopes that can induce neutralizing antibodies and is the prime genomic area selected for vaccine development [22]. The function of ORF3 has not been elucidated.

Although there is no consensus on genotype classification, it is generally accepted that – on the basis of viruses having nucleotide divergence of not more than 20% of the nucleotides in the ORF2 region – five major HEV genotypes exist (Table 23.1). Genotypes 1 and 2 are strictly human pathogens. Genotypes 3 and 4 are likely from swine origin, but also infect humans. Genotype 5 is an avian strain common among chicken flocks that is considered unlikely to infect humans [23]. In addition, genetically heterogeneous isolates from several European countries have been designated as new genotypes, but this concept is not widely accepted. Similarly, two novel HEV genotypes have been described from Argentina [22]. Despite the diversity of HEV genotype, it is accepted that HEV exists as a single serotype [24], a concept that makes possible the development of a broadly protective vaccine.

In 1990, the genome of HEV was cloned from infectious experimental animal bile. These experiments established that the clone ET1.1 represented a genuine portion of the HEV genome [8]. Such advances permitted the development of sensitive and accurate assays that allow the diagnosis of the infection, better understanding of its epidemiology, and development of candidate vaccines.

Epidemiology

Hepatitis A virus

Acute hepatitis A is a reportable infectious disease in the United States with a 90% decline in incidence since 1995. In 2006, there were 3,579 reported cases of HAV infection, corresponding to a rate of infection of 1.2 per 100,000, which was down from 4 per 100,000 in 2001. With the underreporting of cases and the occurrence of asymptomatic infections taken into consideration, the true number HAV infections in 2006 was calculated to be 32,000, which was down from 93,000 in 2001 [25,26]. The greatest rates of decline have been among children from states where routine vaccination of children has been recommended since 1999. The highest rate of reported disease has historically been among children aged 5–14 years. However, due to the rapid rate of decline in children, rates are similar among different age groups, with adults aged 20–44 years holding the highest rate of disease in 2006 [27].

The epidemiologic risk factors for HAV infection reported for the US population in 2006 were as follows: unknown, 65%; international travel, 15%; sexual or household contact with a patient who has hepatitis A, 10%; other contact with hepatitis A patient, 12%; male homosexual activity, 9%; food or water-borne outbreak, 8%; child or employee in a daycare center, 4%; contact with a daycare child or employee, 4%; and injection drug use, 2% [27].

HAV infection generally follows one of three epidemiologic patterns [28]. In countries where sanitary conditions are poor, most children are infected at an early age. Although earlier seroepidemiologic studies routinely showed that 100% of preschool children in these countries had detectable antibody to HAV (anti-HAV) in serum, presumably reflecting previous subclinical infection, subsequent studies have shown that the average age of infection has increased rapidly to 5 years and above, when symptomatic infection is more likely. For example, 82% of 1,393 Bolivian school children were shown to have detectable anti-HAV. When they were stratified into two groups according to family income, a significant difference was found between the groups: 95% of children from low-income families had detectable anti-HAV versus 56% of children from high-income families [29]. The second epidemiologic pattern is seen in industrialized countries, where the prevalence of HAV infection is low among children and young adults. In the United States, the prevalence of anti-HAV is approximately 10% in children but 37% in adults [30]. The third epidemiologic pattern is observed in closed or semiclosed communities, such as some isolated communities in the South Pacific, where HAV is capable (through epidemics) of infecting the entire population, which then becomes immune.

Table 23.2 Detection of hepatitis A virus (HAV) and infectivity of human secretions or excretions.

Secretion/excretion	Comment	Reference
Stool	Main source of infection. HAV is detectable during the incubation period and for several weeks after the onset of disease. After the onset of symptoms, HAV is detectable in 45% and 11% of fecal specimens from the first and second week, respectively, whereas HAV RNA (by a polymerase chain reaction assay) is detectable for 4–5 months	Coulepis et al. [35]; Rosenblum et al. [36]
Blood	Viremia is present during the incubation period. Blood collected 3 and 11 days before the onset of symptoms caused post-transfusion infection in donors. Chronic viremia does not occur	Francis et al. [37]; Harden et al. [38]
Bile	HAV has been detected in the bile of chimpanzees infected with HAV	Schulman et al. [39]
Urine	HAV is detected in low titer during the viremic phase. A urine sample infected one of 12 subjects after oral inoculation. Urine contaminated with blood was also infectious	Giles et al. [40]; Findlay [41]
Nasopharyngeal	Unknown in humans. HAV has been identified in the oropharynx of experimentally infected chimpanzees	Cohen et al. [42]
Semen, vaginal fluid	Uncertain. HAV may be detectable during the viremic phase	Berge et al. [43]

Thereafter, newborns remain susceptible until the virus is reintroduced into the community.

Whatever the epidemiologic pattern, the primary route of transmission of HAV is the fecal–oral route, by either person-to-person contact or ingestion of contaminated food or water. Although rare, transmission of HAV by a parenteral route has been documented following blood transfusion [31,32] or use of blood products [33]. Cyclic outbreaks among users of injection and noninjection drugs and among men who have sex with men (up to 10% may become infected in outbreak years) have been reported [34]. Table 23.2 provides information about the detection of HAV and its infectivity in human body fluids [35–43].

Approximately 11–22% of patients with acute hepatitis A require hospitalization with an average length of stay of 4.6 days costing, on average, US$7,926 per patient in 2004 [44]. In one outbreak involving 43 persons, the total cost was approximately $800,000 [45]. On average, 27 workdays are lost per adult case of hepatitis A. In adolescents and adults, the combined direct and indirect costs associated with HAV infection in the United States totaled approximately $488.8 million in 1997 compared with $93 million in 2006 [44]. This is a direct result of the dramatic reduction in infections seen since the introduction of the HAV vaccine combined with the US HAV vaccination policies [46].

Hepatitis E virus

Like HAV, the primary route of transmission of HEV is the fecal–oral route, most often via contaminated water. HEV causes outbreaks of acute hepatitis or is a source of sporadic, self-contained infections. The massive waterborne outbreaks of acute hepatitis in New Delhi in the 1955–1956 period [47] were diagnosed as "classic" waterborne hepatitis A. However, serologic testing of the available specimens in 1980 ruled out acute hepatitis A and acute hepatitis B allowing the recognition of the infection as non-A, non-B hepatitis [48]. Since then, at least 17 HEV outbreaks have occurred in India [49] and more than 50 in Asia, Africa, and the American continents [22]. In 1975, sporadic cases from Costa Rica were reported in which the illnesses were neither hepatitis A nor hepatitis B [50]. In 1986 and 1987, outbreaks of acute hepatitis occurred in two rural villages in Mexico; 223 cases were diagnosed as non-A, non-B hepatitis, and stool samples from some cases yielded viral particles 32–34 nm in size, similar to the enterically transmitted non-A, non-B hepatitis from Asia [51].

Hepatitis E has been detected among US travelers to endemic regions as well [52]; however, a unique HEV whose genome is significantly different from the Burmese or Mexican strains has been described in the United States in humans and swine [53]. In 2004, approximately 4,000 suspected cases of hepatitis E were reported by health clinics in Darfur, Sudan. Thousands of possible cases were also reported among refugees in Chad and Iraq [54]. Hepatitis E is a common disease in many areas of the world, and it is recognized as a frequent cause of sporadic hepatitis in Asia. It is the second leading cause (behind hepatitis B) of acute clinical hepatitis in adults in North Africa and the Middle East, and is the most common cause in Nepal, India, and throughout Central and Southeast Asia [55,56]. Table 23.3 shows the percentage of clinical viral hepatitis attributable to each of the viral hepatitides in selected regions.

Table 23.3 Etiologies of clinical viral hepatitides among adults in selected regions [56].

Location	Etiology

Adapted from Purcell and Emerson [56].

Anti-HEV has been detected in many areas of the world, including industrialized countries where no defined epidemics have been reported. Some species of animals (swine, rodents, monkeys, etc.) have been found to have detectable anti-HEV [57], raising the possibility of HEV being a zoonotic disease that can be acquired from animals; however, there is no confirmation of such transmission. Other possible zoonotic reservoirs include wild boars, cows, sheep, goats, and deer [55]. In areas where sporadic cases of HEV due to genotypes 3 and 4 occur in humans, swine have been found to have detectable HEV from the same genotypes [58].

Each genotype of HEV that infects humans has a distinct geographic distribution (see Table 23.1 and Fig. 23.1). Genotype 1 is found in most parts of Asia and in northern Africa. Genotype 2 was initially identified in an epidemic in Mexico in the 1980s, but it has also been found in western Africa. Genotype 3 mostly causes sporadic cases in nonendemic areas such as the United States, Europe, South America, and Japan. Genotype 4 also causes sporadic cases in nonendemic regions and has been isolated from cases in Taiwan, China, Japan, and Vietnam [23,56].

The prevalence of antibody to HEV varies in different regions of the world, showing differing patterns even among areas where the disease is endemic. For instance, in a highly endemic area like India, the prevalence of anti-HEV would be expected to mirror that of other enterically transmitted viruses, such as HAV, where nearly all of the population is exposed at a young age. However, the prevalence of anti-HEV in India does not appear to have a substantial increase until the second decade of life, when it levels out at a prevalence of around 40% thereafter. The prevalence of anti-HEV in Egypt, however, where no water-borne epidemics have been reported, more closely resembles that of anti-HAV in developing countries with close to 90% of the population developing the antibody within the first decade of life. In industrialized countries, like the United States, where clinical cases of HEV are rare, the prevalence of anti-HEV is much higher than expected and is even higher than that of anti-HAV in some areas (Fig. 23.2). The highest prevalence of anti-HEV in the United States has been found in states that are large producers of swine, leading to the conclusion that zoonotic transmission of attenuated strains of HEV

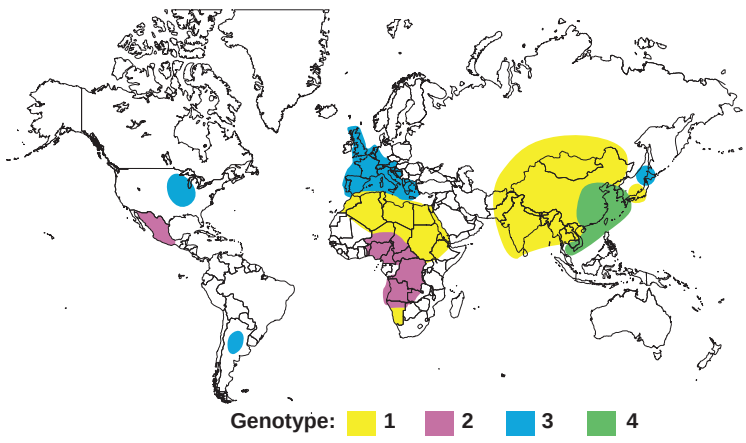

Figure 23.1 Geographic distribution of human hepatitis E virus genotypes. (Reproduced from Purcell and Emerson [56] with permission from Elsevier.)

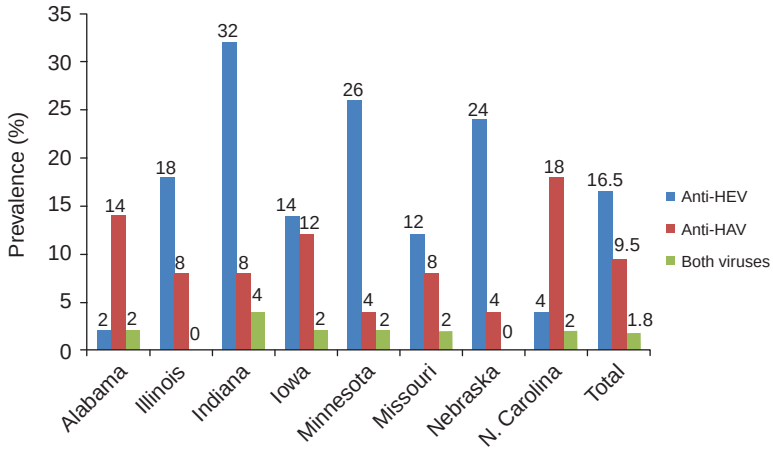

Figure 23.2 Prevalence of anti-hepatitis A virus (anti-HAV) and anti-hepatitis E virus (anti-HEV) in 400 US blood donors from eight states in 2000. (Adapted from Purcell and Emerson [56].)

(likely genotypes 3 and 4) may be the cause of this finding [56]. Supporting this conclusion is the observation that the seroprevalence rate of anti-HEV in Indonesia is ten-fold higher in Hindus than Muslims, which indicates a possible role of consuming pork [55,59]. The meaning of such high prevalences in low endemic areas is still a source of uncertainty. In addition to representing true HEV infection, some scientists attribute the high prevalence to the nonspecificity of the serologic assays, whereas others believe that it may be a cross-reaction with another infectious agent.

Recent reports have also shown that HEV is a cause of graft hepatitis in solid-organ transplant recipients, even in low endemic areas [60–63]. While HEV is typically a self-limited infection, it appears to cause chronic liver disease in some of these immunosuppressed individuals. A French group reported the largest case series to date describing 14 solid-organ transplant recipients receiving immunosuppressive drugs who had an early onset of elevated transaminase levels and were found to have detectable HEV RNA [60]. Eight of these 14 patients had persistent HEV viremia and liver enzyme elevation at follow-ups of 10–24 months, which would indicate evolution to chronic hepatitis. Liver biopsies in some of these patients with chronic hepatitis E showed dense lymphocytic infiltrate of the portal areas with variable degrees of piecemeal necrosis and fibrosis. Of note, the patients who developed chronic hepatitis E had a significantly shorter time between transplantation and development of HEV infection; therefore, their CD2, CD3, and CD4 lymphocyte counts were lower than those of patients whose HEV infection resolved [23]. To date, all reports of chronic hepatitis E infection in solid-organ transplant recipients have been infections with genotype 3, which is the genotype found commonly in domesticated livestock. The persistence of HEV infection in this population could be a phenomenon similar to that seen with other generally self-limited viral agents, such as Epstein–Barr virus and cytomegalovirus, which are also known to cause persistent infections in immunocompromised hosts. Further studies are needed to determine if genotype 1 can also cause persistent infection, as this genotype is responsible for the majority of human HEV infections worldwide.

Pathogenesis

Hepatitis A virus

Once HAV is ingested and survives gastric acid, it traverses the small intestine mucosa and reaches the liver through the portal vein. The precise mechanism of hepatic uptake in humans is unknown (see earlier). In an experimental model on African green monkey kidney cells, the putative cellular receptor for HAV has been identified as a surface glycoprotein [14]. Once the virus reaches the hepatocyte, it starts replicating in the cytoplasm, where it is seen on electron microscopy as a fine granular pattern; however it is not present in the nucleus. HAV is distributed throughout the liver. Although HAV antigen has been detected in other organs (lymph nodes, spleen, kidney), the virus appears to replicate exclusively in hepatocytes. Once the virus is mature, it reaches the systemic circulation through the hepatic sinusoids and is released into the biliary tree through the bile canaliculi, passed into the small intestine, and eventually excreted in the feces.

The pathogenesis of HAV-associated hepatocyte injury is not completely defined. The lack of injury to cells in cell culture systems suggests that HAV is not cytopathic. Immunologically mediated cell damage is more likely. The emergence of anti-HAV could result in hepatic necrosis during the immunologically mediated elimination of HAV.

Hepatitis E virus

Studies in human volunteers and animal models have permitted the characterization of the pathogenesis of

HEV. In humans, abnormal levels of aminotransferases were detected 4–5 weeks after the ingestion of contaminated material, and they remained abnormal for 1–3 months [7,64]. Viral particles were excreted in stool approximately 4 weeks after ingestion of the inoculum, and the shedding lasted approximately 2 weeks when tested by immune electron microscopy. Using molecular biology techniques, shedding of viral particles has been observed close to 2 months after the ingestion. Immunoglobulin M (IgM) antibody to HEV parallels the rise of aminotransferase levels and declines in titer quickly, disappearing in a few weeks, although some patients may have detectable IgM anti-HEV for a few months. The IgG anti-HEV level rises slowly and remains detectable for months, probably years, after the infection.

Little is known about what happens once the virus is ingested. It is likely that the virus traverses through the small intestine and reaches the liver through the portal vein. The precise mechanism of hepatic uptake in humans is not known. Histopathologic features of HEV infection include necroinflammatory processes seen in acute viral hepatitis and cholestatic hepatitis. HEV antigen was observed in the cytoplasm of infected hepatocytes as soon as 10 days after experimental intravenous inoculation and persisted for approximately 3 weeks [65]. Interestingly, in some outbreaks, the cholestatic hepatitis has been described as a gland-like transformation of hepatocytes with bile stasis. The pathogenesis of HEV-associated hepatocyte injury is not completely defined.

Clinical features

Hepatitis A virus

Infection with HAV does not result in chronic disease, but in an acute, self-limited episode of hepatitis. Rarely, acute hepatitis A can have a prolonged or a relapsing course, and profound cholestasis can occasionally occur. Commonly, the incubation period is 2–4 weeks, rarely up to 6 weeks. The mortality rate is low in previously healthy persons. Morbidity can be significant in adults and older children.

The clinical characteristics of cases of hepatitis A reported in 2007 in the United States were similar to those in previous years, with a slight preponderance of cases in men of all age groups. Overall, 73% of patients manifested jaundice, 35% required hospitalization, and 0.8% died. The need for hospitalization increased with age, from 21% among children less than 5 years old to 53% among persons 60 years of age or older [66].

HAV infection usually presents in one of five different clinical patterns: (i) asymptomatic without jaundice; (ii) symptomatic with jaundice and self-limited for approximately 8 weeks; (iii) cholestatic with jaundice lasting 10 weeks or more; (iv) relapsing with two or more bouts of acute HAV infection occurring over a 6–10-week period; and (v) acute liver failure.

Children aged between 2 and 5 years of age are usually asymptomatic, and jaundice develops in only 20% of cases. On the other hand, symptoms develop in 80% of children aged 5 years or older. A high rate of symptoms occurs in adolescents and adults as well. HAV infection with prolonged cholestasis is also a rare variant. The clinical and laboratory findings in this setting can resemble pancreatic cancer, which occasionally leads to invasive diagnostic procedures (inappropriately) because the diagnosis of acute hepatitis may not be readily accepted in patients with jaundice for several months, even in the presence of detectable anti-HAV of the IgM class [67]. A relapsing course is observed in approximately 10% of patients with acute hepatitis A. Shedding of HAV in stool has been documented during the relapse phase. This variant is benign, and the infection ultimately resolves [68]. Neither the cholestatic variant nor relapsing hepatitis A is associated with increased mortality, though the cholestatic variant can prove fatal in the elderly. In all cases, treatment is symptomatic. Acute hepatitis A, unlike hepatitis E, is not associated with an increased mortality rate in pregnant women.

Prodromal symptoms in patients with acute hepatitis A include fatigue, weakness, anorexia, nausea, vomiting, and abdominal pain. Less common symptoms include fever, headache, arthralgias, myalgias, and diarrhea. Dark urine precedes other symptoms in approximately 90% of infected persons; this symptom occurs within 1–2 weeks of the onset of prodromal symptoms. Symptoms of hepatitis may last from a few days to 2 weeks and usually decrease with the onset of clinical jaundice. Right upper quadrant tenderness and mild liver enlargement are present on physical examination in 85% of patients; splenomegaly and cervical lymphadenopathy are each present in 15%. Complete clinical recovery is achieved in 60% of affected persons within 2 months and in almost everyone by 6 months. The overall prognosis of acute hepatitis A in otherwise healthy adults is excellent. Potentially fatal complications (e.g., ALF) develop in a few patients (see below).

Acute HAV infection must be differentiated from other causes of acute viral hepatitis, autoimmune hepatitis, and other causes of acute hepatitis by appropriate serologic testing. However, in some cases, the diagnosis may be difficult to make because the patient may harbor more than one viral infection, such as chronic hepatitis B or chronic hepatitis C, with superimposed acute HAV infection.

Hepatitis E virus

The clinical features of HEV are difficult to differentiate from those of other types of viral hepatitis. The incubation period ranges between 15 and 60 days, usually becoming symptomatic 40 days after exposure. Adults appear

to be at a greater risk of developing symptoms than adolescents and children. Most patients experience malaise, lack of appetite, nausea, and vomiting. A third of infected patients experience fever or abdominal pain. Few patients experience diarrhea, arthralgias, or skin rash. Serum tests show abnormal levels of aminotransferases and hyperbilirubinemia. Most patients do well, and because there are no chronic sequelae, they recover fully. However, acute liver failure is associated with HEV more often than with any other viral hepatitis [69], particularly among pregnant women. Case fatality rates among HEV-infected pregnant women have been reported of between 15% and 25% [70,71]; however, work with experimental pregnant animals failed to show differences in severity of HEV infection when compared with nonpregnant animals [72].

Acute liver failure with hepatitis A and E

Hepatitis A virus

Acute liver failure caused by HAV is rarely seen in children, adolescents, or young adults. However, the case fatality rate in people over 49 years of age with acute hepatitis A is reported to be 1.8%, which is much higher than the overall rate of 0.3% in persons of all ages. Hepatic failure caused by hepatitis A becomes manifest in the first week of illness in approximately 55% of affected patients and during the first 4 weeks in 90%; ALF is rarely seen after 4 weeks [73]. The contribution of HAV to ALF has been reported to be increased in populations classified as hyperendemic for HAV. In a report from India, where 276 patients with ALF were seen between 1994 and 1997, 10.6% of the cases among adults were caused by HAV. HAV had been responsible for only 3.5% of cases among 206 patients with ALF seen in the same community from 1978 to 1981 [74].

Certain populations have increased morbidity and a high risk of ALF from HAV infection. Among these groups are the elderly [75] and persons with chronic liver disease. A 1998 report described the clinical outcome of 256 persons hospitalized for acute hepatitis A in Tennessee from January 1994 through December 1995 [76]. On admission, 89% had experienced prolonged nausea or vomiting, and 26% had a prolonged prothrombin time (>3 seconds); 39 had serious complications (19 were hepatobiliary in nature and 20 were extrahepatic complications), and five (2%) died. Morbidity and mortality correlated with age. Twenty-five percent of patients aged 40 and above had at least one complication as compared with 11% of patients younger than 40 years of age ($P = 0.014$).

Although two reports since the late 1990s have described a decline in the number of cases of acute viral hepatitis among patients with ALF in the United States [77,78], this decline is attributable principally to the control of hepatitis B. The contribution of HAV infection to ALF has remained unchanged since the 1970s, despite the availability of highly efficacious vaccines.

Hepatitis E virus

Acute liver failure resulting in death or liver transplant due to HEV has been observed as well. Unlike HAV, there is not a clear age-dependent severity seen with HEV. Also, the reported case fatality rate of HEV (0.5–4%) is considerably higher than that of HAV. This higher mortality rate with HEV may reflect selection bias as much of the data have been obtained from hospitalized cases that may represent more severe disease [23]. Indeed, in population studies during outbreaks of HEV in India and China, mortality rates have been much lower, ranging from 0.07% to 0.6% [79,80].

The HEV genotype appears to play a role in the severity of illness. ALF has been reported with all genotypes with the possible exception of genotype 2 [81]. Genotype 1, which is the most common subtype in endemic areas, is more pathogenic in humans, whereas genotypes 3 and 4, which can be passed via zoonotic transmission, appear to be less pathogenic in humans [82].

Interestingly, the case fatality rate of HEV infection is much higher in pregnant women, ranging anywhere from 15% to 25%. The reasons for this increased mortality during pregnancy are unclear. Differences in immune and hormonal factors that occur during pregnancy as well as genetic and environmental factors have been postulated [82]. Also, some data have suggested that severe fetal infections and fetal death may lead to more severe maternal outcomes through the production of toxins that overwhelm the maternal circulation [83].

The increased mortality in pregnancy varies across geographic regions as well. In a recent study from a tertiary care center in northern India, hepatitis E infection accounted for 60% of viral hepatitis among pregnant females admitted to the hospital with jaundice. Of these pregnant females with hepatitis E, 55% (73/132) developed ALF [84]. In contrast, no cases of severe acute viral hepatitis from HEV have been reported in Egypt where the prevalence of anti-HEV is high in rural communities. In one recent cohort study of 2,428 pregnant women in the Nile delta, the anti-HEV prevalence was 84.3%; however, no cases of severe acute viral hepatitis were reported [85]. The reasons for this geographic difference are unclear. It could be related to differences in virulence of HEV strains in the different areas, or it could be related to the age of exposure to HEV in different regions and subsequent development of long-lasting immunity or modification of responses to later exposures.

Diagnosis

Hepatitis A virus

Acute hepatitis A is clinically indistinguishable from other forms of viral hepatitis. The diagnosis of infection is based on the detection of specific antibodies against HAV (anti-HAV) in serum. A diagnosis of acute hepatitis A requires the demonstration of IgM anti-HAV in serum. The test is positive from the onset of symptoms [86] and usually remains positive for approximately 4 months [87]. Some patients may have low levels of detectable IgM anti-HAV for more than 1 year after the initial infection [86]. IgG anti-HAV is also detectable at the onset of the disease, remains present usually for life, and is interpreted as a marker of previous HAV infection following clinical recovery. Figure 23.3 shows the typical serological profile seen with acute HAV infection.

Testing for HAV RNA is limited to research laboratories. HAV RNA has been detected in serum, stool, and liver tissue. Viral RNA can be amplified by polymerase chain reaction (PCR) methodology [33]. With a PCR assay, HAV RNA has been documented in human sera for up to 21 days after the onset of illness [88]. The use of HAV RNA testing has been described in a report of 76 French patients with acute HAV infection seen between January 1987 and April 2000; 19 of them had ALF [89]. Ten patients required liver transplantation, and one patient died while awaiting liver transplantation. The HAV RNA status was determined in 39 of the 50 patients in whom sera and clinical data were available, including the 19 with ALF. HAV RNA was detected in 36 of these 50 patients (72%). The likelihood that HAV RNA was undetectable was greater in patients with ALF than in those without ALF ($P < 0.02$). When HAV RNA was detectable, titers were lower in patients with encephalopathy than in patients without ALF (3.6 log versus 4.4 log, $P = 0.02$). These data suggest that the detection of IgM anti-HAV and undetectable or low-titer HAV RNA in patients with severe acute hepatitis may signal an ominous prognosis and the need for early referral for liver transplantation. As in other studies, HAV genotype did not seem to play a role in the severity of clinical manifestations [90].

Hepatitis E virus

For HEV, the development of modern diagnostic tests was possible in part because of cloning of the virus [8] and the development of four recombinant viral antigens representing two distinct antigenic domains from two HEV strains [91]. Before this advance, scientists relied on immune electron microscopy to detect viral particles in stool with the consequent limitations of intensive labor and reduced sensitivity. Enzyme immunoassays are available to detect antibodies against HEV IgM or IgG classes of antibodies [91]. These tests have an 80–100% probability of detecting the markers of acute infection (e.g., IgM anti-HEV). Data are limited to evaluate the longevity of IgG anti-HEV. Some studies have shown that IgG anti-HEV persists for at least 1 year after an acute infection [92]; others have found that it may last longer. When 53 children from the outbreak in Mexico in the period 1986–1987 [51] were tested for anti-HEV 9 years later, 70% were found to have detectable IgG antibody [93]. Figure 23.4 shows the typical serological profile seen with acute HEV infection.

Prevention and treatment

Hepatitis A virus

Recommendations concerning immunoprophylaxis against HAV were published in December 1999 by the Advisory Committee on Immunization Practices (ACIP)

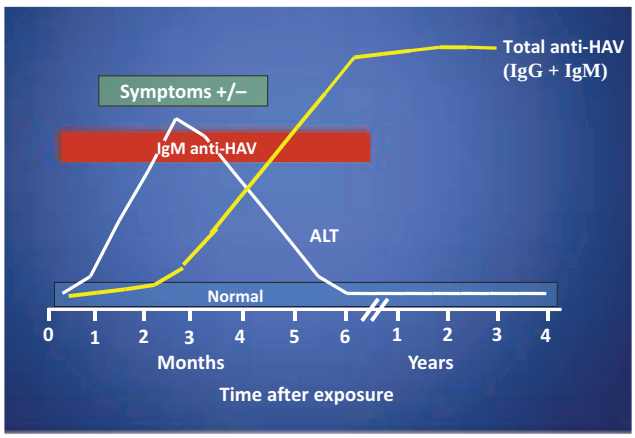

Figure 23.3 Typical serologic profile of acute hepatitis A virus (HAV) infection. ALT, alanine aminotransferase; IgG, IgM, immunoglobulin G and M.

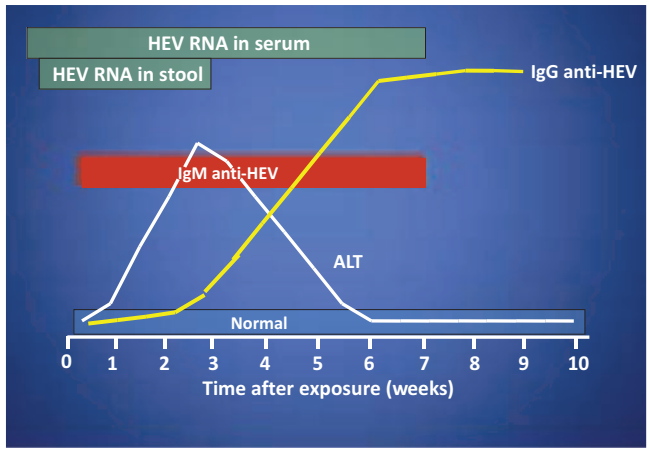

Figure 23.4 Typical serologic profile of acute hepatitis E virus (HEV) infection. ALT, alanine aminotransferase; IgG, immunoglobulin G.

Box 23.1 Groups at high risk of hepatitis A virus infection.

- Healthy persons who travel to endemic areas, work in occupations for which the likelihood of exposure is high, are family members of infected patients, or adopt infants or children from endemic areas
- Persons with chronic liver disease
- Persons who have tested positive for human immunodeficiency virus
- Men who have sex with men
- Users of injection and noninjection illicit drugs
- Persons with clotting factor disorders

[34]. The overall strategy was to protect persons from disease and to lower the incidence of HAV infection in the United States. The available monovalent vaccines were licensed for use in children older than 2 years of age but became licensed for use after 12 months of age [34,94]. In accordance with the 1999 ACIP guidelines, high-risk populations were targeted for immunization. After achieving a dramatic reduction in incidence rates, a universal childhood vaccination policy was enacted in 2006 with the hope of eventually eliminating indigenous HAV transmission in the United States. The decline in rates has intuitively been greater in children than in adults, effectively removing children as a high-risk population and potentially removing the virus's primary reservoir in the United States [27,44]. Currently, all children should receive hepatitis A vaccine at age 1 year or older; high-risk populations are targeted for immunization and are listed in Box 23.1.

There are no specific medications to treat acute hepatitis A; symptomatic treatment is the rule. Attention to sanitation and administration of serum immunoglobulin have been the mainstays of preventing HAV infection. The availability of excellent HAV vaccines has rendered the use of immunoglobulin for preexposure prophylaxis unnecessary. Furthermore, in June 2007, the HAV vaccine was granted approval for postexposure prophylaxis in immunocompetent individuals 12 months to 40 years of age without chronic liver disease [97]. This change was made following the results of a study comparing the efficacy of the vaccine to immunoglobulin in postexposure prophylaxis. There were low rates of clinical infection in both groups: 4.4% of individuals in the vaccine group developed clinical hepatitis A compared with 3.3% in the immunoglobulin group [96]. This study, however, likely excluded asymptomatic infections. In the vaccine group, 162 individuals with positive HAV IgM antibodies were excluded compared with 50 individuals in the immunoglobulin group either due to a lack of symptoms and/or because they did not have an elevated alanine aminotransferase (ALT) more than two times the normal limit. Indeed, it is possible that within this group there existed a number of asymptomatic hepatitis A infections that still posed an infectious risk to others.

The ACIP discussed the findings and limitations of the HAV vaccine versus immunoglobulin noninferiority study taking into account data from Canada and the United Kingdom, countries that have been using the vaccine as postexposure prophylaxis for more than 5 years. They concluded the vaccine is safe and comparable to immunoglobulin in protecting against clinical disease. ACIP guidelines allow for persons who have recently been exposed to HAV and who have not been vaccinated previously to be administered a single dose of single-antigen hepatitis A vaccine or immunoglobulin (0.02 mL/kg) as soon as possible within 2 weeks after exposure. Some of the benefits of the vaccine include long-term immunity if the second dose is received in accordance with the standard vaccine schedule (Table 23.4), cost savings, and a wide availability when compared with immunoglobulin [95]. Although immunoglobulin is considered safe, there is a perceived health risk as it is a blood derived product. Immunoglobulin can cause fever and myalgias just as the vaccine can, but pain at the injection site is usually more pronounced. Postexposure prophylaxis with immunoglobulin can be given safely at the same time as initiation of active immunization with the vaccine [97].

The HAV vaccine was first licensed in the United States in 1995; two inactivated HAV vaccines are commercially available. Extensive use of the vaccines in clinical trials and postmarketing surveillance support the safety and efficacy of these products. Havrix® is manufactured by SmithKline Biologicals (Rixensart, Belgium) and Vaqta® by Merck Sharp and Dohme (West Point, Pennsylvania). Both vaccines are derived from HAV grown in cell culture. The final products are purified and formalin-inactivated; they contain alum as an adjuvant. The basic difference between the two commercially available vaccines is the HAV strain used for preparation. Havrix is prepared with the HM175 strain, whereas Vaqta is prepared with the CR326 strain [98,99]. The difference is of little practical importance because both vaccines are safe and immunogenic. The doses and schedule of immunization are shown in Table 23.4. After vaccination with Havrix, anti-HAV is estimated to remain detectable in serum for approximately 20 years; immunity may last longer [100].

From the time the HAV vaccine was licensed in the United States through to 2005, more than 50 million doses were administered. Worldwide, more than 188 million doses of HAV vaccine were administered through to 2005. Among adults, the most common local side effects were

soreness at the injection site (56%), headache (14%), and malaise (7%). In children, the most common side effects were soreness at the injection site (15%), feeding problems (8%), headache (4%), and injection site induration (4%) [44].

In the United States through to 2005, the national Vaccine Adverse Event Reporting System received 6,136 reports of unexplained adverse events after immunization with the HAV vaccine alone or in combination with other vaccines. Of the 6,136 reports, 871 were considered serious and included Guillian–Barré syndrome, idiopathic thrombocytopenic purpura, elevated liver transaminases, and seizures in children [44]. However, no reported serious event could be attributed definitively to the HAV vaccine, and the reported rates did not exceed the expected background rates. For example, the general population incidence of Guillain–Barré syndrome ranges from 0.5 to 2.4 cases per 100,000 person-years, and among adult HAV vaccine recipients the incidence of Guillain–Barré was 0.2 cases per 100,000 person-years [44].

A combined formulation of hepatitis A and B vaccines (Twinrix®) is available and has an excellent record of efficacy and safety [101]. Although there have been some long-term studies that show antibody persistence in children and adolescents, there is evidence of lower seroconversion rates in children 1–6 years of age when compared with the standard monovalent vaccines [102]. It is therefore currently only Food and Drug Administration (FDA) approved for individuals 18 years of age and older.

As a result of the reduction in endemic cases of hepatitis A in the United States, the largest proportion of patients being infected are nonimmune adults traveling abroad to endemic areas. Even if medical advice is sought prior to travel there is usually insufficient time to complete the standard immunization schedule. Havrix and Vaqta share an FDA-approved accelerated vaccination schedule for this purpose. If given at least 2 weeks prior to travel, a single dose of either monovalent vaccine results in appropriate protective serum antibody titers [95]. On March 28, 2008 the FDA approved an accelerated vaccination schedule for Twinrix that can be completed within 30 days with a booster at 12 months, after studies showed equivalent protection compared with standard and alternate scheduled individual monovalent vaccine doses. After 1 year, HAV seroconversion rates were 100%, and HBV seroconversion rates were 96.4–100% [103,104]. The Twinrix accelerated schedule is being discussed for use in US correctional facilities for new convicts where high-risk activities place them at risk for both hepatitis A outbreaks and hepatitis B infections [105]. The dosing schedules are shown in Table 23.4.

Hepatitis E virus

For acute HEV infection, no defined antiviral therapy exists, so treatment is mainly supportive. In cases of acute liver failure from HEV, liver transplantation should be considered. Some investigators have evaluated the efficacy of pre- or postexposure to serum immunoglobulins as prophylaxis to prevent acute HEV hepatitis. Unfortunately, even when using serum immunoglobulins from

Table 23.4 Recommended regimens for hepatitis A vaccination (intramuscular injection in deltoid).

Vaccine	Age (years)	Dose	Volume (mL)	Dosing schedule
Havrix:	1–18	720 ELU	0.5	0 and 6–12 months
	>18	1440 ELU	1.0	0 and 6–12 months
Accelerated schedule	1+	One age-appropriate dose	Age appropriate	≥2 weeks prior to travel[a]
Postexposure prophylaxis[b]	1+	One age-appropriate dose	Age appropriate	<2 weeks after exposure[a]
Vaqta:	1–18	25 units	0.5	0 and 6–18 months
	>18	50 units	1.0	0 and 6–18 months
Accelerated schedule	1+	One age-appropriate dose	Age appropriate	≥2 weeks prior to travel[a]
Postexposure prophylaxis[b]	1+	One age-appropriate dose	Age appropriate	<2 weeks after exposure[a]
Twinrix:	≥18	720 ELU HAV, 20 mg HBV	1.0	0, 1, and 6 months
Accelerated schedule	≥18	720 ELU HAV, 20 mg HBV	1.0	0, 7, and 21–30 days[a]
Postexposure prophylaxis				Not FDA approved

[a]Boosters necessary for long-term protection: Vaqta at 6 months; Havrix between 6 and 12 months, and Twinrix at 12 months (not FDA approved).
[b]For individuals exposed to HAV who were not previously immunized against HAV.

endemic regions (e.g., India), no clinical benefit was observed [106]. Prevention against HEV infection is associated with hygienic measures and clean water. No vaccine for human use is commercially available yet, but several recombinant HEV proteins have been evaluated as vaccine candidates. Table 23.5 shows some of these vaccines [107].

GlaxoSmithKline (GSK) Biologicals has worked on the development of a hepatitis E vaccine to protect adolescents and adults. The vaccine is a 56 kDa recombinant product expressed in insect cells from a baculovirus vector. It was initially developed at the National Institutes of Health (NIH) in the United States and subjected to successful phase I studies [108]. Recently, a blinded, placebo-controlled study was conducted in Nepal involving 2,000 adults from the Royal Nepalese Army. The study was a collaboration between GSK, the US Army, the Royal Nepalese Army, and the US NIH. The vaccine was administered as three injectable doses at 0, 1, and 6 months, and it was shown to be safe and immunogenic. The vaccine efficacy was calculated to be 97% among vaccine recipients because only three subjects among the 898 who were fully immunized developed acute HEV, while 66 of the 896 placebo recipients had acute HEV [109].

While promising, this study had several limitations. First, the subjects were overwhelmingly young men (mean age 25 years). Further study is therefore needed to determine if the vaccine is safe and effective for women of child-bearing age, children, and other populations at high risk, including those with chronic liver disease. Also, the study looked at clinical disease rate and not HEV infection rate, so no inference can be made about the vaccine's effectiveness at reducing transmission of the virus within a community. Finally, the anti-HEV antibody titers were significantly decreased in a large percentage of the study subjects by the end of the follow-up period, so the duration of protection from the vaccine needs to be further studied [23]. According to a recent *Vaccine* conference report, the vaccine "needs 4–5 years' more work and further investment of at least US$ 50 million for research and development to reach a licensing stage" [55].

A Chinese scientific group has been developing another HEV vaccine named HEV 239. Like the GSK vaccine, this vaccine is produced with truncated structural proteins but is more extensively truncated, consists of 23 nm virus-like particles, and is expressed in *Escherichia coli*. In a randomized, controlled phase II clinical trial of the vaccine it was administered as either two or three injectable doses at 0 and 6 months, or at 0, 1, and 6 months. The study showed that vaccination with two or three doses induced protective antibodies in 98% or 100% of subjects, respectively. New HEV infections (inferred by asymptomatic seroconversion or rise in antibody titers) occurred less often in vaccine recipients than in control subjects, thereby indicating that the vaccine was protective [110]. A phase III trial of this vaccine was recently completed as well. The study included over 100,000 participants, of whom 48,693 received three doses of the vaccine. Fifteen of 48,663 participants in the placebo group developed hepatitis E compared with none in the vaccine group during a follow-up period of 12 months. The vaccine was therefore considered 100% effective after three doses [111]. The duration of protection as well as the safety and efficacy in high-risk populations (i.e., pregnant women, infants, and chronic liver disease patients) remains unknown.

Antiviral therapy for chronic HEV has been considered and attempted. A recent report detailed treatment for chronic HEV in two immunocompromised patients. Both subjects received daily oral ribavirin 12 mg/kg for 12 weeks. At the end of therapy and during an 8–12-week follow-up, the patients stopped shedding HEV, their liver tests normalized, and the HEV RNA remained undetectable. Ribavirin was considered potentially effective in patients with chronic HEV [112].

Immunization against hepatitis A virus in patients with chronic liver disease

Persons with chronic liver disease are at increased risk of HAV- and HEV-related morbidity and mortality if they become infected with one of these viruses. Therefore, preexposure prophylaxis with the HAV vaccine has been recommended for patients with chronic liver disease who are susceptible to HAV [113]. This recommendation should be extended to pre- and postliver transplant recipients, although the immunogenicity of the HAV vaccine is reduced in these persons [114,115].

An episode of acute hepatitis in a patient with underlying chronic liver disease poses the risk of considerable morbidity and mortality. Although the current guidelines recommend immunization against HAV for all patients with chronic liver disease [34], the results of several cost-effective analyses have been conflicting. A report published in 2000 found that saving the life of one patient with HCV infection by HAV vaccination would cost 23 million Canadian dollars [116]; however, some of the assumptions in this report have been challenged [117]. Two other studies of patients with chronic hepatitis C showed a decided benefit to immunization against HAV [118]. The methods used in these studies were dissimilar, and some analyses may have been insensitive to the incidence of HAV or may have underestimated the economic and societal costs of a case of ALF. Universal immunization against HAV during childhood before the possible occurrence of chronic liver disease offers the promise of preventing HAV infection [119].

Multiple choice questions

23.1 What is the gold standard to diagnose acute hepatitis A?

a A history of recent ingestion of raw oysters.
b Alanine aminotransferase >1,000 U/L.
c Detectable IgM anti-HAV.
d Detectable total anti-HAV (IgG and IgM).

23.2 If after 3 years of receiving full immunization against HAV, the antibody is no longer detectable, which of the following should the patient do?

a Be immunized again.
b Retest for anti-HAV.
c Be told that immunologic memory exists despite absence of anti-HAV.
d Await newer vaccines.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 24
Hepatitis B and D

Anna S. F. Lok[1] *& Francesco Negro*[2]

[1]Division of Gastroenterology, University of Michigan Medical Center, Ann Arbor, MI, USA
[2]Departments of Internal Medicine, and of Pathology and Immunology, University of Geneva Medical Center, Geneva, Switzerland

Key concepts

- There are approximately 350 million hepatitis B carriers worldwide and 1 million carriers in the United States. The prevalence of hepatitis B virus (HBV) infection is related to the predominant mode of transmission and the age at infection.
- Acute HBV infection may manifest as subclinical hepatitis, icteric hepatitis, or acute liver failure. Chronic HBV infection may manifest as inactive carrier state, chronic hepatitis, cirrhosis, or hepatocellular carcinoma (HCC).
- HBV vaccination has been shown to prevent HBV infection as well as HBV-related HCC.
- The aims of antiviral treatment of chronic hepatitis B are to suppress HBV replication, induce remission in liver disease, and prevent the development of cirrhosis and HCC.
- Approved treatments of chronic hepatitis B include interferon-α (standard and pegylated), lamivudine, adefovir, entecavir, telbivudine, and tenofovir.
- Hepatitis D virus is dependent on HBV. Hepatitis D occurs as coinfection with HBV or superinfection in persons with chronic HBV infection. Interferon-α is the only effective treatment for chronic hepatitis D.

Hepatitis B

Epidemiology

Hepatitis B infection is a global public health problem. It is estimated there are approximately 350 million hepatitis B virus (HBV) carriers in the world, of whom over 600,000 die annually from hepatitis B-associated liver disease [1]. In the United States, an estimated 0.8–1.4 million individuals are chronically infected with HBV [2].

Prevalence

The prevalence of HBV infection varies in different geographic areas (Table 24.1). The wide range in carrier rate is related to differences in the predominant mode of transmission and the age at infection. In low prevalence areas such as the United States, western Europe, Australia, and New Zealand, the hepatitis B surface antigen (HBsAg) carrier rate is approximately 0.1–2%. In intermediate prevalence areas like the Mediterranean countries, Japan, India, and Singapore, the carrier rate is approximately 3–5%. In high prevalence areas such as Southeast Asia and sub-Saharan Africa, the carrier rate is 8–20%. The prevalence of current and past HBV infection is estimated to be 5% in the United States and more than 50% among adults in Southeast Asia and Africa. In general, there is an increasing prevalence of HBV infection with age. Within the United States, the prevalence of HBV infection is higher among African-Americans, Hispanics, and Asians than in the white population.

In most high prevalence areas such as China, perinatal transmission is the major mode of spread, accounting for 40–50% of chronic HBV infection. However, horizontal spread during the first 2 years of life is the major mode of transmission in other endemic areas including Africa and the Middle East. The exact reason for the preponderance of perinatal transmission among Orientals is not clear but is at least in part related to the high prevalence of hepatitis B e antigen (HBeAg) among Asian carriers of reproductive age – 40–50% versus 10–20% among African carriers of the same age group [3,4]. In intermediate prevalence areas, transmission occurs among all age groups but early childhood infection accounts for most cases of chronic infection. In low prevalence areas, most infections are acquired in early adult life through unprotected sexual intercourse or intravenous drug use. The age at infection has a significant impact on the clinical outcome because chronic infection occurs in approximately 90% of infants infected at birth, in 25–50% of children infected between the age of 1 and 5 years, and in less than 5% of those infected during adult life [5–8].

Table 24.1 Patterns of hepatitis B virus infection.

	Prevalence		
	High	**Intermediate**	**Low**
Carrier rate	8–20%	3–7%	0.1–2%
Geographic distribution	Southeast Asia China Pacific Islands Sub-Saharan Africa Alaska (Eskimos)	Mediterranean basin Eastern Europe Central Asia Japan Latin and South America Middle East	United States and Canada Western Europe Australia New Zealand
Predominant age at infection	Perinatal and early childhood	Early childhood	Adult
Predominant mode of transmission	Maternal–infant Percutaneous	Sexual Percutaneous	Sexual Percutaneous

Mode of transmission

Transfusion

The exclusion of paid donors and the application of hepatitis B serologic screening in the 1970s dramatically reduced the incidence of post-transfusion HBV infection. In the United States, both HBsAg and hepatitis B core antibody (anti-HBc) are used for blood donor screening. Anti-HBc was initially used as a surrogate marker for non-A, non-B hepatitis virus. Anti-HBc has been retained after the implementation of hepatitis C testing to detect donors who are in the window phase during recovery from acute hepatitis B or who have low level chronic HBV infection. The residual risk of transfusion-related hepatitis B in the United States is approximately 1 in 300,000 [9], while the residual risk of transfusion-related hepatitis B in China, where HBV infection is endemic and blood donors are screened for HBsAg only, is 1 in 17,500 [10].

Recently, there have been debates on the role of nucleic acid testing (NAT) of blood donors. One review concluded that NAT for HBV will probably detect only a few more donor units that may be associated with risk of transmitting HBV infection compared with serologic screening for HBsAg and anti-HBc [11]. With the current estimated 13 million donations per year in the United States and 1.8 transfused components per donation, the introduction of NAT would be expected to prevent 30–35 HBV-containing transfusions per year. NAT has a higher yield and may be more cost-effective in high prevalence areas where additional screening for anti-HBc is not practical.

Percutaneous transmission

Percutaneous inoculation of blood or body fluids plays a major role in the transmission of hepatitis B infection. Needle sharing by intravenous drug users is an important route of transmission of hepatitis B. The reuse of contaminated needles for tattoos, acupuncture, and ear piercing also provides opportunities for percutaneous transmission.

Sexual transmission

In the United States and many developed countries, sexual transmission is the most important mode of spread of HBV. The Centers for Disease Control and Prevention reported that sexual transmission accounted for almost 50% of acute HBV infection among individuals in whom data on risk factors were available [12]. A high prevalence of chronic HBV infection has been reported in men who have sex with men as well as in heterosexuals with multiple sex partners. The annual incidence of new HBV infections among homosexual men decreased significantly in the 1980s as a result of education on safe sex practice to prevent human immunodeficiency virus (HIV) infection [13]. However, recent reports in the United States suggest that both heterosexual transmission and transmission among homosexual men are again on the rise [12]. The risk of sexual transmission of HBV infection is associated with the number of lifetime sex partners, low education level, paid sex, and history of sexually transmitted diseases.

Perinatal transmission

Perinatal transmission of HBV infection is rare in countries where universal vaccination of newborns is implemented. The risk of maternal–infant transmission is related to the HBV replicative status of the mother. The risk is 85–90% for infants born to HBeAg-positive mothers and 30% for infants born to HBeAg-negative mothers [14]. More recent studies have demonstrated that maternal serum HBV DNA levels correlate better with the risk of transmission [15]. Maternal–infant transmission

takes place at the time of delivery by maternal–fetal transfusion or exposure to maternal blood during passage through the birth canal and postnatally through intimate mother–baby contact. Intrauterine transmission is uncommon. This explains why passive–active immunization at birth has an efficacy rate of more than 90% in the prevention of HBV infection [16]. Cesarean section has not been shown to eliminate the risk of perinatally acquired HBV infection [17] and should not be routinely recommended for carrier mothers. Although HBsAg can be detected in breast milk, there is no evidence that HBV infection can be transmitted by breastfeeding [18]; infants born to carrier mothers may be breastfed if they have been vaccinated. The risk of transmission during amniocentesis is also low [19]. Universal vaccination of all newborns and the additional administration of hepatitis B immunoglobulin (HBIg) to those who are born to carrier mothers were initiated in many Southeast Asian countries in the 1980s. These programs have led to a significant reduction in HBsAg carrier rate as well as a decrease in the incidence of hepatocellular carcinoma (HCC) among children [20]. As of 2008, 92% of the countries in the world have integrated HBV vaccination into their childhood immunization programs.

Health care environment

Hepatitis B virus is the most commonly transmitted blood-borne virus in the health care setting [21]. Transmission generally occurs from patient to patient or from patient to health care personnel via contaminated instruments or accidental needlestick injury. Despite the implementation of universal precautions, outbreaks of HBV infection continue to occur in health care settings even in developed countries. A review of cases of viral hepatitis in the United States from 1998 to 2008 in health care settings outside hospitals revealed 18 outbreaks with 173 persons with new/acute HBV infection. These outbreaks occurred mainly in outpatient clinics or ambulatory hemodialysis centers due to lapses in infection control measures like syringe reuse, contamination of injectable medications or flush solutions, and the reuse of fingerstick devices meant only for single use [22]. Transmission of HBV infection from health care workers to patients is rare. One outbreak was traced to a cardiothoracic surgeon despite no identified flaws in precautions on infection control during surgeries [23]. Nosocomial transmission can be prevented by screening of blood and blood products, use of disposable needles and equipment, proper sterilization of surgical instruments, enforcement of infection control measures, and vaccination of health care workers.

In many developed countries, guidelines have been established to define the parameters within which health care workers with hepatitis B can practice. The Society for Healthcare Epidemiology of America recommended that HBsAg-positive health care providers with serum HBV DNA $>10^4$ genome equivalents/mL should routinely use double-gloving for all instances in which gloving is recommended, and that these providers should not perform activities identified as associated with a risk for provider-to-patient HBV transmission [24]. Similar recommendations were made by a European consortium [25]. It has been proposed that health care workers with high HBV DNA levels receive antiviral therapy to enable them to return to work without risking nosocomial infection. These workers will need to be monitored to insure that serum HBV DNA levels remain suppressed.

Hemodialysis patients

Patients with renal failure on hemodialysis may be infected through blood transfusions, contamination of dialysis machines or equipment, as well as interpersonal horizontal transmission in the dialysis units. Improved infection control and the availability of vaccines have reduced the annual incidence of HBV infection among hemodialysis patients from 3% in 1980 to 0.1% in 1993 in the United States and has remained stable in the past decade [26]. However, dialysis patients have impaired antibody response to vaccines. Therefore, vigilance is still needed to prevent outbreaks.

In a recent survey of all US chronic hemodialysis centers [26], the percent of patients vaccinated against HBV infection increased from 47% to 56% and the percent of staff vaccinated increased from 87% to 90% between 1997 and 2002. A possible contributing factor for continued transmission of HBV infection in adult hemodialysis units appears to be the presence of occult HBV infection (serum HBsAg-negative but HBV DNA-positive). In a study of 241 adult hemodialysis patients in a North American urban center [27], only two patients (0.8%) were HBsAg-positive but nine (4%) HBsAg-negative patients were HBV DNA-positive. Another study of 585 Italian dialysis patients found that 1.9% were HBsAg-positive and 36% anti-HBc-positive, none of the anti-HBc-positive patients had detectable serum HBV DNA [28].

Transplantation

Organ donors are routinely screened for HBsAg. Transmission of HBV infection has been reported after transplantation of extrahepatic organs such as kidneys from HBsAg-positive donors. This may be related to residual blood in the vascular pedicles due to inadequate flushing. The transmission of HBV infection has also been reported after transplantation of avascular tissues such as corneas [29] but this is believed to be rare.

The role of anti-HBc testing in organ donor screening is uncertain because of the possibility of false-positive results, the potential loss of up to 5% of donors even

in low endemic areas [30], and the uncertainty about the infectivity of organs from donors who are HBsAg-negative, anti-HBc positive [31]. The incidence of HBV infection from donors with isolated anti-HBc is very low (0–2%) in heart and kidney recipients but varies from 0% to 78% in liver recipients [30,32–34]. A recent study found that the estimated probability of undetected hepatitis B viremia is higher among tissue donors compared with first-time blood donors and the addition of NAT to the screening of tissue donors is expected to reduce the risk of HBV infection [35].

Other transmission routes

In endemic areas, horizontal transmission among children may result from close bodily contact leading to the transfer of virus across minor skin breaks and mucous membranes. Blood-feeding insects like mosquitoes have been demonstrated to serve as vectors for HBV transmission in animal models but firm evidence for this mode of transmission in humans is lacking. Various body secretions have been reported to test positive for HBsAg but only semen and saliva have been consistently shown to harbor infectious virions. Although HBV DNA has been detected in the saliva of some hepatitis B carriers, there is no convincing evidence that hepatitis B can be transmitted orally [36,37]. As HBV survives for a long time outside the human body, transmission via contaminated environmental surfaces and daily articles such as toothbrushes, razors, eating utensils, or even toys may also be possible.

High-risk groups

Health care workers have a higher hepatitis B carrier rate than the general population. The prevalence is particularly high among surgeons, pathologists, and physicians working in hemodialysis and oncology units. Apparent skin breaks, minor cuts, and accidental needlestick injuries serve as portals of entry. Other health care workers having increased risk of HBV infection include dentists and laboratory personnel who have contact with serum. Institutionalized mentally handicapped persons as well as their attendants and family members also have a high rate of hepatitis B infection. Despite screening of blood products, patients requiring frequent transfusion of blood or blood products have an increased risk of contracting hepatitis B infection. Other high-risk groups include intravenous drug users, particularly those who share syringes, men who have sex with men and promiscuous heterosexuals, immigrants from HBV endemic countries, and spouses, sexual partners, and household members of HBV carriers.

Changing epidemiology

The worldwide incidence of HBV infection is decreasing [1]. Mass vaccination of newborns and catch-up vaccination of children and adolescents have played a major role in reducing HBV infection among infants and children. Increased public awareness of hepatitis, educational campaigns to prevent HIV infection leading to modification of high-risk sexual behavior, and reduction of syringe sharing among intravenous drug users have contributed to the decrease in HBV infection among adults.

In the United States, the incidence of acute hepatitis B has significantly declined over the past decade. According to the Centers for Disease Control and Prevention, there has been an 82% decline in the incidence of acute hepatitis B between 1990 and 2007 [38]; the most significant decline was seen among children aged <15 years. Sexual transmission among susceptible individuals remains a significant risk factor for hepatitis B transmission in the United States. This is in part related to lack of resources and infrastructure for vaccination of adults as well as missed opportunities. Another important aspect of HBV epidemiology is that in many developed countries, immigrants from countries that are endemic for HBV infection now constitute an increasing proportion of those with chronic HBV infection [39]. These studies suggest that screening and immunization of susceptible adults, along with immunization of children (especially if they were born in countries where universal vaccination is not in place) whose parents immigrated from HBV endemic countries, is important in controlling HBV infection in developed countries.

Vaccination against hepatitis B

Indications

Vaccination against hepatitis B remains the mainstay of prevention. Universal vaccination of all newborns or at least newborns of all HBV-infected mothers is currently practiced in most countries throughout the world. The World Health Organization (WHO) has recommended that a combination of hepatitis B and childhood vaccines be used where possible, to reduce the logistic costs of vaccine delivery, especially in areas where it is most needed. In some developed countries, where universal vaccination of all newborns is not in place, vaccination of adolescents to prevent sexual transmission is implemented. The vaccination of adults is recommended for high-risk groups including health care workers, men who have sex with men, persons with multiple sex partners, injection drug users, sex partners, and household members of HBV carriers, public safety workers, institutionalized patients, and patients on chronic hemodialysis (Box 24.1) [39,40].

Administration schedule

There are two types of hepatitis B vaccines, plasma-derived and recombinant; the latter is currently used in most countries. Recombinant HBV vaccines consist of

Box 24.1 Indications for hepatitis B vaccine.

- All newborns[a]
- All children and adolescents not vaccinated at birth
- High-risk adults:
  - Men who have sex with men
  - Persons with multiple sexual partners
  - Injection drug users
  - Patients on hemodialysis
  - Institutionalized patients
  - Health care workers and public safety workers
  - Spouse, sexual partners, and household members of hepatitis B virus carriers

[a]For infants born to carrier mothers, hepatitis B immune globulin (HBIg) is also administered at birth.

HBV small S protein (HBsAg) produced by yeast or mammalian cells. Hepatitis B vaccine has been successfully combined with hepatitis A vaccine and with diphtheria, tetanus, and acellular pertussis and inactivated poliovirus vaccine without reducing its efficacy. These combination vaccines facilitate the integration of HBV vaccination into routine childhood immunization, reducing the number of injections and increasing the rate of compliance. Hepatitis B vaccine is usually administered intramuscularly in three doses at 0, 1, and 6 months, the dose being 10–20 μg in adults and 5–10 μg in children (Table 24.2). For adults, the injections are given in the deltoid muscle, whereas in newborns and young children the recommended site is the anterolateral thigh. In patients with hemophilia, it is recommended to administer the vaccine subcutaneously.

For infants born to HBsAg-negative mothers and unvaccinated children/adolescents up to 19 years of age, three doses (at 0, 1, and 6 months) of vaccine at half strength should be administered. For adults 20 years and older, the same regimen is implemented using full doses (10 μg of Recombivax HB® or 20 μg of Engerix-B®). An alternative two-dose schedule had been approved for adolescents.

For newborns of HBsAg carrier mothers, HBIg 0.5 mL and the first dose of vaccine should be administered within 12 hours of birth, using different sites. A combination of HBIg and hepatitis B vaccine has been shown to be 95% efficacious in preventing perinatal transmission of HBV infection [16,41,42].

For patients on hemodialysis or immunocompromised patients, higher doses of vaccine are needed: 40 μg of Recombivax HB or Engerix-B. Hepatitis B surface antibody (anti-HBs) titers should be monitored annually, and booster doses administered when the anti-HBs titer falls below 10 IU/L.

Follow-up testing for protective antibodies is recommended for individuals who continue to be at risk, including infants born to HBsAg-positive mothers, health care workers, hemodialysis patients, and sexual partners of HBsAg carriers. Some vaccines have also incorporated pre-S1 (large S) and/or pre-S2 (middle S) proteins to increase the immunogenicity but these vaccines are not available in most countries.

Table 24.2 Hepatitis B vaccines and dosage recommendations.

Vaccine brand[a]	Age group (years)	Dose (μg)	Volume (mL)	Number of doses
Engerix-B	0–19	10	0.5	3
	≥20	20	1.0	3
Recombivax HB	0–19	5	0.5	3
	≥20	10	1.0	3
(Optional two doses)	11–15	10	1.0	2

[a]For hemodialysis patients, the recommended dose is 40 μg with each dose (Engerix-B 40 μg/2.0 mL and Recombivax HB dialysis formulation 40 μg/1.0 mL).

Efficacy

A protective response – defined as an anti-HBs titer of more than 10 IU/L – is achieved in approximately 95% of vaccine recipients. Several studies have shown that vaccination is effective in inducing protective immunity and in preventing HBV infection in men who have sex with men [43–45], and in newborns of carrier mothers [16,41,46]. In countries where the prevalence of HBeAg among carrier mothers is low, it has been shown that vaccine alone has similar efficacy as a combination of vaccine and HBIg in preventing perinatal infection [46]. Although this approach can be cost saving, it may not be adequate in countries where the prevalence of HBeAg among carrier mothers is high or in countries where a high percent of HBeAg-negative mothers have high serum HBV DNA levels.

Factors associated with nonresponse and the management of vaccine nonresponders

Approximately 2.5–10% of vaccine recipients fail to respond with adequate anti-HBs titers after one course of HBV vaccine. The reasons for nonresponse are several and include older age, obesity, chronic medical illnesses (such as renal failure, diabetes, and cirrhosis), immunosuppression (such as in patients with HIV infection or organ transplantation), and technical problems (such as intragluteal injection and inadvertent freezing of the vaccines). Nonresponse to HBV vaccine has been reported to be associated with impaired lymphocyte activation as well as genetic factors, including certain human leukocyte

antigen (HLA) class II genes such as HLA-DRB1*0301 and cytokine gene polymorphisms [47,48].

For individuals who fail to respond after a full course of vaccination, the recommendation is to repeat another course of vaccine. If a person still remains a nonresponder, further vaccination is usually not effective but most of these individuals can mount an adequate immune response upon infection because exposure to HBV stimulates both T- and B-cell responses to HBsAg as well as hepatitis B core antigen (HBcAg). Nonresponders to two courses of vaccine should be tested for HBsAg as some may be undiagnosed carriers.

Durability of vaccine response and need for boosters

Several studies have shown that 30–66% of individuals had protective levels of anti-HBs (≥10 IU/L) for 15 years or more after receiving HBV vaccines and 90% had an anamnestic response after booster vaccination [49–52]. Breakthrough infections are rare and appear to occur mostly among those who did not have an initial response to vaccination. A recent study suggested that anamnestic responses may wane over time. In this study, 105 young adults vaccinated at birth with no detectable anti-HBs were revaccinated and only 48% had an anamnestic response [53]. The need for booster vaccinations among young adults who were vaccinated at birth is controversial.

Impact of vaccination

Hepatitis B virus vaccination has been shown to reduce the incidence of acute HBV infection and HCC, and the prevalence of chronic HBV infection [20,54–56]. HBV vaccine is the first vaccine that has been shown to prevent cancer (HCC) in humans. After the implementation of a nationwide vaccination program for newborns and children in 1984, the carrier rate among children in Taiwan decreased from 10% to 1.2% and the incidence of childhood HCC decreased by 70% [20]. In the United States, universal vaccination of all newborns was implemented in 1991 and it was expanded to include vaccination of all adolescents aged 11–12 years in 1995, and children aged less than 18 years, who had not been vaccinated previously, in 1999. This has resulted in a 90% reduction of acute hepatitis B in children and adolescents.

Safety of vaccines

The safety of HBV vaccines has been well established. The most common adverse reaction is soreness over the injection site. Other adverse reactions include low-grade fever, malaise, headache, arthralgia, and myalgia. Hepatitis B vaccines have no teratogenic effects and can be administered during pregnancy [57,58].

There has been concern about the possibility of hepatitis B vaccine leading to the development of demyelinating central nervous system diseases including multiple sclerosis and Guillain–Barré syndrome. However, many studies have failed to show a statistically significant temporal or causal association between HBV vaccine and these neurologic or immunologic conditions [59–62]. Because of concerns about mercury exposures, current preparations of HBV vaccines do not contain thimerosal as a preservative.

Special settings

Individuals with isolated hepatitis B core antibody

The presence of an isolated anti-HBc does not always denote prior exposure to HBV infection. HBV vaccination has been recommended to differentiate those who have had prior exposure from those with false-positive anti-HBc test results [63]. With improved specificity of anti-HBc assays, most individuals with isolated anti-HBc have genuinely positive test results and do not need to be vaccinated but there is no harm if vaccine is administered.

Patients on chronic hemodialysis

All patients on chronic hemodialysis should be vaccinated. Because response to HBV vaccine is impaired in patients with renal failure and dialysis patients have an increased risk of HBV infection, anti-HBs titer should be monitored annually and a booster vaccination administered if the anti-HBs titer decreases to <10 IU/L.

Patients with chronic liver disease

Hepatitis B vaccination, along with vaccination against hepatitis A, is recommended for all patients with underlying chronic liver disease. Acute hepatitis B superimposed on chronic hepatitis C has been reported to be associated with increased risk of liver failure [64]. The immune response to HBV vaccines among patients with chronic liver disease is similar to healthy subjects with no liver disease, but response rates are decreased in patients with cirrhosis and may be <50% in patients with decompensated cirrhosis awaiting liver transplantation [65,66]. Therefore, it is recommended that HBV vaccination should be administered early, before a patient develops cirrhosis.

Patients with human immunodeficiency virus infection

Several reports have suggested that patients with HIV infection have a blunted response to HBV vaccine compared to HIV-negative individuals. A large, randomized, double-blind study of two doses of recombinant HBV vaccine [67] showed that a response was seen in 34% and 47% in the standard and double dose groups, respectively.

Response rates were higher in those with a high CD4 count and low HIV RNA level. Anti-HBs titers should be checked 1 month after completion of the vaccine series to document response. Revaccination can be considered in those with no immune response. Among responders, anti-HBs titers drop more rapidly than in immunocompetent persons and breakthrough infections have been reported when anti-HBs titers decrease to <10 IU/L.

Novel methods of vaccine administration

In an effort to reduce the number of injections and to increase compliance, several combination vaccines have been developed. They include combinations of hepatitis A and B vaccine for adults and children, and a hexavalent vaccine against diphtheria, pertussis, tetanus, polio, *Haemophilus*, and hepatitis B for children. These combined vaccines have been shown to be safe and to have similar immunogenicity as the monovalent vaccines [68,69].

Various strategies have been examined to improve immunogenicity of HBV vaccines. One approach is to use more potent adjuvants [70,71]; another is to activate mucosal T cells through nasal vaccination [72]. Other approaches include intradermal administration, coadministration with interleukin 2, and incorporation of pre-S1 and/or pre-S2 antigens [73–75].

Diagnosis

The diagnosis of hepatitis B was revolutionized by the discovery of Australia antigen, now called HBsAg, by Blumberg in 1965 (76). During the ensuing decade, serologic assays for HBsAg and anti-HBs with increasing sensitivity and specificity were developed. In the 1970s, additional HBV antigens and antibodies were identified and serologic assays for their detection established. Advances in molecular biology techniques led to the development of assays for the direct determination of virus replication, and polymerase chain reaction (PCR) assays currently in use can detect as little as 10 IU of HBV DNA per mL of serum. The diagnosis of HBV infection can also be made by the detection of HBsAg or HBcAg in liver tissues by immunohistochemical staining and of HBV DNA by Southern hybridization, in situ hybridization, or PCR.

Serologic diagnosis

Hepatitis B surface antigen and hepatitis B surface antibody

Hepatitis B surface antigen is the serologic hallmark of HBV infection. HBsAg appears in serum 1–10 weeks after an acute exposure to HBV, approximately 2–6 weeks before the onset of hepatitis symptoms or elevation of alanine aminotransferase (ALT). In patients who subsequently recover, HBsAg usually becomes undetectable after 4–6 months. Persistence of HBsAg for more than 6 months implies chronic infection. The disappearance of HBsAg is followed by the appearance of anti-HBs. Although anti-HBs is produced early in the course of acute infection in individuals who subsequently recover, it is frequently not detectable until after a window period of several weeks to months when neither HBsAg nor anti-HBs can be detected (Fig. 24.1). The appearance of anti-HBs marks the recovery from hepatitis B. In most patients, the presence of anti-HBs persists for life, thereby conferring long-term immunity. Anti-HBs is the only protective antibody induced by most of the currently available vaccines, which consist of recombinant HBsAg only.

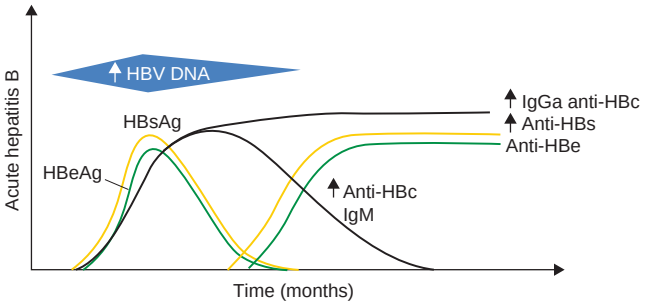

Figure 24.1 Serologic markers during acute hepatitis B virus infection. anti-HBc, hepatitis B core antibody; anti-HBe, hepatitis B e antibody; anti-HBs, hepatitis B surface antibody; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; IgG, immunoglobulin G; IgM, immunoglobulin M.

HBV can be classified into nine genotypes [77,78] and four major serotypes. All HBV serotypes share one common antigenic determinant, "a," which is a conformational epitope located in the HBsAg. There are two additional pairs of mutually exclusive subtypic determinants "d" or "y" and "w" or "r" constituting the four major serotypes: adr, ayr, adw, and ayw. Antibodies to the "a" determinant confer protection to all HBV serotypes [79]. At least 50% of the anti-HBs that develops after recovery from acute hepatitis B or immunization with hepatitis B vaccines is directed against the "a" determinant, providing cross-protection against other serotypes of HBV.

Coexistence of HBsAg and anti-HBs has been reported in approximately 24% of HBsAg-positive individuals [80]. In most instances, the antibodies are directed against one of the subtypic determinants and not the common "a" determinant and are unable to neutralize the circulating virions. These individuals should therefore be regarded as carriers.

Pre-S1 and pre-S2 antigens have been detected in patients infected with HBV. In general, the presence of these antigens correlates with the detection of HBV DNA and virus replication [81]. During recovery from acute hepatitis B, antibodies to pre-S1 and pre-S2 antigens appear early [82], prior to the detection of anti-HBs.

Hepatitis B core antigen and hepatitis B core antibody

Hepatitis B core antigen is an intracellular antigen that is expressed in infected hepatocytes. It is not detectable in serum. Its antibody – anti-HBc – however, can be detected throughout the course of HBV infection. During acute HBV infection, anti-HBc is predominantly immunoglobulin M (IgM) class. IgM anti-HBc is the first antibody to be detected (Fig. 24.1). It usually appears within 1 month after the appearance of HBsAg. It is the sole marker of HBV infection during the window period, that is, the time gap between the disappearance of HBsAg and the appearance of anti-HBs [83]. During convalescence, the titer of IgM anti-HBc declines while the titer of IgG anti-HBc increases. Therefore, the detection of IgM anti-HBc is usually taken as an indication of acute HBV infection. However, in 20% of patients, IgM anti-HBc may remain detectable up to 2 years after the acute infection. In addition, low-titer IgM anti-HBc persists in most patients with chronic HBV infection. Therefore, the reliability of IgM anti-HBc in the differentiation of acute from chronic HBV infection depends on the cutoff level in the assay. Even in assays with high cutoff values, IgM anti-HBc can be detected in patients with chronic HBV infection during exacerbations [84]. This may lead to misdiagnosis of acute hepatitis B in patients who are not previously known to have had chronic HBV infection. Studies in endemic areas demonstrated that many patients presenting with acute hepatitis who test positive for HBsAg have exacerbations of chronic hepatitis B and not acute hepatitis B, and that less than 1% of immunocompetent adult patients with genuine acute hepatitis B progress to chronic infection [8,85].

IgM anti-HBc titers have been reported to correlate with ALT and serum HBV DNA levels in patients with chronic hepatitis B, especially during exacerbations [86]. IgG anti-HBc persists along with anti-HBs in patients who recover from acute hepatitis B and in association with HBsAg in those who progress to chronic HBV infection.

An isolated presence of anti-HBc in the absence of HBsAg and anti-HBs has been reported in 0.4–1.7% of blood donors in low prevalence areas [87,88] and in 10–20% of the population in endemic countries [63,89]. An isolated detection of anti-HBc may occur during the window period of acute hepatitis B when the anti-HBc is predominantly IgM class, many years after recovery from acute hepatitis B when anti-HBs has fallen to undetectable levels, or after many years of chronic HBV infection when the HBsAg titer has decreased below the level for detection. The clinical significance of isolated anti-HBc is complex. Although HBV DNA has been detected in the serum of individuals with isolated anti-HBc, the frequency of detection varies from 0% to 20% [90,91]. Transmission of HBV infection has been reported from blood and organ donors with isolated anti-HBc but the incidence ranged from 0.4% to 78% [33,90,92], the risk being highest when livers from anti-HBc-positive donors are transplanted into seronegative recipients. Several studies found that 50–70% of asymptomatic individuals with isolated anti-HBc had false-positive test results [63,93]; the false-positive rate has decreased with improved anti-HBc assays. The evaluation of individuals with isolated anti-HBc should include repeat testing for anti-HBc, HBsAg, anti-HBs, and hepatitis B e antibody (anti-HBe). Individuals with evidence of chronic liver disease and those with HIV infection should be tested for HBV DNA to exclude low-level chronic HBV infection.

Hepatitis B e antigen and hepatitis B e antibody

Hepatitis B e antigen is a secretory protein that is processed from the precore protein. It is generally considered to be a marker of HBV replication and infectivity. Its presence is usually associated with high levels of HBV DNA in serum. Epidemiologic studies reported significantly higher rates of transmission of HBV infection from HBeAg-positive carrier mothers to their babies [94,95] and from HBeAg-positive patients to health care workers who sustain needlestick injuries [96].

During acute HBV infection, HBeAg appears shortly after the appearance of HBsAg. In patients who recover, HBeAg to anti-HBe seroconversion precedes that of HBsAg to anti-HBs seroconversion (see Fig. 24.1). Anti-HBe may persist for many years after the resolution of acute hepatitis B. In patients with chronic HBV infection, HBeAg may persist for years to decades (Fig. 24.2). During the HBeAg-positive phase, most patients have high levels of HBV DNA in serum and active liver disease. In patients with perinatally acquired HBV infection, there may be an immune tolerant phase with normal ALT levels and minimal inflammation in the liver. Seroconversion from HBeAg to anti-HBe is usually associated with a marked decrease in serum HBV DNA level and remission of liver disease. However, some

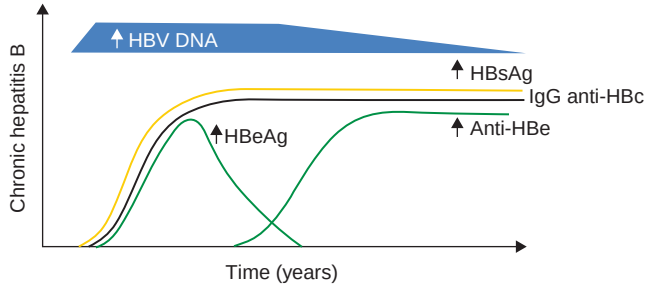

Figure 24.2 Serologic markers during chronic hepatitis B virus infection. anti-HBc, hepatitis B core antibody; anti-HBe, hepatitis B e antibody; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus.

anti-HBe-positive patients continue to have active liver disease and detectable HBV DNA in serum. This may be due to low levels of wild-type HBV or the presence of precore HBV variants.

Tests for hepatitis B virus DNA in serum

Quantification of HBV DNA in serum is important in determining the phase of chronic HBV infection, in predicting risks of clinical outcomes, and in monitoring response to treatment. Currently, most diagnostic laboratories use real-time PCR assays that have a lower limit of detection of 10–50 IU/mL and a range of linearity up to 8–9 $\log_{10}$ IU/mL. It should be noted that fluctuating HBV DNA levels are common in patients with chronic HBV infection; therefore, the HBV DNA level on a single occasion may not be accurate in assessing HBV replicative status and the need for antiviral therapy. With PCR assays, HBV DNA can be detected up to 2–3 weeks before the appearance of HBsAg in patients with acute HBV infection. Recovery from acute hepatitis B is accompanied by a rapid decrease in serum HBV DNA level but HBV DNA may remain detectable for many years [97].

In patients with chronic HBV infection, spontaneous or treatment-induced HBeAg seroconversion is usually accompanied by a marked decrease in serum HBV DNA level but HBV DNA frequently remains detectable except in patients who have lost HBsAg. The major role of serum HBV DNA assays in patients with chronic HBV infection is to assess HBV replication and candidacy for antiviral therapy and to monitor response to antiviral treatment.

Rarely, tests for HBV DNA in serum help to identify HBV as the etiology of liver disease in HBsAg-negative patients. This is especially important in patients with acute liver failure, who may have cleared HBsAg by the time they present [98]. Most patients with chronic liver disease due to occult HBV infection have low levels of HBV, whereas a small percent may be infected with HBV variants that downregulate the production of HBsAg or produce aberrant HBsAg that cannot be detected in conventional serologic assays [99].

Diagnostic algorithm

The diagnosis of acute hepatitis B is based on the detection of HBsAg and IgM anti-HBc (Table 24.3). During the initial phase of infection, markers of HBV replication, HBeAg and HBV DNA, are present. Recovery is accompanied by the disappearance of HBV DNA, HBeAg to anti-HBe seroconversion, and subsequently HBsAg to anti-HBs seroconversion. Rarely, patients may have entered the window period at the time of presentation and IgM anti-HBc is the sole marker of acute HBV infection in these patients. This situation is more common in patients with acute liver failure where virus clearance tends to be more rapid.

Past HBV infection is diagnosed by the detection of anti-HBs and anti-HBc (IgG). Immunity to HBV infection after vaccination is indicated by the presence of anti-HBs only.

The diagnosis of chronic HBV infection is based on the detection of HBsAg and IgG anti-HBc (Table 24.3). Additional tests for HBV replication, HBeAg and serum HBV DNA, should be performed to determine if the patient should be considered for antiviral therapy. Tests for hepatitis C and hepatitis D should also be performed to rule out superinfection with other hepatitis virus(es).

Clinical manifestations

The spectrum of HBV infection varies from subclinical hepatitis, anicteric hepatitis, and icteric hepatitis to acute liver failure during the acute phase; and from inactive carrier state to chronic hepatitis, cirrhosis, and HCC during the chronic phase. The clinical manifestations and outcome of HBV infection depend on the age at infection, the level of HBV replication, and the immune status of the host. Perinatal or childhood infection is usually associated with few or no symptoms but a high risk

of chronicity, whereas adult-acquired infection is usually associated with symptomatic hepatitis but a low risk of chronicity.

Acute hepatitis B virus infection

Approximately 70% of patients have subclinical or anicteric hepatitis during acute HBV infection; only 30% have icteric hepatitis. Symptomatic hepatitis is rare in neonates and it occurs in approximately 10% of children less than 4 years old and in approximately 30% of adults.

Symptoms and signs

The incubation period of acute HBV infection lasts 1–4 months. This period may be shorter in patients who have been exposed to a large inoculum. During the prodromal period, a serum sickness-like syndrome may develop. This is followed by an insidious onset of constitutional symptoms including malaise, anorexia, nausea, and occasionally vomiting, low-grade fever, myalgia, and easy fatigability. Patients may have altered gustatory acuity and smell sensation. Some patients may experience right upper quadrant or midepigastric pain. In patients with icteric hepatitis, jaundice usually begins within 10 days after the onset of constitutional symptoms. Constitutional symptoms generally subside as jaundice develops. Clinical symptoms and jaundice usually disappear after 1–3 months but some patients may have persistent fatigue even after the ALT levels have returned to normal.

Physical examination can be unrevealing in many patients. The most common findings include low-grade fever, clinical icterus, and soft, mildly tender hepatomegaly. Splenomegaly may be found in approximately 5–15% of patients. Rarely, palmar erythema or spider nevi can be detected. Patients with acute liver failure may present with features of hepatic encephalopathy, progressive decrease in liver span, and ascites.

Laboratory findings

The elevation of liver enzymes – ALT and aspartate aminotransferase (AST) – is the hallmark of acute hepatitis. Values of 1,000–2,000 IU/L are typically seen during the acute phase. An increase in liver enzymes may precede the onset of symptoms. In patients with icteric hepatitis, the increase in bilirubin levels usually lags behind the increase in ALT levels. Although the peak ALT level reflects the degree of hepatocellular injury, it has no correlation with prognosis. Prothrombin time is the best indicator of prognosis in patients with acute hepatitis. In patients who recover, ALT levels usually return to normal values after 1–4 months, followed by normalization in bilirubin levels. An elevation of ALT levels for more than 6 months suggests chronic liver injury and persistent infection.

Histologic findings

Liver biopsy is seldom indicated in acute hepatitis. Histologic changes of acute hepatitis include lobular disarray, acidophilic degeneration of hepatocytes, focal lobular necrosis, disruption of bile canaliculi with cholestasis, portal and parenchymal infiltration of inflammatory cells, as well as hypertrophy and hyperplasia of Kupffer cells and macrophages. Inflammatory infiltrates are predominantly lymphocytes and macrophages. In patients with severe hepatitis, hepatocyte necrosis is more extensive leading to bridging.

Sequelae

The risk of chronicity is inversely proportional to the age at infection. Less than 5% of immunocompetent adults with acute HBV infection progress to chronic infection, but up to 90% of those infected during infancy will develop chronic infection [5–8]. Acute liver failure due to HBV has declined in the last decade but HBV remains the most common viral cause of acute liver failure [100]. It is estimated that only 0.1–0.5% of acute hepatitis B runs a fulminant course. Mortality from acute liver failure is high, approaching 80%, unless liver transplantation can be performed. Contrary to transplantation for HBV cirrhosis, reinfection after liver transplantation for acute liver failure is uncommon.

Chronic hepatitis B virus infection

Symptoms and signs

In areas of low or intermediate prevalence, approximately 30–50% of patients with chronic HBV infection have a history of classic acute hepatitis that progressed to chronic infection. The remaining 50–70% of patients with chronic HBV infection in these areas and most of those in high prevalence areas (predominantly perinatal infection) have no prior history of acute hepatitis. Many patients with chronic HBV infection are asymptomatic, while others have nonspecific symptoms such as fatigue. Occasionally mild, right upper quadrant pain may be present. Patients with chronic HBV infection may experience exacerbations that may be asymptomatic or mimic acute hepatitis with fatigue and jaundice and in rare instances hepatic decompensation.

Physical examination may be unrevealing or there may be stigmata of chronic liver disease such as spider angioma and palmar erythema, and a mild hepatomegaly. In patients with cirrhosis, additional findings such as splenomegaly may be present. As the liver disease advances, hepatic decompensation may develop

manifesting as variceal bleeding, ascites, peripheral edema, jaundice, and hepatic encephalopathy.

Laboratory findings

Laboratory tests can be entirely normal even in patients with cirrhosis. Mild to moderate AST and ALT elevation may be the only biochemical abnormality in many patients with chronic hepatitis B. ALT levels may range from normal to five-fold elevated. Very high ALT levels, more than 1,000 IU/L, may be seen during exacerbations. Markers of impaired hepatic synthetic function may be observed during the exacerbations, especially in patients with underlying cirrhosis. In addition, an increase in α-fetoprotein (AFP) levels, up to 1,000 ng/mL, may be present [101]. In these cases, the AFP levels tend to parallel or follow the ALT levels. Progression to cirrhosis is suspected when the platelet count is decreased, when there is hypoalbuminemia, hyperbilirubinemia, prolongation in prothrombin time, and when the AST : ALT ratio is greater than 1. It has been suggested that the upper limit of normal for ALT in most diagnostic laboratories is too high and the true normal is closer to 20–30 IU/L [102,103].

Histologic findings

Liver biopsy is useful in assessing the severity of liver damage, in predicting prognosis, and in monitoring response to treatment. However, liver histology can improve significantly in patients who have a sustained response to antiviral therapy or spontaneous HBeAg seroconversion and it can worsen rapidly during exacerbations of hepatitis B.

The predominant histologic findings include inflammatory cell infiltration in the portal tracts and periportal necrosis. The inflammatory infiltrate consists mainly of mononuclear cells. Periportal necrosis may be mild or severe leading to disruption of the limiting plate (piecemeal necrosis or interface hepatitis). As the liver damage progresses, fibrous tissue is deposited initially within the portal tracts, later extending into the centrilobular (zone 3) areas and adjacent portal tracts, forming bridging fibrosis and eventually cirrhosis. In some patients, ground glass hepatocytes that stain positive for HBsAg can be found. Recent studies showed that these cells are found in association with the retention of HBsAg [104]. To provide a more objective assessment of liver injury, several numeric scoring systems have been established to permit statistical comparisons of necroinflammatory activity and fibrosis [105–107]. An international panel recommended that the histologic diagnosis should include the etiology of hepatitis, the grade of necroinflammatory activity, and the stage (extent of fibrosis) of the liver disease [108].

Immunohistochemical staining reveals the presence of HBsAg in patients with chronic HBV infection. The distribution of HBsAg can be either membranous or cytoplasmic. In patients with high levels of HBV replication, HBcAg can also be demonstrated. The distribution of HBcAg is usually nuclear but the distribution is shifted to the cytoplasm in patients with exacerbations or active liver disease [109].

Extrahepatic manifestations

Extrahepatic manifestations have been reported in patients with both acute and chronic HBV infection. Extrahepatic manifestations are more commonly associated with acute hepatitis B than other forms of acute viral hepatitis and may be present in approximately 10–20% of patients with chronic HBV infection. They are believed to be mediated by circulating immune complexes, the formation of which is favored by high levels of HBV replication.

Serum sickness

Acute hepatitis B is sometimes heralded by a serum sickness-like syndrome manifested as fever, skin rash, polyarthralgia, and arthritis. Skin and joint manifestations usually subside rapidly with the onset of jaundice.

Polyarteritis nodosa

Approximately 10–50% of patients with polyarteritis nodosa (PAN) are found to be HBsAg-positive. The decline in HBV infection over the past decade, especially in developed countries, has also been associated with a decrease in frequency of HBV-related PAN [110]. Immune complexes involving HBV antigens and antibodies are believed to trigger the vascular injury. Vasculitis may affect large, medium, and small-sized vessels in multiple organs, including cardiovascular (pericarditis, hypertension, cardiac failure), renal (hematuria, proteinuria), gastrointestinal (abdominal pain, mesenteric vasculitis), musculoskeletal (arthralgia, arthritis), neurologic (mononeuritis, central nervous system involvement), and dermatologic (rashes) systems. A review of 348 patients with PAN seen over a 42-year period found that 35% were HBV related [111]. The fact that HBV-related PAN is related to virus-mediated immune complexes suggests that therapy should be directed against HBV itself. Case reports and case series have suggested a possible role of interferon (IFN) therapy as well as nucleos(t)ide analogs (NUCs) alone or in combination with plasma exchange [112–115]. One study found that HBeAg seroconversion was associated with the complete remission of PAN [115].

Glomerulonephritis

Hepatitis B virus-related glomerulonephritis is more often found in children and the incidence has been declining since the implementation of HBV vaccination programs. Membranous glomerulonephritis is most

common, especially among children, but membranoproliferative glomerulonephritis, mesangiocapillary and focal glomerulonephritis, minimal change disease, and IgA nephropathy have also been reported [116]. Immune complexes of hepatitis B surface, core, and e antigens and antibodies together with complement components have been demonstrated in glomerular basement membrane and mesangium [117]. The severity of the renal disease does not correlate with the severity of the liver disease.

Approximately 30–60% of children with HBV-related membranous glomerulonephritis undergo spontaneous remission. A substantial proportion of adults (30%) may progress to renal failure. IFN has been reported to induce remission of HBV-related renal disease in small clinical trials, especially among patients with membranous glomerulonephritis [118,119]. An improvement of renal disease has also been reported with lamivudine [120]. A meta-analysis found that HBeAg clearance was associated with remission of nephrotic syndrome [121].

Essential mixed cryoglobulinemia

Mixed cryoglobulinemia is a systemic disease involving mainly small vessels presenting as glomerulonephritis, arthritis, and purpura. HBsAg, anti-HBs, and HBV-like particles have been demonstrated in cryoprecipitates [122] but recent studies questioned the association between chronic HBV infection and essential mixed cryoglobulinemia.

Papular acrodermatitis (Gianotti–Crosti disease)

Papular acrodermatitis is strongly associated with HBs antigenemia in children, particularly among those under the age of 4 years [123,124]. Circulating HBsAg and anti-HBs immune complexes are thought to play a role in the pathogenesis [123]. It manifests as symmetric, erythematous, maculopapular, nonitchy (or nonpruritic) eruptions over the face, buttocks, limbs, and occasionally the trunk, lasting for 15–20 days. Evidence of acute hepatitis may coincide with the onset of the skin eruption or, more commonly, begins as the dermatitis starts to wane.

Aplastic anemia

Isolated cases of severe aplastic anemia occurring in the early phase of acute hepatitis have been reported [125]. However, one study suggested that most cases of hepatitis-associated aplastic anemia are not related to hepatitis viruses but are mediated by immunopathologic mechanisms [126].

Special patient groups

Pediatric patients

Acute HBV infection has been estimated to account for 10–25% of all cases of childhood acute hepatitis. Extrahepatic manifestations including arthralgia, arthritis, skin rash, and Gianotti papular acrodermatitis are common and have been reported in 25% of patients.

Despite the availability of HBV vaccines, HBV infection remains the most important cause of chronic hepatitis in pediatric patients. The clinical manifestation of chronic HBV infection in children is dependent on the age at infection. Perinatal HBV infection results in a high rate (90%) of chronic infection and a prolonged replicative phase. Children with perinatally acquired HBV infection are usually asymptomatic with normal ALT values despite high serum HBV DNA levels. The progression of liver disease may occur over time, particularly in those who remain HBeAg-positive and in those with other etiologies of liver disease such as hepatitis C virus (HCV) coinfection and alcoholism [127,128]. Cirrhosis is uncommon in children and appears to be more frequent in boys and in those with a history of acute hepatitis [129]. HCC has also been reported among children with chronic HBV infection [127,130]. It is more common among Asian children, and in children with cirrhosis or a family history of HCC. HBV-related acute liver failure is extremely rare in children. Most reported cases occurred in infants born to HBeAg-negative mothers [131].

Immunocompromised patients

The clinical manifestations and natural course of chronic HBV infection in immunocompromised patients may be different from that in immunocompetent patients because of enhanced HBV replication and impaired immune response. Immunosuppressive therapy can increase HBV replication directly by stimulating the glucocorticoid responsive element in the enhancer region of the HBV genome [132] or indirectly by diminishing the immune response. Abrupt withdrawal of immunosuppressive therapy, as in cyclical chemotherapy or a rapid tapering of steroid treatment, has been reported to be associated with exacerbations of liver disease in HBsAg carriers as well as in persons with past HBV infection [133, 134]. These exacerbations are believed to be due to massive lysis of infected hepatocytes as the immune system recovers. Although most of the exacerbations are asymptomatic, fatal hepatic decompensation has been reported [133,135]. Prophylactic antiviral therapy has been shown to reduce the incidence of hepatitis flares associated with HBV reactivation [136].

Patients with chronic renal failure on hemodialysis have an increased risk of HBV infection. Dialysis patients are usually HBeAg- and serum HBV DNA-positive but have no symptoms, normal ALT levels, and minimal liver damage on liver biopsies [137]. The clinical course of postrenal transplantation is, however, very different, with exacerbations, rapid progression to cirrhosis, and an increased risk of HCC and death from liver failure

[138–141]. Recent reports showed that preemptive treatment with lamivudine decreased the risk of reactivation of hepatitis B post transplantation [142,143]. In addition, lamivudine has been reported to be effective in treating hepatitic flares and hepatic decompensation due to reactivation of hepatitis B after renal transplantation. The American Society of Transplantation and the American Society of Transplant Surgeons Clinical Practice Guidelines for the care of renal transplant recipients recommend that all HBsAg-positive renal transplant recipients receive antiviral prophylaxis, preferably with tenofovir or entecavir or lamivudine. Additionally, the guidelines recommend that patients who have developed resistance to lamivudine should be treated with tenofovir or adefovir, and that HBsAg-negative patients who have an anti-HBs titer of <10 IU/L should receive a booster vaccination [144].

Patients with HIV infection have a high prevalence of HBV infection. This is probably related to the similarities in the mode of transmission of HBV and HIV. In western countries, 6–10% of patients with HIV infection are coinfected with HBV and both viruses are acquired in adult life. In countries where HBV is endemic, 10–25% of patients with HIV infection are coinfected with HBV; most of the coinfected patients develop chronic HBV infection as infants and then acquire HIV as adults. Patients who are coinfected with HBV and HIV tend to have higher serum HBV DNA levels, lower ALT levels, lower rates of spontaneous as well as treatment-related HBeAg seroconversion, and a higher risk of cirrhosis [145–148]. Reactivation of HBV replication has been described in association with HIV infection [149] and may lead to an acceleration of liver disease progression [150,151]. In contrast, HBV coinfection does not appear to have any significant effect on the rate of progression of HIV disease [147,152]. Flares of hepatitis B and deaths due to liver failure have also been reported in patients receiving highly active antiretroviral therapy (HAART). The exacerbations are felt to be related to "immune reconstitution" with subsequent immune-mediated injury directed against infected hepatocytes [153]. Several studies have shown that patients coinfected with HIV and HBV have an increased risk of liver-related mortality compared to those with HIV or HBV monoinfection [154,155].

Natural history

The natural course of HBV infection is determined by the interplay between the virus (HBV replication, HBV genotype, and viral variants), host (age, gender, race/ethnicity, genetic make-up, and immune response), and environment (alcohol, concomitant infection with other viruses – HCV, hepatitis D virus (HDV), and HIV – and carcinogens such as aflatoxin).

Progression from acute to chronic hepatitis B virus infection

The overall rate of progression from acute to chronic (persisting for >6 months) HBV infection has been estimated to be 5–10%. The risk is inversely proportional to the age at infection: 90% for perinatal infection, 20% for childhood infection, and less than 5% for adult infection [5–8]. Careful analyses of patients presenting with "acute hepatitis B" found that the risk of progression to chronic HBV infection among immunocompetent adults was less than 1% after the exclusion of patients who had acute exacerbations of chronic HBV infection.

Hepatitis B virus infection is a life-long infection

The advent of sensitive molecular virology assays has revolutionized the concept of viral clearance and recovery from HBV infection. Many studies found that HBV DNA and a vigorous immune response to HBV antigens can be detected more than 10 years after recovery from acute HBV infection, that is, HBsAg to anti-HBs seroconversion [156,157]. These findings indicate that HBV persists but is contained by the host immune response. This accounts for reports of chemotherapy-induced reactivation of HBV replication in patients with "recovered" HBV infection [133].

The likelihood of spontaneous viral clearance in patients with chronic HBV infection is very low because of the presence of extrahepatic reservoirs of HBV, the integration of HBV DNA into the host genome, and the presence of an intracellular conversion pathway whereby newly replicated HBV DNA reenters the hepatocyte nuclei and is used to amplify covalently closed circular HBV DNA (cccDNA) [158]. This intracellular pathway enables the establishment of a pool of transcriptional templates in the hepatocyte without the need for multiple rounds of reinfection.

Clinical course of chronic hepatitis B virus infection

The natural course of chronic HBV infection is characterized by fluctuations in the level of HBV replication and activity of liver disease. The clinical course of chronic HBV infection can be considered as comprising four phases (Fig. 24.3), although not all patients go through every phase.

Immune tolerant phase

In patients with perinatally acquired HBV infection, the initial phase is characterized by high levels of HBV replication: the presence of HBeAg and high levels of HBV DNA in serum (10^6–10^{10} IU/mL), normal ALT, and minimal changes on liver biopsy [159–161]. A mild degree of liver injury despite high levels of HBV replication is believed to be due to immune tolerance to HBV. The

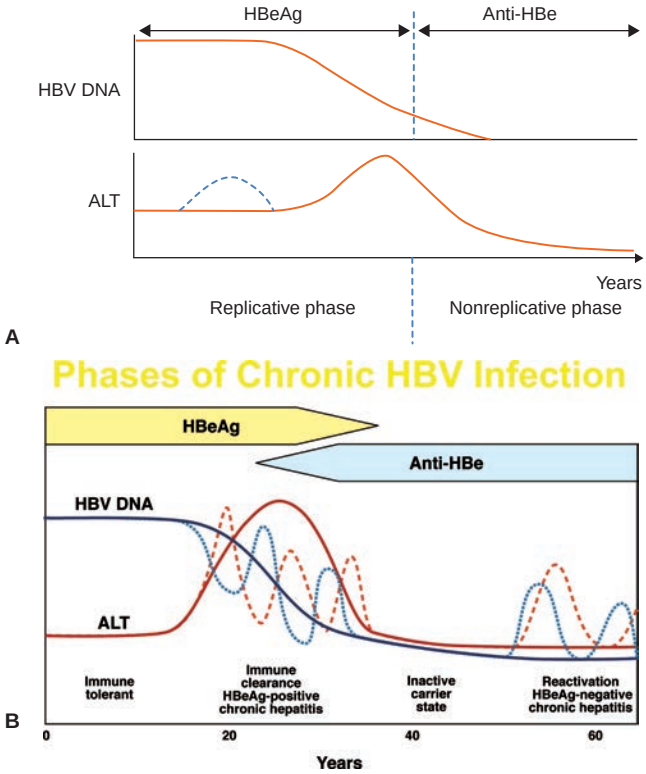

Figure 24.3 Natural history of chronic hepatitis B virus (HBV) infection. ALT, alanine aminotransferase; anti-HBe, hepatitis B e antibody; HBeAg, hepatitis B e antigen.

exact mechanism(s) for immune tolerance is unknown. Experiments in mice suggest that transplacental transfer of maternal HBeAg may induce a specific unresponsiveness of helper T cells to HBeAg [162]. Because HBeAg and HBcAg are cross-reactive at the T-cell level, deletion of the T-helper cell response to HBeAg results in an ineffective cytotoxic T-cell response to HBcAg.

During the immune tolerant phase, which lasts one to four decades, there is a very low rate of spontaneous HBeAg clearance. The cumulative rate of spontaneous HBeAg clearance is estimated to be approximately 2% during the first 3 years [163] and only 15% after 20 years of infection [164]. The persistence of high levels of viremia in adolescents and young adults accounts for the high frequency of maternal–infant transmission of HBV in Asia. The lack of assistance from immune-mediated viral clearance also contributes to a low rate of treatment-related HBeAg seroconversion.

A study from Taiwan that followed 240 adult patients who presented in the immune tolerant phase found that only 5% progressed to cirrhosis and none to HCC during a mean follow-up of 10.5 years [165], confirming that there is very little liver injury during this phase. In patients with childhood or adult-acquired HBV infection, the immune tolerant phase is short-lived or absent.

Immune clearance phase/HBeAg-positive chronic hepatitis

This phase is characterized by the presence of HBeAg, high levels of serum HBV DNA, and active liver disease (elevated ALT and necroinflammation on liver biopsy). In patients with perinatally acquired HBV infection, transition from the immune tolerant to the immune clearance phase usually occurs during the second to fourth decades of life. Most patients with childhood or adult-acquired HBV infection are already in the immune clearance phase at presentation.

During this phase, spontaneous HBeAg clearance occurs at an annual rate of 10–20% (Fig. 24.3) [164, 165]. HBeAg seroconversion is frequently but not always accompanied by biochemical exacerbations [164,166]. These exacerbations are believed to be due to a sudden increase in immune-mediated lysis of infected hepatocytes, and are often preceded by an increase in serum HBV DNA level and a change in the distribution of HBcAg from nuclear to cytoplasmic localization in the hepatocytes.

Most exacerbations are asymptomatic but some are accompanied by symptoms of acute hepatitis. Occasionally, IgM anti-HBc may be detected leading to misdiagnosis of acute hepatitis B in previously unrecognized carriers. Exacerbations may be associated with increase in AFP levels [101]. In approximately 2.5% of patients (especially those with preexisting cirrhosis), exacerbations may result in hepatic decompensation and rarely death from hepatic failure [167].

Not all exacerbations lead to HBeAg seroconversion [164,168,169]. Some patients have abortive immune clearance. These patients may develop recurrent exacerbations with intermittently undetectable serum HBV DNA with or without transient loss of HBeAg. Repeated episodes of necroinflammation may increase the risk of cirrhosis and HCC. Exacerbations are more commonly observed in men than in women [169] and may account for a higher incidence of HBV-related cirrhosis and HCC among men.

An important outcome of the immune clearance phase is HBeAg to anti-HBe seroconversion. Factors associated with higher rates of spontaneous HBeAg seroconversion include older age, higher ALT levels, and HBV genotype B (compared to genotype C) [164,170,171]. High ALT levels are believed to be a reflection of a vigorous host immune response, accounting for its strong correlation with spontaneous as well as treatment-related HBeAg seroconversion. A study of 483 patients who had no evidence of cirrhosis or HCC at the time of HBeAg seroconversion found that the 15-year cumulative risk of HBeAg-negative hepatitis, cirrhosis, and HCC was 31.2%, 3.7%, and 2.1% for those who seroconverted before the age of 30 years and 66.7%, 42.9%, and 7.7%, respectively, for those

who seroconverted after the age of 40. This indicates that earlier HBeAg seroconversion is associated with better prognosis [172].

Inactive carrier phase

This phase is characterized by the absence of HBeAg, presence of anti-HBe, persistently normal ALT levels, and low or undetectable serum HBV DNA (usually $<10^3$ IU/mL) (see Fig. 24.3). Liver biopsy generally shows mild hepatitis and minimal fibrosis but inactive cirrhosis may be observed in patients who had accrued substantial liver injury during the preceding immune clearance phase.

The inactive carrier phase may persist indefinitely, in which case the prognosis is generally favorable, especially if this phase is reached early. This is supported by the finding of comparable survival between HBsAg-positive blood donors (almost all were HBeAg-negative and had normal ALT at baseline) and uninfected controls over a 30-year period [173]. However, inactive carriers are still at risk of HCC and liver-related death. A study of 20,069 subjects in Taiwan including 1,932 inactive HBsAg carriers followed for a mean of 13.1 years found that the annual incidence of HCC and liver-related death was 0.06% and 0.04%, respectively, among the inactive carriers and 0.02% and 0.02% among the HBsAg-negative controls [174].

Some patients in the inactive carrier phase eventually clear HBsAg. The annual rate of HBsAg clearance has been estimated to be 0.5–2% [171,175] but HBsAg clearance does not occur at a linear rate, being very uncommon during the early stages and increasing over time [175]. HBsAg clearance is generally accompanied by undetectable serum HBV DNA, normalization of ALT, and improved liver histology [176]. However, low levels of HBV DNA may be detectable in some patients, more so in the liver than serum. The prognosis of patients who have cleared HBsAg is excellent but HCC has been observed in patients who cleared HBsAg after the age of 50 years or after progression to cirrhosis as well as in those with HCV coinfection [177,178].

Some inactive carriers have reactivation of HBV replication later in life. Reactivation may occur spontaneously or as a result of immunosuppression, and may be due to wild-type HBV or HBV variants that abolish or downregulate HBeAg production. In one study of 283 Chinese patients followed for a median of 8.6 years after spontaneous HBeAg seroconversion, 67% had sustained remission, 4% had HBeAg reversion, and 24% had HBeAg-negative chronic hepatitis [179]. Cirrhosis developed in 8% and HCC in 2%, the risk being higher in those who had active hepatitis after HBeAg seroconversion.

Reactivation of hepatitis B virus replication/HBeAg-negative chronic hepatitis

This phase is characterized by the absence of HBeAg, presence of anti-HBe, detectable serum HBV DNA, elevated ALT, and chronic inflammation ± fibrosis on biopsy (see Fig. 24.3). Patients in this phase are usually older and have more advanced liver disease because this represents a later phase in the course of chronic HBV infection. Serum HBV DNA levels are lower than in HBeAg-positive patients but may reach 10^8–10^9 IU/mL.

The hallmark of this phase is its fluctuating course. In one study where patients were monitored at monthly intervals, 36% had persistently elevated ALT, 20% had fluctuating abnormal ALT, and 44% had fluctuating ALT with intermittently normal values [180]. Several investigators have attempted to define cutoff HBV DNA levels that would differentiate patients with HBeAg-negative chronic hepatitis from inactive carriers; because of the fluctuating course, serial testing is more reliable than any single HBV DNA level in verifying the inactive carrier state [181,182].

HBeAg-negative chronic hepatitis was originally reported in Mediterranean countries. It has now been reported in all parts of the world. The geographic variations in the prevalence of HBeAg-negative chronic hepatitis are related to the predominant HBV genotype in that region. Recent studies in Europe, Asia, and the United States have all reported an increased prevalence of HBeAg-negative and a decreased prevalence of HBeAg-positive chronic hepatitis [183,184]. This may be related to increased awareness of HBeAg-negative chronic hepatitis, a decrease in new HBV infections due to vaccination, and a progression of the existing pool of HBV carriers to later stages of chronic HBV infection.

Latent/occult hepatitis B virus infection

Occult HBV infection is defined as the detection of HBV DNA in persons who are HBsAg-negative [99,185]. HBV DNA is more often detected in liver than in serum. The prevalence of occult HBV infection is higher in countries that are endemic for HBV, in individuals with serologic markers of previous HBV infection, and in those with HIV or HCV infection. Occult HBV infection is more common among patients with cirrhosis or HCC [99,186]. Many of these patients probably had chronic HBV infection for decades leading to liver damage but HBsAg is no longer detectable when cirrhosis or HCC is diagnosed. Low levels of HBV may also be a cofactor of liver disease in patients with chronic HCV infection or other causes of chronic liver disease.

Sequelae of chronic hepatitis B virus infection

The sequelae of chronic HBV infection vary from inactive carrier state to chronic hepatitis, cirrhosis, hepatic

decompensation, HCC, and death. The clinical outcome of patients with chronic HBV infection depends on the severity of liver damage prior to sustained HBeAg seroconversion and the durability of the inactive carrier phase.

The annual rate of progression from chronic hepatitis to cirrhosis has been estimated to be 2–5% for HBeAg-positive and 3–10% for HBeAg-negative patients [187]; the higher rate in HBeAg-negative patients is related to older age and more advanced liver disease at presentation. Factors that have been reported to be associated with an increased rate of progression to cirrhosis include: host (older age, male), virus (persistent high levels of HBV replication, HBV genotype (C > B), coinfection with HCV, HDV, and HIV), and environment (alcohol and, more recently, obesity) [187,188].

The annual rate of progression from compensated cirrhosis to hepatic decompensation has been estimated to be 3–5% [187]. Survival after the development of compensated cirrhosis is favorable initially (85% at 5 years) but decreases dramatically after the onset of decompensation to 55–70% at 1 year and 14–35% at 5 years [187]. The lifetime risk of a liver-related death has been estimated to be 40–50% for men and 15% for women among patients with perinatally acquired chronic HBV infection [189].

The annual rate of HCC development has been estimated to be 0.5–1.0% for noncirrhotic carriers and 2–3% for patients with cirrhosis [187]. Risk factors for HCC include: host (older age, male, being Asian, having first-degree relatives with HCC), virus (high levels of HBV replication, HBV genotype (C > B), core promoter mutations, coinfection with HCV), and environment (alcohol, aflatoxin, and, more recently smoking, obesity, and diabetes) [187,188]. It is important to note that although HCC is more common among patients with cirrhosis, 30–50% of HCC associated with HBV occurs in the absence of cirrhosis.

There is overwhelming evidence that high serum HBV DNA levels, delayed HBeAg seroconversion, and HBV reactivation with or without seroreversion after HBeAg loss are associated with increased risk of cirrhosis, HCC, and liver-related mortality [171,172,190–194]. One of the largest studies, including more than 3,500 HBsAg-positive Chinese adults aged 30–65 years, followed for a mean of 11 years, found that compared to carriers with serum HBV DNA $<4\log_{10}$ copies/mL, those who had serum HBV DNA $>6\log_{10}$ copies/mL at entry had an adjusted relative risk of 6.5 for cirrhosis and 6.1 for HCC [193,194].

Several studies from Asia reported that genotype C is associated with more rapid progression to cirrhosis and an increased risk of HCC compared with genotype B [191,195–197]. These findings may be related to observations that patients with genotype C undergo spontaneous HBeAg seroconversion later and have a higher frequency of core promoter mutations [170,183].

Coinfection of hepatitis B virus and hepatitis C virus

Acute coinfection of HBV and HCV has been reported in transfused patients as well as in intravenous drug users. Coinfection with HCV may delay the onset and shorten the duration of HBs antigenemia as well as lowering the peak ALT levels compared with acute HBV infection alone [198]. These findings suggest that HCV coinfection may interfere with the replication of HBV leading to attenuation of liver damage. However, acute coinfection of HCV and HBV has been reported to increase the risk of fulminant hepatic failure [199]. HCV superinfection in HBsAg carriers typically manifests as acute icteric hepatitis and is associated with a high risk of hepatic decompensation and death from hepatic failure [200]. HCV superinfection has also been reported to decrease HBV DNA levels and to be associated with earlier HBsAg clearance [201,202]. Patients coinfected with HCV and HBV have higher risks of cirrhosis and HCC compared to patients infected with either virus alone [203,204].

Hepatitis B virus and hepatocellular carcinoma

Worldwide, HCC is the third most common cause of cancer deaths, accounting for approximately 500,000 deaths each year. The vast majority (85%) of HCC is concentrated in eastern and southeastern Asia and sub-Saharan Africa where HBV infection is endemic. Several lines of evidence support an etiologic association between chronic HBV infection and HCC. There is a close correlation between the geographic distribution of HBsAg carriers and the occurrence of HCC [205]. Long-term follow-up studies of HBsAg carriers showed a marked increase in risk of HCC. One study of 22,707 Taiwanese men followed for a mean of 8.9 years found that the incidence of HCC was 495/100,000 per year for HBsAg-positive and 5/100,000 per year for HBsAg-negative men, with a relative risk of 98 [189]. HBV vaccination and antiviral therapy have both been shown to reduce the incidence of HCC [20,206].

Mechanisms of hepatocarcinogenesis

Chronic HBV infection can induce HCC directly by activating cellular oncogenes or by inactivating tumor suppressor genes, or indirectly through chronic liver injury, inflammation, and regeneration [207].

Integrated HBV DNA is frequently found in neoplastic as well as non-neoplastic liver tissue of patients with HBV-related HCC. Integration of HBV DNA may activate cellular protooncogenes or suppress growth-regulating genes. Integration of HBV DNA can also induce carcinogenesis via transactivation. Integration of the intact or

truncated versions of the *X* gene is found in most HCCs. The HBx protein has been shown to be a potent and promiscuous transactivator of viral as well as cellular enhancers and promoters and may play an important role in carcinogenesis [208]. The integration of HBV DNA can also cause cancers indirectly via chromosomal deletions or translocations.

An alternate path by which chronic HBV infection leads to HCC is through the induction of liver injury. Chronic liver cell injury initiates a cascade of events characterized by increased rates of cellular DNA synthesis and impaired cellular repair, thereby setting the scene for acquired mutations. During regeneration, transformed cells that have a growth advantage are selected resulting in clonal expansion and eventually tumor formation. Clinical studies demonstrate that long durations of high levels of HBV replication and active hepatitis increase the risk of HCC.

Hepatitis B virus genotypes and variants

The HBV genome consists of four partially overlapping open reading frames: the *pre-S/S* gene that codes for the envelope proteins, the *pre-C/C* gene that codes for the e antigen and core protein, the *P* gene that codes for the DNA polymerase and reverse transcriptase, and the *X* gene that codes for a protein of unclear significance. Although HBV is a DNA virus, it is prone to mutations with a rate of nucleotide substitutions estimated at 1×10^{-5} to 3×10^{-5}/site per year [209]. This is related to the reverse transcription of an RNA intermediate during the replication cycle of HBV.

Hepatitis B virus genotypes

Hepatitis B virus can be classified into nine genotypes designated A to I [77,78,210]. The geographic distribution of HBV genotypes is summarized in Table 24.4. There is an association between HBV genotypes and precore and core promoter variants. The most common precore variant ($G_{1896}A$) is predominantly found in patients with HBV genotypes B, C, and D and rarely in patients with genotype A [183,211,212]. This accounts for the high prevalence of HBeAg-negative chronic hepatitis and the precore stop codon variant ($G_{1896}A$) in Asia and the Mediterranean basin and their low prevalence in the United States and northern Europe. The most common core promoter variant ($A_{1762}T$, $G_{1764}A$) is more frequently found in patients with HBV genotypes A, C, and D [183].

Table 24.4 Geographic distribution of hepatitis B virus (HBV) genotypes.

HBV genotypes	Distribution areas
A	Northwest Europe, North America, Central Africa
B	China, Japan, Indonesia, Vietnam
C	China, Japan, East Asia, Korea, Vietnam, Polynesia
D	Mediterranean basin, Middle East, India
E	Africa
F	American natives, Polynesia
G	United States, France
H	Mexico, Latin America

Several studies suggest that HBV genotypes may be related to the rate of recovery or likelihood of a fulminant course during acute infection; these studies involved small numbers of patients and the data need to be confirmed.

Studies in Asia where genotypes B and C are predominant found that genotype B is associated with a lower prevalence of HBeAg, earlier HBeAg seroconversion, higher likelihood of sustained remission after HBeAg seroconversion, and less active liver disease compared with genotype C [170,213–215]. HBV genotype B is also associated with a slower rate of progression to cirrhosis and HCC [195–197,216–218]. One study in Taiwan found that the incidence of HCC among carriers with genotype C infection was more than double those with genotype B infection, 786 versus 306 per 100,000 person-years [197]. Data on the relation between other HBV genotypes and HBV replication and liver disease are scanty. Available data suggest that genotype A is associated with a higher likelihood of sustained virologic and biochemical remission after HBeAg seroconversion than genotype D [219]. A study in Alaska confirmed that genotype C is associated with a lower rate of HBeAg seroconversion compared with other genotypes and that genotype F is associated with a high incidence of HCC [220,221].

HBV genotype may also affect the response to IFN therapy. Several studies reported that HBeAg-positive patients with genotypes A and B have higher rates of HBeAg loss than those with genotypes C and D after IFN therapy [222–224]. Patients with genotype A also have higher rates of HBsAg loss [225]. NUCs appear to be equally effective in virus suppression across all HBV genotypes [226].

Precore variants

Among the naturally occurring HBV mutations, mutations in the precore region have been most extensively studied (Fig. 24.4). The precore region consists of 87 nucleotides (29 amino acids) that precede the core region. The *preC/C* gene codes for two 3.5 kb RNA transcripts. The precore mRNA is slightly longer and codes for the precore/core protein that is processed to a smaller secretory protein – HBeAg [227]. The pregenomic RNA serves as a template for reverse transcription into the (–) strand HBV DNA. It also serves as an mRNA for translation into the core protein and polymerase protein.

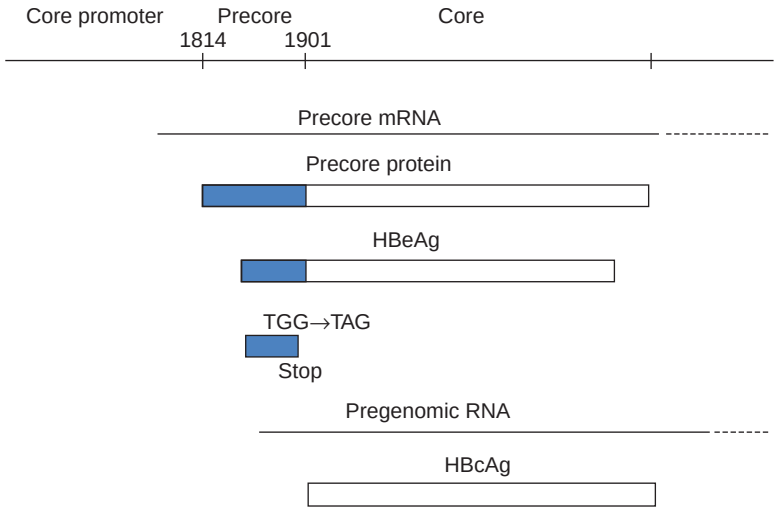

Figure 24.4 Transcription and translation of precore/core open reading frame. Precore mRNA is translated into precore protein, which is processed at the N and C terminal ends to hepatitis B e antigen (HBeAg). Mutation of nucleotide 1896 from G to A converts codon 28 in the precore region from tryptophan to a stop codon, thereby preventing production of HBeAg. Pregenomic RNA is translated into core and polymerase protein and reverse transcribed into hepatitis B virus DNA. HBcAg, hepatitis B core antigen.

The predominant mutation in the precore region is a G-A change at nucleotide 1896, creating a stop codon at codon 28 (Box 24.2) [228]. This mutation leads to premature termination of the precore/core protein, thereby preventing the production of HBeAg.

Initial reports of the $G_{1896}A$ variant came from the Mediterranean countries and Japan. This variant has been detected in diverse geographic areas [183,229]. A recent study found that the precore variant can be found in up to 30% patients with chronic HBV infection in the United States [183]. The variability in the prevalence of the $G_{1896}A$ variant in different countries is related to the predominant HBV genotype. The $G_{1896}A$ variant is replication competent and transmission has been documented in humans as well as in chimpanzee experiments [230–232]. However, infection with precore HBV variant is less likely to progress to chronic infection, possibly due to the lack of the tolerogenic effect of HBeAg.

The $G_{1896}A$ variant is usually found in HBeAg-negative patients but may be present as a mixture with wild-type virus in HBeAg-positive patients. It has been observed to emerge or become selected around the time of HBeAg seroconversion [233,234]. The $G_{1896}A$ variant was initially thought to cause more severe liver disease because it was found in patients with severe chronic hepatitis or acute liver failure [230,231,235,236] but it has also been detected in anti-HBe-positive asymptomatic carriers [237]. Therefore, the $G_{1896}A$ mutation alone may have no direct pathogenic role; instead host immune response and mutations in other regions of the HBV genome may be more important in determining the severity of liver disease.

Box 24.2 Common forms of hepatitis B virus (HBV) variants.

HBeAg-negative phenotype

Precore region

- G-A at nt 1896, tryptophan stop at codon 28 (G1896A, eW28X)

Core promoter region

- A-T at nt 1762 and G-A at nt 1764 (A1762T, G1764A, ×K130M, ×V131I)

HBIg/HBV vaccine escape

S gene

- Glycine–arginine at codon 145 (sG145R)

Antiviral resistance (primary resistance mutations)

P gene (reverse transcriptase/polymerase region)

- Lamivudine A181V/T, M204V/I
- Adefovir A181V/T, N236T
- Entecavir T184G, S202G/I, M250V
- Telbivudine M204I
- Tenofovir A181V/T, A194T, N236T
- A181V/T Alanine–valine or threonine at codon 181
- T184G Threonine–glycine at codon 184
- A194T Alanine–threonine at codon 194
- S202G/I Serine–glycine or isoleucine at codon 202
- M204V/I Methionine–valine or isoleucine at codon 204
- N236T Asparagine–threonine at codon 236
- M250V Methionine–valine at codon 250

HBeAg, hepatitis B e antigen; HBIg, hepatitis B immune globulin; nt, nucleotide.

Core promoter mutations

Mutations in the core promoter region can also decrease HBeAg production by downregulating the transcription of the precore mRNA. The most common core promoter variant has dual mutations involving A to T change at nucleotide 1762 and G to A change at nucleotide 1764 ($A_{1762}T$, $G_{1764}A$) (Box 24.2). These two changes result in amino acid substitutions in codons 130 and 131 of the overlapping *X* gene. Unlike precore variants, core promoter variants can be detected in similar proportions of HBeAg-negative and HBeAg-positive patients. Core

promoter variants were reported to be more common in patients with acute liver failure [238,239] and have been shown in many studies to be associated with HCC [240, 241]. A cohort study in Taiwan found that the multivariate adjusted hazard ratios of developing HCC were 1.76 for genotype C versus B, 1.73 for core promoter mutations versus wild-type core promoter sequence, and 0.34 for precore mutations versus wild-type precore sequence [197].

S gene mutations

Vaccinees

Mutations in the *S* gene have been described in infants born to carrier mothers despite adequate anti-HBs response after vaccination [242–244]. The most common mutation involves a glycine to arginine substitution at codon 145 (G145R) in the "a" determinant (Box 24.2). This mutation has been shown to exhibit decreased binding to monoclonal anti-"a" antibodies thereby allowing the virus to escape neutralization. Chimpanzee experiments demonstrated that the G145R variant is infectious [245], raising concerns about the possibility of widespread dissemination of vaccine escape variants. One study from Taiwan found that the prevalence of vaccine escape variants among HBsAg-positive children increased after the introduction of universal vaccination, from 7.8% in 1984 to 23% in 1999 [246] but the carrier rate decreased from 9.8% to 0.7% during the same period [247]. Another study among 784 preschool children in four Pacific Island countries, who received HBV vaccine, failed to detect any "a" determinant mutation [248]. These data suggest that the emergence of vaccine escape mutants occurs rarely and has not diminished the efficacy of HBV vaccines. Apart from G145R, other mutations in the "a" determinant have also been reported. Some of these variants may yield false-negative results in serology assays that rely on monoclonal antibodies but practically all the S variants can be detected in HBsAg assays that utilize polyclonal anti-HBs for capture and/or detection.

Liver transplant recipients

Mutations in the HBV *S* gene have also been reported in liver transplant recipients who developed HBV reinfection despite prophylaxis with monoclonal or polyclonal anti-HBs (HBIg) [249–251]. Most of the mutations are located in the "a" determinant, the most common being the G145R mutation. Prophylaxis with a combination of HBIg and NUC decreases the risk of immune escape and rate of reinfection [252].

Pre-S mutations

Deletions and mutations in the pre-S1 and pre-S2 regions have also been described and are more commonly seen in patients with progressive liver disease or HCC [253].

P gene mutations

Naturally occurring HBV polymerase gene mutations are rarely reported. The most common *P* gene mutations have been found in association with the use of NUCs for the treatment of chronic HBV infection (see Box 24.2).

Treatment

The main goal of treatment of chronic hepatitis B is to prevent cirrhosis, hepatic decompensation, and HCC. This goal is best achieved by eradicating HBV before there is irreversible liver damage. However, it is not possible to eradicate HBV because of the presence of extrahepatic reservoirs of HBV, the integration of HBV DNA into the host genome, and the presence of an intracellular conversion pathway that replenishes the pool of transcriptional templates (cccDNA) in the hepatocyte nucleus without the need for reinfection [158]. Parameters used to assess response include normalization of serum ALT, decrease in serum HBV DNA level, loss of HBeAg with or without detection of anti-HBe (for HBeAg-positive patients), loss of HBsAg, and improvement in liver histology.

Currently, there are seven approved treatments for hepatitis B: standard and pegylated IFN-α, and five NUCs – lamivudine, adefovir, entecavir, telbivudine, and tenofovir. Responses to these treatment in phase III trials are summarized in Table 24.5.

IFNs are administered for predefined durations while NUCs are usually administered until a specific endpoint is achieved. The difference in approach is related to the observation that HBeAg seroconversion frequently occurs a few months after cessation of IFN treatment, presumably because of the lag between immune priming and decrease in expression of viral protein, whereas viral relapse is inevitable if NUCs are withdrawn prior to achieving the therapeutic endpoint. For HBeAg-positive patients, virus suppression can be sustained in 50–90% patients if NUC treatment is stopped after HBeAg seroconversion is achieved and at least 6 months of consolidation therapy is administered. For HBeAg-negative patients, relapse is frequent even when HBV DNA has been suppressed to undetectable levels for more than a year.

IFNs have antiviral, antiproliferative, and immunomodulatory effects. The antiviral effects of IFN depend on its binding to specific receptors, which then triggers a series of intracellular events including activation of 2′,5′-oligoadenylate synthetase (2′5′-AS). IFNs also have immunomodulatory functions that may be important in eradicating virus infections.

Table 24.5 Responses to 48–52 weeks of approved treatments of hepatitis B in treatment-naïve patients.

Response	No treatment (%)	Pegylated IFN ± lamivudine (%)[a]	Lamivudine (%)	Adefovir (%)	Entecavir (%)	Telbivudine (%)	Tenofovir (%)
HBeAg-positive patients							
Undetectable HBV DNA	0–17	69/25	36–44	21	67	60	76
HBeAg seroconversion	4–6	22/27	16–21	12–21	21	22	21
Loss of HBsAg	0–1	3/3	~1	0	2	0	3
Normalization of ALT	7–24	46/39	41–75	48–61	68	77	68
Histologic improvement	NA	41/38[b]	49–56	53	72	65	74
Genotypic resistance	0	4/0	15–30	0	0	11	0
HBeAg-negative patients							
Undetectable HBV DNA	0–20	87/63	60–73	51	90	88	93
Loss of HBsAg	<1	2/3	<1	0	<1	<1	0
Normalization of ALT	10–29	49/38	62–78	72	78	74	76

Genotypic resistance	0	0	10–25	0	0	5	0

[a] Responses in patients who received pegIFN monotherapy/pegIFN + lamivudine.
[b] Assessed at week 72 (24 weeks after discontinuation of treatment).
ALT, alanine aminotransferase; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; IFN, interferon; NA, not available.

Standard interferon-α

Efficacy

1 *HBeAg-positive chronic hepatitis.* Several meta-analyses confirmed a beneficial effect of IFN therapy in HBV DNA suppression, ALT normalization, and HBeAg loss [254,255].
2 *HBeAg-negative chronic hepatitis.* Results of randomized controlled trials showed that treated patients were more likely than controls to have viral suppression but most patients relapsed when treatment was stopped. One study found a higher rate (30%) of sustained response after 24 months of IFN-α therapy compared with 15–20% rates reported in other studies that administered IFN-α for 12 months [256] suggesting that a longer duration of treatment may increase the rate of sustained response.
3 *HBV DNA-positive clinical cirrhosis*. Patients with histologic cirrhosis but no evidence of hepatic decompensation appeared to tolerate IFN-α treatment. However, IFN-α even when administered in very low doses is associated with a high risk of serious infections and severe exacerbations leading to hepatic failure in patients with clinically evident cirrhosis [257,258].

Role of prednisone priming

Steroid withdrawal has been observed to be frequently accompanied by a flare in serum ALT levels and HBeAg seroconversion. Prednisone priming followed by IFN-α treatment had very little additional beneficial effect compared with IFN-α alone [259] and there is a risk of fatal exacerbation in patients with underlying cirrhosis.

Long-term outcome of therapy with interferon-α

Hepatitis B e antigen-positive patients

Most HBeAg-positive patients who responded to IFN-α therapy are able to maintain their response. Relapses usually occur within 1 year of cessation of treatment, but delayed reactivation can occur. Among the sustained responders, an increasing proportion cleared HBsAg during the course of follow-up. The percent of sustained responders who cleared HBsAg within 5 years of HBeAg clearance varied from 65% in one US study [260], to 19–24% in European studies [261–263], to 0–9% in two studies from Asia [264,265] despite similar durations of follow-up. A sustained antiviral response, especially in those who clear both HBeAg and HBsAg, is almost invariably accompanied by normalization of ALT levels and a decrease in necroinflammation but residual liver damage may be present. Follow-up of 101 male patients who participated in a controlled trial of IFN-α therapy in Taiwan for 8 years found that treated patients had a lower incidence of HCC (1.5% versus 12%, $P = 0.04$) and a higher survival rate (98% versus 57%, $P = 0.02$) compared to controls but there was no difference in the rate of new onset of cirrhosis [265]. Clinical benefits were not observed in a study from Hong Kong [266]. IFN-α has not been shown

to decrease the incidence of HCC in European or North American patients, probably because of the low rate of HCC in untreated patients. However, studies comparing the outcome of responders versus nonresponders found that patients who cleared HBeAg had better overall survival and survival free of hepatic decompensation and a clinical benefit was most evident among patients with cirrhosis [255,261,262,267,268].

Hepatitis B e antigen-negative patients

Relapse after cessation of IFN-α treatment is frequent, with sustained response rates of only 15–30% [269,270]. Among the long-term responders, approximately 20% cleared HBsAg after 5 years of follow-up [271]. IFN-α therapy did not have any overall effect on survival, complication-free survival, or HCC, but patients with sustained response had significantly lower rates of hepatic decompensation [270,271].

Dose regimen

IFN-α is administered as subcutaneous injections. The recommended dose for adults is 5 MU daily or 10 MU thrice weekly and for children is 6 MU/m^2 thrice weekly to a maximum of 10 MU. The recommended duration of treatment for patients with HBeAg-positive chronic hepatitis B is 16–24 weeks. Patients with HBeAg-negative chronic hepatitis B should be treated for at least 12 months; one study suggested that higher rates of sustained response can be achieved with 24 months of treatment [256].

Pegylated interferon-α

The attachment of polyethylene glycol to a protein (pegylation) reduces its renal clearance, and decreases immunogenicity of the protein, with a resultant increase in the half-life of the pegylated protein. Clinical trials suggest that efficacy of pegylated IFN-α (pegIFN-α) is similar to or slightly better than standard IFN-α. PegIFN-α has the advantage of more convenient administration and more sustained virus suppression and has largely replaced standard IFN-α.

Efficacy

1 *HBeAg-positive chronic hepatitis.* In one phase II trial, 194 patients were randomized to receive 90, 180, or 270 μg pegIFN-α2a weekly or 4.5 MU standard IFN-α2a thrice weekly for 24 weeks. A higher percent of patients who received pegIFN-α had HBeAg seroconversion: 32% versus 25% of those who received standard IFN-α [272]. In a subsequent phase III trial, 814 patients were randomized to receive pegIFN-α2a 180 μg weekly, pegIFN-α2a 180 μg weekly + lamivudine 100 mg daily, or lamivudine 100 mg daily for 48 weeks. At the end of treatment, virus suppression was most marked in the group that received the combination therapy: mean HBV DNA reduction in the three groups was 4.5, 7.2, and 5.8 $\log_{10}$ copies/mL, respectively [273]. HBeAg seroconversion was similar in the three groups at the end of treatment (27%, 24%, and 20%, respectively), but significantly higher in the two groups that received pegIFN-α when response was assessed 24 weeks after treatment was stopped (32%, 27%, and 19%, respectively) (Table 24.5). These data indicate that pegIFN-α2a monotherapy was superior to lamivudine monotherapy in inducing HBeAg seroconversion, and comparable to the combination therapy of pegIFN-α2a and lamivudine. Similar results were reported in two trials, in which pegIFN-α2b was administered in tapering doses (100 → 50 μg) for 52 weeks or 1.5 μg/kg for 32 weeks. Twenty-four weeks after treatment was stopped, one study reported identical rates (29%) of HBeAg seroconversion in patients who received pegIFN-α2b monotherapy with and without lamivudine [274], whereas the other study reported a significantly higher rate of HBeAg seroconversion in those who received a combination of pegIFN-α2b and lamivudine versus those who received lamivudine only, 36% versus 14% [275].

Follow-up of patients in one study of pegIFN-α2b for a mean of 3.5 years after completion of pegIFN ± lamivudine found that 37% had lost HBeAg and 11% had lost HBsAg [225]. The rate of HBsAg loss was significantly higher in patients with genotype A infection: 28% compared to 3% in those with non-A genotypes. Among the initial responders, 81% had durable HBeAg loss and 30% had HBsAg loss.

2 *HBeAg-negative chronic hepatitis.* In a phase III trial of pegIFN-α in HBeAg-negative patients, 552 patients were randomized to receive 48 weeks of pegIFN-α2a 180 μg weekly, a combination of pegIFN-α2a 180 μg weekly + lamivudine 100 mg daily, or lamivudine 100 mg daily. Virus suppression was most marked in the group that received combination therapy: the mean HBV DNA reduction at week 48 in the three groups was 4.1, 5.0, and 4.2 $\log_{10}$ copies/mL, respectively [276]. However, the sustained response (HBV DNA undetectable by PCR and normalization of ALT at week 72) was comparable in the groups that received pegIFN-α2a alone or in combination with lamivudine, and superior to the group that received lamivudine monotherapy: 15%, 16%, and 6%, respectively (Table 24.5). Three years after completion of treatment, a serum HBV DNA of <10,000 copies/mL was maintained in 22.6% versus 9.4%, ALT normalization in 31.3% versus 18.9%, and HBsAg loss in 8.7% versus 0% of patients who received pegIFN ± lamivudine versus lamivudine alone, respectively [277].

Dose regimen

The recommended dose of pegIFN-α2a for both HBeAg-positive and HBeAg-negative hepatitis is 180 μg weekly for 48 weeks. The optimal dose and duration of pegIFN-α2b for hepatitis B is unclear.

Adverse effects of standard and pegylated interferon-α therapy

Interferon-α therapy is associated with a broad spectrum of side effects. The most common side effect is an initial influenza-like illness: fever, chills, headache, malaise, and myalgia. Other common side effects include fatigue, anorexia, weight loss, and mild increase in hair loss. IFN-α has myelosuppressive effects, but significant neutropenia ($<1{,}000/mm^3$) or thrombocytopenia ($<60{,}000/mm^3$) requiring dose reduction or premature termination are uncommon except in patients who have decreased cell counts prior to treatment. The most troublesome side effect of IFN-α is emotional lability: anxiety, irritability, depression, and even suicidal tendency. These symptoms can occur in the absence of a prior history of emotional problems. IFN-α has been reported to induce the development of a variety of autoantibodies. In most instances, this is not accompanied by clinical illness. However, both hyper- and hypothyroidism that require treatment have been reported. In addition, there have been reports of worsening liver disease as a result of IFN-α-induced exacerbation of an underlying autoimmune hepatitis. Rarely, retinal changes and even impaired vision have been reported.

Predictors of response to standard and pegylated interferon-α

Predictors of response to standard and pegIFN-α are similar. The strongest predictor of response in HBeAg-positive patients is the pretreatment ALT level [278,279]. Other factors that have been identified to be associated with a higher rate of IFN-related HBeAg seroconversion include high histologic activity index, low HBV DNA level, and HBV genotypes A and B versus C and D [223,224]. Retrospective analyses found that patients who experienced a greater decline in HBeAg or HBsAg titer during treatment were more likely to undergo HBeAg seroconversion [280].

Factors associated with a higher rate of sustained response in HBeAg-negative patients include low pretreatment HBV DNA level, undetectable HBV DNA at the end of 48 weeks of treatment, and HBV genotype B or C versus D [281]. Two studies showed that patients who experienced a greater decline in HBsAg titer during treatment and those who had a lower HBsAg titer at the end of treatment were more likely to have sustained virologic response during post-treatment follow-up [282,283].

Lamivudine

Lamivudine is the (–) enantiomer of 2′,3′-dideoxy-3′-thiacytidine. It is phosphorylated to the triphosphate (3TC-TP), which competes with deoxycytidine triphosphate (dCTP) for incorporation into growing DNA chains causing chain termination.

Efficacy

Lamivudine monotherapy is effective in suppressing HBV replication and in ameliorating liver disease.

1 *HBeAg-positive chronic hepatitis B.* Randomized clinical trials of patients who received lamivudine for 1 year reported that HBeAg seroconversion occurred in 16–21% of treated patients compared to 4–6% of untreated controls (see Table 24.5) [284–286]. Histologic improvement, defined as a reduction in necroinflammatory score of ≥2 points, was observed in 49–56% of treated patients and in 23–25% controls. HBeAg seroconversion rates increased with the duration of treatment to approximately 50% at 5 years [287].

   Experience with lamivudine in children is limited. One controlled trial involved 286 children with elevated ALT randomized to receive lamivudine (3 mg/kg/day up to 100 mg/day) or placebo for 52 weeks. A significantly higher proportion of treated children developed HBeAg seroconversion compared to placebo controls, 22% versus 13% [288]. Lamivudine was well tolerated but lamivudine resistance mutations were detected in 19% after 1 year and in 64% after 3 years of treatment [289].

2 *HBeAg-negative chronic hepatitis B.* In one placebo-controlled study, virologic and biochemical response was achieved in 34 of 54 (63%) patients who received 24 weeks of lamivudine therapy versus 3 of 53 (6%) patients on placebo ($P < 0.001$) [290]. Several studies have shown that HBV DNA is suppressed to undetectable levels in 60–73% patients after 1 year of treatment (see Table 24.5) [291,292]. However, the vast majority (~90%) of patients relapsed when treatment was stopped. Extending the duration of treatment results in progressively lower rates of maintained response due to the selection of drug-resistance mutations [293].

3 *Nonresponders to IFN-α treatment.* In a multicenter trial on IFN-α nonresponders, 238 HBeAg-positive patients were randomized to receive lamivudine monotherapy for 52 weeks, a combination of 24 weeks lamivudine and 16 weeks of standard IFN-α, or no treatment. Patients who received lamivudine monotherapy had the highest HBeAg seroconversion rate: 18% compared to 12% and 13%, respectively in the other groups [294]. These data suggest that patients who failed IFN-α treatment have similar responses to lamivudine as treatment-naïve patients and retreatment with a

combination of standard IFN-α and lamivudine did not confer any added benefit compared to retreatment with lamivudine monotherapy.

4 *Advanced liver disease.* Lamivudine has been shown to delay clinical progression in patients with advanced fibrosis or cirrhosis. In a double-blind, randomized, placebo-controlled trial, 651 Asian patients who were HBeAg-positive or had detectable HBV DNA by branched DNA assay (>700,000 genome equivalents/mL), and bridging fibrosis or cirrhosis on liver biopsy, were randomized to receive lamivudine or placebo. After a median duration of 32 months, a statistically significant difference was observed between the two groups for overall disease progression (increase in Child–Pugh score, hepatic decompensation, or HCC) – 7.8% versus 17.7% – as well as in HCC development – 3.9% versus 7.4% [206]. The benefit was observed mainly among those patients who did not have virologic breakthrough. These data indicate that antiviral therapy can improve clinical outcome in patients who have maintained virus suppression.

5 *HBV DNA-positive clinical cirrhosis.* Studies of lamivudine in patients with decompensated cirrhosis have shown that lamivudine treatment is well tolerated and can stabilize or improve liver function, thereby obviating or delaying the need for liver transplantation. However, these studies showed that clinical benefit takes 3–6 months, and that HCC can occur even among patients with clinical improvement [295–298]. Furthermore, hepatitis flares secondary to drug resistance can lead to a rapid worsening of liver failure.

Predictors of response

Pretreatment serum ALT is the strongest predictor of response among HBeAg-positive patients. Pooled data from four studies with a total of 406 patients who received lamivudine for 1 year found that HBeAg seroconversion occurred in 2%, 9%, 21%, and 47% patients with pretreatment ALT levels within normal, one to two times normal, two to five times normal, and more than five times normal, respectively. The corresponding figures for 196 patients in the placebo group were 0%, 5%, 11%, and 14%, respectively [279]. There are no data on predictors of response to lamivudine treatment of HBeAg-negative patients.

Durability of response

Durability of HBeAg seroconversion has been reported to vary from 50% to 80%. In a follow-up report of patients in the United States and Europe, who completed 1 year of lamivudine treatment, 30 of 39 (77%) patients with HBeAg seroconversion had a durable response after a median follow-up of 37 months (range 5 to 46 months) [299]. In addition, eight (20%) patients developed HBsAg seroconversion. Some studies reported lower rates of durability [300–303]. Several factors have been identified as being associated with increased durability of HBeAg seroconversion, including longer duration of consolidation treatment (continued treatment after HBeAg seroconversion), younger age, lower HBV DNA level at the time treatment was stopped, and genotype B versus C; the most consistent factor appears to be duration of consolidation treatment [300,302,304]. Although there are no good direct comparison data, it appears that durability of lamivudine-induced HBeAg seroconversion is less than that for IFN.

Among HBeAg-negative patients, durability of virus suppression after 1 year of lamivudine treatment is less than 10%. One study reported that durability of virologic response can be improved to 50% in patients who have completed 2 years treatment [305].

Lamivudine resistance

The selection of lamivudine resistance mutations is the main concern with lamivudine treatment. The most common mutation affects the YMDD motif of the HBV DNA polymerase (methionine to valine or isoleucine M204V/I) [306]. Alanine to threonine or valine substitution at position 181 (A181T/V) has also been shown to be associated with lamivudine resistance but is far less common than the M204V/I mutation. Genotypic resistance can be detected in 14–32% of HBeAg-positive patients after 1 year of lamivudine treatment [284–286] and increases with the duration of treatment to 60–70% after 5 years of treatment [287]. The rates of lamivudine resistance in patients treated for HBeAg-negative chronic hepatitis B varies from 10% to 56% at 2 years [290,292,307]. In vitro studies showed that the M204V/I mutation decreases replication fitness of HBV [308,309], but that compensatory mutations such as leucine to methionine substitution (L180M), valine to leucine substitution (V173L), and changes at L80 selected during continued treatment can restore replication fitness. Therefore, over time, serum HBV DNA levels continue to increase and virologic breakthrough is usually followed by biochemical breakthrough and in some instances hepatitis flares and hepatic decompensation. The frequency of hepatitis flares increases with the duration of lamivudine resistance, from 43% in year 1 to greater than 80% after 3 years [287].

Long-term outcome of lamivudine-treated patients

Follow-up of patients receiving continued lamivudine treatment showed that the rates of maintained virologic and biochemical response decrease with time due to the selection of drug-resistance mutations. As a group, liver histology after 3 years of treatment is improved compared to baseline but histologic benefit after the first year of

treatment is negated among patients with virologic breakthrough [299]. Despite increasing rates of breakthrough infection, two studies with a median follow-up of 2–4 years reported that lamivudine treatment decreased the overall rate of hepatic decompensation as well as liver-related mortality [310,311].

Adverse events

In general, lamivudine is very well tolerated. Various adverse events, including a mild (two- to three-fold) increase in ALT level have been reported in patients receiving lamivudine, but these events occurred with the same frequency among the controls.

Dose regimen

The recommended dose for adults with normal renal function and no HIV infection is 100 mg daily PO. Dose reduction is necessary for patients with renal insufficiency. Patients with HIV coinfection should be treated with 150 mg b.i.d. doses in addition to other antiretroviral therapies. The recommended dose for children is 3 mg/kg/day with a maximum dose of 100 mg/day.

Adefovir dipivoxil

Adefovir is a nucleotide analog of adenosine monophosphate. It can inhibit reverse transcriptase as well as DNA polymerase activity. In vitro and clinical studies showed that it is effective in suppressing wild-type as well as lamivudine-resistant HBV.

Efficacy

1 *HBeAg-positive chronic hepatitis.* A phase III clinical trial included 515 patients with compensated liver disease randomized to receive two doses of adefovir (30 or 10 mg daily) or placebo (see Table 24.5) [312]. After 48 weeks of treatment, histologic improvement was observed in 59%, 53%, and 25%, respectively. The proportion of patients with undetectable HBV DNA was 39%, 21%, and 0%, respectively. Normalization of ALT was observed in 55%, 48%, and 16%, whereas HBeAg seroconversion occurred in 14%, 12%, and 6%, respectively. All assessments of response showed a statistical difference between the two treatment groups and the placebo group, and a trend indicating superiority of the 30 mg dose. However, 8% of patients in the 30 mg dose group had nephrotoxicity defined as a reproducible increase in serum creatinine by $\geq$0.5 mg/dL. Cumulative HBeAg seroconversion was estimated to be 48% after 5 years of treatment [313].

2 *HBeAg-negative chronic hepatitis*. A phase III clinical trial included 185 patients with compensated liver disease randomized to receive adefovir 10 mg daily or placebo [314]. After 48 weeks of treatment, patients who received adefovir were more likely to have improvement in liver histology (77% versus 33%), undetectable HBV DNA (51% versus 0%), and normalization of ALT (72% versus 29%) (see Table 24.5). A follow-up report of 70 patients who completed 5 years of continued adefovir treatment showed that serum HBV DNA was undetectable in 53% and ALT normalized in 59% [315].

3 *Lamivudine-resistant HBV.* Clinical trials confirmed that adefovir is effective in suppressing lamivudine-resistant HBV [316,317]. Although adefovir monotherapy has similar antiviral efficacy to combination therapy of adefovir and lamivudine, sequential monotherapy increases the risk of adefovir resistance. In patients with decompensated liver disease, the addition of adefovir has been shown to result in clinical improvement, reduction in risk of recurrent hepatitis B postliver transplant, and possibly increased survival [318,319]. One study included 128 pre- and 196 post-transplant patients [318]. Among the patients who received 48 weeks treatment, 81% of the pre- and 34% of the post-transplant patients had undetectable HBV DNA, and 76% and 49%, respectively had normalization of ALT. The Child–Turcotte–Pugh score improved in more than 90% of patients in both groups, and 1-year survival was 84% for the pre- and 93% for the post-transplant patients. Follow-up of 226 pretransplant patients showed that viral suppression was maintained in 65% of patients [320].

Predictors of response

Retrospective analyses of data from the two phase III clinical trials showed that HBV DNA reduction was comparable across the four major HBV genotypes (A to D) [226], but an association between adefovir-related HBeAg seroconversion or durability of response and HBV genotypes could not be analyzed because of the small number of responders.

Durability of response and long-term outcome of adefovir-treated patients

Follow-up of 45 patients for a median of 150 weeks off treatment found that HBeAg seroconversion was maintained in 41 (91%) patients. The high rate of durability may be related to a long duration of consolidation treatment [321].

Among HBeAg-negative patients, viral suppression was sustained in only 8% of patients who stopped adefovir after 1 year of treatment [322]. Most patients who continued treatment up to 5 years maintained their response and HBsAg loss was observed in 5% of patients after 4–5 years of continued treatment [315]. Long-term treatment was also associated with a decrease in fibrosis score but HCC developed in 3% of patients. A preliminary report of 33 patients who had received adefovir for

4–5 years and had been followed for up to 5 years after cessation of treatment showed that all patients had virologic relapse initially but 18 patients subsequently had virologic and biochemical remission and nine of these patients later lost HBsAg [323].

Dose regimen

The approved dose of adefovir for adults is 10 mg daily PO. Dose adjustment is necessary in patients with impaired renal function. Although higher doses appeared to have more potent antiviral effect, concerns for nephrotoxicity limit their use in clinical practice. Adefovir at the approved dose of 10 mg daily is ineffective in inhibiting HIV replication.

Adverse events

Adefovir is in general well tolerated. The most worrisome adverse event is nephrotoxicity – an increase in serum creatinine and/or renal tubular defects manifested as hypophosphatemia and Fanconi syndrome. Nephrotoxicity has been reported in 3% of patients with compensated liver disease after 4–5 years of continued adefovir therapy [315], and in 6% of patients on the transplant waiting list, 47% of patients who underwent liver transplantation during the study, and 21% of post-transplant patients after a median of 39–99 weeks of treatment [320]. Concomitant nephrotoxic medications or hepatorenal syndrome may contribute to the higher frequency of nephrotoxicity in post-transplant patients and in patients with decompensated liver disease. Renal function should be monitored in all patients receiving adefovir and dosing intervals should be adjusted in patients with an estimated creatinine clearance of less than 50 mL/min.

Adefovir resistance

Resistance to adefovir was not seen in clinical trials of nucleoside-naïve patients who received 48 weeks of treatment [324]. However, mutations conferring resistance to adefovir (asparagine to threonine substitution N236T and A181V/T substitution) have been described [325,326]. Follow-up of 67 HBeAg-negative patients who participated in the phase III trial found that the cumulative rate of resistance increased from 0% at 1 year to 29% after 5 years of treatment [315]. Risk factors for adefovir resistance include suboptimal virus suppression and sequential monotherapy.

In vitro and human studies showed that adefovir-resistant HBV variants are susceptible to lamivudine, telbivudine, and entecavir. However, in patients with prior lamivudine resistance, a reemergence of lamivudine resistance mutations has been reported shortly after the reintroduction of lamivudine [327].

Entecavir

Entecavir is an orally administered cyclopentyl guanosine analog. In vitro studies showed that entecavir is effective in suppressing lamivudine-resistant HBV but susceptibility is reduced compared to wild-type HBV. Entecavir has also been found to be effective in suppressing adefovir-resistant HBV in in vitro studies.

Efficacy

1 *HBeAg-positive patients*. In a phase III clinical trial 715 patients with compensated liver disease were randomized to receive entecavir 0.5 mg or lamivudine 100 mg daily (see Table 24.5). At week 48, entecavir resulted in statistically higher rates of histologic (72% versus 62%), virologic (67% versus 36%), and biochemical (68% versus 60%) responses compared to lamivudine [328]. However, despite more potent viral suppression (6.9 versus 5.4 $\log_{10}$ copies/mL), HBeAg seroconversion rates were similar in the two groups: 21% versus 18%. In a follow-up report of 146 patients who received entecavir for up to 5 years, the percent of patients with undetectable serum HBV DNA increased from 55% at the end of year 1 to 83% at the end of year 2 and 94% at the end of year 5 [329]. ALT normalization was maintained in 85% of patients at year 5. At the end of year 2, HBeAg seroconversion was observed in 31% and HBsAg loss in 5% of the original cohort of 354 patients. Among the 141 patients who remained HBeAg-positive at the end of year 2, 33 underwent HBeAg seroconversion and two lost HBsAg by year 5 [329]. It should be noted that in this long-term treatment study, a higher dose of entecavir (1.0 mg daily) was used after year 2. A trial of 69 patients found that entecavir resulted in more marked viral suppression than adefovir [330]. Another trial of 139 patients showed that entecavir and telbivudine resulted in a similar decline in serum HBV DNA after 24 weeks of therapy [331].

2 *HBeAg-negative patients*. In a phase III clinical trial, 648 patients with compensated liver disease were randomized to receive entecavir 0.5 mg or lamivudine 100 mg daily. At week 48, entecavir resulted in statistically higher rates of histologic (70% versus 61%), virologic (90% versus 72%), and biochemical (78% versus 71%) responses compared to lamivudine (see Table 24.5) [332].

3 *Decompensated cirrhosis*. Entecavir has been shown to be effective in suppressing HBV replication and in improving the Child–Turcotte–Pugh score and model for endstage liver disease (MELD) score in patients with decompensated cirrhosis [333].

4 *Lamivudine-refractory HBV*. In one study 286 patients, who had persistent viremia while on lamivudine with or without confirmed lamivudine-resistance mutations, were randomized to receive entecavir 1.0 mg or

lamivudine 100 mg daily. At week 48, entecavir resulted in statistically higher rates of histologic (55% versus 28%), virologic (19% versus 1%), and biochemical (61% versus 15%) responses compared to lamivudine, and a nonstatistical difference in rate of HBeAg seroconversion [334]. During continued treatment, genotypic resistance to entecavir increased from 6% in year 1 to 51% in year 5 [335] indicating that entecavir is not an optimal treatment for patients with lamivudine resistance.

Predictors of response

Entecavir appears to be equally effective in decreasing the serum HBV DNA level and in inducing histologic improvement in Asians and whites, and across HBV genotypes A to D. Among HBeAg-positive patients, response rates are lower in patients with minimally elevated ALT. Retrospective analysis of the phase III trial in HBeAg-positive patients found that patients with pretreatment ALT <2 times normal had lower rates of HBeAg seroconversion (8% versus 23%), undetectable serum HBV DNA (48% versus 73%), and normal ALT (55% versus 73%) compared with those with pretreatment ALT >2 times normal [336]. Predictors of response in HBeAg-negative patients have not been determined.

Durability of response

Of the 74 HBeAg-positive patients who lost HBeAg during the first year and who discontinued treatment at week 48, suppression of serum HBV DNA to undetectable levels, normalization of ALT, and HBeAg seroconversion was sustained in 39%, 79%, and 77%, respectively after 24 weeks of follow-up [337]. It should be noted that most of these patients had no or a very short duration of consolidation therapy. Viral suppression was sustained in only 3% of HBeAg-negative patients who stopped treatment at week 48 [338].

Dose regimen

The approved dose for nucleoside-naïve patients is 0.5 mg daily PO and for lamivudine-refractory patients is 1.0 mg daily PO. Doses should be adjusted for patients with an estimated creatinine clearance of less than 50 mL/min.

Adverse events

Entecavir had a similar safety profile including on-treatment ALT flares as lamivudine in clinical trials. Studies in rodents exposed to doses 3–40 times those in humans found an increased incidence of lung adenomas, liver cancers, and brain gliomas [339]. Long-term follow-up studies are ongoing to determine if these observations have relevance to humans. Lactic acidosis has been reported in one case series of patients receiving entecavir for liver failure [340], but lactic acidosis has not been observed in other studies of entecavir in patients with decompensated liver disease and may be a class effect of NUCs.

Entecavir resistance

Resistance to entecavir occurs through a two-hit mechanism with an initial selection of M204V/I mutation followed by amino acid substitutions at rtT184, 202, or 250. In vitro studies showed that mutations at these positions on their own have a minimal effect on susceptibility to entecavir, but susceptibility to entecavir is greatly decreased when one of these mutations is present with M204V/I mutation [341]. Resistance to entecavir is rare in nucleos(t)ide-naïve patients. A report of 108 patients found that only 1.2% of nucleos(t)ide-naïve patients had entecavir resistance after 5 years of treatment [335]; however, it should be noted that the number of patients studied is small and a higher dose (1.0 mg) of entecavir was used during years 3–5. Follow-up of 33 lamivudine-refractory patients found that 51% of patients had evidence of entecavir resistance after 5 years of high-dose (1.0 mg) entecavir treatment [335]. These data are not surprising because the preexisting presence of the M204V/I mutation decreases the barrier to entecavir resistance.

Emtricitabine

Emtricitabine is a potent inhibitor of HBV replication. It selects for the same resistance mutations as lamivudine. In one phase II trial, emtricitabine 200 mg daily resulted in a significantly higher rate of histologic (62% versus 25%), virologic (54% versus 2%), and biochemical (65% versus 25%) responses at week 48 but HBeAg seroconversion rates were identical – 12% in the two groups [342]. Antiviral resistance mutations were detected in 13% of patients who received emtricitabine.

Tenofovir

Tenofovir disoproxil fumarate is a nucleotide analog. It is approved for treatment of HBV infection as Viread® (tenofovir only) and also approved for treatment of HIV infection as Viread or Truvada® (tenofovir + emtricitabine as a single pill). Tenofovir is structurally similar to adefovir. In vitro studies showed that tenofovir and adefovir are equipotent. Because tenofovir appears to be less nephrotoxic, the approved dose is much higher than that of adefovir, 300 mg versus 10 mg daily. This may explain why tenofovir has more potent antiviral activity in clinical studies.

Efficacy

Two phase III trials of tenofovir were conducted, one in HBeAg-positive ($n = 266$) and one in HBeAg-negative ($n = 375$) patients with compensated liver disease. Patients were randomized to receive tenofovir 300 mg or adefovir 10 mg daily in a 2 : 1 ratio. At week 48, patients

in the adefovir group were rolled over to tenofovir treatment. At week 72, patients in both groups with detectable serum HBV DNA received additional treatment with emtricitabine.

1 *HBeAg-positive patients.* At week 48, tenofovir resulted in a significantly higher proportion of patients with undetectable serum HBV DNA (76% versus 13%), ALT normalization (68% versus 54%), and HBsAg loss (3% versus 0%), and similar rates of histologic response (74% versus 68%) and HBeAg seroconversion (21% versus 18%) compared with adefovir (see Table 24.5) [343]. At week 144, 71% of the patients had undetectable serum HBV DNA, 26% had HBeAg seroconversion, and an estimated 8% had HBsAg loss [344].
2 *HBeAg-negative patients.* At week 48, tenofovir resulted in significantly more patients with undetectable serum HBV DNA (93% versus 63%) [343]. ALT normalization (76% versus 77%) and histologic response (72% versus 69%) were similar in the two groups (see Table 24.5). At week 144, 87% of the patients had undetectable serum HBV DNA but none of the patients lost HBsAg [345].
3 *Lamivudine-refractory HBV*. Studies of patients who had previously received treatment with lamivudine showed that tenofovir is effective in suppressing lamivudine-resistant HBV. Case series and retrospective studies suggest that switching from lamivudine to tenofovir monotherapy is sufficient in suppressing lamivudine-resistant HBV [346,347], but larger studies are needed to determine whether resistance to tenofovir will emerge with longer duration of follow-up.
4 *Adefovir-resistant HBV*. In vitro studies showed that adefovir resistance mutations N246T and A181V/T are associated with a three to four-fold decrease in response to tenofovir. Available data indicate that tenofovir is effective in suppressing serum HBV DNA levels in patients with adefovir resistance but viral suppression is less marked compared with nucleos(t)ide-naïve patients and adefovir resistance mutations persist [346,348]. These data indicate that tenofovir is not an appropriate treatment for adefovir-resistant HBV.

Dose regimen

The approved dose of tenofovir is 300 mg orally once daily. The dose should be reduced in patients with an estimated creatinine clearance of <50 mL/min.

Adverse events

Tenofovir is less nephrotoxic than adefovir. However, tenofovir has been occasionally reported to cause Fanconi syndrome and renal insufficiency [352–354]. Almost all of these adverse events occurred in patients with HIV coinfection receiving antiretroviral therapy. A decrease in bone density has also been reported and may be related to increased loss of phosphate through the kidneys [355]. Although the effect appears to be mild and short-lived, the effect on bones is more prominent in children and tenofovir should not be used in children. In the two phase III clinical trials, serum creatinine remained stable over 3 years. Only two patients experienced an increase in serum creatinine ≥0.5 mg/dL and four patients (<1%) experienced a reduction in serum phosphorus <2 mg/dL which resolved on continued tenofovir therapy [343].

Tenofovir resistance

Tenofovir-resistant HIV mutations had been reported in patients who received tenofovir for HIV monoinfection. However, there is no corresponding site in the HBV genome. One study reported virologic breakthrough and alanine to threonine substitution (rtA194T) in two patients with HIV/HBV coinfection who had prior lamivudine resistance [349], but the association between this mutation and tenofovir resistance is controversial [350,351]. In vitro and in vivo data indicate that rtA181V/T and rtN236T mutations are associated with a decreased response to tenofovir.

In the two phase III clinical trials, virologic breakthroughs were observed in 2.3% of patients during the first year but tenofovir resistance HBV mutations were not detected in any of these patients [343]. Continued surveillance for up to 3 years did not identify any patient with tenofovir resistance mutations, but patients at the highest risk of antiviral resistance, those in whom serum HBV DNA remained detectable at week 72, received additional treatment with emtricitabine. Therefore, data on resistance to entecavir monotherapy beyond 72 weeks cannot be determined.

Telbivudine

Telbivudine is a nucleoside analog with potent antiviral effects against HBV. However, it is associated with a high rate of drug resistance and selects for the same mutations as lamivudine.

Efficacy

1 *HBeAg-positive patients.* A phase III clinical trial of 921 patients showed that a significantly higher percent of patients who received telbivudine had undetectable HBV DNA compared with those who received lamivudine: 60% versus 40% and 56% versus 39% after 1 and 2 years treatment, respectively (see Table 24.5) [356,357]. Telbivudine also resulted in a significantly higher percent of patients with normalization of ALT: 70% versus 62% at 2 years; but HBeAg seroconversion was similar, 35% versus 29% at 2 years.
2 *HBeAg-negative patients.* In a phase III trial of 446 HBeAg-negative patients, telbivudine resulted in a

higher percent of patients with undetectable HBV DNA compared with those who received lamivudine: 88% versus 71%, and 82% versus 57%, after 1 and 2 years treatment, respectively (see Table 24.5) [356,357]. ALT normalization was observed in a similar percent of patients at 1 and 2 years.

Predictors of response

Patients with undetectable serum HBV DNA by 24 weeks of treatment had significantly higher rates of response and significantly lower rates of antiviral resistance at week 96 compared to patients with HBV DNA $\geq 4 \log_{10}$ copies/mL at week 24. However, a small percent of these rapid responders were noted to have virologic rebound due to drug resistance by week 96 [358].

Dose regimen

The approved dose of telbivudine is 600 mg daily. Doses should be reduced for patients with an estimated creatinine clearance of <50 mL/min.

Adverse events

Telbivudine is well tolerated when used as monotherapy and has a safety profile similar to lamivudine. However, cases of myopathy and peripheral neuropathy have been reported. In the phase III trials, an asymptomatic grade 3 or 4 increase in creatine kinase was observed in 12.9% versus 4.1% of patients after 1 year of telbivudine and lamivudine, respectively [356]. During continued treatment up to year 4, a grade 3 or 4 increase in creatine kinase was observed in 16% and myositis in 0.5% [359]. Telbivudine in combination with pegIFN was associated with a higher rate and an earlier onset of peripheral neuropathy compared with telbivudine monotherapy.

Telbivudine resistance

Mutations associated with telbivudine resistance (rtM204I and rtA181V/T) are similar to those associated with resistance to lamivudine except that rtM204V has not been observed. Telbivudine is associated with a high rate of drug resistance. In the phase III trials, genotypic resistance after 2 years of treatment was observed in 25% of HBeAg-positive and in 11% of HBeAg-negative patients [357].

Clevudine

Clevudine is a pyrimidine nucleoside analog that is effective in inhibiting HBV replication. Clinical trials showed that clevudine in doses of 30 mg daily for up to 24 weeks was well tolerated. Serum HBV DNA became undetectable in 59% of HBeAg-positive and in 92% of HBeAg-negative patients [360,361]. A unique feature of clevudine is the durability of viral suppression, persisting for up to 24 weeks after withdrawal of treatment in some patients. Clevudine selects for the same resistance mutations as lamivudine, rtM204V/I and rtA181V/T. A major problem with clevudine is the occurrence of myopathy, which is related to mitochondrial toxicity, in patients who received treatment for longer than 24 weeks [362,363]. The onset of symptoms has been reported to occur as early as 8 months and usually manifests as proximal muscle weakness, although involvement of the bulbar muscles has also been observed. Global clinical trials and the development of clevudine have been terminated.

Combination therapies

The potential advantages of combination therapies are additive or synergistic antiviral effects, and diminished or delayed resistance. The potential disadvantages of combination therapies are added costs, increased toxicity, and drug interactions. To date, none of the combination therapies evaluated have been proven to be superior to monotherapy in inducing a higher rate of sustained response. Although several combination therapies have been shown to reduce the rate of lamivudine resistance compared with lamivudine monotherapy, there are as yet no data to support the suggestion that combination therapies will reduce the rate of resistance to antiviral agents that have a high genetic barrier to resistance such as entecavir or tenofovir.

Standard or pegylated interferon-α and lamivudine

The combination of IFN-α and lamivudine seems logical because monotherapy with each agent is effective, and IFN-α and lamivudine have different mechanisms of action.

1. *Treatment-naïve patients*. Five large trials (one using standard IFN-α and four using pegIFN-α, four in HBeAg-positive patients and one in HBeAg-negative patients) were conducted comparing a combination of IFN-α and lamivudine to lamivudine alone and/or IFN-α alone [273–276,286]. All studies found that combination therapy had greater on-treatment virus suppression but there was no difference in the sustained off-treatment virologic response compared to IFN-α alone. All studies showed that combination therapy resulted in higher rates of sustained off-treatment response compared to lamivudine alone. Although combination therapy was associated with lower rates of lamivudine resistance compared with lamivudine monotherapy, a low rate of lamivudine resistance was encountered compared to none in patients who received IFN-α alone.
2. *Interferon-α nonresponders*. Combination therapy of standard IFN-α and lamivudine is not more effective than lamivudine alone in the retreatment of IFN-α nonresponders [294].

Lamivudine and adefovir

1 *Nucleosid(t)e naïve patients*. One trial included 115 HBeAg-positive patients randomized to receive a combination of lamivudine and adefovir or lamivudine alone. At week 104, serum HBV DNA was undetectable in 26% versus 14%, ALT normalization in 45% versus 34%, and HBeAg seroconversion in 13% vsersus 20% in patients who received combination therapy and lamivudine monotherapy, respectively (*P* was not significant for all responses) [364]. Genotypic resistance was less common in the patients who received combination therapy, 15%, versus 43% in the patients who received lamivudine monotherapy. These data indicate that a combination of lamivudine and adefovir as de novo therapy does not have additive or synergistic antiviral activity and resistance to lamivudine is decreased but not completely prevented.
2 *Patients with lamivudine-resistance.* One small trial in patients with compensated liver disease showed that a combination of adefovir and lamivudine was not superior to adefovir alone in decreasing serum HBV DNA levels [316]. However, hepatitis flares were less frequent during the transition period in the combination therapy group. Several studies showed that adding adefovir is superior to switching to adefovir for patients with lamivudine-resistant HBV [365,366]. Preliminary data suggest that switching to tenofovir monotherapy may be sufficient in suppressing lamivudine-resistant HBV [346], possibly because it has more potent antiviral activity than adefovir, but long-term efficacy needs to be confirmed.

Lamivudine and telbivudine

One trial conducted in nucleoside-naïve HBeAg-positive patients demonstrated that a combination of lamivudine and telbivudine had no advantage over telbivudine alone [367]. In fact, the combination group showed a trend toward an inferior result in all parameters: virus suppression, ALT normalization, HBeAg seroconversion, and mutations in the YMDD motif. These data suggest that lamivudine and telbivudine, both being L-nucleosides, may antagonize each other by competing for the same binding site on the HBV reverse transcriptase.

Immunomodulatory therapy

Nonspecific immunomodulation is largely ineffective in clearing HBV infection.

Thymosin

Thymic-derived peptides can stimulate T-cell function. Thymosin is well tolerated but data on efficacy are conflicting [368–371]. A meta-analysis that included five controlled trials with a total of 353 patients concluded that patients treated with thymosin were significantly more likely than controls to have a virologic response [372]. The maximal rate of response was not seen until 12 months after discontinuing therapy. Thymosin is approved for the treatment of hepatitis B in some countries, mainly in Asia.

Hepatitis B virus-specific immunomodulation

S and pre-S antigen vaccines

Several uncontrolled trials have reported that vaccines with HBV S with or without pre-S antigens used for the prevention of HBV infection were effective in inducing an anti-HBs response and in decreasing serum HBV DNA levels in patients with chronic hepatitis B [373,374]. These data need to be confirmed in controlled clinical trials.

Deoxyribonucleic acid vaccination

Unlike peptide vaccines, vaccination with plasmid DNA that expresses viral proteins in situ can stimulate not only a B-cell but also a T-cell (both helper and cytotoxic) response. In addition, DNA vaccines lead to more prolonged expression of viral proteins [375]. One pilot study reported that DNA vaccination was effective in activating T-cell response and in decreasing serum HBV DNA levels in patients with chronic HBV infection [376].

T-cell vaccines

Patients with chronic HBV infection have been demonstrated to have an impaired cytotoxic T-lymphocyte (CTL) response to HBV antigens, resulting in ineffective virus clearance. One phase II study showed that CTL response can be stimulated in patients with chronic HBV infection who were inoculated with a vaccine that contained an HLA-restricted HBcAg CTL epitope, but the antiviral effect was weak [377].

Recommendations for the treatment of chronic hepatitis B

Current therapy of chronic hepatitis B has limited long-term efficacy. Therefore a, careful balance of patient's age, severity of liver disease, likelihood of response, and potential adverse events is needed before treatment is initiated. Guidelines and recommendations for treatment have been developed by professional societies and at an National Institutes of Health Consensus Conference [378–381]. Table 24.6 summarizes current recommendations on whom to treat and when to start treatment. Because of the fluctuating nature of chronic HBV infection, the risk of liver-related morbidity and mortality and the likelihood of response may vary as a patient progresses through the course of chronic HBV infection. Therefore, continued monitoring is essential for risk assesment.

Table 24.6 Recommended strategies for patients with chronic hepatitis B.

HBeAg	HBV DNA (IU/mL)	ALT[a]	Recommended strategy
+	>20,000	≤2 × ULN	Monitor ALT and HBV DNA levels every 3–6 months Consider biopsy in persons >40 years, ALT 1–2 x ULN, or with family history of HCC Consider treatment if biopsy shows moderate inflammation or advanced fibrosis
+	>20,000	>2 × ULN	Observe for 3–6 months, treat if no spontaneous HBeAg loss Immediate treatment if jaundice or clinical decompensation Duration of treatment: pegIFN, 48 weeks; NUC, until 12 months after HBeAg seroconversion
–	<2,000 2,000–20,000	≤ ULN 1 to >2x ULN	Monitor ALT and HBV DNA every 3–6 months for 1 year, then every 6–12 months Consider biopsy in persons >40 years, ALT > ULN, or with family history of HCC Consider treatment if biopsy shows moderate inflammation or advanced fibrosis
–	>20,000	> ULN	Initiate treatment Duration of treatment: pegIFN, 48 weeks; NUC, until HBsAg loss
+/–		Compensated cirrhosis	HBV DNA <2,000: initiate treatment if ALT elevated HBV DNA >2,000: initiate treatment regardless of ALT Duration of treatment: indefinite or until HBsAg loss
+/–		Decompensated cirrhosis	Refer for liver transplant HBV DNA detectable: initiate treatment regardless of HBV DNA/ALT level

ALT, alanine aminotransferase; HBeAg, hepatitis B e antigen; HBV, hepatitis B virus; HCC, hepatocellular carcinoma; NUC, nucleos(t)ide analog; pegIFN, pegylated interferon; ULN, upper limit of normal.
Adapted from Lok and McMahon [40].

In choosing which antiviral agent to use as initial therapy, consideration should be given to the safety and efficacy of the treatment, duration of treatment needed to achieve the desired response, risks of drug resistance, costs of the treatment, as well as patient preference, and for women – when and whether they plan to start a family. IFN-α is contraindicated in patients with acute liver failure, decompensated cirrhosis, or severe exacerbation of chronic hepatitis B and in patients with medical or psychiatric conditions that may be exacerbated by IFN-α. Other patients may be treated with either IFN-α or NUCs. The advantages of IFN-α treatment include a finite duration of treatment, higher rates of HBeAg and HBsAg loss, and lack of drug resistance, while the disadvantage is the frequent occurrence of adverse events. PegIFN-α is administered for 48 weeks in both HBeAg-positive and HBeAg-negative patients. The advantages of NUCs is the ease of administration and the rare occurrence of adverse events, allowing them to be used in patients with decompensated cirrhosis, severe exacerbations of chronic hepatitis B, or acute liver failure. The disadvantages of NUCs include the risk of drug resistance and the need for long durations of treatment. NUCs are administered indefinitely in patients with cirrhosis. In precirrhotic patients, NUCs are administered until 12 months after HBeAg seroconversion in HBeAg-positive patients and indefinitely or until HBsAg loss in HBeAg-negative patients. Among the approved NUCs, tenofovir and entecavir are preferred because of their potency and high genetic barrier to resistance (low resistance rate).

Patients who failed to respond to IFN may be retreated with NUCs. Patients who failed with NUCs should be tested for antiviral drug resistance mutations, particularly if the patient failed with more than one NUC, to confirm that treatment failure is related to genotypic resistance and to guide selection of rescue therapy. Virologic breakthrough defined as >1 log increase in serum HBV DNA from nadir or redetection of HBV DNA in serum after its initial disappearance, is the first manifestation of antiviral drug resistance and may precede biochemical breakthrough (elevation of ALT after initial normalization) by months to years. Genotypic resistance is defined as the detection of signature antiviral resistance mutations. Rescue therapy should be initiated early, once virologic breakthrough or genotypic resistance is confirmed. Rescue therapy is less effective if treatment is initiated when serum HBV DNA levels are high and compensatory mutations have been selected. Table 24.7 lists the options for rescue therapy.

Table 24.7 Rescue therapy options for antiviral-resistant hepatitis B virus.

Type of resistance	Preferred rescue therapy	Other options
Lamivudine or telbivudine resistance	Tenofovir – add or switch	Add adefovir Switch to tenofovir + emtricitabine
Adefovir	Entecavir – add or switch	Switch to tenofovir + emtricitabine Add lamivudine or telbivudine (if no prior resistance to these two drugs)
Entecavir	Tenofovir – add or switch	Add adefovir

Hepatitis D

Hepatitis D is caused by a defective virus: the hepatitis D virus. Although HDV is often referred to as hepatitis delta virus, the term hepatitis D virus is preferred. HDV can replicate autonomously [382] but the simultaneous presence of HBV is required for complete virion assembly and secretion.

Hepatitis D virus structure and replication

The HDV virion comprises an RNA genome, a single HDV encoded antigen, and a lipoprotein envelope provided by HBV and consisting of the same proteins found in the envelope of the HBV virion. The HDV genome is a small single-stranded circular RNA (1676–1683 nucleotides in size) with structural analogies to plant viroids and a high degree of self-complementarity causing the molecule to collapse into a rod-like structure [383]. Significant sequence heterogeneity exists among HDV isolates and a classification into eight clades has been proposed [384]. The only antigen associated with HDV, the hepatitis D antigen (HDAg), is a structural component of the virion: about 70 molecules of HDAg are complexed with the HDV RNA genome to form a ribonucleoprotein structure (Fig. 24.5) [385]. Hepatocytes are the only host cells where HDV replicates at very high levels [386]. HDV replicates via transcription into a full-length complementary RNA (antigenomic HDV RNA) [383]. HDV virion assembly and release is dependent on the simultaneous presence of HBV, which provides the envelope proteins.

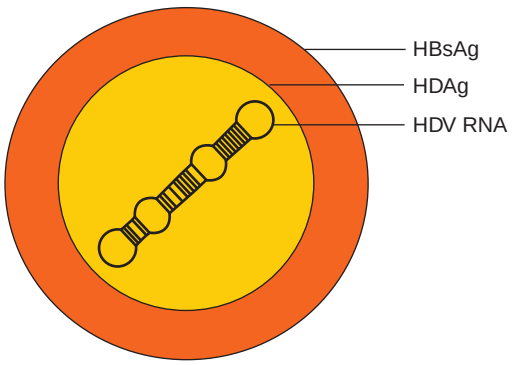

Figure 24.5 Schematic representation of the hepatitis D virus (HDV) virion with extensive intramolecular base pairing of the HDV RNA genome. HBsAg, hepatitis B surface antigen; HDAg, hepatitis D antigen.

Patterns of hepatitis D virus infection

Due to its dependence upon HBV, HDV infection always occurs in association with HBV infection. The clinical and laboratory findings vary with the type of infection. *Coinfection of HBV and HDV* in an individual susceptible to HBV infection results in an acute hepatitis clinically indistinguishable from classic acute hepatitis B and is usually self-limited, although a fulminant course has been frequently reported among injection drug users [387]. The rate of progression to chronic infection is similar to that observed after HBV monoinfection [388]. *HDV superinfection* of a chronic HBsAg carrier may present as a severe acute hepatitis in a HBV carrier, or as an exacerbation of preexisting chronic hepatitis B. Progression to persistent HDV infection is typical [389].

Epidemiology

Data on HDV epidemiology have mostly been gathered in HBV carriers superinfected with HDV. It was estimated that approximately 5% of the HBV carriers worldwide may be infected with HDV [390]. However, substantial changes in HDV epidemiology have occurred in the past decades. Improvements in socioeconomic conditions, an increased awareness of the risk of transmitting infectious diseases fostered by AIDS prevention policy, and aggressive vaccination campaigns against HBV have all contributed to a dramatic decrease in the incidence of HBV infection and the spread of HDV infection [391–394]. HDV prevalence, however, stopped decreasing at the end of the 1990s, at least in Europe, where it has remained mostly stable [395]. This is partly due to an increased immigration from endemic regions (such as eastern Europe or the Middle East), although intravenous drug use, high-risk sexual practices, and body modification procedures may also play a role. In general, although HDV infection is dependent on HBV infection, the geographic distribution of HDV infection does not parallel

that of HBV, as areas endemic for HBV may be almost HDV-free. The level of HDV endemicity is only partially related to the route of transmission. Sexual transmission of HDV is less frequent than in the case of HBV infection, especially among male homosexuals [396].

Diagnosis

Hepatitis D antigen elicits a specific immune response consisting of antibodies of the IgM and IgG class (anti-HDV). In HDV-infected individuals, the timing of appearance and level of HDV RNA, HDAg, and anti-HDV in serum, together with the pattern of HBV markers, allow three HDV-related clinical entities to be identified: acute HBV/HDV coinfection, acute HDV superinfection of a chronic HBV carrier, and chronic HDV infection (Table 24.8). Due to the dependence of HDV on HBV, the presence of HBsAg is necessary for the diagnosis of HDV infection. The additional presence of IgM antibody to hepatitis B core antigen (IgM anti-HBc) is necessary for the diagnosis of acute HBV/HDV coinfection.

In acute HDV infection, serum HDAg appears early and is short-lived and may escape detection [397]. Total anti-HDV antibody appears late in acute infection, and repeated testing is recommended since anti-HDV seroconversion may be the only way to diagnose acute HDV infection in the absence of other markers of HDV infection [397,398]. Anti-HDV of the IgM class is transient and delayed if the course of acute hepatitis D is self-limited, but is of high titer and long-lasting if HDV infection progresses to chronicity. Although it may be the only serum marker of acute HDV infection [397], anti-HDV IgM lacks specificity since it is usually found at high titers in chronic hepatitis D. As discussed above, differentiation between HBV/HDV coinfection and HDV superinfection in an HBV carrier depends on the detection of high-titer IgM anti-HBc, found only in patients with coinfection.

The development of anti-HDV hampers the detection of HDAg further along the course of infection, due to the formation of immune complexes. The most sensitive way to diagnose active HDV infection is the detection of HDV RNA in serum by reverse transcriptase-polymerase chain reaction (RT-PCR) [399,400]. HDV RNA is an early and sensitive marker of HDV replication in acute hepatitis D [401] and confirms infection in chronic hepatitis D. Furthermore, quantitative determination of HDV RNA is the test of choice for measuring HDV replication in patients undergoing antiviral treatment [402]. Although the detection of intrahepatic HDAg by immunohistochemistry was formerly proposed as the gold standard for the diagnosis of ongoing HDV infection [403], the detection of HDV RNA in serum by RT-PCR is more sensitive, especially during late stages of the disease.

In summary, HDV coinfection should be suspected in patients with acute hepatitis B at high risk of blood-borne infection, such as in intravenous drug users, in persons from HDV endemic countries, or in those presenting a severe course. Coinfected patients have high-titer IgM anti-HBc. Markers of HBV replication may precede or follow those of HDV. Occasionally, patients may have already seroconverted to anti-HBs, e.g., at the time of the second phase of a biphasic hepatitis. These patients should still be positive for IgM anti-HBc. Serum HDV RNA is usually positive at presentation, but if this assay is not available total anti-HDV should be repeatedly tested to document seroconversion.

In acute hepatitis of undetermined origin in an HBV carrier, tests for HDV should be considered to rule out HDV superinfection. Since HDV superinfection may occur in previously unrecognized HBV carriers, distinguishing between this condition and acute HBV/HDV coinfection may be difficult.

Testing for HDV should also be carried out in patients with chronic hepatitis B, who live or have lived in HDV endemic countries or who are at high risk of HDV infection, to rule out simultaneous chronic HDV infection. This is best achieved by screening for total anti-HDV antibody and then confirmed by staining for HDAg in liver tissues and/or measurement of serum HDV RNA. In chronic HDV infection, HBV replication is usually suppressed, and patients are typically anti-HBe-positive.

Table 24.8 Diagnosis of hepatitis D virus (HDV) infection.

	Acute HDV/HBV coinfection	HDV superinfection of HBV carrier	Chronic HDV infection
HDAg	Early and short-lived	Early, but soon masked by anti-HDV	Undetectable (masked by antibodies)
Anti-HDV, IgM	Transient and delayed	High titer and long-lasting	High titer
Anti-HDV, IgG	Late, increasing titers	Late, increasing titers	High titer
HDV RNA	Early and sensitive marker	Early and sensitive marker	Usually high level
IgM anti-HBc	Positive	Negative	Negative

anti-HBc, hepatitis B core antibody; HBV, hepatitis B virus; HDAg, hepatitis D antigen; IgG, immunoglobulin G; IgM, immunoglobulin M.

Pathogenesis and natural history

The mechanisms by which HDV induces liver damage (referred to as hepatitis D) are unknown, but are largely thought to be due to the host immune response [383].

The clinical sequelae of HDV infection encompass a spectrum of manifestations from fulminant liver failure to an asymptomatic carrier state. In general, HDV superinfection has been associated with an accelerated progression of liver disease, with an increased risk of HCC [404].

Overall, the degree of expression of HDV-related liver disease depends on the interplay of HDV-associated (such as HDV genotype), host-associated (such as immune response), and helper virus-associated (such as HBV genotype and replication level) factors. The HDV genotype seems important since infection with genotype 3, which is predominant in South America, induces a particularly severe acute hepatitis with high risk of liver failure [405]. On the other hand, genotype 2, which prevails in the Far East, is infrequently associated with a fulminant course; likewise, chronic hepatitis D with this genotype seems less progressive [406]. The HBV genotype has been shown to affect HDV RNA levels and to correlate with outcome [407,408]. Finally, high levels of HBV replication are associated with more severe liver damage in persons coinfected with HDV [409].

Treatment

The primary endpoint of treatment is the suppression of HDV replication, which is accompanied by normalization of ALT level and amelioration of hepatic necroinflammatory activity. Undetectable HDV RNA in serum and HDAg in the liver document the suppression of HDV replication. A secondary, albeit rarely observed, endpoint is the eradication of HBV infection, with HBsAg to anti-HBs seroconversion.

The only drug effective in the treatment of chronic hepatitis D is IFN-α. The mechanism of action of IFN-α in hepatitis D is unclear. In vitro studies showed that IFN-α does not have antiviral activity against HDV [410,411]. HDV directly interferes with the early steps of the IFN-α signaling pathway [412]. Thus, the efficacy of IFN-α in patients with chronic hepatitis D may depend on its antiviral activity on HBV or on immune modulatory effects. The total number of chronic hepatitis D patients who have been treated with IFN-α (both standard and pegylated) and reported in the literature is small. Thus, it is difficult to draw firm conclusions on the efficacy, optimal dose regimen, and factors predictive of response to IFN-α.

In early clinical trials using standard IFN-α, the results were rather disappointing. In a large multicenter study, 61 Italian patients with chronic hepatitis D were randomly assigned to receive IFN-α in doses of 5 MU/m^2 body surface area three times a week (t.i.w.) for 4 months, followed by 3 MU/m^2 t.i.w. for an additional 8 months, or placebo [413]. At the end of follow-up, the proportion of patients with undetectable HDV RNA was similar in the two groups (45% versus 33%). Likewise, liver histology also improved with similar frequency in the two groups (57% versus 36%; *P*, not significant). In another study, 42 patients with chronic hepatitis D were randomly assigned to receive two different doses (9 MU versus 3 MU t.i.w.) of IFN-α for 48 weeks or placebo [414]. Complete response (normal ALT level and undetectable serum HDV RNA at the end of treatment) was more frequent in the 9 MU group (50%, 21%, and 0% in the three arms, respectively). Treatment with 9 MU doses of IFN-α was associated with a marked improvement in liver histology. However, none of the patients had sustained clearance of HDV RNA. A follow-up report found that ALT normalization correlated with improved hepatic function [415]. Compared to treatment with low-dose IFN-α or placebo, those who received high dose IFN-α were more likely to have a sustained decrease in serum HDV RNA levels, and some patients had HDV clearance. Patients in the high-dose group were also more likely to have improvement in histologic activity and fibrosis and survival.

More recent work has evaluated the efficacy of pegIFN-α. Response rates seem more encouraging in comparison with standard IFN-α. One study found that some nonresponders to standard IFN-α cleared HDV RNA when retreated with a 6-month course of pegIFN-α [416]. Nonetheless, pegIFN-α is still insufficient to cure most chronic hepatitis D patients. In a prospective trial from Italy, 38 patients received 48 weeks of pegIFN-α2b (1.5 μg/kg/week) with or without ribavirin, followed by another 24 weeks of pegIFN-α alone. At the end of follow-up, only 21% of patients had undetectable HDV RNA and 26% had a biochemical response [417]. In a small trial from France, a sustained virologic response was achieved in six of 14 patients (43%) treated for 12 months with pegIFN-α2b (1.5 μg/kg/week) [402]. Another small study from Germany showed a sustained virologic response in merely two of 12 patients (17%) [418]. This work suggested also a treatment futility rule for patients with a less than 3 log decrease of serum HDV RNA after 6 months of treatment. A negative pretreatment predictor of response seems to be the presence of cirrhosis. A recent large trial compared 32 patients who received pegIFN-α2a plus adefovir, 29 patients who received pegIFN-α2a plus placebo, and 30 patients who received adefovir alone for 48 weeks [419]. At week 48, HDV RNA was undetectable in 23%, 24%, and 0%, in these three groups, respectively. The efficacy of pegIFN was sustained for 24 weeks after treatment; HDV RNA was undetectable in 28% of patients who received pegIFN

with or without adefovir and none of those who received adefovir alone.

These data confirmed the efficacy of pegIFN in suppressing HDV replication. NUCs active against HBV replication have no effect on HDV replication and do not have additive effects when combined with pegIFN [419, 420,421].

Prevention

The mainstay of prevention of HDV infection is vaccination against its helper virus, HBV. Anti-HBs-positive chimpanzees have been successfully vaccinated against experimental HDV infection [422]. However, passive prophylaxis with HBIg has not completely prevented reinfection of transplanted livers by HDV.

CHAPTER 25

Hepatitis C

Jama M. Darling, Stanley M. Lemon, & Michael W. Fried

UNC Liver Center, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Key concepts

- Hepatitis C infection is a leading cause of morbidity and mortality with a global prevalence of approximately 3%.
- Diagnosis of chronic hepatitis C relies on establishing the presence of risk factors or evidence of liver disease and testing patients with sensitive and specific serologic and virologic assays.
- Hepatitis C virus (HCV) is a single-stranded RNA virus with one open reading frame that encodes a large polyprotein. Viral proteases are required for protein processing and viral replication. Replication can be profoundly inhibited by drugs that target these enzymes, which is the rational for the newest generation of HCV therapeutics.
- Hepatitis C is a heterogeneous virus with multiple genotypes that have important implications for therapeutic response.
- Pegylated interferon (pegIFN) and ribavirin achieve sustained virologic response in 45–80% of patients, depending upon genotype.
- Response-guided therapy utilizes the change in hepatitis C viremia during treatment to modify the treatment course or the choice of therapeutic regimens.
- Small molecules, such as protease inhibitors, combined with pegIFN and ribavirin will further enhance treatment response and minimize the emergence of viral resistance. Additional side effects may occur in these triple therapy combinations.

A discovery that changed the practice of hepatology

When sensitive serologic tests for hepatitis A virus (HAV) and hepatitis B virus (HBV) infection became available in the mid-1970s, it became clear that most cases of post-transfusion hepatitis could not be attributed to either virus [1,2]. This led to the description of a new disease entity termed "non-A, non-B" (NANB) hepatitis, and prompted a fierce search for a new, previously unrecognized hepatitis virus. Post-transfusion and community-acquired NANB hepatitis were increasingly recognized as potential causes of cirrhosis and hepatocellular carcinoma [3,4]. An early breakthrough in identifying the virus came with the demonstration that chimpanzees (*Pan troglodytes*) were susceptible to NANB infection when inoculated with blood products from affected patients [5,6]. This proved that the disease was due to an infectious agent, which was then shown to be susceptible to lipid solvents and capable of passing though a 50–80 nm filter, and thus likely to be a small, enveloped virus [7,8]. The responsible agent, hepatitis C (HCV), was subsequently identified by a group of scientists led by Michael Houghton, who screened a λ-phage complementary DNA (cDNA) expression library derived from chimpanzee material for reactivity with serum antibodies from patients with chronic NANB hepatitis [9,10]. Antigen expressed by a single molecular clone, 5-1-1, was recognized only by serum antibodies from patients with well-documented NANB hepatitis, setting the stage for all future work on HCV [11]. Arguably, the discovery of HCV was the most important discovery in modern hepatology, leading to an explosion of research in the virology, epidemiology, and therapeutics of this disease, which is now curable in many patients.

Hepatitis C virus virology

Classification and genome organization

Hepatitis C virus is classified in the genus *Hepacivirus* of the family Flaviviridae. It is an enveloped, hepatotropic virus with a positive-sense, single-stranded RNA genome about 9.6 kb in length (for a detailed review, see [12]). The genome is organized to include untranslated RNA segments (UTRs) at both ends and a single large open reading frame encoding a giant 327 kD polyprotein that is processed by cellular and virally encoded proteases into ten

mature viral proteins (Fig. 25.1). The viral RNA lacks the 5′ methylated cap structure typical of cellular mRNAs, and contains a highly conserved internal ribosomal entry site (IRES) within the 5′ UTR that directs cap-independent initiation of translation. There are six well-defined genotypes of HCV, which differ in nucleotide sequence at ~30% of base positions [13].

Untranslated RNA segments

The 5′ and 3′ UTRs are highly conserved in sequence and adopt conserved secondary and tertiary RNA folds that recruit cellular and viral factors required for translation of the polyprotein and replication of the RNA [12,14]. Phylogenetic, biochemical, and mutational analyses suggest that the 342 nucleotide-long 5′ UTR is comprised of four distinct structural domains, designated stem loops I–IV [15,16]. The 5′ 125 nucleotides constitute domains I and II, which are essential for RNA replication [17]. Within this region of the RNA, between stem loops I and II, are two sites that bind the cellular microRNA, miR-122, an interaction that is critically important for viral translation and genome amplification [18,19]. Downstream, the IRES is formed by nucleotides 45–342 (domains II–IV), and thus partially overlaps the RNA replication signals at the extreme 5′ terminus of the genome. Its folded structure has high affinity for the 40S ribosomal subunit, and directs the cap-independent assembly of a 48S ribosomal complex on the viral RNA [20,21]. The IRES also binds eukaryotic initiation factor, eIF-3, and initiates translation without a requirement for other canonical cellular transcriptional factors [20,21].

The 3′ UTR is 200–235 nucleotides in length and consists of three distinct regions: a variable region, a poly-U/UC tract, and an absolutely conserved 98 nucleotide-long "3′ X" region [22]. The 3′ X region folds into conserved stem-loop structures that are involved in RNA–RNA and RNA–protein interactions essential for efficient replication of the viral RNA [23,24].

Structural proteins

The amino terminus of the polyprotein is proteolytically processed by the endoplasmic reticulum (ER) resident signal peptidase to produce a series of structural proteins that are components of the infectious virus particle (Fig. 25.1). These include the ~23 kD, 191-amino-acid-residue-long core protein [25], which is further processed by another cellular membrane-resident protease, signal peptide peptidase, removing the C-terminal signal sequence to yield the ~21 kD mature core protein [26–29].

The core protein has been implicated in a variety of interactions with a wide array of host cell proteins, leading potentially to pleiotropic effects on the cell [30]. Important host factors that putatively interact with the core protein include those involved in cell signaling, transcription, apoptosis, lipid metabolism, immunomodulation, oxidative stress, cell cycle regulation, and carcinogenesis (reviewed in [30–33]).

The HCV genome encodes for two envelope glycoproteins, E1 and E2, which are processed from the polyprotein by cellular signal peptidase. Both the glycoproteins are embedded in the viral envelope, which is derived from host membranes, as noncovalent heterodimers [34] due to charged residues within the transmembrane domains [35]. They appear to interact with the core protein, as well as NS2 (see below). The E2 glycoprotein plays a major role in viral entry as it binds to the HCV co-receptor CD81, a member of the tetraspanin family of proteins that is central to HCV entry and that is expressed on the surface of the hepatocytes, and scavenger receptor B1 (SR-B1) [36–38].

Nonstructural proteins

Downstream of the envelope proteins within the polyprotein are p7 and NS2 (see Fig. 25.1). p7 is a viroporin, a membrane-embedded ion channel that prevents the acidification of intracellular vessicles [39]. p7 is essential for HCV infectivity in the chimpanzee model [40] and plays a

crucial role in the assembly and release of infectious virions from infected cells by protecting nascent viral particles from an acidic environment [39,41].

NS2 plays a dual role in viral replication, contributing both to processing of the polyprotein and assembly of the viral particle. It is a membrane-bound protein that is cleaved from the polyprotein at its N-terminus by signal peptidase [42]. Its C-terminus is processed by an autocatalytic proteinase activity residing in the C-terminal domain of NS2 and the N-terminal domain of NS3 [43–45]. The NS2-3 protease is an unusual enzyme as it is a dimeric structure with two composite active sites, in which the active site residues within each site are derived from both members of the dimer [46]. Thus two copies of the polyprotein must be expressed and capable of interacting with each other prior to processing beyond the NS2–3 junction. Although NS2 is not required for viral RNA synthesis and genome amplification [47], recent data suggest that NS2, but not its protease activity, plays a crucial role in viral assembly [48–50]. It acts as a scaffold, bridging the envelope proteins to NS5A and other nonstructural proteins in an early step in particle assembly, and also participates in a late stage of virus assembly that confers and/or enhances infectivity [51,52].

The nonstructural proteins NS3–5B are both necessary and sufficient for robust replication of the genome in cultured hepatoma cells [47]. All of these proteins are associated with intracellular membranes, and serve as components of the membrane-bound replicase complex (sometimes referred to as the "membranous web") that is responsible for viral RNA synthesis. Most if not all of these proteins are multifunctional, a common attribute of small RNA viruses such as HCV that have limited genetic coding capacity. The NS3 protein contains two distinct, independently folding structural domains, an amino terminal serine protease, and a carboxy terminal helicase [53]. The protease comprises the first 180 amino acids of the protein.

The chymotrypsin-like NS3/4A serine protease [54] is the major protease activity expressed by HCV. It is responsible for cleavage at the NS3–4A junction and other sites downstream within the polyprotein, thereby generating the remaining nonstructural proteins: NS4A, NS4B, NS5A, and NS5B (see Fig. 25.1) [55]. It also cleaves at least two cellular proteins – mitochondrial antiviral signaling protein (MAVS, also known as IPS-1, Cardif, or VISA) [56] and Toll-like receptor (TLR)/interleukin 1 (IL1) receptor domain-containing adaptor-inducing interferon-β (TRIF, otherwise known as TICAM-1) [56–58] – both of which are signaling adaptor proteins involved in the induction of interferon synthesis in virus-infected cells [59].

The carboxy terminal two thirds of NS3 is a superfamily-2 helicase with nucleoside triphosphatase (NTPase), RNA translocase, and unwindase activity [60]. It is indispensable for viral replication [61,62]. The NS3 helicase domain plays a central role during an early step in virion assembly [63–65].

NS4A is a cofactor for the NS3 serine protease, as described above. Since it is a membrane-bound protein, it is likely to mediate the membrane association of NS3 [66]. NS4B is an integral membrane protein that induces formation of the "membranous web" [67,68], the probable site of HCV RNA replication within cells [69]. It contains a guanosine triphosphatase (GTPase) activity and associates with the early endosome Rab5 protein [70,71].

The NS5A protein is unique, with no known human or viral homologs other than NS5A in the closely related GB virus B (GBV-B). It appears to have multiple functions in the virus life cycle and to interact with numerous viral and host proteins [72], but it is poorly understood at a mechanistic level. It is a phosphoprotein [73–75], and the phosphorylation status of NS5A may regulate various aspects of genome replication and virus assembly [76,77]. NS5A possesses three distinct domains, which are separated by segments of the protein that are relatively disordered. The N-terminal domain (domain I) contains a zinc-binding motif, and is essential for viral RNA replication [78]. The middle domain of NS5A is involved in antagonizing innate immune responses, while the C-terminal domain III of NS5A is poorly conserved between different viral genotypes and has been considered to be relatively unstructured [79]. NS5A appears to play an important role in the assembly of infectious particles, as it interacts with NS2 and is also recruited to the surface of cytoplasmic lipid droplets decorated with the viral core protein [52,80,81]. NS5A, in association with NS2, is also likely to act at a later step in virus production, following intracellular particle assembly but prior to the release of infectious virus [51].

NS5B, the viral RNA-dependent RNA polymerase (RdRp), is the catalytic core of the replicase complex that directs the synthesis of new RNA genomes. It is anchored to cellular membranes via its carboxy terminal hydrophobic tail [82]. Although NS5B can catalyze both primer-independent and primer-dependent RNA synthesis in vitro, the available evidence supports primer-independent, de novo RNA synthesis regulated by a conformational change in the polymerase [83–85]. Like all RdRps, NS5B lacks proofreading capability, and has a relatively high rate of base mis-incorporation. The error-prone nature of HCV RNA synthesis, coupled with selective immune pressure, generates extensive sequence diversity and quasispecies heterogeneity [86].

Replication cycle

It is not possible to culture wild-type strains of HCV efficiently in cell culture, and this has impeded the elucidation of the viral life cycle. However, much has been

learned from the development of RNA replicons, in which the segment of the HCV genome encoding the core NS2 proteins is replaced by a sequence encoding a selectable marker (for example, neomycin phosphotransferase) and translation of the downstream nonstructural proteins (NS3–5B) is initiated by a heterologous, picornaviral IRES [47]. These RNAs replicate efficiently in Huh7 human hepatoma cells, and appear to do so by a process that is similar if not identical to RNA replication in HCV-infected cells. Some replicons have been engineered to express the entire viral polyprotein, or easily quantifiable reporter enzymes such as firefly luciferase. Beginning about 2005, however, it became possible to generate infectious virus and study the entire virus life cycle in cell culture using an unusual genotype 2a cDNA clone. This clone was isolated from a Japanese patient with a rare case of fulminant hepatitis C, designated as JFH-1 (Japanese fulminant hepatitis 1) [87,88]. The JFH-1 clone has been used as the backbone for a number of chimeric viral RNAs that are also capable of producing infectious virus when transfected into Huh7 cells [50,89, 90]. A highly cell-culture-adapted genotype 1a genome containing five adaptive mutations (H77S) has also been shown to produce virus when transfected into Huh7 cells, but does so with less efficiency than JFH-1 RNA [91,92]. Virus produced in vitro by transfection of either JFH-1 or H77S RNA is infectious for the chimpanzee.

Viral entry into the hepatocyte is a complex process that is initiated by interactions of the envelope glycoproteins with glycosaminoglycans on the cell surface [93–95]. This is followed by specific receptor interactions leading to clathrin-mediated endocytosis [96], and delivery of the viral RNA to the cytoplasm via an organized, stepwise process [36,97,98]. Early steps in this process include the engagement of the CD81 and SR-B1 co-receptors, both of which have been shown to bind to the E2 glycoprotein and to mediate infectious virus entry [99]. Subsequent steps in entry involve cellular proteins associated with tight junctions – claudin-1 [100] and occludin [101] – but it is not clear that these proteins engage in direct interactions with the viral envelope.

Following entry and uncoating of the viral genome [102], the IRES directs initiation of polyprotein translation. This, like all subsequent steps in the life cycle, occurs within the cytoplasm. The nascent polyprotein is co-translationally processed by cellular and viral proteases, as described above, giving rise to the seven nonstructural and four structural viral proteins described in the preceding section. These proteins are involved in the formation of membrane-associated replication complexes, and the assembly of new viral particles [12]. As with other positive-strand RNA viruses, replication proceeds in an asymmetric fashion with a single copy of negative-strand RNA producing multiple copies of positive-strand genomes, leading to a 10–100-fold excess of positive- over negative-strand molecules. Importantly, only a small proportion of the nonstructural proteins produced by the virus appear to be engaged in this process of RNA synthesis [103]. Finally, newly synthesized viral genomes and structural proteins (core, E1, and E2) are assembled as virions, in a process that is facilitated by multiple nonstructural proteins, as described above, in association with lipid droplets. Mature viral particles appear to be released from infected cells via an unusual mechanism that usurps some components of the very low density lipoprotein (VLDL) secretory pathway [104,105]. This may account for the very low density of mature virions [106] and their association with host ApoE lipoprotein [107–109].

Innate immune response to HCV

Most persons with acute HCV infection fail to clear the virus and progress to chronic hepatitis C (reviewed in [59]). Virus-specific T-cell immunity is important in determining the infection outcome. While the mechanisms that underlie the failure of adaptive T-cell responses to clear infection remain undefined, there is growing evidence that early innate cytokine and chemokine responses play a fundamental role in shaping later adaptive immunity, and that these early responses to virus infections are critical to successful antigen-specific B- and T-cell immunity [110–113]. There has thus been increasing interest in how HCV infection is sensed by the innate immune system in the liver, and how the virus may have evolved to overcome these early host responses, including the antiviral effects of interferon (IFN). Current evidence suggests that HCV disrupts IFN responses at three levels: (i) the induction of IFN synthesis following sensing of the infection by retinoic acid-inducible gene I (RIG-I) and Toll-like receptor 3 (TLR3), pathogen-associated molecular pattern (PAMP) receptors that recognize double-stranded viral RNA (dsRNA) in cytosolic and extracellular compartments, respectively; (ii) IFN-induced signaling through the Janus kinase and signal transducer and activator of transcription (Jak-STAT) pathway following binding of type I IFNs to their receptor; and (iii) the effector function of some interferon-stimulated genes (ISGs), such as protein kinase R (PKR) (reviewed in [59]).

Innate immune sensing of hepatitis C virus infection

Interferon regulatory factor 3 (IRF-3) is a highly regulated transcription factor constitutively expressed in the cytoplasm in a latent, inactive form. It plays a key role in the induction of IFN synthesis [114]. Infections with RNA viruses such as HCV are associated with the

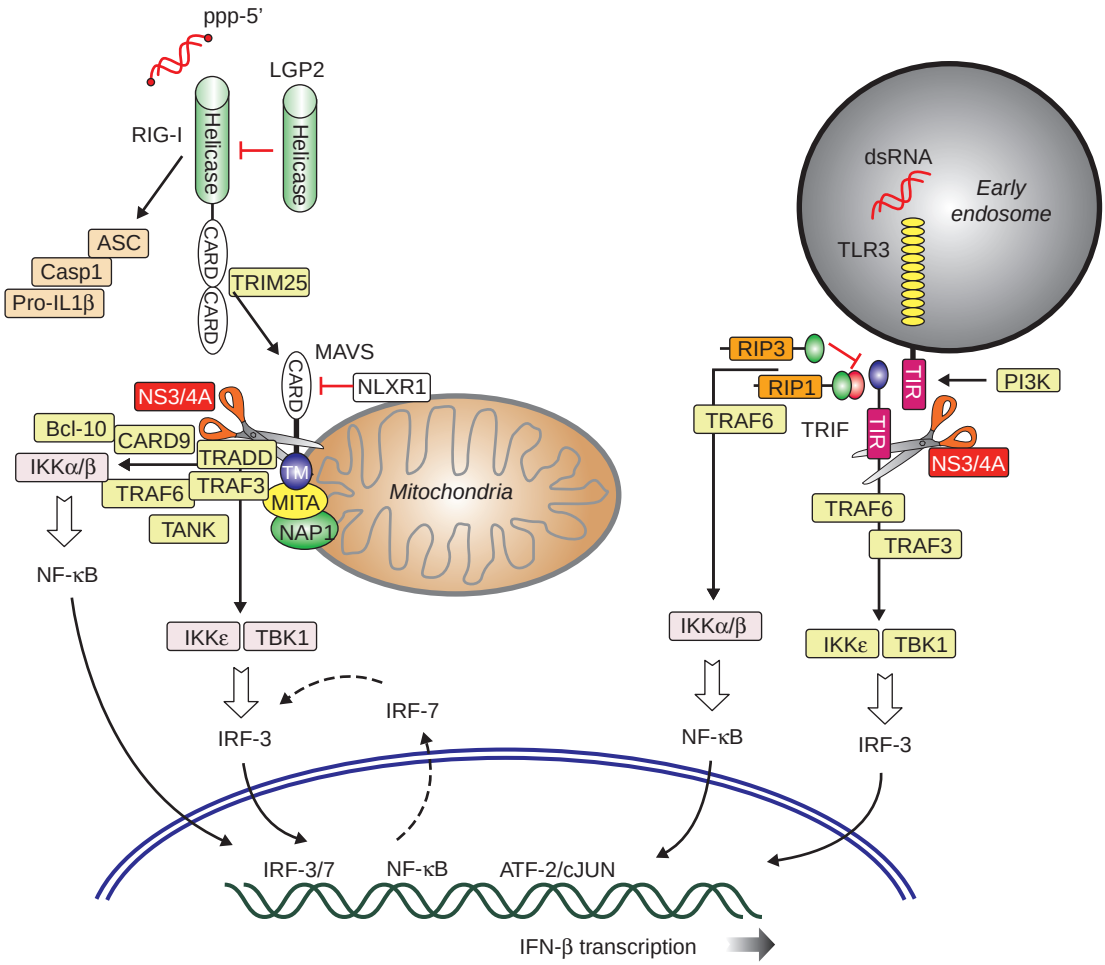

Figure 25.2 Retinoic acid-inducible gene I (RIG-I) and Toll-like receptor 3 (TLR3) sensing of viral RNAs. IFN, interferon; IRF, interferon regulatory factor; MAVS, mitochondrial antiviral signaling; NF-κB, nuclear factor κB; TRIF, TLR/IL-1 receptor domain-containing adaptor-inducing interferon-β. (Reproduced from Lemon [59] with permission from American Society for Biochemistry and Molecular Biology.)

production of dsRNA, an essential replication intermediate. This RNA is distinct from cellular RNAs and is sensed by and activates signaling pathways leading to C-terminal phosphorylation of IRF-3. This results in the dimerization and nuclear transport of IRF-3, where in coordination with nuclear factor κB (NF-κB) and activating transcription factor 2 (ATF-2)/c-Jun, it activates the IFN-β promoter, leading to the synthesis of type I IFN-α/β [115]. IRF-3 can be activated through several distinct signaling pathways initiated by different sensors (Fig. 25.2). RIG-I, a DExD helicase family member, senses HCV RNA in the cytosol [116–118]. TLR3, which is expressed in an early endosomal compartment, senses HCV dsRNA in a luminal compartment [119]. Both pathways culminate in IRF-3 activation and type I IFN synthesis, and, when activated, both partially restrict HCV replication [116,119]. A third, potentially important, sensor is TLR7, which signals through the related IRF, IRF-7. Little is known about its role in the induction of IFN responses to HCV in the liver, but recent studies suggest its potential importance [120]. Although they act to some extent redundantly, these sensors differ in terms of: (i) the PAMPs they sense; (ii) the cell types in which they are expressed; and (iii) the adaptor proteins they utilize and signaling pathways they activate (reviewed in [59]).

RIG-I signaling

RIG-I (DDX58) is a DExD-box helicase expressed within the cytoplasm of hepatocytes. It senses short non-self double-stranded (ds) and single-stranded (ss) RNAs with free 5′ triphosphates [121–123]. Once engaged by its RNA ligand, RIG-I undergoes a conformational change [124], promoting its self-association as well as interactions with its adaptor protein, MAVS, through shared caspase recruitment domains (CARDs) [57,125,126]. This leads to the assembly of a signaling complex on the mitochondrial surface, where MAVS is located, that activates downstream noncanonical kinases of the IkappaB kinase

(IKK) complex that in turn direct the phosphorylation of IRF-3 [127]. A large number of other signaling partners participate in the formation of this complex, which is both positively and negatively regulated (reviewed in [59]). RIG-I has been shown to sense HCV infection in Huh7 hepatoma cells, leading to transient nuclear translocation of IRF-3 and activation of the IFN-β promoter [128]. Injection of large amounts of synthetic HCV RNA into the tail vein of mice delivers the RNA directly to the liver, resulting in activation of RIG-I signaling [117]. Studies using this system suggest that a conserved poly-(U/C) sequence within the 3′ UTR of HCV is a PAMP that is specifically recognized by RIG-I.

NS3/4A, the major protease expressed by HCV, inhibits activation of the IFN-β promoter in cells containing HCV replicons [129]. This is due to NS3/4A-mediated cleavage of the RIG-I adaptor protein MAVS [57,58]. Proteolysis occurs close to the C-terminus of MAVS, releasing it from the mitochondrial membrane and eliminating its capacity to signal. Although RIG-I initially senses HCV infection in hepatoma cells, signaling is shut down as infection progresses, NS3/4A accumulates, and MAVS is degraded [116]. The NS3/4A-mediated shutdown of RIG-I signaling can be reversed by small molecule NS3/4A protease inhibitors, but such reversal appears to occur only at concentrations far exceeding the effective antiviral concentration of drugs (EC_{50}) [130]. Why higher drug concentrations are required to restore signaling and IFN synthesis is unknown. The fact that restoration of RIG-I signaling is only observed at high drug concentrations suggests that protease inhibitors are unlikely to provide any therapeutic advantage over other small molecule antivirals based on this mechanism [130].

There is good clinical evidence that HCV functionally disrupts RIG-I signaling by targeting MAVS for cleavage by NS3/4A, as immunoblots show MAVS to be cleaved in liver biopsies from some patients with chronic hepatitis C [116]. Despite this, intrahepatic IFN-stimulated gene responses are observed in many patients, particularly those who are refractory to treatment with pegylated interferon (pegIFN) and ribavirin [131]. These responses are likely induced through alternative signaling pathways, or may originate in newly infected cells that have yet to accumulate sufficient NS3/4A to ablate signaling.

TLR3 signaling

In addition to the cytosolic RIG-I-like receptors, membrane-bound TLRs also sense RNA virus infections and are equally, if not more, important in activation of T-cell responses [113]. HCV disruption of these sensing pathways could thus be very important for persistence. TLR3 is expressed within an early endosomal compartment where it senses extracellular dsRNA molecules greater than 40–50 base pairs in length [132,133]. Structural models suggest that the dsRNA binds sites at opposite ends of a horseshoe-shaped TLR3 ectodomain and that this results in its dimerization [134]. Dimerization leads to signaling through its cytosolic, Toll–interleukin 1 receptor homology (TIR) domain, resulting in recruitment of the adaptor protein, TRIF (see Fig. 25.2) [135,136]. Although many details remain uncertain, TRIF then relocates to distinct punctate cytoplasmic bodies to which tumor necrosis factor (TNF) receptor-associated factor 6 (TRAF6), TRAF3, and TANK-binding kinase 1 (TBK-1) are recruited [133]. This leads to phosphorylation of IRF-3 and subsequent activation of the IFN-β promoter, providing a pathway to induction of IFN synthesis that operates in parallel to the RIG-I pathway [135,137]. TLR3 ligation of dsRNA also strongly induces NF-κB activity and proinflammatory cytokine synthesis via interactions of TRIF with receptor-interacting protein 1 (RIP-1) kinase [135,138].

Both TLR3 and TRIF are expressed in human hepatocytes, and primary human hepatocyte cultures induce a robust IFN response when stimulated with poly-(I:C), a dsRNA surrogate that acts as a TLR3 ligand [119,139]. These responses are blocked by the HCV NS3/4A protease, which is capable of cleaving TRIF [56,140]. The amino acid sequence of TRIF at the site of NS3–4A cleavage is closely related to the sequence at the NS4B–5A junction in the HCV polyprotein, representing a remarkable example of molecular mimicry. TRIF is absolutely required for TLR3-mediated IFN responses [136,141], and TRIF expression and TLR3 signaling were ablated in HeLa cells containing an HCV replicon [56]. Signaling was restored by treating the cells with a protease inhibitor [56].

TLR7 signaling

Plasmacytoid dendritic cells (pDCs) are professional IFN-producing cells that are recruited to sites of viral infection and play a central role in effective antiviral host responses [25]. pDCs express TLR7 and TLR8, which sense guanosine- or uridine-rich ssRNA molecules associated with RNA virus infections. In response to these ligands, pDCs secrete enormous quantities of types I and III IFN-α/β/λ, producing as much as 1–2 units/cell/24 h [25]. pDCs are the source of most IFN produced in response to many types of RNA virus infections in mice. pDCs are activated when viral RNA is sensed by TLR7, which, like TLR3, is expressed in an endosomal location. Autophagy appears to play a key role in this process [44]. TLR7 signals through a third, widely utilized adaptor protein, myeloid differentiation response gene 88 (MyD88), directly activating IRF-7, which is expressed at high abundance in pDCs. While there is no widely-accepted evidence that HCV replicates in pDCs, co-cultivation of human pDCs with Huh7 cells infected with

the JFH-1 strain of HCV results in abundant secretion of IFN-α, while exposure of pDCs to purified virus does not [120]. While the mechanism is not clear, the infected Huh7 cells in some way "present" viral ssRNA to the pDCs, thereby inducing IFN production through the TLR7 pathway. Such a hypothesis is consistent with infiltration of abundant BDCA2+ (blood dendritic cell antigen 2) pDCs in the liver of patients with hepatitis C [142]. Furthermore, this could explain the source of the IFN driving ISG expression in the liver of many patients with chronic hepatitis C [131], despite disruption of TLR3 and RIG-I signaling. TLR7 may also be expressed at low levels in hepatocytes, as a potent TLR7 agonist has been shown to induce an antiviral response in Huh7 cells containing an HCV replicon [143]. It is not known whether HCV inhibits TLR7 signaling.

Hepatitis C virus and interferon resistance

In addition to its ability to disrupt signaling pathways involved in the induction of IFN synthesis, HCV may also block the antiviral actions of IFN. Activated IRF-3 induces the synthesis of IFN-α/β, as described above. It also controls transcription of type III IFNs, including IFN-λ3 (otherwise known as IL28B) [144], which recent genome-wide association studies show to be of crucial importance both in resolution of acute HCV infection and in response to therapy [145,146].

Once its synthesis is induced through any of the pathways described above, IFN-β is secreted from the cell. It then binds the type I IFN-α/β receptor (IFNAR), resulting in autocrine/paracrine activation of the Jak-STAT pathway. This leads in turn to expression of many dozens of ISGs controlled by promoters containing IFN response elements (ISREs). Among the genes induced are the α-IFNs as well as IRF-7; the latter forms heterodimers with IRF-3 and acts to amplify the induction of ISGs [147]. IFN-l binds a distinct heterodimeric receptor comprised of IL10R2 and IFN-LR1 subunits, but utilizes the same Jak-STAT signaling pathway downstream to activate ISG transcription [148]. Thus it induces the same complex of ISGs. Activated IRF-3 also directly mediates the transcription of a subset of ISGs, some of which (like ISG56) have direct antiviral activity against HCV [149,150]. Despite this elaborate orchestration of antiviral gene expression, many HCV-infected patients fail to mount an effective antiviral response to either endogenous IFN or exogenous pegIFN and ribavirin therapy.

Recent studies in both patients and HCV-infected chimpanzees have begun to provide some mechanistic insights concerning this lack of response to IFN [131,151]. Poor therapeutic responses to pegIFN were found to be associated with high intrahepatic transcription of ISGs prior to treatment. In contrast, patients who experienced a rapid virologic response (RVR: negative serum HCV RNA after 4 weeks of treatment) to pegIFN had little ISG expression in the liver before therapy, but demonstrated impressive upregulation of ISGs when treated [131]. Importantly, the ISG response to pegIFN in RVR patients did not exceed that found before treatment in nonresponder patients. The preactivation of ISGs was confined largely to the liver, and was not present in peripheral blood mononuclear cells (PBMCs) (highlighting the need to characterize IFN responses in liver, not PBMCs) [131]. These seminal observations indicate that some patients do not induce an IFN response despite being infected with HCV, while the virus persists in others in the face of a robust IFN-mediated antiviral response.

These observations raise two important questions. The first relates to the source of the IFN driving the ISG response in some infected patients. As mentioned above, it may be produced by newly infected hepatocytes through RIG-I or TLR3 sensing of viral RNA prior to the expression of sufficient NS3/4A to shut down signaling [116]. Or, alternatively, IFN might be produced by uninfected hepatocytes that sense dsRNA in the extracellular environment through TLR3-mediated signaling [119]. Yet another possibility is that HCV infection might be sensed by TLR7 in infiltrating pDCs [120]. An equally important question is how the virus survives despite robust ISG expression. This may be due to viral evasion of the antiviral actions of specific ISGs, such as PKR, which is antagonized by NS5A [152]. Alternatively, given the diversity of antiviral ISGs potentially induced by IFN-α, HCV may disrupt Jak-STAT signaling downstream of the IFNAR to escape the antiviral actions of IFN.

While Jak-STAT signaling is not completely disrupted, recent studies have directly documented that it is impaired in HCV-infected human liver tissue ex vivo [153]. Several mechanisms have been proposed to account for this (Fig. 25.3) (reviewed in [59]). Core protein may inhibit Jak-STAT signaling by interacting directly with STAT1, leading to reduced phospho-STAT1 [154,155]. In addition, protein phosphatase 2A (PP2A) is upregulated in transgenic mice expressing core protein [156]. This leads to reduced methylation of STAT1 due to inhibition of protein arginine methyl transferase 1 (PRMT1), which promotes its association with protein inhibitor of activated STAT1 (PIAS1), a negative regulator of STAT1 gene transcription [153,157,158]. Other data suggest that poor treatment outcome may be related to enhanced hepatic expression of suppressor of cytokine signaling 3 (SOCS3), which impedes Jak-STAT signaling [155,159].

Poor responses to pegIFN therapy are also associated with increased expression of ubiquitin-specific peptidase 18 (USP18, or UBP43) [131,160]. USP18 interacts with

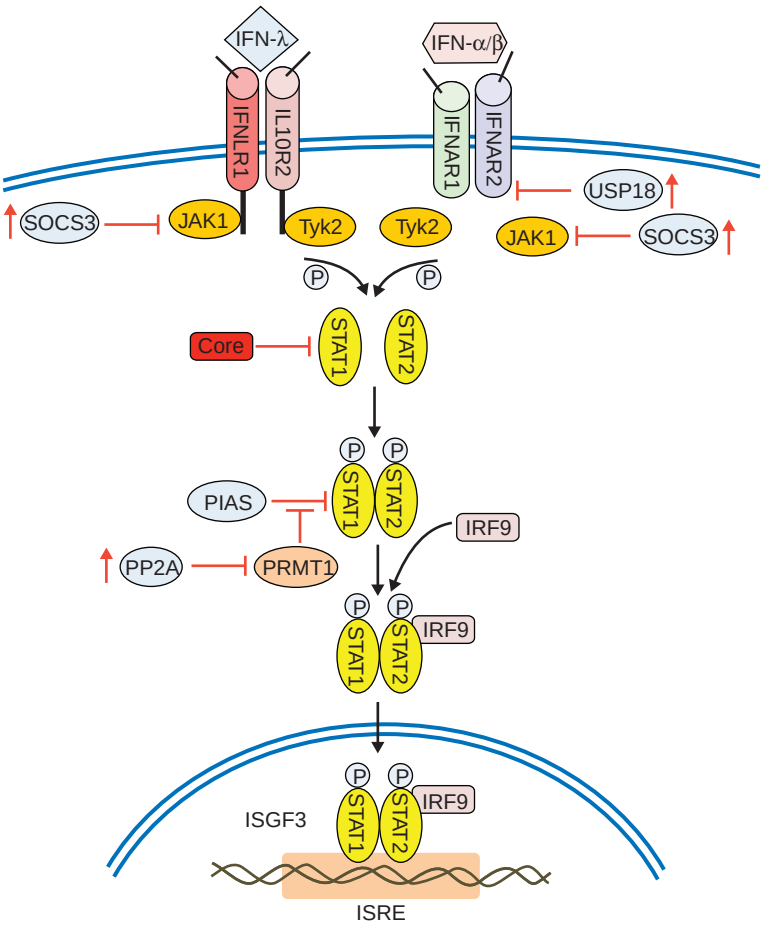

Figure 25.3 Interferon-induced Jak–STAT signaling in hepatitis C. IFN, interferon; IERS, interferon response elements. (Reproduced from Lemon [59] with permission from American Society for Biochemistry and Molecular Biology.)

the IFNAR2 subunit of IFNAR, and may thus suppress Jak-STAT signaling induced by type I IFNs [161]. USP18 also possesses ISG15 deconjugase activity, and silencing its expression in cell culture potentiates the antiviral activity of IFN-α against HCV [162]. Like Jak-STAT signaling induced by type I IFN, IFN-l-induced signaling is subject to suppression by PP2A and SOCS3, but would not be affected by the interaction of USP18 with IFNAR2 [161]. This is an interesting observation given the potent influence of *IL28B* polymorphisms near the IFN-λ3 gene, both in natural clearance of HCV infection and in the response of HCV to pegIFN therapy (discussed further below) [145,146].

Interactions of hepatitis C virus with host immune cells

Hepatitis C virus–host interactions commence immediately with infection as HCV interacts with elements of the innate immune system and modifies cellular antiviral components. These interactions may influence the development of acquired immunity, which is essential for HCV clearance. Conventional dendritic cells (cDCs) are highly specialized antigen-presenting cells (APCs) that can activate both primary and secondary immune responses through the presentation of antigens mediated by major histocompatibility complex (MHC) class I or class II molecules. Maturation and functional differentiation of cDCs in HCV infection are altered with decreased IL12 and increased IL10 production [163,164]. Furthermore, cDCs obtained from HCV-infected patients may exhibit impaired proliferation and stimulatory activity [164–166]. None the less, there does not seem to be a global impairment of cDC function in chronic HCV. Deficient function of cDCs at critical times early in infection may lead to impaired T-cell priming and contribute to delayed cellular responses.

Natural killer (NK) cells are part of the innate immune system and provide a first-line defense against viral infections because they require no priming to trigger cytotoxic activity and produce IFN-γ. The normal liver has a unique group of resident lymphocytes with up to 65% being NK cells, γ/δ T cells, or NK-like T cells, compared with less than 20% in peripheral blood [167]. The role of NK cells in the control of HCV infection remains undefined but they may play a role in viral clearance. Genetic factors determine the responsiveness of NK

cells via human leukocyte antigens (HLAs) and killer-cell immunoglobulin-like receptors (KIR). Homozygosity for HLA-C1 and KIR2DL3 resulted in a higher rate of spontaneous clearance of HCV infection with low inocula [168]. This KIR/HLA pair delivered a lower inhibition signal, which translated into easier activation of NK cells with viral stimulation. This is supported by faster NK-cell degranulation and IFN-γ release in vitro [169]. Interestingly, the inflammatory environment in the HCV liver may alter NK responses from IFN-γ production towards cytotoxicity, resulting in ongoing liver damage [170,171]. This polarized NK-cell phenotype correlates with alanine aminotransferase (ALT) levels, suggesting participation of virus-induced effector NK cells in liver necroinflammation [170,171]. The HCV protein E2 binds to human CD81 on NK cells and directly inhibits NK-cell function in vitro but this inhibition does not occur when E2 is part of an infectious virion [172,173]. NK cells are potent activators of cDCs and, conversely, cDCs may stimulate NK-cell activity. In chronic HCV infection, NK cells isolated from patients are impaired in their ability to activate cDCs owing to overexpression of the inhibitory receptor CD94/NKG2a as well as production of TGF-β and IL10, which blunt the adaptive response [174].

Adaptive immune responses against hepatitis C virus

The key to development of vaccines and novel immunotherapies to combat HCV lies in careful study of the cellular immune responses of those who successfully clear virus. Most work in humans is done either retrospectively or in incidental patients who present with symptomatic acute infection or with needlestick injuries. Although there is currently no small animal model of HCV infection, the common chimpanzee *Pan troglodytes* is a faithful, replicative model of HCV infection and provides an opportunity to carefully dissect components of immune responses to HCV in a controlled, prospective manner.

CD4+ T-cell responses

CD4+ T cells are specifically activated when their receptors engage complexes of peptides and MHC class II molecules. Their responses are typically characterized by proliferation and/or cytokine production following incubation with recombinant viral proteins or overlapping peptides. Differential cytokine production underpins the specific types of T helper (Th) induced immune responses. CD4+ T cells are absolutely essential for successful immune responses against HCV. The appearance of HCV-specific T cells in the peripheral blood and liver in acute infection precisely coincides with a drop in viral load [175]. A vigorous and multispecific CD4+ T-cell proliferative response against HCV antigens in acute infection correlates with successful clearance [176–178] and this response must be sustained or viral recrudescence will occur [179–181]. This proliferative response is accompanied by IFN-γ and IL2 production [182,183]. The evolution of this multispecific CD4+ T-cell response initially targets a limited number of dominant epitopes and then spreads to additional targets once viremia is better controlled [184].

In resolved infection, HCV-specific CD4+ T memory cells are maintained in the absence of virus; they are expandable in vitro with antigen stimulation and mediate appropriate effector functions [185–187]. When HCV-specific CD4+ T cells from the peripheral blood of recovered versus chronically infected patients are evaluated for cytokine production, responses are predominantly of the Th1 type [185,187,188] and are ten times more frequent in resolvers than chronics and four times more broad [187]. The strength of HCV-specific T-cell responses correlates inversely with viral loads in chronic disease [185,187]. Loss of virus-specific CD4+ T cells may be epitope dependent, with cells specific for core antigen being more readily detectable [189,190].

Since HCV-specific CD4+ T-cell responses in the peripheral blood are generally weak or absent using functional assays, MHC class II peptide tetramers have been used to directly analyze the phenotypes of circulating HCV memory cells in resolved infection. HCV-specific CD4+ T cells were not detected in the peripheral blood in chronically infected patients using class II tetramers. The majority of HCV-specific CD4+ T cells analyzed had a central memory phenotype [191]. These cells, when exposed to antigen, can rapidly proliferate and produce IL2 [192] and are critical for the expansion of memory cytotoxic T lymphocytes (CTLs) [193–195]. As is seen in class I tetramer-based analyses of HCV-specific CD8+ T cells from resolvers [196], the class II tetramer-positive population is polyclonal, utilizing multiple TCR Vβ chains [191]. Using this method of detection, HCV-specific CD4+ memory T cells are 10–100 times less frequent in peripheral blood than their CD8+ counterparts.

CD8+ T-cell responses

CD8+ T cells recognize viral peptides presented by MHC class I molecules on the surface of infected cells. Activation of CD8+ T cells by peptide–MHC complexes can lead to cytolytic and noncytolytic viral control and eradication. HCV-specific T cells appear 5–9 weeks post exposure [180, 197]. As illustrated in Fig. 25.4, a multispecific (targeting multiple viral proteins) and polyclonal (using multiple T-cell receptors) CD8+ T-cell response in the first weeks of acute HCV infection correlates with successful clearance of virus [180,181,197,198]. Frequencies of HCV-specific CTLs at specific epitopes in acute infection may exceed

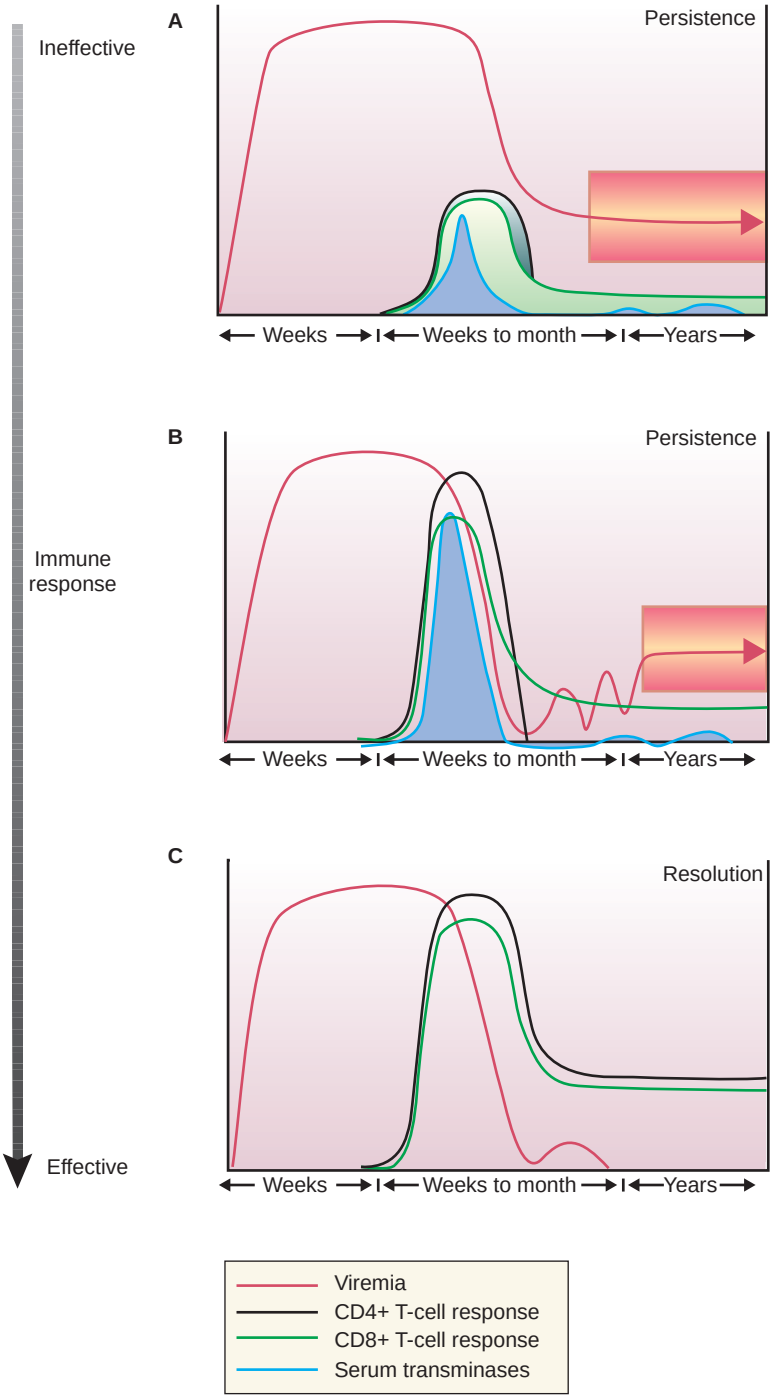

Figure 25.4 Viral and T-cell kinetics with serum transaminases in acute HCV infection. (A–C) Three possible patterns are represented depending upon the strength and durability of the T-cell response including viral persistence due to lack of T-cell response, viral persistence due to lack of durability of T-cell response, and viral clearance with robust and sustained T-cell response. (Reproduced from Bowen and Walker [734] with permission from Nature.)

3–4%. If these robust CD4+ or CD8+ T-cell responses are delayed, transient, or too narrowly focused, viral persistence will ensue. Early in acute infection when ALT levels are elevated, HCV-specific CD8+ T cells exhibit impaired proliferation and cytotoxicity and produce limited amounts of IFN-γ [180,199]. This "restrained phenotype" of CTL is seen in other viral infections and is consistent with high antigen exposure and elevated levels of programmed death 1 (PD-1) [200–202]. Interestingly, in those who clear infection, this dysfunction resolves when HCV-specific CD4+ T-cell responses develop and viremia ceases [180,182]. During acute infection, a broadly targeted CTL response in the liver may be seen in the absence of biochemical liver disease, which may be secondary to noncytolytic effector functions similar to those seen in HBV infection [181,203]. IFN-γ-mediated

inhibition of HCV RNA is 100–1,000 times more effective that cytotoxicity [204].

Once HCV infection is established, HCV-specific CD8+ T cells may still be detected in peripheral blood by tetramer analysis [205–208]. In persistent infection, there are a lower frequency of HCV-specific CTLs and fewer epitopes recognized, although some responses can approximate resolved infection [209]. When compared with CTLs from resolved infection, HCV-specific CD8+ T cells in chronic infection show impaired function, as discussed below [208]. Although most virus-specific CTLs are concentrated in the liver [205], they have not been consistently associated with disease severity [210,211]. Proinflammatory cytokines have been correlated with severity of liver fibrosis [212,213] implicating both antigen-specific and -independent mechanisms of hepatocellular injury. Importantly, in those who resolve infection, HCV-specific memory T cells can be recovered from blood and liver decades after exposure [214,215] and provide some protection against reinfection.

B-cell responses

A role for antibodies in HCV protection or clearance has been difficult to define. Resolution of HCV infection in patients deficient in B cells (agammaglobulinemia) argues that antibodies are not essential for successful HCV immunity [216,217]. Humans and chimpanzees who resolve HCV infection appear to exhibit antibody responses that are weaker (lower titer), target fewer proteins, and may be quickly lost [197,218]. Neutralizing antibodies appear late in HCV infection (8–20 weeks), and increase in titer, breadth, and cross-reactivity over time [219]. They are often isolate specific and difficult to identify from patient to patient [220]. Likewise, neutralizing antibodies exert immune selection pressure, particularly in the hypervariable region of E2 and contribute to quasispecies development [220,221]. In a cohort of chimpanzees challenged with HCV, viral clearance was not associated with anti-E1 or anti-E2 antibodies [222]. Similar findings were reported in a group of Irish women infected by HCV-contaminated gammaglobulin [223]. Nonspecific immunoglobulins (IgG) and IgG-secreting B cells are increased in chronic HCV [224]. It is posited that HCV may stimulate B cells in a B-cell receptor-independent manner resulting in enhanced conversion to Ig-secreting cells [224]. Clonal expansion of B cells is seen within the liver, bone marrow, and peripheral blood in chronic HCV infection and is associated with mixed cryoglobulinemia and non-Hodgkin lymphoma [224,225]. These are further discussed in the HCV natural history section below.

Strategies for viral persistence

A striking feature of HCV infection is the rapidity of viral spread after a percutaneous exposure, which often reaches maximum titers weeks before immune responses are detectable [180]. The ability of HCV to outpace the CD8+ T-cell response or to subvert early innate responses may contribute to its propensity to develop chronic infection. Discussed below are several strategies which HCV may employ to evade T-cell responses.

T-cell anergy

HCV-specific T cells from patients with chronic infection are functionally impaired or "anergic." Over time, these virus-specific T cells become progressively impaired to the point that only weak IFN-γ production remains as a readout [180,198,208,226]. This is not a universal phenomenon in chronic viral infections [206]. HCV-specific CD8+ T cells may be impaired even after viral clearance, which makes their role in viral persistence less clear [206]. These functionally impaired HCV-specific CD8+ T cells are associated with a weak CD4+ T-cell response to HCV antigens [208]. In murine and human systems, maintenance of effective CTL responses in chronic viral infections is dependent upon virus-specific CD4+ T cells that may develop decreased proliferation with repeated antigen exposure [227,228]. Dysfunctional HCV-specific T cells express PD-1 secondary to chronic antigen stimulation [229]. In general, T cells that undergo chronic antigen stimulation lose function over time until only IFN-γ secretion remains [230], as can be seen in chronic HCV infection. PD-1 ligand is highly expressed in liver and its interaction with PD-1-expressing T cells results in apoptosis [231]. Impaired CD8+ T-cell effector function in chronic HCV infection may also be a result of direct interaction with HCV proteins. Extracellular (nonvirion-associated) core protein can bind to the complement receptor gC1qR on T cells [232] and inhibit T-cell proliferation and IFN-γ production [233]. In chronic HCV infection, cellular immune responses are present and may play a role in controlling viremia but lack the fortitude to eliminate virus. Restoring CD8+ T cells to functional competence appears dependent upon the presence of functional CD4 help and appropriate antigen concentrations.

Mutational escape

Hepatitis C virus has a high propagation rate and replicates via an RNA-dependent RNA polymerase that lacks a proofreading mechanism. Each infected individual has their own signature virus made up of quasispecies that result from the error-prone replication process in conjunction with host pressures on the virus [234]. HCV prolifically generates minor viral variants with the potential to avoid immune recognition. Both T and B cells (discussed earlier) provide immune selection pressure on the virus. Based on full-length HCV sequencing studies, HCV escape mutants are selected on a population level in the context of the prevailing HLA haplotypes. When

HCV is transmitted to a person with a different HLA type, it reverts to the original sequence, which is indirect evidence of HLA-restricted selection pressure [235, 236]. Mutations at targeted MHC class I-restricted epitopes were first demonstrated in the chimpanzee model, with human studies characterizing acute infection or single source outbreaks soon to follow [235,237–239]. The highest level of CD8+ T-cell-mediated selection pressure occurs during acute infection and decreases with chronicity [237,240]. Importantly, loss of CD4+ T-cell help during acute infection leads to CD8+ T-cell escape mutations and viral persistence [241]. Viral epitopes may be lost due to amino acid substitutions, which result in proteasomal destruction [235], altered binding to MHC molecules [235,242], or poor recognition by CD8+ [237,242] or CD4+ T cells [243]. While mutational escape can occur at class II-restricted epitopes, this is rare when compared with class I-restricted sites [244]. Altered peptide ligands may also downregulate T-cell responses against wild-type virus or decrease the priming of new T cells [242]. T-cell receptor (TCR) diversity can influence escape mutations as one or a few TCRs recognizing an epitope are less able to constrain the emergence of escape mutations [245]. Some of the more successful T-cell responses in HCV are against epitopes which do not "allow" sequence changes due to high viral replication fitness cost [246]. While no single mechanism fully explains how HCV evades the adaptive immune response, a lack of CD4+ helper T cells during critical times in infection may strongly contribute to viral escape mutations and T-cell anergy.

Regulatory T cells

A subset of HCV-specific CD8+ T cells derived from the liver of a chronically infected patient were noted to produce the immunosuppressive cytokine IL10 [247]. This was the first MHC class I-restricted T-cell population with the potential to modulate antiviral T cells. HCV-specific T cells that preferentially produce IL10 can be expanded from liver, and suppress IFN-γ production and proliferation of HCV-specific T cells in vitro [248]. IL10 levels are elevated in chronic HCV infection and may be able to attenuate necroinflammatory changes in the liver [249,250]. In addition to a group of intrahepatic regulatory CD8+ T cells, there is another group of CD4+ T cells found in HCV patients that may have immune modulating features.

Immunoregulatory CD4+CD25+ T cells (T regs) mediate T-cell suppression through cell–cell interactions and have been implicated in the development of self-tolerance [251]. Repetitive stimulation with immature dendritic cells can induce the formation of T regs in vitro [252]. Patients with chronic HCV infection have an increased frequency of T regs in the peripheral blood when compared with normal or recovered controls, and these cells can directly suppress IFN-γ production by HCV-specific CD8+ T cells, thereby rendering them less effective [187,253,254]. Depletion of these CD25+ T cells resulted in increased responsiveness of HCV-specific T cells in vitro, but suppression extended to other antiviral T cells such as Epstein–Barr virus (EBV) [253,255]. Likewise, T reg-mediated suppression did not differ between those who cleared HCV infection and those who developed persistent disease [256]. This implies that T regs may be a generalized "brake" for the cellular immune response in the setting of chronic inflammatory stimuli like HCV.

Immune responses with antiviral therapy

Studying successful immune responses against HCV secondary to antiviral therapy increases our understanding of the complex interplay between virus and host in chronic infection. The mechanisms by which IFN-α and ribavirin aid in the clearance of HCV are not completely understood. IFN-α has antiviral effects through ISGs as well as immunomodulatory effects [257], and ribavirin augments the induction of critical ISGs [258] and interferes with viral replication efficacy [257,259]. Immunomodulatory actions of IFN-α include the promotion of memory T-cell proliferation and the prevention of T-cell apoptosis as well as the stimulation of NK-cell activation and cDC maturation [260]. IFN-α promotes antiviral Th1 cytokines and upregulates class I and II which increases antigen presentation. Likewise, by decreasing viral load, IFN-α may improve the function of downregulated HCV-specific T cells that have been under constant antigen stimulation.

T-cell analyses during treatment-induced clearance have yielded differing results. Patients who develop a strong proliferative CD4+ T-cell response to multiple HCV antigens early in treatment and maintain this response successfully, clear the virus [188,261]. Sustained virologic response and histologic improvement was more likely to occur in patients with a vigorous, multispecific CD4+ T-cell response that persisted during and after treatment. Transient responses resulted in viral recurrence [188]. Limited studies examining common class I-restricted CD8+ T-cell epitopes have found that successful clearance on therapy is associated with increased frequency of HCV-specific CTLs [262] and conversion from a monoclonal to a polyclonal CTL response [196].

Others have found that the breath and frequency of HCV-specific CTL responses in acute infection decrease on IFN-α treatment and that patients with viral breakthrough may also exhibit a strong HCV-specific response [183,263,264]. Part of the discrepancy may be due to which functional studies are utilized as well as from which compartment these HCV-specific T cells are obtained. Most of the analyses are from T cells in the

peripheral blood although IFN-α exerts much of its effects in the liver. After liver transplant, recurrent HCV infection develops in virtually all newly transplanted livers and liver biopsies are commonly used to assess recurrent disease severity. Despite immunosuppression, transplant patients with recurrent HCV infection can develop an early, multispecific CD4+ T-cell response against HCV antigens in the liver [265], and those who are able to sustain their CD4+ T-cell response with IFN-α therapy are able to successfully clear virus [266]. This argues that compartmentalization effects of IFN-α may exist. Likewise, administration of IFN-α therapy early in acute HCV infection results in a rapid decline in HCV-specific T cells likely due to the sudden departure of short-lived effector T cells and not memory T cells [264]. Interestingly, antiviral therapy in acute infection is able to "rescue" a small subset of polyfuctional HCV-specific memory T cells [267]. Capitalizing on this population of T cells may be important in the design of therapeutic vaccines.

Direct acting antiviral agents including protease and polymerase inhibitors are being added to the HCV antiviral armamentarium. Areas in the HCV NS3 protease and NS5b polymerase are under both HLA-driven pressures as well as drug selection [268], meaning that viral escape mutants may predate treatment. As noted earlier in this section, maximally upregulated intrahepatic ISGs before treatment predict failure to respond to pegIFN-α and ribavirin [131]. Secretion of IFN-γ by intrahepatic CTLs and NK cells also contribute to ISG expression [269]. The chronic activation of innate immune responses in chronic HCV correlates with increased interferon-γ-inducible protein 10 (IP-10) levels and treatment failure [270]. Similarly, chronic stimulation of HCV-specific CTLs identified by elevated levels of PD-1 also predict failure to respond [271]. Diminishing the effects of chronic immune stimulation by the virus may aid in the development of future therapies.

Correlates of protective immunity against hepatitis C virus

Unlike infection with hepatitis B where neutralizing antibodies against surface antigen exist, the role for antibodies in clearance and/or protection in HCV infection has been difficult to prove. Successful resolution of acute HCV infection in chimpanzees is associated with a robust HCV-specific CD8+ T-cell response but a weak and short-lived antibody response to multiple HCV antigens [197]. HCV-specific memory T cells were found in the peripheral blood of recovered patients exposed two decades earlier, while 42% had no detectable antibody response [214]. Also, HCV-specific CTLs have been cloned from the livers of recovered chimpanzees and humans years after infection [215]. These HCV-specific memory T cells appear to protect recovered chimpanzees against reinfection with homologous, heterologous, and cross-genotype HCV [272–274]. Previously recovered chimpanzees rechallenged with HCV have an attenuated course compared with primary infection with lower viral titers and ALT levels and more rapid resolution of viremia, indicating that a degree of protective (but not sterilizing) immunity exists against HCV [272, 274,275]. Immune protection can be lost if chimpanzees are challenged multiple times with HCV [276], similar to that observed in multiply transfused patients [277]. When injection drug users were followed prospectively for HCV viremia, those who had been previously exposed to HCV and had cleared infection (HCV antibody-positive and RNA-negative) were 12 times less likely to develop persistent HCV infection than those infected for the first time [278]. Taken together, these data argue that an HCV-specific memory immune response exists and provides some protection against reinfection.

To dissect the essential components of the recall immune response against HCV, recovered chimpanzees were rechallenged with homologous strain virus. The duration and peak of viremia diminished after the second infection and was associated with rapid and robust expansion of functional memory helper and cytotoxic T cells [215,272]. The rapid control of the second challenge was seen prior to an increased anti-HCV antibody titer [215], substantiating the claim that the humoral component is not necessary for protection against HCV persistence. The CD8+ T-cell responses trailed the HCV-specific CD4+ responses, and functionally active CD8+ T cells were associated with a phenotypic change to effector memory cells [272]. Antibody depletion of CD8+ T cells prior to the third infection greatly prolonged viremia, and infection was not terminated until memory CD8+ T cells recovered [215]. To further elucidate the essential components of protective HCV immunity, two additional recovered chimpanzees were depleted of CD4+ T cells prior to homologous rechallenge [241]. Despite the detection of strong HCV-specific CD8+ T-cell responses in the liver, HCV RNA persisted at low levels for >300 days indicating that CD8+ memory T cells alone were not sufficient for HCV resolution without CD4+ T-cell support. These experiments demonstrate that CD8+ T cells are essential for viral clearance and that their success rests on the adequacy of CD4+ T-cell help.

Vaccine strategies

As previously discussed, spontaneous clearance of HCV leads to long-lived memory T cells that control and rapidly clear HCV on repeat exposure. There are three types of HCV vaccines which are being pursued. The first prevents initial infection (sterilizing immunity), the second prevents viral persistence in those who become infected (enhances the clearance rate above the

background level of spontaneous clearance), and the third increases the rate of sustained virologic response in those who are chronically infected (therapeutic vaccine). Since much of the morbidity of HCV is associated with chronic disease, a prophylactic vaccine that prevents persistent infection rather than sterilizing immunity is a reasonable approach. Unfortunately, there is still no immunocompetent, small animal model for HCV infection so the chimpanzee remains the only model in which vaccines can be tested.

Choosing the correct target antigens in HCV is difficult due to high genetic diversity and the potential to escape from the vaccine-induced immune response. Inducing cross-neutralizing antibodies by targeting the envelope region remains a possibility [279] but there is intense variation in this region. Despite conflicting data, antibodies against surface glycoproteins have been shown to "control" viremia in vivo [280–282]. The most comprehensive prophylactic vaccine studies have used an oil/water adjuvanted HCV envelope gpE1/gpE2 vaccine designed to induce neutralizing antibodies and focused T-cell responses [283,284]. Another successful approach used DNA plasmid to induce anti-E1E2 immune responses and found modified infection and rapid clearance of HCV associated with high anti-envelope antibody titers [285]. T-cell vaccines have been the primary focus of prophylactic and therapeutic vaccines due to the importance of the HCV-specific T-cell response in viral clearance. T-cell vaccines are also able to target the more conserved areas of the virus, including nonstructural proteins. Different approaches have been used to generate T-cell responses against HCV antigens, including the use of virus-like particles and defective or attenuated viral vectors with or without priming of the immune system with DNA plasmids [286,287].

There are at least a dozen chimpanzee studies published that evaluate prophylactic HCV vaccines (reviewed in [288]). Prophylactic vaccine goals include the induction of neutralizing antibodies, the stimulation of HCV-specific T cells, or both. Prophylactic vaccines have been moderately successful at inducing a response similar to natural infection. In vaccinated animals, peak titers were lower and the virus was controlled more quickly, similar to rechallenged animals. A summary of the published studies evaluating prophylactic HCV vaccines reveal a 61.9% chronicity rate among naïve animals, 28.3% among vaccinated animals, and 16.7% in rechallenged animals [288]. Those vaccines that include nonstructural proteins alone generate a strong T-cell response but still have a high rate of persistence, whereas structural proteins (core/E1/E2) have a chroncity rate of 13.8%, similar to natural infection [288]. Qualitative differences in T-cell responses may result depending upon the type of antigen utilized. Inclusion of envelope proteins with the nonstructural targets may have a beneficial effect on vaccine-induced T-cell responses.

There are multiple different therapeutic vaccines under development, which are being tested in patients with chronic HCV or healthy controls [288]. Most focus on boosting the HCV-specific T-cell responses against nonstructural proteins via a variety of delivery methods. All appear to decrease viral load to some degree and strengthen T-cell immunity but the effects are short lived. Immune escape from the vaccine-induced T-cell responses is a concern, hence therapeutic vaccines may be most effective if given with additional antiviral therapy. Likewise, delivery of co-stimulatory molecules to aid in T-cell performance is also being explored.

Epidemiology

It is estimated that between 2% and 3% of the global population is infected with hepatitis C, corresponding to approximately 130–170 million individuals (Fig. 25.5) [289–293]. However, it is acknowledged that prevalence data are incomplete from many areas of the world so that the true prevalence may be underestimated. HCV prevalence varies among different global regions as reported by the World Health Organization (WHO) [289,294,295]. The highest estimated prevalence of HCV infection is in Africa (5.3%) followed by the eastern Mediterranean region (4.6%), western Pacific region (3.9%), Southeast Asia (2.2%), and Europe (1%) [289]. Within these regions, prevalence of hepatitis C is also variable and may reflect unique circumstances or local practices that foster HCV transmission (discussed further below). Thus, the prevalence of HCV infection in southern European countries such as Spain, Italy, and Greece ranges between 2.5% and 3.5%, compared to a prevalence of <1% in northern European regions such as the United Kingdom and Scandinavia [289,290]. Similarly, one of the highest rates of HCV infection is noted in Egypt where the prevalence is estimated at 11–14%.

Chronic hepatitis C is the most common cause of liver disease in the United States and is responsible for 12,000 deaths annually, although the morbidity and mortality associated with HCV infection will continue to increase over the next few decades [290,296,297]. A report by the Institute of Medicine concluded that the current surveillance system for viral hepatitis in the United States is not optimal and provided specific recommendations to improve state and federal surveillance programs in order to provide accurate and timely representations of the burden of viral hepatitis in the United States [298]. Despite these perceived limitations, the Sentinel Counties Study of Viral Hepatitis conducted by the Centers for Disease Control and the third National Health and Nutrition

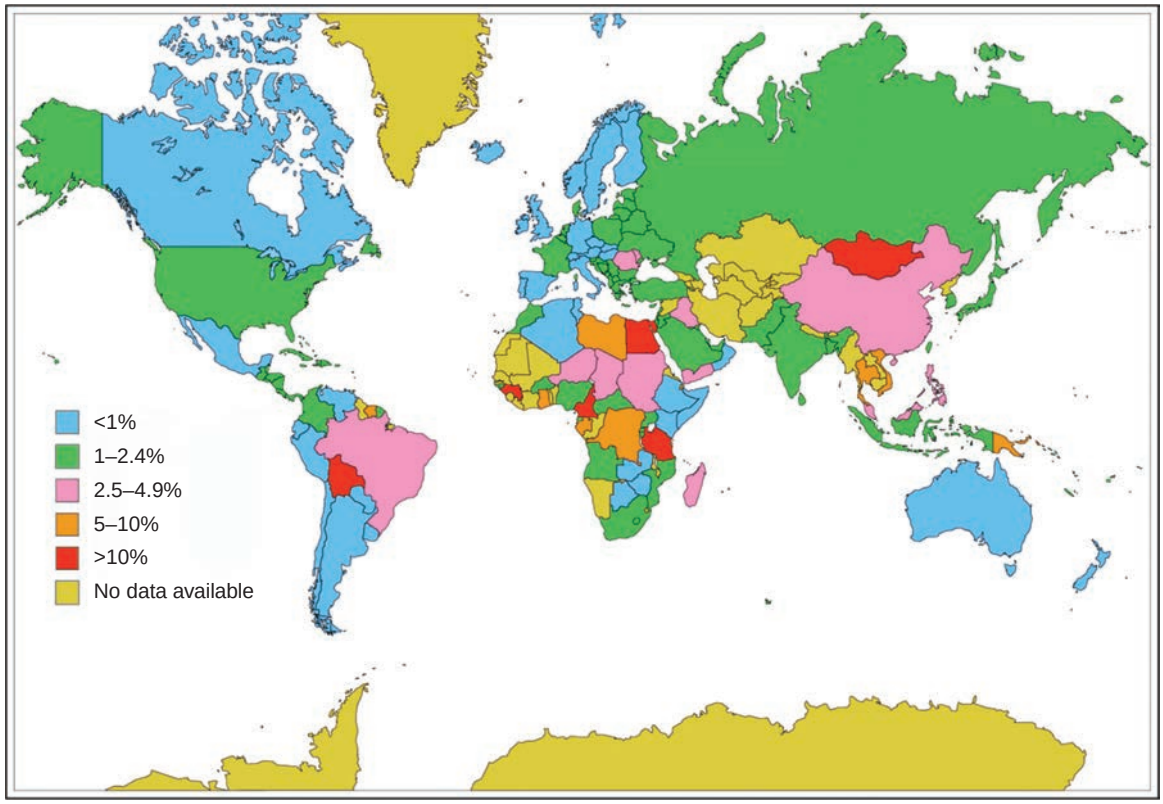

Figure 25.5 Global epidemiology of hepatitis C infection. (Reproduced from Cohen [293] with permission from American Association for the Advancement of Science.)

Survey (NHANES III) provided important epidemiologic data regarding the incidence and prevalence of hepatitis C in the United States and also served as the basis for projections regarding the future burden of this disease [291,299–301]. Modeling of the trends in HCV infection in the United States suggest that infection with HCV was uncommon in the early 1960s (45 infections per 100,000 persons) and peaked in the late 1980s (80–200 infections per 100,000 persons) with an estimate of 200,000 to as many as 500,000 new infections annually during this period [295,300]. By the early 1990s there was an 85% decrease in reported new HCV infections, likely due to a sharp decrease in intravenous drug use, with an estimated current annual incidence of less than 18,000–20,000 cases [302,303].

Utilizing serum samples from participants in the most recent NHANES study, the prevalence of antibody to HCV (anti-HCV) was 1.6% (95% CI, 1.3–1.9%), which corresponds to an estimated 4.1 million people (95% CI, 3.4–4.9 million) in the United States [292,301]. Chronic infection characterized by detectable HCV RNA was found in 1.3% of the participants (3.2 million persons; 95% CI, 2.7–3.9 million). These prevalence data are likely underestimates of the true prevalence of HCV infection in the United States since they did not include participants who were institutionalized, incarcerated, or homeless – all populations with a high rate of HCV infection [292,301].

The prevalence of HCV in the United States also shows marked gender and racial disparities. Age-adjusted prevalence estimates indicate that the majority of HCV-infected persons were born between 1945 and 1964, now roughly corresponding to them being between 50 and 60 years of age [301]. The prevalence of anti-HCV by race, age, and gender is shown in Fig. 25.6. Among all male participants, a peak prevalence of 6% occurred between the ages of 40 and 49 (at the time of the survey) while the prevalence in females was ~2%. The highest prevalence of HCV infection, ~14%, was found in male, non-Hispanic, black participants between the ages of 40 and 49 years, compared with approximately 6% of male, non-Hispanic, white participants in the same age group (Fig. 25.5) [301].

Risk factors

Several risk factors account for the majority of cases of transmission of hepatitis C, including intravenous drug use, blood transfusions from unscreened donors, and

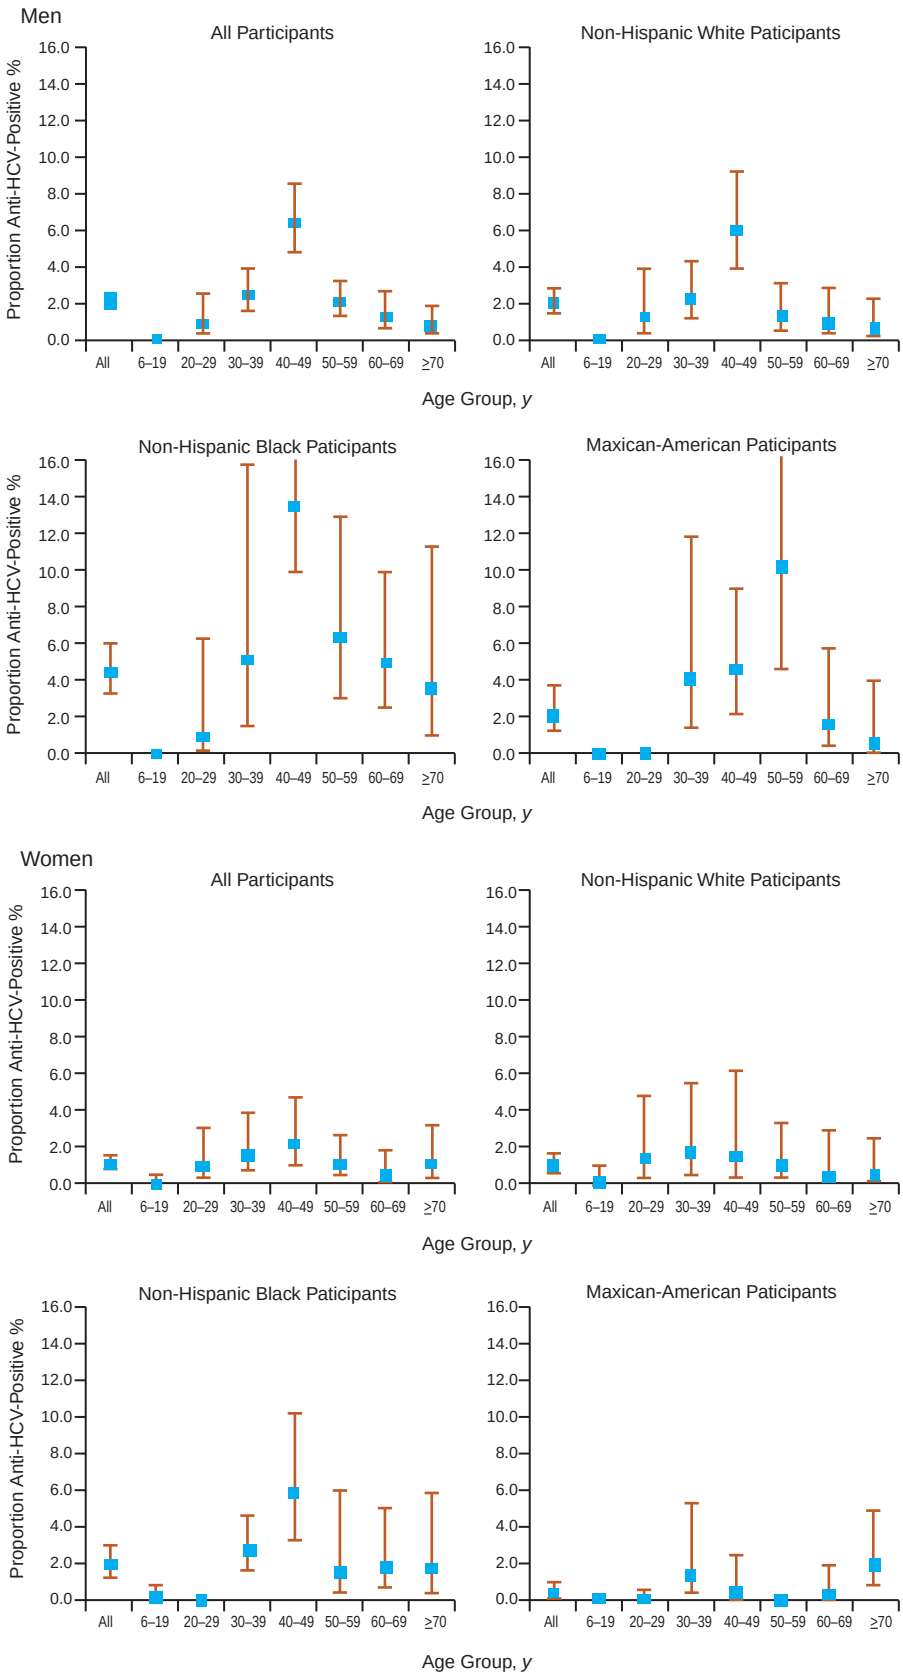

Figure 25.6 Age- and race-adjusted prevalence for men (A) and women (B) of hepatitis C infection in the United States. (Reproduced from Armstrong et al. [301] with permission from American College of Physicians.)

iatrogenic exposure from unsafe injection practices [295]. The relative importance of these risk factors may vary by country and developed nation status. Other risk factors such as sexual transmission, perinatal exposure, and health care occupational exposures occur infrequently.

Intravenous drug use

Intravenous drug use is the most common risk factor for acquiring hepatitis C in developed countries such as the United States, the European continent, and Australia, among others [290,295,299,304,305]. From the NHANES study, the prevalence of anti-HCV was found to be 48% in those between the ages of 20 and 59 years who had ever injected illicit drugs and it is estimated that up to 80% of current infections are due to a past history of injection drug use [301]. Among long-term injection drug users the prevalence of hepatitis C infection has been reported to be as high as 94%. The prevalence of anti-HCV among persons who had engaged in intravenous drug use for less than 1 year was already 65%, indicating that this activity is a highly efficient mode of HCV transmission [306]. Although sharing syringes has been most frequently implicated in the transmission of HCV, the shared use of other drug preparation equipment may have contributed to infection in an estimated 37% of recent HCV infections [307].

Illicit drug use other than marijuana has also been linked to higher rates of HCV infection [301]. In particular, the extent of the risk of intranasal cocaine has been debated [308–311]. A systematic review found the prevalence of HCV infection among noninjecting drug users to range between 2.3% and 35.3%, suggesting that other routes of transmission besides purely percutaneous exposures may occur [312]. However, inconsistent methodologies and case ascertainment in these studies have prevented firm conclusions about this controversial issue such that the risk of noninjecting drug use remains unsettled.

Unsafe therapeutic injection practices

In developing countries, unsafe therapeutic injection practices, where syringes or needles may be reused without sterilization, continues to contribute to incident cases of hepatitis C and remains a major transmission risk for blood-borne infections [294,295,313]. WHO estimates that 30% of hepatitis C infection, or 2–4 million annual cases, can be attributed to unsafe injection practices in low-income countries. Perhaps the most compelling story of unsafe injection practices resulting in tragic consequences is derived from a nationwide campaign in Egypt to eradicate schistosomiasis [314,315]. Millions of Egyptians were administered intravenous tartar emetic over a 30-year period beginning in the 1950s and ending in the 1980s when effective oral therapies became available. The number of intravenous injections administered correlated directly with the prevalence of HCV infection in Egypt and soon surpassed schistosomiasis as the leading cause of liver disease in that country. Furthermore, the increasing incidence of hepatocellular carcinoma is now being driven by advanced liver disease due to hepatitis C. Similarly, parenteral therapy for trypanosomiasis has been implicated in HCV transmission in equatorial Africa [316]. In Asia, folk remedies that involve skin piercing have been shown to contribute to high rates of HCV infection in certain regions [317]. Programs to promote safe injection practices have been implemented by WHO in recognition of the gravity of this problem.

The failure of aseptic techniques during medical procedures is rare in developed countries. Nevertheless, a recent outbreak at a Las Vegas endoscopy center in which ten patients were infected after the reuse of multidose anesthetic vials [318], as well as numerous other case reports of similar types of exposures, underscores the importance of continued vigilance and strict adherence to infection control measures [319].

Blood transfusions

Post-transfusion hepatitis develops in approximately 10% of individuals and subsequent serologic testing has indicated that at least 85% of cases were due to hepatitis C [295,301]. Patients who received blood transfusions prior to 1992 are considered to be at risk for hepatitis C infection with an odds ratio of 2.6 compared with individuals who did not receive transfusions, and older patients are more likely to have acquired HCV infection as a result of blood transfusions [301]. Overall, it has been estimated that past blood transfusions account for about 10% of cases of chronic hepatitis C.

Rates of non-A, non-B post-transfusion hepatitis were markedly decreased as efforts to improve the safety of the blood supply were sequentially implemented. These included the use of all-volunteer donors, screening of donors for surrogate markers of NANB hepatitis (such as serum ALT activity and markers of hepatitis B infection), testing for human immunodeficiency virus (HIV), and eliciting a history of risk factors for blood-borne infections [295]. Nevertheless, a background rate of transfusion-associated hepatitis remained until 1990 when anti-HCV antibody testing was implemented in the United States, shortly after the discovery of the hepatitis C virus [295]. Later generation antibody assays, more sensitive and specific for hepatitis C, were utilized and eventually screening also included nucleic acid testing which virtually assured the safety of the United States' blood supply [320].

Certain populations of patients requiring multiple transfusions were placed at extraordinary risk for hepatitis C infection prior to adequate donor screening

procedures. The estimated prevalence of anti-HCV among patients with thalassemia ranges between 4.4% and 85%. In a thalassemia registry from North America, 35% of registrants had evidence of hepatitis C infection [321]. Similarly, among patient with sickle cell disease, the prevalence of HCV infection, estimated to be between 10% and 20%, is related to the number of transfusions received [322,323].

The greatest burden of hepatitis C infection is found in patients with hemophilia who received factor concentrates prior to the mid-1980s. Coagulation factor concentrates were derived from pooled plasma, often from thousands of donors, which led to a large number of patients with hemophilia being infected with HIV and HCV. It has been estimated that in the United States 80% of persons with hemophilia during that time period became infected with hepatitis C [324,325]. Viral inactivation procedures such as solvent detergent exposure, nanofiltration, and heat treatment dramatically diminished the risk, while the subsequent availability of recombinant factors has virtually eliminated the threat of blood-borne infections for younger persons with hemophilia [324]. Nevertheless, infection with hepatitis C and progression to advanced liver disease is a leading cause of morbidity and mortality among persons with hemophilia [325–327]. A study from Italy analyzing mortality among a population of patients with hemophilia between 1990 and 2007 attributed 13% of overall deaths to complications related to hepatitis C [328]. Furthermore, the predominant causes of mortality have shifted with the advent of effective therapies for HIV infection. Between 2000 and 2007, more patients with hemophilia died from HCV-related complications than from acquired immune deficiency syndrome (AIDS), underscoring the importance of antiviral therapy for this population [328]. Patients with hemophilia and hepatitis C respond in a similar manner to nonhemophilic populations when treated with interferon-based therapies [329–331].

Sexual transmission

Sexual transmission of hepatitis C occurs rarely and usually is associated with specific cofactors. Early epidemiologic studies demonstrated that individuals with an increased number of lifetime sexual partners (>10) have an increased prevalence of anti-HCV antibody [310]. HCV RNA sequences have been inconsistently isolated from biologic specimens such as semen and vaginal secretions, although direct infection from these sources in humans has not been demonstrated [332,333]. Cases of transmission to heterosexual partners have been reported and HCV phylogenetic analyses have suggested the potential for sexual transmission [334,335]. However, a comprehensive review critically evaluated 80 published studies related to sexual transmission of hepatitis C and concluded that sexual transmission was extremely rare and usually occurred only under special circumstances [336]. Among longitudinal studies of HIV-negative heterosexual couples where the index partner was infected with hepatitis C, there was no increased risk of transmission to partners even after a decade of follow-up [336]. In the few instances of potential sexual transmission, other common source exposures could not be completely excluded. Preexisting sexually transmitted infection, such as herpes simplex type II and trichomonas, appears to increase the risk of HCV acquisition among heterosexual partners [336].

The presence of HIV infection, on the other hand, has regularly been associated with a higher likelihood of sexual transmission of HCV in both heterosexuals and among men who have sex with men (MSM) [336–339]. Recent case reports of acute HCV infection among MSM from Europe suggest that the incidence is increasing [337]. The increased rate of acquisition and transmission of HCV in MSM may be due to higher HCV viral loads associated with HIV infection or other factors such as concomitant high-risk sexual activity [336,338].

Perinatal transmission

Transmission of hepatitis to a neonate from an HCV-infected mother has been extensively investigated in retrospective and prospective studies and has been reviewed [339,340]. The perinatal transmission rate from HCV RNA-positive mothers is estimated to range between 4% and 10% [341]. The rate increases substantially to between 6% and 23% when the mother is coinfected with HIV. An increased risk of perinatal transmission appears to be associated with higher levels of maternal HCV RNA, and this may be the mechanism by which vertical transmission is increased in HIV-positive mothers, although conflicting data have been reported [340,341]. HCV genotype is not associated with differences in the vertical transmission of HCV.

Obstetric procedures such as amniocentesis and invasive monitoring with fetal scalp electrodes have been associated with an increased risk of neonatal transmission, although no specific recommendations regarding these procedures exist due to the limited data [339,340]. There are no randomized trials evaluating the impact of mode of delivery, vaginal versus cesarean, with neonatal infection [342]. However, most observational studies have not shown differences in the rate of perinatal transmission for women with only HCV infection. The European Paediatric Hepatitis C Network enrolled a total of 1,474 HCV-infected women of whom 35% were also infected with HIV [343,344]. In HIV-negative mothers, no effect on mode of delivery or breastfeeding was identified. However, in HIV-coinfected mothers, cesarean section decreased perinatal transmission by 60% and those

breastfeeding were four times more likely to transmit HCV to their child.

Recent recommendations by the Centers for Disease Control [341] established that for women with chronic hepatitis C infection who are uninfected with HIV, no changes to routine delivery and breastfeeding are required. However, for mothers coinfected with HCV and HIV, scheduled cesarean delivery and proscription of breastfeeding (when safe infant formula is available) are recommended in order to diminish the risk of neonatal transmission.

Occupational exposure in health care providers

The prevalence of hepatitis C infection in health care providers is similar to that in the general population in the United States, indicating that occupational exposure is not a major risk factor for transmission [345,346]. The likelihood of acquiring hepatitis C from a needlestick injury from an HCV-infected patient is estimated to be approximately 2%. Rare cases of blood splash exposure have been reported. A larger inoculum is associated with a higher risk of transmission, and injuries with hollow-bore needles transmit HCV more frequently than solid instruments. Similarly, higher levels of viremia of $>10^6$ copies/mL are also associated with an 11-fold higher risk of transmission compared with levels of $<10^4$ copies/mL [346]. Health care workers who sustain a needlestick injury from an index case with hepatitis C should be reassured about the low rate of infection. There is no role for postexposure prophylaxis [347]. Baseline liver enzymes and anti-HCV antibody should be obtained immediately and follow-up testing performed at 1, 3, and 6 months [348,349]. The absence of HCV RNA in the needlestick recipient using a sensitive polymerase chain reaction (PCR)-based assay at 4 and 8 weeks of exposure can further reduce the anxiety associated with accidental exposure [348–350]. Patients with evidence of acute infection should be followed to determine if spontaneous resolution will occur or be treated within 12–16 weeks after infection in order to maximize the chances of cure (see the section on acute hepatitis C).

Diagnosis and testing

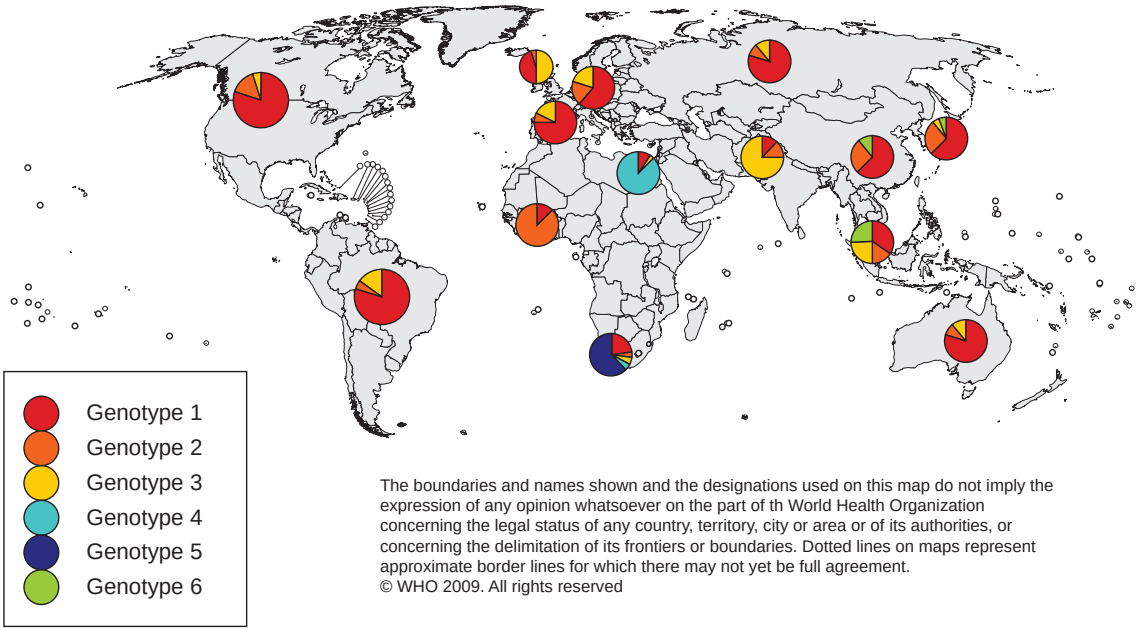
The clinical validation of the first anti-HCV antibody assay was reported by Harvey Alter and colleagues in 1989 [351]. All patients with post-transfusion chronic NANB hepatitis seroconverted for anti-HCV with a mean delay of 22 weeks after transfusion. The anti-HCV antibody was detected in 88% of the donor serum implicated in the transmission of NANB hepatitis in these patients, while surrogate markers for blood-borne pathogens used for blood donor screening at the time – elevated serum ALT activity and anti-hepatitis B core (anti-HBc) antibody – were detectable in only about 50% of donors. Numerous seroepidemiologic studies confirmed that anti-HCV was an important diagnostic marker for hepatitis C infection and transmissibility of infected blood products [291,352,353].

A positive anti-HCV antibody is a marker of past or current infection with hepatitis C. A single fusion polypeptide, designated C-100, derived from the NS4 nonstructural region of HCV formed the basis for the first-generation anti-HCV enzyme-linked immunosorbent assay (ELISA), which was licensed in 1990 [353,354]. The reliance on only one target antigen produced false-negative and false-positive results. Subsequent generations of assays have incorporated antigens from additional regions of the HCV genome, including NS3 and NS5, which improved the sensitivity and specificity of the anti-HCV antibody assay [355]. Furthermore, these refinements shortened the duration from exposure to detection of anti-HCV seroconversion to less than 3 weeks [356]. Therefore, the anti-HCV antibody by enzyme immunoassay (EIA) remains the best screening test for the diagnosis of hepatitis C, and current assays have a specificity of >99% [354].

False-negative anti-HCV antibody testing may rarely occur in severely immunosuppressed patients, patients with agammaglobulinemia, and patients on hemodialysis [296]. Nucleic acid testing for HCV RNA should be performed in these populations when patients have unexplained aminotransferase abnormalities with a negative anti-HCV. Despite an excellent specificity, false-positive EIA results may also occur, particularly among populations with a low prevalence of HCV infection such as volunteer blood donors. Signal to cutoff ratios of >4.0 are highly associated with true exposure to hepatitis C infection and additional serologic testing is not routinely recommended, although nucleic acid testing to demonstrate viremia is important [354]. When signal to cutoff ratios are low, supplemental testing with a recombinant immunoblot assay (RIBA), which assesses the reaction of a patient's sera to multiple HCV antigens, may assist with diagnosis. A positive anti-HCV antibody supplemented with a positive RIBA (positive reaction to two or more HCV antigens) indicates a true past or present infection with HCV. A negative RIBA indicates a false-positive anti-HCV antibody test without HCV infection and the patient may be reassured without further evaluation of HCV [354]. An indeterminate RIBA may occur in the earliest stages of infection or in association with a false-positive screening antibody. Patients with an indeterminate RIBA should have another serologic test performed at least 1 month later, along with consideration of nucleic acid testing for HCV RNA (Table 25.1).

Table 25.1 Interpretation of diagnostic tests for hepatitis C infection.

Anti-HCV	RIBA	HCV RNA	Interpretation	Action
+	+	Detectable	Current HCV infection	Evaluate for chronic liver disease, test HCV genotype
+	+	Undetectable	Past HCV infection with spontaneous or treatment-induced viral clearance	Repeat HCV RNA testing in 3–6 months to confirm absence of viremia
+	–	Undetectable	False-positive anti-HCV	No further follow-up for HCV required
+	Indeterminate	Undetectable	Likely false-positive anti-HCV, particularly in patients without risk factors	Repeat HCV RNA testing in 3–6 months to confirm absence of viremia



HCV, hepatitis C virus; RIBA, recombinant immunoblot assay.

Nucleic acid testing for hepatitis C using highly sensitive assays is of critical importance for confirming persistent viremia in chronic infection and for assessing the response to antiviral therapy. Qualitative assays detect only the presence or absence of HCV RNA in plasma or serum, while quantitative assays provide a measurement of the amount of virus per unit of volume. Historically, HCV RNA assays were inconsistent in their results, with widely varying sensitivities and specificities leading to false-positive and -negative results [357]. Clinical specimens also require careful sample handling to avoid degradation of HCV RNA. The WHO developed guidelines and standards for HCV RNA assays that included utilizing the international unit per milliliter as the only recognized unit of measurement, incorporating an internal standard or external validation method into commercial assays, and defining acceptable levels of sensitivity and reproducibility of results [358]. These requirements enabled greater confidence in the results of commercial assays for diagnostic and therapeutic purposes and greatly advanced the management of patients with chronic hepatitis C.

HCV nucleic acid analysis relies on either amplification of the detection signal or amplification of the nucleic acid target [358]. The branched DNA method of signal amplification detects HCV RNA with a lower limit of quantification of 615 IU/mL [358,359]. This level of sensitivity is generally inadequate for measuring response to antiviral therapy where the goal is viral eradication. Thus, the most frequently utilized commercial qualitative and quantitative assays rely on target amplification, either by transcription-mediated amplification (TMA) or by reverse transcription polymerase chain reaction (RT-PCR), which provides a much higher sensitivity and a broad dynamic range [358]. One qualitative TMA assay (Versant®, Siemens) provides the lowest level of HCV RNA detection of 10 IU/mL. Other qualitative assays using RT-PCR methods have a lower limit of detection of 50 IU/ml (Amplicor v2.0® and Cobas v2.0®, Roche). Any of these are adequate for determining the presence or absence of HCV RNA in untreated hepatitis C infection.

Early quantitative assays were substantially less sensitive than qualitative assays for detecting viral nucleic acid, and at times a combination of both types of assays were required to determine sustained virologic response. However, technologic advances have obviated the need for multiple assays, although limitations still exist regarding precise quantitation at high viral levels or with certain genotypes [360,361]. There are several important features of quantitative assays to consider, particularly with response-guided treatment algorithms (discussed below). The dynamic range of quantification defines the lower and upper limits of quantification for the assay. A broader dynamic range allows for better quantification of HCV RNA at the highest levels of viremia prior to initiation of treatment. The broadest dynamic ranges are seen in assays using real-time RT-PCR methodology (COBAS TaqMan®, Roche; and Abbott) where the upper limit of quantification is 10^7 IU/mL [358]. More important is defining the lowest level at which HCV RNA is measured. The lower limit of quantification (LLQ) refers to the lowest level of HCV RNA that can be confidently, reproducibly quantified by the assay. The lower limit of detection (LLD) is the lowest level at which an assay will detect the presence of any viral nucleic acid, although below the threshold for which assignment of a numeric value is possible. Assays should have similar thresholds of LLQ and LLD. Real-time RT-PCR assays provide the best LLQs (ranging between 12 and 43 IU/mL) and LLDs (12–15 IU/mL). There is ongoing debate about the relevance of LLQs versus LLDs in the era of direct acting antiviral agents and their clinical significance for treatment response requires further study [362].

Hepatitis C is a heterogeneous virus with at least six major genotype and multiple subtypes that have a varied geographic distribution (Fig. 25.7) [363]. Genotype 1 is the

Figure 25.7 Geographic distribution of HCV genotypes. (Reproduced from WHO 2009 with permission.)

most common genotype around the world and accounts for approximately 75% of infections in the United States [364]. The remaining infections in the United States are usually genotype 2 (14%) or genotype 3 (8%) [364]. Recently, a high prevalence of genotype 3a has been identified in injecting drug users in Europe although genotype 3 is also an important infection in Pakistan. Genotype 4 is most common in the Middle East, particularly in Egypt. Genotypes 5 and 6 are most prevalent in South Africa and Southeast Asia, respectively [363].

The HCV genotype forms the basis for recommendations regarding the duration of treatment with pegIFN and ribavirin, and correct classification has important prognostic implications for therapy. The gold standard for HCV genotyping is direct sequencing of an HCV genomic region, such as NS5B or core/E1 [359,365]. While considered to be the most accurate method and the most precise for subtyping, direct sequencing is labor intensive and requires a high degree of technical expertise such that it is not practical for clinical use. Several commercial genotyping assays are available that focus on the highly conserved 5′ UTR of the HCV genome. The line probe reverse hybridization assay (Versant HCV LiPA®, Bayer) is the most widely used method for HCV genotyping. PCR products from amplification of the 5′ UTR are hybridized to a membrane containing genotype-specific probes and the pattern of hybridization bands determines the HCV genotype [365]. Early versions of this assay could not reliably differentiate genotype 1 from genotype 6, nor provide accurate differentiation of the most common subtypes. A second generation LiPA assay adds sequences from the HCV core region to improve differentiation of genotypes and subtypes. TRUGENE® 5′ NC genotyping is a sequenced-based assay directed at the 5′ UTR and results correlate well with LiPA and other assays that utilize the 5′ UTR region [365]. Accurate subtyping (1a versus 1b) will become more important with direct-acting antiviral agents since the development of viral variants to protease inhibitors appears to be more frequent in genotype 1a than in 1b.

Since most patients with chronic hepatitis C are asymptomatic, the diagnosis and management of hepatitis C relies on applying the aforementioned serologic and nucleic acid tests to individuals with risk factors for HCV or evidence of chronic liver disease [366]. Thus, health care providers should routinely inquire about potential risk factors for the acquisition of hepatitis C and test their patients accordingly. Epidemiologic studies in the United States have demonstrated that the majority of people infected with hepatitis C (~85%) had at least one of three characteristics noted: abnormal serum ALT activity, a history of intravenous drug use, or a history of blood transfusion. Targeting any of these risk factors would identify most cases of hepatitis C infection (Table 25.2) [301].

When patients with HCV infection are identified, health care providers should counsel patients about measures to decrease the risk of HCV transmission [296]. Persons infected with hepatitis C should avoid sharing toothbrushes or shaving equipment and keep bleeding

Table 25.2 Recommendations for testing for hepatitis C virus (HCV) infection.

Testing required	Testing not routinely required
Persons who have at any time injected illegal drugs regardless of number of events	Health care, emergency medical, or public safety workers
Persons who received a transfusion or organ transplant before July 1992	Pregnant women
Persons who received clotting factor concentrates before 1987	Household contacts
Persons who were at any time on long-term hemodialysis	General population
Persons with persistently abnormal alanine aminotransferase levels	
Persons with needlestick, sharp, or splash exposure to HCV-positive blood	
Children born to an HCV-positive mother	
Sexual partners of HCV-infected patients	

wounds covered to prevent others from contact with their blood. HCV-infected patients should not donate blood, body organs, other tissues, or semen. Patients should be reassured that the risk of sexual transmission is low and modifying sexual practices within monogamous relationships is not required [296].

Natural history

Acute hepatitis C virus infection

Acute infection with HCV is asymptomatic in the majority of individuals, with only a minority seeking medical attention. HCV RNA in the serum is the first evidence of infection and is usually detectable 7–21 days after exposure [367]. The titer of the HCV inoculum is negatively associated with time to detection of virus in the serum [368]. HCV-specific antibodies are detectable 20–150 days postexposure (average 50 days) even when using the third generation assays [369,370]. If there is a high clinical index of suspicion for acute HCV infection, an HCV RNA should be obtained in the absence of detactable anti-HCV antibody. Serum aminotransferases increase 4–12 weeks postexposure and can range from mildly elevated to >1,000 U/L. Jaundice occurs in less than 20% but this clinical sign may be associated with higher rates of spontaneous clearance [369,371]. Symptoms of acute HCV infection are similar to other forms of viral hepatitis and include malaise, fatigue, myalgias, nausea, and right upper quadrant pain. This clinical syndrome can persist from days up to 12 weeks, especially with acute icteric disease [372]. Fulminant presentation is rare in acute hepatitis C infection unless other underlying chronic liver disease is present. HCV RNA levels may fluctuate dramatically during acute infection, ranging from very high to undetectable. Following successful therapy for acute hepatitis C infection, a marked decline in anti-HCV antibodies is seen post-treatment [373]. In those who spontaneously clear HCV, one study found that 42% had no detectable anti-HCV antibodies two decades postexposure although HCV-specific memory T cells were recoverable from the peripheral blood [214].

While spontaneous clearance of HCV is possible, the risk of developing chronic infection is the highest for any hepatotropic viral infection. The mechanism by which the virus evades immune recognition and establishes a foothold is further discussed in the section on HCV pathogenesis. In earlier cohort studies of blood donors, transfusion recipients, and injection drug users, chronicity rates of 76–86% were reported, although selected populations may have lower rates of chronicity [374–376]. Children who received infected blood products developed chronicity in 55–71% of cases [377,378]. Likewise, only 55% of young women who received HCV-contaminated anti-rhesus D immunoglobulin in Ireland and Germany developed chronic infection [379,380]. Female injection drug users also have higher rates of spontaneous clearance when compared with males [381]. Therefore, gender and age at the time of acquisition of HCV are important factors associated with chronicity versus clearance.

Host, viral, and environmental factors have been associated with the likelihood of viral resolution or chronicity. Selected polymorphisms near the *IL28B* gene, which encodes for interferon-λ3, are strongly tied to both spontaneous and treatment-induced viral clearance [145,146,382]. In one study, the presence of the CC haplotype at rs12979860 was associated with a spontaneous clearance rate of approximately 55% compared with only 16–20% in those with the TT haplotype [146]. The frequency of spontaneous HCV clearance varies markedly across ethnic groups [383] and may be partly explained by the differences of allele frequency of this *IL28B* polymorphism among different populations. The global frequency of the favorable allele for HCV clearance is highest in East Asia, intermediate in Europe, and lowest in Africa [145,146]. This likely explains at least part of the discrepancy in spontaneous clearance rates observed between Caucasians at 36.4% and African-Americans at 9.3% in a large, US-based study of injection drug users [376].

The association with *IL28B* genotype, clinical presentation, and viral clearance was further refined by evaluating German women who had been exposed to HCV genotype 1b through contaminated anti-D immunoglobulin [384]. The spontaneous clearance rate in women with the CC genotype was 64.2% and was not significantly associated with jaundice. Interestingly, of those with the CT genotype, 50% with jaundice cleared infection spontaneously while <20% did so in the absence of jaundice. The clearance rate in the TT group was low regardless of clinical presentation [384]. This study suggests that the association between jaundice and viral clearance in acute infection differs according to *IL28B* genotype. A more vigorous innate immune response in those with the CC genotype may enable viral clearance without the cell-mediated injury associated with jaundice in acute HCV infection. Other immunologic factors associated with spontaneous viral clearance included carriage of the class I HLA B57 allele as well as the class II alleles HLA DRB1 and DQB1 [385–387]. Spontaneous viral clearance at low infectious doses has also been tied to low inhibitory NK-cell responses associated with homozygosity for HLA-C1 and KIR2DL3 [168]. When injection drug users were followed prospectively for HCV viremia, those who had been previously exposed to HCV and cleared infection (HCV antibody-positive and RNA-negative) were 12 times less likely to develop persistent HCV infection than those infected for the first time [278].

Viral coinfection and alcohol consumption are additional factors that influence spontaneous viral clearance. In one study conducted in US Veterans, alcohol and HIV coinfection negatively impacted spontaneous HCV clearance during primary infection, while HBV coinfection was positively associated with HCV clearance [388]. Patients with HIV coinfection are less likely to spontaneously clear acute HCV infection, as are those with heavy alcohol use [371,376,388]. Size of inoculum, mode of acquisition, and viral genotype have not been consistently linked to viral clearance although genotype 3 may have a higher spontaneous clearance rate [389].

Chronic hepatitis C virus infection

Most patients who present with chronic HCV infection are completely asymptomatic [390]. The most common but least specific complaint is fatigue and this may improve with successful treatment of HCV [390–392]. Other symptoms include myalgias, arthralgias, nausea, anorexia, and decreased concentration [390,391]. In one study, patients with histologically mild HCV infection were noted to have cognitive impairment and specifically decreased concentration and speed of working memory when compared with patients who had cleared HCV infection [393]. This was independent of depression or drug abuse history. Several studies have noted lower quality of life scores with the diagnosis of chronic HCV that are independent of disease severity [394–397]. Longitudinal studies reassessing these parameters following successful treatment have not been conducted. Symptoms related to extrahepatic manifestations of chronic HCV infection can occur and are discussed in a separate section. Once cirrhosis develops, patients may have more overt symptoms including worsening fatigue, fluid retention, confusion from encephalopathy, or gastrointestinal bleeding [390].

Serum aminotransferases fluctuate over time in patients with chronic HCV and up to one third will have a persistently normal ALT activity [398]. Most have levels 1.5–3 times the upper limit of normal, rarely more than ten-fold elevated. Unfortunately, aminotransferase levels do not serve as an accurate surrogate for liver histology [399–401]. Patients with persistently normal activity may have evidence of inflammation and fibrosis on liver biopsy although it may be milder with attenuated progression [372]. Markedly elevated ALT (more than ten-fold) correlates with piecemeal necrosis on biopsy and an aspartate aminotransferase (AST) : ALT ratio of >1 may correlate with histologic cirrhosis [399,402,403]. Likewise, during chronic HCV infection, viral load fluctuations of about 1 log are common but viral load does not correlate with disease severity in immunocompetent hosts. Hence, liver biopsy remains the most accurate measurement of disease activity and severity in chronic HCV (see histology section).

In those who develop chronic HCV infection, disease progression is quite variable, with only a portion developing serious complications including cirrhosis or hepatocellular carcinoma (HCC). Natural history studies of HCV are tempered by which population is studied and for how long. Few studies go beyond 20 years and most are cross-sectional. Unfortunately, the onset of hepatitis C infection is usually silent and its course prolonged, making natural history studies difficult. Likewise, multiple host and environmental factors affect HCV progression rates (discussed below).

Cirrhosis estimates over a 20-year period vary from 4% to 24% depending upon the group evaluated. Healthy blood donors found to have HCV developed cirrhosis at a rate of about 4% (95% CI, 1–7%) over 20 years, while a post-transfusion cohort had a 24% (95% CI, 11–37%) rate of cirrhosis development over the same period. Similarly, a community-based series had a 20-year cirrhosis rate of 7% (4–10%) while patients referred to liver clinics had a mean frequency of cirrhosis of 22% (18–26%) [404,405]. A systematic review of 111 studies evaluating the natural history of HCV estimated the cirrhosis prevalence at 16% after 20 years of infection [406]. While cross-sectional analyses may provide an estimate of fibrosis progression in chronic HCV infection, paired biopsy studies are the

most accurate way to assess fibrosis progression. In five paired biopsy studies, progression of at least one fibrosis stage was seen in 27–41% with average follow-up periods of 2.2–6.5 years [407–411]. These data support the practice of considering a repeat staging biopsy at various intervals in the setting of chronic HCV infection.

The development of cirrhosis is often clinically silent but physical examination and laboratory values may be helpful in diagnosing this stage of disease [412]. Spider angiomata, palmer erythema, and splenomegaly may be present on exam with blood tests revealing decreased albumin, elevated bilirubin, or decreased platelet count from portal hypertension [413]. Unlike in chronic hepatitis B infection, only chronic HCV patients with advanced fibrosis or cirrhosis are at increased risk of developing HCC. The risk for the development of HCC in the setting of chronic HCV infection is about 3% per year (1–7%) [414–416]. Older age, male sex, African-American race, and obesity as well as steatosis and diabetes are independent risk factors for HCC development in the setting of HCV cirrhosis [417–422]. Screening for HCC using abdominal imaging should be instituted in all HCV patients with advanced fibrosis or cirrhosis [423]. α-Fetoprotein (AFP) is used to assist in the diagnosis of HCC but is a poor screening test for the detection of HCC in the setting of chronic HCV. In a large cohort of American patients with chronic HCV who had advanced fibrosis or cirrhosis, baseline AFP levels were >20 ng/mL in 16.6% in the absence of HCC [424]. Higher AFP levels were seen in cirrhotics, women, and African-Americans [424]. Serum AFP levels correlated strongly with serum ALT, AST, and the degree of hepatic inflammation on liver biopsy, suggesting that AFP production is enhanced in the presence of injury, possibly resulting from increased hepatocyte turnover. Also, a third of the patients in this study who developed HCC did not have an AFP level >20 ng/mL.

Once a patient with chronic HCV has developed cirrhosis, the risk of decompensation of their liver disease is about 4% per year. The most common decompensation events include the development of ascites, followed by variceal bleeding and encephalopathy [425]. This is based on a study of 384 patients with compensated cirrhosis from HCV infection who were followed over time. From this same cohort, the 3-, 5-, and 10-year survival rates of compensated HCV cirrhosis were 96%, 91%, and 79%, respectively. Unfortunately, once a patient has developed decompensation, the 5-year survival falls to around 50% without liver transplant (Fig. 25.8) [425,426]. For this reason, patients with cirrhosis should be referred for

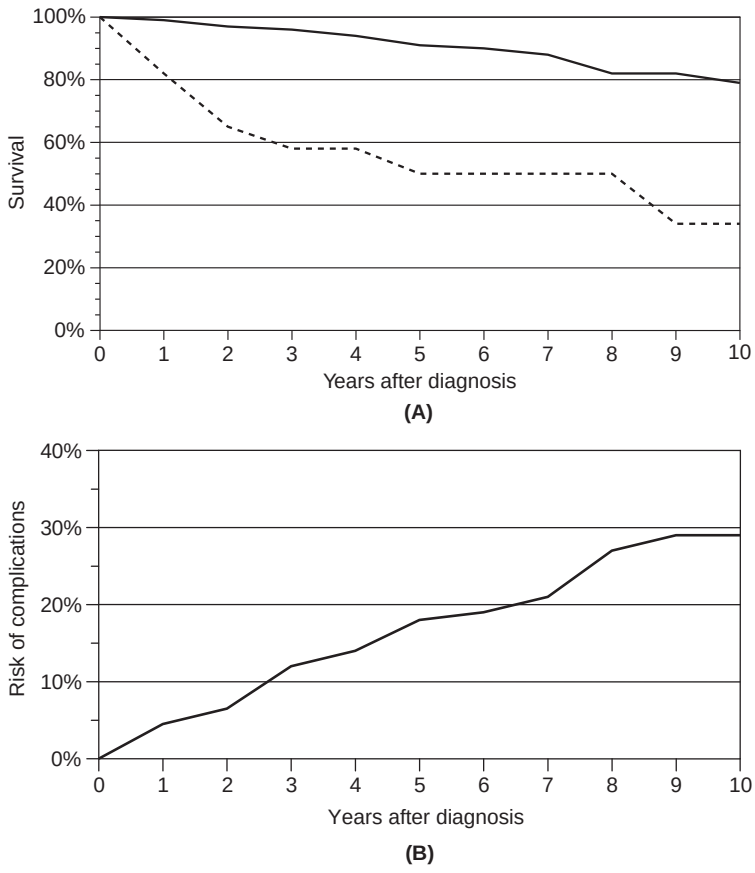

Figure 25.8 (A) Survival in patients with cirrhosis due to chronic hepatitis C. Effect of complications and decompensation. Solid line, compensated cirrhosis; dashed line, decompensated cirrhosis. (B) Risk of developing decompensated liver disease among patients with stable cirrhosis due to chronic hepatitis C. (Reproduced from Fattovich et al. [425] with permission from Elsevier.)

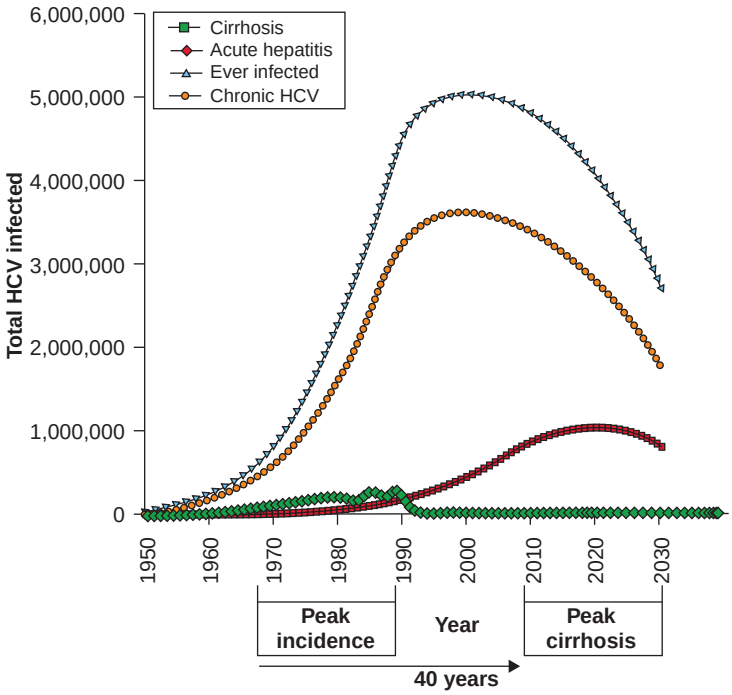

Figure 25.9 Estimates by year of prevalent cases of cirrhosis, acute hepatitis, and chronic hepatitis C virus (HCV), and ever infected cases. Peak prevalence of HCV infection was in 2001 while the highest prevalence of cirrhosis is projected between 2010 and 2030. (Reproduced from Davis et al. [297] with permission from Elsevier.)

transplantation when they experience their first major complication of cirrhosis (ascites, variceal bleeding, or hepatic encephalopathy) or when they develop evidence of hepatic dysfunction (Child–Pugh score >7 or model for end-stage liver disease (MELD) score >10) [427]. HCV cirrhosis is currently the leading cause for liver transplantation in the United States. While recurrent HCV in the graft is universal unless the patient has a treatment-induced cure prior to transplant, long-term outcomes are similar to other etiologies [428]. The majority of patients transplanted for HCV-related cirrhosis or HCC will have minimal injury with HCV recurrence, but up to 30% will have progressive disease leading to cirrhosis by 5 years post-transplant [429]. Also, less than 5% will have severe recurrence of HCV associated with cholestasis and aggressive fibrosis (whose features are described in the histology section). Recurrent HCV post liver transplant and risk factors for progressive disease are further discussed elsewhere in this volume.

Death certificate data indicate that HCV-related mortality has increased substantially since 1995, especially in persons 45 years and older, with the most significant increases in males and non-Hispanic blacks [430]. It has now become an important cause of premature mortality due to the relatively young ages of those dying from HCV-related deaths [430]. As previously mentioned, few natural history studies go beyond 20 years and modeling is the best way to assess the long-term impact of HCV infection. A multicohort natural history model of HCV infection published in 2010 projected that the proportion of US patients with cirrhosis from chronic HCV will peak at around 1 million in 2020 and reach 45% of those infected by 2030 (Fig. 25.9) [297]. Hepatic decompensation and HCC will continue to increase over the next decade with those older than 60 years being most affected. The projected peak for HCV-related HCC is 2019, at about 14,000 cases. Interestingly, the authors noted that antiviral therapy could significantly alter disease end-points from a population perspective. Based on their model, treatment of all infected patients in 2010 could reduce the risk of liver-related deaths by 36% in 2020, reinforcing the need for more aggressive HCV diagnosis and treatment [297].

Factors linked to disease progression

Host, viral, and environmental factors are associated with progressive fibrosis and cirrhosis. Acquisition of HCV infection after the age of 40 is associated with more rapid progression of liver injury [404,431]. In addition, duration of infection and advancing age are risk factors for cirrhosis, perhaps due to decreased regenerative capacity and waning immunity in an older liver [432]. Fibrosis progression is not linear and some models suggest that the risk of fibrosis progression increases with age [433]. Males are 2.5 times more likely to develop cirrhosis and HCC when compared with females [431]. Since this risk is independent of alcohol consumption and body mass index, estrogens may have some protective affects against fibrosis development [434,435]. Interestingly, African-Americans have a three times higher risk of developing HCC when compared with Caucasians [436], yet other studies have

found a slower histologic progression rate and lower ALT levels [437,438]. The cause of this discrepancy is unclear. Several studies have found an association between the degree of inflammation on liver biopsy and the rate of fibrosis progression over time [439,440]. Patients who have moderate to severe inflammation on biopsy may have an accelerated rate of fibrosis [432].

Liver iron accumulation is a common finding on biopsy in chronic HCV regardless of HFE genotype (see histology section below) [441]. Both iron storage and HFE mutations have been associated with fibrosis and, more specifically, risk for severe fibrosis [442–445]. For those without HFE mutations, iron accumulation is usually mild and is reflected by elevated serum ferritin levels [446]. Increased hepatic iron may also contribute to increased inflammatory activity and progressive fibrosis in HCV infection [446,447] including observations from a small longitudinal study [448]. An improvement in histologic activity index (HAI) and reduction in aminotransferase levels have been observed after phlebotomy in patients with chronic HCV [449,450]. Hepatic iron may play a part in hepatic injury via the production of oxygen-derived free radicals. Lower responses to interferon therapy have also been correlated to increased stainable iron in the liver, but unfortunately phlebotomy pretreatment has minimal effect on antiviral response [449,451,452].

As discussed in the histology section, steatosis is a common finding on liver biopsy in patients with chronic HCV, with the majority having at least mild steatosis (<30%) [453]. This feature is important from both an etiologic stand point as well as for its clinical significance. Patients with genotype 3 HCV have virally associated steatosis that correlates with HCV titers and resolves with successful antiviral therapy [454]. Steatosis in patients with genotype 1 infection is associated with components of the metabolic syndrome. Obesity, diabetes, and insulin resistance (as well as excess alcohol intake) have all been linked to hepatic steatosis in patients with chronic HCV. Interestingly, African-American patients with HCV genotype 1 infection have a lower prevalence of hepatic steatosis than Caucasians in a large US-based study [455].

Hepatic steatosis as well as superimposed steatohepatitis are important risk factors for fibrosis progression in chronic HCV infection [456–459]. Metabolic steatosis appears to be a common cofactor for increasing liver necroinflammatory activity and accelerating fibrosis in chronic HCV infection [457]. Steatosis negatively impacts on response to antiviral therapy and increases the risk of developing HCC by 2.8-fold [421,460]. Obesity is also a metabolic risk factor for the development of HCC in the setting of chronic HCV infection. In a study of 1,431 HCV patients followed for up to 10 years, the risk of HCC increased in proportion to body mass index with obese patients (hazard ratio 3.10) being at higher risk than overweight patients (hazard ratio 1.86) [418]. Likewise, insulin resistance is associated with steatosis in genotype 1 infection even in the absence of overt diabetes [461]. Diabetes and insulin resistance are strongly associated with advanced fibrosis in genotype 1 infection. One group demonstrated that diabetic patients were twice as likely to have advanced fibrosis (60%) compared to those with insulin resistance without overt diabetes (30%) [462]. In population-based studies, diabetes carries a two to threefold increased risk of HCC independent of other factors [422] and this has been confirmed in patients with chronic HCV infection [420].

While viral factors such as genotype, viral load, and quasispecies have not been consistently linked to outcome, coinfection with other viruses or parasites may influence disease course in chronic HCV infection (Table 25.3). Dual infection with hepatitis B can result in faster progression to cirrhosis although one virus usually predominates [463,464]. Coinfection with schistosomiasis and HCV, which is common in Egypt, is associated with more aggressive fibrosis than HCV infection alone [465]. In the era of highly active antiretroviral therapy (HAART), end-stage liver disease has emerged as a serious cause of morbidity and mortality in patients with HIV, with chronic HCV being the causal agent in the

Table 25.3 Factors associated with increased disease progression in chronic hepatitis C infection.

Host factors	Viral factors	Environmental factors
Older age at acquisition	Coinfection with HBV	Alcohol intake >50 g/day
Duration of infection	Coinfection with HIV	Regular marijuana use
Male gender		
Obesity		
Hepatic steatosis		
Insulin resistance		
Hepatic iron overload

majority [466]. Coinfection with HIV in the setting of chronic HCV may have markedly elevated HCV RNA levels and carries a two to five-fold increased risk of advanced fibrosis or cirrhosis [467–469]. In one study, the median time to cirrhosis for HCV/HIV coinfected patients was 26 years (95% CI, 22–34 years), while a matched cohort of HCV-monoinfected patients had a mean time to cirrhosis of 38 years (95% CI, 32–47 years) [470]. The severity of HIV disease may also identify patients with the highest risk of HCV progression, such as those with low CD4 counts or detectable HIV viral load [471–473]. Most data regarding accelerated fibrosis in the setting of HIV were collected pre-HAART. Multiple studies have now shown a beneficial effect of HAART on progression of liver disease in the setting of HCV/HIV coinfection, including a decrease in liver-related mortality [470,474,475].

Heavy alcohol consumption (>50 g/day) is clearly associated with accelerated fibrosis and cirrhosis in chronic HCV patients. In a meta-analysis evaluating more than 15,000 people with chronic HCV infection, the pooled relative risk of cirrhosis development with heavy alcohol intake was 2.33 (95% CI, 1.67–3.26) [476]. In this study, heavy alcohol use was defined as 210–560 g/week or 2.3–5.6 drink equivalents per day. Interestingly, the effects of HCV and alcohol intake at 50 g/day appear to be additive in their profibrogenic effects on the liver, but at >125 g of alcohol per day the effects on the liver are synergistic [477]. Light or moderate alcohol intake and its effect on HCV fibrosis is more controversial. In a study of 800 HCV patients undergoing liver biopsy, alcohol intake was evaluated as none, light, moderate, or heavy. Only a consumption of >50 g/day had an association with fibrosis, not lesser amounts [478]. As there continues to be a paucity of conclusive information linking light or moderate alcohol use with accelerated fibrosis in HCV, it is recommended that those with HCV either abstain from alcohol or limit alcohol intake to two drinks per day for men or one drink per day for women [479]. In addition to alcohol consumption, other external factors may play a role in fibrosis progression in the setting of chronic HCV. Daily marijuana use has been associated with more rapid hepatic scarring [480,481], while daily coffee consumption may decrease risk of fibrosis progression [482,483].

Extrahepatic manifestations

While HCV infection is most often thought of as a liver disease, some have advocated that it should be considered a systemic disease. Chronic HCV has been associated with numerous extrahepatic manifestations [484]. The list of possible associations is long, but those strongly associated with HCV have been proven based on pathogenic and epidemiologic data. Small studies with inadequate controls or selection bias are often misleading. For those complications where the pathogenesis is virally mediated, HCV therapy is the treatment of choice to alleviate symptoms (see HCV treatment section below).

B-cell lymphoproliferative disorders, which include essential mixed cryoglobulinemia and non-Hodkin lymphoma (NHL) are the best studied of the extrahepatic HCV disorders. Cryoglobulins found in patients with chronic HCV are primarily mixed cryoglobulins type II or III. The key components in this form of cryoprecipitate are monoclonal or polyclonal IgM rheumatoid factor and polyclonal IgG directed against HCV viral antigens [485]. While cryoglobulins can be detected in up to 50% of chronic HCV patients [486], only about 5–10% manifest symptoms consistent with a small- to medium-vessel vasculitis. The hallmark of mixed cryoglobulinemia syndrome is the clinical triad of weakness, arthralgias, and palpable purpura, which usually involve the lower extremities [487]. Peripheral neuropathy is also commonly seen as well as Raynaud phenomenon, sicca syndrome, and membranoproliferative glomerulonephritis. All patients with chronic HCV should be questioned about symptoms of mixed cryoglobulinemia, and if present cryocrit, rheumatoid factor, and urinalysis should be performed.

Sequencing of the antigen recognition region of the immunoglobulin heavy chain on B cells from liver, peripheral blood, and bone marrow from patients with chronic HCV infection has shown that oligoclonal expansion of B cells, specifically within the liver, is highly associated with mixed cryoglobulinemia [488]. It is likely that B-cell clones begin expanding in the liver and circulate to other compartments. Since mixed cryoglobulinemia syndrome is clearly virally mediated, a trial of HCV treatment is usually warranted unless multiorgan involvement precludes it. Mixed cryoglobulinemia can also be associated with a bcl-2 rearrangement and may evolve into a frank B-cell NHL in 8–10% [489]. Interestingly, B cells harboring this mutation regress after successful viral clearance [490]. Sustained activation of B cells through host and viral mechanisms may lead to successive mutational events eventually driving the lymphoproliferative disorder towards independence from viral stimulation.

Even in the absence of overt mixed cryoglobulinemia, HCV infection has been associated with the development of B-cell NHL [491–493] as well as primary hepatic lymphoma [494]. A meta-analysis of 48 studies found the prevalence of NHL in HCV patients was 15% compared with about 1.5% in the general population [491]. For low-grade lymphomas, a trial of antiviral therapy is often indicated. Monoclonal gammopathy, usually monoclonal gammopathy of undetermined significance (MGUS), is another HCV-associated lymphoproliferative disorder most often seen with genotype 2 in patients over the age of 60 years [495,496].

There are several dermatologic conditions associated with HCV including leukocytoclastic vasculitis, which is by far the most common manifestation of mixed cryoglobulinemia (Fig. 25.10A). Porphyria cutanea tarda (PCT) is a skin disorder associated with decreased levels of hepatic uroporphyrinogen decarboylase activity (Fig. 25.10B). Clinically, it is characterized by photosensitivity, skin fragility, and vesicles or bullae that are often hemorrhagic. There is a strong association between the sporadic form of PCT and chronic HCV infection [497]. PCT can be "triggered" by HCV infection in genetically predisposed individuals but does not appear to be a direct result of the virus. Iron overload also plays an important role in the pathogenesis of PCT and iron levels should be checked in these patients. Likewise, phlebotomy should be undertaken prior to antiviral treatment as many symptoms improve with iron depletion alone and can be made worse with ribavirin-induced hemolysis [498]. Lichen planus is a mucocutaneous disease with a predominance of CD4+ T cells on biopsy. Up to 27% of oral lichen planus patients are HCV-positive and HCV RNA has been isolated from mucous membrane biopsies supporting this association (499) [499,500]. Lichen planus may actually worsen on interferon therapy, possibly due to increased stimulation of cell-mediated immunity. Necrolytic acral erythema results in pruritic, psoriasis-like skin lesions in an acral distribution on the dorsal side of hands and feet. HCV antibodies were found in all 30 patients who presented with this disorder in one series [501]. Some reports confirm improvement with antiviral therapy as well as with the treatment of zinc deficiency [502].

A high prevalence of type 2 diabetes mellitus has been observed in patients with chronic HCV independent of liver disease [503,504]. While risk factors such as older age, obesity, advanced fibrosis, and family history may play a role [504], this association has been somewhat difficult to reconcile with the virus. Insulin resistance without overt diabetes has been associated with fibrosis progression and high HCV RNA [505,506]. The most compelling argument for a viral association is that the risk of diabetes development decreases with successful response to antiviral therapy [507,508].

Histology

Liver biopsy remains an important part of the evaluation of patients with chronic HCV infection. It provides confirmation of diagnosis based on characteristic features, exclusion of other liver diseases, and assessment of grade and stage of disease. Histologic features beyond the stage of fibrosis such as steatosis or iron deposition may also have predictive value in disease progression and efficacy of antiviral therapy. Assessment of these should be routinely requested as part of the staging liver biopsy pathology report.

Of all the histologic features of chronic HCV, the most characteristic are prominent lymphoid aggregates, steatosis, and bile duct damage. While these features may be seen in chronic hepatitis B or autoimmune hepatitis, they are more frequently observed in biopsies from patients with chronic HCV [453]. Lymphoid follicles are seen in about 60% of liver biopsies from chronic HCV patients [453]. Immunohistochemical studies have shown that these lymphoid follicles are comprised of B cells surrounded by a T-cell zone [509]. There is growing evidence that these lymphoid follicles contain true germinal centers where B cells are activated and undergo differentiation, clonal selection, and proliferation, presumably in response to local antigens [510, 511]. Oligoclonal expansion of B cells, specifically within the liver, is highly associated with mixed cryoglobulinemia [488].

Steatosis is seen in approximately 55% (40–70%) of biopsies taken for HCV staging [441]. It is usually

macrovesicular and graded as mild to moderate (<30%), although the percent of affected hepatocytes differs with varied grading systems. The distribution of steatosis in HCV may be zonal (with increased fat in acinar zone 1 or 3), panacinar, or focal [441]. Infection with genotype 3 as well as high body mass index have been consistently associated with the degree of steatosis in multivariate analyses [458,512,513]. Viral steatosis associated with genotype 3 infection diminishes following successful antiviral therapy [460,513] and may be associated with HCV core protein [514]. Concomitant steatohepatitis is seen in about 5% of HCV biopsies [441] and is associated with more aggressive fibrosis in both alcoholic and nonalcoholic disease [456,515]. Histologic features of steatohepatitis – including zone 3 injury, ballooning hepatocytes, Mallory bodies, and perisinusoidal fibrosis – are further discussed elsewhere in this textbook. The presence of metabolic steatosis on biopsy has also been associated with resistance to interferon-based therapy [460].

About 25% of HCV biopsies will have bile duct damage consisting of swelling, vacuolization, and nuclear irregularity of biliary epithelial cells [453]; predominantly lymphocytes, but sometimes plasma cells or neutrophils, will infiltrate the duct. In contrast to primary biliary cirrhosis, which can result in ductopenia, the ducts are not destroyed in chronic HCV.

Multiple staging systems have been proposed for chronic HCV with slightly different definitions and scoring but the principles are the same. In general, *grading* of a liver biopsy reflects inflammatory disease activity. *Staging* focuses on fibrosis assessment ranging from none to cirrhosis. Once cirrhosis is reached, clinical scales such as MELD or Child–Pugh must be used to further characterize HCV disease. While noninvasive techniques continue to be developed for determining the degree of fibrosis, liver biopsy remains the gold standard for determining fibrosis stage in the noncirrhotic liver.

Table 25.4 outlines various staging systems, allowing comparison between the different systems regarding spectrum of fibrosis. The extent of fibrosis affects both the natural history of HCV as well as the response to interferon-based therapy [460,516]. The Metavir system is the most widely used in clinical practice today [517]. It is the simplest but the accuracy of grading and staging relies heavily on the adequacy of the specimen and the experience of the pathologist reading the liver biopsies [518]. Biopsies of less than 2 cm may lead to underscoring of fibrosis [519,520]. The Ishak scale subdivides cirrhosis into incomplete and definite cirrhosis, which may be useful in clinical trials [521].

Most systems divide inflammation into portal, periportal (interface hepatitis), lobular, and focal components. An evaluation of hepatocyte or confluent necrosis is also made [441]. The HAI of Knodell [522] and the modified HAI of Ishak [521] are most frequently used to assess inflammation and fibrosis semiquantitatively in clinical trials. Most patients have mild inflammation but moderate or severe grades of inflammation have been associated with accelerated fibrosis [439,440]. Therapeutic interventions often have the greatest effect on inflammatory activity (grading) but successful antiviral therapy is associated with improvement in fibrosis score (staging). A large treatment study with paired liver biopsies found that successful viral clearance was associated with fibrosis stability/improvement in 88% and cirrhosis regression in 64% [523].

Increased iron staining is a common finding in chronic HCV and is seen in about 40% of liver biopsies regardless of HFE genotype [441,447]. Increased hepatic iron may also contribute to necroinflammatory changes (higher grading) and progressive fibrosis in HCV infection [446, 447]. Stainable iron is also appreciated more often with cirrhosis. Improvement in HAI has been observed with phlebotomy in patients with chronic HCV, especially males [449,450]. Lower responses to interferon therapy have been correlated to increased stainable iron in the liver, particularly within the reticuloendothelial system [524]. In addition to iron staining, some pathologists

Table 25.4 Staging systems for evaluating hepatic histology in chronic hepatitis C.

Score	Knodell	Ishak	Scheuer	Metavir
0	None	None	None	None
1	Portal	Portal	Portal	Portal

4	Cirrhosis	Diffuse bridging	Cirrhosis	Cirrhosis
5		Extensive bridging		
6		Cirrhosis		

routinely perform periodic acid–Schiff diastase (PAS/D) staining on liver biopsies. The majority of patients with PAS/D-staining globules have an undetected α_1-antitrypsin (AAT) abnormality [525]. In the setting of chronic HCV, even patients with heterozygous AAT deficiency (PI*Z) may develop a more progressive liver injury [526,527].

Fibrosing cholestatic hepatitis (FCH) is a particularly aggressive form of recurrent HCV seen post liver transplant in a minority of patients. Although uncommon, it has a high morbidity and mortality as well as histologic features that are different from those seen in chronic HCV. The histologic features of FCH include marked cholestasis, ballooning of hepatocytes, and pericellular fibrosis [528]. It is important to recognize the early features of FCH as this may be the only time to intervene prior to graft loss. The first abnormality appears to be recurrent HCV with cholestasis but fibrosis develops soon after (within several weeks), and both continue to worsen [529]. Early fibrosis consists of delicate pericellular bands that gradually extend until the classic fibrosis pattern becomes discernable. FCH is usually evident in the late-stage form, but the subtle features of cholestasis and early sinusoidal fibrosis can easily be overlooked. A novel sinusoidal fibrosis scoring system and cholestasis scoring system have been proposed to aid in the diagnosis of this entity (529).

The proportion and distribution of infected hepatocytes in chronic hepatitis C has been difficult to determine using conventional immunohistochemistry and in situ hybridization methods. Using two-photon microscopy with fluorescent, semiconductor quantum dot probes, Liang and colleagues were able to visualize core and NS3 proteins as well as dsRNA from patient liver samples [530]. Interestingly, between 7% and 20% of hepatocytes were infected in patients with HCV RNA levels of 10^5 IU/mL or greater. Infected cells were in clusters, which suggested spread of the virus from cell to cell. dsRNA, a product of viral replication, was abundant within cells at the center of the clusters, but was often sparse in cells at the periphery, consistent with more recent infection of cells at the periphery.

Therapy

Rapid progress has been made in establishing effective therapy for chronic hepatitis C since the virus was discovered in 1989. Sustained virologic response rates (SVRs) have increased from 5–10% with standard interferon therapy to over 40% when standard interferon is combined with ribavirin. Modification of interferon (pegylation) to improve its pharmacokinetics further has increased rates of SVR. Finally, combining these agents with direct-acting antiviral agents has now pushed SVR rates to over 70% for patients with genotype 1 infection. The path to maximizing SVR with novel therapeutic regimens is described below.

Assessing response to antiviral therapy

Patterns of response to antiviral therapy are shown in Fig. 25.11. The goal of antiviral therapy of chronic hepatitis C is sustained virologic response defined as undetectable HCV RNA in the serum when measured 6 months after the end of treatment. Patients who remain with undetectable HCV RNA at this time point have an extremely durable response such that the relapse rate when evaluated up to 7 years after treatment is less than 1% [531]. Indeed, the persistent inability to detect HCV RNA in serum or in hepatic tissue using sensitive molecular techniques implies that permanent viral eradication has occurred and that SVR is analogous to "cure" of

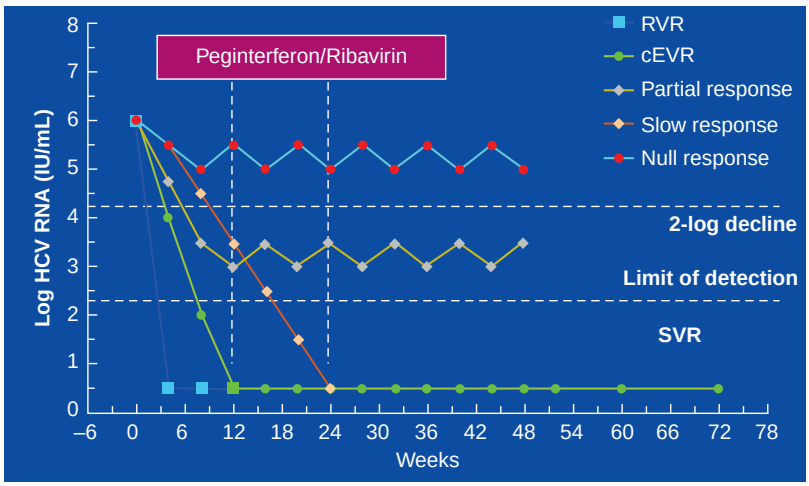

Figure 25.11 Patterns of response to antiviral therapy. cEVR, complete early virologic response; HCV, hepatitis C virus; RVR, rapid virologic response; SVR, sustained virologic response.

Table 25.5 Definitions of treatment milestones and their implications for response-guided therapy.

Response	Time to assess	Definition	Implication
RVR: rapid virologic response	4 week	HCV RNA undetectable	Best positive predictor for SVR; may respond as well with only 24 weeks of treatment
pEVR: partial early virologic response	12 week	HCV RNA decreased by ≥2 logs from baseline	Failure to achieve EVR associated with almost no chance of SVR and treatment can usually be stopped
cEVR: complete early virologic response	12 week	HC RNA undetectable	cEVR associated with higher chance of SVR
ETR	End of treatment	HCV RNA undetectable	On treatment response; observe for SVR or relapse
SVR: slow virologic response	24 weeks after treatment	HCV RNA undetectable by PCR or TMA	Eradication of virus

ETR, end-of-treatment response; HCV, hepatitis C virus; PCR, polymerase chain reaction; TMA, transcription-mediated amplification.

this chronic viral infection [532,533]. However, some conflicting and controversial evidence exists whereby HCV viral sequences have been detected in peripheral blood mononuclear cells even in patients with SVR, although no clinical sequelae have been shown in these patients [534,535]. Nevertheless, patients who achieve a SVR have consistent improvement in several parameters of hepatic disease and also demonstrate long-term clinical benefits. Serum ALT activity usually decreases into the low normal range and hepatic histology shows marked decrease in necroinflammatory activity. Improvement in hepatic fibrosis may also occur [533,536,537]. Importantly, patients who have achieved a SVR as a result of antiviral therapy have lower rates of subsequent hepatic decompensation and hepatocellular carcinoma compared with treatment failures [538–540]. A study of 21,000 US Veterans suggested that SVRs after antiviral therapy were associated with a significant decrease in all-cause mortality compared with treated patients who did not achieve SVRs [541].

Definition of nonresponse and relapse

Patients who remain with detectable HCV RNA throughout a course of therapy are considered to be nonresponders. Within the nonresponder category, null responders achieve the least reduction in HCV RNA, usually less than a 1 log decrease in HCV levels by 12 weeks of treatment, and are considered the most refractory to pegIFN and ribavirin therapy. Partial responders may have multiple log-fold decreases in HCV RNA in serum but always have detectable viremia during treatment (see Fig. 25.11) [542,543].

In contrast, relapsers are those who do achieve undetectable HCV RNA during treatment, as measured by a sensitive standardized assay, but then recur with HCV RNA measurable in the serum after the end of a prescribed treatment regimen. Relapsers can be further categorized based upon the time point at which they cleared virus for the first time (Table 25.5). Rapid virologic responders achieve undetectable viremia by week 4 of treatment. Patients who achieve undetectable viremia for the first time at week 12 have had a complete early virologic response (cEVR), whereas those whose HCV RNA decreased by at least 2 logs at this point but remained detectable are considered to have had only a partial early virologic response (pEVR). Patients with a pEVR who then become undetectable by week 24 are considered to have a slow virologic response (Table 25.5) [542]. Accurate characterization of virologic response during treatment may influence decisions regarding retreatment of patients with new triple therapy combinations, as will be discussed below.

Interferon and ribavirin

Interferon is effective treatment for chronic hepatitis C

In 1986, several years before the discovery of the hepatitis C virus, the first report of successful treatment for NANB hepatitis was published by Hoofnagle and colleagues from the National Institutes of Health (544). Ten patients received recombinant human α-interferon (IFN-α) at doses between 0.5 million and 5 million IU for 4–12 months. Serum aminotransferases rapidly decreased during therapy in most patients and remained normal in those with prolonged therapy. Hepatic histology also demonstrated improvement in some patients. This uncontrolled series suggested that interferon could achieve clinical improvement in patients with NANB hepatitis and provided a rationale for more comprehensive studies of interferon for chronic hepatitis C.

Davis and colleagues [545] published a large placebo-controlled trial that randomized patients to 6 months of therapy with IFN-α-2b at either 1 or 3 million IU thrice weekly or placebo. Normalization of ALT was achieved in 46% of those treated with 3 million IU, compared with only 28% treated with the lower dose. A significant reduction in periportal and lobular inflammation was also observed in liver biopsy specimens. However, 51% of patients with an initial biochemical response relapsed once treatment was discontinued. This landmark study confirmed that patients with chronic hepatitis C could benefit from treatment with interferon, although the high frequency of relapse was a harbinger of challenges that we continue to face today. A smaller placebo-controlled trial by Di Bisceglie and colleagues published simultaneously demonstrated nearly identical results [546].

Another early controlled trial of IFN-α-2b for NANB hepatitis included 252 patients with anti-HCV antibody [547]. Patients were treated for 6 months with IFN-α-2b at 3 million IU and then randomized to either stop therapy, continue for an additional 12 months, or continue a lower dose for an additional 12 months. In those treated for a total of 18 months with the higher dose of interferon, 22% maintained normalization of serum ALT after discontinuation of therapy, compared with only about 10% in those with shorter treatment duration group or receiving lower doses of interferon. As with most studies of this era, the protocol was initiated prior to the availability of routine HCV RNA testing and this was not a prospective end-point. Retrospective analysis of a small subset of patients for whom frozen sera was available indicated that HCV RNA could be eradicated in some patients. Again, this study provided insights into themes that would become important as attempts were made to optimize treatment with interferon-based regimens; longer duration of therapy with interferon improved response rates and decreased the likelihood of relapse.

A flurry of subsequent studies utilizing interferon further supported the importance of this agent for the treatment of hepatitis C [548]. However, biochemical response rates remained fairly constant despite attempts to further manipulate dosing and treatment duration. Lindsay and colleagues [549] treated patients with 3, 5, or 10 million IU thrice daily for the first 12 weeks of therapy to determine if higher initial doses improved biochemical response rates. Higher doses of interferon did not increase the likelihood of sustained biochemical response, which overall was quite low and ranged between 8% and 17%. Furthermore, dose escalation in patients who had not had a biochemical response by week 12 did not improve the rate of sustained normalization of serum ALT activity once treatment was discontinued. This study also demonstrated that patients with genotype 1 were less likely to be responsive to treatment than those with genotypes 2 and 3 [549].

By 1999, approximately 76 randomized controlled trials of interferon for the treatment of chronic hepatitis C had been performed as reported in a meta-analysis [550]. Importantly, later studies included in this analysis had begun to measure HCV RNA in serum, the sustained clearance of which would become the definitive, desired outcome for antiviral therapy. In aggregate, these trials indicated that 17% of patients treated with interferon remained HCV RNA-negative for at least 6 months after therapy was discontinued, indicating sustained virologic response. This meta-analysis also suggested that longer duration of therapy and higher doses of interferon were associated with a better rate of sustained virologic response [550].

The road to ribavirin combination therapy

The greatest incremental advance in the treatment of hepatitis C was the recognition that ribavirin, a relatively obscure medication with antiviral activity against a broad range of RNA and DNA viruses including Flaviviridae, could dramatically increase the rate of SVR when it was combined with IFN-α-2b [551]. Ribavirin is a guanosine nucleoside analog approved initially for the treatment of respiratory syncytial virus in neonates [552]. Several postulated mechanisms of action of ribavirin for the treatment of hepatitis C have been proposed since its clinical utility for this disease was recognized. These theories and supportive evidence have been detailed in excellent reviews by Feld, Hoofnagle, and Chung et al. [257,553]:

1. Ribavirin may directly inhibit hepatitis C virus replication by acting as a chain terminator when ribavirin triphosphate is incorporated into viral RNA by viral RNA polymerases. However, high concentrations of ribavirin, not achieved in clinical settings, were required to demonstrate this activity [554].
2. Ribavirin may act as an inhibitor of inosine monophosphate dehydrogenase (IMPDH). Depletion of guanosine triphosphate in this manner will prevent viral RNA synthesis. Interestingly, this concept has been tested clinically in patients treated with pegIFN and ribavirin combined with mycophenylate mofetil, an IMPDH inhibitor used as an immunosuppressant in transplantation. No additive effects on viral suppression were noted with mycophenylate [555].
3. Ribavirin may increase the rate of naturally occurring mutations leading to defective HCV RNA that decreases the ability of HCV RNA to replicate. Studies of the frequency of mutations in patients with hepatitis C treated with ribavirin have yielded conflicting results [257,553].
4. Ribavirin may have immunomodulatory activity by altering the balance between different types of CD4+

T-cell responses, perhaps favoring sustained virologic clearance [257,553].

5 A recent, intriguing proposed mechanism of ribavirin action suggests that ribavirin augments the regulation of interferon-signaling genes. Feld and colleagues [556] measured mRNA expression in hepatic tissue obtained from patients after an injection of pegIFN. Those who had been pretreated with ribavirin had upregulation of interferon signaling genes compared with those who had not received ribavirin. A subsequent study demonstrated that ribavirin improved early viral kinetics in patients who demonstrated an initial response to pegIFN and that this also correlated with measures of enhanced interferon signaling gene expression [557].

Ribavirin monotherapy improves serum alanine aminotransferase activity

The availability of ribavirin with its broad, albeit poorly understood, antiviral activity led to several studies to evaluate ribavirin as a single agent for the treatment of chronic hepatitis C. In two studies that treated patients only with ribavirin 1,200 mg daily for 12 months, serum aminotransferases decreased to normal or near normal in about 35–40% of patients. Concomitant improvement in necroinflammatory activity was also found in liver biopsies obtained at the end of treatment [558,559]. These results were rarely sustained, however, and once ribavirin was discontinued serum ALT activity returned to baseline values in most patients. In these early studies, HCV RNA levels remained unchanged despite the other measures of clinical improvement. Prolonged therapy with ribavirin in patients who did not respond to interferon and ribavirin yielded similar results [560]. Among patients who remained HCV RNA-positive after 24 weeks of interferon and ribavirin, those randomized to continue ribavirin monotherapy for an additional 48 weeks had improvement in serum aminotransferases and hepatic histology, with no effect on HCV RNA levels in serum. These studies demonstrated that there is no role for ribavirin monotherapy for the treatment of chronic hepatitis C.

Combining ribavirin with interferon substantially improves antiviral response

With essentially negative results from the ribavirin monotherapy trials, it was unexpected that combining ribavirin with interferon would provide such dramatic improvement in outcomes compared to interferon alone. Indeed, combination therapy of interferon and ribavirin has remained the cornerstone of treatment for chronic hepatitis C. The first suggestion that ribavirin enhanced outcomes was reported in a small pilot study by Brillanti and colleagues in 1994 [551]. Twenty patients who had not responded to interferon previously were randomly assigned to retreatment with interferon plus ribavirin or interferon alone. Remarkably, 40% of patients treated with combination interferon and ribavirin had undetectable HCV RNA when measured 9 months after treatment discontinuation, compared with none in the interferon-only group [551].

Two seminal studies published in 1998 confirmed this initial report and established combination therapy as the standard of care for all patients with chronic hepatitis C [561]. McHutchison and colleagues [561] randomized over 900 patients to treatment with IFN-α-2b alone or IFN-α-2b plus ribavirin (1,000–1,200 mg/day) for 24 or 48 weeks. The SVR for those treated with combination therapy was 31% and 38% (24 and 48 weeks, respectively) compared with only 6% and 13% for those treated with interferon monotherapy. Genotype 1 patients had a substantially lower rate of SVR even when treated with combination therapy: 28% and 16% with 24 or 48 weeks of treatment, respectively. Nearly 70% of patients with genotype 2 or 3 had a SVR, regardless of treatment duration [561]. In a separate study, the rate of SVR was 43% for those treated with interferon and ribavirin for 48 weeks [562]. Several independent factors (genoype 2 or 3, HCV RNA <2 million copies/mL, age less than 40 years, minimal fibrosis stage, and female gender) were associated with a higher likelihood of SVR.

Modification of interferon with pegylation improves pharmacokinetics

Standard recombinant alpha interferons utilized in the past to treat chronic hepatitis C have short half-lives of approximately 6 hours which necessitated dosing several times per week [563,564]. These unmodified forms of interferon administered subcutaneously were characterized by rapid absorption with high peak levels of interferon concentration achieved within hours, followed by rapid disappearance from the serum, without attainment of steady state concentrations. Combining an inactive polyethylene glycol (PEG) moiety with a native protein to improve pharmacokinetic parameters has been applied to a number of therapeutic agents, including epoetin-α and chemotherapeutic agents [565]. Peginterferon-α-2b (PEG-Intron®, Merck), approved by the US Food and Drug Administration (FDA) in 2001, consists of a 12 kD linear PEG molecule attached covalently to the IFN-α-2b molecule; while peginterferon-α-2a, approved in 2002 (Pegasys, Hoffman La-Roche), links a 40 kD branched PEG molecule to IFN-α-2a [564]. These enhancements diminish clearance of both interferons and prolong the half-lives to approximately 24 hours and 65 hours, respectively, which allows for once-weekly administration [563, 564,566]. PegIFN-α-2b is predominantly excreted through the kidney while pegIFN-α-2a is hepatically metabolized. The size and structure of the PEG moiety also impacts upon other parameters such as volume of distribution,

rate of absorption, and biologic activity although, as discussed below, clinical outcomes with either pegIFN combined with ribavirin is similar [563,567].

Peginterferon combined with ribavirin improves rates of sustained virologic response

Pivotal clinical trials of pegIFN-α-2b and -2a were reported in 2001 and 2002, respectively [568,569]. Manns et al. [569] randomized over 1,500 patients to treatment for 48 weeks with either: (i) pegIFN-α-2b 1.5 μg/kg/week; (ii) pegIFN-α-2b 1.5 μg/kg/week for 4 weeks then decreased to 0.5 μg/kg/week; (iii) or IFN-α-2b 3 MU subcutaneously three times per week. All patients received ribavirin 1,000–1,200 mg/day. Overall, SVR rates (54%, 47%, and 47%, respectively) demonstrated that the higher dose pegIFN was significantly more effective. Among genotype 1 patients, rates of SVR were 42% for the higher dose pegIFN compared with 34% for the lower dose pegIFN and 33% for the standard interferon arm. Genotype 2 or 3 patients, as expected, fared better with SVR rates as high as 82% with higher dose pegIFN. Several pretreatment characteristics were associated with SVR, including non-1 genotype, lower baseline viral load, lighter weight, younger age, and the absence of cirrhosis. Logistic regression analysis indicated that the dose of ribavirin on a mg/kg basis was an important factor in determining treatment outcome. Thus, patients who received more than 10.6 mg/kg/day of ribavirin had higher rates of SVR for all dose groups and genotypes [569].

Fried and colleagues [568] compared the efficacy of three treatment regimens: pegIFN-α-2a 180 μg/week alone or in combination with ribavirin 1,000–1,200 mg/day, or standard interferon and ribavirin. The best rate of overall SVR, 56%, was achieved in those treated with pegIFN-α-2a and ribavirin compared with 44% of those treated with standard interferon and ribavirin and only 29% with pegIFN alone. Genotype 1 patients had SVR rates of 46%, 36%, and 21%, respectively, while patients with genotype 2 or 3 achieved a SVR in 76% of those treated with pegIFN-α-2a and ribavirin. Three factors, non-1 genotype, age less than 40 years, and body weight of 75 kg or less were independently associated with virologic response [568].

Refining treatment regimens to optimize response

The above registration trials established the superior efficacy of peginterferons combined with ribavirin for the treatment of chronic hepatitis C. Subsequent analyses of these data and additional studies sought to further refine the treatment algorithm in order to maximize the chances of response while minimizing exposure to medications with a substantial burden of side effects. Hadziyannis et al. [570] randomized over 1,300 patients to four arms of treatment with pegIFN-α-2a 180 μg/week plus ribavirin at doses of either 1,000–1,200 mg/day or 800 mg/day for either 24 or 48 weeks' duration. The factorial study design that included patients with genotypes 1, 2, and 3 allowed for several comparisons between ribavirin dosing and treatment duration across genotypes. The results confirmed that genotype 1 patients required higher doses of ribavirin (1,000–1,200mg/day) for 48 weeks. Those treated for 24 weeks or with only 800 mg/day of ribavirin had a higher chance of relapse once therapy was discontinued. In contrast, patients with genotypes 2 or 3 did equally well regardless of duration or ribavirin dosing suggesting that 24 weeks of treatment with only 800 mg/day of ribavirin was sufficient [570].

In aggregate, these studies provided the rationale for FDA approval of the two pegIFN preparations and the general recommendations for the treatment of chronic hepatitis C, which are based upon HCV genotype, as shown in Table 25.6. PegIFN-α-2b is administered subcutaneously once weekly as a weight-based dose (1.5 μg/kg/week) while pegIFN-α-2a is administered as a fixed weekly dose of 180 μg/week. Both drugs must be combined with ribavirin for maximal efficacy, although with modest differences in ribavirin dosing recommendations. In general, a 48-week course of treatment is recommended for patients with genotype 1 or 4 utilizing

Table 25.6 Standard recommendations for dosing and duration of treatment of peginterferon (PEG) and ribavirin according to viral genotype.

Genotype	PEG dose (per week)	Ribavirin dose (mg/day)	Duration (weeks)	SVR (%)
1	180 μg PEG-α-2a *or* 1.5 μg/kg PEG-α-2b	800–1,400 (weight based)	48	41–42
2	180 μg PEG-α-2a *or* 1.5 μg/kg PEG-α-2b	800	24	60–84
3	180 μg PEG-α-2a *or* 1.5 μg/kg PEG-α-2b	800	24	60–84
4	180 μg PEG-α-2a *or* 1.5 μg/kg PEG-α-2b	1,000–1,200	48	55
5	180 μg PEG-α-2a *or* 1.5 μg/kg PEG-α-2b	1,000–1,200	48	64
6	180 μg PEG-α-2a *or* 1.5 μg/kg PEG-α-2b	1,000–1,200	48	63

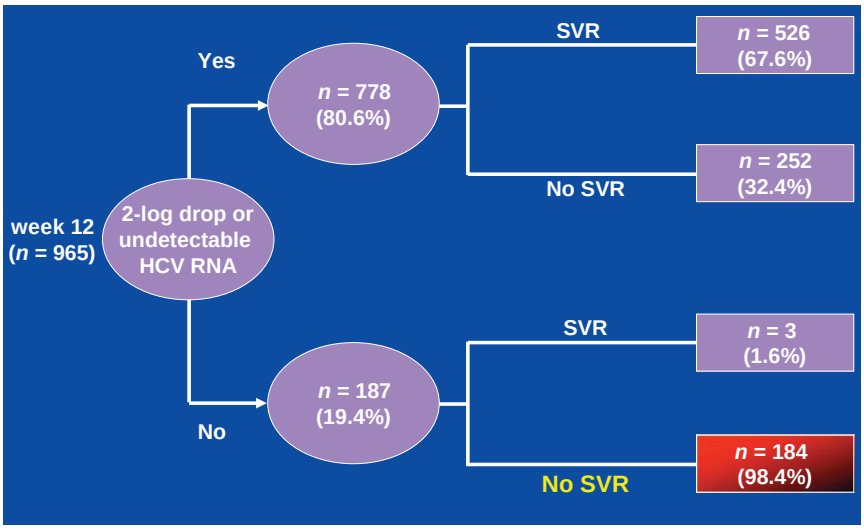

Figure 25.12 Absence of early virologic response is associated with treatment failure with pegIFN and ribavirin. HCV, hepatitis C virus; SVR, sustained virologic response. (Reproduced from Davis [571] with permission from Plenum.)

higher doses of ribavirin. Treatment termination is recommended when patients fail to achieve undetectable viremia by week 24 of a planned 48-week course of therapy for patients with genotype 1. Patients with genotypes 2 or 3 may be treated for 24 weeks with only 800 mg of ribavirin. Recommendations for other genotypes are based on sparse data but follow similar recommendations as for genotype 1.

Response-guided therapy

The standardized treatment recommendations described above solely rely on differences in viral genotypes to dictate a course of therapy. In practice, there is ongoing assessment of virologic response to determine the advisability of continuing therapy when SVR is unlikely. This is to guide whether a prolonged course of pegIFN and ribavirin may be warranted to decrease the chance of relapse in slow virologic responders, and also to determine whether therapy can be successfully shortened without sacrificing the chances for SVR among those who rapidly respond to pegIFN and ribavirin. As will be discussed in detail below, response-guided therapy will form the basis of treatment recommendations for triple therapy combinations of pegIFN and ribavirin combined with a hepatitis C protease inhibitor or other direct-acting antiviral agents in the future.

Viral kinetics is associated with the likelihood of sustained virologic response

The rapidity with which a patient clears HCV RNA during therapy has important implications for subsequent treatment outcome [542]. The earliest studies of pegIFN and ribavirin combination therapy retrospectively evaluated the kinetics of viral response to determine when treatment failure was all but assured. Absence of an early virologic response (EVR) has the best negative predictive value for treatment outcome [568,571]. Thus, patients who failed to achieve an EVR (either complete or partial) had a vanishingly small chance of ultimately achieving SVR, and stopping futile therapy at week 12 of treatment was considered on an individual basis (Fig. 25.12). Conversely, patients who achieve a RVR have the highest chance of achieving a SVR (over 90%) during the initial course of therapy [572,573]. In a retrospective analysis of patients with genotypes 1–4 treated with pegIFN-α-2a and ribavirin, RVR was attained in only 16% of individuals with genotype 1 and in 60–71% of those with genotype 2 or 3. However, among those with RVR, the rate of SVR was high across all genotypes ranging from 88% to 100% (Fig. 25.13). Baseline factors predictive of RVR included genotype non-1, lower initial viral load, higher ALT levels, absence of advanced fibrosis, and younger age. Notably, the presence of RVR was most predictive of SVR when compared with baseline characteristics regardless of HCV genotype, although the *IL28B* genotype was not included in this analysis [572]. Taken to the extreme, several investigators have also suggested that viral declines within the first 24–72 hours of treatment initiation are also highly predictive of subsequent outcome [574]. However, these observations have not been clinically embraced to alter therapeutic regimens.

Utilizing rapid virologic response to shorten treatment in genotype 1

As mentioned previously, 48 weeks of treatment for genotype 1 patients yields a better rate of SVR than a shorter 24-week treatment duration due to a lower relapse rate (the difference between end-of-treatment virologic response and sustained virologic response). However, the recognition that patients with RVR, present in about 15%

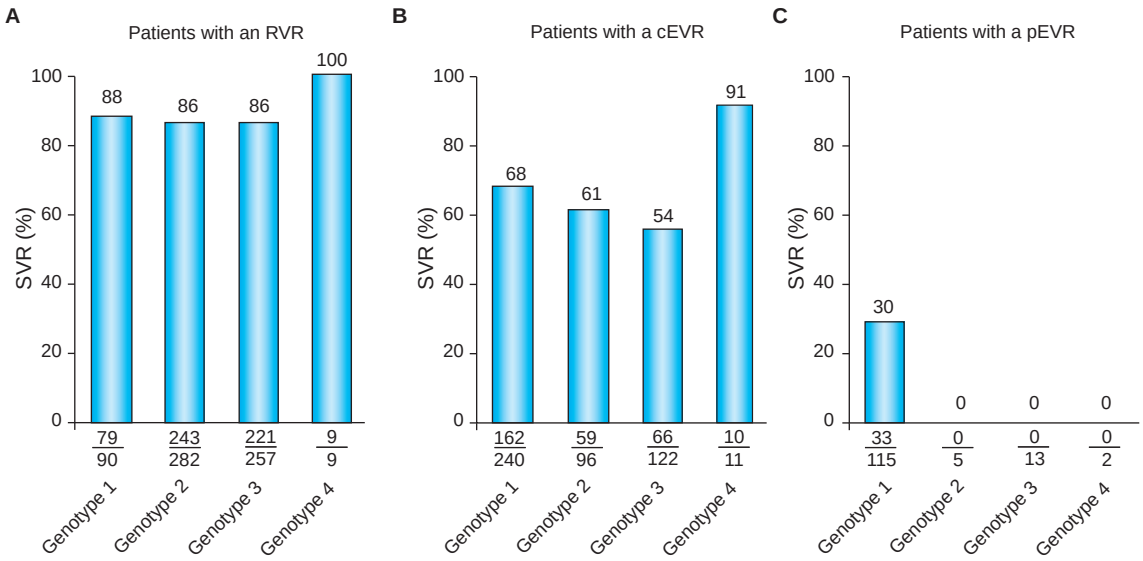

Figure 25.13 Likelihood of achieving sustained virologic response (SVR) related to achieving rapid virologic response (RVR), complete early virologic response (cEVR), or partial early virologic response (pEVR) across all genotypes with treatment with pegIFN and ribavirin. (Reproduced from Fried et al. [572] with permission from Elsevier.)

of patients treated with pegIFN and ribavirin, had the highest chance of SVR led to retrospective and prospective studies to determine whether a treatment duration shorter than the recommended 48 weeks would be effective for this subgroup with the highest likelihood of success. Indeed, interrogation of large databases that included patients with genotype 1 treated for only 24 weeks with pegIFN and ribavirin demonstrated that the rates of SVR among those who had first achieved RVR were comparable to those treated for 48 weeks [575]. Baseline viral loads of less than 600,000 IU/mL were most highly associated with this response.

Several trials have prospectively treated patients with genotype 1 and RVR for only 24 weeks [576]. In a single-arm study of patients with a pretreatment viral load of <600,000 IU/mL, Zeuzem and colleagues treated those who had first achieved an RVR with pegIFN-α-2b and ribavirin for a total of 24 weeks and found an SVR rate of 89% [577]. The PREDICT study utilized a response-guided algorithm to treat RVR patients with genotype 1 and a low viral load for 24 weeks [578]. This study yielded an SVR of 88% for the short treatment duration, adding support to the assertion that 24 weeks of treatment was sufficient for those with RVR. Other studies that prospectively embedded a 24-week treatment arm for patients who achieved RVR within a response-guided protocol also found similar results – that patients with RVR with low baseline viral loads received maximal benefit from only 24 weeks of treatment with pegIFN and ribavirin [579–581]. Common to all these studies was the diminished rate of relapse when RVR was attained, which was only approximately 10% [581].

These data led to the recommendation incorporated into European practice to truncate therapy to 24 weeks for patients with genotype 1 and a low baseline viral load who had achieved RVR. It should be noted that all of these studies on shortened duration of therapy in genotype 1 patients have been performed in populations outside the United States in whom therapeutic responses are generally more favorable for a variety of reasons, including race (and, by inference, attendant *IL28B* genotype) and differences in body mass index, among others features. Therefore, the application of shortened duration of therapy to US populations who achieve RVR may be considered but approached with caution, particularly in patients with multiple factors associated with poor treatment outcomes.

Utilizing rapid virologic response to shorten treatment in genotype 2 or 3

Patients infected with genotype 2 or 3 have the highest rates of SVR compared with other genotypes. Although the recommended treatment duration is already shorter than that of genotype 1 (24 weeks versus 48 weeks), a number of studies have also investigated whether treatment duration times as short as 12 weeks can be utilized in this population without compromising SVR [576]. Mangia and colleagues [582] randomized genotype 2 or 3 patients to treatment with a standard 24-week regimen of pegIFN-α-2b and weight-based ribavirin

(1,000–1,200 mg/day) or to a response-guided treatment whereby patients achieving RVR received only 12 weeks of treatment and non-RVR participants completed 24 weeks of therapy. Similar overall rates of SVR were achieved in both the fixed 24-week duration and the RVR-guided regimen (76% and 77%, respectively). Numeric differences in SVR among those who achieved RVR (91% versus 85%) were not statistically significant, suggesting that the shorter treatment regimen was not inferior to the fixed 24-week regimen. However, the end-of-treatment relapse rate was noted to be higher in the short duration treatment arm despite a RVR.

The largest study to investigate truncated therapy in genotypes 2 and 3 was performed by Shiffman et al. [583]. Nearly 1,500 patients were randomized a priori to either 16 weeks or 24 weeks of treatment with pegIFN-α-2a plus ribavirin 800 mg/day. In this study, a response-guided algorithm was not prospectively incorporated but post hoc analyses provided important information. The overall SVR rate was significantly lower in the 16-week treatment arm compared with the standard 24-week treatment regimen (62% versus 70%, respectively). An increase in relapse was evident among patients treated for 16 weeks (31% versus 18%). Multivariate analysis suggested that treatment response was positively associated viral genotype 2 versus genotype 3, low viral load at baseline (<400,000 IU/mL), age <45 years, weight <80 kg, higher serum ALT activity, the absence of advanced fibrosis, and longer treatment duration [583]. Patients with lower pretreatment HCV RNA had similar rates of SVR with either treatment duration (~80%). Even among patients who achieved RVR, the rate of SVR was still lower in those treated for a shorter duration (79% versus 85%). Strikingly, among non-RVR patients the SVR rate was low regardless of duration of therapy: 26% (16 weeks) and 45% (24 weeks) [583].

The interpretation of these multiple studies regarding shortening therapy for genotypes 2 and 3 is hampered by differences in treatment duration, variability in prospective randomization based upon RVR, and also differences in the dosing of ribavirin. Numerically lower response rates and higher relapse rates for patients treated with 12–16 weeks of therapy appear to be a consistent theme, which has been analyzed in a recent meta-analysis [584]. Thus, these data suggest that 24 weeks remains the optimal treatment duration for most patients with genotypes 2 or 3, although an ideal patient with a low viral level <400,000 IU/mL who achieves RVR may be considered for shortened duration of treatment. However, the impact of negative prognostic factors such as African-American race, HIV coinfection, cirrhosis, and obesity has been incompletely characterized and thus shortened therapy should only be selectively considered [576].

Slow virologic response

Approximately 15% of patients treated with pegIFN and ribavirin exhibit a slow virologic response defined as undetectable HCV RNA between weeks 12 and 24 of therapy. These patients have lower rates of SVR compared with patients who clear HCV RNA earlier in their treatment. Modeling of viral kinetics with slow virologic response suggested that a standard 48-week course of therapy would be insufficient [585]. It was postulated that a longer duration of undetectable viremia of at least 36 weeks would minimize relapse and maximize the chances of SVR [585].

Several studies have contributed to the body of evidence suggesting that prolonging treatment with pegIFN and ribavirin for slow virologic responders may be beneficial [576]. Berg and colleagues [586] performed one of the earliest studies to evaluate whether extended therapy with pegIFN and ribavirin would enhance rates of SVR. Patients with genotype 1 were randomized to treatment with pegIFN-α-2a and ribavirin 800 mg/day for either 48 or 72 weeks. SVR rates for both groups were almost identical. However, post hoc analysis demonstrated that slow virologic responders had a significantly higher rate of SVR (29% versus 17%) and a lower relapse rate (40% versus 64%) when treated for 72 weeks. The TeraVic-4 study focused on patients who failed to achieve a RVR and prospectively randomized them to 48 weeks or 72 weeks of therapy with pegIFN-α-2a and ribavirin 800 mg/day. Again, significant improvement was seen in SVR with prolonged treatment (44% versus 28%) along with diminished relapse rates [586].

Pearlman and colleagues [587] performed the most relevant study on this topic for clinicians in the United States. This single-center study of genotype 1 patients included a representative population with numerous treatment-resistant characteristics such as African-American race, high baseline levels of HCV RNA, and advanced fibrosis. Slow virologic responders treated with pegIFN-α-2b and ribavirin 800–1,400 mg/day for 72 weeks had a significantly higher rate of SVR compared with those who received a standard 48-week regimen (38% versus 18%). Relapse rates were also lower with the extended treatment duration [587].

Interestingly, a multicenter study performed in Europe did not support the concept that prolonged therapy was beneficial in patients with slow virologic response. The SUCCESS trial also randomized slow virologic responders to pegIFN-α-2b and weight-based ribavirin for either 48 weeks or 72 weeks [588]. In the intention-to-treat analysis SVR rates were similar for the extended duration treatment (48%) to those treated for only 48 weeks (43%). However, the study did show that relapse rates were ~14% lower with prolonged therapy, although this was not statistically significant.

Furthermore, in post hoc analyses of adherent patients and those who completed treatment, a numeric but statistically insignificant advantage for prolonged therapy was also evident [588].

A meta-analysis examined all randomized controlled trials to date that have evaluated extended duration of therapy for patients with a non-RVR [589]. Despite heterogeneity in the trials regarding type of interferon, ribavirin dosing, criteria for randomization, and populations studied, the authors concluded that prolonged therapy with pegIFN and ribavirin in slow virologic responders provided about a 15% higher chance to achieve SVR (95% CI, 4–26%) along with a similar decline in the chance for relapse, which likely was the contributing factor to improved SVR [589].

Importance of ribavirin, side effects, and management

Ribavirin is critical to the success of pegIFN combination therapies, including direct-acting antiviral regimens, in spite of controversy over its mechanism of action. The critical threshold for ribavirin dosing is approximately 11 mg/kg/day and doses below that level are associated with lower rates of response for patients with genotype 1 [569]. From modeling studies of ribavirin exposure versus response, higher doses of ribavirin (up to 15 mg/kg/day) are also found to be associated with higher rates of anemia and SVR [590,591]. Thus, ribavirin dosing in the range of 13–15 mg/kg appears to be the best balance between optimized efficacy and intolerable hemolytic anemia that develops at higher doses. Indeed, an informative pilot study of ten patients whose ribavirin dosing was increased until target serum levels were achieved demonstrated an impressive rate of SVR but with severe anemia requiring growth factor supplementation and, in some cases, blood transfusion [592].

Lack of adherence to ribavirin throughout a course of therapy is highly predictive of treatment failure and patients that maintain the highest levels of treatment adherence, greater than 80% of their prescribed medications, have the best rates of SVR [593]. Retrospective analyses indicate that modest dose reductions of ribavirin have a minimal impact on rates of sustained response. However, dose reductions to less than 60%, usually associated with temporary or permanent discontinuation of ribavirin, will significantly decrease the likelihood of SVR [594]. This was underscored in a clinical trial that randomized patients, already negative for HCV RNA at week 24, to either discontinue ribavirin (while maintaining pegIFN dosing) or continue combination therapy with pegIFN and ribavirin for the remaining 24 weeks of treatment [595]. Lower rates of SVR and significantly higher relapse rates were seen in patients who discontinued ribavirin early.

Ribavirin is highly concentrated in erythrocytes through a nucleoside es transporter and induces an extravascular hemolysis in essentially all patients [596]. The mechanism of hemolysis is related to depletion of erythrocyte adenosine triphosphate stores and increased susceptibility to oxidative damage to red blood cell membranes [597]. Peginterferon also contributes to anemia through its effect on bone marrow suppression. The average decrease in hemoglobin during combination therapy is approximately 2.5 g/dL, although the range is quite wide and severe anemia (hemoglobin <10 g/dL) may develop in up to 25% of patients [568,569,598]. Interestingly, the presence of severe anemia with standard dosing of ribavirin may also be a pharmacodynamic marker for adequacy of ribavirin dosing and is associated with higher SVR [599]. Severe anemia contributes to the fatigue, malaise, and diminished quality of life while on combination antiviral therapy.

Stepwise dose reduction by 200 mg decrements is the cornerstone of management for ribavirin-induced anemia. Ribavirin achieves steady-state concentrations in serum between weeks 4 and 6 of treatment, coinciding with the development of early and sometimes severe anemia. Product labeling recommends dose reduction of ribavirin when hemoglobin falls to <10 g/dL. However, the slope of hemoglobin reduction may also provide clues as to who will be at greatest risk for severe anemia. A decrease in hemoglobin of 1.5 g/dL at week 2 of therapy has been associated with the risk of severe anemia and treatment interruption at later time points [600]. Thus, close monitoring of hemoglobin early during the course of treatment, and modest dose reduction when severe anemia is likely to develop, may obviate the need for dose interruption or the addition of growth factors.

Epoetin-α (EPO) is effective for mitigating the anemia of ribavirin-induced hemolysis and also improves quality of life for those who have developed severe anemia [601,602]. The use of erythropoietic-stimulating agents due to the development of early-onset anemia (within 8 weeks of starting HCV treatment) was retrospectively associated with improved rates of SVR and less treatment discontinuation [599]. For anemia that developed later during combination antiviral treatment, the addition of EPO had no impact on these parameters. Few studies have prospectively evaluated the impact of EPO on SVR rates. EPO use was associated with improved rate of SVR when higher doses of ribavirin (~15 mg/kg/day, 1,000–1,600 mg/day) were initiated but had no impact on SVR with standard ribavirin dosing [602]. Whether modest dose reductions would have accomplished similar results could not be ascertained from this study. A recent study that randomized genotype 1 anemic patients during pegIFN and ribavirin treatment

demonstrated an improvement in sustained response with EPO administration (SVR = 60%) compared to management with dose reductions of 200–400 mg/day (SVR = 34%) [603].

While selected patients with severe anemia may potentially benefit from adjunctive therapy with EPO, these agents are not approved by regulatory authorities for the treatment of ribavirin-induced anemia. Furthermore, enthusiasm for the use of erythropoeitic growth factors has been tempered by the occurrence of the rare complication of red cell aplasia, as well as the concern for thrombosis risk when hemoglobin values increase to over 12 g/dL as a result of EPO administration [604].

A genome-wide association study, confirmed in a second independent dataset, of patients treated with pegIFN and ribavirin has identified variants in the gene for inosine triphosphatase that appear to protect patients from ribavirin-induced hemolysis [605,606]. Patients with two polymorphisms associated with inosine triphosphatase deficiency had lower rates of anemia and lower rates of anemia related to ribavirin dose reductions. The protective mechanism of these variants remains speculative but may involve competition between the accumulation of inosine triphosphate and ribavirin triphosphate within red blood cells. The role of inosine triphosphatase (ITPA)-variant genetic testing in clinical practice remains to be defined.

Alternatives to ribavirin with similar efficacy and fewer adverse events would be of great potential benefit. Taribavirin is an oral prodrug of ribavirin with a distinct structure that diminishes the ability of this agent to enter erythrocytes, thus resulting in less anemia [607]. Phase III clinical trials confirmed the lower incidence of anemia, however they failed to meet the end-point of SVR rates seen with ribavirin [608,609]. A recent phase II study utilizing weight-based doses of taribavirin demonstrated comparable rates of SVR and diminished anemia compared to standard ribavirin. At the highest doses of taribavirin (30 mg/kg/day) a stepwise increase of anemia was noted suggesting that increasing the taribavirin dose above this level would mitigate its advantage over standard ribavirin.

IL28B genotype and treatment response

Numerous host, environmental, and virologic factors have been associated with outcomes of interferon-based therapies. Ge and colleagues identified the single most important pretreatment host factor from an elegant genome-wide association study of over 1,100 patients treated with pegIFN and ribavirin in the IDEAL study [145,567]. Investigators identified a single nucleotide polymorphism (SNP) (rs12979860) on chromosome 19, 3 kb upstream of the *IL28B* gene encoding IFN-λ3, which was strongly associated with SVR. Patients with the favorable CC genotype were twice as likely to have a SVR as patients with the TT or CT genotypes (Fig. 25.14). The SVR rate among European-Americans with the CC allele was ~80%, while for those with genotype CT or TT the SVR rates were ~40% and ~35%, respectively. The influence of the *IL28B* genotype remained the strongest predictor of outcome when it was compared with other pretreatment factors known to be associated with treatment

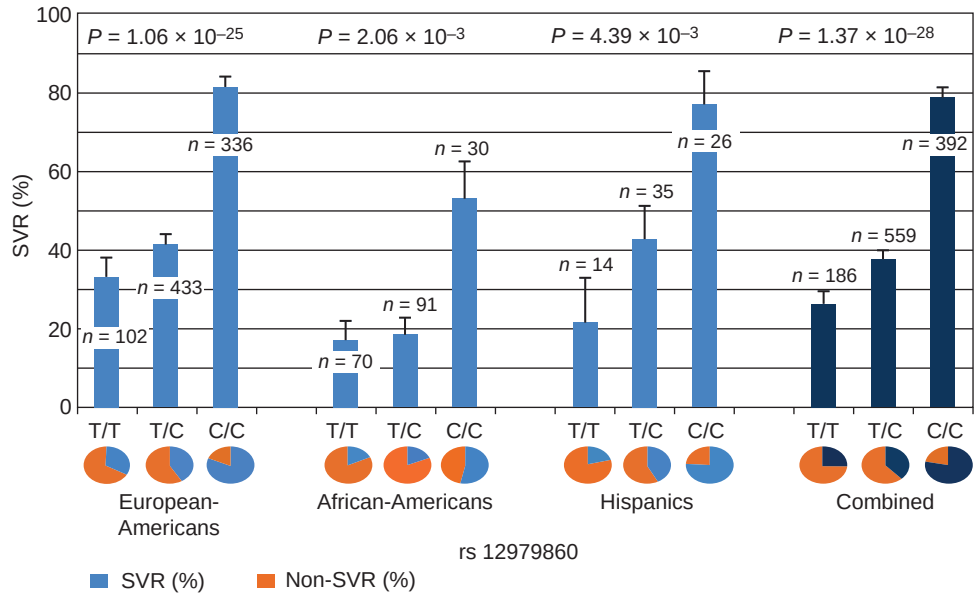

Figure 25.14 *IL28B* genotype and likelihood of sustained virologic response (SVR) CC genotype is the most favorable for treatment response. (Reproduced from Ge et al. [145] with permission from Nature.)

response, such as baseline viral load, extent of hepatic fibrosis, and race.

Interestingly, the same relative association was identified in African-American patients; however, the absolute rates of SVR remained lower among African-Americans even in those with the favorable CC genotype when compared with European-Americans. Further analyses in this study demonstrated that the frequency of the C allele varied across different racial groups. African-Americans were least likely to harbor the C allele, while East Asians had the highest frequency. Thus, it appears that the *IL28B* genotype accounts for a significant proportion, estimated to be ~50%, of the racial disparity in response to interferon-based therapies although other factors remain to be elucidated [145].

A flurry of studies confirmed and expanded these initial findings in global populations from Asia, Australia, and Europe, and additional cohorts in the United States [382,610–612]. Although methodologies were different and several additional SNPs, such as rs8099917 – some of whom were in linkage disequilibrium with rs12979860 – were identified, the robust association of SVR with SNPs in the IL28B region was unequivocal [611]. The association was evident as well in HIV/HCV coinfected patients [382].

The impact of *IL28B* on viral kinetics was also investigated [613]. In genotype 1 patients, the *IL28B* CC genotype was associated with a steeper decline in HCV RNA during the first phase of viral clearance, with CC genotype having a median reduction of viral load of $-2.6\ \log_{10}$ IU/mL, compared to less than $-1\ \log_{10}$ IU/mL decrease for other genotypes at week 2 of therapy. RVR (undetectable HCV RNA at week 4) was also significantly more frequent in patients with the CC genotype, compared to the CT or TT genotypes (28% versus 5% and 5%, respectively) [613]. Among patients with HCV genotype 2 and 3, where the overall response rate is high, there was only a modest but significant relationship between SVR and *IL28B* genotype. The greatest impact of the *IL28B* genotype was in patients who did not achieve RVR, in whom SVR rates for CC, CT, and TT genotypes were 87%, 67%, and 29%, respectively [614].

The mechanism associated with *IL28B* genotype and therapeutic response remains largely speculative, as discussed above and reviewed previously [610,611]. Several studies have evaluated the relationship between *IL28B* with interferon signaling gene (ISG) expression in liver tissue and peripheral blood mononuclear cells [615,616]. Elevated ISG expression prior to antiviral therapy is associated with diminished therapeutic response [131,556]. Interestingly, intrahepatic expression of ISGs was shown to correlate with *IL28B* genotype, whereby patients with a favorable responder *IL28B* genotype had lower baseline expression of ISG and, thus, presumably, a better chance of responding to antiviral therapy. Expression of *IL28B* mRNA in liver tissue was not associated with *IL28B* genotype. In contrast, another study that evaluated intrahepatic ISG expression concluded that *IL28B* polymorphisms and intrahepatic ISG expression appeared to be independent predictors of antiviral response [617]. Additional insights into the relationship between *IL28B* and ISG is provided in a study by Darling and colleagues [618] that demonstrated that serum interferon-γ-inducible protein (IP-10), a marker of responsiveness to interferon-based therapies, significantly enhanced the predictability of *IL28B* genotype, particularly for patients with non-CC genotypes. IP-10 levels in this study were also independent of *IL28B* genotype [618].

IL28B genotyping assays are now available commercially, although their role in clinical practice remains to be clearly defined. Certainly, the absence of a favorable genotype should not be used to exclude an otherwise suitable candidate for treatment since a large proportion of patients with an unfavorable *IL28B* genotype will still respond to pegIFN and ribavirin. However, individual genotype data may be used to counsel patients about their pretreatment likelihood of response and allow them to make informed choices about beginning treatment with pegIFN and ribavirin or waiting until triple therapy regimens are available. The impact of *IL28B* genotype with triple therapies is not known at this time. Preliminary data suggest that the potent antiviral activity of protease inhibitors will ameliorate to a large extent the negative effects of an unfavorable *IL28B* genotype, although final results from retrospective analyses and prospective clinical trials are still pending.

Patient selection for therapy

According to the National Institutes of Health Consensus Statement on Management of Hepatitis C, all patients are potential candidates for antiviral therapy [350]. In practice, various issues must be considered prior to embarking on treatment with pegIFN and ribavirin, specifically assessing the risks and benefits of treatment for an individual patient. There are few absolute contraindications to treatment with pegIFN and ribavirin. However, female patients who are pregnant, considering pregnancy within 6 months of completing a course of ribavirin, or unwilling to use adequate contraception (including female partners of male patients) should not be treated due to the teratogenic risk of ribavirin. Ribavirin-induced hemolytic anemia may also exacerbate symptomatic coronary artery disease. Poorly controlled psychiatric diseases, including recent suicide attempts, are also absolute contraindications to therapy due to the frequent neuropsychiatric side effects of pegIFN [296].

Numerous other relative contraindications or cautions are listed in the product inserts of pegIFN preparations,

including the presence of autoimmune diseases that can be exacerbated by the immunomodulatory actions of pegIFN, hemoglobinopathies such as sickle cell anemia or major thalassemia that will be worsened by ribavirin, end-stage kidney disease in whom ribavirin clearance is diminished resulting in intractable anemia, and decompensated cirrhosis where treatment has been associated with fatal outcomes. Decisions about treating patients with any of these conditions, and others not listed here, must be carefully considered on an individual basis [296]. Furthermore, treatment decisions should also weigh other factors such as severity of liver disease, likelihood of treatment success, likelihood of tolerating treatment with pegIFN and ribavirin, and patient motivation.

Side effects of therapy

Clinicians must counsel patients about the natural history of hepatitis C, expected outcomes, and the potential side effects of treatment, all tailored to the specific clinical situation of the individual patient in order to arrive at an informed decision about treatment. Quality of life, in all its dimensions, is diminished during treatment with pegIFN and ribavirin as measured by standardized instruments such as SF-36, Health-Related Quality of Life Questionnaire, Hepatitis Quality of Life Questionnaire, and the Sexual Health, and Work Productivity and Impairment Index [619,620]. The side effects of pegIFN and ribavirin are well known and have been reviewed in detail in a number of publications [598]. Influenza-like symptoms (low-grade fever, myalgia, arthralgia) are most common during the first few weeks of combination antiviral therapy and can be managed successfully with analgesics and antipyretics. Insomnia, headache, and gastrointestinal symptoms of nausea, vomiting, and diarrhea are also common and may be symptomatically managed. Injection site reactions, usually mild, may occur with pegIFN preparations. Skin rash from ribavirin, manifested usually as a maculopapular eruption, occurs in less than 10% of patients and may be managed with topical or systemic antihistamines [621]. Continued treatment is warranted provided the skin manifestations are not progressive. Laboratory abnormalities (anemia and thrombocytopenia) are the most frequent indications for dose reduction (either temporary or permanent), which occurs in up to 25% of patients. In the registration trials of pegIFN-α-2a and pegIFN-α-2b, combined with ribavirin, 10–14% of patients prematurely discontinued therapy due to adverse events.

Hematologic abnormalities

Ribavirin-induced anemia has been discussed previously. PegIFN causes neutropenia and thrombocytopenia due to its suppressive effects on the bone marrow. Dose reductions of pegIFN are recommended in the product insert when neutrophil counts fall below 750 cells/cm^3. However, retrospective analysis in several studies has not identified an association between neutropenia and increased risk for infections. Thus, a more liberal dose reduction criterion (<500 absolute neutrophils $x10^6$/L) has been adopted prospectively in some studies without an increase in adverse events [622]. Therefore, the use of granulocyte colony-stimulating factors should be reserved only for the most severe neutropenia not responsive initially to dose reduction of pegIFN. The incidence of clinically significant thrombocytopenia is low and usually responds to dose reduction to maintain platelet counts above 50,000 $\times$ 10^6/L. Only 3% of patients discontinued treatment due to thrombocytopenia [598].

Interferon-associated depression

A high proportion of individuals with chronic hepatitis C have psychiatric co-morbidities, including substance abuse, that complicate antiviral therapy [623]. Up to 75% of patients referred for evaluation may be initially deferred from treatment due to these concurrent issues [624]. Prior to starting interferon-based therapy at a tertiary referral center, a remarkable 47% reported a past history of depression and 14% reported anxiety [625]. The frequency of preexisting psychiatric disease and the incidence of interferon-associated neuropsychiatric adverse events is variable and somewhat dependent on the method of ascertaining the diagnosis [626].

In registration trials of pegIFN and ribavirin, the most common reason for withdrawal of therapy was interferon-associated depression, which occured by self-report in 20–30% of patients [568,569,598]. In the VIRAHEP-C cohort, a study of African-American and Caucasian-American patients treated with pegIFN-α-2a and ribavirin, depression as defined by a screening instrument was present at baseline in 12% of patients [627]. These patients were more likely to have psychiatric adverse events, to begin antidepressants during treatment, or to have earlier treatment discontinuation, although their SVR rate was not significantly different from those without baseline depression. New-onset depression developed in 26% of patients, usually during the first 12 weeks of combination antiviral therapy. One third of patients started antidepressants during the course of the study. Interestingly, patients with new-onset depression were less likely to discontinue treatment (6% versus 15%) and had similar SVR rates compared with those who did not develop depression (47% versus 38%). There was no difference in the rates of depression before or during treatment between the African-American and the Caucasian-American participants [627].

Specific questions about depressive symptoms and past history of depression, treatment with antidepressants, suicide attempts, or psychiatric hospitalizations

suggest significant psychiatric disease that may be a contraindication to interferon-based therapies. Those with poorly controlled mood disorders or who have had treatment-limiting depression during prior interferon treatment warrant evaluation by mental health professionals. Patients with stable depression, including those on pharmacologic therapy, with access to mental health providers may be treated with interferon-based therapies albeit with close monitoring for exacerbation.

Studies that have evaluated prophylactic selective serotonin reuptake inhibitor (SSRI) antidepressants have not demonstrated consistent benefit in decreasing the rate of major depression, although the severity of depressive symptoms during treatment has been reduced in those with elevated depressive symptoms at baseline [628]. Patients who experienced major depression during an earlier course of interferon have lower depression scores during retreatment when preemptively started on an SSRI [629]. Thus, selective use of pretreatment antidepressants appears warranted in those at highest risk for interferon-associated depression. In all others, symptom-directed management when depressive symptoms occur may be the best strategy. Depression first manifested during antiviral therapy can usually be managed with antidepressants, such as an SSRI, that have been shown to ameliorate symptoms and allow for completion of antiviral therapy [630]. Selecting the best agent for an individual patient should involve weighing the benefits against the potential for adverse events and drug–drug interactions [626]. Pharmacologic therapy, close monitoring, and regular follow-up with mental health providers will maximize the chances of successful antiviral treatment.

Uncommon side effects

Package inserts for both pegIFN preparations list numerous uncommon side effects that clinicians should be aware of and should consider in their differential diagnosis of symptoms during pegIFN and ribavirin therapy.

Thyroid dysfunction may develop in approximately 10% of patients treated with interferon-based regimens. Risk factors include female gender and the presence of pretreatment thyroid autoantibodies, although these are not measured routinely [631]. Patients should be monitored clinically and for changes in thyroid-stimulating hormone approximately every 12 weeks during therapy and during 6 months of post-treatment follow-up. Hypothyroidism can usually be managed with thyroid hormone replacement while continuing pegIFN and ribavirin. Mild hyperthyroidism may be managed symptomatically while still on therapy although progressive or severe hyperthyroidism may require discontinuation of antiviral therapy as well as thyroid ablative regimens. Thyroid abnormalities may spontaneously resolve in the majority of patients once pegIFN is discontinued.

Ocular abnormalities include cotton wool spots, retinal hemorrhage, and retinal vein thrombosis [632,633]. Patients with risk factors for diabetic or hypertensive retinopathy should undergo baseline fundoscopic examination as part of their routine medical follow-up. Cotton wool spots are frequently evanescent and rarely prompt discontinuation of therapy. Retinal hemorrhage has been reported in patients undergoing routine ophthalmologic examination with or without visual symptoms and may also resolve with continued treatment. Visual loss from retinal vein thrombosis and retinal detachment has also been reported and should prompt discontinuation of treatment. Patients with visual disturbances during pegIFN and ribavirin therapy require close ophthalmologic follow-up.

Interstitial pneumonitis is another extremely rare complication of interferon-based therapies with fewer than 100 reported cases in the literature [634]. However, interstitial pneumonitis may progress to respiratory failure and death and, thus, must be differentiated from other pulmonary processes such as bacterial/viral pneumonia, interferon-induced sarcoidosis, or the benign, dry cough that may be seen with ribavirin administration. Pneumonitis is usually characterized by fever, dyspnea, and characteristic findings on chest X-ray or high-resolution chest computed tomography. Prompt recognition and immediate discontinuation of pegIFN may prevent progression, although severe cases may require steroid therapy.

Treatment of hepatitis C virus in special populations

Cirrhosis and decompensated cirrhosis

Many patients present to medical attention for the first time with evidence of cirrhosis and portal hypertension due to the asymptomatic nature of hepatitis C infection. Patients with decompensated cirrhosis are not candidates for treatment with pegIFN and ribavirin due to the high rate of morbidity and mortality. However, patients with well-compensated cirrhosis may be treated with these agents although rates of SVR are somewhat lower than for earlier stages of liver disease [568,569,635]. Hepatic decompensation as a result of interferon-based therapy has been rarely reported so careful selection of treatment candidates and regular monitoring for adverse events and hepatic dysfunction is warranted. Patients with cirrhosis and portal hypertension may have lower levels of platelets and neutrophils at baseline, which further complicates the management of this population. Patients with cirrhosis who achieve a SVR have diminished complications of liver disease during long-term follow-up and may remain free of HCV infection after liver transplantation [635–638]. There is still a risk for hepatocellular

carcinoma in the presence of cirrhosis so that appropriate surveillance is indicated despite the resolution of HCV infection [637].

African-Americans and Latinos

Racial disparity exists in the response to pegIFN and ribavirin for chronic hepatitis C [639,640]. The VIRAHEP-C study treated more than 400 African-American and Caucasian-American patients with pegIFN-α-2a and ribavirin at conventional doses [622]. SVR was 28% in African-American and 52% in Caucasian-American participants. As discussed above, a large proportion of the racial disparity can be attributed to the prevalence of the unfavorable *IL28B* genotype in African-Americans, although other factors as yet unidentified contribute to differences in therapeutic response. A study of Latino patients also demonstrated a diminished rate of SVR compared with non-Latino white patients: 34% versus 49%, respectively [641]. Reasons for ethnic disparities in this group remain speculative.

Coinfection with human immunodeficiency virus

Patients with chronic hepatitis C who are coinfected with HIV represent unique challenges for the management of hepatitis C. The natural history of hepatitis C with HIV coinfection appears to be truncated, with patients progressing more rapidly to cirrhosis compared with hepatitis C infection alone. As antiretroviral therapy has become more effective with more patients living with HIV infection, the incidence of HCC is one of the non-AIDS defining cancers that has increased in the last decade in the United States and is a leading cause of liver-related mortality among HIV/HCV coinfected patients in a report from France [642–644]. Furthermore, HIV patients with chronic hepatitis C may have a higher incidence of hepatotoxicity from antiretroviral therapy, which can complicate management of HIV infection [645]. Thus, HCV viral eradication is warranted in an attempt to prevent complications and improve outcomes in this population.

Drug–drug interactions, particularly with ribavirin, must be evaluated and HIV treatment regimens potentially altered to minimize the risk of added toxicities. The use of didanosine (DDI) is prohibited during HCV therapy due to the increased risk of mitochondrial toxicity and lactic acidosis. Increased anemia has been observed in patients treated with azidothymidine (AZT) and ribavirin [644]. Abacavir, another guanosine analog that may compete with ribavirin for intracellular phosphorylation, has been associated with diminished antiviral response to pegIFN and ribavirin, although another study has recently challenged this assertion [646,647]. A recent study suggested that laboratory evidence of mitochondrial toxicity, itself associated with higher dosage of ribavirin, was also associated with higher rates of SVR [648].

Patients with HIV infection under adequate control with CD4 counts above 200 are generally considered good candidates for HCV therapy provided they have no additional contraindications to pegIFN and ribavirin. Guidelines for monitoring treatment response utilizing a response-guided approach, importance of ribavirin exposure, and management of adverse events are similar to those for the HCV monoinfected population. Several studies have evaluated both pegIFN preparations combined with ribavirin for the treatment of HCV/HIV coinfected patients. Unfortunately, SVR rates are consistently lower in the HIV-positive population, ranging from 29% to 36% for genotype 1 disease and 55% to 60% for genotypes 2 and 3 [649]. Several studies have investigated *IL28B* genotype and treatment response in the coinfected population. Although the overall SVR rates are substantially lower, the relationship between favorable CC and unfavorable CT or TT genotypes is still evident in this group [650,651].

Early studies utilized lower doses of ribavirin due to concerns related to drug–drug interactions and adverse events [652–654]. A recent multicenter study randomized over 400 genotype 1 patients to pegIFN-α-2a and ribavirin at doses of either 800 mg/day (FDA-approved labeling) or conventional doses of 1,000–1,200 mg/day based on body weight [655]. SVR rates for both arms were similar and disappointing, 19% versus 22%, respectively. The suboptimal treatment responses to current therapies coupled with the unfavorable natural history among HCV/HIV coinfected populations underscores the critical need for more effective therapies. Triple therapy combinations with pegIFN, ribavirin, and protease inhibitors remain under investigation although no preliminary data are currently available in the HIV-positive population.

Hepatitis C in renal disease and dialysis

Testing for hepatitis C is routinely recommended for patients on hemodialysis. In the United States, approximately 15% of these patients have evidence of hepatitis C infection, although the prevalence varies around the world with prevalence rates of 2.6% and 22.9% reported in the United Kingdom and Spain, respectively [296]. While most patients on hemodialysis have independent risk factors for HCV infection, such as blood transfusion or intravenous drug use, a measurable rate of de novo acquired hepatitis C has been reported and can be traced to a breakdown of universal precautions during the dialysis procedure [296,656,657]. The hemodialysis machine and dialysis membranes themselves are not considered sources of HCV infection and patients do not need to be dialyzed on dedicated machines.

Higher mortality rates have been reported in dialysis patients with hepatitis C infection compared with noninfected patients. Similarly, studies of patients who

underwent kidney transplantation indicate that survival for HCV-positive recipients and their grafts diverge from observed outcomes in the HCV-negative transplant population during long-term follow-up [658,659].

Treatment for hepatitis C in patients with chronic kidney disease is associated with generally lower response rates and higher rates of adverse events [660,661]. Treatment must be modified according to the severity of renal impairment. For patients with intact glomerular filtration rate, treatment with pegIFN and ribavirin can be managed according to published guidelines. Standard interferon or pegIFN at reduced doses (pegIFN-α-2a 135 μg/week and pegIFN-α-2b 1.0 μg/kg/week) can be administered to patients on hemodialysis. Interestingly, SVR rates utilizing interferon-based monotherapy are higher in those on dialysis (SVR ~30%) than historically reported from other populations treated with interferon alone [296,661]. Extreme caution is required with the use of ribavirin in the setting of hemodialysis since this medication is not dialyzed and hemolytic anemia will worsen. Ribavirin is contraindicated when the glomerular filtration rate falls below 50 cm^3/min although several small studies have utilized low-dose weekly dosing, or dosing titrated to blood ribavirin levels in an attempt to improve SVR and minimize adverse events [661].

Treatment of chronic hepatitis C in patients following kidney transplantation has not been routinely recommended due to concerns of renal graft dysfunction and rejection, which has been reported in the majority of participants in small clinical trials of interferon-based treatment [662]. The notable exception are those patients who develop fibrosing cholestatic hepatitis, a rapidly progressive, frequently fatal, liver injury reported in several types of solid organ transplantation [663]. Interferon-based therapy may improve liver injury due to fibrosing cholestatic hepatitis even in the absence of SVR [296,664].

Cryoglobulinemia and glomerulonephritis

The pathogenesis of cryoglobulinemia has been discussed above. The clinical manifestations of cryoglobulinemia associated with hepatitis C infection are quite variable but may include purpuric skin rash due to a leukocytoclastic vasculitis usually on the lower extremities, glomerulonephritis with potential to progress to chronic kidney disease, and peripheral neuropathy [665,666]. In a large study from Italy nearly 50% of 343 consecutively evaluated patients with chronic hepatitis C had measurable cryoglobulins [667]. However, few had cryoglobulinemic syndromes or signs of vasculitis. The presence of cryoglobulins in this large prospective cohort did not impact upon the development of cirrhosis, overall survival, or the response to interferon-based treatments.

Treatment with pegIFN and ribavirin can be considered for patients with hepatitis C and mild manifestations of cryoglobulinemia. When patients have progressive vasculitis and organ damage, therapy is focused on gaining immediate control of the vasculitis utilizing therapies such as corticosteroids, plasma exchange, cyclophosphamide, or rituximab, which has been shown to exert its effect through the suppression of cryoglobulin-producing B cells [666]. Once stable, definitive treatment with pegIFN and ribavirin can be considered.

Membranoproliferative glomerulonephritis, usually in association with cryoglobulinemia, is the most common form of kidney disease associated with hepatitis C [657]. Treatment with interferon and ribavirin resulting in SVR has been associated with improvement in proteinuria and kidney function.

Acute hepatitis C

Clinicians rarely identify acute hepatitis C since the majority of infections are asymptomatic. Approximately 50% of patients with acute hepatitis C will spontaneously resolve the acute infection without treatment [668,669]. Thus, patients should be followed initially with serial quantitative HCV RNA determinations to determine whether spontaneous resolution may occur. Within the first 12 weeks of presentation, persistently high levels of viremia with failure to demonstrate log-folds of decline in viremia as a prelude to undetectable HCV RNA suggests that spontaneous resolution is unlikely and treatment should be instituted, if possible. Delaying therapy beyond 12–16 weeks appears to be associated with diminished treatment response approaching the expected rates of SVR for chronic HCV.

Numerous studies have evaluated a variety of treatment regimens for acute hepatitis C utilizing either standard interferon or pegIFN monotherapy for treatment durations ranging between 4 and 24 weeks [668,670–672]. Impressive therapeutic responses for patients treated in the acute phase of HCV infection are seen with rates of SVR usually greater than 80%. These results are significantly higher than historical studies of chronic HCV infection, emphasizing the importance of early diagnosis and treatment of acute HCV once spontaneous clearance is excluded. The best treatment regimen remains controversial, although treatment for between 12 and 24 weeks of treatment is likely the optimal duration as currently recommended. One study evaluated 8, 12, or 24 weeks of treatment with pegIFN-α-2b and attained a SVR in 68%, 82%, and 91% of patients, respectively [673]. Genotypes 2, 3, and 4, and those with a rapid virologic response did well with shorter duration of therapy, while genotype 1 patients did best with 24 weeks of treatment in the acute setting. Thus, consideration can be given to individualizing therapy based upon virologic response, however this must be weighed against the risk of relapse for an individual patient. Combination therapy with ribavirin

has been used to treat acute HCV [674]. SVR rates have also been uniformly excellent, although the contribution of ribavirin compared with pegIFN monotherapy cannot be ascertained from the currently available data.

Treatment-experienced patients

The decision to embark on a repeated course of therapy must be individualized for each patient by considering the potential benefits when options are limited and the chances for success are quite low [543,675]. The likelihood of SVR during a second course of treatment with pegIFN and ribavirin is associated with the prior response achieved during their first course of combination therapy. Prior null and partial responders are least likely to benefit from another course of treatment with pegIFN and ribavirin, with SVR rates rarely surpassing 15% [676]. Success rates may be even lower when there are multiple unfavorable treatment factors. Previous pegIFN/ribavirin nonresponders with a constellation of unfavorable treatment characteristics, such as advanced fibrosis and high viral load, had only a modest response when treated with consensus interferon. The SVR rate was 7% and 11% when patients were treated with either 9 or 15 μg of consensus interferon daily, respectively, combined with ribavirin [677]. SVR rates were higher (32%) if patients had demonstrated at least a 2-log decrease in viremia during their previous course of pegIFN/ribavirin.

Prior relapsers have a better chance of achieving SVR during a second course of treatment. Poynard and colleagues [678] retreated over 2,300 prior nonresponders and relapsers (all with advanced fibrosis) with pegIFN-α-2b and ribavirin (800–1,400 mg/day) for 48 weeks. The SVR rate was 38% among prior relapsers but only 14% among prior nonresponders. This marked difference in success rates between relapsers and nonresponders further emphasizes the importance of accurately characterizing prior treatment response. Genotype non-1, HCV RNA <600,00 IU/mL, and lower fibrosis stage were associated with improved treatment response. Patients who failed to clear HCV RNA by week 12 of retreatment had no chance of SVR, suggesting that a short trial of retreatment incorporating firm stopping rules could minimize futile therapy.

Modifying a treatment course to improve response

Intensifying treatment regimens with higher doses of pegIFN, higher doses of ribavirin, or extended duration of therapy in these patients has met with only limited success. Extending therapy to 72 weeks has been shown to decrease relapse rates among genotype 1 slow virologic responders. A four-arm study compared 12 weeks of higher dose induction of pegIFN with standard doses in combination with ribavirin for either 48 or 72 weeks [679]. Similar rates of SVR were attained in the induction dose (16%) or standard dose group (14%) treated for 72 weeks. These were higher than the 48-week treatment regimens, suggesting that the duration of therapy rather than the induction dose of pegIFN was of greater importance in prior treatment failures.

Role of maintenance therapy

Prolonged treatment with pegIFN alone has been investigated in an attempt to decrease adverse clinical outcomes among patients with advanced fibrosis. The HALT-C study treated a large cohort of these patients with a low dose of pegIFN-α-2a for 3.5 years to determine if maintenance therapy, without viral eradication, would decrease the rates of fibrosis progression, hepatic decompensation, and HCC [680]. In a rigorously controlled trial, there were no differences in the rates of these events between the treated group and an observational control group. A preliminary report from this study suggested that the incidence of HCC was decreased in the treated population, which only became evident after year 6 of follow-up [681]. The CO-PILOT study treated 555 patients with advanced fibrosis with low-dose pegIFN-α-2b or colchicine for up to 4 years. In both intention-to-treat (ITT) and per-protocol analyses, the rates of clinical end-points (death, liver transplant, HCC, or worsening Child–Pugh score) were similar between the two groups [682]. In a subset of patients with portal hypertension, those treated with maintenance pegIFN had a lower incidence of variceal hemorrhage. Nearly 50% of patients discontinued treatment prematurely during the study. At this point, maintenance therapy cannot be endorsed for prior nonresponders to therapy.

For all of these strategies that utilize intensified/modified treatment regimens, one must consider the costs and side effects against the marginal benefit gained by treatment-experienced patients. Furthermore, new direct-acting antiviral agents, in triple combination therapy with pegIFN and ribavirin, will provide many patients with additional therapeutic options and a greater chance of success.

Direct-acting antiviral agents

The treatment of chronic hepatitis C will be transformed with the availability of direct-acting antiviral agents that specifically target critical enzymes in the replication of HCV. As described above, several HCV proteins possess well-defined enzymatic activities, including NS2 (a *cis*-acting protease), NS3/4A (serine protease-helicase), NS4B (GTPase), and NS5B (RNA-dependent RNA polymerase) that serve as targets for HCV therapy (Fig. 25.15).

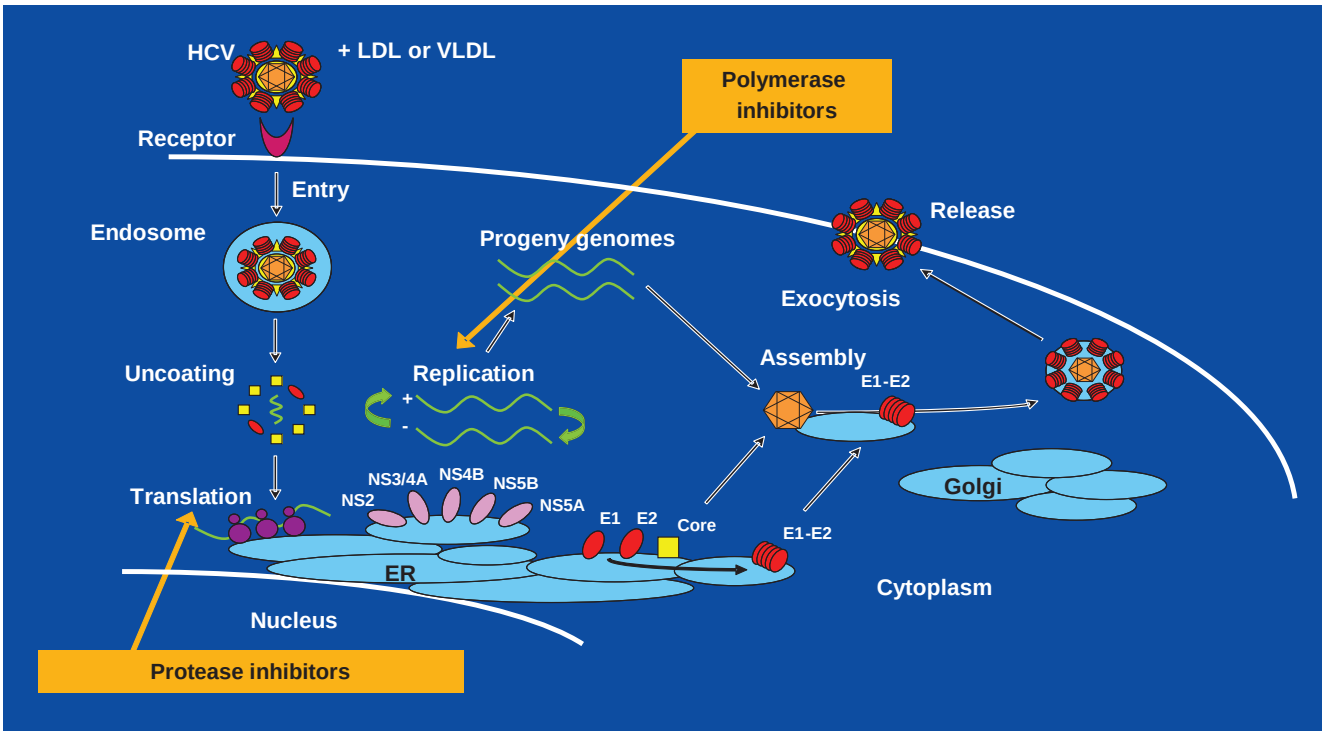

Figure 25.15 Targets for small molecule antiviral therapy. (Reproduced from Racanelli and Rehermann [732] with permission from Elsevier.)

The NS3/4A protease and NS5B polymerase have proven to be particularly promising targets for developing antiviral drugs against HCV. Inhibition of NS3/4A protease activity, because of its essential role in polyprotein processing, ablates virus replication. Inhibitors of the NS5B polymerase also block replication of the virus by preventing synthesis of the viral RNA. In a departure from prior antiviral drug discovery efforts, however, recent work has proven that HCV proteins that lack defined enzymatic activity (e.g., NS5A) also may be exceptionally good targets for antiviral drug development.

A major generic issue with the use of most small molecule antivirals against HCV is the relatively rapid selection of drug-resistant virus. This is fueled in part by the error-prone nature of HCV RNA replication, coupled with high-level replication of the virus in the typical infected individual [683]. In clinical practice, this will be countered by the use of these novel therapeutics as a component of combination therapy, at first together with pegIFN/ribavirin and eventually all-small-molecule combinations.

NS3/4A protease inhibitors

The NS3/4A protease plays a central role in processing the HCV polyprotein, and is distinct structurally from cellular proteases. Early studies demonstrated that the protease is subject to inhibition by short peptide sequences representing the carboxy terminal NS3 sequence [684]. Although the substrate-binding cleft is otherwise unusually broad and shallow for a viral protease, it has been possible to design peptidomimetic compounds with substantial inhibitory activity. Such compounds fall into two general classes: linear peptidomimetics (e.g., telaprevir and boceprevir) and macrocyclic compounds (e.g., ciluprevir (BILN2061), danoprevir (ITMN-191), and TMC434350). While protease inhibitors also block HCV-induced MAVS and TRIF cleavage, there are no data suggesting that the resulting rescue of endogenous IFN responses contributes to their antiviral effect in infected persons. As with many small molecule antivirals, protease inhibitors present a relatively low barrier to resistance, with resistant virus emerging rapidly in many patients placed on monotherapy with these compounds [685,686].

NS5B polymerase inhibitors

A large number of small molecule inhibitors of the NS5B polymerase have been identified. These fall into two general types: nucleoside analogs that bind into the active site, and non-nucleoside inhibitors (NNIs) derived from a variety of chemical backbones including

benzimidazoles, benzothiadiazines, and thiophene 2-carboxylic acids [687–689]. Nucleoside analogs typically demonstrate potent inhibition of polymerase activity; they undergo phosphorylation within the cell and generally act by competing with other nucleotide triphosphates as well as by chain termination of nascent RNA strands. Available evidence suggests that the nucleoside analogs provide a high barrier to resistance, as mutations within the active site that confer resistance to these inhibitors typically result in virus with very low replication fitness [690]. Non-nucleoside polymerase inhibitors appear to inhibit only the initiation of RNA synthesis, not elongation [691]. NNIs are typically less potent than the nucleoside analogs, and present a much lower barrier to resistance with treatment leading to relatively rapid selection of resistant virus mutants with good replication fitness.

Nonenzymatic polyprotein targets

Potent inhibitors of HCV replication directed against NS5A, a nonstructural protein with no known enzymatic function, have been identified in high-throughput, cell-based screens for chemical compounds that inhibit HCV replicon amplification. Exactly how these NS5A inhibitors function is not known, but they may be interacting with dimeric NS5A and possibly blocking its ability to participate in replicase assembly or function. Consistent with the in vitro potency observed with these compounds, a single dose of BMS-790052 produced a 3.6 $\log_{10}$ decline in plasma virus load [692]. Recent clinical data suggest that these compounds, like the protease inhibitors and allosteric inhibitors of NS5B, may present a relatively low barrier to resistance, especially for genotype 1 virus. Other nonenzymatic targets exist for the development of antiviral agents, including the interaction of miR-122 with the 5′ UTR of the HCV genomic RNA [693] and an interaction of NS4B with viral RNA [694].

Protease inhibitors

The landmark study of BILN-2061, a macrocyclic NS3 protease inhibitor, was published in 2003 and demonstrated dramatic viral inhibition of HCV RNA in patients with genotype 1. After only 48 hours of treatment with a twice-daily oral solution of BILN-2061, most patients had HCV RNA levels below the limit of quantitation, corresponding to a decrease of approximately 3-logs of HCV RNA [695]. Viremia gradually returned to pretreatment levels within 1 week of cessation of therapy. Subsequent short-term studies in more patients confirmed these impressive virologic responses [696]. However, optimism for this compound was arrested when animal toxicology studies demonstrated cardiac toxicity over a 4-week dosing period, which led to permanent discontinuation of the development of BILN-2061. Nevertheless, proof of concept had been established that an NS3 protease inhibitor could be a potent treatment for chronic hepatitis C. This discovery led to an intensive period of drug development, continuing today, of multiple classes of drugs targeting different aspects of HCV replication. Dozens of direct-acting antiviral agents have been synthesized and are being tested in human studies with varying degrees of success; some agents are proceeding along the pathway toward approval and clinical use while many others have failed due to efficacy or safety issues.

Telaprevir and boceprevir, also protease inhibitors, have successfully completed phase III clinical trials and are expected to be approved by the US FDA in 2011. The development of these agents has provided important insights into the promises and perils of direct-acting antiviral therapy and has provided a roadmap for exciting new therapies.

Telaprevir in treatment-naïve patients

Telaprevir is a selective, covalent NS3/NS4 protease inhibitor active against the protease of genotypes 1–4 in studies of the HCV replicon [697,698]. The short half-life of telaprevir, approximately 4–5 hours, necessitates frequent dosing and current studies have utilized telaprevir 750 mg administered every 8 hours, although higher doses administered every 12 hours are under investigation.

A phase Ib study treated patients with three different regimens of telaprevir monotherapy or placebo for a total of only 14 days [699]. Remarkably, all patients treated with telaprevir 750 mg administered every 8 hours achieved at least a 3-log reduction in HCV RNA with a median maximal decrease of –4.77 $\log_{10}$ from baseline. This dose appeared to be optimal for subsequent phase II and phase III studies. However, this study also confirmed that telaprevir monotherapy was not viable for the treatment of chronic hepatitis since virologic breakthrough and viral variants with reduced sensitivity to telaprevir were identified in patients [700].

Studies of utilizing replicons demonstrated that NS3 variants expected with telaprevir remained sensitive to interferon, and clinical studies, fortunately, confirmed that the combination of telaprevir with pegIFN and ribavirin mitigated the impact of viral resistance [701–703]. Kieffer and colleagues [702] performed a detailed analysis of viral resistance and the impact of pegIFN on subsequent virologic response. Patients who developed virologic rebound during telaprevir monotherapy had multiple resistant variants at the end of a 14-day course of treatment. When these patients were then treated only with pegIFN and ribavirin, HCV RNA became

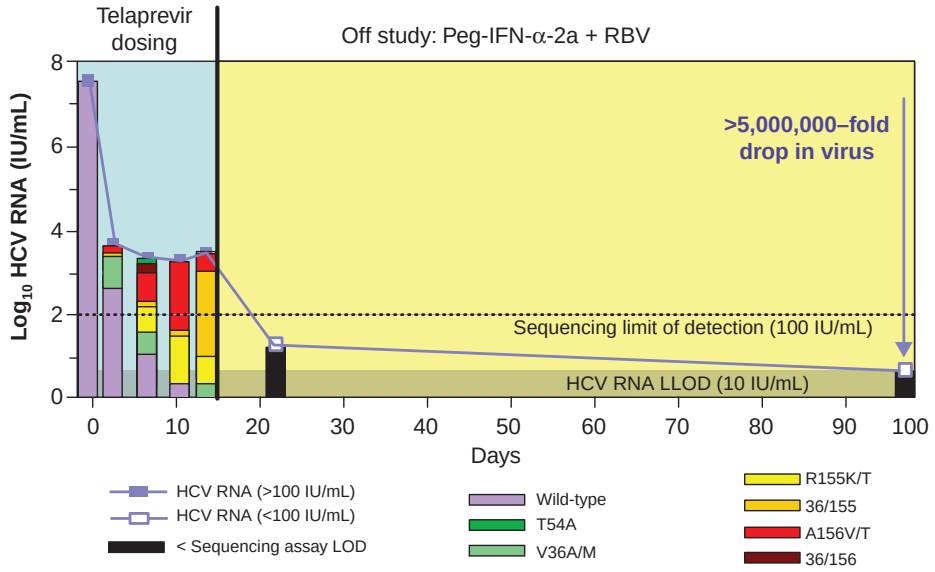

Figure 25.16 Resistance virus is selected with telaprevir alone but declines with pegylated interferon-α-2a (pegIFN-α-2a) and ribavirin (RBV). HCV, hepatitis C virus; LLOD, lower limit of detection; LOD, limit of detection. (Reproduced from Kieffer et al. [702] with permission from Plenum.)

undetectable (Fig. 25.16). A separate small cohort of patients who were initially treated with telaprevir and pegIFN demonstrated a more consistent decline in HCV RNA with only rare resistant mutations detected during the initial 14 days of treatment. Furthermore, subsequent therapy with only pegIFN and ribavirin maintained patients with undetectable viremia [702]. This important study provided the rationale for triple combination therapy as a way to prevent the selection of telaprevir resistant variants. A detailed discussion of viral variant-associated protease inhibitors will be provided below.

The encouraging results from phase I studies provided impetus for a series of phase II trials that incrementally contributed to our understanding of the clinical utility of telaprevir. In a study designated PROVE1, noncirrhotic genotype 1 patients were randomized to 12 weeks of treatment with telaprevir 850 mg every 8 hours + pegIFN and ribavirin [704]. Two arms of the study extended treatment with pegIFN and ribavirin only for an additional 12 weeks (24 weeks total treatment) or for 36 weeks (48 weeks total treatment). In order to qualify for a shorter duration of therapy, patients were required to have a RVR (undetectable HCV RNA at week 4). RVR was achieved in 81% of patients in both arms and SVR rates were 61% and 67%, respectively. A small number of patients in an exploratory regimen were treated with triple therapy for only 12 weeks without any additional pegIFN/ribavirin and achieved an SVR of 35%, while in the pegIFN and ribavirin control group, the rate of SVR was 41%. Virologic breakthrough was seen in 7% of patients treated with telaprevir. Adverse events were more frequent in the telaprevir-containing arms and the most common reason for treatment discontinuation was skin rash (7%). Thus, triple therapy for 12 weeks followed by pegIFN and ribavirin significantly improved the rate of SVR over pegIFN and ribavirin alone. Total treatment duration of 48 weeks did not appear to increase SVR compared with the 24-week telaprevir regimen [704].

PROVE2 sought to investigate whether ribavirin contributed to SVR in the presence of telaprevir and also to further investigate the feasibility of shortening the duration of therapy in a population of European patients with genotype 1 [705]. The study design included two arms treated for only 12 weeks with either triple therapy or pegIFN and telaprevir (no ribavirin). SVR in these arms was 60% and 36% and, importantly, demonstrated that the absence of ribavirin impaired antiviral response by permitting more virologic breakthrough and relapse [705]. The study also confirmed that SVR for a complete course of only 12 weeks of triple therapy (60%) was, again, numerically, inferior to 12 weeks of triple therapy plus 12 weeks of pegIFN and ribavirin (69%), although the SVR rate was higher than that seen in PROVE1 for the same treatment regimen (60% versus 35%, respectively).

The foregoing studies informed the plans for phase III trials that have recently been reported [706]. The study design for ADVANCE is shown below. Patients ($n = 1{,}088$) were randomized to therapy with telaprevir plus pegIFN-α-2a 180 μg/week and ribavirin 1,000–1,200 mg/day for either 8 weeks or 12 weeks, both of which were followed with pegIFN and ribavirin only for an additional 12 weeks. Using a

response-guided treatment algorithm, patients who achieved RVR and maintained undetectable viremia through week 12 stopped treatment with a total duration of 24 weeks of therapy. Those not achieving RVR received up to 48 weeks total duration of therapy. Patients in the control arm were treated with pegIFN and ribavirin at conventional doses and accepted stopping criteria. Approximately two thirds of patients achieved RVR in the telaprevir-containing arms, compared to only 9% in the control group. About 60% of patients remained eligible to receive only 24 weeks of treatment. The difference was attributed to either premature discontinuation of telaprevir due to adverse events or the development of virogical breakthrough. SVR rates in the 12-week and 8-week triple therapy arms were 75% and 69%, respectively, both significantly greater than the control arm of 44%. Of note, the virologic failure rate was lower in the 12-week triple therapy arm compared with the 8-week regimen (5% versus 10%, respectively) [706].

ILLUMINATE was another phase III trial with a noninferiority design to compare a 24-week regimen to a 48-week regimen in patients with a RVR [707]. All patients received an initial 12 weeks of triple therapy with telaprevir. Those who achieved undetectable viremia at weeks 4 and 12 were randomized to either an additional 12 weeks or 36 weeks of dual combination therapy with pegIFN and ribavirin. Approximately 60% of patients were eligible for randomization having achieved and maintained RVR during the first 12 weeks of triple therapy treatment. Among these RVR patients, 92% treated for only 24 weeks achieved a SVR compared with 88% of those treated for 48 weeks. The difference in response indicated that 24 weeks was noninferior to 48 weeks of treatment [707].

Boceprevir

Boceprevir is another peptiometic, ketoamide NS3 protease inhibitor that has demonstrated potent efficacy in patients with genotype 1 infection. A phase Ib study in prior interferon nonresponders assigned noncirrhotic patients to treatment sequentially with boceprevir monotherapy for 7 days, followed by pegIFN-α-2b for 14 days, and then boceprevir combination therapy for 14 days [708]. The sequence of treatment was altered and two different doses of boceprevir (200 or 400 mg three times daily) were used, yielding a six-arm study design. The study demonstrated that the mean maximal decrease in HCV RNA in the higher boceprevir monotherapy dosing group was $-1.61\ \log_{10}$ after 1 week while the combination of boceprevir and pegIFN yielded a greater mean maximal change of $-2.48\ \log_{10}$ during the same period. The combination treatment was well tolerated with few serious adverse events [708]. A subsequent phase II study in a difficult-to-treat null responder population, defined as failure to achieve an EVR, suggested that a higher dose of boceprevir (800 mg three times daily) would be optimal and also further reinforced the importance of ribavirin in triple therapy combinations [709].

Encouraging results in the nonresponder population informed the design of a large phase II study in treatment-naïve genotype 1 patients. SPRINT-1 randomized 595 patients in a complex seven-arm design to evaluate treatment duration and a novel lead-in strategy, whereby some patients received pegIFN and ribavirin alone for the first 4 weeks followed by the addition of boceprevir while others received all three drugs from treatment inception [710]. Thus, patients received a total of either 28 or 48 weeks of treatment. The results indicated that all four boceprevir-containing regimens had significantly better rates of SVR (ranging between 54% and 75%) compared to the pegIFN and ribavirin control arm (38%). RVR rates for those treated with boceprevir during the initial 4 weeks of treatment were also higher. Overall, attainment of RVR was associated with the best rates of SVR, ranging between 74% and 94%. Furthermore, relapse rates were lowest in the patients treated for 48 weeks with boceprevir (3–11%), either with or without the pegIFN/ribavirin lead-in phase, compared with shorter duration of therapy (24–30%) [710].

The inclusion of a lead-in phase in this study also demonstrated that the lowest rates of virologic breakthrough (4%) occurred in patients who received pegIFN and ribavirin alone, before initiation of boceprevir, compared with those receiving triple therapy with treatment initiaition (9%) [710]. Population sequencing confirmed the presence of viral mutants resistant to boceprevir. A viral kinetic analysis evaluating the likelihood of SVR with the change in HCV RNA during the first 4 weeks of the lead-in phase suggested that patients who had an initial decline of HCV RNA of at least $1.5\ \log_{10}$ had comparable rates of SVR with the 28-week regimen (SVR = 73%) or the 48-week regimen (SVR = 80%).

This study also included one treatment arm using a lower dose of ribavirin to determine if the addition of boceprevir could allow for ribavirin-sparing regimens. For all efficacy parameters, lower dose ribavirin was suboptimal with lower rates of SVR, and higher rates of relapse and virologic breakthrough confirming the ongoing importance of adequate ribavirin dosing even with triple therapy combinations.

The phase III study of boceprevir, SPRINT-2, was recently presented [711]. Two cohorts of patients, nonblack ($n = 938$) and black ($n = 159$), were prospectively included and analyzed separately. Patients were randomized to treatment with pegIFN-α-2b 1.5 μg/kg/week and ribavirin 800–1,400 mg/day as a lead-in during the first 4 weeks of treatment. Boceprevir 800 mg t.i.d. was added after 4 weeks and patients were treated for another 44 weeks with triple therapy (fixed duration of 48 weeks)

or for a total of 28 weeks utilizing a response-guided algorithm, whereby patients were required to achieve RVR and maintain undetectable viremia through week 20. Approximately 47% of patients were eligible for the shorter treatment duration based upon the favorable viral knetic response. SVR rates in both the fixed duration and the response-guided algorithm boceprevir arms among non-black patients were significantly better than the pegIFN and ribavirin control arm: 68% and 67% versus 40%, respectively. Similarly, although SVR rates were substantially lower for black participants, the same benefit of boceprevir was evident with SVR rates of 53% for the fixed duration and 42% for the response-guided algorithm arms, compared with 23% in the control group. Resistance-associated variants were developed most commonly among patients with the least decrease in HCV RNA ($<1\ \log_{10}$) during the 4-week lead-in phase [711].

In aggregate, these series of phase II and phase III studies demonstrated several important points related to protease inhibitor therapy with telaprevir and boceprevir:

1 Teleprevir and boceprevir are potent protease inhibitors that must be used in combination with pegIFN and ribavirin to minimize viral resistance.
2 Ribavirin remains a critical component of triple therapy combination in order to further diminish viral resistance and prevent relapse.
3 Triple therapy combination with protease inhibitors significantly improves rates of SVR compared with combination therapy with pegIFN and ribavirin alone.
4 The recommended treatment algorithms differ between telaprevir and boceprevir. Telaprevir treatment should incorporate triple therapy beginning with treatment inception while boceprevir regimens should utilize a 4-week lead-in with pegIFN and ribavirin alone before adding boceprevir. Both regimens should incorporate response-guided algorithms to determine the duration of therapy and to guide when protease inhibitors and/or all drugs should be discontinued in order to minimize viral resistance and exposure of patients to futile therapy.
5 The rate of RVR is substantially increased with triple therapy and many patients will be eligible for a shortened treatment regimen of 24–28 weeks total duration based on a response-guided treatment algorithm.

Adverse events of telaprevir and boceprevir

The majority of adverse events associated with triple therapy combinations can be ascribed to the well-known side effects of pegIFN and ribavirin. Nevertheless, some adverse events are accentuated with the addition of a protease inhibitor and new treatment emergent events, unique to this class, have also been described. In the phase III telaprevir studies, the rate of treatment discontinuation with all study medications during the period of triple therapy treatment was low and ranged between 7% and 8% compared to 4% in the control arm [706,707]. In the ILLUMINATE study intention-to-treat population, 17% of patients ultimately discontinued all study drugs due to adverse events during the entire duration of the study. Up to 12% of patients discontinued only telaprevir for any adverse event, most frequently skin rash (7%) of patients treated with telaprevir for 12 weeks [707]. The skin rash was predominantly eczematous and resolved when telaprevir therapy was discontinued, as recommended for moderate or severe progressive skin rash. Mild to moderate rash was managed with topical agents and/or oral antihistamines. Pruritus, in the absence of rash, and gastrointestinal disturbance were also more frequent with telaprevir.

Anemia was also more common in regimens including telaprevir, inducing an additional 1 g/dL decline of hemoglobin in excess of that with pegIFN and ribavirin alone. In the ADVANCE study, up to 40% of patients treated with telaprevir had hemoglobin <10 g/dL compared to 14% in the control arm. Anemia was managed with ribavirin dose reduction and hematopoietic growth agents were prohibited [706].

In the boceprevir SPRINT-2 study, treatment discontinuations due to adverse events were similar in the fixed duration boceprevir regimens and the control group (16% in each), while slightly lower in the response-guided algorithm arm (12%) [711]. Treatment with boceprevir was associated with increased anemia; 49% of patients developed anemia during boceprevir treatment compared with only 29% in the control arm. Erythropoietic-stimulating agents were allowed to be prescribed in this study and over 40% of patients received epoetin-α for anemia management during boceprevir treatment, compared with 23% of controls. Dysgeusia, abnormal taste, was also more frequent with boceprevir therapy.

Triple therapy in treatment-experienced patients

Treatment-experienced patients with genotype 1 who do not achieve a sustained virologic response to pegIFN and ribavirin will benefit from the availability of direct-acting antiviral agents [543].

Telaprevir for treatment-experienced patients: phase II results

PROVE3 treated both nonresponders (~60%) and relapsers (~40%) with telaprevir [712]. The study evaluated the impact of different durations of triple therapy, different total treatment duration, and the importance of ribavirin. In an effort to minimize the development of viral resistance, treatment was discontinued if HCV RNA remained detectable at week 4. Among prior relapsers, SVR was achieved in 76% of those treated

for a total duration of 48 weeks (24 weeks of telaprevir triple therapy followed by 24 weeks of dual pegIFN and ribavirin). The SVR rate in patients treated with only 24 weeks' total duration (12 weeks of triple therapy and an additional 12 weeks of dual combination therapy) was 69%. Prior nonresponders had substantially lower rates of SVR, although nearly 40% achieved SVR with these regimens [712]. Interestingly, when telaprevir and pegIFN were used without ribavirin, the rate of SVR was substantially diminished, emphasizing the importance of ribavirin in triple therapy combinations. The risk of virologic breakthrough, defined as an increase of HCV RNA of more than 1 log from baseline or to more than 100 IU/mL if previously undetectable, was more frequent in previous nonresponders than previous relapsers. By week 24 of treatment, up to 13% of prior relapsers and 45% of prior nonresponders had evidence of virologic breakthrough [543,712].

Telaprevir for treatment-experienced patients: phase III results

The study design of the phase III REALIZE trial, reported only in preliminary form [713], included triple therapy with pegIFN, ribavirin, and telaprevir for 12 weeks begun simultaneously or with a prior lead-in of pegIFN and ribavirin, followed by pegIFN and ribavirin for a total of 48 weeks. In previous relapsers, the SVR rate was 86% in the combined telaprevir arms and 57% in partial responders. The SVR rate in previous null responders was only 31%, confirming the differential response based upon prior experience with dual combination therapy. Only 24% of prior relapsers, 15% of prior partial responders, and 5% of prior null responders achieved SVR when retreated with pegIFN and ribavirin.

Boceprevir for treatment-experienced patients

RESPOND-2 is a phase III trial reported only in preliminary form that included nonresponders and relapsers treated with boceprevir [714]. The three-arm study, in which null responders were excluded, compared a response-guided regimen including boceprevir with a fixed duration 48-week triple regimen versus 48 weeks of pegIFN and ribavirin. Top-line results indicate that 75% of prior relapsers and 52% of prior nonresponders treated with a fixed triple therapy boceprevir regimen achieved SVR. Relapsers and nonresponders in the response-guided treatment arm also had substantial SVR rates of 69% and 40%, respectively [714].

Protease inhibitor resistance

As these small molecule inhibitors of the NS3/4A protease are likely to be licensed for clinical use in the near future, it is appropriate to focus on the special issues posed by the emergence of resistance to these drugs. The highly replicative nature of HCV infection coupled with the error-prone nature of viral RNA synthesis sets the stage for a rapid emergence of resistance to almost any small molecule inhibitor used as monotherapy. As many as 1×10^{12} virus particles are produced each day in a typical, chronically infected individual [715]. The NS5B RNA-dependent RNA polymerase lacks a proof-reading mechanism, and the base misincorporation rate is as high as 10^{-3} to 10^{-4} per nucleotide. Since the genome is only $\sim 10^4$ nucleotides in length, each of the 10^{12} newly synthesized copies of the RNA genome produced each day in the typical patient is likely to contain one or more base substitutions. While many, perhaps most, of these base substitutions are detrimental to viral fitness, others may allow for escape from a particular virus-neutralizing antibody, cytotoxic T-cell clone, or small molecule therapeutic.

All possible single, most double, and many triple nucleotide substitutions are likely to be present in the viral quasispecies prior to the initiation of protease inhibitor therapy [716]. In one study that examined treatment-naïve patients for preexisting resistance mutations, 44.4% of genotype 1b patients had at least one identifiable mutation at sites associated with resistance to one of 27 small molecule antivirals targeting NS3 or NS5B (i.e., protease inhibitors, nucleosides, and non-nucleoside polymerase inhibitors) and 2.7% had mutations in both NS3 and NS5B [268]. A greater frequency of preexisting mutations would undoubtedly be found with more extensive sequencing. Most resistant mutants are present at relatively low frequencies in pretreatment quasispecies, because they are less fit and do not replicate as efficiently as the wild type, but they rapidly become dominant when replication of wild-type virus is suppressed with an antiviral. The emergence of resistance is thus due most often to selection of preexisting variants and not de novo mutations in the virus.

Two general structural classes of HCV protease inhibitors have been developed thus far. Boceprevir and teleprevir are both linear peptidomimetic ketoamides [717,718]. Several other inhibitors now in phase I/II development (i.e., ITMN191, TMC435, and MK7009) [719–721] and are macrocyclic compounds. A variety of amino acid substitutions near the NS3 protease active site can result in resistance to both classes of inhibitors, with the specific responsible mutations dependent on the chemical class and compound (Fig. 25.17). In general, mutations involving Val36 and Thr54 are associated with resistance against the linear ketoamides, while mutations at Asp168 cause resistance to the macrocyclics. However, there is a great deal of overlap, and mutations at Arg155 and Ala156 typically cause high-level cross-resistance to drugs in both groups (Fig. 25.17). Clinical experience in dealing with these mutant viruses is limited. Some may still respond

Figure 25.17 Resistance profiles of protease inhibitors.

to continued inhibitor therapy to some extent, while others may not. Most will be replaced over time by wild-type virus when the drug is discontinued, but how long this will take and how complete this replacement will be is uncertain. Also uncertain is the extent to which prior emergence of resistance to one protease inhibitor will render a patient not likely to benefit from treatment with another – i.e., class resistance.

Many of the mutations have a significant negative impact on viral fitness (replication capacity), both in cell culture and in infected humans. For example, a common resistance mutation (A156T) lowers the capacity of RNA replicons to undergo autonomous amplification in cell culture [722,723]. However, replicons containing drug-resistance mutations are not universally impaired in their ability to replicate as RNA, as those with V36A, Q41R, T54A, A156S, or I170A mutations appear to replicate at least as well as wild-type virus [724–728]. A subset of mutations has also been shown to impair the assembly of infectious viral particles [729].

In general, the first protease inhibitors to be licensed will be restricted in their activity to genotype 1 viruses due to intergenotypic sequence variation at the NS3/4A active site. Newer, second-generation protease inhibitors now under development may provide broader genotype coverage, and also may have increased activity against resistant variants emerging during therapy to first-generation inhibitors. It is too early to predict whether these second-generation inhibitors will be of clinical use in treating these resistant viruses, however.

Since protease inhibitor resistance mutations occur within the NS3 protein, they have no effect on the susceptibility of the virus to polymerase (NS5B) or NS5A inhibitors. The reverse is also true, but both of these classes of antiviral drugs have their own sets of resistant mutants that they select. Resistance to any of these antivirals has no known impact on the susceptibility of virus to pegIFN/ribavirin.

Progress towards interferon-free regimens

It is evident that triple therapy combinations will be the next therapeutic innovation that clearly enhances rates of SVR. However, clinicians and patients would welcome all oral therapies without injectable pegIFN in an attempt to minimize adverse events and extend treatment to populations who are not candidates for interferon-based regimens. As discussed earlier, knowledge of hepatitis C replication pathways and novel drug development strategies have provided numerous potential targets for HCV treatment that are in early stages of exploration.

The INFORM-1 study demonstrated proof-of-concept that combining two classes of direct-acting antiviral agents in a short-term study, without pegIFN or ribavirin, could induce viral suppression without the development of viral resistance [730]. The two drugs used in this study have complementary profiles. RG7128 is a nucleoside NS5B polymerase with a high genetic barrier that is predominantly excreted through the kidneys. Danoprevir is an NS3 protease inhibitor with a typical-for-class lower genetic barrier that is predominantly metabolized in the liver. Genotype 1 patients ($n = 88$) were randomly assigned to treatment for 13 days with different dosages of RG7128 combined with danoprevir. Among treatment-naïve patients, the median change in HCV RNA compared with baseline was –5.1 $\log_{10}$. Remarkably, among prior null responders also included in this study, the median decrease of HCV RNA was –4.9 $\log_{10}$. Importantly, all patients had a continuous decline in HCV RNA that was maintained throughout the short dosing interval. Viral sequencing of the protease and polymerase domains in patients with detectable HCV RNA at the end of treatment did not demonstrate any resistant mutations [730].

These promising data have enabled other short-term clinical studies to test the efficacy of combining various classes of drugs without interferon. These have only been reported in preliminary form to date and success rates have varied. In one study of a protease inhibitor and a non-nucleoside polymerase inhibitor, the absence of ribavirin resulted in substantially lower rates of virologic response and higher rates of viral breakthrough and resistant mutations, suggesting that, once again, ribavirin may be indispensable even in interferon-free regimens [731]. Much debate surrounds the feasibility of curing hepatitis C without interferon as well as defining the optimal duration of therapy and which drugs/classes of drugs would be most efficacious, particularly among patients with unfavorable treatment characteristics. A small proof-of-principle study treated prior null-responder patients with only an oral combination of BMS-790052 (NS5A inhibitor) and BMS-650032 (NS3 protease inhibitor) for 24 weeks. Four of 11 patients (36%) achieved sustained virological response with oral combination, demonstrating for the first time that human HCV infection could be eradicated in the absence of interferon or ribavirin [732]. These exciting results will likely lead to a rapid acceleration of development of interferon-free, oral combination regimens to treat chronic hepatitis C.

PART VI

Alcohol and Drug-induced Liver Disease

Overview

Willis C. Maddrey

Fortunately, significant progress is being made in identifying the mechanisms through which drugs harm the liver. Based on new observations, researchers are developing innovative ways to identify groups of patients who are at heightened risk. The potential for causing hepatotoxicity is a factor to be reckoned with in the development of any new drug. Attention must be paid to hepatic effects during the design process with continued attention throughout drug testing. The process of obtaining regulatory approval is often influenced by what happens to the liver. It is necessary to develop provisional plans for ongoing assessment to detect any hepatic issues that may arise once a new agent is on the market.

With the identification of new disease-related targets, there are remarkable arrays of novel drug candidates and biologic agents filling the developmental pipelines of pharmaceutical companies throughout the world. Furthermore, there is a parallel universe of agents, often poorly defined, used as herbal remedies. With each new drug evaluated, attention is given to an assessment of its risk profile with special consideration directed towards recognition of hepatic abnormalities that are or may be related to the drug.

Many promising agents have failed because of recognition of adverse hepatic events. In an individual patient, when abnormal liver test results are noted or, in rare situations in which clinically apparent liver injury appears, the focus of clinical attention may shift from concerns over treatment of the primary problem to a salvage operation to minimize serious liver injury. Regulatory agencies are keenly aware of the importance of hepatic risk which, if identified, may delay or prevent approval. The evaluation process for a new agent does not end with approval and release.

How the hepatic risks are presented and explained to clinicians have important consequences. The confidence a clinician has in prescribing a new agent is affected if there are special warnings regarding the potential risk of hepatic injury. A black box warning can significantly limit the use of a drug. It is widely appreciated that once a drug is marketed, liver changes that were not apparent during structured clinical trials may be detected. It only takes a case or two of serious hepatic injury to cause a promising agent in the late stages of development to be abandoned or lead to the recall of a drug already on the market.

Loss of an effective drug because of hepatotoxicity is a manifestation of a therapeutic promise gone awry. The approaches by which a hepatic signal caused by a drug is identified and ways to estimate the extent of risk are becoming more refined. Factors that influence the risk of developing a hepatic reaction to an individual agent include the age and sex of the patient, the state of nutrition (obesity or malnutrition), interactions with other drugs, the hepatic effects of the underlying disease for which the drug is being used, and the ever-present concerns regarding the use of alcohol.

We now know there is much more to the story of drug-induced hepatotoxicity than attributing liver abnormalities to exposure to a damaging reactive intermediate. Extensive evaluations of drug metabolism have been broadened and encompass consideration of the roles of cytochrome P450s, nuclear receptors, transporters, and many other pathways.

Considerable attention is being given to the role of immune responses, both innate and delayed, that develop as the result of exposure to drug metabolites. These may determine the initiation and progression of drug-induced liver injury.

The stories of the evolution of knowledge regarding the hepatic risks of drugs, including acetaminophen, isoniazid, phenytoin, halothane, diclofenac, statins, and amoxicillin-clavulanic acid, are only a few of those fully described in the chapter on "Drug-induced liver injury." The list of drugs that affect the liver in some way goes on and on, and it is important for the clinician to know

the risk profile of the agents that he or she uses. Drug-induced hepatic injury can mimic almost all liver diseases – from hepatitis, to fat accumulation, cholestasis, granulomas, and even the development of benign and malignant hepatic tumors. In some patients, such as those receiving treatment for cancer, human immunodeficiency virus (HIV), and fungal disorders, the number of drugs the patient is receiving may be overwhelming. In that setting, if liver abnormalities are detected, the issue is which suspect caused the injury. A clinician may have to diligently search for the culprit causing liver changes. The important first step is to consider the possibility that the observed liver abnormalities may have been caused by a drug. Once the possibility is considered, the search for the causative agent begins. An important confirmation that a drug was the cause of injury is if resolution occurs following its withdrawal.

Now new windows of understanding are opening. The concept of idiosyncrasy is being better understood. When only one in many thousands of individuals receiving a drug develops an adverse reaction, there must be a reason that this person was singled out. The genetic underpinnings controlling drug metabolism, disposition, and the immune responses occurring at many stages are increasingly being defined. There are evolving new concepts regarding the influences of the interplay between the genetic profile of the patient and the conditioning effects of risk factors. A few of the new observations appear to be relevant to increasing our understanding. The extent of metabolism of a given agent is important – drugs that are highly metabolized are riskier. Furthermore, the dose required to obtain the desired therapeutic effect has a role – the lower the needed dose of a drug, the smaller the risk.

The liver is faced with new challenges whenever a novel chemical is presented. Most of the time, the liver rapidly adapts. The concept of hepatic adaptation to the newly administered drug is of considerable interest. It is well known that many agents cause some elevations in aminotransferase levels soon after their initial introduction with a subsequent return to normal despite continued administration. Adaptation (tolerance) may occur in a variety of ways. One is through the development of enhanced pathways to dispose of reactive intermediates, thereby reducing or abolishing the hepatic effects, or in others, adjustment in the intensity of innate immune responses. The inability of a few individuals to adapt may well be a major contributor to the development of clinically apparent disease.

Among the guidelines to judge the risk of drug-induced hepatocellular injury is the observation by Dr Hyman Zimmermann that patients who have elevated aminotransferase levels associated with clinical jaundice are at increased risk of proceeding to an unfavorable outcome. If a drug, during development, causes even a few patients to have considerable elevations of aminotransferases and bilirubin, that drug receives special attention. Large-scale studies from around the world have confirmed the validity of the Zimmermann observation that there is an approximate 10% risk of mortality (or need for liver transplantation) in patients who have elevated aminotransferase levels (greater than three times the upper limit of normal) and elevated serum bilirubin levels (greater than two times the upper limit of normal). Furthermore, increased attention is paid to those drugs that cause slight increases in aminotransferase levels in many patients – the "where there is smoke, there is fire" concept.

Pre-drug genetic profiling is receiving increasing attention. There is much to be gained from determining if an individual has genetically influenced risk factors and under what circumstances that patient is at increased risk. It may be that a genetically susceptible individual will only develop serious hepatic disease if any of several environmental factors (e.g., obesity or alcohol use) are present. Important information has come from the genomic profiling of a few patients who have an unquestioned adverse hepatic reaction to an agent and comparing these patients with a control group who did not have a reaction. However, there are several problems with a widespread application of this approach. One of these is the difficulty in obtaining index cases of clearly related liver injury from a particular drug. There may be very few affected individuals even in a large trial. A second issue is making sure that the comparator individuals have similar characteristics, including ancestry. It is abundantly clear that the adverse reactions from some therapeutic agents vary remarkably in different racial groups. Of course, these observations apply to considerations of likely benefit as well as risks.

It is well established that only a few patients with an allele that predisposes to hepatic injury from a specific drug will develop a clinically apparent liver problem when exposed. Identifying the multiple hits required to cause significant injury is a challenge. How to effectively use genetic profiling during drug development to identify patients who are likely to have a problem is an area of intense research. As a result of identifying genetically susceptible individuals, some useful agents – which in the past would have been (or have been) discarded during development or even withdrawn from the market – may be reintroduced to patients who are shown on screening not to be genetically predisposed to develop an adverse hepatic event.

The future of understanding ways to make drugs safer is bright and in the two chapters devoted to drug-induced liver injury our colleagues have provided a sturdy platform.

Whereas severe drug-induced liver injuries caused by approved drugs are quite rare, alcohol-induced liver diseases are quite common. Clinicians of many disciplines are fully versed in caring for patients who are chronic alcoholics. Alcohol has been known to have adverse health consequences throughout recorded history. In many western countries, alcohol remains the most important cause of cirrhosis and its consequences. From epidemiologic studies, there is no question that there are dose and duration of exposure relationships between the use of alcohol and the development of liver disorders. However, individual responses to alcohol use and abuse vary widely.

Liver injury caused by alcohol is an established precursor to the development of cirrhosis and hepatocellular carcinoma. The medical status of patients with chronic alcoholism and liver disease is complex with the often coexistent presence of cardiomyopathy, pancreatitis, predisposition to infection, propensity to accidents, vitamin deficiencies, and a wide variety of neurologic problems. The interactions between alcohol abuse, obesity, nonalcoholic steatohepatitis, and chronic hepatitis C and B are well recognized. In many patients, there may be several causes that contribute to the progression of hepatic fibrosis. Often the excessive use of alcohol appears to be the most important. There is considerable evidence that there are interactions between alcohol-induced hepatic injury and injury related to chronic hepatitis C and hepatitis B. It is established that patients with chronic hepatitis C respond less readily to presently available therapy if alcohol intake is continued during treatment.

Fatty liver occurs regularly in patients who use alcohol in excess. Once considered benign, alcohol-induced fatty liver has been shown to be a contributor in the progression of liver disease and the role of metabolically active fat is being given attention at many research centers around the world.

The search for genetic factors that predispose some patients who use alcohol in excess to progress to cirrhosis and, conversely, others, even those who consume prodigious amounts of alcohol, not to develop serious injury, goes on. In the chapter on "Alcoholic liver disease" the current state of knowledge of the role of genetic influences on the responses to alcohol and the progression of some patients to cirrhosis is fully presented.

The important role of the stellate cell as a production center for collagen has received considerable attention. Many influences, including acetaldehyde, a variety of cytokines, and reactive oxidative products lead to stellate cell transformation. It would be a great stride forward if methods could be developed to modulate the formation of collagen and to stimulate the degradation of already established fibrosis. A way to preferentially induce stellate cell apoptosis would be a welcome advance.

There are hopes (not yet realized) that new pharmacologic approaches that decrease the craving for alcohol will augment current efforts directed to the treatment of alcoholism. For patients with severe alcohol-induced necrosis (alcoholic hepatitis), the judicious use of pentoxyphylline and corticosteroids are helpful, at least in the short run. The use of agents to inhibit proinflammatory cytokines has fallen from favor because of risks of infection, but careful patient selection and attention to dose may resurrect interest in this approach. The role of liver transplantation in patients who have alcohol-induced cirrhosis has been an area fraught with discussion and emotion. However, the favorable follow-up results of liver transplantation in these patients cannot be denied. Hopefully, the day will soon come when advances in stem-cell biology will find a role in the patient with advanced cirrhosis caused by alcohol.

CHAPTER 26

Alcoholic Liver Disease

Srinivasan Dasarathy & Arthur J. McCullough

Department of Pathobiology, Cleveland Clinic Foundation, Cleveland, OH, USA

Key concepts

- About 90% of heavy drinkers (more than 60 g alcohol per day) show evidence of fatty livers, while only 10–35% develop alcoholic hepatitis and 5–15% develop cirrhosis.
- The daily intake of alcohol that results in liver injury varies and depends on a number of risk factors. Alcoholic liver disease develops at lower doses in females, Hispanics, obese subjects, and patients with hepatitis C infection.
- Insights into the pathogenesis of alcohol-induced liver injury have improved significantly but the translation into clinical benefit has been slow. Interactions amongst the products of alcohol metabolism, hepatic parenchymal and nonparenchymal cells, and cytokine release all contribute to the injury and progression of disease.
- The importance of continued abstinence and correction of nutritional deficiencies are major components in the long-term management of alcoholic liver disease.
- Alcoholic hepatitis has a variable mortality and the prognosis is determined most commonly by the modified discriminant function. The model of end-stage liver disease is being increasingly used to predict outcome in alcoholic hepatitis even though standard cutoff values are not available.
- Anti-inflammatory therapy with corticosteroids and anticytokine therapy with pentoxifylline are effective and evidence-based therapies for patients with severe alcoholic hepatitis. Response to corticosteroids after 1 week of therapy is being used increasingly to predict outcome of therapy.
- Patients with end-stage alcoholic liver disease should be considered for liver transplantation. Six months of abstinence is still considered to be a requirement prior to transplant, but this length of time may be adjusted on an individual basis.
- Liver transplantation is now considered standard of care in patients with decompensated alcoholic cirrhosis and the results are similar to nonalcoholic patients. Recidivism remains a concern and a number of models are being identified to predict post-transplant alcohol abuse. Liver transplantation for acute alcoholic hepatitis continues to be a matter of debate.

Alcohol is the most frequently used and socially acceptable hepatotoxin worldwide [1]. Geographic patterns of alcohol intake and the prevalence of alcoholic liver disease are changing constantly and recent reports question the stabilization of its use in western European countries, Canada, and Australia [2,3]. Approximately two thirds of adult Americans drink some alcohol [4]. The majority drink light or moderate amounts and do so without problems [5–8]; however, a subgroup of drinkers become dependent on alcohol and have the disease of alcoholism or alcohol use disorders [9–11]. Another group of drinkers are alcohol abusers (and problem drinkers) who experience negative consequences of drinking (e.g., unemployment, loss of family, or accidental injury or death). These patients are not considered to be alcohol dependent [8,12]. Failure to recognize alcoholism remains a significant problem and impairs both the prevention and management of alcoholic liver disease (ALD) [12,13]. The clinical features of *t*olerance, *p*hysical dependence, *i*mpaired control, and *c*raving which define *al*coholism (Table 26.1), as well as their acronym TyPICal, are suggested as aids to the clinician for making the diagnosis. For more complete and formal diagnostic criteria of alcohol use disorders, publications by various organizations including the American Psychiatric Association and the World Health Organization are recommended [14,15].

Disease spectrum

Alcohol affects the liver depending on the dose and the duration of use or abuse [16–18]. The spectrum of

Table 26.1 Characteristics of alcoholism, based on the acronym TyPICal, which is used as an aid in the diagnosis of alcoholism.

Characteristic	Clinical feature
Tolerance	A state of adaptation in which increasing amounts of alcohol are needed to produce the desired effects
Physical dependence	A typical withdrawal syndrome appears upon interruption of drinking, which is relieved by alcohol itself or other drugs in the alcohol/sedative group
Impaired control	Total alcohol intake cannot invariably be regulated once drinking has begun at any drinking occasion
Craving	A dysphoria of abstinence that leads to relapse

alcohol-related liver injury varies from asymptomatic hepatomegaly to profound hepatocellular failure and portal hypertension [19–21]. Pathologically this is translated into fatty infiltration of the hepatocytes at the stage of asymptomatic hepatomegaly to frank cirrhosis with decompensation in the end stage [19,22,23]. There are at least five histologic manifestations of ALD and these include: fatty liver or steatosis, acute alcoholic hepatitis, chronic hepatitis, hepatic fibrosis, and cirrhosis [24]. Of these, chronic hepatitis is a stage that has been reported in ALD but its diagnosis has been questioned [25,26].

Figure 26.1 displays the different stages and evolution of ALD and Table 26.2 lists the histologic characteristics and describes their prevalence in the different stages of ALD [24]. Even though these are considered to be distinct stages, multiple stages can exist simultaneously in a given patient [19]. Fatty liver develops in about 90% of those who drink more than 60 g/day of alcohol but may also occur with lower levels of alcohol use [27–29]. Fat localizes initially to the perivenular or centrilobular region of the liver [27,30,31]. Decreased energy stores due to hypoxia and a shift in lipid metabolism, along with a shift in the redox reactions caused by the preferential oxidation of alcohol in zone 3 of the hepatic lobule, are the reasons for this localization (Fig. 26.2) [27,32]. Simple, uncomplicated fatty liver is usually asymptomatic and considered reversible [33]. Once fatty infiltration is severe, particularly with a mixed (macro-/microvesicular) pattern and associated with giant mitochondria or perivenular fibrosis[31,34], progression to fibrosis and cirrhosis occur in up to 8–20% of patients [35].

Progression of ALD culminates in scarring and development of cirrhosis [36]. Although it is usually micronodular, it is occasionally mixed micro- and macronodular

[21,37]. Fibrogenesis is believed to start in the perivenular area and is influenced by the amount of alcohol ingested [31,38]. Perivenular fibrosis and deposition of fibronectin occurs in 40–60% of patients who ingest more than 40–80 g/day for an average of 25 years. However, the thickness of the perivenular fibrosis does not correlate with the amount of alcohol ingested. It should also be noted that the occurrence of the fibrotic features was more than twice that of the frequency of cirrhosis. Although this may be partly related to sampling error, the disparity between the frequency of fibrosis and the development of cirrhosis suggests that factors other than fibrogenesis are involved in the progression to cirrhosis in patients with ALD [35,39,40].

Figure 26.3 shows the estimated prevalence of the different histologic forms of alcohol-mediated liver injury amongst heavy drinkers [24]. This emphasizes the heterogeneity of the patient populations with regard to disease severity and individual susceptibility to alcohol. Amongst patients who are heavy drinkers, 90–100% will show histologic evidence of fatty liver but only 10–35% will develop alcoholic hepatitis and 8–20% will develop cirrhosis [35,41,42].

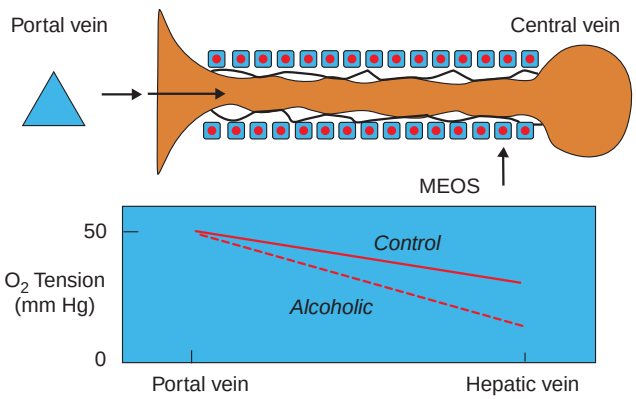

Figure 26.2 Oxygen gradient between the portal area (zone 1) and the pericentral area (zone 3) of the hepatic lobule. The metabolism of alcohol increases oxygen consumption and causes the largest gradient in zone 3. MEOS, microsomal ethanol oxidizing system.

Risk factors

Only a subset of individuals who ingest significant amounts of alcohol progress beyond fatty liver and develop alcoholic hepatitis or cirrhosis. Therefore, other factors must play a role in placing these individuals at risk for developing these more severe forms of ALD [43,44]. A number of risk factors have been proposed (Fig. 26.4), but none of them can either singly or in combination completely explain the reason why only a subset of those ingesting large amounts of alcohol develop ALD [45,46].

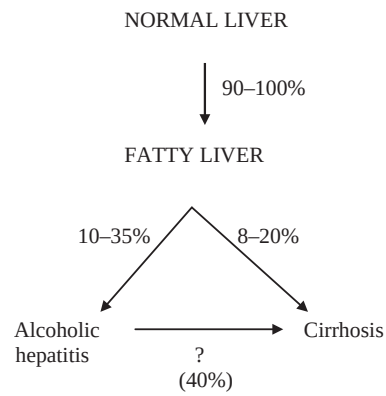

Figure 26.3 Percentage of heavy drinkers who develop the different stages of alcoholic liver disease.

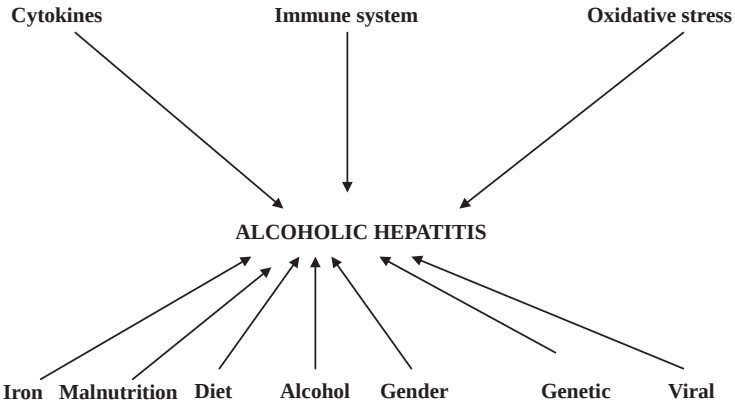

Figure 26.4 Risk factors that may be cofactors required for the development of advanced alcoholic liver disease.

Ethnicity

Ethnic differences in the prevalence of alcohol-related liver disease and associated mortality have changed with time [47]. In the first half of the twentieth century, when reporting of mortality was done for Caucasians and non-Caucasians (comprised predominantly of African-Americans), the mortality was significantly higher for the former. By the mid-1950s, this reversed and the mortality for non-Caucasians exceeded that of Caucasians. Later, when data were published for different ethnic groups, a two-fold increase in transaminases occurred more frequently in Hispanics and blacks than in Caucasians [48, 49]. South Asian (Indian) non-Muslim men have also been observed to have a higher rate of alcoholic cirrhosis at a younger age and after a shorter duration of alcohol abuse [50]. It is not clear if the ethnic differences are the result of genetic polymorphisms, the quantity or type of alcoholic beverages consumed, or co-morbidities [47].

Alcohol

The quantity of alcohol ingested (independent from the form in which it is consumed) is the an important risk factor for the development of ALD [51–53]. A significant correlation exists between per capita consumption and the prevalence of cirrhosis but this relation is not linear [54, 55]. Epidemiologic evidence exists for a marked reduction in the prevalence of ALD with diminished alcohol ingestion during war rationing, prohibition, and increased cost [56,57].

Available evidence indicates that there is an increased risk of developing cirrhosis with the ingestion of >60–80 g/day of alcohol in men and >20 g/day in women consumed for 10 years or longer [18,47,58]. Even in these groups, only 6–41% of those drinking at these levels develop cirrhosis [18,47,59]. In the Dionysos study, even in patients with very high daily alcohol intake (>120 g/day) only 13.5% developed alcohol-induced liver damage [58,60]. The risk of cirrhosis or noncirrhotic chronic liver disease also increased with a total lifetime alcohol intake of more than 100 kg or daily intake of >30 g/day [58]. The odds of developing cirrhosis or noncirrhotic liver disease with a daily alcohol intake of >30 g/day was 13.7 and 23.6, respectively, when compared with nondrinkers.

The type of alcohol consumed may also determine the risk of development of liver disease [61]. In a large survey of over 30,000 persons in Denmark, beer or spirits were found to be more likely to be associated with liver disease. It was also observed that in people who drank heavily, consumption of wine lowered the all-cause mortality [62,63]. It is, however, unclear if wine drinking was itself protective or was a surrogate for other healthy behavior such as the consumption of fruit and vegetables [63]. Alcoholic beverages that contain a higher content of short chain aliphatic alcohols have been associated with a high prevalence of liver cirrhosis [64].

Another factor that has been identified is the contribution of the pattern of drinking to the development of liver injury. Drinking outside meal times has been reported to increase the risk of alcoholic liver disease by 2.7-fold compared with those who consumed alcohol only at meal times [65]. This was not, however, reproduced in a subsequent French study [66]. Binge drinking, which may be considered to be a form of outside meal drinking, and has been defined by some workers as five drinks for men and four drinks for women, has also been shown to increase the risk of ALD and all-cause mortality [67,68]. Binge drinking has also been shown to be associated with the degradation of a large quantity of mitochondrial DNA that contributes to steatohepatitis as well as reperfusion injury, both of which result in significant damage to the hepatocytes and potentially to the nonparenchymal hepatic cells [69]. Increasing evidence is accumulating that

Table 26.3 Relative risk of alcoholic liver disease (ALD) at different levels of alcohol intake.

Weekly units of alcohol	Alcoholic cirrhosis		Alcoholic liver disease	
	Men	Women	Men	Women
<1	3.7	1.09	1.8	1.0
1–6	1.0	1.0	1.0	1.0
7–13	0.9	4.1[a]	1.1	2.9[a]
14–27	1.6	3.1[a]	1.4	2.9[a]
28–41	7.0[a]	16.8[a]	3.8[a]	7.3[a]
42–69	13.0[a]	NR	5.9[a]	NR
≥70	18.1[a]	NR	9.1	NR

[a]Represents a statistically significant increased relative risk of having ALD.
NR, not reported.

the pattern of binge drinking is common in early adulthood, predicts alcohol abuse behavior in later adulthood, and increases the risk of ALD [2,70].

Gender

Women have been found to be twice as sensitive to alcohol and to develop more severe ALD at lower doses and with a shorter duration of alcohol consumption than men [27,71–75]. As compared with men, in whom 80 g of daily alcohol was considered to be a hazardous amount, early data suggested the hazardous level to be 60 g/day in women [76]. Since the majority of those individuals developing ALD ingested more than 35 units per week, a "safe" limit of alcohol intake had been suggested to be 21 units/week in men and 14 units/week in women [76,77]. However, data from the Copenhagen City study suggest that a lower quantity, more than 7 units/week, may be toxic in women [55,78]. The data in Table 26.3 and Fig. 26.5 confirm the association between increased alcohol intake and ALD, the lower threshold toxic dose, and the increased female susceptibility for ALD. On a practical level 1 unit of alcohol (1 ounce of "spirits" (40% alcohol), one 12-ounce beer (5% alcohol), or one 4-ounce glass of wine (12.5% alcohol) contains approximately 10 g of alcohol for wine and spirits, and 14.4 g of alcohol for beer. This is based on a specific gravity of 0.8 for alcohol and the average alcohol content of beer. These amounts may vary depending on the actual alcohol content of the beer, which varies significantly amongst commercial brands (Table 26.4), as well as the size of the pour for wine and spirits.

This increased female susceptibility has been related to gender-dependent differences in the hepatic metabolism of alcohol [27,79]. An alteration in gastric metabolism

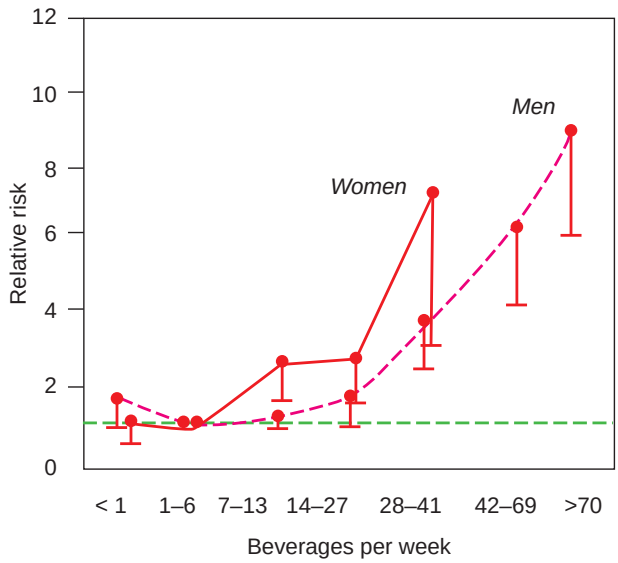

Figure 26.5 Risk of alcoholic liver injury increases with increasing quantity of alcohol intake. This risk is higher in females at all doses of alcohol ingestion.

Table 26.4 Alcohol content of commercial beer.

Brand	Alcohol content (%)	
	Light	Regular
Molson	2.41	3.88
Budweiser	3.88	4.82
Busch	4.12	5.19
Miller	4.40	4.80
Stroh's	4.45	4.68
Michelob	4.52	4.99

of alcohol is another explanation to explain female susceptibility to developing ALD [71,79–81]. First-pass gastric metabolism of alcohol does indeed exist in humans [79], but gastric metabolism of alcohol may not be large (10–30% at most), decreases with gastric injury, may not occur during most standard meals or realistic life conditions, and may vary among races since it has not been observed in Orientals [82,83]. Furthermore, the lack of increased risk of ALD in postgastrectomy patients has also refuted this hypothesis [84]. Experimental evidence exists for estrogen-induced endotoxemia and exaggerated hepatic inflammatory response to alcohol [85,86].

Malnutrition and diet

Dietary habits and nutritional status may also be important risk factors for the development of ALD [18,20, 87–89]. Early studies conducted in hospitalized chronic alcoholic patients with liver disease led to the misconception that protein-calorie malnutrition was a necessary risk factor for ALD [89,90]. However, alcohol is directly hepatotoxic and does not require preexisting malnutrition to result in liver injury [91,92]. In addition, even though alcohol adversely affects energy and protein metabolism, the prevalence and extent of protein-calorie malnutrition are similar in alcoholic and nonalcoholic cirrhosis [93].

Micronutrient abnormalities also potentially aggravate liver disease. Hepatic vitamin A depletion activates the stellate cells and results in hepatic fibrosis with alcohol abuse. Vitamin E levels are depressed in alcoholic cirrhosis and may contribute to enhanced membrane lipid peroxidation and hepatocyte damage [94].

Other nutritional disorders, including obesity, and dietary habits may be important risk factors [18,95,96]. Data from France suggest that obesity may be an independent risk factor for developing ALD (Fig. 26.6) [96]. In alcoholic patients from China, excess body weight was associated with a 5.6-fold increase in risk of ALD [65]. Increased tumor necrosis factor activity and hepatic insulin resistance, which are associated with obesity, seem to contribute to the aggravation of ALD [97]. Obesity also makes the liver susceptible to alcohol-mediated injury by metabolic activation of CYP2E1, oxidant stress, and immune hyperreactivity in the liver [98]. It is currently unclear whether the hepatotoxic consequences of obesity and ethanol ingestion are additive or synergistic. High-fat diets are also necessary to promote alcohol-induced liver disease in animals (Fig. 26.7) [99,100]. Polyunsaturated fats in the diet have been shown to aggravate the hepatotoxic effects of alcohol in animal studies but no corroborating human data exist as yet [101]. The incidence of cirrhosis also appears lower than expected in countries with high intakes of saturated fat – an epidemiologic finding that is independent from other risk factors and supported by animal data [102,103]. The clinical significance of these observations is not yet known.

Recently, there is increasing interest in identifying the abnormal signaling pathways involved in the muscle loss in cirrhosis due to both the direct effects of alcohol as well as portosystemic shunting. Myostatin is a transforming growth factor β (TGF-β) superfamily member that has been shown to inhibit both skeletal muscle growth and protein synthesis following portosystemic shunting [104]. Furthermore, rats fed alcohol have an increased skeletal muscle expression of myostatin [105]. Recently, plasma concentrations of myostatin have been reported to be elevated in patients with cirrhosis [106]. These observations are of great clinical interest because of the potential to inhibit myostatin and thereby increase muscle mass without altering the underlying disorder.

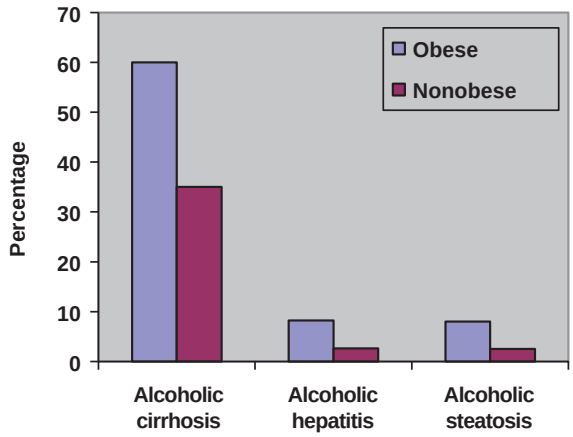

Figure 26.6 Prevalence of obesity in different forms of alcoholic liver disease in obese and nonobese patients. (Adapted from Naveau et al. [96].)

Genetic factors

Environmental factors alone cannot explain the variable susceptibility to alcohol, and genetic factors appear to provide a predisposition to both alcoholism and ALD [107–110]. There has been growing interest in defining genetic factors, which include functional polymorphisms in genes that may contribute to the pathophysiology of ALD [111–113].

Alcohol metabolism

Much of the initial work focused on genes involved in the metabolism of alcohol: alcohol dehydrogenase (ADH), acetaldehyde dehydrogenase (ALDH), and the cytochrome P450 system (CYP4502E1) [114–117]. The most common reported abnormality is an increased frequency of *ADH321* (the gene that encodes for the γ-1ADH isoenzyme that is capable of faster alcohol metabolism to acetaldehyde), which when combined with abnormalities in the ALDH2-2 allele (slow acetaldehyde metabolism) results in high acetaldehyde concentration [114,118,119].

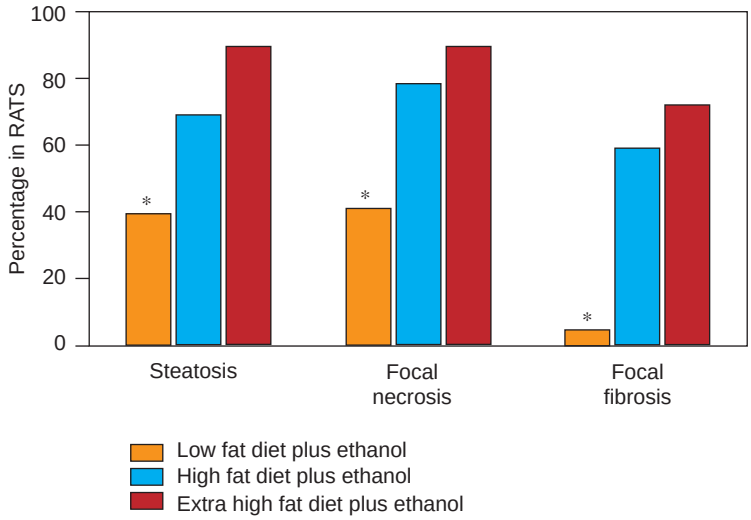

Figure 26.7 The effect of a high-fat diet on the severity of liver disease with alcohol feeding in experimental rats. *, $P < 0.05$.

Such an abnormality may be responsible for some of the hepatotoxicity of alcohol and mediates the flushing and enhanced alcohol sensitivity commonly observed in Asians [120–122]. Patients in Japan have a higher frequency of ADH2-1, and an increased frequency of ALDH2-1 has been reported in patients who were alcoholics (with or without liver disease) than in controls [123]. However, the data regarding a specific ADH/ALDH pattern in patients with ALD are conflicting.

The genetic pattern of P4502E1 (the microsomal enzyme primarily involved in alcohol metabolism) has been studied because it generates reactive oxygen species (ROS) when metabolizing alcohol [122,124]. A specific polymorphism identified as the c2 allele has been shown to result in an increased expression of hepatic CYP2E1 activity. An increased prevalence of the c2 allele has been reported in Japanese but not Chinese alcoholic subjects with ALD [123,125,126]. A higher prevalence of the c2 allele in Mexican-Americans than Caucasians has also been reported [127]. However, a meta-analysis of nine independent studies has shown that there was no relation between the c2 allele and the development of ALD among Caucasians [116,128].

Mitochondrial dysfunction

Mitochondrial dysfunction has been identified in the liver of patients with ALD, and a reduced activity of the mitochondrial form of superoxide dismutase 2 (SOD2) was expected to have a reduced activity. In French patients with ALD, a polymorphism in the gene with a valine to alanine mutation at position 1183 of the *SOD2* gene was observed but this resulted unexpectedly in an increase in SOD2 activity [129]. In a subsequent study from England, no association was observed between SOD2 polymorphism and ALD [130]. Polymorphisms in glutathione-*S*-transferase type μ1 and θ1 have also been reported to occur more frequently in patients with advanced forms of ALD [112].

Cytokines and the immune system

Data supporting a role for the endotoxin-mediated release of cytokines in the pathogenesis of ALD have suggested a different set of candidate genes with a potential role in disease susceptibility [131–133]. Small studies that have reported an association between advanced ALD and promoter polymorphisms in the genes encoding the endotoxin receptor CD14 and interleukin 10 (IL10) need further confirmation [134–137].

These abnormalities suggested an upregulation of immune response in these patients [138,139]. Reported targets of this immune response are autoantigens, which include alcohol dehydrogenase, cytochrome P450 isoforms CYP2E1/CYP3AH, and endogenous protein adducts to ethanol metabolites or products of lipid peroxidation [140,141]. Polymorphisms in tumor necrosis factor α (TNF-α) (associated with alcoholic hepatitis), type I collagen (associated with cirrhosis) genes, and the gene encoding cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) (which functions as a suppressor of T-cell mediated immune response in patients with ALD) have been reported [139,142–147]. Studies from England and Spain have reported polymorphisms in the gene encoding for IL10, a cytokine that downregulates inflammatory response, that results in lower levels of IL10 in patients with ALD [143,148].

An integrated view of genetic polymorphisms and the consequent immune mediated liver injury has been suggested by the observations that CTLA-4 gene polymorphism and lower activity was associated with an increase in antibodies to the hydroxyethyl CYP2E1 adducts and development of liver disease [147,149]. Despite interesting and valuable new information in this area, there is

variability in the reported association between genetic and phenotypic abnormalities in different studies and racial populations. Specific genetic abnormalities for a susceptibility to alcohol abuse and the development of ALD have not yet been firmly established [128].

Based on extensive published data on the role of gene polymorphisms in ALD, early reports of association have not been confirmed across populations or in subsequent, more rigorous studies [150]. Hence the role of gene polymorphisms, even though interesting, needs validation by large-scale cross-ethnic and cross-national studies.

Viral infection

There is a strong association between hepatitis C and ALD [151,152]. Unlike hepatitis B, hepatitis C infection appears to be strongly involved in the development of advanced ALD [153]. An increased prevalence of hepatitis C virus (HCV) has been reported in patients with ALD (Fig. 26.8) [154,155]. Hepatic injury by alcohol is synergistic with that of HCV because HCV plus alcohol predisposes to more advanced liver injury than alcohol alone [152,156, 157]. Compared to ALD patients without HCV infection, ALD patients with HCV infection have more severe histologic features, develop their disease at a younger age, have decreased survival, and have a higher incidence of hepatocellular carcinoma (HCC) [151,152,158]. The progression of fibrosis is most rapid in male patients who continue to abuse alcohol [153,159]. Although a daily dose of >50 g of alcohol has been shown to be a risk factor for fibrosis in patients with HCV infection, even a moderate consumption of alcohol (<50 g/day) has been shown to result in a dose-dependent increase in liver disease [157,160]. Despite these observations, the precise toxic threshold is not known and maybe lower and nonuniform amongst patients at risk. The estimated rate of progression is shown in Fig. 26.9 [41,153,160–163]. The prevalence of HCV also increases proportionally as the liver injury becomes more severe, with the relative risk for developing cirrhosis estimated at 8.7 in ALD patients with anti-HCV [164–166]. A French study showed that both mortality and the length of hospital stay was longer in patients with alcohol abuse and hepatitis C [163]. In addition, the presence of HCV is reported to be the major risk factor for the development of HCC [167]. In patients with alcoholic cirrhosis, the 10-year absolute cumulative occurrence risk of HCC has been reported to be as high as 81% in anti-HCV-positive patients as compared with 19% in anti-HCV-negative patients [157,168–170]. Although one study has questioned this association between progression of HCV and alcohol consumption [171], the consensus of data is highly suggestive of an unfavorable interaction between them [151]. Patients with hepatitis C should therefore be strongly urged to abstain from alcohol.

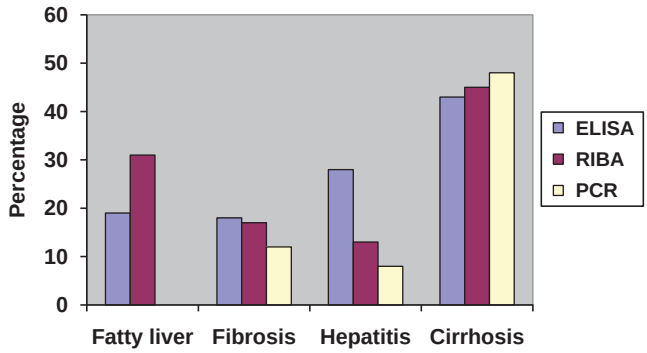

Figure 26.8 Prevalence of various markers of hepatitis C in patients with different forms of alcoholic liver disease. ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction; RIBA, recombinant immunoblot assay.

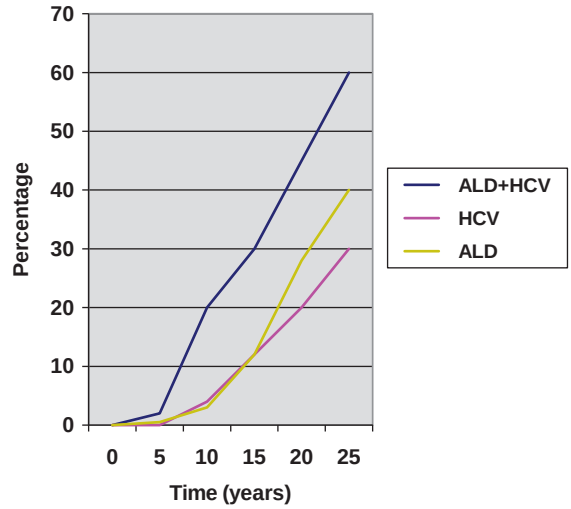

Figure 26.9 Progression of fibrosis with alcoholic liver disease (ALD) and hepatitis C virus (HCV). (Data from references [41,153,160–163].)

Iron overload

There is increasing recognition that iron accumulation with chronic alcohol consumption contributes to progressive hepatocellular injury. Both iron-rich beverages like wine and stimulation of exogenous iron absorption from food contribute to this [35,172]. An inadequate upregulation of the iron hormone hepcidin and an increase in transferrin receptor Trf1 have been suggested to contribute to the iron accumulation in both parenchymal and Kupffer cells [173,174]. Both alcohol and the reactive oxygen species generated during ethanol metabolism have been suggested to result in the alteration in iron-metabolizing genes [35,152]. Increased iron accumulation with alcohol not only contributes to hepatocellular injury, but also is believed to be a significant factor in the development of HCC in these patients [152].

Diagnosis

The diagnosis of ALD is often made in the context of a history of significant alcohol intake, physical signs of liver disease, and supporting laboratory data [20,175,176]. However, denial of alcohol abuse is significant [177,178]. Physicians usually identify less than 50% of their patients with drinking problems and institute specific recommendations even less frequently [179,180]. Both the physical findings and laboratory evidence for ALD may be absent or nonspecific, especially in patients with mild ALD or early cirrhosis [21,181–183]. Therefore, the clinician has to rely on indirect evidence of alcohol abuse, such as questionnaires, information from family members, or nonhepatic laboratory tests to suggest or strengthen a clinical suspicion of ALD [184–186].

General screening

Screening for alcohol abuse and failure to treat the same is common in clinical practice [187]. Alcohol abuse or alcohol dependence is diagnosed based on the amount of alcohol ingested, the social and psychologic consequences of alcohol abuse, the presence of other alcohol-related diseases, and past incidents of trauma (such as frequent falls, lacerations, burns, fractures, or emergency department visits) [188,189]. The diagnosis of ALD consists of both the documentation of alcohol abuse and evidence of liver disease [21,138]. Both clinical and supporting laboratory data for liver disease and alcohol abuse are required for this. Furthermore, alcohol may be one of a number of factors causing the liver disease and the specific contributory role of alcohol alone may be difficult to assess in a patient with multifactorial liver disease. Biochemical tests have been considered to be less sensitive than verbal tests in screening for alcohol abuse [190,191]. Biochemical tests have, however, been considered useful in identifying relapse after abstinence [190,192,193].

A combination of patient self-reports with corroboration from the family or close friends is considered essential in the diagnosis of alcohol abuse. Various questionnaires that have been used in the past for the detection of alcohol dependence and abuse include the CAGE and MAST (Michigan alcoholism screening test) tests [190,194,195]. The alcohol use disorders identification test (AUDIT) is a ten-item questionnaire that has been discussed in detail in previous editions of this textbook (Box 26.1) [196]. The major perceived limitation of the full AUDIT questionnaire is the length of time required to administer it. A number of brief screening instruments have been developed that include CRAFT, brief AUDIT, and RAPS4 [197,198]. The details of these instruments are beyond the scope of this review and have been discussed elsewhere [199]. The brief screening questionnaire,

Box 26.1 Alcohol use disorders identification test (AUDIT) questionnaire. This consists of ten questions with scores assigned to the answers.

1 How often do you have a drink containing alcohol?
- 0 Never
- 1 Monthly or less
- 2 Two to 4 times a month
- 3 Two to 3 times a week
- 4 Four or more times a week

2 How many drinks containing alcohol do you have on a typical day when you are drinking?
- 0 One or 2
- 1 Three or 4
- 2 Five or 6
- 3 Seven to 9
- 4 Ten or more

3 How often do you have six or more drinks on one occasion?
- 0 Never
- 1 Less than monthly
- 2 Monthly
- 3 Weekly
- 4 Daily or almost daily

4 How often during the last year have you found that you were not able to stop drinking once you had started?
- 0 Never
- 1 Less than monthly
- 2 Monthly
- 3 Weekly
- 4 Daily or almost daily

5 How often during the last year have you failed to do what was normally expected from you because of drinking?
- 0 Never
- 1 Less than monthly
- 2 Monthly
- 3 Weekly
- 4 Daily or almost daily

6 How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?
- 0 Never
- 1 Less than monthly
- 2 Monthly
- 3 Weekly
- 4 Daily or almost daily

7 How often during the last year have you had a feeling of guilt or remorse after drinking?
- 0 Never
- 1 Less than monthly
- 2 Monthly
- 3 Weekly
- 4 Daily or almost daily

8 How often during the last year have you been unable to remember what happened the night before because you had been drinking?
- 0 Never
- 1 Less than monthly

2 Monthly
3 Weekly
4 Daily or almost daily

9 Have you or someone else been injured as a result of your drinking?
0 No
2 Yes, but not in the last year
4 Yes, during the last year

10 Has a relative, friend, doctor, or other health worker been concerned about your drinking or suggested that you should cut down?
0 No
2 Yes, but not in the last year
4 Yes, during the last year

RAPS4 (rapid alcohol problems screen 4), has been compared to CAGE in patients from the National Alcohol Survey [200]. The RAPS4 had a higher sensitivity (0.86) compared with CAGE (0.67). Both had similar specificity (0.95 versus 0.98) across gender and ethnicity. Comparing brief versions of the AUDIT to the full AUDIT in the primary care setting showed variable sensitivity and specificity of the brief versions [198]. A quantity frequency (QF) score that includes questions on drinking frequency can be added to RAPS and the combined instrument, RAPS-QF, outperformed CAGE. It appears that quantity frequency will be a major component of brief questionnaires that are being developed to replace the full AUDIT.

Clinical differentiation of the different stages of ALD is difficult at times and there is no single marker that definitively establishes the etiology of liver disease to be alcohol and laboratory tests are often needed to confirm the diagnosis. Recent studies have suggested that the brief versions may be adequate to diagnose alcohol abuse [201,202]. Recently published American Association for the Study of Liver Diseases (AASLD) guidelines suggest that regardless of the screening instrument selected, it is important for clinicians to incorporate screening into their clinical practice because this may improve the ability of clinicians to predict long-term clinical outcomes [195].

Physical examination

On physical examination, patients with ALD may show a constellation of abnormalities that are related to portal hypertension (ascites, splenomegaly, abdominal wall collaterals, and a venous hum), alcohol abuse and hepatic injury (cutaneous telangiectasia, palmar erythema, finger clubbing, Dupuytren contractions, and peripheral neuropathy), and feminization (gynecomastia and hypogonadism). Detailed discussions of the physical signs have been published recently and will not be discussed here [21,191,203].

Although some of the physical findings are more commonly observed in ALD (parotid enlargement, Dupuytren contracture, and especially those associated with alcohol abuse and feminization) than in non-ALD, no single physical finding or constellation of findings is 100% specific or sensitive for ALD [204]. Furthermore, there is significant interobserver variability for most of these physical findings, which is dependent on the experience of the examiner and the physical finding being sought [203,204]. When present, certain findings on physical examination such as ascites, poor nutritional status, and cutaneous telangiectasia indicate significant liver injury and poor prognosis [205–207]. However, even in the absence of significant liver injury, physical findings associated with alcohol abuse may be present and then subsequently improve with abstinence [208]. Physical examination of the liver, which may be normal in the presence of ALD, does not provide accurate information regarding liver volume [209]. Its major role is to define the characteristics of the consistency of the liver's lower edge rather than to delineate disease etiology or liver volume.

Other organ dysfunction in ALD includes cardiomyopathy, skeletal muscle wasting, pancreatic dysfunction, and alcoholic neurotoxicity that may coexist with ALD. Evidence of these must be sought during the clinical examination so that appropriate treatment may be provided [210–212]. Prognosis in these patients is determined by evidence of clinical decompensation, including encephalopathy, ascites, edema, and gastrointestinal bleeding [195]. Recently, in a large study from Sweden, the prognosis of patients with ALD was reported to be worse and the clinical course to be more aggressive than in nonalcoholic liver disease [213]. The authors recognized that this may, however, be due to continued alcohol use or abuse, poor follow-up, and noncompliance with therapy in these patients.

In summary, physical examination alone is unable to either establish the diagnosis of ALD or delineate ALD from non-ALD and must be considered in the context of the patient's history and laboratory findings.

Laboratory abnormalities

The various laboratory tests used to diagnose ALD are shown in Box 26.2. Low sensitivity and specificity limit the usefulness of γ-glutamyltransferase (GGT) to diagnose alcohol abuse [214–216]. Serum transaminases have been used in the diagnosis of ALD [217]; serum aspartate aminotransferase (AST) is raised only 2–6 times in severe acute alcoholic hepatitis. Levels of AST >500 IU/L or ALT >200 IU/L should suggest an etiology other than alcoholic hepatitis. In about 70% of patients the AST : ALT ratio is higher than 2, but this is of greater value in noncirrhotic patients; ratios greater than 3 are essentially

Box 26.2 Typical laboratory abnormalities in alcoholic liver disease.

Serum enzymes
- AST>>>ALT
- AST usually <500 IU and ALT <200 IU
- Alkaline phosphatase and γ-glutamyl transpeptidase: both usually elevated to a variable degree

Immunoglobulins
- Both IgG and IgA are elevated

Metabolic alterations
- Hyperglycemia
- Hypertriglyceridemia
- Hyperuricemia
- Electrolyte abnormalities
- Low potassium, magnesium, and phosphorus

Tests of liver function
- Serum albumin, prothrombin time, and serum bilirubin: usually normal until significant liver injury is present

Hematologic abnormalities
- Mild anemia is common (usually macrocytic)
- Platelets (normal to markedly decreased)
- Elevated white blood cell count
- Leukemoid reactions associated with alcoholic hepatitis

diagnostic for ALD, with the specificity increasing as the ratio increases. Macrocytosis is seen in individuals abusing alcohol but lacks sensitivity. A combination of raised GGT and mean corpuscular volume (MCV) has a sensitivity of 30–40% for diagnosing alcohol abuse. Serum carbohydrate-deficient transferrin (CDT) is a specific and sensitive test for alcohol use independent of liver disease but is more accurate in men ingesting over 60 g daily alcohol [218]. Frequent determination of serum ethanol levels during the patient's visits to the physician's office is another simple but often ignored method of assessing alcohol use. Other sensitive indices include fucosylated haptoglobin and serum secretory immunoglobulin A (IgA), but both need prospective testing at multiple centers before their validity can be confirmed [219–221]. A direct comparison of four markers of alcohol consumption showed that the overall accuracies of GGT and CDT were the highest to detect alcohol drinking, while sialic acid and P3NP (amino terminal of pro-collagen III) were of value in differentiating liver disease from alcohol abuse [222]. Serum hyaluronic acid has been used alone [223] and in combination with other tests [224] to detect the stage of liver disease in ALD. These and other promising biomarkers require additional studies in this area [34].

In symptomatic patients, nonspecific findings include elevated uric acid, lactate, and triglycerides and a decrease in magnesium, glucose phosphate, and potassium. Polyclonal hyperglobulinemia and an increase in circulating IgA also occur with ALD [225]. It must be reiterated that no specific laboratory test exists that is specific for ALD.

Nonalcoholic steatohepatitis (NASH) is a distinct clinical entity with histologic features suggestive of alcohol abuse with little or no alcohol ingestion [226]. This is seen in association with other features of the metabolic syndrome [227]. There are many similarities in the pathogenesis of NASH and alcoholic steatohepatitis, but the critical component of the injury in ALD is the consumption of significant amounts of alcohol. There are no reliable laboratory tests or histologic patterns that reliably differentiate NASH from alcoholic steatohepatitis.

Liver biopsy

A liver biopsy is useful but not essential in the management of ALD [228]. The role of liver biopsy in ALD is shown in Box 26.3. A liver biopsy is helpful in establishing the diagnosis, because as many as 20% of patients with alcohol abuse have non-ALD or other coexisting forms of liver disease [229]. Clinical and biochemical indicators are poor markers of the severity of liver disease and a biopsy is needed to establish the stage and severity of the liver disease [228,230]. A biopsy assumes greater importance in patients who continue to have abnormal liver tests after a period of abstinence of approximately 3–4 months. Liver biopsy is usually safe with a low morbidity and mortality, but precautions should be taken as for any other patient undergoing a liver biopsy. In patients with a diagnosis of acute alcoholic hepatitis with a coagulation profile precluding a percutaneous liver biopsy, consideration should be given to performing a transjugular biopsy.

Box 26.3 Role of liver biopsy in alcoholic liver disease.

Diagnosis
- Confirm diagnosis
- Exclude other causes of liver disease (primary or concomitant)
- Assess extent of liver damage

Prognosis (adverse)
- Neutrophilic infiltration
- Stenosis of central veins
- Number of hepatic stellate cells, giant stellate cells, and lipid vesicles in stellate cells
- Number of Kupffer cells
- Degree of liver cell necrosis
- Perivenous fibrosis

Therapeutic decision
- Prior to steroid therapy

The histologic features of alcohol-induced hepatic injury include steatosis (fatty change), lobular hepatitis, periportal fibrosis, Mallory bodies, nuclear vacuolation, bile duct proliferation, and fibrosis or cirrhosis [19]. The development of large droplet (macrovesicular) steatosis (fatty liver) is the earliest and most common manifestation of ALD. It is often clinically asymptomatic and completely reversible on abstinence [231]. It is most prominent in the centrilobular regions but in severe cases may involve the entire lobule [232]. It is most commonly diagnosed on ultrasound, demonstrating fatty change with increased echogenicity of the liver parenchyma [233].

Alcoholic hepatitis is characterized by liver cell damage, neutrophilic infiltration of the lobules, and fibrosis [24,207]. Steatosis and hepatitis may exist independent of each other and do not imply a continuum of changes. The liver cell damage in alcoholic hepatitis includes hepatocyte necrosis, ballooning degeneration, and lobular inflammation that affect the perivenular regions in the earliest stages [38]. Ballooning is secondary to the accumulation of protein and water. Mallory bodies are irregular, refractile, eosinophilic, cytoplasmic structures with a beaded form that stain positive for ubiquitin [234]. They have been shown to be aggregated cytokeratin intermediate filaments as well as other proteins. Mallory bodies, giant mitochondria, neutrophilic infiltration, and fibrosis may be seen in other conditions besides ALD [235]. In contrast to their presence in simple fatty liver, megamitochondria in alcoholic hepatitis have been reported to be associated with a milder form of alcoholic hepatitis, a lower incidence of cirrhosis, and fewer complications with a good long-term survival [236]. Alcoholic hepatitis is associated with perivenular and pericellular fibrosis as a consequence of hepatic stellate cell (HSC) activation. Compared with patients who consume alcohol and have normal hepatic histology, inactive cirrhosis, or active alcoholic cirrhosis, patients with acute alcoholic hepatitis without cirrhosis had a 2–5-fold increase in the number of HSCs and a 7–15-fold increase in the number of giant HSCs. There was also a marked increase (15–20-fold) in the number of lipid vesicles in the giant HSCs [237]. These changes are associated with an increase in the extent of perisinusoidal collagenization. Perivenular fibrosis is considered to be a harbinger to future cirrhosis, especially in patients who continue to abuse alcohol or those who are coinfected with HCV [31,166]. Sclerosing hyaline necrosis is a more extensive degree of alcoholic hepatitis and is associated with extensive fibrosis [238]. The number of Kupffer cells and serum levels of TNF-α, IL6, and IL12 were significantly higher in patients with ALD than in controls [239]. In patients with severe steatohepatitis, there is stenosis of the central veins and the degree of stenosis correlates with the amount of ascites and hyperbilirubinemia and the peripheral leukocyte counts [240]. Histologically, the appearance of Mallory bodies increases significantly as venoocclusive lesions become more severe, but these lesions do not correlate with the degree of sinusoidal neutrophilic infiltration.

There are a number of nonalcoholic hepatic disorders (NASH, total parenteral nutrition, and certain drugs – corticosteroids, amiodarone, and synthetic estrogens) that may mimic ALD histologically and have been reviewed extensively elsewhere [241,242]. In particular, it may be necessary to perform a liver biopsy in order to identify other diseases that may mimic ALD clinically. Histologic differentiation between these diseases may be difficult. Perivenular fibrosis, which is similar but not identical to that often described in ALD, has been described in hepatitis C infection [164,243,244]. This emphasizes the need for a detailed evaluation of the histology and appropriate clinical correlation in these diseases. Excessive iron accumulation with siderosis of both hepatocytes and Kupffer cells occurs in up to two thirds of patients with ALD [245]. This is secondary to increased intestinal absorption, prior transfusion, or, rarely, spur cell anemia [246]. A liver biopsy should be performed in those patients who have biochemical findings suggestive of iron overload (total iron-binding capacity (TIBC) saturation >45%) in order to rule out hereditary hemochromatosis (HHC), by calculating the hepatic iron index. This is because both HCV infection and ALD can each individually cause biochemical abnormalities suggestive of HHC [247,248]. In the alcoholic patient without cirrhosis, the presence of moderate periportal hemosiderosis should warrant testing for *HFE* (the abnormal gene in the majority of patients with hemochromatosis), in addition to biochemical tests of iron overload (serum iron, TIBC, ferritin) [248]. The diagnosis of *HFE*-HHC in patients with clinical features consistent with *HFE*-HHC and/or biochemical evidence of iron overload is based on the results of the screening tests, transferring iron saturation, and serum ferritin concentration, and of confirmatory tests such as molecular genetic testing for the p.C282Y and p.H63D mutations in the *HFE* gene and/or histologic assessment of hepatic iron stores on liver biopsy [172].The current guidelines published by the AASLD recommend that for patients with a diagnosis of severe alcoholic hepatitis, liver biopsy should be done only if medical treatment is contemplated and if there is reasonable uncertainty about the underlying diagnosis [195].

Imaging studies

Imaging studies have been used to diagnose the presence of liver disease but may not have a specific role in establishing alcohol as the etiology of liver disease. The diagnosis of fatty change, established cirrhosis, and HCC are suggested by ultrasound or computed tomography (CT)

scan and confirmed by other laboratory investigations [228,249]. Altered echogenicity of the liver has been considered to be moderately sensitive but not specific to diagnose fatty change that is associated with alcoholic liver injury. Established cirrhosis can be suspected on CT or magnetic resonance imaging (MRI) based on the findings of a lobular surface of the liver with altered density, but the etiology cannot be established with certainty. Enlargement of the caudate lobe and right posterior notch has been suggested to identify alcohol as the etiology of liver disease [250]. Evidence of portal collaterals and a dilated portal–splenic axis suggest the presence of associated portal hypertension [251]. The major value of imaging studies is to exclude other causes of abnormal liver function tests in a patient who abuses alcohol, such as obstructive biliary pathology or infiltrative and neoplastic diseases of the liver [252]. Another tool for the diagnosis of ALD is hepatic ^{31}P magnetic resonance spectroscopy [253]. This is used to calculate hepatic energy metabolism and phospholipid membrane metabolism. Lower phosphodiesterase to adenosine triphosphate (ATP) ratios have been reported in patients with alcoholic cirrhosis.

Endoscopy

Upper gastrointestinal endoscopy in patients with ALD is used electively to establish the presence of esophagogastric varices and emergently to identify the source of gastrointestinal bleeding. In the clinical situation of alcohol abuse, upper gastrointestinal bleeding may be secondary to a variety of causes that include: Mallory–Weiss tear, peptic ulcer disease, direct alcohol-induced gastric mucosal erosions and injury, portal hypertensive bleeding from varices, or congestive gastropathy secondary to cirrhosis [254,255]. Endoscopy has both diagnostic and therapeutic value in an alcoholic patient with active upper gastrointestinal bleeding.

Pathogenesis

An in-depth discussion of the pathophysiology of alcohol-induced liver disease is beyond the scope of this chapter and several recent major reviews exist [35,256–259]. However, a general understanding of the mechanisms of alcohol-mediated liver damage is essential because it forms the basis of current therapeutic strategies.

In the past, it has been considered that whole-liver tissue analysis would provide an understanding of the pathogenesis of ALD. However, the liver consists of both hepatic parenchymal cells (65%) and nonparenchymal cells (endothelial cells, Kupffer cells/hepatic macrophages, hepatic stellate cells, bile duct epithelial cells, and pit cells/liver natural killer cells) [260–263]. All these cellular components are involved in the pathogenesis of ALD (Table 26.5). Even though the nonparenchymal cells constitute less than a third of the liver volume, they have distinct functions and are involved in cellular homeostasis, hepatocyte support, chemokine release, hepatocyte injury, fibrosis, and cell death [237,239,261,264,265].

Alcohol-induced liver injury is the result of a complex interaction between alcohol metabolism and inflammatory and immune responses that result in cellular injury [35,256]. These include oxidative stress and the consequent inflammatory cellular responses that cause direct injury to hepatocytes in addition to the activation of hepatic nonparenchymatous cells (Fig. 26.10). Additionally, indirect damage to the liver occurs because of endotoxin/cytokine activation, immune-mediated mechanisms, and induction of fibrogenesis [266]. Superimposed on these hepatotoxic mechanisms is the impairment of hepatic regeneration by alcohol, though rat studies have questioned this [267,268].

Direct hepatocyte injury

Hepatocytes are the primary site of alcohol oxidation and there are two major oxidative pathways involved: the alcohol and aldehyde dehydrogenase pathway and the microsomal ethanol oxidizing system (MEOS), the major component of which is CYP2E1 (Fig. 26.10) [270,271]. Thus, ethanol oxidation generates reactive free radicals leading to oxidative stress that is reinforced by depletion of glutathione and vitamin E (antioxidants) [272, 273]. Oxidative stress induces the transcription of several cytokines and the release of growth factors from different cells in the liver that interact with the immune cells mediating hepatocyte injury [262,266,274].

Alcohol dehydrogenase pathway

Alcohol dehydrogenase is an enzyme that produces acetaldehyde, which causes direct hepatocyte damage and immune-mediated damage by the formation of acetaldehyde adducts that are potent immunogens [141, 275]. In addition to acetaldehyde, other aldehydes produced as a result of free radical generation include malondialdehyde (MDA), which has been shown to combine with the cytochrome *c* oxidase subunits IV and V of mitochondria [141]. Antiacetaldehyde adduct IgA and IgG as well as anti-MDA adduct antibodies were found in a significantly higher number of patients with severe alcoholic hepatitis and cirrhosis [225]. Additionally, acetaldehyde and MDA can form hybrid adducts with proteins (MAA adducts), which are also highly immunogenic [276]. These suggest that the ADH pathway provides a strong immunologic mechanism in the pathogenesis of ALD.

Table 26.5 Role of cellular and subcellular organelles in the pathophysiology of alcoholic liver disease.

Target	Mediator	Consequence
Hepatocytes		
Cytochrome P450IIE1	Reactive oxygen species	Lipid peroxidation
Abnormal methionine metabolism SAMe *S*-adenosyl homocysteine	Transmethylation reaction	Nucleic acid, protein, phospholipids
Mitochondria	GSH depletion Membrane fluid abnormality Electron transport chain Mitochondrial DNA breaks	Reactive oxygen species Megamitochondria Defective ATP depletion Apoptosis induction
Hepatocyte growth	Impaired protein synthesis Inhibits calcium mobilization Reduced DNA synthesis	Impaired regeneration
Increased expression of protooncogenes	Increased regenerative proliferation	Hepatoma
Matrix remodeling and deposition	Hepatocyte communication	Impaired apoptosis, regeneration
Kupffer cell/macrophages		
Alcohol-induced damage	Cytokine release Defective IL10 release Defective regulation of local inflammation	Increased TNF-α expression Increased apoptosis Hepatocyte inflammatory cell infiltration
Iron overload (increased absorption)	Impaired function	Endotoxemia
Sinusoidal endothelial cells		
Inflammatory cell Migration Hypoxemia	ICAM expression increased Microvascular circulation abnormalities	Hepatocyte injury
Hepatic T lymphocytes		
Increased activation	TNF-α release	Hepatocyte apoptosis
Hepatic stellate cells		
Oxidative stress Endotoxemia Differential MAT expression	Activation	Lobular fibrosis

ATP, adenosine triphosphate; ICAM, intracellular adhesion molecule; IL10, interleukin 10; MAT, methionine adenosyl transferase; SAMe, *S*-adenosyl methionine; TNF-α, turmor necrosis factor α.

Acetaldehyde also significantly enhances the DNA binding of two major transcription factors: nuclear factor κB (NF-κB) and activator protein 1 (AP-1), and increases their transactivating activities [277]. These observations suggest that acetaldehyde plays a major role in regulating the expression of proinflammatory cytokines by activating NF-κB and AP-1 [278]. Other transcriptional regulators that may be involved are the early growth response 1 (Egr 1), which is regulated by the mitogen-activated protein kinase (MAPK) signaling cascade, and the Janus kinase-associated signal transducer and activator transcription factor (JAK-STAT) [256,257]. Many of these data, however, are from in vitro cell culture and animal models and human application and relevance is not yet clear.

Cytochrome P4502E1 pathway

Cytochrome P4502E1 (CYP2E1) is a component of the MEOS enzyme pathway that plays a major role in inducing oxidative stress and alcohol-induced hepatocellular damage [279]. After chronic ethanol ingestion, a 5–10-fold induction of CYP2E1 occurs that not only metabolizes ethanol but is also responsible for the activation of xenobiotics to toxic metabolites [122,124,279]. This increases the vulnerability of patients who abuse alcohol to solvents, xenobiotic compounds used in industry and therapy, as well as vitamin A precursors (β-carotene and retinol) [280–282]. In contrast to the ADH pathway, which is not inducible in humans, CYP2E1 is induced in humans by ethanol ingestion, and increases the production of ROS and consequent membrane peroxidation that results in

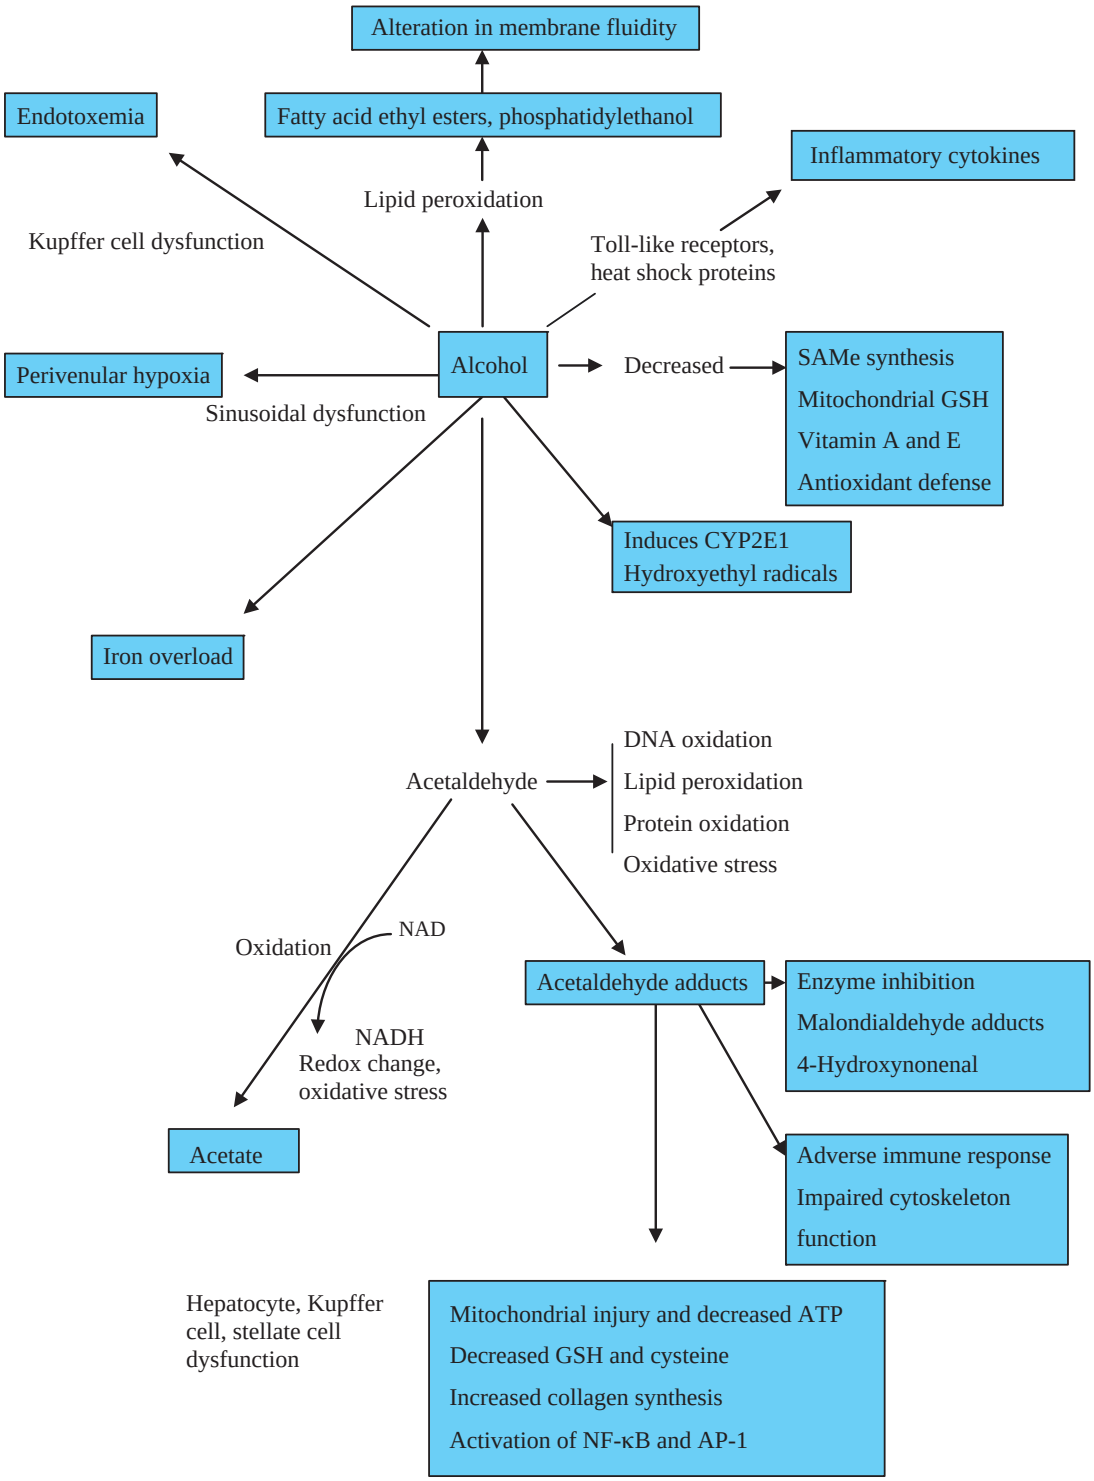

Figure 26.10 Pathogenesis of the role of the hepatocyte and alcohol oxidative pathways in the pathogenesis of alcoholic liver disease. AP-1, activator protein 1; ATP, adenosine triphosphate; CYP2E1, cytochrome P450 system; GSH, glutathione; NAD/NADH, nicotinamide adenine dinucleotide (reduced); NF-κB, nuclear factor κB; SAMe, *S*-adenosyl methionine.

cell damage [270,283]. There is increased generation of superoxide radical and free radical production, including the 1-hydroxyethyl free radical intermediates [149, 284]. Normally, cellular protective mechanisms against oxidative stress prevent the adverse effects of these ROS [285]. In the presence of liver disease and malnutrition, with maximal activation of the system, the detrimental responses predominate and result in tissue injury [286]. Other cytochromes like P4501A2 and -3A4 are also induced and may contribute to the cell injury and ROS generation associated with ethanol ingestion [122].

The CYP2E1 system may not be as essential in the pathogenesis of ALD [287]. CYP2E1 knock-out mice have been shown to be as susceptible to the hepato-injurious effects of ethanol [288]. The induction of other cytochrome enzymes (CYP1A, CYP2A, CYP2B, and CYP3A) also occurs with ethanol and may contribute to the oxidative damage associated with ethanol ingestion. The dissociation of CYP2E1 and ALD is also suggested by the prevention of experimental ALD with gadolinium chloride despite induction of CYP2E1 [289]. Nonetheless, the majority of data suggest that CYP2E1 is involved in the pathogenesis of ALD [260]. Furthermore, studies that have attempted to question the role of CYP2E1 have examined the early stages of ALD, while CYP2E1 plays a role later in the progression of ALD. Finally, levels of CYP2E1 are much lower in mice than rats or humans and caution must be exercised before extrapolating the findings in mice to humans [260].

Abnormal methionine metabolism

The liver plays a central role in methionine metabolism, with the formation of *S*-adenosyl methionine (SAMe) in the presence of the enzyme methionine adenosyl transferase (MAT) [290]. An inactivation of hepatic MAT activity occurs in ALD with a depletion of hepatic SAMe and glutathione (GSH) and decreased transmethylation reactions. These result in impaired antioxidant defense, altered phospholipid composition, and membrane fluidity and possibly altered DNA stability [59]. Finally, the homocysteine that is released as a consequence of altered MAT activity may stimulate hepatic stellate cells and promote hepatic fibrosis [291,292].

Role of hepatic mitochondria

Mitochondrial dysfunction has been observed in alcohol-fed animal models [293]. Increased synthesis of ROS, decreases in mitochondrial membrane potentials, increased oxidative modification, as well as single strand breaks in mitochondrial DNA have been reported [293,294]. These may be inducers of apoptosis and result in hepatocyte death in ALD. Dysregulated apoptosis has been suggested as a key pathogenic event in ALD with activation of effector caspases [262,295–297].

Role of iron accumulation

As already mentioned earlier, the role of increased parenchymal and nonparenchymal iron accumulation results from oxidative stress-mediated suppression of hepcidin and the induction of transferrin receptor 1. Additionally, iron accumulation also contributes to hepatocarcinogenesis [35,173,174].

Other molecular signaling abnormalities

A number of abnormalities are being recognized, including alcohol-mediated inhibition of critical intracellular energy sensor adenosine monophosphate (AMP) kinase, peroxisome proliferator activator receptor γ, coactivator protein α, and sirtuin 1 in the development and progression of ALD [35,298]. Plasminogen activator inhibitor 1 levels were reported to be elevated after alcohol exposure in mice [299]. A detailed review of these is beyond the scope of this current review especially since these mechanistic studies have been conducted in cultured hepatocytes/hepatoma cells or animal models and it is currently unknown if these can be directly translated to human disease pathogenesis.

Indirect hepatocyte injury

Hepatic macrophages (Kupffer cells) generate cytokines (such as TNF-α and TGF-β) that may accentuate or promote liver cell injury [35,262,274]. The role of TNF-α in alcoholic hepatitis is not clear [300]. Elevated serum levels of TNF-α in alcoholic hepatitis have been correlated with disease severity and mortality [142]. The TNF-α receptor 1 knock-out mice are resistant to alcohol-induced liver damage, as shown in Fig. 26.11 [301]. These studies suggest that TNF-α aggravates liver injury in ALD [256,302]. The contribution of Kupffer cells is supported by an attenuated alcohol-mediated hepatic injury by blocking Kupffer cell function [303]. Furthermore, MAT is expressed in

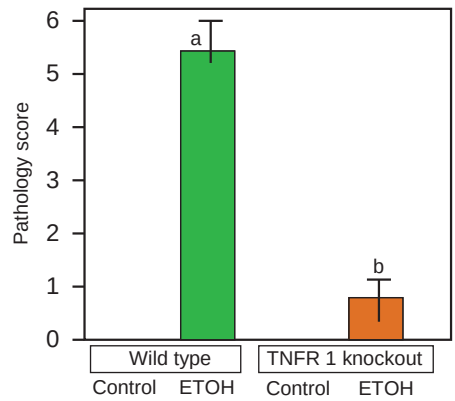

Figure 26.11 Tumor necrosis factor receptor (TNFR) 1 knock-out mice are less prone to alcohol-mediated hepatic injury compared to wild-type control mice. ETOH, alcohol; a, $P < 0.01$ versus control; b, P = NS versus control.

both Kupffer cells as well as sinusoidal endothelial cells, and an alteration in expression of this enzyme system in the three groups of cells (hepatocytes, macrophages, endothelial cells) could contribute to the pathogenesis of injury in ALD [260]. Liver-associated T lymphocytes mediate injury and these may be responsible for both immune-mediated and nonimmune-mediated (via the release of cytokines) hepatic injury [304]. Hepatic stellate cells may be responsible for both matrix remodeling and regulation of local inflammation [237]. An alteration in stellate cell activation may result in fibrosis as well as cell death in ALD [305,306]. Products of lipid peroxidation have the ability to activate the HSC and stimulate fibrogenesis [307]. Increasing evidence is accumulating that in addition to direct oxidative stress-induced injury to hepatocytes, innate immune responses in Kupffer cells, fibrotic events in the stellate cells, and activation of hepatic sinusoidal cells all contribute to the spectrum of alcohol-mediated liver injury. Emerging data show the role of toll-like receptor-mediated signaling in Kupffer cells, and their regulation by heat shock proteins accompanies the activation of a number of transcription factors resulting in hepatocellular injury and fibrosis [256]. The contribution of nonhepatic cellular components to hepatic injury is not entirely understood and warrants further studies to examine the role of these cell types.

Prognostic factors

Alcoholic cirrhosis has a worse prognosis than other forms of cirrhosis (Table 26.6) [308]. A number of adverse prognostic factors for the long-term outcome in ALD have been suggested. They include the development of cirrhosis, ascites, portal hypertension (especially with evidence of encephalopathy), spontaneous bacterial peritonitis, hepatic encephalopathy, hepatorenal syndrome, coagulopathy, severe hyperbilirubinemia, hypoalbuminemia, severe malnutrition, decreased galactose elimination capacity, α-fetoprotein, increasing age, histologic evidence of hepatic inflammation, continued alcohol abuse, and coinfection with other hepatotropic virus infection [20,309–312]. Iron overload and bacterial infections also predict poor outcome in ALD [313,314].

Table 26.6 Survival of patients with different types of cirrhosis.

Etiology	*N*	5-year survival	10-year survival
Alcohol	82	23%[a]	7%[a]
Cryptogenic	13	33%	20%
HCV	62	38%	24%
HBV	42	48%	20%
Hemochromatosis	20	41%	22%
Autoimmune	16	46%	23%
PBC	36	56%	39%

[a] $P < 0.05$ versus other forms of cirrhosis.
HBV, hepatitis B virus; HCV, hepatitis C virus; PBC, primary biliary cirrhosis.
Adapted from Pessione et al. [308].

Scoring system for disease severity

Clinical progress in the therapy of ALD has been limited in part by the lack of accurate predictors of prognosis. This has also resulted in difficulty in comparing outcomes and the results of different treatments due to the nonhomogeneity in the predictors used. Accurate prediction of the prognosis of the most severe form of alcoholic liver disease, alcoholic hepatitis, is necessary to develop reliable treatment strategies for this disease. The modified Maddrey discriminant function (DF), which includes prothrombin time and bilirubin levels, is the most widely used predictor of severity of alcoholic hepatitis [315]. Values of ≥32 are associated with a mortality of 35–40% and are used to identify patients who will benefit from corticosteroid therapy. A patient with a DF of <32 has a survival of 83–90% and these patients do not benefit from corticosteroids [316]. The major limitation of the Maddrey DF is that even though it is a continuous scale, it is effectively used as a dichotomous test at the cutoff of 32. Once patients have a value of ≥32, they are at risk of dying, but this risk is not specified. The presence of encephalopathy has been included by some workers to predict outcome and the decision to start corticosteroids [317]. The model for end-stage liver disease (MELD) and the Glasgow alcoholic hepatitis scale (GAHS) have been used more recently to predict outcome in patients with acute alcoholic hepatitis [317–319]. A MELD score of 21 or higher had the best sensitivity and specificity in predicting 90-day mortality [320]. Other authors have also used the MELD, and a score of 11 has been used as a cutoff to predict outcome [321]. These studies have compared MELD with the Maddrey DF and found MELD to be either equally sensitive and specific or superior to the DF in predicting the outcome in acute alcoholic hepatitis [317].

The limitations of MELD include the difficulty in calculating the score at the bedside, the variable predictive value amongst studies, and the inclusion of serum creatinine, which limits its usefulness in the presence of hyperbilirubinemia as this reduces the accuracy of creatinine measurement [322]. The GAHS has been validated in a large population of patients studied up to day 84, allowing assessment of not only the short-term outcome at days 28–30 but also the intermediate clinical course of the disease [319]. The key components of GAHS include age, white blood cell count, blood urea, prothrombin time, and

Table 26.7 Five-year survival in alcoholic liver disease showing the effect of abstinence.

Time period of study (years)	*N*	Survival (%)		Reference
		Stopped drinking	Continued drinking

serum bilirubin [318,319]. It is still unclear if GAHS can be universally applied, and both MELD and GAHS need to be extensively studied by different groups before they are accepted as a predictor of outcome and replace the widely used Maddrey DF. Dynamic models that incorporate changes in laboratory values have been used that include changes in MELD or DF at 1 week, a change of ≥ 2 in MELD in the first week, and the bilirubin response at 1 week [317,323]. Despite these reports, the DF remains the most commonly and widely accepted prognostic measure in acute alcoholic hepatitis. It has also been used in patients with acute on chronic alcoholic liver disease even though it has been validated only in patients with acute alcoholic hepatitis.

Abstinence

Abstinence is a major goal of therapy and remains a fundamental factor in the management of ALD [308,324]. It is perhaps the most important but difficult therapeutic intervention for ALD [271,325]. A recent review of 118 studies on survival in cirrhosis found only 12 of these examined the effect of alcohol intake on outcome [326]. Abstinence has been shown to improve the outcome and histologic features of hepatic injury, to reduce portal pressure, and to decrease progression to cirrhosis (Table 26.7), but this effect may be lower in female patients [71,240,310, 327–332]. Furthermore, a survival analysis of abstinent alcoholic cirrhotics infected with HCV when compared with patients with HCV cirrhosis who had never consumed alcohol showed no difference [333].This improvement can be relatively rapid, and in 66% of patients abstaining from alcohol a significant improvement was observed in 3 months [208,334]. Continued alcohol ingestion results in increased portal hypertensive bleeding especially in patients who have bled in the past and worsens both short- and long-term survival [255]. The deleterious effect of continued alcohol ingestion on the outcome compared with the abstinent population is shown in Fig. 26.12.

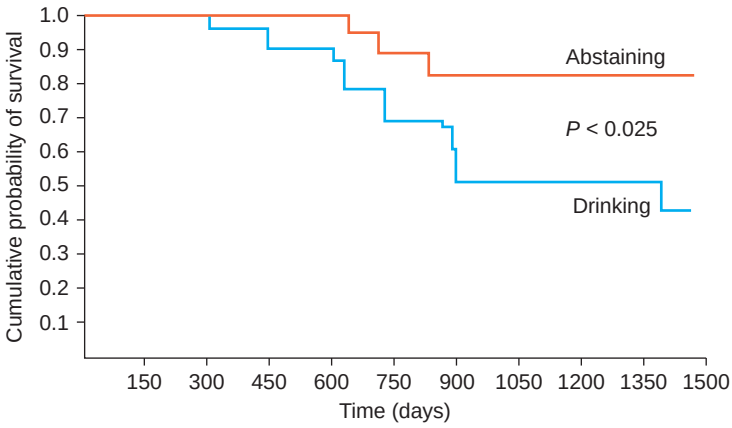

Figure 26.12 Effect of abstinence on long-term survival (Kaplan–Meier survival curve). (From Merkel et al. [310].)

Recidivism is the major risk in all patients at any time following abstinence [335,336]. Estimates of recidivism vary depending on the time course of follow-up, the definition chosen and the population studied. Over the course of 1 year, relapse rates range from 67% to 81% [337]. No controlled trials exist on the benefits of alcohol abstinence and the effects of recurrent drinking on ALD. Cohort studies, however, have consistently demonstrated that abstinence does improve survival at all stages of the disease [308,327]. Several drugs have been tried to help sustain abstinence. Naltrexone, a pure opioid antagonist controls the craving for alcohol. A Cochrane systematic review of the use of naltrexone and nalmefene in 29 randomized controlled trials concluded that short-term treatment with naltrexone lowered the risk of relapse of alcohol abuse [338]. Naltrexone, however, has the potential to cause hepatocellular injury that is of importance especially in patients who continue to drink. Acamprosate (acetylhomotaurine) is a novel drug with structural similarities to excitatory amino acids and γ-aminobutyric acid (GABA) and is associated with a reduction in withdrawal symptoms [339]. In 15 controlled trials, the efficacy of acamprosate has been demonstrated in reducing withdrawal symptoms but the effects on survival are not yet available [340]. The primary benefit of acamprosate is for patients who have become abstinent but it is not effective in inducing remission [195]. Recently, newer agents are being considered but their short- and long-term efficacy and safety in alcoholic liver disease are currently unknown [341]. Few studies have examined the benefit of interventions to induce abstinence and maintain it in patients with alcoholic cirrhosis. One study using baclofen, a GABA-B receptor antagonist, has shown benefit in maintaining abstinence [342]. The AASLD practice guidelines recommend strict abstinence in patients with ALD and have graded abstinence to class 1b on the evidence base [195].

Exercise has been shown to ameliorate the alcohol-induced hepatic injury in rats [343]. It is possible that a healthy behavior pattern in humans would reinforce abstinence in addition to its beneficial effect on ALD [63]. Human studies should be encouraged given the multiple beneficial effects of exercise. Before recommending exercise in patients with ALD, the possible underlying cardiomyopathy and hepatopulmonary syndrome of cirrhosis need to be excluded.

Hepatic inflammation

The presence of hepatic inflammation appears to be the single most important prognostic histologic factor in patients with ALD [20,344,345]. In a study of 217 patients (140 cirrhotics and 77 noncirrhotics) with biopsy-proven ALD, the presence of hepatitis indicated a poor prognosis [345]. Patients with cirrhosis and hepatitis had increased 1- and 5-year mortality rates of 27% and 47%, respectively. This contrasts with cirrhotic patients without hepatitis who had a survival rate similar to patients with no cirrhosis or hepatitis. These data have been indirectly confirmed as the presence of polymorphonuclear cells on liver biopsy was found to be a prognostic factor for early and late survival [311].

Hepatitis C

As discussed previously, the presence of HCV is another factor that causes inflammation in these patients [152, 346]. The decision to use antiviral therapy in those ALD patients with HCV infection should be determined on an individual basis. Since the data available indicate that active drinking will reduce the efficacy of interferon therapy for HCV infection, the potential use of interferon or other antiviral agents must be decided on an individual basis [347–349]. However, the potential efficacy of antiviral therapy may be improved by abstinence and therefore the potential for HCV therapy may be a motivational factor [348]. A recent Dutch study, however, suggested that response to therapy is maintained even in patients with alcohol use but this needs to be validated given previous data to the contrary [350].

Interaction with other drugs

The activation of the microsomal oxidative enzyme pathways also enhances the hepatotoxicity of other drugs, especially acetaminophen. A combination of an enhanced cytochrome P450 system and decreased hepatic glutathione results in severe toxicity. A significant proportion (64%) of patients who developed acetaminophen toxicity are reported to be alcohol abusers [351,352]. Furthermore, the majority of patients reported taking doses that were well below the accepted toxic range [353]. Awareness and suspicion of the diagnosis are the most important factors in the management of these patients. Diagnostic clues include very high aspartate transaminase (above 1,000 U/L) and a prolonged prothrombin time. Early and accurate diagnosis is essential due to the high mortality and need for early therapy [354].

Therapy

Therapy is based on the stage of the disease at which it is started and the pathogenetic event being targeted (Table 26.8) [271,355]. The primary treatment modalities that have been evaluated in the acute phase of alcoholic hepatitis include agents to suppress inflammation (corticosteroids) and anticytokine therapy (pentoxifylline, infliximab, etanercept), nutritional improvement (enteral and parenteral supplements including amino acids, anabolic steroids), modifiers of metabolism

Table 26.8 Pathophysiology of alcoholic liver disease and potential therapies.

Direct injury		Indirect injury	
Proposed treatment[a]	**Mechanism**	**Proposed treatment[a]**	**Mechanism**
PUL[3]	Membrane damage	Antibiotics, nutrition	'Gut' function
S-adenosylmethionine	Oxidative stress	Anti-TNF-α[2]	Cytokines
N-acetylcysteine[3]	Oxidative stress	Pentoxifylline[1], steroids	Cytokines
PTU[2]	Hypermetabolism	γ-Interferon	Cytokines
		Steroids[1]	**Immunologic mechanism**
		Colchicine[2], PUL[3]	Fibrogenesis
	Regenerative capacity: nutrition[3], oxandrolone[3], hepatotropic agents		

[a] Some therapies were investigated in randomized, placebo-controlled trials and were found to be either: (1) effective, (2) ineffective, or (3) possibly effective.
PUL, polyunsaturated lecithin; PTU, propylthiouracil.

(propylthiouracil), and inhibitors of hepatic fibrosis (colchicine) [59]. Once cirrhosis is established, complications of cirrhosis – which include evidence of chronic hepatic failure (encephalopathy, ascites) as well as portal hypertension (variceal bleeding) – are treated along similar lines as in patients with non-ALD with additional attention given to other organ dysfunction associated specifically with alcohol [355,356].

Treatment of alcoholic hepatitis

Therapy for acute alcoholic hepatitis is determined partly on factors that estimate mortality. These indices are calculated based on laboratory tests, and the most commonly used index is the Maddrey discriminant function: ((prothrombin time prolongation over controls in seconds) $\times$ 4.6) + serum bilirubin in mg/dL [316]. A number of previously used predictors such as the Child–Turcotte–Pugh score and the combined clinical and laboratory index have fallen out of favor due to low diagnostic accuracy [345,357]. The MELD and GAHS have been gaining interest as accurate predictors of outcome [319]. The Lille scoring system of the response to therapy at 1 week is considered to be a robust measure of outcome as well as of response to therapy [358,359].

A number of biomarkers have been suggested to diagnose the severity of alcoholic hepatitis but are not yet in routine clinical practice [360,361].

Corticosteroids

Rationale

Corticosteroids have been used to suppress the inflammatory and immune response directed against neoantigens that is induced by acetaldehyde adducts, which include liver-specific lipoprotein, liver membrane antigen, Mallory bodies, and epitopes of protein–aldehyde adducts in the liver [362]. Specific immune targets that have been considered targets of corticosteroids include malondialdehyde and acetaldehyde adducts, autoantibodies to P4502E1 and P4503A4, and antibodies to liver membrane antigen [363]. There is enhanced cytotoxicity of lymphocytes towards hepatocytes in patients with alcoholic hepatitis [262,364]. Steroids also exert a direct antifibrotic effect by suppressing the expression of extracellular matrix proteins in the liver [133]. Finally, inhibition of cytokine synthesis in response to gut-derived endotoxins by glucocorticoids also contributes to their beneficial effects in ALD.

Clinical trials

Corticosteroids have been the most extensively used treatment of alcoholic hepatitis but their efficacy still remains controversial. Of a total of 13 randomized controlled trials, five showed that corticosteroids reduce mortality compared with placebo, while eight others found no difference in outcomes (Table 26.9) [365–377]. Although the results are not consistent, differences in study design may explain the different outcomes. These include variability in dose and duration of therapy, selection of patients (e.g., varying time intervals before randomization or inconsistent use of disease severity scoring), possible misclassification (a consequence of inclusion without liver biopsy), and severity of illness, concomitant medical problems, or medications, as well as undiagnosed chronic viral hepatitis infections. Despite these variations,

Table 26.9 Results of randomized controlled trials of corticosteroid use in patients with alcoholic hepatitis showing the different death rates.

CI, confidence interval; RR, relative risk.
Summarized from O'Shea and McCullough [377].

two separate meta-analyses [378,379] found a benefit to the use of steroids. One meta-aggression using a different statistical weighting of the different trials [380] suggested no benefit of corticosteroid therapy after attempting to control for potential confounders. In one meta-analysis, steroid treatment provided a protective efficacy of 27% of patients with hepatic encephalopathy, which increased to 40% among higher quality trials and in 51% of patients without gastrointestinal bleeding (Table 26.10) [378]. In the most recent meta-analysis, no statistical effect of steroids on mortality in alcoholic hepatitis was reported but it did demonstrate an improvement in outcome in patients with encephalopathy and/or a DF of ≥32 [381].

Table 26.10 A meta-analysis of the efficacy of corticosteroid use in patients with alcoholic hepatitis with or without hepatic encephalopathy.

Trial characteristic	*N*	RR (95% CI)[a]	Protective efficacy (1 – RR)
With hepatic encephalopathy			
All trials	11	0.73 (0.58–0.92)	27%
GI bleeding excluded	7	0.49 (0.33–0.72)	51%
GI bleeding not excluded	4	1.06 (0.76–1.48)	NS
Quality score ≥4	7	0.56 (0.38–0.83)	44%
Quality score <4	3	1.05 (0.75–1.47)	NS
"Best estimate"[b]	5	0.64 (0.42–0.97)	36%
Without hepatic encephalopathy			
All trials	9	1.07 (0.68–1.71)	NS
GI bleeding excluded	5	1.01 (0.36–2.81)	NS
GI bleeding not excluded	4	1.21 (0.72–2.04)	NS

Quality score <4	3	1.18 (0.65–2.13)	NS
"Best estimate"[b]	4	1.01 (0.35–2.91)	NS

[a]If the 95% CI includes unity (1) then there is no significant therapeutic benefit (or protective efficacy) of corticosteroids for that subgroup.
[b]Best estimate is based on those trials with: (i) a quality score of 4; (ii) a baseline equivalence between groups; and (iii) an exclusion of active GI bleeding.
CI, confidence interval; GI, gastrointestinal; *N*, number of trials; NS, not significant; RR, relative risk.

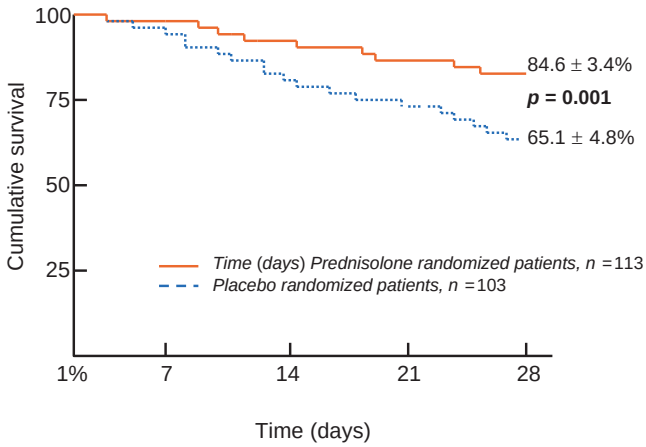

Figure 26.13 Effect of corticosteroids on the mortality of patients with alcoholic hepatitis (discriminant function score ≥32) undergoing the 28-day treatment. Data are from three randomized controlled trials [369,370,374].

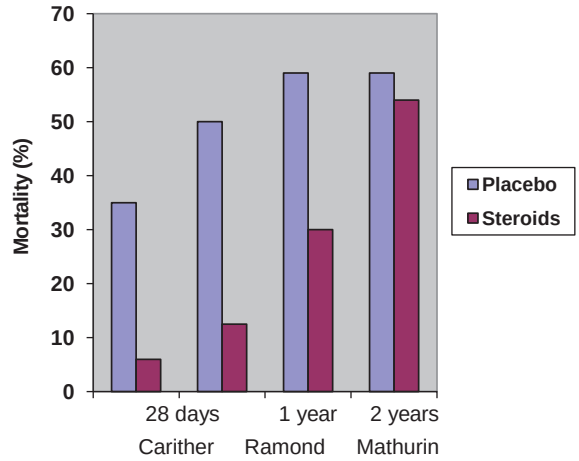

Figure 26.14 Corticosteroids show benefit on 1-year but not at 2-year mortality figures in alcoholic hepatitis [31,369,374].

The major limitation of these meta-analyses was that they were not designed to analyze individual patient data. A reanalysis of the pooled raw data from the three recent placebo-controlled randomized trials, restricted to patients with a DF ≥32, concluded that patients treated with corticosteroids had a significantly higher survival at 28 days than those given placebo: 84.6% versus 65% (Fig. 26.13) [315,316]. Therapy with corticosteroids, age, and serum creatinine were the independent predictors of outcome in these patients. Based on these data, the number needed to treat was calculated to be 5 (i.e., five patients treated to prevent one death). A recent analysis of individual data from five randomized controlled trials showed that corticosteroids significantly improved 28-day survival in patients with severe alcoholic hepatitis. The survival benefit was mainly observed in patients classified as responders by the Lille model [382].

In addition to these observations on the short-term benefits of corticosteroids in acute alcoholic hepatitis, a follow-up study showed that steroids improved the survival at 1 year but not 2 years in these patients (Fig. 26.14) [312]. The long-term benefit of corticosteroids in acute alcoholic hepatitis is uncertain. A number of factors may contribute to these results and include recidivism, co-morbidities, and progression of disease.

These observations provide a number of suggestions for the management of alcoholic hepatitis [377]. Approximately five to seven patients need to be treated to avoid one death. This necessitates careful selection of patients to avoid the side effects of corticosteroids in the other four to six patients who will derive no clinical benefits or may suffer the adverse effects of corticosteroids. This means excluding patients with active infection and being certain of the diagnosis (liver biopsy may be necessary) because histologically confirmed alcoholic hepatitis correlates poorly with the clinical impression of alcoholic hepatitis [311]. As many as 28% of patients with a clinical picture of alcoholic hepatitis do not have histologic features of alcoholic hepatitis on liver biopsy. Only patients with severe disease (as defined by the presence of hepatic encephalopathy, the DF, the MELD score, or the GAHS) should be treated with corticosteroids. Another recently identified marker is the early change in bilirubin (ECB) at 7 days, which has been shown to accurately identify those patients not likely to respond to corticosteroids [323]. Finally, based on pharmacologic considerations (prednisone is converted to its active form, prednisolone, in the liver), published data indicate that prednisolone (40 mg daily for 4 weeks followed by a taper) should be used rather than prednisone. One may conclude from these observations that corticosteroids reduce mortality by up to 25% in alcoholic hepatitis, but the mortality still remains high (44%) in patients treated with corticosteroids. Therefore, other therapies or combination of therapies need to be considered [315].

Anticytokine therapy

Rationale

Cytokines are essential to the processes of hepatocyte inflammation, cell death, and regeneration. Serum levels of TNF, as well as, IL1, IL6, and IL8 are elevated in alcoholic hepatitis [266,383,384]. Human studies have shown that levels of soluble TNF receptors correlate linearly with an increased risk of mortality and that serum levels of TNF are high on admission and correlate with mortality [385]. In addition, monocytes from patients with alcoholic hepatitis produce TNF-α at higher levels than controls in response to endotoxin. Based on these observations,

clinical trials have been performed using therapy targeted towards blocking TNF-α.

Pentoxifylline

Rationale

Pentoxifylline is a phosphodiesterase inhibitor used in the treatment of peripheral vascular disease based on its ability to increase erythrocyte flexibility, reduce blood viscosity, and inhibit platelet aggregation [386]. Pentoxifylline also reduces the production of TNF-α, IL5, IL10, and IL12 [387]. It also has been shown to decrease the transcription of IL2 and TNF-α promoters in transiently transfected normal T cells, to inhibit the activation of NF-κB and nuclear factor of activated T cells, and to stimulate the activation of protein-1 and cAMP response element-binding proteins. In an animal model of cirrhosis it reduced portal pressure [388].

Clinical trials

A 4-week double-blind prospective randomized trial in 101 hospitalized patients with severe alcoholic hepatitis (Maddrey score ≥32) treated with either pentoxifylline (400 mg three times a day) or placebo showed a significantly decreased mortality with pentoxifylline therapy (23% with pentoxifylline and 42% with placebo) (Fig. 26.15) [386]. Hepatorenal syndrome was the major cause of death in both groups, but significantly more frequent in the placebo group. The difference in mortality between the two groups suggests a number needed to treat of 4.7, which is almost identical to the number arrived at by Mathurin et al. when comparing the use of steroids and placebo [311]. In another study, 29 patients who did not respond to corticosteroids (absence of early decline of bilirubin) were switched to pentoxifylline for 28 days and compared with 58 matched patients who continued corticosteroids. No survival benefit was observed with pentoxifylline at 2 months [389].The mechanism whereby pentoxifylline decreased the development of hepatorenal syndrome is unclear, but could be related to either direct effects on the liver (through any of the above possible mechanisms) or, alternatively, by a direct renal effect. Plasma concentration of TNF-α did not decrease with pentoxifylline during the study [386] and suggests a TNF-α-independent mechanism for this therapy.

Infliximab

Clinical trials

Two small uncontrolled pilot studies using infliximab (IgG1 monoclonal antibody to TNF) suggested a benefit in alcoholic hepatitis [390,391]. A subsequent randomized controlled trial using infliximab (10 mg/kg) in combination with prednisolone (40 mg/day) versus prednisolone alone was begun in a total of 36 patients [392]. The trial was terminated prematurely because of the significantly higher mortality related to infection in the infliximab group compared with the controls (39% versus 11%) (Fig. 26.16). This study has been criticized based on the specifics of the study design (especially in the relatively high dose of infliximab) as well as the premise for the use of such therapy [393].

Etanercept

Etanercept, a P75-soluble TNF receptor–Fc fusion protein neutralizes soluble TNF and excludes an effect on membrane bound TNF. A single study in 13 patients with moderate or severe alcoholic hepatitis for a 2-week duration showed that the 30-day survival rate for patients receiving etanercept was 92% [394]. Adverse events (including an infection, hepatorenal decompensation, and gastrointestinal bleeding) necessitated premature discontinuation of etanercept in 23% of patients. In a multicenter, randomized, double-blind, placebo-controlled study of

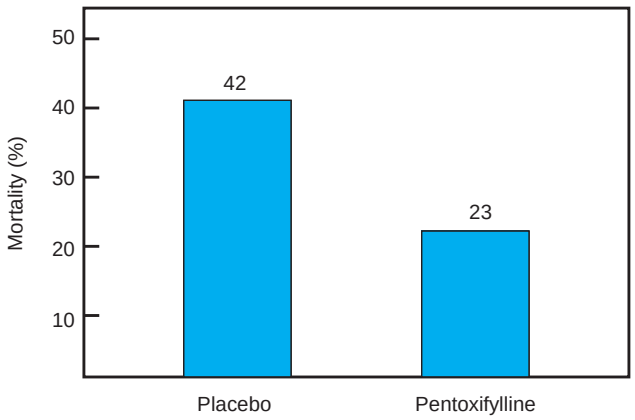

Figure 26.15 Pentoxifylline lowers mortality in acute alcoholic hepatitis compared with placebo.

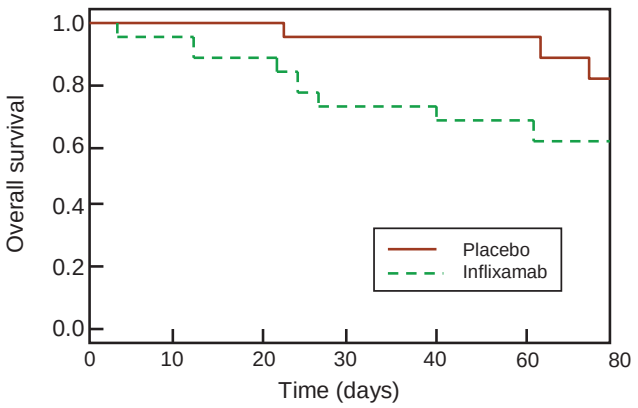

Figure 26.16 Kaplan–Meier survival curve demonstrating lower survival with infliximab compared with placebo when administered to patients with acute alcoholic hepatitis. (Adapted from Naveau et al. [392].)

etanercept in 48 patients with severe alcoholic hepatitis (MELD score ≥15) no difference in 1-month mortality rates was found between the two groups. However, 6-month mortality was significantly higher in the patients treated with etanercept (57.7% versus 22.7%). Serious adverse events were also significantly higher in those patients treated with etanercept [395].

In summary, the results of measures directed against TNF-α appear controversial. Based on the data from the studies using infliximab and etanercept in alcoholic hepatitis, the extent to which complete TNF inhibition (via antibody or receptor blockade) is beneficial is unknown and there may be concerns about serious adverse events, including higher mortality, in the treated patients. In addition, questions have been raised regarding the extent to which TNF inhibition is of benefit in this disease as TNF has been shown to be important in hepatic regeneration [267].

Antioxidants

Rationale

A major mechanism of alcohol-related liver injury is mediated by the generation of superoxides, the induction of cytochrome P4502E1 activity, and the product of inducible nitric oxide synthetase-related oxidative stress (Fig. 26.17) [396,397].

In vitro studies indicate that oxidative stress sensitizes lymphocytes to TNF-α-mediated cytotoxicity that is mediated through the cellular death domain pathways [398]. In addition, blood vitamin E levels and mitochondrial glutathione are decreased by ethanol [399,400].

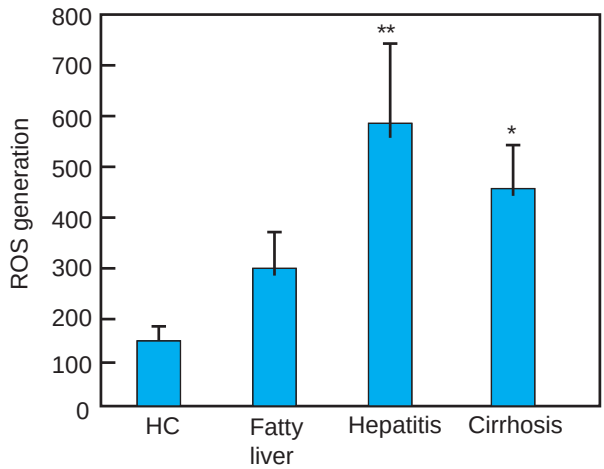

Figure 26.17 Nonstimulated neutrophils release greater quantities of reactive oxygen species (ROS) in patients with alcohol-induced liver injury compared with placebo. The release of ROS is greater with increasing severity of liver injury. HC, healthy controls; *, $P < 0.05$ versus HC; **, $P < 0.01$ versus HC.

These lead to an imbalance between alcohol-induced oxidative stress and the endogenous components of cellular defense against oxidative stress. Antioxidants also attenuate NF-κB activation and TNF-α production in monocytes of patients with alcoholic hepatitis and rat Kupffer cells in vitro [383].

Clinical trials

Vitamin E when used alone was not shown to be significantly beneficial in either alcoholic hepatitis or alcoholic cirrhosis [401,402]. However, neither of these studies were optimally designed and there are data suggesting that vitamin E when combined with other antioxidants may improve outcome in alcoholic hepatitis [403].

N-acetylcysteine (NAC) has been used either alone or in combination with other antioxidants. A combination (NAC, β-carotene, vitamins C and E, selenium, methionine, allopurinol, and desferrioxamine) had lower 30-day survival when compared with corticosteroids in patients with alcoholic hepatitis but this survival difference was lost at 1 year of follow-up [404]. In another study in patients with severe alcoholic hepatitis, stratified by gender and corticosteroid therapy, the response to a loading dose of NAC (150 mg/kg) followed by 100 mg/kg/day for 1 week and daily doses of vitamins A–E, biotin, selenium, zinc, manganese, copper, magnesium, folic acid, and coenzyme Q for 6 months was examined. Antioxidant therapy was found to have no benefit either alone or in combination with corticosteroids at 6 months [405]. In another study published only as an abstract, 87 patients with alcoholic hepatitis (Maddrey DF ≥32) were randomized to corticosteroids with or without NAC. Patients in the NAC arm had a better 1-month survival but this did not persist at 3 and 6 months. A more recent study of intravenous NAC failed to demonstrate any survival benefit at 6 months [406]. These data suggest that despite initial promise, NAC does not seem to confer major survival benefits and any further use of this agent should be as part of clinical studies.

Nutritional supplementation

Rationale

Nutritional therapy for ALD is based on the observations of a high prevalence of protein-calorie malnutrition in ALD, which consists of skeletal muscle loss or sarcopenia, loss of fat mass, and cachexia that includes both muscle and fat loss [91,94,407]. A combination of liver disease, as well as direct toxicity of alcohol on skeletal muscle protein metabolism, contribute to this high prevalence of sarcopenia and cachexia in these patients. The metabolic abnormalities in ALD that contribute to nutritional deficiencies are shown in Box 26.4. Aggressive nutritional therapy should supply optimal nutritional replacement to correct preexisting malnutrition and to provide sufficient amino

Box 26.4 Nutritional deficiency, poor intake, and consequent metabolic derangements in alcoholic liver disease.

Related to hepatic dysfunction

- Poor intake: anorexia, change in mental status, and abdominal distension (ascites)
- Malabsorption: portal hypertensive enteropathy and bile salt deficiency
- Metabolic derangement: decreased respiratory quotient and protein synthesis. Increased amino acid oxidation and resting energy expenditure

Related to alcohol

- Energy metabolism: anorexia and inhibition of ATP production
- Protein synthesis: increased protein breakdown and decreased synthesis.
- Cytokine mediated: TNF-induced apoptosis and decreased DNA synthesis. Increased energy expenditure

Micronutrient imbalances

- Thiamine, folic acid, pyridoxine, vitamin A, vitamin C, vitamin K, hypocalcemia, hypomagnesemia, low selenium, and zinc. Choline and lecithin low

ATP, adenosine triphosphate; TNF, tumor necrosis factor.

acids to encourage hepatic regeneration and reverse sarcopenia. Adequate protein intake is to be encouraged because the previously considered risks of encephalopathy have been found to be overstated. The nutritional requirements in ALD are shown in Table 26.11.

Clinical trials

In a large trial of over 200 patients with ALD, 100% prevalence of nutritional deficiency was reported [408]. Furthermore, protein-calorie malnutrition correlated with short- and long-term mortality and the degree of liver dysfunction in patients with ALD, and improved nutritional status correlated with increased survival [408]. Based on these observations, amino acid infusions have been used in the therapy of alcoholic hepatitis [409]. A total of eight randomized controlled trials and six open labeled trials have been published in patients with alcoholic hepatitis, six studies showing beneficial results and two negative results [195,410,411]. The beneficial results were related to improved histology and/or liver function tests. Improved survival was only reported in a single study [412]. Overall mortality in all studies combined was 17% in the treated group and 9.6% in the control group ($P > 0.05$). In the two studies reporting a negative result, there was a large proportion of patients with inactive cirrhosis rather than active hepatitis [413,414]. As is true with all artificial feedings, the enteral route is preferred over the parenteral route if possible. Based on these results, one may conclude that routine protein restriction is not needed in patients with alcoholic hepatitis with or without cirrhosis even if encephalopathy is present provided oral feeds can be tolerated. However, if encephalopathy worsens with protein-based diets, special amino acid formulations enriched in branched chain amino acids should be considered [415].

A number of trials have examined various nutritional therapies for patients with cirrhosis (Table 26.12). These trials demonstrate that both short-term [416–419] and long-term nutritional intervention provides therapeutic benefit for a number of important clinical outcomes [420–422]. Nutritional therapies have also been used successfully in cirrhotic patients undergoing liver transplant and cirrhotic patients with hepatocellular cancer [423]. Practical guidelines for daily dietary feeding in ALD are shown in Box 26.5.

Myostatin antagonists are currently being tried in human disease with early promising results and, if found

Table 26.11 Nutritional requirements in patients with alcoholic liver disease.

			Energy substrate	
	Protein (g/kg/day)	Energy (kcal/kg/day)	% CHO	% Fat
Alcoholic hepatitis	1.0–1.5	30–40	67–80%	20–33%
Cirrhosis (uncomplicated)	1.0–1.5	30–40	67–80%	20–33%
Cirrhosis (complicated):

N	Patient profile	Therapy	Benefit	Reference
Short-term studies				
31	Decompensated alcoholic liver disease	Hospitalized enteral feeding (Isocal® 1.5 g protein/kg)	Encephalopathy, serum bilirubin, antipyrine clearance	Kearns et al. [417]
26	Malnourished cirrhosis	Standard oral diet (30–35 kcal/kg daily)	Improved nutritional status and nitrogen balance	Campillo et al. [418]
35	Severely malnourished cirrhotics	Hospitalized enteral feeding (2,115 kcal)	Child score Improved survival ($P = 0.065$)	Cabré et al. [437]
Long-term studies				
71	Alcoholic cirrhosis and hepatitis	Enteral tube feeding (2,000 kcal/day) or steroids	Higher mortality due to steroids related to infection	Cabré et al. [416]
174	Advanced cirrhosis	BCAA versus lactalbumin/ maltrodextrin 14.4 g/day	Improved Child score Trend to improved survival	Marchesini et al. [419]
64	Chronic encephalopathy	BCAA versus casein supplements (0.24 g/kg)	Encephalopathy Nitrogen balance Bilirubin	Marchesini et al. [420]
32	Symptomatic cirrhosis BCAA/AAA <1.0	BCAA supplements (16 g) Enteral supplements (1,000 kcal)	Delayed death Less frequent hospitalization for sepsis	Yoshida et al. [421]
51	Decompensated alcoholic cirrhosis	Oral supplements (1,000 kcal + 34 g protein)	Less frequent hospitalizations for infections	Hirsch et al. [422]
31	Child B and C	Nutritional supplement (Ensure®) 1,000 kcal + 35 g protein	Improved nutrition and cell-mediated immunity	

AAA, anti-F actin antibody; BCAA, branched chain amino acid.

effective, will form a novel method of reversing the sarcopenia of alcoholic cirrhosis [424].

Other evaluated agents

A number of other agents have been evaluated and these include propylthiouracil, colchicines, and anabolic steroids.

Propylthiouracil

Rationale

Alcoholic hepatitis is associated with a hypermetabolic state with increased energy expenditure and oxygen consumption by the hepatocytes [425]. This could be blocked by propylthiouracil.

Clinical trials

There have been two controlled trials of short-term propylthiouracil in alcoholic hepatitis [426,427]. No difference in mortality was reported in these studies. A Cochrane meta-analysis of six randomized controlled clinical trials of propylthiouracil in patients with alcoholic liver disease (includes steatosis, fibrosis, hepatitis, and/or cirrhosis) found no significant difference between placebo and propylthiouracil in the all-cause or liver-related mortality, complications of liver disease, or liver histology [428].

Colchicine

Rationale

Colchicine inhibits collagen production, increases hepatic collagenase activity, mobilizes ferritin deposits, and inhibits cytokine production.

Clinical trials

There have been two studies reported on the use of colchicine in the therapy of alcoholic hepatitis with no therapeutic benefit [429,430]. A Cochrane review of 15 randomized trials including 1,714 patients concluded that colchicine has no role in alcoholic hepatitis outside controlled clinical trials [431].

Anabolic steroids

Rationale

The anabolic steroids testosterone and oxandrolone have been shown to improve hepatic histology in fatty liver and improve the synthetic functions [377]. In contrast to testosterone, oxandrolone has higher nitrogen-retaining and myotrophic properties. Co-treatment with nutritional supplementation may result in further improved results.

Box 26.5 Guidelines for daily dietary feeding in alcoholic liver disease.

- Protein = 1.0–1.5 g/kg BW
- Total calories = 1.2–1.4 × REE with a minimum of 30 kcal/kg BW:
  50–55% as carbohydrate (preferably as complex carbohydrates)
  30–35% as fat (preferably high in unsaturated fat and with adequate essential fatty acids)
- Nutrition should be given enterally by voluntary oral intake and/or by small-bore feeding tube; PPN is second choice; TPN is last choice
- Salt and water intake should be adjusted for patient's fluid volume and electrolyte status
- Liberal multivitamins and minerals
- Specialized BCAA-enriched supplements are not usually necessary:
  Most patients tolerate standard AA supplements
  Reserve BCAA formulations for patients who cannot tolerate the necessary amount of standard AAs (which maintain nitrogen balance) without precipitating encephalopathy
  Avoid supplements providing only BCAAs; they do not maintain nitrogen balance
  Conditionally essential AAs as well as all essential AAs are needed
  Conditionally essential AAs are those that normally can be synthesized from other precursors, but cannot be synthesized in cirrhotic patients. These include choline, cystine, taurine and tyrosine
- Night time snack consisting of 500–700 cal should be given

AA, amino acid; BCAA, branched chain amino acid; BW, body weight; PPN, peripheral parenteral nutrition; REE, resting energy expenditure; TPN, total parenteral nutrition.

Adapted from reference [1998].

Clinical trials

A multicenter trial of oxandralone in alcoholic hepatitis showed no difference in 30-day hospital mortality compared with placebo [370]. However, patients with moderate but not severe disease had improved 6-month survival. The Cochrane systematic meta-analysis of anabolic steroids in alcoholic hepatitis did not show a benefit in mortality, complications, or other outcome measures [432].

We conclude that all these other evaluated agents have a secondary role, if any, as an experimental option in alcoholic hepatitis.

Liver transplantation

Even though liver transplantation has been traditionally considered to be the definitive therapy for ALD once cirrhosis has developed and patients have been abstinent, there is increasing interest in offering this option for patients with severe alcoholic hepatitis [315,322]. However, spontaneous improvement may occur with abstinence making transplantation unnecessary and, without adequate abstinence, it is believed that the risk of recidivism is high [208,433–435].

Long-term management of alcoholic liver disease

Although less acute than alcoholic hepatitis, continuous long-term management is an important component of the treatment of patients with ALD.

Nutritional therapy

Protein-calorie malnutrition is widely prevalent in ALD [408] and is associated with many of the major complications observed in cirrhosis (infection, encephalopathy, ascites) and indicates a poor prognosis. Consequently the importance for the clinician to recognize and understand the significance of malnutrition in these patients has been emphasized. Current literature on nutritional management of alcoholic cirrhosis has been reviewed recently [436].

Enteral feeding for 3–4 weeks in hospitalized, severely malnourished, or decompensated cirrhotic patients improved survival ($P < 0.065$), hepatic encephalopathy, liver function, and Child–Pugh score, as compared with controls receiving a standard oral diet [437]. In longer term studies, Marchesini and co-workers compared equinitrogenous amounts of dietary branched chain amino acids (BCAAs) versus casein supplements in patients with chronic hepatic encephalopathy for 3–6 months [420]. BCAAs significantly improved encephalopathy, nitrogen balance, and serum bilirubin compared with casein. Hirsch supplemented 34 g of protein and 1,000 kcal to a regular diet in decompensated alcoholic cirrhotics and reduced hospitalizations for infections over a 1-year period [422]. These studies are important because they emphasize the concept that patient selection and long-term therapy may be important factors for employing and demonstrating the benefits of nutritional therapy. Because standard nutritional supplements are effective and the cost of BCAAs is high, the use of BCAA-enriched formulations should be restricted to patients who cannot tolerate nutritionally required amounts of standard formulations.

Changes in dietary feeding patterns may also be beneficial. After an overnight fast, cirrhotic patients obtain more than 70% of nonprotein-calories from fat as compared with 40% in normal volunteers [438]. Therefore, patients with alcoholic cirrhosis have early recruitment of alternative fuels and have metabolic profiles similar to those observed with prolonged fasting. Consequently it has been demonstrated that patients with cirrhosis should not be allowed to starve for extended periods of time and require frequent interval feedings, in particular a night

time snack and morning feeding that improve nitrogen balance [195,439–441].

It now seems clear that long-term aggressive nutritional therapy is necessary and reasonable for these patients. General goals and practical points for nutritional therapy in chronic liver disease (see Table 26.11 and Box 26.5) have been suggested, but three additional points need to be emphasized [411,442]. First, nutritional assessment should be an ongoing process. Second, multiple feedings, emphasizing breakfast and a night time snack, with a regular oral diet at higher than usual dietary intakes (1.2–1.5 g/kg for protein and 35–40 kcal/kg for energy) seem indicated [439–441]. Third, during intermittent acute illness or exacerbations of the underlying chronic liver disease, above normal protein (1.5–2.0 g/kg and 40–45 kcal/kg for energy) feeds improve protein-calorie malnutrition [411,438,442].

Propylthiouracil

The hypermetabolic state induced by alcohol ingestion can be ameliorated by propylthiouracil [425]. Direct vasodilator effects of propylthiouracil and well as its antioxidant potential have been suggested to be of value in alcoholic cirrhosis.

Clinical trials

In a large prospective study, involving 310 patients, therapy with propylthiouracil for up to 2 years showed improved survival in the treated group compared to placebo [443]. However, a Cochrane review of propylthiouracil in alcoholic liver disease reviewed six randomized controlled trials with a total of 710 patients administered propylthiouracil or placebo. There was no significant benefit of propylthiouracil compared to placebo on mortality (both total and liver related), complications of liver disease, or liver histology. There was an increase in nonserious adverse effects that was not significant [428].

S-adenosyl methionine

Rationale

S-adenosyl methionine is produced from methionine and ATP in the presence of the enzyme SAMe synthetase, also known as methionine adenosyl transferase (MAT) [444]. SAMe is the principal biologic methyl donor involved in transmethylation, transulfuration, and aminopropylation. The transulfuration pathway is responsible for GSH synthesis – the main cellular antioxidant. Impaired MAT activity occurs in cirrhosis resulting in impaired methionine metabolism with increased levels of methionine and homocysteine [291]. Deficient MAT results in low SAMe levels and hence low GSH. Exogenous GSH is not useful therapeutically because it does not penetrate the hepatocytes. Cysteine is a precursor of GSH, and methionine is the precursor of cysteine. Cysteine and methionine administration have been unsuccessful in correcting the deficiency of GSH. Oral administration of SAMe bypasses the deficit in SAMe synthesis from methionine.

Clinical trials

Oral SAMe administration has been shown to be effective in humans studies in ALD after a few initial disappointing results [444,445]. SAMe supplementation improved survival in patients with alcoholic cirrhosis who were Child class A and B [445]. In contrast, the Cochrane data base, based on eight randomized controlled trials with 330 patients in different stages of ALD, did not demonstrate any significant effect of SAMe on mortality, liver-related mortality, complications, or liver transplantation in patients with ALD [446]. It concluded that SAMe should not be used for ALD outside randomized clinical trials.

Colchicine

Colchicine has been used in alcoholic cirrhosis with beneficial results reported but few hepatologists prescribe this agent. This may be related to doubts cast on the results of the largest study that reported on the use of colchicine in cirrhosis [447], its potential toxicity, and need for long-term use before any potential benefits can be observed. A systematic meta-analysis by the Cochrane group showed that a total of 14 randomized trials with 1,150 patients have been studied (patients with alcoholic fibrosis, alcoholic hepatitis, and/or alcoholic cirrhosis as well as patients with viral-induced or cryptogenic fibrosis and/or cirrhosis) [431]. The results showed that there was no benefit on overall mortality, liver-related mortality, liver function tests, or histology, with an increased risk of adverse effects related to colchicine therapy. Based on the evidence currently available, colchicine cannot be recommended in the therapy of established alcoholic cirrhosis.

Antiviral therapy

Alcohol use even in moderate quantities has been suggested to worsen the course of hepatitis C [157,448]. Additionally, it has been shown that the response rates to interferon-based treatment protocols are less effective in the presence of active alcohol use [449]. It is therefore recommended that therapy for hepatitis C be started only in patients who become abstinent. If hepatitis C can be eradicated, the long-term prognosis of ALD should improve.

Liver transplantation for ALD

Alcoholic liver disease is the second most common indication for orthotopic liver transplantation (OLT) for chronic liver disease in the western world [450,451]. In the United States, even though specific candidate selection criteria vary from center to center, patients with ALD are transplanted in virtually all programs [452]. The reasons for the resistance to transplant patients with ALD

include the pretransplant socioethical issues of donating organs to patients who have perceived self-inflicted liver disease while others who did not pursue such an active self-injurious course wait and potentially die [453,454]. Other concerns include questions regarding the patient's ability to comply with the complex clinical protocols and immunosuppressive regimens after the transplantation, the rate of recidivism to a behavior of alcohol abuse, and recurrence of injury to the transplanted liver [335]. As the number of OLTs in ALD increases, it is becoming more acceptable to transplant these patients as their outcome after OLT is similar to that in nonalcoholic patients [454,455].

Six months of abstinence has been recommended as a minimal listing criterion allowing chemical dependency issues to be resolved during this period. Adherence to the 6-month abstinence could result in a resolution of the anti-inflammatory effects of recent alcohol consumption and thus may make OLT unnecessary in a subset of these patients [434]. The requirement for a fixed abstinence period, the so-called 6-month rule, as a predictor of future abstinence is arbitrary but used most often [456]. However, many abstinence experts are skeptical about this rule because it ignores the complex nature of addictive behavior and it does not accurately predict future drinking by alcoholic candidates for liver transplantation [455–457]. Others, however, have demonstrated that duration of abstinence predicts post-transplant recidivism and recommend at least 6 months of abstinence [433, 435]. A recent study that predicted trajectories of alcohol consumption after liver transplantation also suggested that a period of abstinence is an independent predictor of post-transplant recidivism [458]. These studies, along with recent data indicating that a period of abstinence will permit the recovery of liver function [208], suggest that a minimum of 6 months abstinence is a reasonable recommendation despite many opinions to the contrary.

An evaluation of the peritransplant period in ALD showed that patients were more ill at the time of OLT and likely to have prolonged intensive care unit stays and increased blood product requirements [459]. Decreased acute and chronic rejection after OLT have been reported in patients with ALD compared with nonalcoholic subjects and is probably related to the depression in cellular immunity from the alcohol abuse prior to the OLT [460–462]. There have been a total of 22 published reports on the outcome of liver transplantation in alcoholic patients in over 11,500 patients followed over 11 years, with the largest number being from the European Transplant Registry (Table 26.13) [335,451,459,463–485]. Short-term (1-year) graft survival and patient survival are similar in patients with alcoholic and nonalcoholic cirrhosis.

One third to one half of alcoholic liver recipients will report some use of alcohol in the first 5 years after transplantation [454]. A recent report has reviewed the published data on recidivism after liver transplantation [450]. Rates of recidivism at 3–5 years after OLT have been reported at between 11% and 49% [325,335,468,469, 475,481,486]. It should be emphasized that the rate of recidivism depends on the method used to assess alcohol use and abuse. Higher rates have been reported with objective criteria like urine and blood alcohol levels, carbohydrate-deficient transferring, or a detailed structured interview rather than unstructured questioning of the patient [487,488]. However, recipients who relapse into alcohol use after OLT have similar or potentially lower graft failure rates compared to non-ALD patients. Poor follow-up attendance and noncompliance with therapy is observed in only a minority of patients, and graft rejection rates are similar for patients with ALD (acute rejection 41%, chronic rejection 5.6%) compared with the non-ALD patients (acute rejection 43.7%, chronic rejection 6.2%) [451,454,489]. Since length of sobriety seems to be the most powerful predictor of recidivism, OLT should be offered to appropriately selected patients with ALD [458].

One of the issues that is still unresolved is the role of OLT in acute alcoholic hepatitis. In studies using retrospective histologic analysis of the explanted liver, superimposed alcoholic hepatitis did not worsen the outcome after OLT [490,491]. However, patients in these studies had been abstinent for 3–12 months, had a Maddrey DF <32, and had variable clinical and biologic features of alcoholic hepatitis at the time of OLT. Therefore, the role of OLT in acute alcoholic hepatitis is unresolved at this time [322]. With the availability of living donor transplantation and extended criteria donor, this is likely to further the debate on this issue.

Potential new treatment options

Various nonconventional treatment options have been considered promising in the therapy of ALD. Recently, advances in the understanding of the pathogenesis of ALD have suggested new targets for more successful intervention. Some of the nontraditional treatment options include the following:

1 *Silymarin*. Silymarin (milk thistle) is a mixture of flavinolignans (silibinin, silidianin, silichristin, silybin), of which silybin is the most active [492]. The exact mechanism of action of silymarin is not yet clear but is most likely related to its antioxidant properties. There have been six published trials of silymarin in patients with ALD in doses ranging from 80 to 420 mg/day for time periods of 4 weeks to 6 years with a total of 302 patients treated with silymarin and 305 patients with placebo [492]. Normalization of liver function tests, improvement in liver histology, and possibly longer survival were observed in a significantly higher proportion of patients treated with silymarin compared with

placebo. No adverse effects were reported. A Cochrane systematic review and meta-analysis of the 13 published studies of silymarin in ALD and hepatitis B- or C-related liver diseases showed that the overall methodologic quality of the studies was low. Based on high-quality trials, milk thistle does not significantly influence the course of patients with alcoholic and/or hepatitis B or C liver diseases [493].

2 *Other agents*. Thalidomide, misoprostol, adiponectin, and probiotics have been shown in preliminary reports to have anticytokine properties [393,494–496]. However, it must be emphasized that in the past many promising treatments have not passed the test of time as treatment for ALD and alcoholic hepatitis. Emerging data suggest a role for TNF-α-mediated apoptosis in alcoholic hepatitis, and therapy targeting this cytokine to inhibit apoptosis may be effective [497]. However, current poor results with TNF-α antagonists (infliximab, etanercept) are concerning and need to be considered before planning future trials.

3 *Complementary and alternative medications*. A number of alternative treatment options in addition to those discussed above have been reviewed [377,492]. There are not adequate clinical data available to make any recommendations since most of these studies were in animal models or in vitro systems.

Future directions

In light of a still incomplete understanding of the involved pathophysiologic mechanisms and conflicting data regarding the efficacy of specific interventional therapies of ALD, a conservative approach seems justified. These include general supportive care, aggressive nutritional interventions, and the judicious use of corticosteroids and pentoxifylline in selected patients with severe alcoholic hepatitis. In addition, abstinence from alcohol, treating the co-morbidities of obesity and hepatitis C, and continuous nutritional monitoring are prudent on a long-term basis, with liver transplantation offered for select patients with progressive disease. Algorithms have been proposed for both alcoholic hepatitis and long-term management of ALD (Figs 26.18 and 26.19). Although these

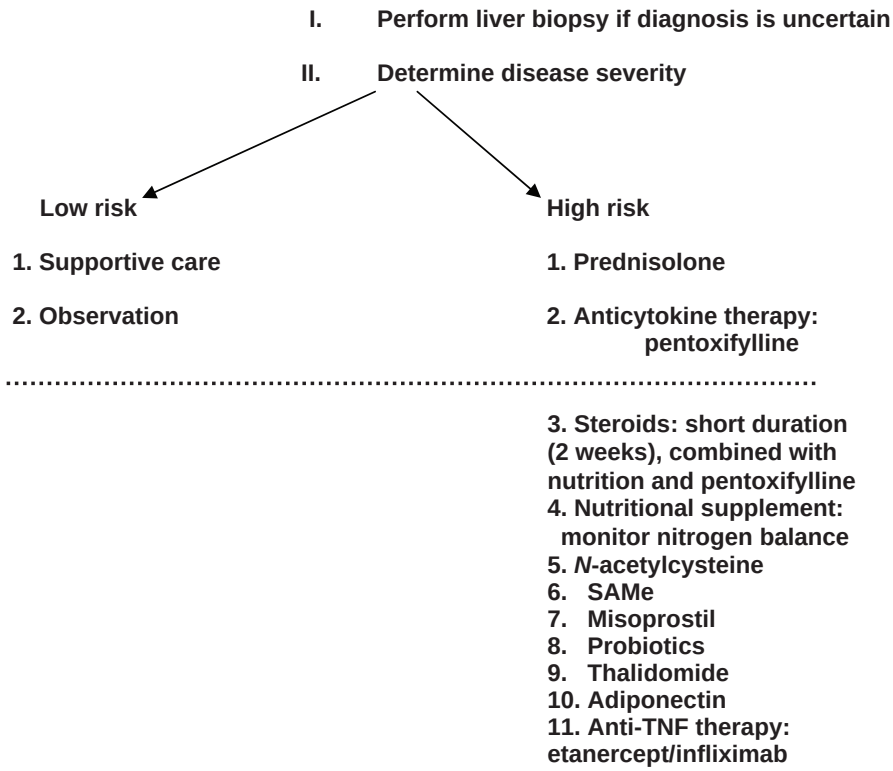

Figure 26.18 Proposed therapeutic algorithm for alcoholic hepatitis. High-risk patients are those with severe disease as defined by a modified discriminant function ≥32, the presence of encephalopathy, or a MELD score ≥18–21. Therapies under the broken line remain experimental but merit further study. SAMe, *S*-adenosyl methionine; TNF, tumor necrosis factor.

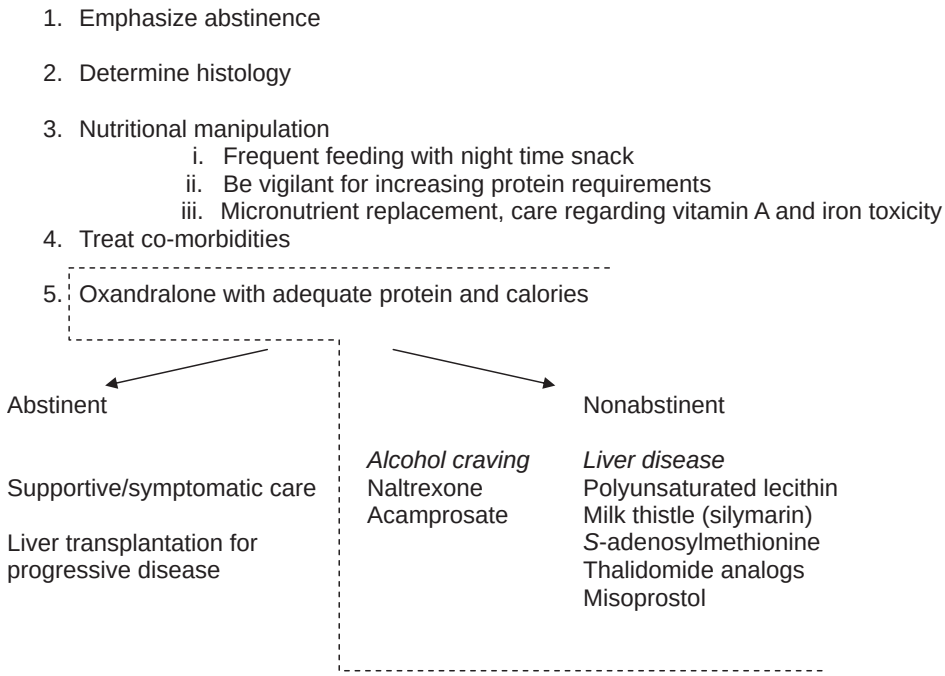

Figure 26.19 Proposed therapeutic algorithm for the long-term management of alcoholic liver disease. Liver biopsy is indicated if diagnosis is uncertain, especially if there is serologic evidence of iron overload or viral infection. Both hepatitis C and obesity (if patient is abstinent) should be treated if present. Therapies within the broken line remain experimental but merit further study.

algorithms are by necessity incomplete, they are provided to stimulate different approaches to this disease and to emphasize several of the following important issues:

1 Abstinence and dietary manipulation should be emphasized in the long-term management of these patients. The issue of abstinence from alcohol will play an important role in determining medical treatment as well as candidacy for liver transplantation.
2 The high prevalence of hepatitis C must be considered regarding its potential influence upon prognosis and therapeutic strategies.
3 Future therapeutic directions should aim at specific pathophysiologic mechanisms of alcohol-induced hepatocellular damage as well as the regulation of hepatic regeneration in this disease. Combination therapy targeting both direct and indirect mechanisms of alcohol-induced hepatocellular damage as well as the regenerative capacity of the injured liver may prove to be necessary after assessment of disease severity and prognosis. Clinical trials of combined therapy are needed and include:
   - A mechanism to reduce hypermetabolism and centrilobular hypoxia/ischemia.
   - A means to maintain or enhance gut integrity. The role of nutrition needs to be investigated. Furthermore, more objective and systemic ways to assess the function and integrity of the intestinal mucosa are required.
   - The role of bowel sterilization with antibiotics to decrease bacterial translocation and endotoxin- and cytokine-mediated liver damage.
   - Modification of immunologic mechanisms.
   - Altering cytokine-mediated inflammation and fibrosis. Potential therapeutic interventions include antibodies or antagonists to specific cytokines of pathogenetic importance and drugs that modulate the actions of these cytokines. Despite the available, somewhat compelling animal and in vitro data, therapies directed against anti-TNF may be particularly helpful but the poor outcome of published trials must be considered before new studies are undertaken.
   - The inhibition of fibrogenesis by blocking factors, which promote fibrogenesis, and by stimulating collagen degradation or suppressing collagen gene expression.
   - The regulation of iron metabolism, altering iron accumulation to reduce the progression of fibrosis and development of hepatocellular carcinoma.
   - Hepatotropic agents to maximize the capacity of cell repair.
   - Exploring new strategies to decrease lipid peroxidation and its sequelae. SAMe, *N*-acetylcysteine, and vitamin E may be particularly relevant in this area.
   - Orthotopic and living donor liver transplantation are a realistic option for alcoholic cirrhosis and increasing evidence supports a period of abstinence before listing. Their roles in alcoholic hepatitis continue to remain a matter of debate.

Conclusions

Alcoholic liver disease is a common illness, which develops in only a subgroup of people who chronically use or abuse alcohol. The hepatotoxic dose of alcohol is nonuniform and dependent on incompletely understood risk factors, which include gender, ethnicity, hepatitis C, nutritional status (particularly obesity), iron accumulation, and possibly genetic factors. These factors, in addition to a variable natural history and changing epidemiology, especially with regard to binge drinking and pathophysiology, can make ALD difficult to diagnose and frustrating to manage.

The management of the complications of chronic liver disease (ascites, portal hypertension-associated bleeding, encephalopathy, and hepatocellular) is similar in alcoholic and nonalcoholic liver disease. However, abstinence remains the cornerstone of therapy for ALD. There is also consensus for the use of corticosteroids and pentoxifylline in severe alcoholic hepatitis, for maintaining good nutritional status, for treating co-morbidities in all forms of ALD, and for liver transplantation in carefully selected patients with end-stage ALD. No other therapies can be recommended at the present time, although nascent data suggest that a number of newer therapies may be effective, as discussed above. The recently published practice guidelines for the management of ALD provide evidence-based therapy.

Building on our increased knowledge of the molecular basis of ALD, a greater understanding of the pathophysiology of ALD, the interactive role of other cofactors in causing hepatotoxicity, and translation to human disease need to remain a major focus of alcohol research.

Multiple choice questions

26.1 **The most effective therapy for acute alcoholic hepatitis with hepatic encephalopathy is which of the following?**

a Infliximab.
b Corticosteroids.
c Etanercept.
d Lactulose.

26.2 **Liver transplantation is considered a standard therapeutic option in patients with decompenstated alcoholic cirrhosis because of which of the following?**

a The graft and patient survival are similar to that in nonalcoholic cirrhosis.
b Recidivism rates are low even without abstinence.
c Mortality is higher than with cirrhosis of other etiologies.
d There is a lower risk of post-transplant complications in alcoholic cirrhosis than in post-hepatitis cirrhosis.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 27
Drug-induced Liver Disease

Shivakumar Chitturi & Geoffrey C. Farrell

Department of Hepatic Medicine, Australian National University Medical School and Gastroenterology and Hepatology Unit, Canberra Hospital, Garran, Australia

Key concepts

- Over 300 agents in current use have been implicated in causing drug-induced liver injury (DILI), but there is strong evidence for causality with fewer than 30.
- Most implicated drugs cause liver disease in fewer than one in 10,000 persons exposed; the frequency of hepatotoxicity is variously influenced by genetic factors, age, gender, intake of other drugs or alcohol, nutritional status and preexisting liver disease.
- Interactions between drugs, liver, and other diseases can increase risk and worsen DILI; examples include highly active antiretroviral treatment and hepatitis C virus infection; tamoxifen and nonalcoholic fatty liver disease; methotrexate, diabetes, and hepatic fibrosis; and antituberculosis drugs with chronic hepatitis B and hepatitis C.
- The clinicopathologic spectrum of DILI ranges from nonspecific injury to acute and chronic hepatitis, granulomatous hepatitis, cholestatic reactions, vascular lesions and hepatic tumors.
- Although characteristic "signature" patterns are observed with some drugs, others are associated with diverse clinical syndromes.
- While the liver biochemistry profile may aid initial evaluation, liver biopsy remains the gold standard for defining the type and extent of drug-induced liver disease.
- Pathogenic mechanisms underlying DILI include dose-dependent injury, metabolic idiosyncrasy, and immunoallergic reactions. The latter may be part of the reactive metabolite syndrome, a multisystem disorder with hallmarks of hypersensitivity.
- Supportive measures remain the cornerstone in management. Early recognition of drug toxicity and immediate withdrawal of the offending drug are critical. *N*-acetylcysteine remains pivotal in managing acetaminophen overdoses. It has also shown to be of value in acute liver failure (grades I and II encephalopathy) resulting from drugs other than acetaminophen. Corticosteroids are not routinely recommended, but may be valuable in selected cases showing pronounced hypersensitivity characteristics (e.g., allopurinol). Anecdotal evidence favors the use of ursodeoxycholic acid in the setting of protracted cholestasis. Early consultation with a liver transplant centre is mandatory for individuals developing progressive impairment of liver function.
- Serial liver test profiles are often recommended to facilitate early detection of liver injury. However, with few exceptions, the sensitivity and cost-effectiveness of this approach remains untested.
- Clinical evaluation of symptoms that could be drug related is critical in facilitating early detection of DILI.
- Herbal hepatotoxicity and use of recreational drugs (of abuse) should now be considered in the differential diagnosis of all liver disorders.

Introduction

Terminology and definitions

Hepatotoxicity is liver injury caused by foreign compounds (*xenobiotics*). These include prescribed and nonprescribed therapeutic agents (*drugs*), including "over-the-counter" pharmacologic agents, herbal and other complementary and alternative medicines (CAM), and a vast array of other organic and inorganic substances that may be ingested deliberately or accidentally. The latter compounds may contaminate the environment, workplace, or home. Thus, xenobiotics include pesticides, herbicides, and plant, fungal, and microbial products, each of which may have toxic and/or carcinogenic properties. The present chapter will concentrate on drug-induced liver injury (DILI), in which hepatotoxicity is caused by medicinal drugs or those used by individuals for therapeutic, nutritional, or recreational purposes; the latter including drugs of abuse. While passing reference is made to other hepatotoxins, the interested reader is referred to specialized texts for a comprehensive coverage of environmental and industrial hepatotoxicity [1,2].

Injury to the liver is largely defined by increased blood levels of proteins that are liberated from damaged hepatocytes; a typical example is alanine aminotransferase (ALT). In order to implicate a drug as the cause of ALT elevation we need to know: (i) that there is no other

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.
© 2012 John Wiley & Sons, Ltd. Published 2012 by John Wiley & Sons, Ltd.

hepatic process that could account for the test abnormality (e.g., steatosis); (ii) that the logistics (particularly the temporal relationships) relating the drug intake and liver test abnormality are consistent and compelling, and (3) that ALT elevation really means that the liver is injured. There is often a considerable amount of uncertainty in each of these three areas. Some practical implications will be dealt with in later sections on hepatic adaptation (physiologic responses by the liver when exposed to drugs) and diagnosis.

We have avoided the term "hepatic dysfunction" in this text because of the confusion between injury, adaptation, and indices that truly reflect functions of the liver. Likewise, the pathologically meaningless term "transaminitis" (an ALT elevation without histologic evidence of liver injury) will not be used; DILI is now preferable and in widespread use. When the presence of a major (fivefold or greater) elevation of ALT clearly indicates liver injury, or when one or more of the *functions of the liver* are abnormal (e.g., low levels of plasma proteins like albumin and clotting factors synthesized by the liver, or clinicopathologic evidence of impaired bile flow (*cholestasis*)), it is *highly probable* that a drug to which the person has been exposed is the cause of liver disease. Ideally, however, the definition of *drug-induced liver disease* requires histopathologic characterization rather than syndromic recognition of liver test abnormalities. Although the distinction between injury and disease is sometimes artificial, because they clearly overlap, it will be maintained wherever possible in this chapter so as to provide insights into the clinical significance of hepatic adverse drug reactions.

As new drugs emerge, the evidence that they induce liver injury is often weak and circumstantial. It is sometimes hotly debated because of the implications for further use and marketing of valuable therapeutic agents, or for medicolegal implications [3]. In order to partly meet the challenge of possible newer types of DILI that are not yet well defined, we have included a section on "emerging therapies." Another definitional challenge is that drugs may sometimes alter physiologic parameters that impact on hepatic viability. In particular, some drugs can profoundly reduce hepatic blood flow and oxygen delivery, induce hyperthermia, or modify arterial supply to major bile ducts, each of which can result in liver injury that may be minor or profound. Cocaine, general anesthetic agents, alcohol, intra-arterial floxuridine, and "ecstasy" are agents that most likely produce liver injury by such indirect mechanisms rather than by direct hepatotoxicity or adverse drug reactions.

Another challenge for defining drug-induced liver disease is the increasing number of circumstances in which drug ingestion appears to contribute to chronic liver disease or hepatic tumours. The lead time ("*latent period*") to onset or diagnosis of such associations is many months or years. As a result, repeated observations and case–control studies are essential to ensure they are not chance associations, while experimental evidence from laboratory or animal studies is desirable in order to invoke biologically plausible mechanistic explanations for this type of effect of the drug on the liver.

Thus, there is no "gold standard" by which drugs can be proved to have a unique etiologic role in liver disease, particularly as some of the disorders with which they are associated appear very similar or identical to syndromes associated with other causes. Further, it is increasingly apparent that drugs may interact with each other or with other hepatotoxins (particularly alcohol) as part of *interactive hepatotoxicity*, as well as with viruses (human immunodeficiency virus (HIV), hepatitis B virus (HBV, and hepatitis C virus (HCV)), immune mechanisms (HIV/acquired immune deficiency syndrome (AIDS) and bone marrow transplantation), and metabolic factors (nonalcoholic steatohepatitis (NASH)) to accentuate or cause liver injury. Such interactions may be exceedingly difficult to recognize or to prove, and near impossible to quantify as "relative risk" by conventional epidemiologic techniques. The evidence implicating the involvement of drugs in liver injury associated with more complex medical settings will be discussed in a later section.

Dose-dependent hepatotoxicity and hepatic drug reactions

Some agents possess a high degree of *intrinsic hepatotoxic potential*; they cause *dose-dependent liver injury* in humans and usually many other species. The history of industrial hepatotoxicity is replete with such examples, including dimethylnitrosamine, carbon tetrachloride, tetrachloroethane, trinitrotoluene, phosphorus, tannic acid, and vinyl chloride. Some early therapeutic drugs and anesthetic agents (arsenicals, chloroform) have also been assigned to this category, although older studies are inadequate in ascertaining causal mechanisms because viral hepatitis, hepatic perfusion, and tissue oxygenation could not be assessed by contemporary criteria. Among today's drugs, very few are dose-dependent hepatotoxins (Box 27.1). For those that are, as illustrated by acetaminophen, it is not the chemical structure of the parent drug that is responsible for the liver injury, but rather the production of chemically reactive metabolites that interfere with the integrity of the liver. It follows that for most dose-dependent hepatotoxins, a range of host factors predicate the amount of reactive (toxic) metabolites that accumulate, thereby determining the risk of liver injury for a given dose of the toxicant.

The vast majority (more than 95%) of drugs implicated as causing DILI are clearly *not* dose-dependent human hepatotoxins, although some of them (usually

Box 27.1 Examples of dose-dependent hepatotoxins.

- Acetaminophen (paracetamol)
- Drugs used in cancer chemotherapy (especially used with radiotherapy); cyclophosphamide, busulphan, bis-chlorethyl-nitrosourea.
- Amodiaquine
- Hycanthone
- Carbon tetrachloride, dimethylnitrosamine, methylenedianiline
- Plant and fungal toxins: pyrrolizidine alkaloids, aflatoxin
- Ethanol
- Metals: copper, iron, mercury
- Bile salts

at high, nonpharmacologic doses) produce experimental liver injury. This relative "intrinsic hepatotoxic potential" tends to be roughly proportional to the risk of liver injury in humans [2]. There is also evidence for a few agents that liver injury is partially dose dependent (e.g., perhexiline maleate, tacrine, dantrolene, cyclophosphamide, sex steroids, and cyclosporine). However, the frequency with which such agents cause liver injury among those exposed is either low or extremely small, ranging from 0.5–2% with chlorpromazine and isoniazid, through more typical rates of 1–10 cases per 100,000 persons exposed, to even lower rates (e.g., one case per 1,000,000 persons exposed) with minocycline, and some of the oxypenicillins and nonsteroidal anti-inflammatory drugs (NSAIDs) (Table 27.1).

It is clear that for these rare, dose-independent, unpredictable or *idiosyncratic drug reactions* to occur, it is the host response to the drug that often determines liver injury, not the dose or chemical structures of the agent and its metabolites. Idiosyncratic hepatotoxicity is difficult to reproduce in other species, and it is therefore hard to ascertain the pathogenetic mechanisms involved. Clinical recognition will always remain a challenge because most doctors will never encounter individual reactions, or will observe them no more often than once or twice in a professional lifetime.

Table 27.1 Frequencies of some types of idiosyncratic drug-induced liver diseases.

Frequency[a]	Drugs
5 to 20/1,000 exposed	Isoniazid, chlorpromazine, dantrolene
1 to 2.5/10,000 exposed	Estrogen-induced cholestasis
0.5 to 20/10,000 exposed	Ketoconazole
1 to 10/100,000 exposed	Diclofenac, sulindac, phenytoin, flucloxacillin
0.5 to 3/100,000 exposed	Amoxicillin-clavulanate, nitrofurantoin, terbinafine, dicloxacillin
≤1 to 10/1,000,000 exposed	Minocycline

[a]Based on published data referred to in the text.

Two broad types of pathogenic mechanism could account for idiosyncratic hepatic drug reactions. The first is *metabolic idiosyncrasy*, in which pathways of drug metabolism or disposition favor drug accumulation or formation of toxic metabolites. The underlying determinants include pharmacogenetic variability of drug metabolism, and expression of "antistress" and antioxidant cell defense pathways. The metabolic idiosyncrasy concept now needs to be extended to consider ways in which the liver, a highly adaptable organ, normally counters the "stress" of potentially damaging chemicals. Thus, using experimental toxicants, it has become evident that foreign compounds, drug metabolites, and resultant oxidative stress can stimulate or interrupt intracellular signaling pathways that converge on target genes involved in stress responses, cell death, or cell cycle regulation. Alternatively, they may directly activate transcriptional regulators to the same effect, or more indirectly interfere with cell integrity and cell death pathways by their interactions with mitochondrial function and integrity. The latter includes mitochondrial DNA (mtDNA) and the unique "guardian role" of mitochondria for cell survival as well as in energy generation. Drugs can alter the regulation of adenosine triphosphate (ATP)-dependent transporters that actively pump drug metabolites out of hepatocytes, particularly via canalicular pathways that are physiologically engaged in the generation of bile flow. Drugs, reactive metabolites and oxidative stress can interact with the cytoskeletal determinants of cellular transport, receptor signaling, and cell–cell communication (see Chapter 28). Recently, the concept of partial dose dependency has been raised again in cases of idiosyncratic liver injury (it was originally noted by Hyman Zimmerman among others in the 1980s); drugs with daily doses greater than 50 mg have been overrepresented in cases of significant hepatotoxicity. Whether this is related to overrepresentation of drug classes with higher doses (NSAIDs, antimicrobials) or true dose dependency needs to be verified [4]. Likewise, it has been "rediscovered" [2] that drugs undergoing significant hepatic metabolism are more often implicated in causing hepatic injury when compared with drugs that do not [5].

The alternative pathogenic mechanism underlying idiosyncratic hepatic drug reactions is an *immunoallergic* response. This refers to classic "hypersensitivity" in the sense that repeated exposure results in an exaggerated and unhelpful tissue-based or systemic injurious inflammatory response. Immunoallergic reactions are even less

well understood than metabolic idiosyncrasy for their role in DILI. The possible immunologic mechanisms have been reviewed elsewhere [6,7]. Some are examples of drug-induced autoimmunity in which the liver is the principal organ involved, implying that the drug (or its metabolites) has induced immune dysregulation [6]. Syndromes of chronic hepatitis with hyperglobulinemia and autoantibodies (e.g., with nitrofurantoin, minocycline, or diclofenac) are examples of such an immune-based mechanism. There is increasing evidence that, for a subset of reactions, reactive metabolites are involved with recruiting inflammatory mechanisms, as haptens with molecular mimicry [8,9]. Regulation of hepatic cytokines may also be important as shown by studies of drug hepatotoxicity in mice with targeted disruptions of interleukin 4 (IL4), IL10, or cyclooxygenase 2 mediators that help prevent allergic hepatitis [7]. Recruitment of eosinophils to the liver in the later stages of idiosyncratic drug reactions may depend on expression of the chemokine eotaxin [10].

It is often not possible to clearly distinguish between what seem like diametrically different causative mechanisms. They may overlap, particularly because hepatic inflammatory reactions appear to evoke the liver's own innate immunity, as seen by the presence of liver lymphocytes and activated Kupffer cells (resident macrophages) as well as by the activation of toll-like receptors (TLRs) [11]. Ultimately, it is most likely that the principal factors predicating idiosyncratic drug reactions are *genetically determined* [12,13]. This provides a challenge for future studies directed at prevention, and for timely interventions to avoid the adverse clinical outcomes that are unacceptably common for some agents and reactions (see "Improving outcomes" below).

Importance of drug-induced liver disease

The importance of drug-induced liver disease is summarized in Box 27.2. The pertinent factors are the disproportionate frequency, severity,and potential for preventing serious hepatic adverse drug reactions in older people. Some newer aspects include the potential of drugs to produce synergistic hepatotoxicity in persons with, for example, viral hepatitis, HIV/AIDS, HBV/HCV, and NASH, as discussed later (in the section on the role of drugs in multifactorial disease). The low frequency of reactions for many commonly used drugs can delay the recognition of DILI; continued ingestion of the causative agent is the single most important determinant of adverse outcome. In addition to the key responsibility of physicians for early diagnosis and stopping exposure to potentially implicated agents, they have moral, ethical, and medicolegal responsibilities to prevent, mitigate, and report iatrogenic disease.

The increasing number of pharmacologic agents associated with DILI is a major challenge for clinicians [2,12, 14–20]. In addition to case recognition, this invokes consideration of what level of patient information should be regarded as appropriate at the time of prescribing drugs, and how that information should be imparted to the consumer.

Box 27.2 Factors that contribute to the importance of drug-induced liver disease (DILI).

- About 6% of all adverse drug reactions result in DILI
- DILI occurs with a higher frequency among severe adverse drug reactions
- DILI is the most frequent cause for post-marketing withdrawal of medications
- DILI is a preventable or correctable cause of acute and chronic liver disease
- About 5% of cases of jaundice or acute hepatitis in the community result from DILI
- A higher proportion (10–40% depending on age) of cases of hepatitis admitted to hospital are due to DILI
- DILI is an important cause of acute liver failure (more than 50% of cases in United States: 36% from acetaminophen, 16% idiosyncratic hepatic drug reactions)
- DILI is a common cause of undiagnosed liver injury, particularly among persons aged more than 50 years
- More than 300 currently used drugs are cited in the literature as potential causes of DILI
- A low frequency of liver injury leads to cases often being overlooked, and difficulty in attributing causality to drugs
- One agent may cause more than one pattern of DILI
- Early diagnosis and stopping drug exposure are critically important in avoiding progression and poor outcomes
- A poor understanding of pathogenic mechanisms in DILI makes reactions difficult to predict and prevent
- The role of drugs is important in synergistic hepatotoxicity with viral hepatitis, NASH, HIV/AIDS, bone marrow, and organ transplantation
- There is a moral/ethical responsibility to prevent or minimize iatrogenic disease
- There are medicolegal implications of this responsibility (informed consent, practice standards, due diligence, etc.)

AIDS, acquired immune deficiency syndrome; HIV, human immunodeficiency virus; NASH, nonalcoholic steatohepatitis.

Diversity of clinical expression

Drugs have become the greater mimickers of "natural" liver diseases. Thus hepatic drug reactions range from nonspecific abnormalities of liver tests (which may represent minor degrees of liver injury or hepatic adaptation), through clinicopathologic features of cholestasis, acute hepatitis, and acute liver failure, to more exotic syndromes like hepatic sinusoidal or venous outflow obstruction syndromes, nodular regenerative hyperplasia

(NRH), chronic hepatitis resembling autoimmune hepatitis, hepatic fibrosis, NASH, cirrhosis, and benign or malignant liver tumors. It therefore remains crucial that physicians should always consider a possible drug or toxic etiology, irrespective of the pattern of liver injury. A common pitfall is to impute causality to known causes of liver disease that happen to be present (HCV, alcohol, and gallstones are common "confounders") in what are actually cases of DILI. Another challenge is the propensity of some drugs to cause more than one clinicopathologic syndrome, as discussed later for oral contraceptive steroids (OCSs), diclofenac, and nitrofurantoin.

Epidemiology and risk factors

Epidemiology

In discussing how commonly a drug causes liver injury, it is important to note that the term "incidence" (the number of new cases in a period of time) is not particularly helpful because the onset of adverse drug reactions is nonlinear with time; they tend to occur within the first few weeks or months of treatment. A better descriptor is the proportion of persons exposed to the agent who develop the reaction. This proportion is best described by the *frequency of the reaction* within the affected group; the latter is expressed ideally as the number of persons exposed, but surrogate estimates are often used, such as the number of prescriptions written or the number of person-years of drug ingestion. Other estimates of the frequency of adverse drug reactions or risk of hepatotoxicity come from prescription event monitoring or record linkage conducted prospectively by health maintenance groups, and from case–control studies. More commonly used methods include voluntary (or mandated) reporting of reactions to agencies that monitor adverse drug reactions or drug manufacturers. However, this approach is weakened by the inherent inaccuracies of case definition and the vagaries of case documentation, factors that depend on the skill and motivation of observers.

Drugs that carry a high frequency of liver injury are usually recognized as hepatotoxic during phase III trials, which typically involve hundreds or a few thousand persons, or during the first 2 years of post-marketing surveillance (which may involve hundreds of thousands or millions of subjects) [3]. Nefazodone, bromfenac, lumiracoxib, and troglitazone are examples of agents withdrawn because of a high frequency of severe liver injury. More often, recognition of DILI comes several years after the release of a new agent, often with a flurry of case reports, small series, and analyses of larger repositories of information held by drug-monitoring authorities or pharmaceutical companies. More recent examples include amoxicillin-clavulanate, oxypenicillins, diclofenac, sulindac, and troglitazone [21–24]. Such "mini-epidemics" serve principally to highlight how often early reactions to the implicated agents may have been overlooked, or become evident during massive prescribing of vigorously marketed new drugs. The latter phenomenon is illustrated by hepatic reactions to flucloxacillin in Australia, where the number of prescriptions written per million people greatly exceeded that of any other country [25].

Reliable information about the risk of liver injury is available for less than 30 of the 300 or so currently used drugs that have been implicated as possible or likely causes of drug-induced liver disease (Table 27.1). The most significant issue confounding the epidemiology of DILI is the lack of diagnostic accuracy in case definition. As discussed next, this depends entirely on probabilistic evidence surrounding the onset of the reaction and its resolution or recurrence in relation to drug exposure, on the exclusion of other hepatobiliary diseases, and occasionally on ancillary evidence of an adverse drug reaction.

When drugs contribute to but are not the unique cause of liver disease, it may be possible to assign a relative risk. This has been attempted in the case of OCSs and liver tumours [26,27], OCSs and hepatic venous outflow obstruction [28], aspirin and Reye syndrome [29], and methotrexate and hepatic fibrosis among those who drink appreciable quantities of alcohol [30].

Risk factors for incidence and severity

The factors that increase the risk of DILI may include dose, duration of treatment, blood levels, the site of metabolism, age, gender, coincidental metabolic disorders or genetic predisposition to hypersensitivity reactions, concomitant exposure to other drugs or environmental agents, and underlying liver disease (Table 27.2).

Genetic factors

It seems likely that host predisposition to idiosyncratic hepatic drug reactions may simply reflect the dual requirements for altered expression of relevant genes and for exposure to particular drugs under particular circumstance; halothane, OCS cholestasis, valproic acid, and phenytoin reactions are those for which more than one case has occurred in the same family [11]. Phenytoin is an example of the reactive metabolite syndrome (RMS) pattern of severe skin reactions often associated with systemic involvement, amongst which DILI is common [31]. Known causative agents for RMS, its risk factors, and clinical features are summarized in Table 27.3. Individuals have a 25% likelihood of developing adverse drug toxicity if a first-degree relative has experienced a similar reaction; the chances are even higher with other risk factors such as HIV/AIDS, systemic lupus erythematosus (SLE),

Table 27.2 Risk factors for the incidence and severity of drug-induced liver diseases.

Risk factor	Representative agents	Importance
Age	Isoniazid, nitrofurantoin, halothane, troglitazone Valproic acid, salicylates	Age >60 years increases frequency and severity More common in children
Gender	Halothane, minocycline, nitrofurantoin, dextropropoxyphene Amoxicillin-clavulanate, azathioprine	More common in women, especially chronic hepatitis More common in men
Dose	Acetaminophen, some herbal medicines Anticancer drugs; perhexiline, tacrine, oxypenicillins, dantrolene Methotrexate, vitamin A	Risk of hepatotoxicity depends on blood levels Partial relationship to dose Total dose, dose frequency, and duration of exposure influence risk of hepatic fibrosis
Genetic factors	Halothane, phenytoin, sulfonamides Amoxicillin-clavulanate Diclofenac Valproic acid	Multiple cases in families, in vitro test results Strong HLA association Association with specific gene polymorphisms (see text) Familial cases, association with mitochondrial enzyme deficiencies
Other drug reactions	Isoflurane, halothane, enflurane Erythromycins, other macrolide antibiotics Diclofenac, ibuprofen Sulfonamides, COX-2 inhibitors	Cross-sensitivity reported between these classes of drugs
Concomitant drugs	Acetaminophen Valproic acid	Isoniazid, zidovudine, and phenytoin lower hepatotoxic dose threshold and increase severity Other anticonvulsants increase risk
Excessive alcohol use	Acetaminophen hepatotoxicity Isoniazid, methotrexate	Lowers dose threshold and worsens outcome Increases risk of liver injury and hepatic fibrosis
Nutritional status:		
Obesity	Halothane, tamoxifen, methotrexate	Increases risk of liver injury, NASH, or hepatic fibrosis
fasting	Acetaminophen	Increases risk of hepatotoxicity
Liver disease	Hycanthone, pemoline Antituberculosis chemotherapy, ibuprofen	Increases risk of liver injury Increases risk of liver injury with chronic hepatitis B and C
Other diseases:		
Diabetes mellitus	Methotrexate	Increases risk of hepatic fibrosis
Psoriasis	Methotrexate	Increases risk of hepatic fibrosis
HIV/AIDS	Sulfonamides (cotrimoxazole)	Increases risk of hypersensitivity
Renal failure	Tetracycline, methotrexate	Increases risk of liver injury and hepatic fibrosis
Organ transplantation	Azathioprine, thioguanine, busulfan	Increases risk of vascular toxicity

AIDS, acquired immune deficiency syndrome; COX-2, cyclooxygenase 2; HIV, human immunodeficiency virus; HLA, human leukocyte antigen; NASH, nonalcoholic steatohepatitis.

and antecedent intake of valproic acid or corticosteroids (Table 27.3).

As well as determining the expression and inducibility of cytochrome P450 (CYP) pathways of drug oxidation, conjugation reactions, and antioxidant enzymes (Chapter 28), genetic factors encode ATP-dependent pathways of drug elimination from hepatocytes, through the canalicular membrane into bile or via the basolateral membrane into sinusoidal blood [32]. Regulation of the immune response, including hepatic innate immunity, is also genetically determined. Other genes encode the structure of the cytoskeleton, heat shock proteins, and cellular resistance against activated cell death pathways, all potential variables in the pathogenesis of DILI. The characterization of which genes are involved in hepatic reactions to clinically relevant agents provides an outstanding challenge in the field of drug-induced liver disease, as reviewed elsewhere [33]. The likelihood that more than one "abnormality" (genetic polymorphisms, extreme variation) is required before tissue destructive responses occur would explain the rarity of most reactions. Already it is known that inherited defects of mitochondrial metabolism and mtDNA repair clearly predispose to valproate hepatotoxicity [33,34] (see later section

Table 27.3 The reactive metabolite syndrome and hepatic drug reactions

Drugs implicated	Risk factors	Clinical and laboratory features
Sulfonamides Clozapine Anticonvulsants (phenytoin, lamotrigine, phenobarbital, carbamazepine) Some NSAIDs Aminopenicillins Chinese herbal medicines Quinolones Protease inhibitors (nevirapine, abacavir) Allopurinol Minocycline	First-degree relative with serious rash to same drug (1 in 4 risk), or metabolically cross-reacting drug HIV/AIDS (100-fold increased risk) Systemic lupus erythematosus (10-fold increased risk) Corticosteroids at time of starting drug (4.4-fold increased risk) Valproic acid at time of starting new anticonvulsant (4–10-fold increased risk)	Onset: 1–6 weeks (up to 12 weeks) Sentinel symptoms: fever, pharyngitis, malaise, headache, periorbital edema, otalgia/headache, mouth ulcers, rhinorrhea Serious rash: erythematous, Stevens–Johnson syndrome, toxic epidermal necrolysis, erythema multiforme Lymphadenopathy (16%), splenomegaly Hepatic reactions: cholestasis, hepatitis, granulomas (13%) Nephritis (9%) Pneumonitis (6%) Hematologic (neutropenia, thrombocytopenia) (5%) Encephalitis/meningitis (5%) Myositis (4%) Colitis (2%) Arthritis, transient hypothyroidism Blood tests: neutrophilia (shift to left); atypical lymphocytes, acute phase reactants (early); eosinophilia (often late)

AIDS, acquired immune deficiency syndrome; HIV, human immunodeficiency virus; NSAIDs, nonsteroidal anti-inflammatory drugs.

below), and there are strong associations between human leukocyte antigens (HLA) and cholestatic drug reactions to amoxicillin-clavulanate, flucloxacillin, and tiopronin [35–39]. Weaker associations between HLA molecules and particular types of drug hepatitis have been also reported [40].

Age and sex

The frequency and severity of hepatic drug reactions both increase with age (Table 27.2). The explanations are likely to be multifactorial and include: increased exposure, higher probability of multiple drug therapy, and biologic effects of aging on drug disposition, especially altered hepatic uptake as the result of decreases in blood flow and/or diffusion of drugs across the hepatic microvasculature into hepatocytes [41]. Conversely, a small number of DILIs are more common in children, particularly those that involve mitochondrial injury, such as valproic acid hepatotoxicity and Reye syndrome.

Women are more likely than men to develop drug-induced hepatitis after exposure to nitrofurantoin, sulfonamides, diclofenac, minocycline, troglitazone, and halothane. Chronic hepatitis caused by the first four of these agents (and historically with methyldopa and oxyphenisatin) has an even higher (80–90%) female gender predominance. Some cholestatic reactions are more common in men (Table 27.2); these include amoxicillin-clavulanate- and azathioprine-induced vascular injury in transplant recipients, as well as anabolic steroids for reason of their greater use by men. The biologic explanation for sex differences in some types of hepatic drug reactions remains unclear.

Exposure to other drugs and toxins

Patients taking more than one agent have an increased risk of adverse drug reactions, including DILI [42–45]. Particularly relevant examples include acetaminophen, isoniazid, valproic acid, and anticancer drugs [43–46]. A possible relationship between agents that alter canalicular bile pathways has also been intimated, including interactive hepatotoxicity between OCSs and other drugs to produce prolonged cholestatic reactions [42].

Chronic excessive intake of ethanol is a risk factor for hepatotoxicity with acetaminophen, isoniazid, nicotinamide, and methotrexate.

Nutritional status

Fasting predisposes to acetaminophen hepatotoxicity because of its effects on drug conjugation and oxidation pathways, as well as on hepatic glutathione (GSH) levels. It has also been proposed that malnutrition increases the risk and severity of hepatotoxicity from drugs used to treat tuberculosis [47], but controlled studies are lacking. Overnutrition (obesity) increases the risk of halothane

hepatitis. The increased risk of NASH and hepatic fibrosis amongst those taking methotrexate, estrogens, tamoxifen, or corticosteroids (Table 27.2) will be discussed later.

Past history, and other medical disorders

Instances of cross-reactivity to similar agents have been reported with haloalkane anesthetics (halothane, enflurane, isoflurane), isoniazid and pyrazinamide, sulfonamides and some cyclooxygenase 2 (COX-2) inhibitors, some NSAIDs, and macrolide antibiotics. Such cross-reactivity is surprisingly uncommon, but a history of any previous adverse drug reaction increases the risk of DILI to other agents. It is again emphasized that *a previous reaction to the same drug* is the single most important factor predisposing to acute liver failure or chronic liver disease from DILI.

Renal failure predisposes to methotrexate-induced hepatic fibrosis and tetracycline-induced fatty liver, while renal and other solid organ transplantation is a risk factor for hepatic vascular injury with azathioprine. Likewise, disorders associated with hepatic venous outflow obstruction, such as venoocclusive disease (VOD) (now termed the sinusoidal obstruction syndrome, SOS; the terms VOD and SOS will be used interchangeably in this chapter), are attributed to cancer chemotherapeutic agents prescribed during bone marrow transplantation (as well as with radiotherapy) [48]. Rheumatoid arthritis, and possibly SLE, appears to increase the risk of salicylate hepatotoxicity and sulfasalazine-induced hepatitis. The risk of drug reactions (including hepatitis) to both sulfonamides and sulfones is greatly increased among persons with HIV/AIDS and also in SLE (Table 27.3), while diabetes (as well as obesity, alcohol, renal failure, and preexisting liver disease – see below) predisposes individuals to hepatic fibrosis during methotrexate therapy.

Preexisting liver disease

Early studies of chlorpromazine, halothane, and methyldopa reactions clearly demonstrated that other liver disorders, including alcoholic cirrhosis and cholestatic liver diseases, did not predispose to these archetypical examples of idiosyncratic drug hepatitis. On the other hand, for a few agents where partial dose dependency or metabolic mechanisms appear likely, preexisting liver disease may be a risk factor for incidence and severity (Table 27.2). These drugs include nicotinamide (niacin), hycanthone, pemoline, and some anticancer drugs [49–52]. The risk of methotrexate-induced hepatic fibrosis is also increased in the presence of other forms of liver disease [53]. More recently, interactions between chronic viral hepatitis and accentuation of liver injury have been described, including an apparently heightened risk of reactions to antituberculosis chemotherapy, ibuprofen, flutamide, cyproterone acetate, and highly active antiretroviral therapy (HAART) [54–60].

Improving outcomes

Prevention

Given the central role of the liver in drug metabolism and disposition, and the rarity of most types of liver injury with what are otherwise valuable therapeutic agents, it is impossible to completely prevent all cases of DILI. General approaches to primary prevention include appropriate use of drugs (nonpharmacological approaches whenever possible, optimal choice of agents based on efficacy and safety, case selection, avoiding polypharmacy where possible, avoiding excessive dosage), restricted availability and blister-packaging of over-the-counter medication (see section on acetaminophen below) [61], physician and public education about possible drug side effects, how to recognize and what to do about them, and monitoring for adverse drug reactions. Conveying appropriate recommendations about dose limitations for agents like acetaminophen, nicotinamide, and complementary and alternative medicine (CAM) would prevent many instances of DILI.

Careful adherence to dosage guidelines (or use of blood levels) has virtually abolished severe cases of methotrexate-induced hepatic fibrosis (see later section), tetracycline-induced mitochondrial injury, and aspirin hepatitis. Avoiding repeated halothane administration within a 28-day period, or in people with suspected previous halothane sensitivity, would prevent many cases of this serious form of drug-induced hepatitis.

For selected agents with known hepatotoxicity, and particularly when treatment is likely to extend for longer than 2–4 weeks, it may be appropriate to first establish that liver function tests (LFTs) are normal before starting treatment, and then estimate LFTs or conduct other safety monitoring during therapy. However, although such "LFT monitoring" is often suggested as one approach to prevent serious outcomes of DILI (particularly by authors of single case reports, and by manufacturers who share liability in litigation cases), there is little evidence to support this as a general policy [62,63]. Thus, the high costs and inconvenience of such screening, the need to determine appropriate testing intervals (4 weeks is usually too long for agents that can cause acute liver failure), the weak specificity of abnormal results for identifying serious hepatotoxic potential, and the difficulty of defining a threshold at which the drug should be discontinued, all thwart the logistics of monitoring drug treatment with liver tests. It particularly needs to be appreciated

that 7.5% of subjects receiving placebo in clinical trials have persistently raised ALT levels [64]. In the absence of symptoms, it is difficult to specify a level of ALT abnormality at which treatment should be discontinued. Generally, it is recommended that the drug be stopped if ALT exceeds five times the upper limit of normal (ULN) (approximately 250 U/L). More importantly, *any* abnormality of serum bilirubin or albumin concentration or prothrombin time and the presence of any symptoms are clear indications to stop therapy.

In practice, there are few agents for which liver test monitoring is strongly endorsed, as discussed in later sections – these include methotrexate, isoniazid, etretinate and other synthetic retinoids, ketoconazole, anticancer drugs, and prolonged therapy with minocycline. Conversely, the "statins" (3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors) are a group of commonly used drugs that rarely cause significant liver injury [65], and for which the recommendation (by the manufacturers) for LFT monitoring is now considered inappropriate.

Management

The most important aspect is early recognition and discontinuation of a putative causative agent. At each visit, patients should be warned to report any untoward new symptoms, and particularly fever, systemic symptoms (e.g., malaise: "I don't feel these tablets agree with me, doctor;" see also the sentinel symptoms listed in Table 27.3), anorexia, nausea, and vomiting. Presentation after jaundice has developed is often too late to avoid a severe reaction, with its potential for developing liver failure or prolonged cholestasis. When patients report symptoms of a possible drug reaction, physicians should immediately check liver tests to establish whether or not there has been a change from baseline; in cases of doubt, the agent should be discontinued.

Following drug discontinuation, most adverse drug reactions will resolve spontaneously, rapidly, and completely, but this is not always the case. Drugs with a prolonged half-life are particularly associated with protracted hepatic drug reactions. Amiodarone, etretinate, ketoconazole, and hypervitaminosis A are examples, but a delayed resolution of liver injury with several other drugs can occur on some occasions. In severe reactions, hospitalization is advisable, and further evaluation is carried out if the diagnosis is unclear. Otherwise, relief of symptoms is all that is required. As for any type of hepatic injury, older age carries an increased risk of severe liver injury. Repeated vomiting, deepening jaundice, and development of even subtle laboratory or clinical features of liver failure are indications for admission. Transfer to a liver failure unit should be considered and/or discussions with a liver transplant team should be initiated before the decline into hepatic coma, bleeding from coagulation disorder, sepsis, and hepatorenal failure.

In cases of dose-dependent hepatotoxicity, approaches to management include testing for drug levels and monitoring the clinical condition of the poisoned person. Attempts to remove unabsorbed drug by aspiration of the stomach contents should be considered for agents like acetaminophen, metals, and toxic mushrooms; other approaches (administration of charcoal or other resins or osmotic cathartics) are generally unlikely to be effective, although they have been advocated for poisoning with toxic mushrooms [66]. Likewise, approaches to remove residual drug from the body, such as with chelating resins for drugs with an enterohepatic circulation [67], or by hemodialysis, passage of blood through charcoal columns, or forced diuresis are not effective for most hepatotoxins.

Acetaminophen hepatotoxicity is the only drug-induced liver disorder for which a specific antidote (*N*-acetylcysteine) is available [42]. However, *N*-acetylcysteine has been shown to improve liver transplant-free survival in patients with acute liver failure arising from drugs other than acetaminophen. However, the benefit of this agent is confined to patients with early (grade I to II) but not late (grades III to IV) stages of hepatic encephalopathy [68]. Two agents that have been proposed to control protracted hepatic drug reactions are corticosteroids and ursodeoxycholic acid. There are few clear guidelines for their use, and the evidence of efficacy is confined to uncontrolled reports among individual cases or in small series. Older studies with corticosteroids found limited or no efficacy among cases of severe drug hepatitis for methyldopa, iproniazid, isoniazid, chlorpromazine, halothane, phenytoin, and oxyphenisatin [42]. More recent observations indicate occasional responses, particularly when DILI is associated with vasculitis (allopurinol, sulfonamides), and in some (but not all) cases of chronic hepatitis [42]. A reasonable approach is to observe the course for 3–6 weeks after stopping the drug (unless there is evidence of further deterioration), reserving corticosteroids for cases that fail to show clinical or biochemical improvement, or where the distinction between autoimmune and drug-induced chronic hepatitis remains in doubt.

Some experienced clinicians still favor a short course of corticosteroids ("steroid whitewash") to hasten recovery in persons with prolonged drug-induced cholestasis. If the mechanistic basis for such efficacy can be established (upregulating bile acid-metabolizing enzymes (CYP3A4) and canalicular transporters responsible for bile flow via pregnane-X receptors are examples), more appropriate

pharmacologic agents to stimulate clinical resolution could eventually be identified. Meanwhile, corticosteroids have a range of unpleasant or severe side effects; our preference would be to use ursodeoxycholic acid (15 mg/kg body weight) in such cases. A reasonable body of uncontrolled data indicates that about two thirds of such cases will experience a reduction of pruritus and other symptoms, and acceleration of biochemical improvement. Ursodeoxycholic acid is safe, well tolerated, and has been used with frequent success in patients presenting with cholestatic liver injury attributed to amoxicillin-clavulanate, flucloxacillin, and flutamide [69–71], as well as cyclosporine (which is not a form of cholestasis) [72]. Other approaches to treating pruritus are discussed in Chapter 21 and elsewhere [73]. During prolonged cholestatic reactions, fat-soluble vitamin deficiency should be corrected.

Diagnosis

Diagnosis of DILI is always presumptive as it is based on a logistic approach, rather than on absolute criteria and specific diagnostic tests. As a result, there will be varying degrees of certainty about the diagnosis flowing from the strength of supporting evidence. In estimating the likelihood of diagnosis ("*causality assessment*") [74,75], evidence is sought by first considering whether the link between drug ingestion and liver injury is plausible, then excluding other disorders, seeking the presence of any positive features of adverse drug reactions, and finally by assessing indicative features of the liver histology. Attempts have been made to compile these lines of evidence into diagnostic "scales" that give weight to various features [76,77]. Regrettably, these fall down in relation to less common or atypical types of drug-induced liver disease, which are those most difficult to diagnose. They have particular limitations for cases with a long delay between the start of drug ingestion and recognition of liver injury [74,77]. Further, there is uncertainity about the weight that should be given to the need for rechallenge (rarely done in practice), alcohol consumption, and interobserver reliability [78]. Using a structured expert review of suspected cases gave better results than the widely used RUCAM score but the interobserver variation in reporting remains an issue [79].

Clinical suspicion

Some situations in which DILI may be particularly likely are summarized in Box 27.3. Meticulous attention should be paid to the drug history, returning to it as a special investigation with consideration of nonprescribed medications, CAM, and environmental toxins. It may be pertinent to direct inquiry to other household members and primary care providers, and to examine all medications being taken or the contents of drug cupboards, bedside tables and lockers, etc.

Box 27.3 Some situations in which drugs are a particularly likely cause of liver disease.

- The person has started new treatment (including CAM) in the last 3–6 months
- The presence of extrahepatic manifestations, especially rash, lymphadenopathy, and eosinophilia (see also Table 27.3)
- The acute hepatitis is not readily accounted for by hepatitis viruses, other infections, or metabolic or immunologic disorders
- There are atypical features of liver disease – mixed "hepatocellular and cholestatic" reactions, or hepatitis with microvesicular steatosis
- Cholestasis with normal bile duct calibre on hepatobiliary imaging
- Cholestasis after common causes have been excluded, particularly in the elderly
- Histologic features suggest DILD (see text) in cases of cholestasis or acute hepatitis, and hepatitis with hepatic granulomas
- Chronic hepatitis without autoantibodies or hyperglobulinemia
- Abnormal liver tests in complex medical situations
- Obscure or poorly explained liver disease among those taking sex steroids, immunosuppressive agents, or other drugs (including CAM) for years

CAM, complementary and alternative medicine; DILD, drug-induced liver disease.

Time of onset in relation to drug ingestion

Dose-dependent hepatotoxins usually produce overt evidence of liver injury within hours or a few days (see section on acetaminophen). For adverse hepatic drug reactions, there is a *latent period* between commencing the drug and the development of symptoms and/or abnormal liver tests. With immunoallergic types of drug hepatitis, granulomatous hepatitis and drug-induced cholestasis, this is within 4 months (typically 2–10 weeks) in more than three quarters of cases. Occasionally liver injury becomes evident only after the drug is stopped; for amoxicillin-clavulanate this period may be up to 6 weeks. With other types of drug hepatitis presumed to be instances of metabolic idiosyncrasy, the latent period to onset tends to be longer, often 6–26 weeks. For drug-induced chronic liver disease (chronic hepatitis, steatohepatitis, syndromes related to vascular injury), exposure may have been 6 months or longer than 1 year before clinical onset is apparent. Exploring the *chronological relationships* between drug ingestion and the onset and resolution of liver injury is the most important consideration in the diagnosis of DILI [80].

Repeated drug ingestion

Some drugs almost never cause liver injury after the first exposure, but the risk of hepatotoxicity increases with each subsequent treatment course. Halothane, dacarbazine, and nitrofurantoin are recognized examples. For a much broader range of compounds, a personal history of previous reaction to the drug (*inadvertent rechallenge*) is common with severe or prolonged liver injury; isoniazid, NSAIDs, Chinese herbal medicines, germander and chaparral are examples.

In order to provide stronger evidence of causality, *deliberate rechallenge* has been used in the past, employing a single and smaller than usual dose of the suspected hepatotoxin. It has proven particularly valuable to incriminate agents not previous known to be associated with liver injury, and to identify which agent was responsible when the person was taking more than one potentially hepatotoxic drug. A positive response is connoted by a recurrence of fever or other symptoms, and/or a twofold increase of ALT or serum alkaline phosphatase (SAP) [78]; this strongly implicates the drug as the cause of liver injury. However, the application of rechallenge in practice is greatly limited by safety considerations, it should never be conducted without the fullest consideration by both the person involved and their family, and with reference to an Institutional Human Ethics Review Board. Particularly note that deliberate rechallenge is potentially dangerous and should never be attempted for the types of reactions listed in Table 27.3.

Response to discontinuation of the drug

Dechallenge should be followed by improvement in liver tests within days or weeks of stopping the drug; some guidelines have been provided [80]. There are clear exceptions. In DILI caused by ketoconazole, troglitazone, coumarol, etretinate, amiodarone, and minocycline, severe reactions may resolve slowly (months), or incompletely, sometimes with further decline of hepatic function after drug discontinuation. Some instances of drug-induced cholestasis can also be prolonged but failure of jaundice to resolve in suspected hepatic drug reactions more often indicates an alternative diagnosis (e.g., malignant biliary obstruction) is likely and should be reinvestigated.

Clinical features

While the clinicopathologic syndrome associated with exposure to a particular drug may be a useful aid to diagnosis, the diversity of reactions to individual drugs is such that absence of the "drug signature" (or "syndromic recognition") test should *not* be used to exonerate a given drug as the cause of liver injury. In most respects, the clinical features of drug hepatitis or drug-induced cholestasis are not dissimilar from those found with other causes of these disorders. However, identifying specific risk factors for hepatotoxicity (e.g., prolonged fasting, or chronic excessive alcohol intake in a person regularly taking acetaminophen) or the presence of extrahepatic features of drug hypersensitivity (Table 27.3) may suggest the correct diagnosis.

Exclusion of other disorders

It is critical to exclude other liver diseases before attributing liver injury to drugs (Box 27.4). In earlier work, [81] nearly two thirds of reactions reported as drug-induced chronic hepatitis were subsequently ascribed to chronic hepatitis C. Contemporary serologic, viral, immunologic, and imaging tests have facilitated the early diagnosis of most acute viral, vascular, and metabolic liver disorders. Likewise, the cause of cholestasis, and particularly mechanical obstruction of the biliary tract, is usually easy to identify with modern imaging. Approaches to making the correct diagnosis of a drug reaction when the clinical and laboratory features resemble autoimmune hepatitis include the course after discontinuation of the drug, and the response to a short course (4–6 weeks) of corticosteroids if there is not rapid improvement after stopping the drug. If there is an impressive response to

Box 27.4 Drug-induced liver disease is a diagnosis of exclusion. The following factors should be considered.

- Hepatitis viruses: serology and molecular virology (especially HCV RNA)
- Other infectious agents: EBV, CMV, HIV, HSV, and *Coxiella burnettii*
- Autoimmune hepatitis: ANAs, SMAs, LKMs, and immunoglobulin G levels
- Acute biliary obstruction: exclude cholangitis
- Metabolic disorders: Wilson disease, α_1-antitrypsin deficiency, and risk factors for NAFLD/NASH (serum lipids, fasting blood glucose or abnormal glucose tolerance test, insulin, family history of diabetes, features of the metabolic syndrome)
- Vascular disorders of liver: risk factors and imaging with vascular phase (Chapter 33)
- Alcohol
- Bacterial infection
- Hepatic metastases
- Systemic malignancy or lymphoma

ANAs, antinuclear antibodies; CMV, cytomegalovirus; EBV, Epstein–Barr virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; LKMs, liver–kidney microsomal antibodies; NAFLD, nonalcoholic fatty liver disease; NASH, nonalcoholic steatohepatitis; SMAs, smooth muscle antibodies.

corticosteroids followed by relapse after reducing the dose, it allows the physician to assume that the case is actually one of autoimmune hepatitis.

Liver biopsy

The liver biopsy plays a special role in excluding other hepatobiliary disorders, but it may also provide positive evidence to corroborate DILI. Biopsy is most strongly indicated when the cause of liver disease remains in doubt; for example, there may be ambiguous evidence of autoimmunity, or the pattern of reaction may be very unusual or not previously reported for the drug in question. Details such as whether continued treatment with this medication is highly desirable, and whether or not there is rapid improvement after stopping the drug, may influence the decision on whether or not to perform liver biopsy. As for any indication, the justification for liver biopsy must satisfy the question as to "whether the likelihood that this will make a difference to management of the person justifies the inconvenience, discomfort and risks of the procedure". Informed consent is clearly mandatory, and it may be valuable to record in the medical record (or on a signed consent form) why the biopsy is considered valuable in this particular case.

There are no histologic features that are pathognomonic for drug-induced liver disease, and indeed some, such as the presence of occasional eosinophils, are often overinterpreted. Nonetheless, some patterns of hepatic lesions may suggest to an experienced liver pathologist that a drug or toxin could be implicated (Box 27.5). The reader is referred to Chapter 7 for examples of hepatic histopathology in drug-induced liver disease, and to the excellent detailed illustrations found in texts such as Hall [82] and Zimmerman [2], as well as earlier editions of this book.

Box 27.5 Histologic changes that may indicate the operation of drug-induced liver disease.

- Zonal lesions, including necrosis and/or steatosis
- Microvesicular steatosis (often results from mitochondrial injury)
- Necrotic lesions of disproportionate severity for the clinical picture
- Mixed hepatitis and cholestasis
- Destructive bile duct lesions
- Prominent neutrophils, and (in later stages) eosinophils (more than 25%)
- Granulomas
- Vascularity of hepatic tumors: sinusoidal dilatation and peliosis
- Vascular lesions
- Florid steatohepatitis: resembles alcohol-related steatohepatitis more than typical "primary" nonalcoholic steatohepatitis

Specific diagnostic tests

As reviewed elsewhere [7,12], there are no completely validated specific tests for any type of drug-induced liver disease. Interesting data have been presented about the relative specificity of some drug-induced autoantibodies, including anti-M6 (antimitochondrial antibodies) with iproniazid, anti-LKM-2 (against CYP2C9) with tienilic acid, anti-CYP1A2 with dihydralazine, and anti-CYP2E1 with halothane. A test that detects antibodies against trifluoroacetylated (TFA) proteins has been advocated for halothane and other haloalkane-related hepatotoxicity (see later section). However, all such tests have minimal applicability in clinical practice because of their unavailability and lack of standardization, including agreement on what comprises a significant titer of antibodies.

Identifying one causative agent among many

Having established with near certainty that one or more drugs are responsible for an individual case of liver disease, an additional challenge may be to identify which among several is the guilty party. In general, the agent started most recently before the onset of liver injury is the one most likely to be responsible; new and nonproprietary medicines should also heighten suspicion. Otherwise, the drug with the most hepatotoxic track record becomes the prime contender. Whenever possible, all potential hepatotoxins, including therapeutic agents, should be discontinued. If the patient's condition and laboratory tests improve, the drug(s) that seem unlikely to be responsible can be carefully reintroduced.

Clinicopathologic syndromes

The initial "labeling" of cases with apparent DILI relied heavily on the profile of liver test abnormalities (Table 27.4) and not histopathology, which provides a more definitive classification. It should be noted that clinical and laboratory features are not always congruent with liver pathology, and there is much overlap between categories. Thus, although the histologic changes usually mirror the biochemical abnormalities, certain caveats should be borne in mind. First, the alteration of liver enzymes is not synonymous with liver injury and can represent hepatocyte adaptation (below). Second, liver tests may underestimate the severity of liver disease, as with the fairly modest changes in aminotransferase (AT) that may accompany acute liver failure from drug-induced microvesicular steatosis. Conversely, drugs such as estrogens may be associated with a major increase in AT despite bland cholestasis on biopsy, while others (methotrexate, vinyl chloride, arsenic) can cause cirrhosis

Table 27.4 Definition of patterns of liver injury.

	Liver injury		
	Hepatocellular	**Cholestatic**	**Mixed**
ALT >2–3 × ULN	ALT >2–3 × ULN *and* normal SAP	SAP >2 × ULN	ALT >2–3 × ULN *and* SAP >2 × ULN
or	*or*	*or*	*or*
>2 × ULN conjugated bilirubin *or* elevated AST, SAP, and total bilirubin (one of these must be >2 × ULN)	ALT : SAP ratio ≥5*	ALT : SAP ratio ≤2*	ALT : SAP ratio between 2 and 5*

*The ALT and SAP values are expressed as multiples of the upper limit of normal. Note that these patterns are a relatively poor guide to the histologic nature of liver disease (see text).
ALT, alanine aminotransferase; AST, aspartate aminotransferase; SAP, serum alkaline phosphatase; ULN, upper limit of normal.

with minimal or no change in biochemical tests. Third, the pattern of liver tests is most often mixed or relatively nonspecific; this occurs with granulomatous hepatitis, steatohepatitis, cholestatic hepatitis, chronic hepatitis, and minor nonspecific patterns of liver injury.

A relatively simple approach to clinicopathologic classification of drug-induced liver disease is outlined in Table 27.5.

Hepatic adaptation

Many drugs induce abnormal liver tests without causing symptoms or biochemical evidence of *significant* liver disease. Minor elevations of ALT may be transient. In reality, these may indicate minor degrees of nonprogressive injury to key organelles such as mitochondria or cell membranes, without causing cell death and without recruiting an inflammatory response. The nonprogression (often resolution) of these changes may result from the induction of protective processes, such as antioxidant and antiapoptotic pathways; in this sense, minor forms of chemical liver injury are often followed by adaptation of the liver to withstand continuing or more substantial insults. Experimental work has demonstrated the hepatoprotective effects of a small dose of CCl_4 against subsequent massive poisoning, and the phenomenon of ischemic preconditioning substantially abrogates subsequent ischemic or reperfusion injury. The mechanisms of these adaptive processes are of potential importance to the understanding of DILI.

Other forms of "hepatic adaptation" include drug-induced hyperbilirubinemia, as observed with such agents as rifampicin, flavaspidic acid, and cyclosporine, and "induction of hepatic enzymes." Hyperbilirubinemia is best understood as a direct interference with pathways of bilirubin uptake, conjugation, and canalicular excretion into bile. Sustained elevation of enzymes such as γ-glutamyl transpeptidase (GGTP) and serum alkaline phosphatase is seen with phenytoin and other anticonvulsants, rifampicin, alcohol, and warfarin. Because such agents induce hepatic CYP enzymes, this phenomenon is often referred to as "microsomal enzyme induction;" the actual relationship between the activity of drug oxidases and the increased plasma levels of these non-microsomal enzymes is less clear. Potential explanations are that the indirect effects of increased CYP enzyme activity on bile acid metabolism produce more "detergent" metabolites that liberate these enzymes from the hepatocyte plasma membranes, or that stimulate increased synthesis of alkaline phosphatase and GGTP – both these mechanisms may apply. It is important clinically to recognize the difference between these biochemical changes and cholestasis; for example, serum bile acid levels increase with cholestasis or liver injury not with hepatic adaptation.

A morphologic or ultrastructural consequence of microsomal enzyme induction by drugs is the presence of ground glass cytoplasm in hepatocytes, as seen by light microscopy. This results from hypertrophy of the endoplasmic reticulum, which can be confirmed by electron microscopy.

Drug-induced acute hepatitis

Many drugs are associated with acute hepatocellular injury (Box 27.6). There is a latent period between starting treatment and the onset of symptoms or liver test abnormalities. This tends to be shorter (2–6 weeks) for agents clearly associated with immunoallergic mechanisms (see Table 27.3), and more variable and longer for those presumed to be due to metabolic idiosyncrasy. There are often prodromal features of fever, malaise, and other

Table 27.5 Clinicopathologic classification of drug-induced liver disease.

Category	Description	Examples
Hepatic adaptation	No symptoms; raised GGTP and SAP (occasionally ALT) Hyperbilirubinemia	Phenytoin, warfarin, rifampin Rifampin
Dose-dependent hepatotoxicity	Very short interval to onset; symptoms of hepatitis; zonal, bridging, and massive necrosis; ALT >5 × ULN, often >2,000 U/L	Acetaminophen, nicotinic acid, amodiaquine
Other cytopathic changes		
Acute steatosis	Microvesicular steatosis, diffuse or zonal; partially dose-dependent, severe liver injury, features of mitochondrial toxicity (lactic acidosis, pancreatitis)	Valproic acid, didanosine, HAART, fialuridine, L-asparaginase, some herbal medicines, ecstasy
Acute hepatitis	Onset within 1–20 weeks; sentinel symptoms of hepatitis; focal, bridging, and massive necrosis; ALT >5 × ULN; extrahepatic features of drug allergy in some cases (Table 27.3)	Isoniazid, dantrolene, nitrofurantoin, halothane, sulfonamides, phenytoin, disulfiram, etretinate, ketoconazole, terbinafine, troglitazone
Chronic hepatitis	Duration >3 months; interface hepatitis, bridging necrosis, fibrosis, cirrhosis; clinical/laboratory features of chronic liver disease; autoantibodies in some cases	Nitrofurantoin, etretinate, diclofenac, minocycline, mesalamine
Granulomatous hepatitis	Hepatic granulomas with varying hepatitis and cholestasis; raised ALT, SAP, GGTP	Allopurinol, carbamazepine, hydralazine, quinidine, quinine, phenylbutazone
Steatohepatitis	Onset delayed (6–18 months); steatosis, focal necrosis, Mallory hyaline, pericellular fibrosis, cirrhosis; chronic liver disease, portal hypertension	Perhexiline, amiodarone, tamoxifen, toremifene; rarely nifedipine, diltiazem
Cholestasis without hepatitis	Cholestasis, no inflammation; SAP >2 × ULN	Oral contraceptives, androgens, cyclosporin A
Cholestatic hepatitis	Cholestasis with inflammation; symptoms of hepatitis; raised ALT and SAP	Chlorpromazine, tricyclic antidepressants, erythromycins, amoxicillin-clavulanate, angiotensinogen-converting enzyme inhibitors
Cholestasis with bile duct injury	Bile duct lesions and cholestatic hepatitis; clinical features of cholangitis	Chlorpromazine, flucloxacillin, dextropropoxyphene, carmustine, paraquat
Chronic cholestasis	Cholestasis present >3 months	Chlorpromazine, flucloxacillin, trimethoprim-sulfamethoxazole (Table 27.6)
Vanishing bile duct syndrome	Ductopenia; resembles primary biliary cirrhosis but antimitochondrial antibodies absent	
Sclerosing cholangitis	Strictures of large bile ducts	Intra-arterial floxuridine, intralesional scolicidals
Vascular disorders	Sinusoidal dilatation, peliosis, noncirrhotic portal hypertension, NRH, SOS (VOD)	Anabolic steroids, oral contraceptives, vinyl chloride, Thorotrast® (Table 27.6)
Liver tumors	Focal nodular hyperplasia, hepatic adenoma, hepatocellular carcinoma, angiosarcoma	Anabolic steroids, oral contraceptives, vinyl chloride, Thorotrast (Table 27.6)

ALT, alanine aminotransferase; GGTP, γ-glutamyl transpeptidase; HAART, highly active antiretroviral therapy; NRH, nodular regenerative hyperplasia; SAP, serum alkaline phosphatase; SOS, sinusoidal obstruction syndrome; ULN, upper limit of normal; VOD, venoocclusive disease.

"sentinel symptoms" (Table 27.3), followed by rash, lymphadenopathy, or other systemic features of drug hypersensitivity. Clinical features that resemble acute viral hepatitis soon follow, or may be the presenting symptoms; anorexia, nausea, vomiting, and lassitude are prominent among these. Jaundice is present in severe cases. AT levels are raised (see Table 27.4) proportionately more than serum alkaline phosphatase. Serum bilirubin and indices of hepatic synthetic function such as prothrombin time and serum albumin concentration are variably altered depending on the severity and duration of liver injury.

The histologic lesions consist mainly of focal hepatic necrosis, with apoptotic (acidophil) bodies and a mixed inflammatory infiltrate. Bridging necrosis is present in

severe cases and may lead to chronic hepatitis if the causative agent is not withdrawn.

Zonal necrosis is a typical feature of severe liver injury caused by drugs and with chemical or plant toxins. *Zone 3 lesions* (centrilobular or perivenular) are seen with acetaminophen and carbon tetrachloride toxicity but can also occur in acute SOS (or VOD). The overrepresentation of zone 3 lesions in cases of DILI is related to the high metabolic activity of this zone, which generates reactive metabolites. By comparison, isolated *zone 1* (phosphorus or iron poisoning) and *zone 2 lesions* (cocaine toxicity) are extremely rare.

Severe acute hepatitis may culminate in *acute liver failure.* Massive or submassive hepatic necrosis is often present. Acetaminophen (see later section) is the leading cause of drug-induced acute liver failure worldwide, but regional differences exist. Other drugs that have been associated with acute liver failure are listed in Box 27.6.

Mitochondrial injury

Fatty liver (steatosis) can be seen in the vicinity of zonal necrotic lesions or may be the predominant manifestation. Microvesicular steatosis results from mitochondrial injury; decreased numbers of mitochondria are often found. There is often evidence of other organ involvement, particularly pancreatitis, nephrotoxicity, encephalopathy, and metabolic acidosis. The clinical syndrome resembles acute fatty liver of pregnancy. Patients present with nausea, vomiting, abdominal pain, and rapidly evolving encephalopathy. Liver biopsies show accumulation of small fat droplets (microvesicular steatosis) in hepatocytes in a zonal or diffuse distribution. Biochemical features include profound hepatocellular dysfunction with hypoglycemia, coagulopathy, hyperammonemia, and lactic acidemia. There may be a rise in serum bilirubin and AT levels, but these are less pronounced than in other forms of acute hepatotoxicity or hepatitis. Historically, this syndrome was associated with the use of tetracycline in pregnant women, Reye syndrome caused by use of aspirin in febrile young children with influenza B and some other viral infections, and with sodium valproate in very young children with predisposing factors (see later section). Currently, the most important cause is HAART, particularly the nucleos(t)ide inhibitors, but amphetamine analogs used recreationally, especially ecstasy, and buprenorphine misuse can produce similar lesions [83]. The drugs associated with microvesicular steatosis are listed in Box 27.7.

Unlike acute microvesicular steatosis, drug-induced *steatohepatitis* is a type of hepatocellular injury associated with chronic liver disease. Hepatic decompensation can occur. Some drugs associated with steatohepatitis have also been implicated as causing acute liver failure but progression to cirrhosis or liver complications is generally

Box 27.7 Drugs associated with microvesicular steatosis.

slower. Implicated drugs are listed in Box 27.8. The histologic features are indistinguishable from alcoholic steatohepatitis, with varying degrees of steatosis, focal lobular inflammation with polymorphonuclear cells, hepatocellular necrosis, and Mallory bodies. Excluding ethanol abuse is critical. The changes also resemble those found in NASH (Chapter 32). Thus, some associations between drugs used for complications of the metabolic syndrome (diabetes, hypertension, cardiac failure) and steatohepatitis may be fortuitous, while other agents (corticosteroids, estrogens, tamoxifen) may exacerbate NASH due to effects on insulin resistance and lipid turnover. Drug-induced steatohepatitis often causes hepatic fibrosis

in the pericentral (perivenular, or acinar zone 3) and pericellular distribution, a pattern typical for other causes of steatohepatitis. Cirrhosis can develop, leading to hepatic decompensation.

Cholestasis

There are several different syndromes of drug-induced cholestasis (Table 27.6) [84,85]. *Bland cholestasis* occurs without symptoms of hepatitis. Liver biopsies show intrahepatic cholestasis without significant hepatic inflammation. This syndrome is associated with OCS use and occurs more often in women with a family or personal history of cholestasis of pregnancy (Chapter 11). Pruritus is often troublesome, but jaundice is less common. Recovery is the rule but complete resolution can be protracted in some cases.

In *cholestatic hepatitis*, liver histology shows lobular and portal tract inflammation as well as cholestasis. As with other forms of drug hepatitis, clinical onset is with flu-like symptoms but this is soon followed by features of hepatitis, such as anorexia, vomiting, jaundice, and right hypochondrial pain. The latter can be severe and can be misinterpreted as acute cholecystitis. Drugs that cause cholestatic hepatitis can also cause *bile duct injury*; dextropropoxyphene [86] and methylenedianiline (an epoxyresin hardener associated with cases of liver injury or jaundice following industrial exposure or food contamination, most infamously as "the Epping jaundice") cause a striking syndrome of cholangitis [87]. Cholangiolytic (interlobular bile duct) injury is prominent in many cases of drug-induced cholestatic hepatitis. When lesions are severe enough, this can lead to ductopenia or the *vanishing bile duct syndrome* (VBDS).

VBDS is characterized by progressive destruction of segments of the biliary tree [88,89]. Over 30 drugs have been implicated [90–94] but those causing the highest risk of this outcome after drug-induced cholestatic hepatitis are chlorpromazine (7% of cases), the oxypenicillins (particularly flucloxacillin (10–30% of cases)), and the erythromycins (5% of cases) (Box 27.9). The main predictor of VBDS after cholestatic hepatitis may be the initial severity of the bile duct damage [89]. The clinical features resemble primary biliary cirrhosis (PBC) with jaundice, and liver tests indicating cholestasis, hypercholesterolemia, xanthomas, and other manifestations of chronic cholestasis. However, unlike PBC, antimitochondrial antibodies are absent. Hepatic fibrosis is not usually prominent, but biliary cirrhosis can sometimes develop. Resolution may take up to 2 years and is sometimes incomplete.

Large duct bile duct lesions ("sclerosing cholangitis") are an uncommon type of drug-induced injury. Well-characterized historical examples include intra-arterial

Table 27.6 Clinicopathologic syndromes of drug-induced cholestasis.

Type	Clinical and laboratory features	Examples
Acute forms		
Cholestasis without hepatitis ("bland" cholestasis)	Prodromal symptoms, then intense pruritus; SAP >3 × ULN; AT rise is often transient (rarely >3–5 × ULN); bilirubin <12 mg/dL	Estrogens, anabolic steroids, tamoxifen, azathioprine
Cholestasis with hepatitis[a]	Right upper quadrant or generalized abdominal pain; jaundice often present; can simulate acute cholangitis; pruritus less impressive; SAP >3 × ULN in 70%, AT >2–5 × ULN	Chlorpromazine, other phenothiazines, macrolide antibiotics, oxypenicillins, tricyclic antidepressants, amoxicillin-clavulanate, ketoconazole, NSAIDs (sulindac, piroxicam), captopril, enalapril, azathioprine
Cholestasis with bile duct injury[a] (cholangiolytic)	Resembles acute cholangitis (often with cholestatic hepatitis)	Dextropropoxyphene, flucloxacillin, paraquat, methylenedianiline
Chronic forms		
Vanishing bile duct syndrome (see Box 27.9)	Chronic cholestasis; resembles PBC but antimitochondrial antibodies are absent	Chlorpromazine, flucloxacillin, and other oxypenicillins
Large bile duct strictures (similar to sclerosing cholangitis)	Chronic cholestasis; resembles sclerosing cholangitis (but strictures at junction of right and left hepatic ducts)	Floxuridine, intralesional scolicides (2% formaldehyde, hypertonic saline, iodine solution, absolute alcohol, silver nitrate)

[a]Several drugs implicated in causing cholestatic hepatitis may also produce bile duct injury.
AT, aminotransferase; NSAIDs, nonsteroidal anti-inflammatory drugs; PBC, primary biliary cirrhosis; SAP, serum alkaline phosphatase; ULN, upper limit of normal.

floxuridine infusions (which cause an ischemic cholangiopathy) and intracavitary instillation of scolicidal agents [95]. Current practices of targeted chemotherapy for hepatic malignancy, and ultrasound-guided scolicidal therapy have a low risk of drug-induced biliary injury.

Granulomatous hepatitis

Hepatic granulomas are associated with numerous infective, inflammatory, vasculitic, and neoplastic disorders (Chapter 40) [96]. Older studies found that nearly one third of cases of hepatic granulomas were attributable to drugs [97], and it seems likely that drugs remain an important cause of "granulomatous hepatitis." In drug reactions, granulomatous hepatitis may be the sole manifestation of liver injury, but more commonly granulomas accompany other histologic features and represent one of several patterns of hepatic response to injury. Thus, granulomas have been described with many drugs that are better known for other types of pathology, especially acute hepatitis (nitrofurantoin, methyldopa, halothane), but also cholestatic hepatitis (chlorpromazine, phenylbutazone, carbamazepine) and steatohepatitis (amiodarone, calcium channel blockers) (Box 27.10).

The clinical presentation is indistinguishable from other causes or idiopathic granulomatous hepatitis (Chapter 40). Thus, profound lethargy, fever, night sweats, rigors, myalgia, and weight loss are prominent. There is tender hepatomegaly and the spleen is enlarged in 25% of cases. Other extrahepatic manifestations include rashes, particularly a form typifying small vessel vasculitis, lymphadenopathy, and bone marrow granulomas [14]. Serum ALT is often raised, but typically less than serum alkaline phosphatase and GGTP. Jaundice is much less common than with other types of drug-induced acute

- Rosiglitazone
- Tacrine
- Tetrabamate
- Ticlopidine

[a]Well-characterized examples with causality proven. Note that the high frequency with which hepatic granulomas are found in liver biopsies is such that other associations may be fortuitous.
NSAIDs, nonsteroidal anti-inflammatory drugs.

hepatitis, but has been observed when cases overlap with cholestatic hepatitis; carbamazepine and hydralazine are examples. Withdrawal of the offending drug leads to rapid resolution in most cases. A short course of corticosteroids may hasten recovery in special circumstances, particularly cases associated with vasculitis or other extrahepatic complications such as interstitial nephritis; allopurinol and sulfonamides are examples.

Drug-induced chronic hepatitis

Chronic hepatitis is defined by the persistence of symptoms and biochemical or histologic abnormalities for longer than 3 months [14]. All drugs implicated as causing chronic hepatitis have also been associated with acute reactions. Continued ingestion of the drug beyond the phase of acute hepatitis is one of the key factors that leads to the development of chronic hepatitis, cirrhosis, and liver failure. Early recognition and timely withdrawal of the offending drug are therefore crucial.

A distinctive type of drug-induced chronic hepatitis resembling autoimmune hepatitis (AIH) is described. This probably comes about through the process of drug-induced immune dysregulation. The relatively few agents that cause this type of liver disease include nitrofurantoin, diclofenac, methyldopa, and minocycline. More than 80% of reported cases are in women. Characteristic features include fever and arthralgia in addition to signs of chronic liver disease, hypergammaglobulinemia, and antinuclear and/or smooth muscle antibodies.

A second pattern of drug-induced chronic hepatitis is characterized by autoantibodies directed against specific hepatic microsomal proteins (e.g., tienilic acid, halothane). Yet other agents (e.g., etretinate, germander) can be associated with chronic hepatic inflammation and liver cell injury (hepatitis) in the absence of autoantibodies or autoimmune manifestations. Finally, a picture of classic AIH may emerge after an episode of drug-induced acute hepatitis. It is unclear whether the emergence of AIH is related to the unmasking of latent AIH or whether the drug directly induces AIH in susceptible persons.

Hepatic fibrosis

Hepatic fibrosis may be the end result of chronic hepatitis, chronic hepatototoxicity, steatohepatitis, or chronic cholestasis with bile duct injury. However, some drugs and chemicals such as methotrexate, vitamin A, and arsenic can provoke an intense fibrotic reaction *without* a prominent inflammatory response. With these agents, other profibrogenic risk factors, especially ethanol but possibly also obesity, diabetes, insulin resistance, and iron overload, can accelerate fibrogenesis (discussed later for vitamin A and methotrexate).

Vascular lesions

Drugs and chemicals are the most important cause of vascular lesions of the liver. These include histologic curiosities, such as sinusoidal dilatation, through to clinically important disorders such as peliosis hepatis, SOS (VOD), Budd–Chiari syndrome, nodular regenerative hyperplasia, and other causes of noncirrhotic portal hypertension (Table 27.7).

Causative drugs include sex steroids, alkylating chemotherapeutic agents (cyclophosphamide, busulfan, melphalan, dactinomycin), and immunosuppressive agents (azathioprine). In current practice, SOS (or VOD) most often occurs in the setting of bone marrow transplantation, but in the past it was synonymous with pyrrolizidine alkaloid hepatotoxicity resulting from the ingestion of brewed herbal tea mixtures (e.g., "Jamaican morning sickness") [98] or from plant alkaloid contamination of herbal medicines such as comfrey [99]. Epidemics of VOD have also reported in areas where pyrrolizidine alkaloid-contaminated wheat flour has been consumed,

Table 27.7 Drug-induced vascular disorders and tumors.

Vascular lesions	Examples
Vascular disorders	
Peliosis hepatis	Anabolic steroids, azathioprine, oral contraceptives, 6-thioguanine, Thorotrast®
Hepatic sinusoidal obstruction syndrome (venous outflow obstruction, including venoocclusive disease)	Oral contraceptives, pyrrolizidine alkaloids, 6-thioguanine, dacarbazine, gemcitabine
Noncirrhotic portal hypertension	Vitamin A, methotrexate, arsenic, vinyl chloride, azathioprine
Nodular regenerative hyperplasia	Azathioprine, 6-thioguanine, busulfan
Tumors	
Hemangioma	Oral contraceptives (trophic effect on preexisting lesions only)
Focal nodular hyperplasia	?Oral contraceptives (see text)
Hepatic adenoma	Oral contraceptives, anabolic steroids
Hepatocellular carcinoma	Anabolic steroids, danazol, oral contraceptives, Thorotrast, vinyl chloride
Angiosarcoma	Vinyl chloride, thorium dioxide, arsenic

particularly in South Asia and the Middle East. Hepatic vein and portal vein thrombosis can occur in OCS users, although latent or overt myeloproliferative disorders or inherited procoagulant states (such as factor V Leiden) [100] are usually also found in cases of venous thrombosis at these sites (Chapter 33).

Hepatic neoplasms

Drugs and toxins are a rare cause of liver tumors (Chapters 35 and 36), but some associations exist, as exemplified by OCSs and *hepatic adenomas*. OCS use is recorded in over 80% of patients with hepatic adenomas, and there is a strong relationship with dose and duration of estrogen therapy [101,102]. Further, evidence of estrogen dependence of these tumors is evident; regression occurs in a significant proportion of patients after discontinuing OCSs [103]. As discussed later, surgery is still required in most cases.

The relationship between estrogens and *focal nodular hyperplasia* is less clearly etiologic (see later section). As for cavernous hemangiomas, sex steroids, and particularly estrogens, may have trophic effects on these two benign hepatic neoplasms, especially on their vascularity, although this remains controversial [104]; estrogens are therefore not the primary causative factor.

Malignant tumors such as *hepatocellular carcinoma* (HCC) are caused by chronic viral hepatitis in more than 80% of cases (Chapter 36), but in parts of Africa and Asia the ingestion of aflatoxin- or other fungal toxin-contaminated food may play a synergistic role in carcinogenesis. Estrogens increase the risk of HCC in long-term OCS users, but this effect is weak and is overwhelmed in importance by chronic HBV and HCV infection in regions endemic for these viruses [27].

Angiosarcoma is an uncommon liver tumor that was classically associated with the radiocontrast agent Thorotrast® (see also Chapter 36), vinyl chloride monomer, arsenic, and, rarely, androgen use.

Role of drugs in multifactorial liver disease

Viral hepatitis

Patients with chronic hepatitis B or C may be at increased risk of liver injury during chemotherapy for tuberculosis and cancer, during HAART, and after the intake of ibuprofen and possibly other NSAIDs [57–59]. Successful antiviral treatment for chronic hepatitis C reduces the risk of antiretroviral drug hepatotoxicity [105].

A common problem is the person who regularly attends the liver clinic with mild-to-moderate ALT elevation associated with chronic viral hepatitis, who then presents with an ALT >300 U/L. Particularly for chronic hepatitis C, changes due to hepatotoxic drugs are more likely than spontaneous fluctuations of disease severity; drugs are almost always the cause with ALT values that greatly exceed 1,000 U/L. A common culprit is acetaminophen taken in moderate daily dosage when there are factors such as concomitant medication, prolonged fasting, or chronic alcohol excess (see later section). Another frequent scenario is that the person has tried Chinese herbal medicines or some other form of CAM.

Highly active antiretroviral therapy

Abnormal liver tests and clinical evidence of liver disease are common in persons with HIV/AIDS. Contributory factors include chronic hepatitis B or C, hepatobiliary infections and infestations, lymphoma and other tumors, and possibly direct effects of HIV infection (Chapter 41). However, drugs remain the commonest cause of liver injury in this setting. When monotherapy was used against HIV, individual nucleos(t)ide analogs (e.g., didanosine, zidovudine) were associated with uncommon episodes of severe cytopathic liver injury. As discussed later, it seems likely that drug combinations that include protease inhibitors as well as nucleos(t)ide analogs are more toxic than individual agents.

Bone marrow transplantation

As discussed in Chapter 10, hepatobiliary complications of hematopoietic cell transplantation are common, often serious and may be multifactorial in origin. Bone marrow transplantation particularly increases the risk of vascular complications, such as VOD and nodular regenerative hyperplasia. Thus while SOS (or VOD) complicates at least 1% of cases during the use of anticancer drugs, its risk can be as high as 54% after bone marrow transplantation, depending on the regimen used [42]. Of 103 patients undergoing bone marrow transplantation in one series, NRH was present in 23% and SOS (VOD) in 9% [106].

The clinical features are those of portal hypertension, often complicated by bleeding esophageal varices and ascites. Hepatic encephalopathy can occur after an episode of severe upper gastrointestinal hemorrhage. Liver tests may be normal or show minor nonspecific changes. The diagnosis is made histologically; a wedge biopsy may be necessary. In general, the prognosis for NRH is good; complete reversibility may occur in some drug-induced cases [106].

Metabolic syndrome and non-alcoholic steatohepatitis

Steatohepatitis is a form of chronic liver disease in which fatty change is associated with focal liver cell injury, Mallory hyaline, inflammation with mixed cellularity, including polymorphonuclear cells, and progressive hepatic fibrosis in a pericentral (zone 3) and pericellular distribution (Chapter 32). While alcohol is a common etiology, steatohepatitis can be associated with diabetes, obesity, and several drugs (e.g., perhexiline maleate [107] and amiodarone [108]); the term "drug-induced steatohepatitis" is now preferred to "secondary NASH".

Among drugs associated with steatohepatitis during the last 20 years, causality is harder to prove because NASH is so common among patients with insulin resistance, diabetes, and metabolic syndrome (Chapter 32). Thus, calcium channel blockers used for arterial hypertension have been associated with steatohepatitis [109, 110] and methyldopa has been reported to cause cirrhosis in obese middle-aged women [111,112]; these associations may be fortuitous. Other drugs, including estrogens [113], tamoxifen, and glucocorticosteroids may precipitate NASH because of their effects on metabolic risk factors: insulin resistance, type 2 diabetes, obesity, and hypertriglyceridemia. A recent addition to this list is oxaliplatin-based chemotherapy for metastatic colorectal cancer; hepatic steatosis (20–25%) and less commonly NASH (up to 5%) are described. The presence of steatohepatitis confers increased morbidity and poor outcome after liver resection [114].

Postoperative jaundice

Drug-induced liver injury is a common cause of postoperative liver disease. It is usually easy to distinguish underlying hepatobiliary disorders and bilirubin transport abnormalities resulting from tissue hypoxia or systemic infection ("benign postoperative cholestasis" or "jaundice in sick patients") from drug reactions. Halothane-induced liver injury is one of the classic types of hepatic drug reactions but has become much less common now that halothane has been almost completely replaced (in some countries) with equally acceptable and less hepatotoxic agents. Other than halothane, which causes a typical "signature syndrome," few other anesthetics cause significant liver injury. Some cases have been attributed to isoflurane; the evidence and practical implications are discussed later. Postoperative liver injury is also observed with antibiotics (especially amoxicillin-clavulanate, and less commonly with synthetic penicillins or cephalosporins), analgesics (particularly acetaminophen given alone or in drug combinations), dextropropoxyphene, tranquilizers, antidepressants, and (undisclosed) use of herbal medicines.

Liver disease associated with particular classes of drugs

Antimicrobial agents

Penicillins

Hepatic injury associated with natural penicillins (penicillin G, penicillin V) is poorly documented [14]. It has been usually recorded in the setting of anaphylaxis, suggesting a possible ischemic basis for the liver injury rather than direct toxicity [115]. In contrast, the semisynthetic penicillins have been implicated in many hepatic drug reactions, including hepatocellular injury, bland cholestasis, and cholestatic hepatitis that may lead to VBDS (Table 27.8) [116–118].

Oxacillin

There are many reports of abnormal liver tests, mainly raised AT [119,120], with oxacillin. Isolated instances of cholestatic hepatitis or acute hepatitis have also been reported. Most reported cases have occurred in the setting of high-dose, prolonged (>2 weeks), intravenous treatment. Children may be particularly susceptible to this adverse reaction [121]. Onset is within 2 to 43 days. Although eosinophilia has been described, features of hypersensitivity are not conspicuous. The liver test abnormalities usually normalize when the drug is withdrawn.

Table 27.8 Hepatic injury associated with antimicrobial agents.

Drug	Pattern of liver injury	Comments
Amoxicillin, carbenicillin	Minor, nonspecific increase in aminotransferases	
Amoxicillin-clavulanate	Cholestatic hepatitis with bile duct injury; acute hepatitis (15% of cases)	Associated with vanishing bile duct syndrome, granuloma and cirrhosis (single case)
Ampicillin	Acute hepatitis, mixed hepatocellular–cholestatic injury, granulomatous hepatitis	Rarely vanishing bile duct syndrome; cross-hepatotoxicity with cefuroxime
Ampicillin-sulbactam	Cholestatic hepatitis	Single case
Cephalosporins	Minor liver injury, acute hepatitis, cholestatic hepatitis	Rare, mild, and reversible; granulomas (cephalexin); biliary sludge (ceftriaxone)
Chloramphenicol	Hepatocellular, cholestasis	Hepatic injury rare; also reported with chloramphenicol eye drops
Co-trimoxazole	Acute hepatitis, cholestatic hepatitis, granulomatous hepatitis, vanishing bile duct syndrome	Cholestasis recorded with trimethoprim alone; increased risk with HIV/AIDS
Erythromycin	Cholestatic hepatitis	Also with azithromycin, clarithromycin, roxithromycin, and telithromycin (acute liver failure, acute hepatitis)
Flucloxacillin	Cholestasis with bile duct injury; vanishing bile duct syndrome	Similar toxicity with oxacillin, cloxacillin, and dicloxacillin, but possibly less frequent and less severe
Minocycline	Acute and chronic hepatitis	Autoimmune hepatitis-type features (see text)
Nitrofurantoin	Acute and chronic hepatitis, granulomatous hepatitis, cirrhosis	Declining incidence; was common in long-term users (>6 months)
Penicillin G, penicillin V	Acute hepatitis, granulomatous hepatitis	Very rare; hypersensitivity features often present
Quinolones	Mainly cholestasis; rarely hepatitis and fulminant hepatic failure	Overall low incidence; granulomas (norfloxacin)
Sulfonamides	Acute hepatitis, cholestatic hepatitis, granulomatous hepatitis, vanishing bile duct syndrome	Similar toxicity with sulfones, sulfasalazine, and pyrimethamine-sulfadoxine
Tetracycline	Microvesicular steatosis	Rarely vanishing bile duct syndrome
Trovafloxacin	Fulminant hepatic failure	Now withdrawn

AIDS, acquired immune deficiency syndrome; HIV, human immunodeficiency virus.

Flucloxacillin

Over 600 cases of cholestatic hepatitis have been reported, mainly from Europe, Scandinavia, and Australia [122–126]. The frequency of liver injury is between 1 and 10 cases per 100,000 persons exposed [123,125]. Risk factors for flucloxacillin-induced liver injury are high daily doses, prolonged courses (>2 weeks), and age over 55 years [123]. Symptoms usually begin after 1–9 weeks, but can be delayed for up to 6 weeks after the antibiotic course is completed. Nausea, anorexia, and vomiting herald the onset of hepatitis, and are followed by jaundice and pruritus. Constitutional symptoms and weight loss are often striking. Blood tests reflect severe hepatitis with high AT, serum alkaline phosphatase, and GGTP values. Bilirubin levels can be markedly raised [125]. Liver histology shows cholestatic hepatitis with bile duct injury and ductopenia [124]. This is a very severe form of drug-induced liver disease with reported mortality up to 5%. Although most patients recover after drug withdrawal, prolonged cholestasis is observed in 10–30%, and in some cases this can lead to cirrhosis. Management is supportive in the acute phases, but with continued cholestasis ursodeoxycholic acid appears to benefit approximately two thirds of cases [70]. The postulation of an idiosyncratic basis for flucloxacillin liver toxicity is supported by the identification of reactive metabolites capable of inducing cytotoxicity in biliary epithelial cells [127]. However, more recent data showing an association between this hepatic adverse reaction and the presence of a specific HLA allele (HLA-B*5701) invoke the role of inappropriate T-cell responses as a basis for the hepatotoxicity [38]. On the other hand, patients with flucloxacillin-related DILI have certain polymorphisms within pregnane-X receptors, an important

nuclear receptor relevant to bile metabolism and canalicular secretion. Accumulation of the drug is a likely consequence [128]. If, as suggested, drug metabolites could induce adduct formation by covalent binding to cellular proteins and in turn, generating a robust immune response, then both these processes could contribute to DILI [129].

Cloxacillin and dicloxacillin

Some data indicate that cholestatic hepatitis may be less common and possibly less severe with cloxacillin and dicloxacillin, compared with flucloxacillin [126], but this remains unproven and controversial. In other respects, the liver injury and clinical course resemble the flucloxacillin reaction described earlier.

Amoxicillin-clavulanate (Augmentin®)

At least 150 cases of cholestatic liver injury have been attributed to amoxicillin-clavulanate [130,131]. The clavulanate component has been implicated because such toxicity is rare with amoxicillin, whereas other clavulanate–penicillin compounds such as Timentin® (ticarcillin-clavulanate) can cause cholestasis [132]. The frequency of liver injury has been estimated at 1.1–2.7 cases per 100,000 persons exposed [23]. Male gender, age over 60 years, and prolonged courses of treatment are risk factors for hepatic injury. A prospective study from Spain, where Augmentin accounts for 13% of cases of idiosyncratic DILI, noted that acute hepatitis was significantly more common in patients under 55 years (64%) and in those receiving short courses of treatment (mean of 8.8 days) as compared with cholestatic/mixed hepatocellular–cholestatic reactions, which were seen in patients over 55 years (40%) and with longer treatment regimes (mean of 12.7 days) [133]. Although there is a strong association with DRB1*1501-DRB5*0101-DQB1*062 [36,37], this haplotype does not appear to influence the clinical expression and outcomes of amoxicillin-clavulanate hepatitis. Persons with glutathione-*S*-transferase null genotypes (GSTM1, GSTT1), who are unable to detoxify electrophilic compounds, are also susceptible to amoxicillin-clavulanate hepatotoxicity (odds ratio (OR), 2.8) [134]. These genotypes also did not correlate with clinical expression or outcome.

Onset is within 6 weeks (mean, 18 days) of beginning therapy, and rarely up to 8 weeks after its completion. Hypersensitivity features such as fever, rash, and eosinophilia are seen in 30–60% of patients [130]. Bland cholestasis or cholestatic hepatitis is observed in biopsied cases [130]. Bile duct injury and perivenular bilirubinostasis with ceroid pigment deposits are often present. Other histologic features include hepatic granulomas, biliary ductopenia [135] and, rarely, cirrhosis [136]. The majority of patients recover but this can take up to 4 months. Fatalities are rare [136].

Quinolones

Transient AT increases are recorded in 2–3% of recipients but serious liver injury is infrequent, with the exception of trovafloxacin, which was withdrawn due to severe hepatotoxicity [137]. Among the reported cases, cholestatic liver injury predominates, usually occurring within 2–21 days [138,139]. Ciprofloxacin [139], norfloxacin [140], ofloxacin [141], gatifloxacin [142], and moxifloxacin [143] have all been implicated. Instances of hepatocellular injury have also been recorded, including acute liver failure with ciprofloxacin [139] and ofloxacin [141]. Acute cholestatic hepatitis followed by prolonged cholestasis and biliary ductopenia were observed with gatifloxacin [142]. Two elderly subjects with renal impairment developed acute hepatocellular injury with levofloxacin, presumably a consequence of altered pharmacokinetics because levofloxacin undergoes renal elimination [144].

Tetracycline

Tetracycline hepatotoxicity was characterized by microvesicular steatosis resulting in acute liver failure. Risk factors included the administration of high intravenous doses (usually >2 g/day) of tetracycline in pregnancy [42], or to men taking estrogens. The other important risk factor was renal failure, which reduces tetracycline clearance. The clinical features resembled those now seen in some cases of severe liver injury associated with HAART (see later section). Tetracycline hepatotoxicity is attributed to impaired hepatic lipid transport and inhibition of mitochondrial β-oxidation of fatty acids [2]. It is no longer observed now that tetracycline is contraindicated in pregnancy.

Oral tetracycline has been associated with two cases of prolonged cholestasis with bile duct injury; bilirubin levels remained elevated for nearly 3 years in one of these patients [92]. A recent population-based study found that current or past users of oral tetracycline were 2.7–3.7 times more likely to develop liver injury than controls, whereas persons on doxycycline were not at additional risk [145].

Minocycline

Minocycline, a semisynthetic tetracycline used in treating acne, is an important cause of drug-induced liver disease [146–148]. A systematic review identified 65 published cases, while 493 (6%) of over 8,000 adverse drug reactions attributed to minocycline reported to an international pharmacovigilance center were liver related [147]. Two modes of presentation are described. Those presenting with "early-onset" hepatitis (within 5 weeks)

exhibit prominent hypersensitivity features such as exfoliative dermatitis, lymphadenopathy, and eosinophilia; this is typical of the reactive metabolite syndrome (see Table 27.3). Among such cases, six of 16 were in persons of African-Carribean ethnicity, suggesting possible racial susceptibility. By contrast, long-term minocycline recipients (>12 months) present with a clinical and histologic picture simulating autoimmune hepatitis, with fever, arthralgia (>70%), antinuclear and/or smooth muscle antibodies (>90%), and raised globulins [149]. Other features of drug-induced SLE may be present, including arthritis and nephritis [148]. The absence of tissue eosinophilia in some cases may divert attention from a drug etiology. Nearly half (48%) of those affected have been women, most (94%) aged less than 40 years, and many of them in their adolescent years [150]. This reflects, in part, the age of those exposed to prolonged minocycline for the treatment of acne. Autoimmune hepatitis evolving to cirrhosis has been described in a 15-year-old male who continued using minocycline after the onset of symptoms [151].

Most patients recover completely after minocycline is discontinued. However, both acute and chronic hepatitis can be severe, with a few patients needing liver transplantation or dying from liver failure [148]. Occasional patients seemed to benefit from a short course of immunosuppressive therapy, but it is unclear whether spontaneous resolution would have occurred. Among fatal cases, additional factors such as myocarditis or concurrent viral infections may have contributed to the mortality [147].

It is unclear how minocycline induces AIH. The sera of one affected patient contained antibodies that reacted with 50 and 90 kD proteins expressed by human hepatoma cell lines, and with rat CYP proteins [152]. This raises the possibility of molecular mimicry between drug-induced autoantibodies and host proteins. The suggestion that minocycline could have triggered latent AIH seems less plausible because most affected patients recover without immunosuppression, and hepatitis occurs in those who do not exhibit the usual HLA haplotypes (HLA-DR3 and -DR4) associated with AIH [153].

Sulfonamides

Sulfonamides have long been implicated as causing acute and chronic hepatitis, cholestatic, granulomatous, or mixed reactions, and rarely fulminant hepatic failure [154, 155]. Persons with HIV/AIDS [156] are particularly susceptible, implicating immune dysregulation in the pathogenesis of the hepatic injury. On the other hand, 90% of patients with sulfonamide hypersensitivity in one series were identified as slow acetylators [157]; reduced activity of the acetylation pathway may contribute to defective detoxification of a sulfonamide metabolite, or facilitate the CYP-mediated production of a nitroso metabolite [158]. How this triggers an apparent immune-mediated liver injury is unclear.

Sulfonamide-induced liver injury occurs usually in the setting of systemic drug hypersensitivity (see Table 27.3). Symptoms begin early (within 2 weeks) of starting therapy. Associated features include a rash (occasionally with the Stevens–Johnson syndrome), vasculitis, lymphadenopathy, pancreatitis, neuropathy, pancytopenia, and renal failure [42,115].

Sulfonamide combinations: co-trimoxazole, sulfasalazine, fansidar

In addition to other types of sulfonamide-induced liver injury, prolonged cholestasis with biliary ductopenia has been attributed to co-trimoxazole [159]. Significant liver injury has occurred in recipients of sulfasalazine (see below) and pyrimethamine-sulfadoxine (Fansidar®) [160].

Sulfasalazine and mesalamine

Sulfasalazine has been associated with several reports of acute hepatitis [161]. Sulfasalzine-associated hepatic injury was observed more often in patients with rheumatoid arthritis than in inflammatory bowel disease [42, 162]. Reactions are often severe, and at least ten deaths have been recorded. Fever, rash, and arthralgia usually develop within 1–4 weeks. The liver injury was originally ascribed to the sulfonamide component (sulfapyridine). However, other 5-aminosalicyclic acid (5-ASA) compounds, including mesalamine (mesalazine) and olsalazine, can also cause acute hepatitis, implicating the 5-ASA moiety in at least some cases [163, 164]. Sulfasalazine- and mesalamine-related hepatic drug reactions occur with similar frequency (6 and 3.2 per million prescriptions, respectively) [162]. A more recent British surveillance study estimated the frequency of sulfasalazine-related DILI at 0.4% of patients treated [165]. Five of the ten reported cases in this series of patients with rheumatoid arthritis were of Afro-Caribbean ancestry (who only constituted ~12% of the cohort), highlighting possible ethnic differences in the risk of DILI. Mesalazine has also been associated with cholestasis [166] and rarely chronic hepatitis (one report) with hypergammaglobulinemia and antinuclear and smooth muscle antibodies [163].

Dapsone (4,4-diaminodiphenylsulfone)

Liver involvement occurs as part of a severe hypersensitivity syndrome ("sulfone syndrome"). This reaction, another example of the RMS (see above) is reported in up to 1.3% of dapsone recipients [167]. Most cases occurred

within 6 weeks. Liver histology shows acute hepatitis or cholestatic hepatitis. Hepatic granulomas or acute cholangitis are also described [168]. Resolution occurs within 4 weeks of stopping dapsone. Acute liver failure and death are uncommon but have been reported in severe cases. Corticosteroids have been used with success in some cases. However, untreated patients have also recovered whilst fatalities are recorded despite corticosteroid use [167].

Nitrofurantoin

Cases of significant hepatotoxicity still occur with this commonly prescribed urinary tract antiseptic. In a recent survey from Michigan, nitrofurantoin accounted for three of 32 (10%) cases of drug-induced hepatitis [169]. Acute and chronic hepatitis are the most characteristic hepatic syndromes, but varying degrees of cholestasis can occur, as do granulomas.

Nitrofurantoin-induced chronic hepatitis simulates AIH. It is seen only in individuals using nitrofurantoin for more than 6 months; in some cases, exposure has been intermittent and to very small doses of nitrofurantoin, such as those found in cow's milk [170]. Positive rechallenge is well documented, and may occur even after 17 years [171]. The clinical features are those of chronic hepatitis with fatigue, malaise, and nausea, with raised ALT, hypoalbuminaemia, and hyperglobulinemia. Antinuclear antibodies (80%) and smooth muscle antibodies (70%) are often present. Cirrhosis is present in up to 20% of patients with nitrofurantoin-induced chronic hepatitis. Nitrofurantoin is also an important cause of pulmonary fibrosis, and concurrent liver and lung injury are observed in about 20% of persons developing nitrofurantoin hepatitis [172].

Clinical recovery follows nitrofurantoin withdrawal, but the course may be prolonged and sometimes recovery is incomplete [2]. Corticosteroids are not routinely used, but seem to have accelerated recovery in occasional cases [173]. Monitoring liver tests is not likely to be clinically useful or cost-effective.

Erythromycins and other macrolide antibiotics

Erythromycin estolate was recognized as a paradigm of cholestatic hepatitis in the early 1970s, but similar toxicity, albeit far less commonly, has been reported with all the erythromycin esters (rarely with erythromycin base), and with other macrolides, such as clarithromycin [14]. The presence of fever and serum and tissue eosinophilia, along with an accelerated response to rechallenge, is consistent with immunoallergic idiosyncrasy, although intrinsic toxicity may also contribute [174].

Symptoms begin 2–25 days after commencing treatment [114]. Nausea, anorexia, vomiting, and abdominal pain are common. Abdominal pain may be quite severe and mimics acute cholecystitis. Before this syndrome was appreciated, inappropriate cholecystectomy was often performed. Dark urine (bilirubinuria), jaundice, and itch may also occur. The biochemical profile shows raised AT and alkaline phosphatase, with hyperbilirubinemia in severe cases. Peripheral eosinophilia can occur. Liver biopsies show intrahepatic cholestasis and portal inflammation, often accompanied by numerous eosinophils. Rare cases have been associated with chronic cholestasis, with biliary ductopenia on histologic sections.

Most recover after the drug is withdrawn, although liver test abnormalities may take up to 4 months to subside. Cross-sensitivity between erythromycin preparations has been reported [115]. Intravenous erythromycin lactobionate [175] has been implicated in a case of fulminant hepatitis.

Clarithromycin [176], azithromycin [177], and roxithromycin [178] have also been associated with cholestasis or mixed hepatocellular–cholestatic injury. Two reports of fulminant hepatic failure have accrued for clarithromycin; one of these patients was also receiving disulfiram (see also below) [179]. Forty-two cases of acute hepatocellular injury involving telithromycin, a ketolide antibiotic, were reported to the US Food and Drug Administration (FDA) [180]. There were four deaths and one patient required a liver transplant. The frequency of severe liver injury was estimated at one per 370,000 prescriptions. Most cases occurred early (2–43 days; median, 10 days) and presented with fever, abdominal pain, and jaundice. Ascites was present in 17%, and interestingly occurred even in resolving cases suggesting either severe liver injury or a possible serositis. Eosinophilia was present in 19%, raising a possibility of a hypersensitivity reaction [180].

Antituberculous drugs

Of the current antituberculous drugs, hepatotoxicity is an important complication of isoniazid, rifampin, and pyrazinamide, particularly when used in combination. Risk factors for liver injury are shown in Box 27.11. Except for a single report of cholestasis [181], ethambutol appears to be devoid of hepatic adverse effects. Among drugs used in former times, severe hepatocellular injury and cholestasis were recorded with *p*-aminosalicyclic acid, often as part of a multisystem syndrome with hypersensitivity features [2], and acute hepatocellular injury with prothionamide and ethionamide [2]. Ethionamide is still used rarely as a second-line antituberculous drug. Rifabutin causes liver enzyme changes, but these are usually part of hepatic adaptation; hepatitis has not been a problem.

Box 27.11 Risk factors for antituberculosis treatment-related hepatotoxicity.

- Age over 60 years
- Serum albumin <35 g/L
- Female gender
- Increased serum bilirubin, preexisting chronic liver disease
- Hepatitis B surface antigen positivity
- Genetic factors: HLA haplotype associations, glutathione-*S*-transferase mutations
- Multidrug regimens, particularly containing pyrazinamide; ?dosing regimen (daily use more toxic than thrice-weekly regimen)
- Excess alcohol consumption
- CYP2E1 status

CYP2E1, cytochrome P450 2E1; HLA, human leucocyte antigen.

Isoniazid

Frequency and risk factors

The hepatotoxic potential of isoniazid (INH) was established by landmark studies in the late 1960s and early 1970s [182–185]. Minor elevations (less than three-fold) of serum AT occur in 10–20% of subjects during the first 3 months of treatment. These abnormalities often settle with continued treatment and a progressive rise is uncommon. Jaundice occurs in approximately 1% of recipients of INH, but in more than 2% of those aged 50 years or older. In general, liver injury is rare in persons under the age of 20 but severe hepatitis can occur even in children; over a 10-year period (1987–97), eight children required liver transplantation in the United States (0.2% of pediatric liver transplants) [186].

Persons with a history of excessive alcohol use and women, especially of African-American and Hispanic ethnicity, are also at increased risk of toxicity [187]. The presence of hepatitis B, hepatitis C, HIV, or extrapulmonary tuberculosis (OR, 2.3) has been suggested as a risk factor [188]. The relative risk of developing hepatotoxicity if the person was hepatitis C- or HIV-positive was five-fold and four-fold, respectively, and 14-fold with HIV/HCV coinfection. Antituberculous therapy could be reinstituted after successful antiviral therapy against HCV. In another study, persons who were hepatitis B surface antigen (HBsAg) positive were more likely to sustain liver injury than HBsAg-negative individuals [187]. Further, those with positive replication status (i.e., HBeAg-positive) had a higher likelihood of developing hepatotoxicity with INH than those with "inactive" hepatitis B (7.7-fold increased risk). Discontinuation rates were also higher in the former group. Opposing views were expressed in a case–control study [189], in which malnutrition was the only determinant of hepatotoxicity.

Evidence on the influence of the acetylator phenotype has been conflicting. Initial studies conveyed the impression that fast acetylators were at increased risk, but other reports have suggested that the acetylator status is either not a predictor of toxicity [190] or that slow acetylators are more susceptible [191].

Metabolic idiosyncrasy is postulated as the basis for INH toxicity through the generation of a toxic metabolite, most likely hydrazine. This could explain why the risk of severe liver injury is enhanced by concomitant intake of rifampicin [192], and why pyrazinamide (which is structurally similar to both INH and nicotinamide (a dose-dependent hepatotoxin discussed later)) is also associated with an increased risk of more severe hepatotoxicity. Persons carrying certain genetic polymorphisms [193] in key enzymes (e.g., CYP2E1) that enhance reactive metabolite formation, or in those involved in detoxification processes (e.g., glutathione-*S*-transferase) [194], may be predisposed to INH-induced liver injury. An association with certain HLA haplotypes (absence of HLA-DQA1*0102 antigen, and the presence of HLA-DQB1*0201 antigen) was observed in North Indian patients (Box 27.11) [195].

Clinical features, outcome, and management

Prodromal features are those of nonspecific drug reactions or resemble viral hepatitis. Because of the often vague nature of these symptoms, patients taking INH should be warned (repeatedly) about the potential significance of malaise, fatigue, anorexia, nausea, vomiting, and dark urine. Jaundice is the presenting symptom in 10% of patients. Fever, rash, eosinophilia, or other manifestations of drug hypersensitivity are rare. Presentation is within 4 weeks of starting INH in 15% of cases; half the cases present within 2 months, but onset may be delayed from 3 to 12 months in the remainder. A marked rise of AT levels is common, with peak values as high as 4,000 IU/L. Liver biopsy shows lobular hepatitis, often with marked hydropic changes of hepatocytes, and bridging (submassive) or massive (panlobular) hepatic necrosis in fatal cases. Cases associated with apparent chronic hepatitis (without autoimmune features) and cirrhosis have been described rarely, mostly before HCV testing was introduced. These seemed to have been cases of chronic hepatotoxicity not chronic hepatitis, and patients generally recovered after discontinuation of the drug.

Rapid resolution of symptoms and liver test abnormalities occurs when INH is stopped before the onset of liver failure. The almost universal feature of cases leading to liver transplantation or fatal liver failure, from the early 1970s until the present time [184], is continued ingestion of INH after the commencement of symptoms. The case fatality of jaundiced patients exceeds 10%. Management of liver failure is supportive; corticosteroids are of no benefit. Liver transplantation has been performed

successfully [196]. In less severe cases, combination antituberculous treatment can be reintroduced. Guidelines vary as to the method of reintroduction; some advocate introducing one drug at a time (often at lower doses) whereas others have found no difference in the incidence of hepatotoxicity between patients with sequentially introduced drug regimens and those prescribed the full drug combination [197].

Prevention

In the United States, a 9-month course of INH is recommended for tuberculin-positive family members of patients with tuberculosis. Monitoring of ALT, aspartate aminotransferase (AST), and bilirubin is recommended at baseline in high-risk groups (HIV- or HCV-positive individuals, history of alcoholism, previous liver disease, pregnant women, and those presenting in the postpartum period) and during treatment (if baseline values are abnormal and in high-risk groups) [198]. It is now generally agreed that patients taking INH (or other forms of antituberculosis chemotherapy) should be advised to seek medical attention as soon as new symptoms develop, even if these seem nonspecific and relatively minor. Biochemical monitoring does not effectively substitute for clinical monitoring [198]. Thus, one study found that no more than 0.15% of over 11,000 clinically monitored patients receiving INH developed significant hepatotoxicity [198]. In contrast, the most noteworthy aspect of US case reports of liver failure attributable to antituberculosis chemotherapy that resulted in death or liver transplantation has been the failure of patients to report early symptoms, and/or the failure of health care workers to recognize the significance of those symptoms, thereby allowing continued intake of INH [199].

Rifampin

A meta-analysis showed that regimens combining INH and rifampin were associated with a higher incidence of hepatotoxicity (2.5%) than regimens without this combination (1.1%) [200]. Rifampin probably increases both the risk and severity of INH-associated liver disease [192]. The potent CYP-inducing properties of rifampin (exerted via pregnane-X receptors) could facilitate the production of reactive isoniazid metabolites.

On some occasions, rifampin may itself be hepatotoxic, as shown by cases with positive rechallenge and in situations where it is used alone (for example, to relieve pruritus) [201]. In the latter setting (typically in persons with PBC), the frequency of rifampin hepatitis (7.3–12.5%) may be higher than generally recognized [201]. Liver test abnormalities usually occur within 2 months, rarely as late as 14 months, and they mostly conform to a mild hepatocellular pattern [202]. The clinical features resemble viral hepatitis. Histologic features include focal hepatocellular necrosis and apoptosis (acidophilic bodies), especially in zone 3, portal inflammation, and cholestasis. Patients recover when rifampin is stopped. However, continued use of rifampin has been associated with jaundice and impaired hepatic synthetic function; histology showed severe interface and intra-acinar hepatitis together with bridging and confluent necrosis. Therefore, rifampin monotherapy should be initiated at a low dose (150 mg/day) and the dose should be titrated to the clinical response. Rifampin can also be associated with hyperbilirubinemia, possibly due to impairment of canalicular drug transporters [203]. This transport defect is unrelated to hepatocellular injury or cholestasis, and resembles reactions to cyclosporine.

Interstitial nephritis, described with an intermittent use of rifampin, can accompany the liver injury. Conversely, in one series of 60 patients with rifampin nephrotoxicity, concurrent hepatotoxicity was present in 25% [204].

Increased liver enzymes were reported in 12% of recipients treated with high-dose rifabutin, a rifamycin antibiotic. Serious liver injury has not been reported.

Pyrazinamide

Pyrazinamide causes dose-dependent liver injury. High-dose pyrazinamide (40–50 mg/kg) was associated with a greater frequency of hepatotoxicity than the doses used in current regimens (25–35 mg/kg). The concurrent administration of pyrazinamide with isoniazid-rifampin increases the risk of hepatotoxicity compared to dual therapy (OR, 2.8) [205,206].

Significant liver injury has been also documented with a recently approved 2-month rifampin and pyrazinamide regimen for treating latent tuberculosis infection (LTBI). Twenty-three cases of acute hepatitis were reported [207], all developing in the second month of treatment. There were seven deaths and the case fatality rate was estimated to be 0.9 per 1,000 treatment initiations. In some cases, patients continued taking their medications after the onset of symptoms. On the other hand, one patient developed symptoms 6 weeks after the drugs were stopped and eventually needed a liver transplant 1 month later. Many restrictions have been placed in using this drug combination for LTBI. Recommendations include frequent liver test monitoring, the absence of alcohol abuse or history of INH toxicity, and the need for monitoring by experienced physicians [207]. An alternative combination of pyrazinamide with levofloxacin has also fallen out of favor due to the increased frequency of side effects, including DILI [208]. The least toxic prophylactic regimen being explored is using rifampin monotherapy for 4 months; this also has better adherence rates than the 9-month INH-based schedule [208].

Perceptions of the excellent safety of antitubercular drugs in children have been challenged by a report of

Table 27.9 Liver injury associated with antifungal drugs.

Drug	Pattern of liver injury	Comments
Amphotericin	Hepatocellular	Rare
Fluconazole	Raised alanine aminotransferase in 25% of recipients, rarely hepatitis, and fatal hepatic necrosis	Patients with HIV/AIDS may be particularly susceptible
Flucytosine	Transient rise in aminotransferases (10%); hepatic necrosis	Dose-dependent liver injury
Griseofulvin	Cholestasis	Mallory bodies in mice; liver toxicity in humans is rare
Itraconazole	Acute hepatitis, prolonged cholestasis (two cases) with bilary ductopenia (vanishing bile duct syndrome); acute liver failure	Pulse therapy appears safer than continuous dose regimens
Ketoconazole	Hepatitis, cholestasis, fulminant liver failure, and cirrhosis (single case)	Frequency of liver injury approximately 20 per 10,000 persons exposed
Terbinafine	Cholestasis, vanishing bile duct syndrome, and acute liver failure	Frequency of liver injury approximately 1 per million persons exposed

AIDS, acquired immune deficiency syndrome; HIV, human immunodeficiency virus.

hepatotoxicity in Japanese children less than 5 years of age [209]. Ohkawa et al. studied 117 pediatric recipients of antituberculosis treatment. Of these, 8% developed hepatotoxicity; all eight were below 5 years of age and four were receiving pyrazinamide [209].

Antifungal drugs

Liver injury with the oral "azole" antifungal agents is best documented for ketoconazole (Table 27.9), but itraconazole, voriconazole, and fluconazole have been implicated in a few reports [210–213]. Itraconazole is largely perceived as being nonhepatotoxic. However, among more than 69,000 patients who received an oral antifungal agent, ketoconazole and itraconazole were most often associated with DILI; the respective relative risks were 228 and 17.7 compared to nonusers [214]. Further, an FDA public health advisory has been issued after receiving 40 reports of acute liver failure in association with itraconazole; there were 22 deaths and two patients needed liver transplantation. In view of the serious nature of possible (albeit rare) liver injury, a diagnosis of onychomycosis should be clearly established before starting antifungal treatment. Liver test abnormalities are frequent in patients receiving voriconazole but hepatocellular injury is usually mild and reversible [210].

Ketoconazole

Between 5% and 17% of recipients of ketoconazole develop abnormal liver tests. Previous estimates of symptomatic hepatitis varied between 0.7 and 5 per 10,000 persons exposed [210,215] but recent estimates are higher (~20 per 10,000 persons exposed) [214,216]. Biochemical tests most often reflect a hepatocellular pattern, but cholestatic or mixed hepatocellular–cholestatic reactions are also common. Women (female : male ratio 2 : 1) and persons over 40 years of age are particularly susceptible [210,216].

Symptoms develop within 6 weeks in 60% of patients, but can be delayed up to 6 months [210,217]. Jaundice occurs in 50% of those developing acute hepatitis, but up to one third may present with nonspecific symptoms such as nausea, anorexia, and vomiting. Fever, rash, eosinophilia, and other immunoallergic characteristics are uncommon. Liver injury is therefore hypothesized to be a sequel of metabolic idiosyncrasy [218]. Rarely, acute hepatitis and even anaphylaxis can occur rapidly within 1–3 days of rechallenge in persons who have previously received repeated courses [219]. Unintentional positive rechallenge can occur as late as 30 months after the first reaction [220]. Fulminant hepatic failure requiring liver transplantation has been reported [221].

The common histologic changes are diffuse hepatocellular necrosis, particularly evident in zone 3, but cholestasis can be prominent [210]. Recovery is usual after drug discontinuation but progressive liver disease can occur if the drug is continued beyond the onset of symptoms. Several instances of protracted jaundice have been described. Evolution to cirrhosis has been described after an initial episode of acute hepatitis [222].

Table 27.10 Liver injury associated with antiparasitic agents.

Drug	Pattern of liver injury	Reference
Albendazole	Raised aminotransferases (20%), acute hepatitis	Choi et al. 2008 [231]
Amodiaquine	Severe hepatitis (one in 15,000 exposed); dose dependent	El-Mufti et al. 1993 [232]
Antimonials	Steatosis	Zimmerman 1999 [2]
Artemisinin	Raised aminotransferases (0.9%), acute hepatocellular injury	CDC 2009 [233]
Atovaquone-proguanil	Transient alterations in aminotransferases	Looareesuwan et al. 1999 [234]
Chlorguanide	Acute hepatitis (single case)	Oostweegel et al. 1998 [235]
Mebendazole	Acute hepatitis, granulomatous hepatitis	Colle et al. 1999 [236]
Mefloquine	Transient rise in aminotransferases, fatty liver (one case)	Gotsman et al. 2000 [237], Grieco et al. 1999 [238]
Metronidazole	Hepatocellular, cholestasis (few cases)	Lam & Bank 1995 [239], Hestin et al. 1994 [240]
Ornidazole	Acute hepatitis, acute cholestatic hepatitis, chronic hepatitis	Tabak et al. 2003 [241]
Quinacrine	Acute hepatitis, cholangitis	Scoazec et al. 2003 [242]
Quinine	Granulomatous hepatitis (usual presentation), mixed hepatocellular–cholestatic reactions	Farver & Lavin 1999 [243], Katz et al. 1983 [244]
Thiabendazole	Cholestasis, vanishing bile duct syndrome, cirrhosis, sicca syndrome	Rex et al. 1983 [245], Roy et al. 1989 [246]

Terbinafine

An elevation of AT (>2 × ULN) is observed in 3.3% of those treated with terbinafine, but the frequency of symptomatic hepatitis is substantially lower (approximately two per 10,000 persons exposed) [223]. Hepatocellular mixed or bland cholestatic reactions have been reported. Most patients are aged over 50 years. No clear gender differences have been observed [224]. Onset is within 3–8 weeks but the symptoms can appear as long as 2 months after stopping the drug. Liver biopsies show hepatocyte degeneration and canalicular cholestasis with variable portal tract inflammation [84]. Prolonged cholestasis with progressive biliary ductopenia and portal fibrosis [225] can occur. Terbinafine hepatotoxicity has mimicked acute rejection in a liver transplant recipient [226]. Although a rare association, the FDA has received at least 16 reports of fulminant liver failure possibly linked to terbinafine [227]. Such an outcome has been estimated at one per 1 million persons exposed [223]. Recovery is usual with drug discontinuation. There have been anecdotal reports of ursodeoxycholic acid hastening recovery in a few protracted cases [228]. Terbinafine-associated liver injury is probably idiosyncratic because hypersensitivity features are unusual. The recent identification of a hepatotoxic metabolite of terbinafine is consistent with this hypothesis [229]. Liver injury associated with other antifungal drugs is summarized in Table 27.9.

Agents used to treat parasitic infestations

Pyrimethamine-sulfadoxine (Fansidar) has been linked with severe hepatotoxicity with a frequency of approximately one per 100,000 prescriptions. Deaths from hepatic necrosis have been recorded. Because liver injury has been attributed to pyrimethamine as well as sulfonamides (see earlier), it is not clear which component is responsible, or whether interaction between the two components is important [230]. The hepatotoxicity of other antiparasitic agents is summarized in Table 27.10.

Antiretroviral therapy

The frequency of hepatic injury with HAART, which now typically includes three to four agents, is at least 10%. The agents used can be broadly categorized as nucleoside (or nucleotide) reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors, protease inhibitors, and the more recent additions, integrase inhibitors and fusion (entry inhibitors) [247].

Nucleos(t)ide reverse transcriptase inhibitors

Mitochondrial toxicity is a group-specific feature [248]. The first-generation NRTIs, zidovudine, didanosine, and stavudine, have most often been implicated in causing DILI [249]. These agents inhibit mitochondrial DNA polymerase-γ, a key enzyme involved in mitochondrial DNA replication. An additional mechanism of hepatotoxicity may involve oxidative stress, the consequences of impaired oxidative phosphorylation and fatty acyl β-oxidation, and insulin resistance. Reported risk factors for mitochondrial drug toxicity among people with HIV infection include obesity, female gender, and absence of AIDS-defining illness [248]; one study was unable

to confirm the gender predisposition or influence of HIV status [248]. Mitochondrial toxicity is unusual with second-generation NRTIs such as lamivudine, tenofovir, and abacavir.

The hallmarks of mitochondrial hepatotoxicity are extensive microvesicular and/or macrovesicular steatosis, lactic acidosis (sometimes with a shock-like state), and liver test abnormalities progressing to acute liver failure. Asymptomatic hyperlactatemia is common, especially with stavudine [250], but life-threatening lactic acidosis/hepatic steatosis is rare; the estimated risk is 1–15 per 1,000 person-years of antiretroviral use [249]. Onset is usually within 6 months (range, 3–17 months) of starting treatment. The presenting symptoms are nonspecific: nausea, vomiting, diarrhea, dyspnoea, lethargy, and abdominal pain. In many cases there are extrahepatic manifestations, such as myopathy or peripheral neuropathy, and in severe cases pancreatitis and renal failure may follow the onset of the lactic acidosis and liver injury. The discontinuation of drugs is mandatory, but despite this deaths still occur [251].

Non-nucleoside reverse transcriptase inhibitors

Persons receiving nevirapine or abacavir (non-NRTIs) can develop severe hypersensitivity within 6 weeks, manifested by fever, rash, and eosinophilia. In such individuals, further use of these agents is contraindicated (see Table 27.3). Nevirapine has also been implicated in causing severe hepatotoxicity [252], highlighted by cases involving health care workers who developed liver injury after receiving nevirapine as part of postexposure prophylaxis [253]. The FDA received 12 reports of such hepatotoxic reactions during 1997 through 2000; seven recipients developed acute hepatitis, four had asymptomatic increases in serum AT, and one person developed acute liver failure. It is noteworthy that in some cases there was not adherence to the recommended 2-week dose escalation regimen [253].

Nevirapine is no longer recommended for postexposure prophylaxis and should be used with caution in individuals with liver disease and in pregnancy [253]. Sequential toxicity with nevirapine followed by efavirenz has been reported in an HIV/HCV coinfected person [254]. While one study reported a lower frequency of liver toxicity with efavirenz (8%) as compared with nevirapine (15%), there are other reports that did not show significant differences in hepatotoxicity [255]. A combination of genetic, immune, and host factors (low body mass index, pregnancy) have been identified that could help predict nevirapine reactions. In one predominantly Caucasian cohort, HIV-positive individuals with a CD4 percentage over 25% and who also carried the HLA-DRB1*0101 haplotype were at risk of developing liver toxicity with rash/and or fever. Screening for this HLA haplotype could prevent one in 14 potentially fatal reactions [256] among Caucasians with a CD4 percentage over 25%, but these findings have not been replicated [257]. Abacavir hypersensitivity is also associated with certain HLA haplotypes; the presence of HLA-B*5701, HLA-DR7, and HLA-DQ3 had a positive predictive value of 100% in predicting such a reaction [258].

Protease inhibitors

Elevated liver enzymes are common with this class of drugs, but clinical hepatitis is infrequent with the exception of ritonavir (see below) [259]. The agents most often implicated are ritonavir and indinavir. Indinavir and atazanavir may also be associated with unconjugated hyperbilirubinemia in 6–40% of treated persons resulting from inhibition of uridine diphosphate (UDP)-glucuronosyl transferase, a finding that is of no clinical consequence [260]. Severe acute hepatitis can rarely occur with indinavir and atazanavir [261,262]. The association with peripheral and/or tissue eosinophilia in some biopsied cases involving indinavir suggests an immunoallergic form of liver injury [262].

Acute hepatitis has also been reported in 3–30% of those prescribed ritonavir [263]. The illness runs a mild course, and the liver injury responds favorably to drug withdrawal. Rarely, acute liver failure may develop. In these cases, liver histology has shown severe microvesicular steatosis, cholestasis, and extensive fibrosis [263]. By contrast, the combination of low-dose ritonavir (200 mg/day) with other protease inhibitors is not associated with an increased frequency of severe liver injury when compared with protease inhibitors such as nelfinavir or efavirenz [263].

Two studies have addressed the potential impact of underlying chronic viral hepatitis on the toxicity of protease inhibitors. Although hepatotoxicity was more frequent, the liver injury was rapidly reversible in most cases; this suggests that there is no overall detrimental effect of protease inhibitors used in HIV/HCV or HIV/HBV coinfected persons [264]. However, the FDA has raised concerns about the hepatotoxic potential of a regimen involving low-dose ritonavir and tipranavir, a nonpeptidic protease inhibitor, especially in patients coinfected with HBV or HCV infections [265].

Newer anti-HIV drugs

Of these, raltegravir (an integrase inhibitor) and maraviroc and enfuvirtide (fusion inhibitors) have not been associated with significant hepatotoxicity. An earlier member of the latter group (aplaviroc) was associated with hepatotoxicity and has been withdrawn [266]. Raltegravir has been used successfully in patients who have experienced liver injury with other anti-HIV drugs [267].

Monitoring for HAART hepatotoxicity

A few general rules have emerged (Chapter 41). Baseline and serial monitoring of liver tests should be routine. Grade 4 hepatotoxicity (AT × 10 ULN or bilirubin 5 × ULN) warrants immediate discontinuation and use of an alternative drug combination. For lesser changes, frequent monitoring (1–2 weeks) is suggested, with treatment being continued only if there are no signs and symptoms of hyperlactatemia, hepatitis, or hypersensitivity [255].

Cardiovascular drugs

Angiotensin-converting enzyme inhibitors

Drug-induced liver disease is a rare but important complication of this widely prescribed class of drugs. Onset of liver injury has varied from 2 weeks to 4 years after starting treatment [268]. Cholestatic liver toxicity predominates. Recovery is usual but may be protracted (up to 6 months). Fatalities or advanced liver injury (ductopenia, cirrhosis) are infrequent [268].

Captopril is the oldest and possibly most hepatotoxic representative. Reactions to it and to enalapril usually manifest as cholestatic hepatitis, but hepatocellular or mixed hepatocellular reactions can occur both in adults and rarely in children [268]. Enalapril-related cholestatic hepatitis can culminate in biliary ductopenia. However, the short-term outcome seems favorable after drug withdrawal [269]. Hypersensitivity features such as fever, skin rashes, and eosinophilia can accompany captopril hepatotoxicity [268]. Fulminant hepatic failure has been attributed to lisinopril [270], while fosinopril has been associated with bland cholestasis [271]. Three instances of cholestatic liver injury have been recorded with ramipril; liver histology showed cholestasis, bile duct necrosis, bile extravasation, and ductular proliferation. Prolonged cholestasis was observed in one case (14 months); liver biopsy showed biliary cirrhosis [268].

Methyldopa

Methyldopa is much less prescribed now, but it retains a place in managing obstetric hypertension. The history of methyldopa-induced liver injury remains relevant because of the range of hepatic disorders it can produce. These encompass a spectrum of toxicity that includes: asymptomatic elevation of AT, acute hepatitis, chronic hepatitis, cirrhosis, bland cholestasis, cholestatic hepatitis, steatosis, and hepatic granulomas [15,272]. Ten percent to 30% have abnormal liver tests without overt liver disease, and these changes often resolve despite continuation of the drug [2]. Acute hepatitis occurs in less than 0.1% of recipients, usually within 3 months of starting methyldopa; up to 50% present within 2–4 weeks.

The clinical presentation resembles acute viral hepatitis, with anorexia, nausea, and vomiting, followed by jaundice. Serum AT levels are elevated (5–30 × ULN), with moderately raised serum alkaline phosphatase. Liver biopsies show focal or confluent hepatocellular necrosis, acidophilic bodies, and mixed portal/periportal inflammatory infiltrates. Bridging hepatic necrosis and massive hepatic necrosis can occur. Tissue or peripheral eosinophilia is rare. Most patients recover after withdrawal of the drug. However, mortality among patients presenting with jaundice is 10% or higher [272].

Chronic hepatitis or cirrhosis have been reported as the first clinical manifestations of liver injury [272]. In such cases, liver histology shows confluent areas of lobular collapse, periportal necrosis, and inflammation; the latter includes plasma cells and occasional eosinophils [272]. Fibrous septa and established cirrhosis may also be present. Older reports of middle-aged women with steatosis and cirrhosis attributed to long-term methyldopa therapy may have confused drug reactions with NASH [109].

The pathogenesis of methyldopa-induced liver injury has been attributed to either immunologic or metabolic idiosyncrasy; this dramatically illustrates the uncertainty of indirect criteria used to assign etiopathogenic mechanisms of drug-induced liver disease. Female preponderance, positive rechallenge, presence of autoantibodies (antinuclear antibody (ANA), less commonly smooth muscle antibody (SMA)), hypergammaglobulinemia, and a positive Coombs' test have been cited in favor of an immune basis, but many of these characteristics are also observed in patients receiving methyldopa but showing no signs of liver injury. Conversely, there is some evidence that methyldopa can be metabolized to a reactive intermediate (semiquinone or quinone) [2], and this could cause membrane injury or generate a neoantigen target for an immune-mediated hepatodestructive response.

Beta-blockers

The hepatotoxic potential of β-blockers is very low, but reactions to acebutalol, propranolol [2], metoprolol [273] (both hepatocellular), atenolol (hepatitis and cholestasis) [274,275], carvedilol (mixed hepatocellular–cholestatic) [276], and labetalol [277] have been described. Labetalol has been implicated in over 11 reports of acute hepatitis, including three fatal cases [277]; histology showed massive or submassive hepatic necrosis or chronic hepatitis.

Calcium channel blockers

Liver injury associated with the calcium channel antagonists (verapamil, nifedipine, diltiazem) is infrequent. Most reported cases were hepatocellular in nature [278], but other presentations include cholestasis, granulomatous hepatitis (diltiazem) [279], and steatohepatitis

(nifedipine and diltiazem) [280]. As discussed earlier, the association of calcium channel blockers with steatohepatitis may be fortuitous because hypertension is a component of the metabolic syndrome, which predisposes to NASH.

Diuretics

Of the currently used thiazides, chlorthiazide, [14], chlorthalidone, and hydrochlorthiazide [2] have been linked with rare instances of cholestasis. Ticrynafen (tienilic acid), a uricosuric diuretic, now withdrawn, was associated with acute and chronic hepatocellular injury. The case fatality rate was 10% [281]. Experimental studies of tienilic acid toxicity have been of interest because they provide an illustration of drug-induced autoimmune hepatitis. Circulating antibodies directed against hepatic CYP2C9 (which catalyzes oxidation of tienilic acid) were often present in the sera of affected patients [282]. There are a few anecdotal reports of acute hepatitis with spironolactone [14,283].

Hydralazine

Acute hepatitis with bridging necrosis is an occasional complication of hydralazine treatment. Granulomas [284] and cholestasis have also been described [285].

Other antihypertensive agents

Although their overall hepatotoxic potential appears low, cases of liver injury have accrued with all drugs within the angiotensin II receptor antagonist group. Most cases have occurred within 5 months of commencement. Tasosartan was withdrawn at the preregistration stage because of hepatotoxicity [286]. Losartan, valsartan, and candesartan have been implicated in causing acute hepatitis or cholestatic hepatitis [287,288]. Early resolution has been the rule after stopping these agents. Exceptions include two reports of prolonged cholestasis (for 1 year) following irbesartan-associated cholestatic hepatitis and biliary ductopenia accompanied by portal–portal fibrosis with candesartan [287]. Irbesartan has also been implicated in triggering an acute hepatitis with histologic features of AIH. Although autoantibodies were absent, the subsequent course, including steroid responsiveness and relapse with steroid withdrawal, was indistinguishable from AIH [288].

Antiarrhythmic drugs

Amiodarone

Raised ATs (1–5-fold) are observed in up to 25% of amiodarone recipients, but clinically significant liver disease occurs only in 0.6% [289]. The typical histologic lesion is a form of steatohepatitis indistinguishable from NASH and alcoholic liver disease [289,290], with microvesicular and macrovesicular steatosis, hydropic change, Mallory bodies, neutrophilic infiltrates, and pericellular and perivenular fibrosis. Micronodular cirrhosis is present in 15–50% [291] of cases. Other manifestations include granulomas, cholangitis [292], and acute liver failure. The latter may result from severe acute hepatitis or a Reye syndrome-like illness [293], which has been reported within a few days of starting treatment. Amiodarone can also cause acute hepatic injury [294], within hours to days after an intravenous loading dose. Rapid resolution follows drug withdrawal, although a single loading dose can be fatal. In a few cases, positive rechallenge has been observed. The vehicle (polysorbate 80) may be responsible for the hepatotoxicity associated with parenteral amiodarone preparations; the successful reintroduction of oral amiodarone in such cases supports this hypothesis [294].

The onset of amiodarone-induced chronic liver disease is delayed and insidious; most patients have received treatment for at least a year (median, 21 months) [14]. Symptoms include fatigue, weight loss, nausea, vomiting, and abdominal swelling due to ascites. Hepatomegaly, jaundice, and other features of chronic liver disease are evident. Liver test abnormalities are often seemingly minor, even in cases with hepatic decompensation. AT values are increased at least five-fold above normal, with the AST : ALT ratio close to unity; this differs from alcoholic hepatitis. There is a minor increase in serum alkaline phosphatase. In more severe cases there may be jaundice, hypoalbuminemia, and prolongation of prothrombin time. Chronic liver injury from amiodarone is associated with prolonged storage of the drug in the liver, which therefore appears radioopaque on computed tomography (CT) examination because of the iodine content of this iodinated benzofuran derivative [295]. Electron microscopy shows lysosomal inclusions, (representing phospholipidosis) in hepatocytes and other liver cells [296]. The presence of hepatocytes with granular cytoplasm has been suggested as an early marker of amiodarone toxicity [297].

In less severe cases, biochemical resolution occurs between 2 weeks and 4 months after stopping amiodarone. However, in advanced cases the mortality is high, with a progressive decline in liver function despite discontinuing treatment. A likely explanation is that tissue levels of the drug remain high for some time due to the prolonged retention of amiodarone and its principal metabolite *N*-desethylamiodarone in hepatic lysosomes.

Prevention of amiodarone toxicity by baseline and serial monitoring of liver tests has been suggested [298]. In many cases, this is impractical because of the high frequency of abnormal liver tests in people treated with amiodarone due to such factors as cardiac failure, other drugs, or NASH. Further, the presence of right heart failure or prior liver test abnormalities has not been shown

to engender a greater risk of hepatotoxicity [299,300]. Moreover, in one uncontrolled study the cardiac mortality after stopping amiodarone exceeded the total mortality among those who continued the drug despite suspected adverse reactions [291]. Another recommendation is measurement of serum amiodarone levels in long-term amiodarone recipients; ALT elevations were minimal in those with a serum amiodarone concentration of less than 1.5 mg/L [298].

The pathogenesis of phospholipidosis acquired from amiodarone is unclear, but may be related to inhibition of the lysosomal phospholipases, A1 and A2 [301]. Phospholipidosis is a constant association with steatohepatitis, but in animal studies appeared not to be related to it pathogenetically. A series of elegant studies from Hôpital Beaujon in Paris has shown that amiodarone, an amphiphilic cationic compound, accumulates in the anionic milieu of the mitochondrial matrix, and this leads to disruption of mitochondrial electron transport and impairment of fatty acid β-oxidation resulting in microvesicular steatosis, generation of oxidative stress, and lipid peroxidation [109,302].

Other antiarrhythmic drugs

Quinidine is an infrequent cause of hepatocellular injury. Fever and elevated AT levels occur 1–24 weeks after commencing therapy [303]. Liver histology shows hepatic necrosis and granulomas [304]. Recovery is usual after stopping the drug. Procainamide has been associated with hepatic granulomas, hepatocellular injury, and intrahepatic cholestasis [14,305]. Propafenone has been implicated in at least nine cases of predominantly cholestatic jaundice [306]. Most reported cases occurred within 2–6 weeks (range, 2–28 weeks). Liver biopsies showed portal tract inflammation with prominent cholangiolitis. No fatalities were recorded. Resolution occurred several months after drug cessation [306].

Anticoagulants

Unfractionated heparin and low molecular weight heparins can both cause elevation of serum ATs [307]. At least four cases of cholestasis have accrued with unfractionated heparin [307]. Of the currently used oral anticoagulants, the coumarin derivatives (warfarin, phenprocoumon, dicoumarol, acenocoumarol) have been associated with transient increases in liver enzymes, which usually settle without changing therapy. Occasionally, they may cause hepatocellular or mixed hepatocellular–cholestatic injury and bland cholestasis [307]. Several instances of acute hepatitis, including subacute liver failure requiring liver transplantation, have been reported from Germany, where phenprocoumon is used extensively [308]. An alternative coumarin or reintroduction of phenprocoumon can be considered in mild cases. However, reintroduction may be unsuccessful and further cross-reactivity with other coumarins can also occur. In such cases, long-term anticoagulation has been achieved with low molecular weight heparin. Phenindione is now withdrawn; it was associated with severe hypersensitivity reactions and liver injury in up to 10% of recipients [14].

Lipid lowering drugs

Hydroxymethylglutaryl-coenzyme A reductase inhibitors ("statins")

Overall, this class of drugs is not strongly associated with significant hepatic injury, although there appears to be discordance between literature reports and data contributed to drug safety surveillance authorities. The frequency of hepatotoxicity is estimated at approximately one per 100,000 patient-years of exposure; comparative figures for NSAID liver injury are between 2.2 and 50 per 100,000 patient-years of exposure [309]. One to three percent of statin recipients develop a dose-related rise in ATs [309]. These abnormalities settle rapidly with discontinuation of treatment and often also if therapy is not interrupted. Baseline liver test abnormalities do not connote a greater risk of liver injury with the statins. In one study the frequency of severe hepatoxicity (serum bilirubin >3 mg/dL or AT 10 × ULN or baseline values) between a cohort with and without baseline elevation of liver tests was 0.6% and 0.2%, respectively (*P* not significant) [310]. Further, the safety of statins in patients with compensated chronic liver disease has been reiterated [311,312].

Lovastatin [314], pravastatin [315], atorvastatin [316], and simvastatin [317] have been implicated in a few cases of cholestatic hepatitis. Interlobular bile duct injury and prolonged cholestasis have been noted with atorvastatin [316]. Acute liver failure has also been attributed to lovastatin. This is an extremely rare event (less than one per 1 million patient treatment years) and its frequency is similar to the background rates for idiosyncratic acute liver failure in the community. In one Italian study, fluvastatin was associated with the highest rate of hepatic reactions among the statins [318]. Autoimmune hepatitis has been associated with atorvastatin, but the drug appears to have unmasked preexisting AIH rather than induced immune liver injury by itself [319].

Although monitoring liver enzymes is often recommended, this is neither likely to predict toxicity [320] nor to be cost-effective. In the AFCAPS/TEXCAPS study, only 18 of 100,000 AT estimations performed were raised more than three times the upper limit of normal; in none of these instances, did the affected person develop hepatitis [320]. Like amiodarone, the benefits of continued treatment may outweigh the potential (but low) risks of liver injury.

Other lipid lowering drugs

Rare cases of acute hepatitis and cholestatic hepatitis have been attributed to the fibrates [321]. A few cases of chronic hepatitis with portal or bridging fibrosis have been described in persons also receiving statins [322]. Serologic and histologic features resembling AIH were observed but these resolved after the drugs were discontinued. Other than one report of hepatocellular injury with colestipol, bile acid sequestrants have not been implicated in causing liver injury [323]. Reports of AIH and cholestatic hepatitis have been attributed to ezetimibe [324]. Profound conjugated hyperbilirubinemia (bilirubin 648 μmol/L) has been described in a patient with probable nonalcoholic fatty liver disease (NAFLD) related cirrhosis and mild preexisting hyperbilirubinemia [325]. Ezetimibe, in combination with simvastatin, has been also implicated in a case of acute liver failure necessitating liver transplantation [326].

Nicotinic acid (niacin)

The hepatotoxic potential of nicotinic acid has been recognized for more than 60 years. This is a dose-dependent hepatotoxin with liver injury occurring at doses exceeding 2 g/day, but there are rare instances of low-dose (500 mg/day) sustained release (SR) niacin also causing fulminant hepatic failure [327]. Patients taking sulfonylurea drugs and those with preexisting liver disease, particularly alcoholic hepatitis, are at increased risk of nicotinamide hepatotoxicity [328,329].

Both the crystalline unmodified immediate release (IR) and SR preparations have been associated with liver injury [42,330]. SR preparations have improved bioavailability and are therefore more potent (about twice) than equivalent IR preparations; a dose reduction of 50–70% has been recommended [330]. Hepatotoxicity often occurred when the formulation of nicotinamide was changed without appropriate dose modification.

The symptoms of nicotinamide hepatotoxicity begin as early as 1 week to as long as 4 years after initiating therapy. Fatigue, malaise, anorexia, and jaundice are typical features, usually resolving completely when the drug is stopped. Liver biopsies show hepatic necrosis and centrilobular cholestasis. Well-documented cases of fulminant hepatitis have also been attributed to nicotinamide, some necessitating liver transplantation [42,330].

Niaspan is an extended release preparation of nicotinamide with IR characteristics. Its hepatotoxic potential appears to be minimal. Less than 3% of recipients developed elevated AT greater than two times above ULN; most were also receiving statins. Liver tests normalized with dose reduction [331].

Drugs used in the treatment of endocrine disorders

Oral contraceptive and anabolic steroids

Both oral contraceptive steroids and the 17-alkylated anabolic steroids are associated with cholestasis, vascular lesions, and hepatic neoplasms. However, the strength of associations varies with each condition. OCSs are clearly associated with benign hepatic neoplasms, whereas their association with HCC is controversial. By contrast, HCC is well documented in users of anabolic steroids. Likewise, hepatic and portal vein thrombosis is an established adverse effect of OCSs, but not with anabolic steroids. Other vascular lesions, such as peliosis hepatis, are more often observed with anabolic steroids than with OCSs.

Oral contraceptive steroids

Cholestasis

The frequency of cholestasis with OCSs is 2.5 per 10,000 women exposed. Genetic factors influence the frequency of this complication, with a particularly high incidence among women in Chile and Scandinavia. Individuals with a previous history of cholestasis of pregnancy are at high risk (50%). Mild prodromal symptoms, such as anorexia and nausea, followed by pruritus, develop 2–3 months after starting OCSs (rarely as late as 9 months). Serum alkaline phosphatase is moderately elevated, and this is accompanied by a transient increase in ATs, occasionally exceeding 10 × ULN; GGTP levels are often normal. The development of chronic cholestasis is extremely rare [84]. In general, recovery occurs within days to weeks after drug cessation. Hormonal replacement therapy (HRT) is safe in patients with liver disease, but jaundiced patients may experience an increase in bilirubin levels; they should be monitored with liver tests [84].

Benign neoplasms

Oral contraceptive steroids can induce enlargement of preexisting hemangiomas through their trophic effects on the vascular endothelium [332]. Recurrences of hemangiomas have also been described in patients with a history of previously resected lesions [333]. A role for estrogens in the pathogenesis of *focal nodular hyperplasia* (FNH) is plausible because these lesions occur principally in young women (up to 86%) [334]. However, unlike liver adenomas, an increased incidence of FNH has not been observed historically commensurate with the increasing use of OCSs after 1960. Further, FNH can occur in men and other persons not using OCSs [334]. A study of over 200 patients with FNH failed to show a relationship between OCSs or with size or number of FNH lesions [334]. Discontinuation of OCSs did not generally influence the size of FNH, and estrogen-dependent tumors were rare. The authors suggested that hepatic adenomas,

misclassified as FNH, could account for the apparent growth of FNH reported previously with OCSs.

The association between OCSs and *hepatic adenomas* was described nearly 40 years ago. The increasing frequency of this neoplasm paralleled the rising use of OCSs. In the 1970s and 1980s, the annual risk was approximately 3–4 per 100,000 exposed persons [26,102], but this risk is probably now lower with the lower dose estrogen preparations currently used. There is also a relationship with duration of OCS use, so that the risk (compared with nonusers) for long-term OCS users (>10 years) is increased 100-fold. Patients with liver adenomas usually present with a painless or tender right upper quadrant mass, or occasionally with hemoperitoneum secondary to hepatic rupture. Adenomas usually regress after OCSs are withdrawn [103]. However, surgery is recommended for larger lesions to avert possible rupture [335] and because of the small but definite risk of malignant transformation. To prevent hepatic adenomas, an OCS with lower estrogenic potency is preferred. Long uninterrupted periods of OCS use should also be avoided.

Hepatocellular carcinoma

The relative risk for HCC is increased two-fold among women who have ever taken OCSs, and it is increased seven-fold in long-term users (>8 years) compared with age-matched controls [27,336,337]. However, it must be emphasized that estrogen-related HCC is rare, accounting for less than 1% of primary liver cancer in western countries. In countries with a high prevalence of HCC, OCS use is not an independent risk factor owing to the far greater importance of chronic viral hepatitis and aflatoxin [27]. Median age at presentation is 30 years (versus 55 years with other cancers), and HCC occurs at least 5 years after starting intake of combination OCS. The tumors are well differentiated, including fibrolamellar HCC, and have a better short-term outcome than HCC due to other causes [14], but most are eventually lethal.

Anabolic steroids

Cholestasis

At high doses, anabolic steroids often produce reversible bland cholestasis, usually within 1–6 months of beginning treatment. Prolonged jaundice with ductopenia is a very rare complication [338]. Acute hepatitis is also an unusual sequel following self-ingestion of high-dose anabolic steroids [339].

Benign neoplasms

The association with hepatic adenomas is less robust. Many reports were from patients with Fanconi anemia [340], a disorder caused by genomic instability and a resultant high background incidence of neoplasms. However, reports of adenomas among female body builders and in persons taking anabolic steroids for other indications [341] show a probable etiologic association. Oral and parenteral androgens are both implicated [337]. Spontaneous hepatic rupture of a presumed hepatic adenoma has been reported; this patient was also receiving warfarin [342].

Hepatic adenomas were identified in three of 11 long-term users of danazol [343], all patients with hereditary angioneurotic edema. Similar lesions have been also described in patients with SLE and endometriosis. For this reason, surveillance ultrasonography is suggested in long-term recipients of danazol [343] and also for former anabolic steroid users; liver tumors have been described up to 24 years after steroid discontinuation [337]. These tumors can regress with androgen withdrawal [344], but this is not always the case and surgical resection may be required. Danazol has also been implicated in one case of acute hepatic failure in a patient with aplastic anaemia; the liver at autopsy showed diffuse necrosis [345].

Hepatocellular carcinoma

Several cases of HCC have been documented [346], but confounding factors such as viral hepatitis were not clearly excluded in earlier cases. Because some of these tumors metastasize very late and sometimes regress [347], doubts have been expressed about their true nature. It is sometimes difficult to distinguish well-differentiated HCC from adenomas [348]. Further, hepatic adenoma and HCC can coexist. Four reports of HCC have been attributed to long-term danazol use [349]; the underlying diseases were hereditary angioneurotic edema, SLE, and chronic idiopathic thrombocytopenic purpura. These liver tumors were large, well-differentiated carcinomas that did not show regression with drug withdrawal. Serum α-fetoprotein levels were normal in three of the four cases.

Estrogen receptor antagonists

The range of tamoxifen hepatotoxicity includes hepatic steatosis, NASH, and rare instances of submassive hepatic necrosis and even cirrhosis. Of these, the association with hepatic steatosis and NASH is most striking. In one series of 66 women with breast cancer who had received tamoxifen for 3–5 years, 24 showed radiologic evidence of hepatic steatosis [350]. In another study, liver biopsies were obtained from 15 women with moderate-to-severe hepatic steatosis (as designated by a liver : spleen CT ratio of <0.5); 14 showed NASH [351]. The median time to development of NAFLD is around 2 years [352,353]. Beyond 2 years, the incidence of NAFLD was not significantly different from subjects receiving placebo [352]. The metabolic profile of these women resembled that of most patients with NASH; half were obese, and hepatic steatosis correlated with increases in body mass index (BMI) [354]. In one multivariate analysis,

independent factors associated with NAFLD included tamoxifen use (OR, 8.2) and BMI (OR, 1.13) [353]. Tamoxifen can also induce hypertriglyceridemia, a risk factor for NASH. It therefore seems possible that tamoxifen may play a synergistic role with other factors like hyperlipidemia, obesity, and insulin resistance to cause NASH. A more direct role for tamoxifen has been postulated recently based on the results of a study showing inhibition of intrahepatic fatty acid synthesis, which contributes to steatosis [355].

Physicians should be aware of the high frequency of hepatic steatosis (approximately 30%), as determined by hepatic imaging, or NASH in women treated with tamoxifen. Monitoring patients for this adverse effect should include physical examination for hepatomegaly and liver tests. Some authors have also recommended that hepatic imaging (ultrasonography or CT) be performed annually [356]. Liver biopsy is required to establish the severity of the disorder, particularly if liver test abnormalities fail to resolve after stopping tamoxifen, and also to exclude metastatic breast cancer in difficult cases. Many cases improve after stopping tamoxifen [353]; the median time to normalization was 23 months [range, 5–56 months]. Tamoxifen remains a valuable agent for the treatment of breast cancer, and it is not yet clear whether treatment should always be withdrawn permanently. Preliminary experience with bezafibrate appears promising, with improvement in liver imaging characteristics and AT being demonstrated in a small series [351]. An alternate strategy is to attempt optimization of the metabolic milieu, especially in persons with preexisting hepatic steatosis because they have a threefold risk of developing abnormal glucose tolerance with follow-up [354].

Toremifene, a tamoxifen analog, is associated with a lower frequency (<10%) of steatosis or steatohepatitis [356]. Raloxifene, a selective estrogen receptor modulator, has been implicated in two cases of liver injury, one case with acute hepatocellular injury accompanied by eosinophilia, and NASH in the other. Causality could not be clearly established in the second case because this patient could have had preexisting NAFLD as there were features of the metabolic syndrome [357,358].

Antithyroid drugs

The estimated frequency of hepatotoxicity from antithyroid drugs is less than 0.5% [359]. Methimazole and carbimazole have rarely been incriminated in reports of cholestasis or cholestatic hepatitis [360]. By contrast, propylthiouracil reactions usually result in acute hepatitis [361,362], which can be severe. Hypersensitivity features are frequently present. Histologic appearances range from portal inflammation, hepatic granulomas, and cholestasis in milder forms of hepatitis, to submassive or massive hepatic necrosis in severe cases [362]. Chronic hepatitis is a rare complication. Ten acute liver failure-related deaths, including one in pregnancy, have been identified from a review of 36 published cases and an additional case report [361,362]. There is a higher than expected frequency of liver injury among children receiving propylthiouracil as compared with methimazole [363]. Most patients recover, but continued ingestion of the drug after symptoms develop can lead to a poor outcome.

Anesthetic agents

Halothane

In the first years after the introduction of halothane in the mid-1950s, most cases of postoperative massive liver necrosis were readily attributable to nonanesthetic causes, such as shock and hypoxia. However, cases of *unexplained massive hepatic necrosis after anesthesia* appeared to be more common after halothane than after the use of other agents [364]. The clinical syndrome was characteristic, and the temporal relationships between exposure to halothane and the development of liver injury were convincing. This evidence, together with the observations of recurrence after deliberate or inadvertent rechallenge eventually led to the acceptance of *halothane hepatitis* as a real entity. Rare cases of halothane-induced liver injury have also occurred after workplace exposure among anesthetists, surgeons, nurses, and laboratory staff, and after halothane sniffing for "recreational" use. Despite its rarity, the severity of cases of halothane hepatitis and the greater availability of equally acceptable agents have contributed to the virtual abandonment of halothane in industrialized nations, but halothane use remains relevant in many parts of Asia and Africa where cases of liver injury still accrue [365].

Two types of postoperative liver injury have followed the use of halothane. Minor elevations of ALT occur between the first and tenth postoperative day in 10–20% of patients, all of whom remain asymptomatic. The risk of hepatic enzyme abnormalities is higher after a second halothane anesthetic than for agents like enflurane, isoflurane, and desflurane [14,366]. This change in liver tests is rapidly reversible. Its relationship to the more severe lesions of halothane hepatitis is unclear. Potentially the changes could be explained by minor nonspecific toxic injury or by ischemia–reperfusion consequent to the profound reduction of hepatic blood flow that can be ascribed to halothane anesthesia. Halothane hepatitis is a rare, dose-independent hepatic drug reaction. After one halothane anesthetic, the frequency is very low (about one per 10,000 persons), but after two or more halothane exposures within a 28-day period, this increases to 15 per 10,000 exposed persons [14].

The reaction is unrelated to the type of surgery, duration of anesthesia, or to the presence of underlying liver

disease. Halothane hepatitis is extremely rare in children, and more severe in those over 40 years of age. Two thirds of cases are in women. A key feature is repeated exposure to halothane within a relatively short period of time; this is observed in 80% of cases. Further, many patients give a history of previous unexplained, delayed-onset fever, nausea, or jaundice in the postoperative period. Onset of liver injury is earlier after a repeat administration of halothane, and typically increases in severity with each exposure. Obesity is another risk factor, possibly related to increased halothane storage in adipose tissue or the induction of hepatic CYP2E1, an enzyme involved in halothane metabolism. The induction of CYP enzymes has been implicated experimentally in the pathogenesis of halothane-induced liver injury, and one study indicated that co-administration of antiepileptic drugs predisposed patients to halothane hepatitis [367]. A genetic predisposition to halothane-induced liver injury is evident in guinea pigs, and there are human data to invoke familial predisposition, such as instances of several closely related family members experiencing halothane hepatitis [368,369]. Likewise, with the use of an in vitro test that detected injury to peripheral blood mononuclear cells after exposure to phenytoin epoxide, increased susceptibility was noted among patients with halothane hepatitis and their relatives [370].

Fever is common in the first 48 hours after any major surgery, but fever associated with an adverse reaction to halothane is typically delayed until 3–14 days; occasionally a rash is noted. Jaundice occurs within 21 days of halothane exposure, with the median time to onset 9 days after a single anesthetic and 5 days after multiple exposures. Jaundice is usually preceded or accompanied by symptoms of hepatitis. The liver may be swollen and tender, but in severe cases it decreases in size as a result of extensive hepatic necrosis. Liver failure ensues, with bruising, bleeding, clouding of consciousness, and onset of hepatic coma or hepatorenal failure. Renal failure may develop as part of the hepatorenal syndrome, but acute tubular necrosis could result from a nephrotoxic effect of halothane, as has been better documented for methoxyflurane. Liver histology may show zonal, bridging, or panlobular necrosis.

In milder cases, symptoms may not be attributed to a halothane reaction. It is therefore crucial to elicit a full history of earlier anesthetic exposures to prevent fatal cases of halothane-induced liver injury. In more severe cases, hepatic failure may follow a fulminant course. Apart from acetaminophen hepatotoxicity, halothane was the leading cause of drug-induced liver failure until the mid-1980s. The reported mortality is 10–80%, but the higher rates reflect referral to specialized centers [371,372]. In most cases, though, symptoms resolve within 5–14 days and recovery is complete. Rare cases have been reported in which repeated exposure with halothane was implicated as the cause of chronic liver disease [373].

Although an immunologic mechanism has been invoked as part of the causative mechanism [6], immunosuppressive agents do not alter the clinical outcome. Management centers on intensive medical support. Liver transplantation must be considered in cases with a poor prognosis, as presaged by previous episodes, early onset, a serum bilirubin level of more than 200 μmol/L (10 mg/dL), and a prolongation of prothrombin time. In adults, halothane-induced liver disease could have been prevented in 90% of reported cases by attention to the previous history and adherence to safety guidelines. As many as two thirds of cases occur in individuals with a history of previous reactions to halothane, and the majority of cases are associated with repeated use of halothane within 28 days, especially in obese, middle-aged women.

Because halothane may leach out of the tubing of anesthetic devices, prevention of recurrence in sensitized patients requires that the equipment used for anesthesia should never have been exposed to halothane. Cross-sensitivity between halothane and other haloalkane anesthetics is best documented for methoxyflurane, an agent that is no longer used because of nephrotoxicity. Cross-sensitivity with enflurane is likely and for isoflurane is possible, as described later, but it has not been reported for desflurane and sevoflurane.

There is no readily available diagnostic test for halothane hepatitis. Some interest has surrounded use of an antibody test claimed to be 80% sensitive [8], but independent validation is lacking and the test is not widely available. Diagnosis therefore requires careful consideration of the present and past relationships of liver injury to halothane exposure, and excluding other causes of postoperative jaundice.

Other anesthetic agents

Other than halothane, general anesthetic agents in current use have rarely been associated with postoperative liver failure and massive hepatic necrosis. However, the evidence that such agents cause idiosyncratic hepatic drug reactions is strong only for enflurane [14,374,375]. The likelihood that individual haloalkane anesthetics can cause liver injury is related to the extent to which they are metabolized by hepatic CYP enzymes: 20% for halothane, 2% for enflurane, 1% for sevoflurane, and 0.2% or less for isoflurane and desflurane. Accordingly, the estimated frequency of enflurane-related hepatitis is much less than for halothane. The clinical syndrome is similar, with onset of fever within 3 days and jaundice in 3–19 days. At least one case was proved by positive rechallenge [374]. Two thirds of patients had previously been exposed to either enflurane or halothane.

The possibility that isoflurane could be responsible for DILI is more contentious. More than 50 suspected cases were reported to the FDA by 1986, but in two thirds of these another potential cause of liver injury seemed more likely [375]. In the remainder, isoflurane was only one of several possible factors that could cause hepatic damage. There have been a few case reports in which isoflurane seemed to be the likely cause of fatal hepatotoxicity, either because of repeated exposure to isoflurane in the absence of other potential causes of liver injury [376] or because isoflurane had been administered after possible previous sensitization to halothane [377] or enflurane [378]. Isoflurane should be regarded as a possible but very rare cause of hepatotoxicity; the pathogenic mechanism remains unclear.

The newer haloalkane anesthetics, sevoflurane and desflurane appear mostly free from adverse hepatic events, although rare reports have noted an association of liver injury after desflurane and also with sevoflurane [379], including three fatal cases with submassive hepatic necrosis [380]. Two of three cases involved reexposure to sevoflurane, raising the possibility of an immune-mediated hepatic reaction. The lack of trifluoroacetylated protein formation with sevoflurane no longer exonerates it from causing liver damage – another potential reactive metabolite (compound A) produced by the reaction of sevoflurane with carbon dioxide absorbents in the anesthetic circuit could be responsible [379]. Further, immunoglobulin G4 (IgG4) subclass antibodies to CYP2E1 and a 58 kD endoplasmic protein (ERp58) have been documented in cases of desflurane hepatitis [381]. Unlike patients with liver injury, a different subclass of antibodies (IgG1) has been demonstrated in asymptomatic anesthesiologists exposed to volatile anesthetics [382].

Drugs used in the management of diabetes mellitus

Thiazolidinediones

Troglitazone

Elevated AT levels were noted in 0.5–1.9% of clinical trial recipients [383] but reports of acute liver failure only emerged in the postmarketing phase [384]. Troglitazone was implicated in over 75 instances of fatal hepatotoxicity or liver failure requiring hepatic transplantation [384] before it was withdrawn in 1999. The frequency of acute liver failure was estimated at 240 per 1 million person-years of troglitazone exposure [384].

Troglitazone is metabolized by CYP3A4 and CYP2C8. Unlike the newer thiazolidinediones, it has a unique α-tocopherol side chain that is metabolized to a quinone. This raises the possibility of quinone-related liver injury, similar to acetaminophen or methyldopa hepatotoxicity. However, the quinone metabolite is less toxic than the parent compound and an alternative hypothesis implicating mitochondrial injury leading to cell death (via necrosis or apoptosis) is currently favored [386,387]. A potentially aggravating factor is bile salt-induced apoptosis resulting from inhibition of the bile salt export pump (Bsep) by troglitazone or by co-administration of cholestasis-inducing drugs such as glibenclamide [388]. Abrogation of inherent cytoprotective mechanisms (e.g., reduction in heat shock protein 70 levels) may also contribute [389]. Finally, features of drug allergy are unusual [383]. Taken together, the existing data are consistent with an idiosyncratic metabolic form of liver injury. However, the evidence for any of these pathways is weak and/or indirect and speculative, as reviewed elsewhere [385,386].

Risk factors for troglitazone hepatotoxicity have not been clearly defined. Reported cases were generally in older women and obese persons, but this represents the common phenotype of those with type 2 diabetes; detailed epidemiologic studies have not been performed [390]. In Japan, persons carrying mutations of CYP2C19 were overrepresented (50%) in a small series of eight patients with troglitazone-induced hepatocellular injury as compared to those without liver injury (13%) [391]. Likewise, Japanese subjects carrying the combined glutathione-*S*-transferase GSTT1-GSTM1 null phenotype were three times more likely to develop liver injury. However, this phenotype was present in only about 21–59% of those developing liver toxicity, suggesting that other factors may be important [391]. There is no evidence that preexisting liver disease or other drugs predispose to troglitazone hepatotoxicity, although a progressive course reported in one patient was attributed to concurrent simvastatin and troglitazone [392]. Interaction with NASH, which occurs in at least 20% of obese individuals with type 2 diabetes, has not been explored thoroughly [392]. However, many patients affected by troglitazone-induced liver injury had normal liver tests before starting troglitazone treatment.

The onset of troglitazone hepatotoxicity was often as long as 9 months, and sometimes more than 12 months, after starting treatment [393]; rare cases have had a much earlier onset (3 days) [394]. Patients presented with nausea, fatigue, jaundice, vomiting, and symptoms of liver failure. Progression from jaundice to encephalopathy, liver failure, or death was often rapid (average 24 days) [394], even after detection of biochemical abnormalities before the development of symptoms, and in some cases deterioration continued despite cessation of troglitazone intake. Only 13% survived without receiving a liver transplant [394]. Histology from biopsies, explants, or autopsies showed submassive or massive hepatic necrosis, with postcollapse scarring, bile duct proliferation, and some eosinophils [395]. Severe cholestasis has also

been reported [396], but this is sometimes observed in other cases of fulminant hepatic failure (e.g., valproate) and does not necessarily imply any different pathogenic mechanism. The progressive nature of liver injury has been highlighted by patients developing micronodular cirrhosis and portal hypertension after surviving the initial episode of liver injury [397].

Rosiglitazone and pioglitazone

By comparison with troglitazone, serious liver injury is infrequent with these second-generation thiazolidinediones [398]. In clinical trials, a raised ALT (>3 × ULN) was reported in 0.25% and 0.26% of patients treated with rosiglitazone and pioglitazone, respectively [398]. However, analysis of data derived from the FDA's Adverse Event Reporting System revealed 21 cases of significant hepatotoxicity involving both drugs. The onset of liver injury was within 3 months (median, 9 weeks). Rarely, liver injury can occur beyond 1 year of use [399]. Liver histology appearances have varied from cholestatic hepatitis [400], bile duct injury, or granulomatous hepatitis [401] through to submassive hepatic necrosis in fatal cases. Although earlier case reports noted resolution within 3 months in most cases, the recent FDA series highlighted a more ominous course with a case fatality rate of 81% [402]. Assuming that only 10% of adverse drug reactions are reported, the number needed to harm was calculated as 44,000 patient-years of exposure for rosiglitazone and 52,000 patient-years for pioglitazone. However, the validity of these data have been questioned by the manufacturers [403,404] who point to the lack of liver toxicity in clinical trials, the presence of confounding factors, and the known background risk of acute liver failure in patients with type 2 diabetes receiving oral hypoglycemic drugs (1/10,000 person-years) [405]. On balance, it does appear that the risk of liver injury is lower than that for troglitazone but occasional cases of hepatotoxicity can occur with these two drugs, as well as with any treatment for diabetes [405]. Rosiglitazone has been withdrawn due to its cardiac toxicity, and pioglitazone is being actively studied in trials involving patients with NAFLD.

The FDA recommends baseline liver tests when considering treatment with pioglitazone or rosiglitazone, as well as periodic monitoring. If ALT levels remain persistently elevated (>3 × ULN), the drug should be discontinued. As with isoniazid, symptoms suggestive of hepatitis should be assessed immediately. Individuals who have developed jaundice with troglitazone should not receive these thiazolidinediones, although cross-toxicity was not a problem in one reported case [400]. However, biochemical screening is not infallible; it cannot identify cases when there is rapid transition from normal AT to liver failure within 1 or 2 weeks [417]. Further, the troglitazone episode has highlighted the low compliance (<5%) with monitoring recommendations. Finally, the positive predictive value of abnormal liver tests is likely to be suboptimal in patients with type 2 diabetes [406] because of confounding factors such as NAFLD/NASH, chronic hepatitis C, or concomitant drug therapy.

Oral hypoglycemic drugs

Liver injury (typically hepatocellular) was common with older sulfonylureas, such as carbutamide, metahexamide, and chlorpropamide [2,14]. Of the currently used agents, tolbutamide, tolazamide, glibenclamide, and glimepiride have rarely been associated with cholestasis or cholestatic hepatitis [2,407–410]. Considering the structural relationship of sulfonylureas to sulfonamides, it is perhaps not surprising that hypersensitivity phenomena (fever, skin rash, eosinophilia) were present in some cases [410]. Most cases resolved after drug withdrawal, but chronic cholestasis progressing to VBDS has been described with tolbutamide and tolazamide [14]. Death from liver failure has been reported in two patients, one of whom had cirrhosis [410]. There are three reports of acute hepatitis induced by gliclazide, with hypersensitivity features present in one case [411]. Glibenclamide has also been associated with hepatocellular liver injury, and with hepatic granulomas [407].

Other antidiabetic agents that have been rarely associated with liver injury include metformin, repaglinide, acarbose, and human insulin (Table 27.11) [411–415].

Analgesics and drugs used to treat rheumatologic diseases

Acetaminophen

Acetaminophen (paracetamol) hepatotoxicity is an important cause of drug-induced liver injury in most countries [416,417]; currently it accounts for approximately 50% of cases of acute liver failure in the United States [417]. When used in recommended doses (1–4 g/day) acetaminophen is extremely safe [418], but single doses exceeding 15–25 g may cause severe liver injury that is fatal in up to a quarter of cases. Acetaminophen hepatotoxicity usually follows deliberate self-poisoning in an attempted suicidal or parasuicidal gesture. However, up to 30% of cases of acetaminophen hepatotoxicity admitted to hospital now result from "therapeutic misadventure" in which the daily dose has not greatly exceeded recommended safe limits but in which specific risk factors were present (see below) [419,420]. Daily doses of 2–6 g have been associated with fatal hepatotoxicity. Cases associated with actual therapeutic doses are rare and may represent inadequate/unreliable disclosure and documentation as well as other risk factors (see below) and late presentation.

Table 27.11 Liver injury associated with drugs used in diabetes mellitus.

Drug	Pattern of liver injury	Comments
Acarbose (glucosidase inhibitor)	Acute hepatitis; most reported cases from Spain (to date). Cholestasis with voglibose (another glucosidase inhibitor)	Positive rechallenge
Human insulin	Mixed liver injury; all reports from Japan. Resolved when changed to porcine insulin	Positive rechallenge
Metformin (biguanide)	Cholestatic hepatitis, cholestasis, acute hepatitis	Very rare
Repaglinide	Acute hepatocellular injury	Single report
Sulfonylureas	Acute hepatitis, cholestasis, cholestatic hepatitis, vanishing bile duct syndrome, granulomatous hepatitis	Usually reversible but fatalities reported
Thiazolidinediones:		
Troglitazone	Submassive or massive hepatic necrosis, cholestasis	Many fatal cases
Rosiglitazone	Acute cholestatic hepatitis, granulomatous hepatitis	Withdrawn from use
Pioglitazone	Acute hepatocellular injury, cholestatic hepatitis, fulminant hepatic failure	Few reports, fatalities rare

Risk factors

Acetaminophen causes dose-dependent liver injury but individual susceptibility is also important. Thus death has followed the ingestion of single doses of 7.5 g in adults or 150 mg/kg in children, whereas survival has been recorded with massive overdoses (50 g or more) [421]. Age alters individual susceptibility: liver injury has been described even in neonates, but children are considered to be relatively resistant to acetaminophen poisoning [423]. This has been attributed to differences in disposition and metabolism of the drug, but relatively larger liver and kidney sizes (as a proportion of total body weight) is an alternative explanation [423]. However, there is increasing recognition that both intentional and unintentional acetaminophen toxicity can occur in children. Prescribing errors have often been involved in these cases, including the use of adult doses, wrong dosing intervals, concomitant use of other acetaminophen-containing or hepatotoxic products, and host factors – particularly fasting, undernutrition, and drug–drug interactions. Rectal preparations of acetaminophen were implicated in a few cases. The bioavailability of acetaminophen in this formulation can vary up to nine-fold. Furthermore, the slower onset of action encourages repetitive use and consequent cumulative toxicity [424]. Although acetaminophen self-poisoning is more common in women, fatal acetaminophen hepatotoxicity occurs more frequently in men; this is largely due to alcoholism and late presentation [21].

The risk of liver injury is also influenced by concomitant medication use; in one study, NSAIDs and fibrates were associated with a decreased risk of fatal liver injury in women while statins were protective in both sexes. In addition, sympathetic stimulants (in men) and ethanol (in both sexes) increased the likelihood of such toxicity [425]. Conversely, concurrent use of angiotensin-converting enzyme inhibitors or angiotensin receptor II antagonists in younger subjects was associated with a reduced likelihood of death. Finally, Gilbert syndrome, – hereditary unconjugated hyperbilirubinemia due to a polymorphism in the promoter sequence of the conjugating enzyme, bilirubin UDP-glucuronyl transferase – lowers the threshold for acetaminophen hepatotoxicity due to lower activity of the glucuronidation pathway of acetaminophen metabolism.

Clinical features

The clinical evolution of liver injury follows three phases. In the first, anorexia, nausea, and vomiting are prominent. This may last from 12 to 24 hours before symptoms often subside, so that the person often feels well during the second phase, which lasts another 24 hours. Signs of hepatic failure, often with renal insufficiency, appear 48–72 hours after ingestion of acetaminophen (phase 3). Pain over the liver may be pronounced. It is accompanied by jaundice, hypoglycemia, coagulopathy, renal failure, lactic acidosis, and encephalopathy. Myocardial injury has also been described [421]. Renal failure can occur, with or without significant liver injury. In untreated subjects, death occurs between 4 and 18 days after drug ingestion, usually from cerebral edema and/or sepsis from multiorgan failure.

ALT levels are markedly elevated (2,000–10,000 IU/L); indeed, when the cause of acute liver injury is unclear (for example, in an unconscious individual or in a person with chronic hepatitis C), such high AT levels should arouse suspicion of acetaminophen toxicity. These high ALT values are unusual in viral hepatitis but may occur with ischemic hepatitis, and with other forms of DILI, including herbal toxicity (see later section). The following clinical and laboratory indices predicate a poor outcome of acetaminophen hepatotoxicity: prothrombin time >100 seconds, serum creatinine >300 μmol/L, a single

finding of a pH of <7.3 after adequate fluid replacement, or grade 3 or 4 encephalopathy in patients with a normal pH [426]. Other prognostic indices proposed include the APACHE II score and blood lactate, phosphate, and α-fetoprotein levels [427]. None of these indices has been widely adopted, and they await independent validation.

Histology

This includes zone 3 necrosis, with submassive (bridging) or panacinar (massive) necrosis in severe cases [14]. Inflammatory activity is inconspicuous and resolution occurs without fibrosis. Chronic liver injury has been described in patients consuming moderate doses of acetaminophen (2–6 g each day) for many months. Preexisting liver disease or concurrent alcohol intake were not always excluded in such individuals [14], and the rapid resolution after discontinuing acetaminophen abuse implies a form of chronic hepatotoxicity rather than a syndrome of drug-induced chronic hepatitis.

Acetaminophen toxicity with therapeutic doses ("therapeutic misadventure")

Enhanced susceptibility to acetaminophen toxicity is now well recognized both in alcoholic and nonalcoholic individuals. At least 200 instances of inadvertent hepatotoxicity have been recorded in heavy drinkers, which have followed acetaminophen intake for between 1 day and several weeks. In one series, 40% of individuals had taken acetaminophen in excess of 6 g/day [419], but 35% had taken doses below 4 g/day. In other reports, hepatotoxicity has occurred after as little as 1.5–2 g of acetaminophen a day. Data from the US Acute Liver Failure Group revealed that 60% of persons who had taken an unintentional overdose were using an acetaminophen–narcotic combination. It has been suggested that addiction (and, later, tolerance) to the narcotic component induces repetitive use that may not always be recalled or disclosed by the patient [417]. Alcohol enhances CYP2E1 activity, and accompanying malnutrition may contribute to GSH depletion. As in acute self-poisoning cases, AST and ALT are often 40–1,000-fold elevated above the upper limit of normal. This allows ready distinction of cases of acetaminophen hepatotoxicity from alcoholic hepatitis.

The importance of chronic excessive alcohol intake as a potentiator for susceptibility to acetaminophen hepatotoxicity has recently been challenged because in many case reports invoking such an interaction the person had clearly taken a hepatotoxic dose of acetaminophen [418]. Nonetheless, the authors' experience is that therapeutic misadventures with acetaminophen are a common and clinically important type of DILI [428]. A recent study of alcohol–acetaminophen interaction was conducted in an alcohol detoxification unit, with all trial participants receiving 1 g acetaminophen q.i.d. for 2 days or placebo [429]. No differences in hepatotoxicity were observed between the two groups. However, the investigators' assertion that acetaminophen can be safely used in patients with chronic alcohol abuse has been criticized on several grounds, including the selection of persons with serum AT levels of less than 120 U/L, which could have excluded a subset with significant underlying liver disease. The FDA recommends that persons taking more than three drinks of alcohol daily should not receive acetaminophen.

In nonalcoholic patients, fasting has emerged as one of the most important risk factors [430], particularly after near complete deprivation of carbohydrate intake for at least 48 hours. This is a particularly important risk factor for acetaminophen hepatotoxicity in young children. Fasting decreases the activity of hepatic conjugation pathways (both glucuronidation and sulfation) for acetaminophen elimination, increases CYP2E1 activity, and depletes hepatic GSH levels. However, others have contended that fasting has been overstated as a risk factor for acetaminophen hepatotoxicity [431]. They maintain that earlier studies were flawed because CYP2E1 and GSH measurements had not been carried out simultaneously; depletion of GSH is also accompanied by a decrease in CYP2E1 activity [432].

Concurrent medications (isoniazid, zidovudine, phenytoin, and other anticonvulsants) are also important. These agents compete for the "safe" conjugation pathways, and may also induce CYP3A4 (phenytoin) or CYP2E1 (isoniazid), the net effect of which is to promote CYP-mediated oxidation of acetaminophen to its reactive intermediate, *N*-acetyl-*p*-benzoquinone imine (NAPQI). However, human studies do not appear to support a phenytoin–acetaminophen adverse interaction. It is contended that phenytoin induces CYP3A4 only, a relatively minor metabolic pathway; further, it enhances glucuronidation, a key detoxification step [431]. Severe cardiopulmonary disease and renal failure have also been described as settings for acetaminophen hepatotoxicity [432], although the importance of metabolic factors or impaired (fluctuating) hepatic blood flow was not clarified in these studies.

Mechanism of liver injury and the basis for antidote therapy

Acetaminophen undergoes metabolism to glucuronide and sulfate conjugates, which are excreted in the urine. Normally, only a small proportion (~5%) of acetaminophen is oxidized to NAPQI. This reaction is catalyzed by CYP2E1 (which increases with fasting, INH, and chronic alcohol intake) and, to a lesser extent, by CYP3A4 (induced by anticonvulsants, several other drugs, and possibly alcohol). The small amounts of NAPQI formed with pharmacologic doses

of acetaminophen are readily detoxified by hepatic GSH; hepatorenal injury only occurs when GSH reserves are depleted. This provides a rationale for administering *N*-acetylcysteine and methionine, known thiol donors that can replenish intracellular GSH stores [421]. NAPQI binds cellular proteins, including oxidation of thiol groups in mitochondria leading to mitochondrial permeability transition [433]. The ensuing mitochondrial dysfunction generates profound oxidative stress and also facilitates peroxynitrate formation; the latter can also undergo covalent binding with key proteins and further aggravate mitochondrial dysfunction. These events culminate in nuclear and cytoplasmic swelling, cytoplasmic vacuolization, and mitochondrial swelling (oncotic necrosis or oncosis) of hepatocytes and sinusoidal endothelial cells. While apoptosis also occurs, oncosis is considered the principal mode of cell death [434].

Immune mechanisms (in particular, the hepatic innate system) have been increasingly implicated in acetaminophen hepatotoxicity. Acetaminophen-induced hepatocyte death leads to the release of free DNA and the subsequent activation of Toll-like receptor 9 (TLR-9). This activates nuclear factor κB (NF-κB) to increase production of interleukin 1 (IL1) and other cytokines and chemokines leading to neutrophil recruitment. The end result is the amplification of the initial toxic insult [435]. Depletion of natural killer cells (NK cells) and natural killer cell with T-cell receptors (NKT cells) also protects against acetaminophen liver toxicity in mice [436]. As expected, such reduction in liver injury was accompanied by decreased expression of proinflammatory cytokines and chemokines, and reduced neutrophil recruitment.

Prevention of liver injury

Adherence to the recommended therapeutic dose should be stressed as a public health measure. However, both prescribers and consumers should be made aware of the increased risk of acetaminophen toxicity in those who consume excess alcohol and in the setting of prolonged fasting, cardiorespiratory disease, and where other drugs are also being used. Recently, doubts have been expressed about the safety of acetaminophen in patients with underlying liver disease. Although acetaminophen is not contraindicated in such persons, the finding of detectable serum levels of acetaminophen in 20% of persons with acute viral hepatitis-related acute liver failure has raised questions about the safety of acetaminophen in both acute and chronic liver disease [437]. There is a public health need to revise downwards and promulgate altered dosage guidelines for acetaminophen when used in regular daily doses under any of the above high-risk circumstances.

To reduce the impact of impulsive self-poisoning, attempts have been made to restrict pack sizes and change the packing (to bubble packs) of acetaminophen by legislation in the United Kingdom. This has been associated with a 66% reduction in the number of liver transplants for acetaminophen overdose, as well as a reduction in mortality (by 21%) [438]. However, the impact has not been uniform, with only a transient decline in Scotland, and it remains unclear whether the decline in adverse outcomes is attributable to this measure alone [438].

Management of acetaminophen overdose

Gastric lavage with a wide-bore tube is performed in all patients presenting within 4 hours of acetaminophen overdose. Activated charcoal and osmotic cathartics are of no benefit. Serum levels of acetaminophen are often determined at baseline, but a 4-hour postingestion level is a more reliable predictor of the risk of liver injury [439]. The need for antidote treatment is assessed from blood acetaminophen levels by reference to well-established nomograms [440,441]. The 4-hour serum acetaminophen concentration may be misleading in overdoses with extended release preparations [442]; blood acetaminophen levels should be estimated after a further 4–6 hours [442]. In persons presenting with nonaccidental or staggered ingestion of acetaminophen, the total dose ingested and time from ingestion to presentation are important determinants of liver injury. In these cases, hepatotoxicity is likely if the time interval exceeds 24 hours or if the total acetaminophen dose exceeds 150 mg/kg (75 mg/kg in high-risk individuals); *N*-acetylcysteine (NAC) therapy is initiated beyond these thresholds [443].

NAC is the principal antidote. By functioning as a thiol donor, NAC replenishes hepatocellular cytosolic and mitochondrial glutathione stores, and also provides mitochondrial energy substrates [444]. Significant hepatotoxicity is rare when NAC is administered within 16 hours of drug ingestion. Beyond 16 hours, oxidation of acetaminophen to NAPQI is complete and thiol donation is unlikely to prevent hepatocyte or renal tubular cell death. Nevertheless, the benefits of NAC have been shown to extend to patients presenting up to 24 hours after the ingestion, even in patients with acute liver failure [445]. The beneficial effects of NAC in acute liver failure were attributed to improved tissue oxygen delivery [445], although this has been disputed [446].

NAC is administered intravenously in Europe and Australia, and by mouth in the United States [441,447]. The intravenous regimen is now approved by the FDA for persons who cannot or will not tolerate oral NAC.

Treatment protocol

An oral loading dose of 140 mg/kg is followed by 4-hour administration of half this dose for up to 72 hours. Oral

NAC can be discontinued after 48 hours in persons meeting specific criteria at that time (normal liver tests and undetectable acetaminophen levels) [448]. Intravenous administration involves a loading dose (150 mg/kg) of NAC given slowly over 15 minutes, followed by a 4-hour infusion (50 mg/kg) and a 100 mg/kg infusion over 16 hours. A third intravenous (48 hour) protocol has also been evaluated [449]. It has been suggested that, for high-risk patients, the incidence of hepatotoxicity is lower with the oral and 48-hour intravenous regimens when compared to 20-hour intravenous infusion, but direct comparisons have not been performed. A retrospective study using historical controls favoured the use of 20-hour IV NAC for patients presenting within 12 hours of ingestion, and a 72-hour oral NAC regimen for late presentations (>18 hours postingestion) [450]. Only the 20-hour intravenous protocol has been approved by the FDA.

Anaphylactoid reactions to IV NAC are relatively common (6–15%) [451]. They are generally mild and rarely lead to treatment discontinuation, but severe reactions can occur. Male gender and a family history of allergy (OR, 2.89) were identified as risk factors for the development of an anaphylactoid reaction [452]; paradoxically, high plasma acetaminophen concentrations [453] were found to be protective. Guidelines to deal with such reactions [451] include observation during drug administration (with appropriate antidotes readily available), discontinuing the infusion with the onset of angioedema or respiratory symptoms, the administration of antihistaminics, and resumption of the infusion after 1 hour if there are no persistent symptoms. For minor reactions, such as flushing, the infusion can be slowed or continued uninterrupted [451].

Other thiol donors such as methionine may be effective but must be administered within 10 hours. Methionine solutions need to be freshly prepared and often cause troublesome vomiting; their use is restricted to patients with hypersensitivity to NAC. Managing acetaminophen overdoses in pregnant women and in children is along usual lines; in one small study, NAC did not have any major adverse effects to the fetus [454].

Treatment of acute liver failure is described in Chapter 19. Assessment for liver transplantation requires consideration of the psychosocial factors underlying self-poisoning, and the likelihood of survival without transplantation. When liver transplantation has been performed, survival rates exceed 70% [455,456] and long-term outcomes appear reasonable. Still, there are real concerns with regards to noncompliance with medications and the prospect of repeated self-harm in survivors, stressing the need for detailed psychiatric evaluation and support before and after transplantation [455,456].

Dextropropoxyphene

Adverse drug reactions are rare with this opioid analgesic but important, particularly as liver injury may occur in the postoperative period or in other medically complex situations. At least 25 cases of cholestasis with bile duct injury have been reported [86], some proved by inadvertent rechallenge. The majority of those affected are women. Abdominal pain is the most impressive symptom. It is often severe and resembles pain from other causes of cholangitis with which it is often confused, particularly as jaundice is usually present. However, the large bile ducts appear normal at cholangiography. Liver histology shows portal tract edema, irregularity and necrosis of the biliary epithelium, bile ductular proliferation, and a peribiliary infiltrate of neutrophils and eosinophils. Cholestasis is usually evident. Recovery occurs within 1–3 months of stopping dextropropoxyphene.

Nonsteroidal anti-inflammatory drugs

NSAIDs are among the most commonly used prescription and nonprescription drugs, with up to 15% of the population using them in any one year. AT abnormalities are observed in up to 15% of patients taking NSAIDs, but overt hepatotoxicity is much less common with currently used agents. There are distinct differences in the frequency of hepatic injury associated with individual NSAIDs [457], with some agents being virtually free from reported hepatotoxicity and others such as bromfenac, benoxaprofen, and ibufenac having been withdrawn because of fatal liver injury (Table 27.12) [458]. Several pharmacoepidemiologic studies have attempted to categorize risk factors associated with NSAID-associated liver injury, and also to ascertain the hepatotoxic potential of individual NSAIDs. The results of these studies have been conflicting, which could be attributed to methodologic differences, including study settings (hospital versus ambulatory care) and study definitions. Focusing on studies with significant clinical events (i.e., hospitalization and death), Rubenstein and colleagues conducted a systematic review and found a slight (but not significant) increase in the risk of liver injury for current as compared with former NSAID users (OR, 1.2–1.7; P = NS) [458]. Contrary to general belief, women and the elderly were not found to be at greater risk. However, in another study carried out in an ambulatory care setting in France, gender differences were striking; after adjustment for confounding factors, there was a significant association between liver injury and NSAID use in women (OR, 6.49 (1.67–25.2)) [459]. Other risk factors identified in the Rubenstein review were rheumatoid arthritis (as compared with osteoarthritis) and use of nimesulide or sulindac.

Table 27.12 Liver injury associated with salicylates and nonsteroidal anti-inflammatory drugs.

Drug	Pattern of liver injury	Comments
Aspirin and other salicylates	Dose-dependent hepatocellular injury, Reye syndrome (febrile children)	Similar toxicity with sodium salicylate, mesalamine; diflunisal causes cholestasis
Bromfenac	Acute hepatitis, fulminant hepatic failure	Withdrawn from clinical use
Clometacin	Acute or chronic hepatitis, cholestatic hepatitis, cirrhosis, granulomatous hepatitis	Fatalities recorded. Female predominance (chronic hepatitis); some reported cases were later found to have hepatitis C virus infection
COX-2 inhibitors	Cholestatic hepatitis (few reports) with celecoxib or rofecoxib	Overall incidence low
Diclofenac	Acute hepatitis, chronic hepatitis	Women, older patients with osteoarthritis
Ibuprofen	Acute hepatitis, vanishing bile duct syndrome (rare); hepatotoxic potential is low	Hepatocellular injury with pirprofen, fenoprofen, flurbiprofen, and ketoprofen; cholestasis (tiaprofenic acid)
Indomethacin	Acute hepatitis, cholestasis, massive hepatic necrosis (rare)	Low incidence of toxicity
Naproxen	Mixed liver injury	Low incidence of toxicity
Nimesulide	Acute hepatitis, acute liver failure, cholestasis	Female predominance (with acute hepatitis)
Phenylbutazone	Acute hepatitis, cholestasis, granulomatous hepatitis	Similar toxicity as oxyphenbutazone
Piroxicam	Hepatocellular, cholestasis, massive/submassive hepatic necrosis (at least six reports)	Low incidence. Isoxicam and droxicam cause acute cholestatic hepatitis
Oxaprozin	Hepatocellular, fulminant hepatitis	
Sulindac	Cholestatic hepatitis (predominant), acute hepatitis	Hypersensitivity features common

COX-2, cyclooxygenase 2.

NSAID-associated hepatic disease encompasses a clinicopathologic spectrum from acute self-limited hepatitis, cholestasis, cholestatic hepatitis, and hepatic granulomas to fulminant hepatic failure, chronic hepatitis, and chronic cholestasis with ductopenia (Table 27.12) [458]. Consistent with the diverse chemical structures of NSAIDs, both immunologic and metabolic idiosyncratic mechanisms have been invoked.

Sulindac

Sulindac is structurally related to indomethacin but has been implicated more often in DILI. Cholestatic reactions predominate, although appreciable hepatic inflammation was noted in 25% of cases [460]. Sulindac has also been associated with acute pancreatitis, and this may cause extrahepatic biliary obstruction. Women appear more susceptible to liver injury (female : male ratio 3.5 : 1). Nearly 70% of affected individuals are over 50 years old [460]. Hypersensitivity features characteristic of the RMS are common; these include fever, eosinophilia, and cutaneous reactions, including Stevens–Johnson syndrome. Other proposed mechanisms of liver injury include inhibition of multiple hepatic transport proteins by the drug or its metabolites [461] and a synergistic interaction with tumour necrosis factor α (TNF-α); the latter is particularly relevant to the use of sulindac in inflammatory states [462]. Resolution often follows drug cessation but protracted cholestasis can occur. The overall case fatality rate is approximately 5%, attributable both to sequelae of systemic hypersensitivity reactions (Stevens–Johnson syndrome, nephrotoxicity) as well as the liver injury.

Ibuprofen

Ibuprofen rarely causes significant hepatic injury. In the few reported cases, the reactions have been hepatocellular or mixed hepatocellular–cholestatic [14]. There are three case reports of VBDS, including two pediatric cases with associated Stevens–Johnson syndrome; two of these were referred for liver transplantation and the other had prolonged cholestasis [463,464]. The presence of rash, fever, and eosinophilia is suggestive of an immunoallergic reaction. Rare cases of subacute liver failure have followed therapeutic doses as well as ibuprofen overdose. Explant histology showed submassive necrosis [463] or microvesicular steatosis [465]. Recent reports of acute hepatitis induced by ibuprofen ingestion among HCV-positive patients are of interest, but need to be confirmed [57].

Other propionic acid derivatives

Bromfenac has been implicated in several cases of acute liver failure resulting in death or necessitating liver transplantation (Table 27.12) [466]. In most cases, treatment had been instituted for more than 90 days before patients developed malaise and fatigue, followed by symptoms of severe hepatitis that progressed to liver failure over 5 to 37 days. There were no extrahepatic features of drug allergy. The liver pathology showed confluent or zonal necrosis and a predominantly lymphocyte infiltrate. Other propionic acid derivatives associated with liver injury include fenoprofen, ketoprofen, pirprofen, and tiaprofenic acid [15,42].

Diclofenac

Diclofenac has been implicated in more than 200 published cases of hepatic injury [467], some severe and with occasional fatalities. In several cases, causality has been proved by inadvertent rechallenge. Significant hepatotoxicity occurs in about 1–5 per 100,000 persons exposed [24]. Acute hepatitis or mixed hepatocellular–cholestatic injury is characteristic, but chronic hepatitis resembling autoimmune hepatitis has been reported [468]. Women, the elderly, and patients with osteoarthritis appear to be susceptible to diclofenac-induced liver injury. A comparative study of diclofenac with nabumetone found a better safety profile for the latter in elderly patients, with no patient developing an ALT elevation $>2\times$ ULN as compared to 4% in the diclofenac group [469]. However, the relevance of ALT elevation to cases of overt liver disease is unclear.

A prodromal illness or symptoms of hepatitis herald the onset of liver injury, most often within 3 months (range, 1–11 months) of starting diclofenac treatment. This is followed by jaundice and liver failure in severe cases. Fever and rash occur in 25%. Liver tests usually reflect acute hepatitis, but some features of cholestasis may be present; jaundice occurred in 50% of reported cases [467]. In some cases, the clinicopathologic features of ascites, hypoalbuminemia, and hyperglobulinemia indicate chronic liver disease. Liver biopsies usually show acute lobular hepatitis, but confluent necrosis may be seen in severe cases. In chronic cases, periportal inflammation (interface hepatitis) and fibrous expansion of portal tracts are noteworthy.

Resolution usually follows cessation of diclofenac, although fatalities have been recorded, particularly in elderly subjects. Corticosteroids were used successfully in a few cases of chronic diclofenac-induced hepatitis when no clinical improvement had been evident at 3 months after drug discontinuation [469]. Cross-sensitivity between NSAIDs is rare, but has been reported with ibuprofen in a person with a history of diclofenac hepatitis; another had an adverse reaction to tiaprofenic acid [468].

Pathogenic mechanisms involved in diclofenac toxicity include oxidative stress alone or in combination with mitochondrial injury [470]. In certain cases, immune mechanisms may be relevant, especially in those presenting with chronic hepatitis. The presence of diclofenac metabolite–protein adducts in liver tissue raises the possibility of liver injury resulting from direct disruption of critical cellular functions or by elicitation of an immune response to these neoantigens [471]. Supporting this hypothesis is the finding that certain polymorphisms favoring a T helper cell 2 (Th2) mediated antibody response were found more often among patients with diclofenac hepatotoxicity than in healthy controls and persons receiving diclofenac without hepatotoxicity [471]. Genetic susceptibility to diclofenac toxicity is supported by an increased frequency of polymorphisms within genes (*UGT2B7*, *CYP2C8*) encoding metabolic pathways involved in the formation and biliary excretion of bile (*ABCC2*) [472].

Piroxicam

The frequency of hepatic injury with this oxicam derivative is low [14]. Acute hepatitis and cholestasis have been described, and there have been at least six cases of massive or submassive hepatic necrosis [14]. The reaction appears to be dose independent, and immunoallergic features have not been conspicuous. Other oxicam derivatives implicated occasionally in cases of acute cholestatic hepatitis include isoxicam and droxicam [42].

Salicylates

Aspirin causes dose-dependent hepatic injury, usually with increased AT levels. Overt jaundice is uncommon, occurring in less than 5% of those affected [14]. Patients with hypoalbuminemia, juvenile rheumatoid arthritis, and SLE are especially susceptible to salicylate-induced liver injury [14]. Hepatitis resolves rapidly after drug withdrawal and usually does not recur after reintroduction of salicylates at a lower dose. Blood levels of salicylate should not exceed 24 mg/L [14]. Only one death has been recorded [473]. Focal necrosis and lobular inflammation are usual. Other salicylates can cause similar injury [474]. Epidemiologic studies have linked the use of aspirin in febrile children with Reye syndrome but concerted public health campaigns have lead to a major decline (near abolition) in incidence in this disorder.

Ticlopidine is not an NSAID but is discussed here with aspirin because it also inhibits platelet aggregation and is often used for similar indications. Unlike aspirin, ticlopidine-induced hepatotoxicity is dose independent and associated predominantly with cholestasis. More than 30 cases have been reported [475]. The

majority of cases have been in individuals over 55 years old. The onset of symptoms is between 2 and 12 weeks. Rarely, symptoms may commence 1 month after the drug is withdrawn [476]. Histology shows bland cholestasis but cholestatic hepatitis with bile duct injury has been described. Recovery is usual within 3–6 months, but occasionally may take longer than a year [477]. Eosinophilia in some cases and a positive in vitro T-cell stimulation study to ticlopidine have been cited as favoring an immune basis for the liver injury [477]. An association with several HLA subtypes has been reported in Japanese patients; of these, HLA-A*3303 has been linked to cholestatic pattern of liver toxicity (OR, 36.5) [478]. This allele is more common in Asians (11.7%) than in Caucasians (0.53%) and its role in non-Japanese cases awaits clarification.

Although corticosteroids appear to have aided recovery in some cases, their routine use cannot be justified in this older group of patients (mean age, 67 years). One report of cytomegalovirus-associated acute hepatitis following corticosteroid therapy in this setting is a timely reminder of the risks associated with steroid use in this group [479].

Clopidogrel has been successfully substituted for ticlopidine in patients with cholestasis but it is also associated with hepatocellular or hepatocellular–cholestatic injury [480]. Of the 13 reported cases, the onset was between 3 days and 6 months. Positive rechallenge has been documented. All recovered within 1–6 months [480].

Cyclooxygenase 2 inhibitors

In clinical trials, the frequency of hepatic dysfunction (0.8%) with celecoxib was not significantly different from placebo-treated (0.9%) subjects [481]. A recent pooled analysis of 41 studies reiterated these findings and highlighted the lower frequency of hepatic adverse events (1.1%) as compared with diclofenac (4.2%) [482]. However, celecoxib has been now incriminated in a few reports of severe acute cholestatic hepatitis [483]; two patients developed acute liver failure and needed liver transplantation [483]. Another had alcoholic cirrhosis, which raises questions of celecoxib safety in persons with reduced hepatic reserve [484].

Symptoms suggestive of liver injury develop between 4 days to up to 3 weeks after commencing celecoxib. Pruritus, jaundice, and malaise are accompanied by a mixed hepatocellular–cholestatic biochemical profile. Peripheral eosinophilia has been observed in some cases. Resolution occurs within 4 months of discontinuing celecoxib.

Rofecoxib, now withdrawn due to cardiovascular toxicity, was associated with a few reports of cholestatic hepatitis, some prolonged [485].

Nimesulide, another NSAID with preferential COX-2 selectivity has also been associated with several instances of hepatocellular injury, cholestasis, and occasional cases of fulminant hepatic failure [486–488]. Six of 32 patients with acute liver failure of unknown cause presenting to an Irish liver transplant unit between 1994 and 2007 had received nimesulide in the past 6 months; causality assessment implicated this drug in all six cases [487]. Five were middle-aged women, but equal gender distribtion was noted in a report from an Italian registry. The latter report emphasized the high frequency (78%) of patients presenting with jaundice (34% for other drugs) among the nimesulide group. Three of their 14 cases developed signs of liver failure. Interestingly, many of the 14 cases had received a single dose of the medication [488].

Allopurinol

Granulomatous hepatitis is a typical feature of liver injury with allopurinol [489]. Other manifestations include increased ATs in asymptomatic persons, cholestasis, and hepatocellular injury, which can be occasionally severe enough to progress to fulminant hepatic failure. Severe centrilobular hemorrhagic necrosis resembling Budd–Chiari syndrome has also been described [490]. Exfoliative dermatitis, fever, eosinophilia, interstitial nephritis, and microangiopathic vasculitis may be present in these cases. In a few severe cases, corticosteroids have been used with apparent benefit [491].

Benzbromarone, a uricosuric agent, now withdrawn, has been implicated in causing chronic hepatitis, cirrhosis, and fulminant hepatic failure [42]. However, this has been disputed by a review of published data by Lee et al., where only one of four published cases had incontrovertible evidence of DILI [492].

Gold

Hepatic toxicity of gold (gold sodium thiomalate) is usually characterized by mild cholestatic hepatitis. Onset is within 1–4 weeks. Fever, rash, and eosinophilia are often present. Liver biopsies show canalicular cholestasis with minimal hepatocellular degeneration or portal tract inflammation. Resolution is the rule; fatalities are extremely rare [42]. Rarely, prolonged cholestasis with ductopenia and other accompanying features of VBDS (sialadenitis, sicca syndrome) can occur [493]. Hypersensitivity features such as skin rash and peripheral and tissue eosinophilia were present in this case.

Hepatocellular injury is less common, but can be severe, resulting in death [494]. This severe reaction to gold appears to be dose dependent and is more likely the consequence of metabolic toxicity than for cases presenting with cholestatic hepatitis. Submassive or massive hepatic necrosis with a mixed inflammatory infiltrate is observed on liver biopsies. Resolution can be slow [495]. Gold accumulates in the lysosomes (“aurosomes”) in persons undergoing long-term crysotherapy. It has been proposed that liver injury occurs when the lysosomal

storage capacity for gold is exceeded [495]. Other gold compounds containing the same aurothio side group as gold sodium thiomalate (gold thiosulfate, aurothioglucose) are also associated with similar liver injury. Recently, acute cholestatic hepatitis has been reported following an overdose of gold potassium cyanide, a non-aurothiogold compound used in electroplating [496].

Penicillamine

Used in the treatment of Wilson disease and as a disease-modifying agent in rheumatoid arthritis, D-penicillamine has been associated with a range of side effects from nephrotoxicity to provoking autoimmune phenomena. Liver injury is less frequent. Most reports are of cholestatic hepatitis in association with hypersensitivity features [42]. These occur within 2 weeks of commencing treatment. The prognosis is good with resolution occurring within a few weeks after cessation of penicillamine; fatalities are rare [497].

Leflunomide

Leflunomide is a disease-modifying antirheumatic drug. Its principal metabolite, A771726, is highly metabolized and eliminated via the liver. CYP2C9 is probably involved in its metabolism. In clinical trials, 5% of recipients showed mild, reversible changes in AT levels. Concerns about significant liver toxicity were first highlighted by the European Medicines Evaluation agency, which had received 296 reports of hepatic adverse effects, including 15 cases of liver failure with nine of these cases having a fatal outcome. However, assigning a cause–effect relationship has proved problematic because many (78%) were receiving other potentially hepatotoxic drugs, including NSAIDs and methotrexate. Further, other confounding factors were present: alcohol use, abnormal baseline liver tests, heart failure, and failure to comply with recommended doses. The low hepatotoxic potential of leflunomide compared with methotrexate was confirmed in two large cohorts involving over 40,000 patients [498]. A special committee of the FDA concluded that the risk of hepatotoxicity was small with leflunomide, thereby permitting its continued usage [499].

Special caution is advised when leflunomide is used with methotrexate. AT increases are seen more often in persons receiving this combination (22%) as compared with recipients of methotrexate plus placebo (5%). However, normalization of AT was achieved without dose change (59%) or a single dose decrease (29%) [500]. Nevertheless, continued vigilance is necessary because early changes of cirrhosis were observed in a patient taking both these drugs [500]. It has been also suggested that persons carrying a low metabolizing activity polymorphism (e.g., CYP2C9*3) may be at an increased risk of liver injury [501].

The manufacturer recommends baseline and monthly monitoring of liver tests for the first 6 months and thereafter every 2 months. Minor ALT changes ($<2\times$ ULN) should prompt retesting in 2–4 weeks. Dose reduction (from 20 to 10 mg) is suggested if ALT increases above $2\times$ ULN. Increases of ALT greater than $3\times$ ULN or persistent ALT abnormalities should prompt drug withdrawal, together with the use of cholestyramine to facilitate the elimination of leflunomide.

Oncotherapeutic and immunosuppressive drugs

Systemic malignancy is commonly associated with abnormal liver tests [14]. In addition to the direct and indirect effects of neoplastic cells, radiotherapy, sepsis, concurrent medication, viral hepatitis, parenteral nutrition, and hypoxemia may contribute to hepatic liver test abnormalities. This makes it difficult to interpret changes or assign liver toxicity to individual drugs. Interactive toxicity between individual oncotherapeutic drugs also merits special consideration. This is exemplified by the development of hepatic SOS (VOD) with combination chemotherapy, and the potentiation of doxorubicin hepatotoxicity by 6-mercaptopurine.

Antimetabolites and antibiotics are more often linked to significant liver injury than are alkylating agents. Hepatocellular injury is characteristic, but a wide range of histologic lesions may be encountered [15,502]. Steatosis is often present, especially with dactinomycin, L-asparaginase, and methotrexate. Cholestasis is typically associated with the hormonal agents, but can be a feature of liver injury with azathioprine and IL2. A range of vascular lesions, including peliosis hepatis, SOS (VOD), and NRH have been observed, usually in the setting of bone marrow or renal transplantation. Chronic hepatitis can rarely occur with doxorubicin and azathioprine, but cirrhosis is distinctly uncommon, except with methotrexate (discussed below). The hepatotoxicity of commonly used oncotherapeutic agents is summarized in Table 27.13. More in-depth discussions of the subject can be obtained from recent reviews and texts [2,15, 502,503].

Methotrexate

The hepatotoxic potential of methotrexate was recognized soon after it was introduced in the 1950s for the treatment of acute childhood leukemia; significant hepatic fibrosis and cirrhosis were reported in up to 25% of patients [14]. Methotrexate is now used more often in a low-dose weekly regimen for treating rheumatoid arthritis, psoriasis, and other immunologic conditions, including inflammatory bowel disease. The hepatoxicity of low-dose regimens is much lower, but is still debated [504,505]. Although ultrastructural changes can occur,

Table 27.13 Liver injury associated with oncotherapeutic drugs.

Drug	Pattern of liver injury
Antimetabolites	
Azathioprine	Cholestasis, vascular injury, peliosis hepatis, SOS (VOD)
Capecitabine	Hyperbilirubinemia (likely related to hemolysis)
Cytosine arabinoside	Raised AT (with low doses), cholestasis, or hepatocellular injury (with high doses)
5-Fluorouracil	Rare liver injury with intravenous and intra-arterial route (particularly when associated with levamisole); hepatic steatosis; floxuridine causes PSC-like lesions
Gemcitabine	Transient AT changes, cholestatic hepatitis leading to acute liver failure, SOS (VOD)
6-Mercaptopurine	Bland cholestasis, hepatocellular or mixed injury, fatal hepatic necrosis (rare)
Methotrexate	Steatosis, hepatic fibrosis, cirrhosis
6-Thioguanine	SOS (VOD) (in combination treatment), peliosis, hepatocellular injury, or cholestasis (rare)
Antibiotics	
Bleomycin	Low incidence of liver toxicity
Cyclosporin	Mild cholestasis (more accurately – impaired bilirubin transport), usually reversible with dose modification
Dactinomycin	Hepatopathy–thrombocytopenia syndrome (with vincristine); clinically resembles SOS (VOD)
Daunorubicin	SOS (VOD) (in combination treatment)
Doxorubicin	Rarely acute or chronic hepatitis; hepatotoxicity enhanced by 6-mercaptopurine
Mithramycin (plicamycin)	Raised AT (in up to 100%); occasionally centrilobular necrosis, steatosis
Mitomycin C	SOS (VOD), steatosis
Mitoxantrone	Minor increase in AT
Spindle inhibitors	
Paclitaxel, docetaxel	Minor increase in AT
Vincristine	Transient liver enzyme changes; synergistic with irradiation in producing liver injury
Platinum	Liver injury rare
Carboplatin	Acute liver failure (one case), SOS (VOD) (with etoposide)
Cisplatin	Raised AT (high doses), steatosis, cholestasis, minor hepatic necrosis
Oxaliplatin	SOS (VOD)
Topoisomerase inhibitors	
Etoposide	Frequent liver test abnormalities (high dose); occasionally severe hepatitis (standard dose)
Irinotecan, topotecan	Abnormal liver tests; hepatic steatosis and nonalcoholic steatohepatitis (irinotecan)
Alkylating agents	Low incidence of liver injury with this group
Busulfan	Cholestasis, porphyria cutanea tarda, NRH, SOS (VOD) (in combination treatment)
Capecitabine	Hepatocellular
Chlorambucil	Hepatocellular, cholestatic hepatitis, acute liver failure
Cyclophosphamide	Hepatocellular, SOS (VOD) (in combination treatment), steatosis
Ifosfamide	Liver injury rare, cholestasis (two cases)
Melphalan	Minor increase in AT
Thiotepa	Severe hepatotoxicity resembling phosphorus poisoning (rare)
Nitrosoureas	
BCNU, CCNU, streptozotocin	Minor increase in AT; rare fatalities from liver injury (BCNU, CCNU)
Hormonal agents	
Aminoglutethamide	Cholestasis
Flutamide	Cholestatic hepatitis, fulminant hepatic failure; megesterol acetate associated with cholestasis
Tamoxifen	Steatosis, NASH, rarely submassive hepatic necrosis and cirrhosis
Miscellaneous drugs	
Amsacrine	Hepatocellular injury, cholestasis, rarely fatal hepatic necrosis
L-Asparaginase	Microvesicular steatosis, hepatic necrosis, coagulopathy (also with pegasparaginase)
Dacarbazine (DTIC)	SOS (VOD)
Procarbazine, hydroxyurea	Hepatocellular injury

AT, aminotransferases; NASH, nonalcoholic steatohepatitis; NRH, nodular regenerative hyperplasia; PSC, primary sclerosing cholangitis; SOS, sinusoidal obstruction syndrome; VOD, venoocclusive disease.
Original references can be obtained from those cited in references [2,14,532].

Table 27.14 Risk factors for methotrexate liver toxicity.

Risk factor	Importance	Implications for prevention
Age >60 years	Increased risk (? reduced renal clearance)	Greater care in use of methotrexate for older people
Dose	Incremental dose Dose frequency Duration of therapy Cumulative (total) dose	5–15 mg/week very safe Weekly bolus (pulse) safer than daily schedules Consider review of hepatic status every 2–3 years Review hepatic status after each 2 g methotrexate given
Alcohol consumption	Increased risk with daily levels of >15 g (1–2 standard drinks)	Avoid methotrexate use if intake not curbed Consider pretreatment liver biopsy
Obesity, diabetes, metabolic syndrome	Increased risk	Consider pretreatment and progress liver biopsies
Preexisting liver disease	Greatly increased risk Particularly related to alcohol, obesity, and diabetes (NASH)	Pretreatment liver biopsy mandatory Avoid methotrexate, or schedule progress biopsies according to severity of hepatic fibrosis, total dose, and duration of methotrexate therapy. Monitor liver tests during therapy (see text)
Folate supplements	Increased risk of liver injury in persons not receiving folic acid	Concurrent folate therapy recommended
Systemic disease	Risk greater with psoriasis than rheumatoid arthritis	None
Impaired renal function	Reduced systemic clearance of methotrexate	Reduce dose; greater caution with use

NASH, nonalcoholic steatohepatitis.

clinically significant liver disease is now rarely if ever encountered.

The development of hepatic fibrosis during methotrexate therapy is greatly influenced by the factors listed in Table 27.14. Pretreatment variables, such as older age, renal failure, preexisting liver disease, and risk factors for NASH (diabetes, obesity) should be carefully considered before commencing treatment with methotrexate [504]. Alcohol intake, preexisting liver disease, and the total and incremental dose are the most important of these risk factors. In earlier studies, a cumulative methotrexate dose of 3 g was associated with histologic progression in 20% of cases, but only 3% had advanced fibrotic changes [505]. In a meta-analysis of 15 studies, moderate or heavy drinkers (>100 g/week) were more likely to have advanced histologic changes (18%) and to show histologic progression (73%) [505]. Compared to those with rheumatoid arthritis, individuals with psoriasis were also more likely to have advanced changes (7.7% versus 2.7%) and histologic progression (33% versus 24%). Finally, it is noteworthy that preexisting liver test abnormalities are observed in 25–50% of individuals with psoriasis and rheumatoid arthritis.

Clinical features and laboratory data

Minor increases in ALT are seen 1–2 days after starting methotrexate treatment. These changes bear little relevance to the development of hepatic fibrosis, which can only be assessed by liver biopsy. Clinical features are absent or nonspecific for liver disease until complications of portal hypertension and liver failure develop. In these now rare advanced cases, hepatosplenomegaly, ascites, muscle wasting, thrombocytopenia, and hypoalbuminemia can be noted, but jaundice, hyperbilirubinemia, and coagulation disturbances are distinctly uncommon.

Histology

A specific scoring system, devised by Roenigk, is widely used for grading liver histology in methotrexate users [506]. In this system, grades 1 and 2 indicate a variable amount of steatosis, nuclear pleomorphism, and necroinflammatory activity but fibrosis is absent. Higher grades reflect increasing degrees of fibrosis, as follows: grade 3A (few septa), grade 3B (bridging fibrosis), and grade 4 (cirrhosis). The pattern of hepatic fibrosis includes striking pericellular fibrosis, a feature of both alcoholic steatohepatitis and NASH; the possibility that methotrexate itself causes steatohepatitis or accentuates fibrogenesis among persons with underlying "metabolic NASH" has been suggested [53]. However, cases have been reported in which hepatic fibrosis appeared in livers with a relative paucity (or complete absence) of portal and lobular inflammation. Because the extent of hepatic fibrosis is the

Table 27.15 Guidelines for monitoring hepatotoxicity in patients with rheumatoid arthritis and psoriasis during methotrexate treatment.

Approach	Psoriasis (Said et al. 1997 [510], Roenigk et al. 1998 [512])	Rheumatoid arthritis (Kremer et al. 1994 [511])
Pretreatment (laboratory tests)	Routine liver tests, full blood count, urinalysis, blood urea, creatinine, creatinine clearance, hepatitis B/C serology Not mandatory	Same as psoriasis
Pretreatment (liver biopsy)	*Early treatment biopsy* (2–4 months) in patients with risk factors for liver disease (past/current ethanol intake of >1–2 drinks/day, abnormal liver tests, familial liver disease, diabetes, obesity, exposure to hepatotoxic drugs)	Recommended in patients with history of excessive ethanol intake, abnormal baseline AST values, and chronic hepatitis B/C virus infection[a]
During treatment (laboratory tests)	Liver tests at 4–8 weeks (1 week after last dose) Frequent monitoring during initial treatment, during dose escalation, and during episodes where blood methotrexate levels could be elevated (dehydration, impaired renal function, NSAID use) With significant and persistent abnormalities, withhold methotrexate for 1–2 weeks and repeat tests If abnormalities persist, consider liver biopsy	Recommended in patients with history of excessive ethanol intake, abnormal baseline AST, and chronic hepatitis B/C virus infection
During treatment (liver biopsy)	This is with no risk factors for liver disease and normal physical exam and liver tests Liver biopsy is recommended after a cumulative methotrexate dose of 1.5 g[b] If biopsy is normal, repeat at subsequent 1–1.5 g cumulative doses[c]	Liver biopsy recommended if five of nine AST determinations within 12 months (six of 12 if tests are performed monthly) are above the upper limit of normal or serum albumin falls (to less than normal) in controlled rheumatoid arthritis

[a]Current understanding would add "risk factors for NAFLD/NASH, especially the metabolic syndrome."
[b]The authors agree that this should now be 2–4 g.
[c]The authors agree that this should now be for additional 2 g cumulative doses (modified by earlier biopsy findings).
AST, aspartate aminotransferase; NAFLD, nonalcoholic fatty liver disease; NASH, nonalcoholic steatohepatitis; NSAID, nonsteroidal anti-inflammatory drug.

only important abnormality in those taking methotrexate, Richards and colleagues have proposed a new semiquantitative method for the evaluation of liver biopsies in patients with rheumatoid arthritis [507]. The objective is to provide greater sensitivity for detecting early hepatic fibrosis than the Roenigk system, and further validation will be of interest.

Prevention of methotrexate fibrosis

Co-prescription of folic acid is associated with a lower risk of liver injury (OR (CI), 0.10 (0.04–0.21)) [508] without sacrificing efficacy. However, its impact on preventing hepatic fibrosis is unknown [509]. Guidelines have been published for monitoring methotrexate therapy [504,510–512] in patients with rheumatoid arthritis and psoriasis (summarized in Table 27.15). A recent development has been a set of guidelines drawn up by an international panel of rheumatologists [513]. Their recommendations endorse gradual dose escalation of methotrexate, co-prescription of folic acid, and checking ALT/AST alone with blood counts and creatinine every 1–1.5 months until a stable dose is reached and 1–3 monthly thereafter. If the ALT/AST levels rise to 3 × ULN, the panel recommends stopping methotrexate, but the drug can be reintroduced at a lower dose following liver test normalization. Persistently elevated ALT/AST levels greater than 3 × ULN should prompt further diagnostic studies.

A revised threshold for liver biopsy has also been proposed [514]. In this British retrospective study, advanced liver fibrosis was found in 2.6% and 8.2% of patients with psoriasis who had received a cumulative dose of 4 and 5 g, respectively. On this basis, liver biopsy was recommended after a cumulative methotrexate dose of 5 g [514]. The value of liver biopsies to assess methotrexate hepatotoxicity in diseases other than psoriasis and rheumatoid arthritis has not been established. In a study of 32 patients with inflammatory bowel disease receiving long-term methotrexate (mean dose 2.6 g; follow-up 131 weeks), histologic changes were common but minor, and significant fibrosis was rare [514]. Similar considerations apply to methotrexate use in sarcoidosis: hepatic reactions were common, but it proved difficult to separate drug toxicity from sarcoidosis-related liver features [515].

Noninvasive methods for assessing hepatic fibrosis such as assessment of serum biomarkers of hepatic fibrosis and dynamic hepatic scintigraphy, have been proposed as alternatives to liver biopsy but are yet to be validated [42].

Thiopurines

The thiopurines, azathioprine, 6-mercaptopurine, and to a lesser extent 6-thioguanine (6-TG) are extensively used in the management of autoimmune disorders and inflammatory bowel disease [516]. Other than early hypersensitivity reactions, the risk of liver toxicity is relatively high (mean, 1.4% per patient per year). However, underreporting is common. In a prospective series, up to 10% showed DILI [517]. Further, liver test monitoring for thiopurine DILI has not been as well emphasized as the need for full blood counts (to identify myelotoxicity). Monitoring serum thiopurine metabolite levels is not routine but may be helpful if the clinical response is suboptimal or if there are concerns about drug toxicity. Generally, only 6-TG metabolites are measured and the dose of thiopurine increased if there is suboptimal response. However, liver injury can still occur in some individuals who preferentially metabolize the thiopurine to 6-methylmercaptopurine metabolites; the latter have been previously associated with hepatotoxicity. Thus, if monitoring is to be undertaken, it is suggested that both 6-methylmercaptopurine and 6-thioguanine metabolites should be measured [518].

Azathioprine

Azathioprine, the prodrug of 6-mercaptopurine, is an immunosuppressive "steroid-sparing" agent often used in inflammatory bowel and autoimmune diseases (Chapter 22). Hepatic complications are rare. When these complications develop, they may be severe and diverse, and often occur very late after starting the drug. All these factors provide a challenge for appropriate diagnosis and management. DILI associated with azathioprine includes bland cholestasis, cholestatic hepatitis with bile duct injury [519], zonal necrosis, and vascular toxicity [520,521]. The latter encompasses diverse syndromes of SOS (VOD), peliosis hepatis, NRH, and noncirrhotic portal hypertension [521]. HCC has also been recorded in a long-term recipient [522]. Indirect hepatic effects of azathioprine, such as opportunistic infections (e.g., cytomegalovirus) or, rarely, liver infiltration from lymphoma should always be considered. DILI resolves in mild cases but the course may be progressive in severe cases. 6-Mercaptopurine has been successfully used in cases of azathioprine hepatotoxicity [523]. However, 6-mercaptopurine causes dose-dependent hepatocellular necrosis, possibly by favouring 6-methylmercaptopurine production, which can be fatal. Rarely, it is associated with cholestasis [14].

6-Thioguanine

Vascular toxicity, particularly hepatic SOS (VOD), is a characteristic feature of 6-TG hepatotoxicity (see Table 27.13) in the context of hematologic malignancies. Less well recognized is the development of NRH in persons with inflammatory bowel disease. In one study conducted in Los Angeles, 111 patients with inflammatory bowel disease receiving 6-TG were examined for potential hepatotoxic effects. An increase in liver enzymes and reduced platelet counts were found in 26% [524]. These were seen more often in men, and in those with preferential 6-methylmercaptopurine production during treatment with 6-mercaptopurine or azathioprine. Liver histology was available in 38 cases. Reticulin-stained sections showed NRH in 20 cases (53%); conventional hematoxylin and eosin (H&E) sections identified NRH in only four of these cases. Ultrastructural studies demonstrated sinusoidal collagen deposition in 60% (14 of 23), a figure significantly higher than that observed with conventional trichrome stains (34%). SOS (VOD) was observed in one case [525]. NRH was present more often (76%) in patients with abnormal laboratory tests than among those without such abnormalities (33%). NRH may be a consequence of dose-dependent toxicity; no cases of NRH were identified in a Dutch series of 28 cases treated with lower doses of 6-TG than in the American report cited above [526].

Cyclosporine *A*

Between 6% and 86% of organ transplant recipients receiving cyclosporine develop abnormal liver tests [15, 527]. However, these changes are mild and self-limiting. They consist of a transient increase in serum alkaline phosphatase, accompanied by a slight elevation in bilirubin and AT. Most patients do not develop symptoms of cholestasis or hepatitis. The biochemical changes are most evident in the first month after transplantation. However, up to 32% of cases may be associated with prolonged liver test abnormalities [527]. Long-term recipients of cyclosporine are also at risk of developing biliary calculi [528], the consequence of altered bile flow and biliary lipid composition. Cyclosporine-induced liver test abnormalities usually settle with dose reduction or discontinuation of treatment. There is anecdotal evidence that ursodeoxycholic acid may be beneficial in this setting [72].

In experimental models, cyclosporine induces cholestasis by inhibiting Bsep-mediated taurocholate transport, culminating in decreased bile flow [529]. It also disturbs bile salt kinetics by inhibiting bile salt synthesis, reducing the size of the bile salt pool, and increases cholesterol saturation in bile by reducing phospholipid secretion.

Sirolimus

Increases in AT have been observed in liver and renal transplant recipients of sirolimus [530]. Such cases were initially misdiagnosed as representing allograft rejection and were managed (unsuccessfully) with dose escalation. Resolution occurred only when sirolimus was withdrawn. Liver biopsies have shown sinusoidal congestion or mild hepatitis.

Anticonvulsants

Phenytoin

Raised GGTP and serum alkaline phosphatase levels are very often observed in the absence of hepatic injury among people taking phenytoin. This usually reflects enhanced hepatic enzyme synthesis (a form of hepatic adaptation), but in those without adequate sunlight exposure, it is important to exclude vitamin D deficiency arising from enhanced hepatic metabolism of this vitamin. Acute hepatitis, including severe cholestatic hepatitis leading to VBDS, is a very rare but important side effect of phenytoin [2,531], usually as part of the reactive metabolite syndrome (see Table 27.3). There may be an increased rate of hepatic reactions among Afro-Americans compared with whites [42]. Onset is usually within 6 weeks. Biochemical features reflect hepatocellular necrosis with high AT levels, but mixed patterns may occur. In phenytoin hepatitis, liver biopsies show diffuse hepatocellular degeneration and multiple acidophilic (apoptotic) bodies, bridging necrosis, and a prominent lymphocytic or mixed cell inflammatory infiltrate containing neutrophils and eosinophils. Hepatic granulomas may also be present. The combined appearances of lymphocyte beading, mitotic hepatocytes, and granulomas mimic infectious mononucleosis [2].

Phenytoin was one of the first drugs associated with hypersensitivity features now regarded as characteristic of the RMS (also known as the anticonvulsant hypersensitivity syndrome or "pseudomononucleosis" syndrome) [42]. Fever, severe forms of rash, lymphadenopathy, leukocytosis, and Stevens–Johnson syndrome are frequent, and the key link is with visceral involvement including the liver, kidney, bone marrow, and lung (see Table 27.3). Resolution occurs with phenytoin withdrawal, but the case fatality rate of patients developing liver injury is up to 20%. Continued ingestion of phenytoin after the onset of symptoms is associated with a poor outcome. Treatment consists of supportive measures. Corticosteroids have not proved beneficial.

Although the presence of hypersensitivity features suggests immunologic idiosyncrasy, it now seems likely that the primary abnormality is related to the generation of a highly reactive arene oxide metabolite. If detoxification of this metabolite by epoxide hydrolase is inadequate, it binds to cellular macromolecules or initiates oxidative stress, causing cell injury with apoptosis or necrosis. The way in which this reactive metabolite incites profound drug hypersensitivity is less clear, but neoantigenic determinants of immune reactivity, cytokine mobilization, and defects in cell defenses against oxidative stress and proinflammatory stressors are potential candidates. A genetic deficiency of this enzyme has been identified in patients and their family members [532]. Another key enzyme in phenytoin metabolism is CYP2C9; phenytoin-associated VBDS has been described in a patient heterozygous for CYP2C9*3 (an allele conferring low enzyme activity) [532].

Carbamazepine

Liver disorders comprise approximately 10% of adverse drug reactions with carbamazepine [14]. The frequency of liver injury is estimated at 16 cases per 100,000 treatment-years [14]. Granulomatous hepatitis with varying degrees of hepatocellular injury and cholestasis have been reported [42,533,534]. Children may also be affected, including neonates of women receiving carbamazepine in pregnancy [535]. Onset is within 6–8 weeks. The hallmarks of hypersensitivity (fever, rash, angioedema, eosinophilia, and raised IgE levels) are often observed, linking this reaction as part of the RMS observed with other aromatic anticonvulsants (phenytoin, phenobarbitone) metabolized via arene oxides.

Submassive or massive hepatic necrosis has been noted in a few patients. Multiple hepatocellular adenomas were described in a man receiving carbamazepine for 17 years [536], but there is no evident biologic basis for an etiopathogenic role of the drug in this syndrome. The case fatality rate of carbamazepine hepatitis is 10% among those with hepatocellular reactions. Some reported cases of fulminant liver failure were also associated with concurrent acetaminophen intake or antituberculous therapy [537]; the role of interactive hepatotoxicity needs to be considered in such severe cases. Patients presenting with granulomatous and/or cholestatic reactions usually survive, although bile duct injury and VBDS may rarely occur.

Lamotrigine

Indications for lamotrigine include partial and generalized seizures, and as adjunctive therapy in children with refractory epilepsy. Early reports of liver test abnormalities were wrongly attributed to status epilepticus. Subsequently, a small but definite risk of hepatotoxicity was documented [538]. However, attributing causality can be difficult because other potentially hepatotoxic antiepileptic drugs are often co-prescribed.

Acute hepatitis has been reported in ten persons, including two instances of fulminant hepatic failure.

Symptoms developed within 2–3 weeks (range, 6–39 days). Extrahepatic features such as rash, disseminated intravascular coagulopathy, and rhabdomyolysis were sometimes present. Liver biopsies showed acute hepatic necrosis or focal hepatitis with mild portal inflammation [538]. Progressive hepatic necrosis culminating in fatal acute liver failure has been documented. In most other reported reactions, liver injury settled within a few weeks of stopping lamotrigine. Lamotrigine is structurally different from the aromatic anticonvulsants (phenytoin, phenobarbital, carbamazepine). Although in vitro cross-reactivity has been reported in patients with a history of reactions to the older antiepileptic drugs [539], there is no documented clinical cross-reactivity between lamotrigine and these agents.

Valproic acid (sodium valproate)

Risk factors

Up to 40% of recipients of valproic acid (VPA) develop reversible increases in ATs. These changes are frequently observed within the first 2 months of treatment and are unrelated to the rare severe form of liver injury. VPA-associated hepatic injury is independent of dose and duration of treatment. It occurs predominantly in children, particularly those aged less than 3 years. Among 37 fatal cases noted in a retrospective analysis of 400,000 persons taking VPA between 1978 and 1984, children younger than 10 years represented 73% (27 of 37 affected) [540]. Risk factors include a family history of mitochondrial enzyme deficiencies (including urea cycle, long chain fatty acid metabolism defects), Friedreich ataxia, Reye syndrome, having a sibling affected by VPA hepatotoxicity, and multiple drug therapy. There are 26 published cases of VPA liver toxicity in adults [541]. The overall risk of liver injury among persons taking VPA is between one per 500 persons exposed among high-risk groups to less than one in 37,000 in low-risk groups [542]. An association between use of VPA for complex partial seizures and hepatotoxicity has been recently noted [543]. The explanation lies in a genetic polymorphism in the mtDNA repair enzyme, DNA polymerase-γ (POLG). Thus, all four children aged between 3 and 18 years who developed severe VPA-induced liver injury at the Seattle Children's hospital while being treated for complex partial seizures, were genotyped to have POLG mutations. The authors are aware of unpublished data indicating a high frequency of the genetic predisposition factor among a large cohort of VPA hepatotoxicity cases in North America, and it is a strong candidate for the predisposition to this disorder.

Onset, clinical features, and laboratory findings

Symptoms begin 4–12 weeks after starting VPA and are often nonspecific; lethargy, malaise, poor feeding, somnolence, worsening seizures, muscle weakness, and facial swelling are important new symptoms among children prescribed VPA. They may be followed by features more readily attributable to hepatotoxicity, including anorexia, nausea, vomiting, weight loss, right upper quadrant discomfort, or abdominal pain. Jaundice, hypoglycemia, ascites, coagulation disorders, and encephalopathy indicate liver failure with imminent coma and death. Another presentation is with fever and tender hepatomegaly suggestive of Reye syndrome. The prognosis is better in such cases. Yet others exhibit prominent neurologic features, such as ataxia and confusion, with little evidence of hepatic involvement. Additional extrahepatic features observed among patients with VPA hepatotoxicity include thrombocytopenia, pancreatitis, and alopecia. The biochemical features resemble those described earlier for other mitochondrial hepatotoxins: a modest rise in bilirubin and ALT is accompanied by hypoalbuminemia, hyperammonemia, and profound impairment in serum levels of clotting factors synthesized by the liver.

Pathology

Histologic appearances include submassive or massive hepatic necrosis in two thirds of cases [544], and zonal or diffuse microvesicular steatosis in the others; steatosis may also accompany hepatic necrosis. Bile duct injury has been observed in a few cases, but as part of massive or submassive necrosis in which any additional significance is questionable.

Management, outcome, and prevention

This includes supportive measures for underlying metabolic defects and managing acute liver failure. In one retrospective study, L-carnitine supplementation reduced mortality [545]; 20 (48%) of 42 patients treated with L-carnitine survived, as against only five (10%) of 50 patients managed by aggressive supportive care alone. The place of liver transplantation is unclear; it has been performed successfully in some cases, but in others led to worsening of neurologic disease [546].

At least 60 deaths from VPA hepatotoxicity are recorded and the mortality remains high. Prevention is possible by adherence to prescribing guidelines; these include avoiding VPA in combination with other drugs in the first 3 years of life and in children with mitochondrial enzyme defects. Monitoring liver tests is unhelpful because of the high frequency of nonspecific liver test abnormalities. Children and their parents should be urged to report any new symptoms developing within the first 6 months of VPA therapy. In the future, genetic screening for POLG polymorphisms may become appropriate.

Mechanism of liver injury

Unlike the aromatic anticonvulsants, VPA hepatotoxicity is rarely accompanied by manifestations of the RMS [547].

Metabolic idiosyncrasy is probably the principal mechanism of VPA toxicity. Glucuronidation and β-oxidation are the principal pathways of VPA metabolism, but VPA may be metabolized by CYP enzymes to 4-en-VPA, a pathway that is accentuated in persons taking concurrent medications (particularly other anticonvulsants), which induces CYPs. Some VPA oxy-metabolites, and notably 4-en-VPA, inhibit mitochondrial fatty acid β-oxidation. Other metabolic effects of VPA therapy include secondary carnitine deficiency, therapeutic correction of which may be valuable (see above).

Topiramate

A woman receiving topiramate and carbamazepine developed acute liver failure. The explanted liver showed centrilobular necrosis [548]. Another person prescribed topiramate for a bipolar affective disorder developed raised ALT (>700 U/L), hypoalbuminemia, and mild hyperammonemia. Resolution occurred after topiramate was discontinued and other medications including VPA could be resumed without ill effects [549]. By contrast, topiramate used as an add-on anticonvulsant induced acute liver failure [550], which resolved only after VPA was withdrawn.

Felbamate

Cases of acute hepatitis and fatal fulminant hepatic failure have been attributed to felbamate [551]. The majority of affected individuals were women. The overall frequency of liver injury and liver-related death was estimated, respectively, at one per 7,000 and one per 125,000 persons exposed. Half the reported cases occurred between 3 and 6 months (range, 2 weeks to 8 months). The generation of atropaldehyde, a reactive metabolite, could be critical to felbamate toxicity [552]. Felbamate should be reserved for treating refractory epilepsy, especially the Lennox–Gastaut syndrome.

Gabapentin

This drug has been implicated in causing cholestatic hepatitis [553]. Another report of liver injury attributed to gabapentin has been disputed because other potentially hepatotoxic medicines had been co-prescribed [554]. The Committee on Safety of Medicines UK has received reports of four other unpublished cases of jaundice, including one other cholestatic drug reaction. Overall, this drug has low hepatotoxic potential.

Antipsychotic agents, sedative–hypnotics, and antidepressant drugs

Chlorpromazine

Chlorpromazine is historically one of the most important causes of drug-induced liver disease, both because of the relatively high frequency of idiosyncratic reactions, but also because it is the archetypical example of a drug causing cholestatic hepatitis (Table 27.16). VBDS and other complications, such as massive hepatic necrosis, also occur occasionally. Full descriptions of chlorpromazine hepatitis may be found elsewhere [2,14,555]. The essential features are recapitulated here because of what chlorpromazine has taught us about

Table 27.16 Liver injury associated with antipsychotic, sedative–hypnotic and antidepressant drugs.

Drug	Nature of liver injury
Antipsychotic drugs	
Chlorpromazine	Cholestasis, vanishing bile duct syndrome
Clozapine	Hepatocellular injury, acute liver failure
Haloperidol	Cholestasis, vanishing bile duct syndrome
Quetiapine	Acute liver failure (single case)
Risperidone	Raised aminotransferases, cholestatic hepatitis
Sedative–hypnotics	
Barbiturates	Cholestatic or hepatocellular injury
Benzodiazepine	Hepatocellular injury, chronic hepatitis (bentazepam)
Chlormezanone	Cholestasis, hepatocellular injury, acute liver failure
Antidepressants	
Monoamine oxidase inhibitors	Acute hepatitis
Tetracyclic antidepressants	Cholestasis with mianserin, maprotiline
Tricyclic antidepressants	Hepatocellular or cholestatic injury, vanishing bile duct syndrome (amitriptyline, imipramine)
Selective serotonin reuptake inhibitors:	
Fluoxetine	Acute hepatitis, chronic hepatitis
Paroxetine	Raised aminotransferases, chronic hepatitis (one case)
Sertraline	Acute hepatitis (when used alone and also in combination with other drugs), cholestatic hepatitis
Citalopram	Cholestasis
Other antidepressants:	
Bupropion	Raised aminotransferases in trials; acute hepatitis (one case), cholestatic hepatitis
Fluvoxamine	Acute hepatitis
Nefazodone	Raised aminotransferases, occasionally subacute liver failure
Trazodone	Acute and chronic hepatitis, cholestasis, fatal hepatic necrosis
Venlafaxine	Acute hepatitis with zone 3 necrosis, mixed liver injury. Low-dose venlafaxine is associated with hepatocellular injury in a patient with chronic hepatitis B

hepatic drug reactions, and because the agent is still used.

Chlorpromazine is associated with cholestatic hepatitis in 0.2–2% of recipients; the risk increases with age and is higher in women. The onset of prodromal symptoms occurs within 1–6 weeks [555]. Fever and nonspecific systemic complaints are present in over half the patients, but rash is uncommon. Jaundice, pruritus, and generalized or right upper quadrant pain occur later. Serum alkaline phosphatase is elevated more than threefold, along with a moderate rise in the AT and a variable increase in serum bilirubin, depending on severity. Peripheral blood eosinophilia is present in 10–40%. Liver histology is characterized by centrilobular cholestasis, portal inflammation, mild parenchymal injury, and occasionally bile duct damage [555]. Resolution occurs within 12 weeks in the majority of cases, but about 7% develop VBDS.

The brisk response to rechallenge suggests immunoallergic idiosyncrasy but there is evidence of a toxic component to the liver injury. Chlorpromazine, and particularly its hydroxylated metabolites, inhibit plasma membrane Na^+/K^+-ATPase, alter membrane fluidity, and actin polymerization. Genetically determined defects in sulfoxidation of chlorpromazine (the sulfoxide metabolite is inert) have been postulated but are unproven [556].

A similar pattern of cholestatic liver injury has been described less frequently with prochlorperazine [557] and other neuroleptics such as haloperidol [558], pimozide, and sulpiride, including rare cases of VBDS [42].

Sedative–hypnotics

Liver injury is extremely rare with the benzodiazepines and other minor tranquilizers, anxiolytics, or hypnotics. Both hepatocellular and cholestatic reactions are described, but often from times preceding accurate diagnosis of all forms of viral hepatitis [14].

Antidepressants

Monoamine oxidase inhibitors

Iproniazid was one of the first drugs associated with acute hepatitis [2]. These reactions occurred in 1% of recipients and were often severe, including instances of fatal fulminant liver failure. The hydrazine substituent (which iproniazid partly shares with isoniazid, ethionamide, pyrazinamide, and nicotinamide) was probably the hepatotoxic moiety [559]. Hydrazine sulfate can cause severe hepatorenal toxicity [559]. Phenelzine and isocarboxazid have also been associated with occasional instances of hepatocellular injury, but monoamine oxidase inhibitors are now rarely prescribed.

Tricyclic antidepressants

These agents bear structural resemblance to the phenothiazines and are an occasional cause of cholestatic or less commonly hepatocellular injury. Recovery following drug cessation is usual, but prolonged cholestasis has been observed with amitriptyline and imipramine [42].

Selective serotonin reuptake inhibitors and other modern antidepressants

Liver enzyme alterations in asymptomatic persons have been observed with fluoxetine and paroxetine [560]. A few reports of acute and chronic hepatitis have been attributed to the use of selective serotonin reuptake inhibitors (SSRIs) (Table 27.16) [560]. In all reported cases, the liver injury subsided with drug discontinuation.

Nefazodone has been withdrawn after being implicated in inducing acute and subacute liver failure [561]. A Spanish pharmacovigilance study examining antidepressant hepatotoxicity found that nefazodone had the highest frequency of liver injury among these drugs (28.96 per 100,000 patient-years); the comparative figures for fluoxetine, paroxetine, sertraline, and citalopram were less than two per 100,000 patient-years [562]. Of 32 cases of liver injury analyzed by the Canadian adverse drug monitoring programme, 26 (81%) were classified as severe. About half the patients recovered after drug withdrawal but three patients progressed to acute liver failure [563] necessitating liver transplantation. Centrilobular, massive, or submassive hepatic necrosis was observed on histology. Two thirds of affected persons were women aged between 30 and 70 years. While most had been taking the drug for between 3 and 6 months, early liver injury (within 4 weeks) has also been reported [564]. Bioactivation of nefazodone to a reactive quinone-imine metabolite may underlie its hepatotoxicity [565].

Trazodone has been implicated in cases of acute and chronic hepatocellular injury [566]. The onset is usually within 6 months (range, 4 days to 18 months). Positive rechallenge within 2 days of reinstituting the drug has been described [566]. Recovery is complete within 2 months of discontinuing trazodone. Occasional reports note the occurrence of severe hepatotoxicity with combinations of antidepressants or antidepressants with other neuroleptics [42].

The liver toxicity associated with other antidepressants is summarized in Table 27.16 [560].

Cognition modifiers

Tacrine

This reversible cholinesterase inhibitor was formerly used in treating Alzheimer disease. Following initial concerns about possible hepatotoxicity, a seminal observational study was conducted [567]. ALT values greater

than the ULN, 3 × ULN, and 20 × ULN were recorded in 49%, 25%, and 2%, respectively. Among individuals in whom treatment was discontinued due to abnormal liver enzyme changes, biochemical resolution invariably occurred, and 88% were able to resume long-term therapy (usually at a lower dose); there were no fatalities [567]. Only few cases of overt hepatic disease have been reported. Histologic appearances range from mild lobular hepatitis to centrilobular hepatic necrosis, steatosis, and granulomatous hepatitis [568].

The mechanism of tacrine-induced liver injury remains unclear. Hypersensitivity features were observed only infrequently and rechallenge did not produce an exaggerated rise in ALT. Genetic predisposition to tacrine hepatotoxicity may contribute; polymorphisms associated with glutathione-*S*-transferase and IL6 genes have been described [569].

Donepezil

This acetylcholinesterase inhibitor has been implicated in two cases of acute hepatitis [570]. One of these patients who developed fulminant hepatic failure had also been taking sertraline.

Methylphenidate

This sympathomimetic amine is prescribed for pediatric attention-deficit disorder (ADD) and narcolepsy and is also self-administered by intravenous injection in "recreational" use. Hepatocellular injury is documented with therapeutic (oral) and intravenous use [571,572]. The latter reactions are more severe and have been associated with multiorgan failure involving the liver, kidney, pancreas, lung, and central nervous system [572]. A single report has implicated this drug in an autoimmune hepatitis-type presentation. This patient had undergone a liver transplant for chronic hepatitis C and presented with deranged liver tests and had serologic and histologic characteristics consistent with AIH. Partial improvement in liver tests was noted after drug withdrawal but a short course of prednisolone was also used later [573].

Pemoline

This psychostimulant, now withdrawn, was used in children with ADD. Clinical trials revealed mild, reversible liver injury in around 2% of recipients. However, instances of serious liver toxicity were subsequently reported to the FDA; of 13 cases presenting with fulminant hepatic failure, 11 died or required liver transplantation [574]. Onset was usually within 4 weeks but could be delayed for up to 1 year. Liver histology showed focal necrosis, mild steatosis, or portal inflammation.

Rash, fever, or eosinophilia were infrequent [575]. Moreover, the observation of a similar rise in serum AT in twins with ADD supports a hypothesis of genetically determined individual susceptibility [576]. On the other hand, the existence of distinctive cases of steroid-responsive chronic liver disease resembling AIH indicates that immunoallergic mechanisms could also be involved [577]. Zimmerman suggested that persons prescribed pemoline should be monitored for serum AT changes, but it is noted that the onset of acute liver failure can be extremely rapid [575].

Other drugs used in the treatment of neurologic diseases

Riluzole

This glutamate antagonist is approved for the treatment of amyotrophic lateral sclerosis. Increased ALT was observed in 1.3–10% of clinical trial recipients. Two cases of acute hepatitis with microvesicular steatosis have since been reported, with onset respectively at 4 and 8 weeks after starting treatment [578]. Rarely, hepatocellular injury may be delayed for as long as 6 months [579]. Liver test abnormalities settle shortly after riluzole is stopped.

Dantrolene

Dantrolene is a skeletal muscle relaxant used against spasticity. The frequency of liver injury is about 1%. A feature has been the severity (the case fatality is approximately 28%) of the liver injury [580], which in some cases progressed even after stopping dantrolene. Most were over 30 years of age. Up to one third of affected persons were asymptomatic, while others had developed symptoms of hepatitis. Hepatocellular necrosis, often submassive or massive, was the usual histologic characteristic [580]. Chronic hepatitis and cirrhosis have also been observed [581]. Liver tests should be performed every 2 weeks for the first 6 weeks of dantrolene therapy. The drug should be stopped if there is no clinical benefit.

Other drugs with muscle relaxant properties that have been rarely associated with liver injury include phenyramidol (hepatocellular injury), chlormezanone (cholestasis, hepatocellular injury, acute liver failure), and baclofen (serum AT changes) [42].

Tolcapone

This catechol-*O*-methyltransferase (COMT) inhibitor is approved for Parkinson disease. In preclinical trials, significant ALT elevations (>3 × ULN) were present in 1–3% of recipients. Tolcapone has now been implicated in at least four cases of acute liver failure [582], all in women older than 70 years. They presented with jaundice and high ALT levels. Centrilobular necrosis was observed at autopsy in one case. Ultrastructural changes included mitochondrial swelling with disruption of cristae and reduced matrix density. Patients developing severe

hepatotoxicity had not been monitored as recommended [582]. With strict monitoring, hepatocellular injury is infrequent (0.04%); most have only elevated AT without clinically significant liver disease [583].

The mechanism of tolcapone hepatotoxicity could be related to the uncoupling of mitochondrial oxidative phosphorylation, and also through interactions with fatty acid β-oxidation and bile acid synthesis [584]. It is relevant that entacapone, another COMT inhibitor, does not exhibit similar toxicity at comparable concentrations [585]. As compared with tolcapone, entacapone has a greater binding affinity with glucuronidation enzymes, but a lower capacity for penetrating the mitochondrial outer membrane [585]. Of three recent cases of hepatic injury attributed to entacapone, there were confounding factors in two [586]. Overall, the experience with entacapone (over 300,000 patient-years) has confirmed its generally safe track record [586].

Drugs of abuse

3,4-Methylenedioxymetamphetamine ("ecstasy")

This widely used recreational agent has been associated with more than 30 cases of acute liver injury, including several deaths from acute liver failure [587]. In Spain, up to 25% of cases of unexplained acute liver failure in young adults were attributable to 3,4-methylenedioxymetamphetamine (MDMA) [588]. Liver injury was initially described as part of a hyperthermic syndrome with rhabdomyolysis, acute renal failure, and coagulopathy. This was precipitated by vigorous muscle exercise, dehydration, and increased ambient temperatures, particularly during all-night "rave" dancing [588]. However, acute hepatitis can be the sole manifestation of MDMA toxicity; it can occur following ingestion of even a single tablet, although many of the reported cases have involved consumption of MDMA for longer periods.

MDMA is demethylated in the liver by CYP2D6. It was suggested that persons with low-level expression of CYP2D6 (the debrisoquine slow metabolizer phenotype) could be susceptible to MDMA-induced hepatitis, but this has been challenged [42]. Liver biopsies may show acute lobular hepatitis or zone 3 or massive hepatic necrosis, but others have observed chronic cases with hepatic fibrosis [589].

MDA (methylene dianiline) may be confused with MDMA [590] if used in similar settings. This is illustrated by a report of cholestasis in participants of a "technoparty" who had their alcoholic beverage spiked with MDA. Unlike MDMA, which primarily causes hepatocellular injury, MDA toxicity manifests as cholestasis, as exemplified by the 1965 outbreak of jaundice in Epping, England, where bread flour had been contaminated with MDA [86]. Acute right upper quadrant abdominal pain (similar to erythromycin hepatitis) is a prominent symptom.

Phencyclidine

Severe phencyclidine ("angel dust") overdose can lead to submassive hepatic necrosis (accompanied by hyperthermia, rhabdomyolysis, and respiratory and renal failure) [42].

Cocaine

Cocaine is a dose-dependent hepatotoxin in mice [14]. Massive doses self-administered to humans cause liver injury in association with shock and other toxic phenomena [591]. Rarely, cocaine can cause acute hepatitis without altered systemic hemodynamics and following intranasal (as opposed to parenteral) use [592]. In rodents, the histologic lesions include extensive centrilobular, midzonal, or panlobular necrosis, together with microvesicular steatosis [14]. Gender and genetic differences, as well as the activity of CYP enzymes, determine this varied histologic spectrum.

Clinical presentation of cocaine hepatotoxicity is with raised serum AT (over ten-fold in 40% of cases), nearly always accompanied by hypotension, hyperpyrexia, renal failure, myoglobulinuria, and disseminated intravascular coagulation [593]. The high mortality is illustrated by one series of 39 patients, among whom more than 40% died [593]. Thrombotic microangiopathy is a rare complication; early recognition and institution of plasma exchange can be life-saving for this hematologic disorder [594]. The mechanism of liver injury may vary between species – in rodents it involves drug metabolism to toxic, oxy- or nitro-metabolites and factors pertaining to host defenses [2]. In humans, systemic hypotension and hypoxia (and possibly hyperthermia) are more likely to contribute to the liver injury [593] than the direct effects of cocaine on the liver. Induction of hepatic CYP2E1 by alcohol can potentiate the hepatotoxic effects of cocaine experimentally [42].

Drugs used in aversion therapy and treatment of alcohol withdrawal

Tetrabamate (Atrium®)

This drug combination (febarbamate, difebarbamate, and phenobarbital) has been used in France and Spain to treat alcohol withdrawal, tremor, and depression. Phenobarbital is an extremely rare cause of liver injury (cases are similar to phenytoin hepatitis) [14], whereas difebarbamate and febarbamate have not been previously implicated in hepatotoxicity. However, use of the combined preparation (tetrabamate) has been implicated in causing acute hepatitis [595]. Onset of symptoms was between 15 days to 2 years after commencing tetrabamate

[595]. Most recovered after stopping tetrabamate, but two deaths from liver failure were recorded; both occurred in patients who continued taking tetrabamate after the onset of symptoms. Histology shows acute hepatocellular necrosis. Other lesions also described include cholestasis, microvesicular steatosis, and granulomatous hepatitis.

Hypersensitivity features were prominent in some individuals, including the presence of antinuclear and/or smooth muscle antibodies. Therefore, immunologic idiosyncrasy may contribute to the liver injury, but genetic differences in drug metabolism could have also been responsible [42]. Phenobarbital, a potent CYP enzyme inducer, could have also potentially enhanced the production of toxic metabolites from the other co-constituents (cf. VPA and the RMS).

Disulfiram

Disulfiram has been incriminated in over 100 instances of acute hepatocellular injury [596]. Recovery is usual within 2 weeks, but liver tests can take up to 3 months to normalize. The high AT readings distinguish these reactions from alcoholic hepatitis. Rarely, acute liver failure may develop [597] and liver transplantation becomes necessary; the youngest patient undergoing this procedure was only 16 years old [597]. The overall mortality in jaundiced patients was 16% in one series [596]. The frequency of fatal liver injury is estimated at one per 30,000 treated persons per year. Although abnormal AT in the absence of advanced liver disease at baseline does not necessarily predict an increased risk of liver toxicity, patients with underlying cirrhosis may be susceptible to severe liver injury (five of seven reported cases) [596]. The presence of eosinophils (as opposed to hepatocyte dropout) on liver biopsies has been associated with a more favorable outcome.

Cyanamide produces a characteristic ground glass appearance of hepatocytes, which resembles LaFora bodies [598]. This is a form of hepatic adaptation rather than liver injury. The intense immunohistochemical staining of these cytoplasmic inclusions with a polyglucosan-reactive monoclonal antibody suggests that they are derived from altered glucose metabolism [598]. However, cyanamide can rarely cause acute hepatitis, and serial liver biopsies from alcohol-abstinent recipients of cyanamide showed portal–portal and portal–central fibrosis [42].

Chlormethiazole

Previously implicated in only one case of acute cholestatic hepatitis, chlormethiazole has greater hepatotoxic potential than previously appreciated [42]. DILI may be underreported in the context of alcohol withdrawal because of difficulties in separating drug toxicity from the underlying alcoholic liver disease. Hepatocellular or mixed liver injury was described in three recent cases wehre patients were receiving disulfiram for indications other than alcohol withdrawal (insomnia, depression); all were over 70 years of age and treated for less than 2 months. One developed fatal acute liver failure and histology showed submassive necrosis. The other two patients recovered within 2 months.

Antihistamines: H1 receptor antagonists

Transient AT changes are observed in less than 2% of recipients of cetirizine but four reports of liver toxicity have accrued; three were hepatocellular reactions and one patient developed cholestasis [599]. The appearance of a rash, eosinophilia, and the presence of antiliver–kidney microsomal antibodies in two cases is suggestive of drug hypersensitivity. Positive rechallenge (inadvertent) has been reported [42].

Cholestatic drug reactions are also described with terfenadine, cinnarizine, chlorpheniramine, and pizotyline [42]. Loratadine has been linked to two reports of hepatocellular injury, including one patient who developed subfulminant hepatic failure and was transplanted; the liver explant showed massive hepatic necrosis [600].

Gastric acid-lowering agents

H2 receptor antagonists

Although these agents have a good safety profile, serious hepatotoxicity led to the withdrawal of oxmetadine, ebrotidine, and niperotidine, and rare episodes of liver injury have been reported with other members of this group [42]. Cross-reactivity between famotidine and cimetidine has been described [42], but there is no overall evidence of a class effect on hepatotoxicity among these structurally variable drugs.

Compared to nonusers, the relative risk for liver injury was 5.5 for cimetidine and 1.7 for ranitidine (and 2.1 for omeprazole) [601]. The frequency of hepatotoxicity with cimetidine and ranitidine has been estimated at 3–6 per 100,000 and one per 100,000 prescriptions, respectively [601]. The risk of liver injury with cimetidine is highest with doses exceeding 800 mg/day and at the onset of treatment. Cimetidine, ranitidine, and famotidine usually cause acute hepatitis or cholestatic hepatitis [602]. Of 170 cases of H2 receptor antagonist toxicity reported to the Australian Adverse Drug Reaction Advisory Committee, hepatotoxicity constituted 4–8% of reactions. The majority of affected individuals were over 50 years of age [602] and, in this report, hepatic reactions were more frequently reported with ranitidine than with cimetidine or famotidine. Supportive evidence of hypersensitivity features were recorded in a few patients. Others have reported Stevens–Johnson syndrome in association with ranitidine use in two patients with preexisting severe liver disease;

it was suggested that altered hepatic metabolism may have contributed, but no data were presented to support this [42]. However, others point out that markers of hypersensitivity and positive rechallenge have not been consistently demonstrated, leading them to propose an alternative hypothesis for liver injury [42]. In a rat model, significant hepatocellular injury could be elicited in the presence of lipopolysaccharide-induced liver inflammation. On this basis, they suggest that similar mechanisms may underlie human ranitidine hepatotoxicity because these cases were characterized by a preceding cluster of symptoms that could be attributed to endotoxemia (fever, diarrhea, abdominal pain). In turn, the ensuing endotoxemia-related hepatic inflammation could render the hepatocytes susceptible to ranitidine-related liver injury. Interestingly, in the same rat model, coadministration of LPS with famotidine, a less frequent cause of hepatotoxicity, did not elicit significant liver injury

Proton pump inhibitors

A few reports of acute hepatitis or mixed hepatocellular–cholestatic liver injury [42] have been ascribed to the proton pump inhibitors. Although omeprazole was implicated in one case of fulminant hepatic failure, concurrent acetaminophen use was not clearly excluded (see earlier) [42]. Fulminant hepatic failure has also been attributed to rabeprazole [42]. However, the role of rabeprazole in causing fulminant hepatitis appears equally less conclusive because terbinafine had also been prescribed. The authors' assertion that terbinafine hepatotoxicity is usually mild is not consistent with other data presented to the FDA (see earlier section).

Antispasmodic drugs

Two cases of acute hepatocellular injury have been reported with alverine, a smooth muscle relaxant. In the first report, the accompanying peripheral and tissue eosinophilia along with antinuclear antibodies directed against a component of the nuclear envelope (lamin A and C) suggested immune-mediated liver injury. These features were absent in the second case. Both patients recovered after alverine was discontinued [603].

Emerging drugs

A clinical challenge with drug-induced liver disease is provided by instances of hepatotoxicity attributable to recently introduced drugs (Table 27.17). The frequency of liver injury with these drugs will not be known until larger studies are conducted.

Alfuzosin

Three reports of liver injury (hepatocellular and mixed hepatocellular–cholestatic) have been recorded with this α_1-adrenoceptor antagonist used to treat benign prostatic hyperplasia [41,604]. Features of cholestasis with spotty hepatocyte necrosis and pericellular fibrosis with giant cell formation were noted at liver histology [604]. One of these patients had underlying chronic liver disease [604]. Because alfuzosin is extensively metabolized in the liver, it is possible that the ensuing hepatotoxicity in this case was a consequence of increased drug levels. Normalization of liver tests was complete within 6 months of stopping the drug [42].

Table 27.17 Liver injury associated with emerging drugs.

Drug	Nature of liver injury
Alfuzosin	Hepatocellular or mixed hepatocellular–cholestatic injury
Beta-interferon	Raised AT common; clinically significant liver injury rare; can trigger autoimmune hepatitis
Bosentan, sitaxsentan	Raised AT in 8–32%; acute hepatitis
Imatinib mesylate and other tyrosine kinase inhibitors	Raised AT in 35%; acute hepatitis, massive or submassive hepatic necrosis (rare); acute liver failure also with sunitinib; raised AT and/or bilirubin with lapatinib
Infliximab and other tumor necrosis factor antagonists	Bland cholestasis, cholestatic hepatitis with bile duct injury, hepatic granulomas (etanercept), autoimmune hepatitis-like features, reactivation of chronic hepatitis B, acute liver failure (rare)
Leukotriene antagonists (zafirlukast, montelukast)	Submassive or massive hepatic necrosis (zafirlukast), acute hepatitis, cholestatic hepatitis (montelukast)
Orlistat	Cholestatic hepatitis, subacute liver failure (single cases only)
Ximelagatran	Raised AT in 6%; acute liver failure (relationship with drug not definitely established)

AT, aminotransferase.

Bosentan

This endothelin antagonist is prescribed for primary pulmonary hypertension, chronic heart failure, and hypertension. Dose-dependent reversible AT (up to 3 × ULN) increases were observed in 10% of clinical trial recipients, and in 7.6% in a recent postmarketing surveillance report [605]. In a pivotal trial of patients with primary pulmonary hypertension, AT increases of eight times ULN were observed in 3% and 7% of those assigned to the 125 mg b.i.d. group and 250 mg b.i.d. arms,

respectively [605]. The pharmacokinetics of bosentan is unaltered by mild hepatic function impairment (Child–Pugh class A) but the drug is contraindicated if more severe liver disease is present. Reversible acute hepatocellular injury has been described after commencing methotrexate in a patient with scleroderma-related pulmonary arterial hypertension who had been on bosentan for 15 months [606]. Other drug interactions with consequent acute hepatocellular injury have been documented with co-prescription of bosentan/clarithromycin and bosentan/glibenclamide (glyburide) (29% show AT changes) [42]. The latter reaction is probably related to the synergistic effects of the two agents – in a rat model, bosentan inhibited the canalicular bile acid transporter, Bsep [607]. Patients with chronic heart failure also appear to be at an increased risk of liver injury, with up to 18% showing AT elevations in one study.

Dose-dependent AT increases have been reported with sitaxsentan, a selective endothelin receptor antagonist. The cumulative risk of developing raised AT (up to 3 × ULN) after 9 months with the 100 and 300 mg daily doses has been estimated at 8% and 32%, respectively [608]. In addition, six cases of acute hepatocellular injury have accrued with this drug [608]. Onset was within 4 months. Most patients recovered but the liver injury can be severe. One died from pneumonia with evidence of persistent jaundice (bilirubin >200 μmol/L) and another required a liver transplant. Liver histology appearances were consistent with acute hepatitis. Apparent response to corticosteroids in one case and evidence of eosinophil infiltration within the portal tracts in another raises the possibility of an immune reaction. Liver toxicity could be a class effect of this group of drugs because cross-toxicity between bosentan and sitaxentan has been reported [608]. However, to date, ambrisentan has not been associated with such toxicity.

Interferons

Interferon-α has been associated with acute "flares" in patients with hepatitis C, sometimes resulting in viral clearance. It may also rarely activate latent AIH [42]. This may occur if the autoimmune etiology of chronic hepatitis has not been correctly appreciated at diagnosis, or it may represent a direct immune-mediated complication of interferon.

Beta-interferon is used in relapsing–remitting multiple sclerosis. The analysis of pooled data from six randomized controlled trials involving over 2,800 subjects has shown that AT increases are frequent (67% of subjects by 24 months) [609]; most (75%) of these increases occur within 6 months. AT changes settled spontaneously or after dose reduction (in 5%), and only a minority (0.4%) had their medication withdrawn. A retrospective chart review of 844 patients in British Columbia compared three different preparations of interferon-β-1b with respect to their hepatotoxic potential [610]. AT increases of up to 2.5 × ULN, 5 × ULN, and >5 × ULN were found in 23–39%, 1.9–7.8%, and 0–1.9%, respectively; the lowest figures were recorded with the intramuscular preparation of interferon-β-1b. Despite the high frequency of AT changes observed with the β-interferons, clinically significant toxicity is restricted to a few case reports of acute hepatitis [611]. Of the two reported patients developing fulminant hepatic failure [611], one was also receiving nefazodone. Unmasking of AIH has also been observed with interferon-β [42].

Pegylated interferon-α has a higher rate of AT abnormalities than conventional recombinant interferon-α but clinically significant hepatotoxicity has not been reported.

Imatinib mesylate and other tyrosine kinase inhibitors

Imatinib mesylate is approved for chronic myeloid leukemia and gastrointestinal stromal tumors (GISTs). Adverse effects include fluid overload from salt retention and abnormal liver tests; up to 3.5% of treated cases showed AT and/or serum bilirubin changes (median time to onset, 100 days) [42]. These abnormalities usually settled with dose reduction and the drug was withdrawn in only 0.5% of cases on account of hepatotoxicity. A few reports of acute hepatitis have since accrued, including five cases of acute liver failure [612]. Concurrent acetaminophen intake was recorded in two of these cases. Most were patients with myeloproliferative disease but some had advanced GISTs [613]. Positive rechallenge has been documented. Histologic appearances showed acute hepatitis with extensive lobular and portal inflammation or focal hepatic necrosis in less severe cases, and submassive hepatic necrosis in those presenting with acute liver failure [614]. Corticosteroids have been used successfully to achieve resolution in some cases [613] while liver transplantation was needed to rescue patients developing acute liver failure. Interestingly, another structurally similar tyrosine kinase inhibitor, nilotinib, has been used without evidence of cross-hepatotoxicity. On the other hand, there have been reports of acute hepatocellular injury and fatal hepatic failure with sunitinib [615]. Concurrent acetaminophen use was recorded in the latter case; severe hepatic centrilobular necrosis with steatosis was noted at autopsy [615]. Lapatinib, used in treating advanced breast cancer, has also been implicated in hepatotoxicity. Elevations in AT (>3 × ULN) and total bilirubin (>1.5 × ULN) is seen in 6.4% and 8.1%, respectively. The presence of four specific HLA alleles have been correlated with ALT rises; the strongest link is with HLA-DQA1*0201 with an odds ratio of 2.6 (increasing to 18 in cases with ALT >8 × ULN) [616].

Leukotriene antagonists

This group of drugs is used to treat asthma, and includes zileuton, zafirlukast, and montelukast. As a group, reversible increases in AT (>2 × ULN) were recorded in up to 3% of leukotriene antagonist recipients in preclinical trials. Zileuton, the first member of this drug class, was implicated in a single case of acute hepatocellular injury. It has been superceded by zafirlukast and montelukast [617].

Zafirlukast

Over 100 cases of disturbed liver function with zafirlukast have been collated and published online by the manufacturers. These include 46 reports of hepatitis and 14 cases of acute liver failure. The risk of developing acute liver failure was estimated at less than one per 100,000 patient-years. Assigning causality is difficult because details of concomitant drug intake or preexisting liver disease were not provided. Nevertheless, detailed descriptions of clinically significant hepatic injury have been published elsewhere [617]. In these two case series, jaundice was observed in seven of nine cases. Two patients progressed to acute liver failure and needed liver transplantation. Symptoms were delayed until 6 months (range, 1.5–13 months) after starting zafirlukast. Inadvertent rechallenge reproduced the liver injury in one case. Liver explants showed submassive or massive hepatic necrosis. It is important to note that, in persons developing acute liver failure, prodromal features of hepatitis were not always present. The apparent response to corticosteroids in four cases, three of whom had hypersensitivity features such as skin rash and peripheral and tissue eosinophilia, is suggestive of immune-mediated liver injury. However, in another report the absence of hypersensitivity features and the long latent period (13 months) are more consistent with idiosyncratic liver injury [42]. Cross-reactivity with montelukast has not been described [42]. Periodic monitoring of liver tests is suggested [617]. However, the long latent period, lack of prodromal symptoms, and also the relentless progression of liver injury even after drug withdrawal cast doubts on the validity of routine surveillance [617].

Montelukast

Three reports of acute hepatitis have been documented with montelukast. Time to onset of liver injury has been variable (1 month to 2 years) [41,618]. Recovery was complete in all cases. Biochemical resolution can be slow and AT (>2 × ULN) remained elevated for more than 1 year after drug withdrawal. Liver histology showed acute hepatitis or cholestatic hepatitis [617]. A lymphocyte transformation test was reported as positive in one case, supporting a cause–effect relationship [618].

Infliximab and tumour necrosis factor antagonists

Transient AT elevations were recorded with infliximab in combination with methotrexate but no major hepatic adverse effects were noted in clinical trials. However, several reports of hepatotoxicity have since accrued for infliximab and other TNF antagonists including adalimumab, etanercept, and natalizumab [619]. The frequency of liver injury has been estimated at six and 28 per 100,000 patient-years of exposure with infliximab and natalizumab, respectively [619,620]. As expected with the profile of patients with rheumatologic disorders, most have occurred in women (12 of 17 cases; mean age, 43 years) who have also been receiving other hepatotoxic drugs (methotrexate, azathioprine). The onset of symptoms was usually after 4 weeks; occasionally they were delayed beyond 1 year or developed as early as after the first infusion (four of six cases with natalizumab). The clinical presentation is that of an acute hepatitis or with bland cholestasis. AT elevations range from 2 to 50 × ULN, but jaundice or impaired liver synthetic function is uncommon. Antinuclear, smooth muscle, and other autoantibodies are often present (64%). Liver histology appearances have varied from typical acute hepatitic features and autoimmune hepatitis-like patterns through to bland cholestasis, bile duct injury, bridging fibrosis, and granulomatous hepatitis [619]. One patient with severe liver injury required liver transplantation. Otherwise, recovery within 6 weeks is the rule. Corticosteroids have been used with apparent success in the majority of cases with autoimmune features. A successful switch to another TNF-α blocker, etanercept, has been described in patients with infliximab hepatotoxicity [621]. Whether the TNF antagonists are directly hepatotoxic or whether they trigger autoimmune hepatocellular and bile duct damage is not clear. In addition, there are now well-documented cases of chronic hepatitis B reactivation (both HBsAg-positive and HBsAg-negative cases) following infliximab and adalimumab treatment in patients with inflammatory bowel disease and other rheumatologic disorders; antiviral prophylaxis is recommended in rheumatoid arthritis (Chapter 24).

Ximelagatran

This thrombin inhibitor, now withdrawn, was associated with increased AT (>3 × ULN) in 7.9% of long-term recipients. Most (96%) of these biochemical changes decreased to less than two-fold above ULN irrespective of whether the drug was continued or withdrawn. Symptomatic cases have been rare [622]. AT increases were correlated with the presence of certain HLA alleles (DRB1*0701, DQA1*0201) [623]. Three cases of acute liver failure were attributed to this drug but a definitive relationship was not clearly established. Risk factors for liver

injury included prolonged treatment of over 3 months (OR, 6.7), deep vein thrombosis (OR, 5.2), and when used for stroke prophylaxis in patients with atrial fibrillation (OR, 8.3) [622].

Hepatotoxicity of herbal medicines

Whether herbal medicines have any therapeutic benefits in liver disease has yet to be defined, as reviewed elsewhere [624]. However, the growing popularity of complementary and alternative medicine in industrialized societies has brought about an increasing number of cases of herbal hepatotoxicity [625]. Many herbal products have been used for centuries, in part because of their excellent safety record, so that recognition of DILI has seemed surprising. Explanations include nonadherence to recommended doses and concurrent intake of other agents, including conventional medicines (like acetaminophen). Toxicity may also result from the use of newer, more biologically active formulations. For instance, a 78-year-old woman developed acute hepatitis soon after using a ready-made powder formulation of a fungal extract, linghzi (*Ganoderma lucidum*), despite having used this herbal compound previously for a year without toxicity [42]. The only difference was that earlier treatment had been home prepared and presumably was not as concentrated as the marketed product that caused the adverse reaction. Individual susceptibility may also be an important determinant of herbal toxicity. Kava, a reasonably safe and widely used anxiolytic agent with rare hepatotoxicity, appears more likely to cause acute hepatitis [626] in Caucasians with the slow debrisoquine phenotype (low expression of CYP2D6) (also see below under "Kava"). The same phenotype has also been implicated in facilitating senna-associated hepatocellular injury where altered pharmacokinetics with a prolongation of serum half-life and high metabolite levels were demonstrated [42]. In comparison with these agents, others such as the pyrrolizidine alkaloids have substantial hepatotoxic potential.

Some herbal preparations (for example, jin bu huan) could incite an immunoallergic mechanism of liver injury. Others could aggravate preexisting liver disease, as noted with ma huang, which can exacerbate AIH [627]. Rarely, herbal medicines may trigger latent AIH (e.g., dai-saiko-to, black cohosh) [628,629]. Such interactions between herbal medicines and preexisting liver disease are poorly understood. This is an important aspect because many patients with viral hepatitis use herbal remedies, and disclosure is not always forthcoming.

Recurring themes among reports of herbal hepatotoxicity are delayed diagnosis, product contamination, or botanical misidentification [625]. The latter two issues can be rectified by exclusive use of agents prepared according to codes of good manufacturing practice. Relevant legislation governing the sale of herbal products is in place in some countries, but the international availability of herbal medicines by mail and internet ordering partly abrogates such improvements. Greater awareness of possible herbal hepatotoxicity is required on the part of physicians and the public so as to avoid the problem of delayed diagnosis. The implications of continued intake of hepatotoxic chemicals after the onset of liver injury are identical whether it is a conventional medicinal agent or a herbal product. Natural products, often equated with "safety," may be easily overlooked by the patient and doctor. Items not readily identified include skin creams, "natural" sedatives, herbal tea infusions, health tonics, and so-called energy vitalizers.

Some herbal products can complicate the management of patients with chronic liver disease by exacerbating a bleeding tendency (gingko) or by antagonizing the antimineralocorticoid action of spironolactone (glycyrrhizin, licorice) [625]. Agents with immunostimulant actions, such as *Echinacea* and *St John's wort*, can interfere with immunosuppressive therapy and provoke allograft rejection [625].

Herbal hepatoxicity encompasses a range of hepatic pathology from acute hepatitis, steatosis, and fibrosis, through to SOS and submassive or massive hepatic necrosis. Table 27.18 provides an updated account of contemporary agents implicated in significant liver injury, and some well-characterized and illustrative examples are briefly outlined below. More detailed accounts are available in recent reviews [629,630].

Chaparral

Chaparral (*Larrea tridentate*) is marketed as tablets, capsules, or herbal tea infusions. It is used as a dietary "energy" supplement and as a cure for numerous ailments ranging from chicken pox to cancer. Cholestatic hepatitis is the predominant mode of presentation, but chaparral has been associated with acute hepatitis, subacute hepatic necrosis, and acute liver failure [631]. Hepatotoxicity is at least partly dose dependent; dosage recommendations were exceeded in some severe cases [631]. At least three patients have developed end-stage liver disease requiring hepatic transplantation.

Germander

Used as a traditional remedy for many centuries, germander became popular as a slimming aid in the 1980s, particularly in France and Italy. More than 30 cases of liver injury were recorded, mostly in middle-aged women. Acute hepatitis developed 8 weeks after the ingestion of germander capsules or herbal teas [632]. Presence of ANAs, SMAs, and, transiently, antimitochondrial M2 antibodies have been recorded occasionally [633]. Although most patients recovered, several fatalities from

Table 27.18 Herbal remedies and dietary supplements implicated as causing toxic liver injury.

Herbal remedy	Indications	Toxic constituent	Pattern of liver injury
Atractylis gummifera	Purgative, emetic, diuretic	Potassium atractylate and gummiferin	Acute liver failure
Black cohosh	Menopausal symptoms	Not known; contains diterpenoids	Acute liver failure; can trigger autoimmune hepatitis
Boh-gol-zhee	Herbal tea	*Psoralea corylifolea*	Zone 3 hepatic necrosis, acute cholestatic hepatitis
Camphor	Rubefacient	Cyclic terpenes	Abnormal liver tests, encephalopathy
Carp capsules (raw carp gallbladder)	Rheumatism, visual acuity	Cyprinol	Liver enzyme changes (no biopsy) with acute renal failure, hepatic necrosis (rats)
Cascara sagrada	Laxative	Many; ?anthraquinones	Cholestatic hepatitis, portal hypertension
Centella asiatica	Obesity, leprosy, wound care	Pentacyclic triterpenic saponosides	Acute hepatitis, granulomatous hepatitis, cirrhosis
Chaparral leaf	Multiple uses	*Larrea tridentate*	Zone 3 necrosis, massive hepatic necrosis, chronic hepatitis, cholestasis
Chaso, onshido; sennomotokounou	Slimming aid	*N*-nitrosofenfluramine	Submassive or massive hepatic necrosis, acute hepatitis
Chinese herbal medicines (see text)	Multiple uses; skin diseases, health tonic, viral hepatitis	Many; *Dictamnus dasycarpus* present in six cases (in combination)	Liver injury (no histology), acute hepatitis, SOS (VOD), VBDS
Comfrey; gordolobo yerba tea; maté tea; Chinese herbal tea	Health tonic	Pyrrolizidine alkaloids, Compositae	SOS (VOD)
Dai-saiko-to (TJ-9)[a]	Liver disease, especially chronic viral hepatitis	Scutellaria, glycyrrhizin	Acute and chronic hepatitis
Fu fang qing dai wan	Psoriasis	Unknown (multiple herbs)	Acute hepatitis
Germander (tea, capsules) and related *Teucrium* species	Weight reduction, health tonic	Neoclerodane diterpenes (*Teucrium chamaedrys* L.)	Acute and chronic hepatitis, zone 3 necrosis, fibrosis, cirrhosis, acute liver failure (*T. capitatum, T. polium*); zone 3 hepatic necrosis, hepatic fibrosis (*T. polium*)
Greater celandine	Gallstones	*Chelidonium majus*	Acute hepatitis, cholestatic hepatitis, fibrosis
"Green juice"	Dietary supplement	Contains vegetable extracts and micronutrients	Granulomatous hepatitis
Green tea extracts (Exolise®, Hydroxycut®, The Right Approach®)	Herbal tea	?Epigallocatechin-3-gallate	Acute hepatocellular injury, cholestatic hepatitis, submassive or massive hepatic necrosis
Herbalife®	Health supplement	Not known	Acute hepatitis, cholestasis, bile duct injury, giant cell hepatitis, SOS (VOD) (?due to contaminant)
Isabgol	Laxative	Not identified	Giant cell hepatitis (one report)
Jin bu huan anodyne tablets	Sedation, analgesic	*Lycopodium serratum*	Acute and chronic hepatitis, steatosis, fibrosis
Kava	Anxiety disorders	Kavalactone	Diffuse hepatocellular necrosis, cholestatic hepatitis; isolated GGTP increase
Kombucha "mushroom"	Health tonic	Yeast–bacteria aggregate; contains usnic acid	Acute hepatitis
Linghzi	Multiple uses	*Ganoderma lucidum*	Acute cholestatic hepatitis
LipoKinetix®	Slimming aid	?Ephedra, ?usnic acid	Acute hepatitis, acute liver failure

Table 27.18 (*Continued*)

Herbal remedy	Indications	Toxic constituent	Pattern of liver injury
Lycopodium similiaplex	Insomnia	*Lycopodium serratum* and *Chelidonium majus*	Acute hepatitis
Ma-huang	Slimming aid	Ephedrine	Acute hepatitis; exacerbates autoimmune hepatitis
Margosa oil	Health tonic	*Azadirachza indica*	Reye syndrome
Mediterranean remedy	Anti-inflammatory agent	*Teucrium polium*	Zone 3 necrosis, acute liver failure, fibrosis
Mixed preparations: mistletoe, skullcap, valerian	Herbal tonics	Not identified; ?scutellaria. Skullcap has diterpenoids (cf. germander)	Liver injury (no histologic studies)
"Natural laxatives"	Cathartic	Senna, podophyllin, aloin	Senna (acute hepatitis, cholestatic hepatitis)
			Cascara (acute cholestatic hepatitis, bridging hepatic fibrosis)
Noni juice	Food supplement	*Morinda citrafolia*	Hepatocellular injury including cases of acute or subacute liver failure
Oil of cloves	Dental pain	Eugenol	Dose-dependent hepatotoxin, zonal necrosis
Pennyroyal oil (squawmint)	Abortifacient, herbal drug	Pulegone metabolites	Confluent hepatocellular necrosis
Prostata	Prostatism	Saw palmetto	Hepatitis, fibrosis
Red yeast rice	Hypercholesterolemia	HMG-CoA reductase inhibitors including lovastatin	Acute hepatitis
Shark cartilage	Food supplement	Not identified	Abnormal liver tests (no histology)
Sho-saiko-to (TJ-9)[a]	Health tonic, viral hepatitis	Scutellaria, glycyrrhizin, others	Zonal/bridging necrosis, fibrosis, microvesicular steatosis
Shou-wu-pian	Dizziness, premature graying of hair, liver disease	*Polygonum multiflorum* (?anthraquinones); ?stilbene glycosides	Acute hepatitis, acute cholestatic hepatitis
Usnic acid	Slimming aid	Usnic acid	Acute liver failure
Zulu remedy	Health tonic	*Callilepsis laureola*	Hepatic necrosis

[a]TJ-9 is used in Japan and China; there are several alternative spellings, including sho-saiko-to and dai-saiko-to.
GGTP, γ-glutamyl transpeptidase; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; SOS, sinusoidal obstruction syndrome; VBDS, vanishing bile duct syndrome; VOD, venoocclusive disease.

liver failure have been recorded. In some individuals, chronic hepatitis or cirrhosis was evident at presentation. Other case studies suggest that unfavorable outcomes are related more often to continued or repeated drug ingestion after the onset of liver injury. Early recrudescence of liver test abnormalities following rechallenge is suggestive of immunologic idiosyncrasy. The identification of a microsomal target for germander-induced autoantibodies is consistent with this proposal [634]. On the other hand, the demonstration that the constitutive neoclordane diterpenoids in germander are metabolized by CYP3A enzymes to epoxides that can deplete GSH and incite oxidative stress-dependent apoptosis favors a reactive metabolite mechanism of liver injury [635].

Herbal products derived from closely allied medicinal plants *Teucrium polium* L. and *Teucrium capitatum* L. have also been associated with acute liver failure and acute hepatitis with bridging necrosis, respectively [636].

Jin bu huan

Jin bu huan has been implicated in several cases of acute hepatitis [637]. The onset of symptoms occurred after a mean of 20 weeks (range, 7–52 weeks). Focal hepatic necrosis with numerous eosinophils, minor lobular hepatitis with microvesicular steatosis, and bridging fibrosis have been described. Resolution occurred within 8 weeks of discontinuation, but chronic hepatitis has been reported with long-term use [638].

Levo-tetrohydropalmatine, the active ingredient, is structurally similar to the hepatotoxic pyrrolizidine alkaloids (see next). Despite being banned in the United States and Canada since 1994, new cases of jin bu huan toxicity continue to accrue, stressing the need for continued vigilance.

Kava

Extracts of *Piper methysticum* have been used as a traditional ceremonial beverage ("Kava," "Kava Kava") in South Pacific countries. Elsewhere, they are dispensed by alternative medical practitioners as anxiolytics or sedatives. Over 60 cases of hepatotoxicity have been reported worldwide [639]. Most reported cases have occurred in users of alcohol or acetone extracts of the herb, but traditional preparations of kava, which are aqua based, have also been rarely implicated in causing liver injury [640]. The frequency of kava-associated liver injury has been estimated at 0.24–0.26 per million daily doses. Many of the affected individuals have been women (female : male ratio 3 : 1). These included 11 patients with acute liver failure who required liver transplantation [641]; the explants showed pan-acinar necrosis. In less severe cases, cholestatic or lobular hepatitis was noted. Symptoms of liver injury were reported to begin 3–16 weeks after starting ingestion (range, 2 weeks to 2 years; median, 4.5 months). Reversible increase in GGTP has also been recorded in kava users [42], but this appears unrelated to the marked rise in AT seen in patients developing liver injury and could instead reflect adaptation (microsomal enzyme induction).

The hepatotoxic potential of kava has been disputed by phytomedicine practitioners, who cite its safe track record and the presence of alcohol or concurrent hepatotoxic medications in some reports. However, there are well-documented cases occurring in the absence of such confounding factors. Moreover, positive rechallenge has been documented in at least two cases [639].

The active ingredients in kava are collectively termed kavapyrones (or kavalactones). The mechanism of liver injury is unclear but the following have been suggested: inhibition of CYP enzymes, inhibition of cyclooxygenases COX-1 and COX-2, or depletion of hepatic glutathione. An immunoallergic basis has been postulated due to the lack of dose dependency; it is further supported by the presence of autoantibodies, eosinophilia, positive lymphocyte transformation tests, and also the successful use of corticosteroids in some cases. However, metabolic idiosyncrasy appears more plausible as the above "immune" phenomena are lacking in the majority of cases [639,642]. As noted above, the debrisoquine slow metabolizer phenotype may predispose to kava hepatitis in Caucasians. However, studies involving affected Pacific islanders have not confirmed such a relationship [640], which is not surprising given the low prevalence (~1%) of CYP2D6 deficiency in these ethnic groups [626].

Pyrrolizidine alkaloids

Ingestion of these plant alkaloids is endemic in Africa and Jamaica, usually as herbal tea mixtures or extracts derived from mashing and boiling herbal or plant material (decoctions) or even as an enema [629]. Such preparations have been associated with hepatic VOD (SOS), fibrosis, and cirrhosis. Pyrrolizidine alkaloid contamination has also been found in cases of SOS associated with the consumption of Chinese herbal teas and comfrey [630]. In India and Afghanistan, epidemics of SOS have occurred following the contamination of wheat flour with pyrrolizidine alkaloids [643]. In the acute form of SOS, the typical manifestations are abdominal pain, ascites, hepatomegaly, and raised ATs. Liver failure can occur, even during the acute phase, but recovery is also possible. On the other hand, the prognosis is poor for individuals presenting with the chronic form of this disease. Death occurs from liver failure.

Herbal slimming aids

Several cases of acute liver injury have been reported in association with herbal weight reduction remedies [644]. In Japan, 12 women presented with jaundice, fatigue, diarrhea, and a biochemical picture of hepatocellular injury, 5–45 days after commencing Chaso® or Onshido® [645]. Of these, two developed acute liver failure; one survived after a liver transplant and the other died 6 weeks after admission. Pathologic findings were of massive or submassive hepatic necrosis or acute hepatitis. Over 400 cases of hepatotoxicity associated with herbal weight loss aids were reported to the Japanese Health Ministry in 2002; Chaso and Onshido use were recorded in 21 and 135 cases, respectively. *N*-nitrosofenfluramine has been identified as a potential hepatotoxin with these two products, and is a recognized hepatocarcinogen. Other *N*-nitrosofenfluramine-containing compounds associated with liver toxicity include Sennomotokounou® and LipoKinetix® (see below). Over 100 cases, including two deaths from Sennomotokounou liver toxicity were reported to the Japanese Ministry of Health, Labour, and Welfare [644]. Individual susceptibility may be important because the frequency of liver injury appears to be low; the CYP2C19 poor metabolizer phenotype was present in one of two patients with acute hepatitis. An immunoallergic basis was postulated for the other patient, who lacked this phenotype, but developed peripheral and tissue (liver) eosinophilia.

LipoKinetix, a dietary supplement, has been implicated in seven cases of acute hepatocellular injury in Los Angeles, USA [646]. Five of these were Japanese nationals. The onset of liver injury was within 3 months of ingestion

(many within 1 month). Three patients developed acute liver failure but eventually recovered. Recovery was complete within 3 months. Liver histology was not available. The toxic ingredient was not identified among this multicomponent herbal product; potential candidates include ephedra alkaloids or usnic acid. The latter, marketed as a "fat burner," works by uncoupling oxidative phosphorylation. It has been implicated in causing acute liver failure in a 35-year-old woman [647]. The disruption in mitochondrial bioenergetics and generation of oxidative stress could be central to usnic acid hepatotoxicity. Interestingly, usnic acid is also present in kombucha "mushroom", a multipurpose tonic previously implicated in cases of hepatocellular injury [644]. It has also been suggested that usnic acid could be the primary hepatotoxin in LipoKinetix-related liver toxicity. However, the absence of lactic acidosis argues against the involvement of usnic acid, a primary mitochondrial toxin [644]. Another herbal slimming aid, now withdrawn, Hydroxycut® was implicated in several instances of acute hepatitis, including a few reports of acute liver failure necessitating liver transplantation [648].

Natural and synthetic retinoids

Hypervitaminosis A

Risk factors

Vitamin A is a dose-dependent hepatotoxin. Historically, cases of acute hypervitaminosis A with liver injury occurred among arctic travelers who were forced to consume large quantities of polar bear liver. Today, liver injury more often follows self-medication with vitamin A preparations, although rare instances of hypervitaminosis A have followed consumption of large amounts of raw liver alone or in combination with β-carotene-rich vitamins [649,650].

Hepatic injury occurs both with acute ingestion of massive doses (>600,000 IU) and with prolonged ingestion of smaller doses [651]. The mean daily dose of vitamin A in reported cases has been 96,000 IU, and the average duration of ingestion has been 7.2 years (range, 11 days to 30 years) representing a mean cumulative dose of 229 million units [652]. Cirrhosis has occurred in persons with a daily intake of 25,000 IU for 6 years or longer [652]. It is therefore noteworthy that up to 3% of vitamin supplements in the United States recommended for daily use contain 25,000 IU or more of vitamin A. In patients with renal failure, vitamin A doses as low as 4,000 IU/day can lead to hepatotoxicity [653].

Diagnosis: presentation, clinical features, and laboratory findings

In a Belgian series, only about a third of 41 cases were identified correctly at presentation; the average delay in diagnosis was 18 months [652]. Hypervitaminosis A is associated with hepatotoxicity in about 50% of cases. Other features of hypervitaminosis are usually present, such as fatigue, myalgia, bone pain, dry skin, alopecia, gingivitis, xanthosis, headache, neuropsychiatric disturbances, hypercalcemia, and growth retardation [654]. The liver is often enlarged. Splenomegaly, ascites, and signs of portal hypertension are present in severe cases, but jaundice is not usually found.

The clinicopathologic spectrum of hypervitaminosis A-related liver disease includes minor alteration of liver enzymes, peliosis hepatis [655], noncirrhotic portal hypertension with perisinusoidal fibrosis, sclerosis of central veins, and cirrhosis. Decompensated chronic liver disease can occur in the absence of cirrhosis and may be irreversible. Liver enzyme changes are nonspecific. Hypoalbuminemia, prolongation of prothrombin time, and hyperglobulinemia (with predominant IgM) are seen in advanced cases [652]. An increased plasma level of retinyl esters (>10%) as a proportion of total serum vitamin A (normal <8%) has been suggested as a marker of hypervitaminosis A [656], but this is not supported by the NHANES III survey, which showed no correlation between retinyl esters and liver test abnormalities [657]. Further, plasma vitamin A levels may also be normal in patients with hepatic fibrosis [652]. A demonstration of increased hepatic vitamin A stores and the characteristic histologic appearances are a more reliable guide to diagnosis.

Liver pathology

Stellate cells store vitamin A in the liver. As expected, liver biopsies of people with hypervitaminosis A show stellate cell hypertrophy and hyperplasia. This can give rise to sinusoidal compression and a typical honeycombed ("Swiss cheese") appearance. Perisinusoidal fibrosis is often striking, whereas hepatocellular injury is usually minimal. Microvesicular steatosis and focal degeneration have also been reported [658]. Vitamin A deposition is readily detected on fresh liver sections by the characteristic greenish autofluorescence after irradiation with ultraviolet light.

Course and management

Gradual improvement usually occurs after vitamin A is discontinued, but progression from noncirrhotic portal hypertension to cirrhosis may continue [659]. Features of liver failure with established cirrhosis at diagnosis indicate a poor prognosis; most patients die or require hepatic transplantation [660]. This is because turnover of vitamin A stores is very slow [half-life, 58–286 days]. Abstinence from alcohol is advised because ethanol can potentiate vitamin A hepatotoxicity [661].

Synthetic retinoids

Etretinate is an aromatic synthetic retinoid (structurally unrelated to vitamin A) used in the management of psoriasis and other dyskeratotic skin disorders. Abnormal liver tests are found in up to 20% of recipients of etretinate but overt liver injury is less common (<1%). Acute and chronic hepatitis, mild cholestasis and cirrhosis have all been reported [662]. Features of drug allergy are usually not present, although eosinophilia was reported in one case [663]. Recovery can be delayed because of the long tissue half-life of etretinate (120 days). Corticosteroids appeared to induce a clinical response in one report of etretinate-induced chronic hepatitis [662]. It is recommended that patients taking etretinate be monitored with regular liver tests. If the liver enzymes are raised (>3 × ULN), the options are to either perform a liver biopsy to assess the significance of liver injury or discontinue etretinate [14].

Acitretin, the major metabolite of etretinate, has a shorter half-life (50 hours). A large study evaluating sequential liver biopsies on recipients of acitretin did not show significant histologic progression [664]. However, acitretin has also been associated with a few reports of acute hepatitis, including one instance of acute cholestatic hepatitis with bile-duct injury accompanied by marked hyperbilirubinemia (70 mg/dL) [665]. Progressive fibrosis and cirrhosis can occur, despite stopping acitretin [666]. Periodic monitoring of liver function tests is recommended.

Multiple choice questions

27.1 With respect to acetaminophen hepatotoxicity, all of the following statements are true except which one?

- **a** Acetaminophen is the leading cause of acute liver failure in the United States.
- **b** Concomitant use of statins increases the risk of acetaminophen hepatotoxicity.
- **c** Intravenous *N*-acetylcysteine is an alternative to oral *N*-acetylcysteine in treating patients at risk of significant liver injury.
- **d** *N*-acetylcysteine replenishes cytosolic and mitochondrial glutathione and also provides mitochondrial energy substrates.
- **e** *N*-acetylcysteine can be beneficial even in patients presenting with acute liver failure.

27.2 A strong genetic predisposition to developing drug-induced liver injury has been reported for all the following drugs except which one?

- **a** Nevirapine.
- **b** Abacavir.
- **c** Flucloxacillin.
- **d** Atorvastatin.
- **e** Sodium valproate.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 28

Mechanisms of Drug-induced Liver Injury

Paul B. Watkins

Institute for Drug Safety Sciences, University of North Carolina at Chapel Hill, NC, USA

Key concepts

- An initial event in drug-induced liver injury (DILI) is often accumulation of a reactive metabolite over a "threshold." This occurs when the rate at which the reactive metabolite is produced exceeds the rate at which it can be safely eliminated.
- Reactive metabolites can injury cells in many ways, including creating oxidative stress and covalent binding. The mitochondria appear to be a particularly important target for these effects.
- Liver injury can stimulate an innate immune response, which can amplify the death of hepatocytes. The extent of this "collateral damage" appears to be largely based on a balance of pro- and anti-inflammatory cytokines.
- Drug-induced liver injury can resolve spontaneously despite continuation of drug therapy due to adaptation. This can involve altered regulation of hepatocyte enzymes and transporters and probably downregulation of the innate immune response.
- There is increasing evidence that rare or idiosyncratic DILI may result from an adaptive immune attack on the liver. This may occur in response to drug–protein adducts acting as antigens and mild drug-mediated liver injury acting as a "danger signal."
- Genomic approaches currently being undertaken should improve our understanding of the mechanisms that underlie DILI. This should lead to improved methods of preclinical safety testing of new drugs and to personalized medicine tests to improve the safety of existing drugs.

Drug-induced liver injury (DILI) has been traditionally divided into two categories: predictable and unpredictable (or "idiosyncratic"). In reality, these classifications are two ends of a spectrum, with some drugs sharing features of both. Predictable liver toxins produce dose-dependent injury that typically occurs within days of dosing; essentially all patients will develop liver injury if they receive a sufficiently high dose. Drugs that are predictable toxins are generally identified in preclinical (animal) studies, or during the early clinical trials specifically designed to look for dose-related toxicity. If liver toxicity occurs at doses likely to be near those required for significant therapeutic benefit, the drug is generally abandoned from further development. As a result, there are few predictable hepatotoxins in therapeutic use today. One example of a drug that is a predictable hepatotoxin is acetaminophen. As with all predictable toxins, subtoxic exposures can generally be safely tolerated as "the dose makes the poison."

In contrast to predictable toxicity, idiosyncratic toxicity is not clearly dose related and is typically delayed weeks to months after starting dosing. With a true idiosyncratic toxin, only a very small fraction of the total treated patients are susceptible to liver injury even when receiving high doses (i.e., it is the *host* that makes the poison). Animal models, while having value in identifying predictable liver toxins in man, generally are of little help in identifying drugs capable of causing idiosyncratic toxicity. If the toxicity occurs in less than one in 1,000 patients receiving the drug, the toxicity might not be recognized during preapproval clinical trials, and only become evident after regulatory approval for marketing and widespread usage. Recognition that an otherwise good drug can cause idiosyncratic hepatotoxicity often leads to regulatory actions that limit access of patients to that drug, even when most patients are at no risk for toxicity. Idiosyncratic hepatotoxicity has been the major reason for regulatory actions concerning drugs, including failure to approve, marketing restrictions, and withdrawal from the market place [1]. Idiosyncratic hepatotoxicity therefore poses a great problem for physicians, patients, and the pharmaceutical industry. Until the mechanisms underlying idiosyncratic hepatotoxicity are further identified, it is unlikely that industry will be able to design this liability out of new drugs. The vast majority of research on the mechanisms underlying DILI has involved predictable

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.

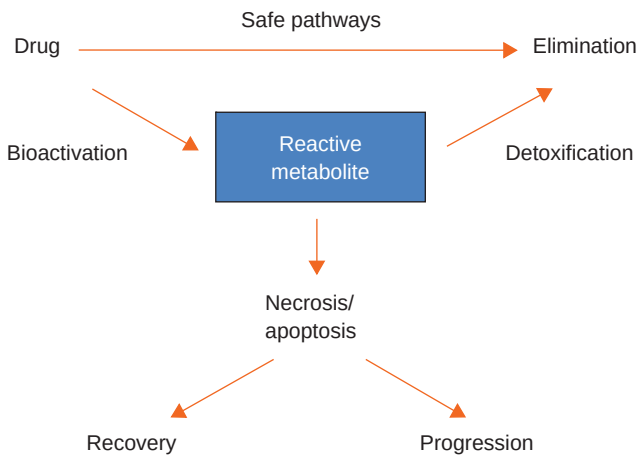
hepatotoxins, particularly acetaminophen. Furthermore, it is generally assumed that the mechanisms underlying predictable toxicity are relevant to idiosyncratic toxicity, but that the latter occurs because of genetic or nongenetic factors that are present only in susceptible patients.

Mechanisms of predictable hepatotoxicity

Most predictable hepatotoxins, including environmental compounds like aflatoxin B1, bromobenzene, and carbon tetrachloride, are relatively harmless to the liver. These, and most other predictable hepatotoxins, are converted in the liver to reactive, or toxic, metabolites generated from the parent (or "protoxin") [2,3]. A general scheme for hepatotoxicity mechanisms involving reactive metabolites is shown in Fig. 28.1. The liver is particularly susceptible to generating reactive metabolites because it is the major organ responsible for drug metabolism and elimination. Furthermore, many of the same enzymes involved in the safe elimination of drugs (nontoxic pathways) have also been implicated in creating reactive and potentially toxic metabolites.

When a reactive metabolite is involved in toxicity, it usually represents only a small fraction of the total metabolism of the drug. Hepatocytes are generally capable of efficiently detoxifying and eliminating reactive metabolites once formed, preventing toxicity. A generally held concept is that the initiating event in predictable hepatotoxicity is the accumulation of the reactive metabolite above some threshold. Accumulation occurs when the relative rates of production of the reactive metabolite exceed its rate of safe removal.



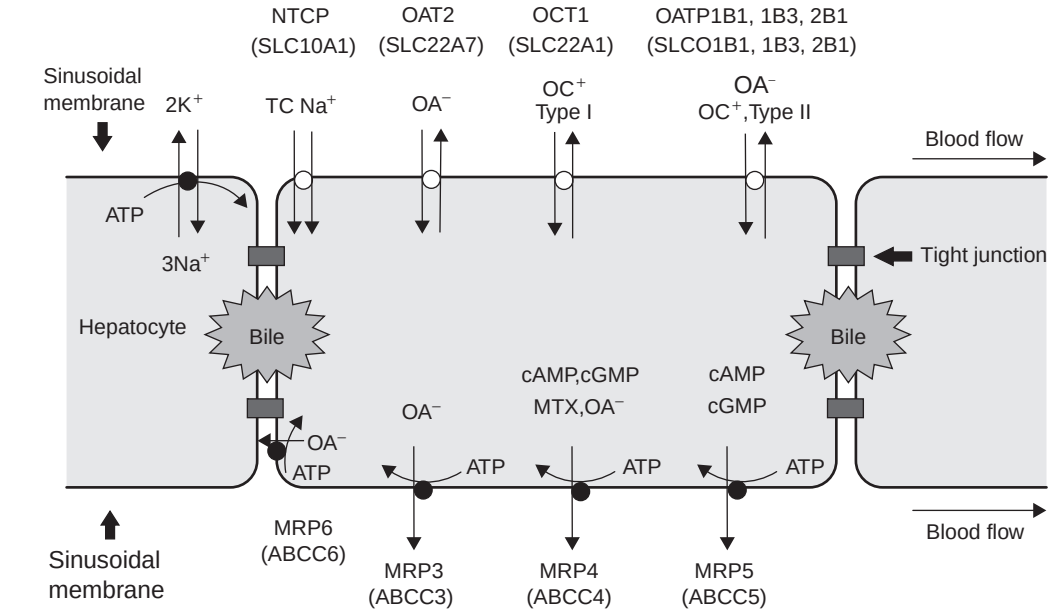


Figure 28.1 Central role of reactive metabolites in drug-induced liver. For most drugs, the major routes of elimination involve the production of metabolites that are safely excreted and therefore represent no threat to the liver cells. Drugs that produce liver injury generally appear to do so through "bioactivation" to reactive or toxic metabolites, which often result from relatively minor metabolic pathways. Fortunately, the liver generally has adequate ability to detoxify these metabolites, allowing their safe elimination. However, under certain circumstances, the reactive metabolite can accumulate in the hepatocyte above a threshold for toxicity, resulting in hepatocyte damage through a variety of mechanisms discussed in the text. For a given level of hepatocyte injury, the outcome may be complete recovery or progression to death, depending on the response of the innate immune system.

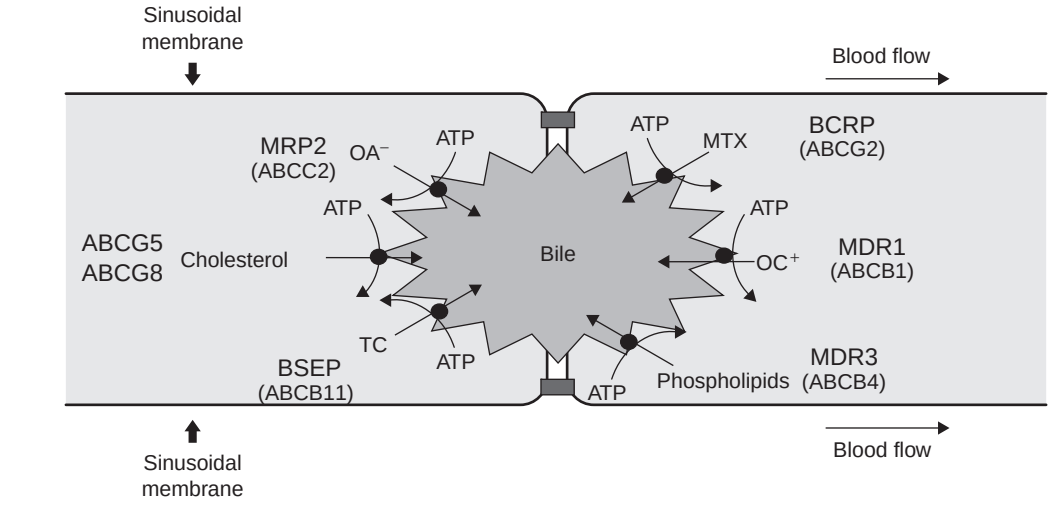
The rate of production of a reactive metabolite in the hepatocyte reflects the intrinsic activity of the enzyme responsible for this conversion (termed "bioactivation" in Fig. 28.1) and the concentration of the parent molecule surrounding the enzyme within the hepatocyte. The concentration of the parent molecule chiefly reflects: (i) the competing rates of uptake into, and efflux out of, the hepatocyte; and (ii) the rate of conversion of the parent molecule to safe and readily excreted metabolites (the competing "safe pathways" shown in Fig. 28.1).



Safe pathways of drug metabolism and transport

The rates of uptake and efflux of drugs (and metabolites) in most cases does not reflect passive diffusion, but rather the activities of specific transport proteins [4,5]. There has been great progress in the identification and characterization of these transporters (Fig. 28.2). Uptake transporters are present on the basolateral membrane of the hepatocyte and effux transporters are present on both the basolateral and canalicular membranes. Once inside the hepatocyte, the rate of conversion of the parent molecule to nontoxic metabolites reflects the activities of a variety of enzymes traditionally divided into two categories: phase 1 and phase 2. Phase 1 reactions result in a direct modification of the primary structure of the drug, usually resulting in the insertion of an oxygen atom in the form of a hydroxyl (-OH) group. Phase 2 reactions involve covalent binding (conjugation) of the drug to polar ligands, usually glucuronic acid or sulfate, often to the hydroxyl group resulting from phase 1 metabolism. The terms phase 1 and phase 2 refer to the fact that often, but not always, drugs must first be subjected to phase 1 metabolism before they can be conjugated. Metabolites generated by phase 1 and phase 2 enzymes are generally actively secreted into bile or back into the systemic circulation for elimination by the kidneys into urine. In most instances, this process appears to reflect active transport by many of the same proteins involved in the efflux of parent drugs (Fig. 28.2). Active efflux of metabolites from the hepatocyte is sometimes termed phase 3.

It is now appreciated that most (but not all) of what was described as phase 1 drug metabolism is the result of the activity of a large family of enzymes termed cytochromes P450, now termed simply P450s or CYPs (pronounced "sips"). Liver P450s metabolize most drugs in use today; in many and perhaps most instances, metabolism by a

A

Figure 28.2 Uptake and efflux transporters in the hepatocyte. (A) Basolateral transporters: the uptake of serum bile acids results from the action of neutral taurocholate protein (NTCP) and to a lesser extent organic anion transport polypepetides (OATPs), which are also involved in the uptake of many drugs. Multidrug resistance-associated proteins (MRPs) are chiefly involved with the efflux of drug and their metabolites, particularly glucuronide and sulfate conjugates. During the recovery phase of hepatotoxicity due to acetaminophen or carbon tetrachloride, there is downregulation of NTCP and several OATPs, and upregulation of several MRPs, including MRP3 and MRP4. The aggregate effects of these changes, which reduce the hepatocyte content of potentially injurious bile acids and xenobiotics, likely account in part for adaptation to hepatotoxicity with recurrent dosing. (B) Canalicular transporters: bile salt excretory protein (BSEP) is the major bile acid efflux pump. Multidrug resistance transporter 1 (MDR1) and MRP2 are responsible for biliary excretion of most xenobiotics and their metabolites. During the recovery phase of hepatotoxicity due to acetaminophen or carbon tetrachloride, there is upregulation of MRP2 and probably MDR1 and BSEP. These changes compliment the altered regulation in basolateral transporters and should further reduce the hepatocyte content of potentially injurious bile acids and xenobiotics and thereby contribute to adaptation with recurrent dosing. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; MTX, methotrexate; OA, organic anionx; OAT, organic anion transporter; OC, organic cation; OCT, organic cation transporter. (Adapted from Chandra and Brouwer [4].)

P450 is rate limiting in the elimination of the parent drug. Most P450s important for drug metabolism derive from three gene families, now termed CYP1, CYP2, and CYP3 [6]. Within each P450 family, there are subfamilies designated by capital letters. Each subfamily generally contains multiple members, designated by Arabic numbers usually reflecting the order in which they were discovered.

A list of the major P450s involved in human drug metabolism is shown in Table 28.1. In many instances, a single P450 represents the major pathway of metabolism of a drug but a single P450 can generally metabolize many different drugs. To identify the P450s that metabolize drugs in development, many pharmaceutical companies use high throughput technology [7] and some are utilizing computer-based (in silico) modeling [8].

The best studied phase 2 enzymes involved in the elimination of nontoxic metabolites are the uridine 5′-diphosphate (UDP) glucuronyltransferases, and the sulfotransferases, which catalyze conjugation to glucuronic acid and sulfate, respectively. Conjugation generally results in enhanced water solubility and elimination in urine and stool. As with the P450s, the UDP glucuronyltransferases and sulfotransferases arise from multigene families [9,10]. High throughput means of assessing which phase 2 enzymes metabolize drugs have been developed [11].

Enzymes involved in generating reactive metabolites

It appears that the initiating step in drug-induced liver injury often involves creation in the liver of a reactive metabolite from the parent molecule (see Fig. 28.1). Reactive metabolites are generally minor products of drug metabolism, and their reactivity can make them very short lived and difficult to detect in biologic systems. For this reason, identifying the precise structure of a reactive metabolite can be challenging.

P450s are the major enzymes capable of generating reactive and potentially toxic metabolites. The identical enzymes involved in the safe metabolism of drugs are those that have been most implicated in the production of hepatotoxic metabolites (see Table 28.1 for examples). In general, P450s are expressed in the highest concentration in zone 3 hepatocytes, and this in part accounts for the predominance of pericentral necrosis in some forms of DILI (such as that due to acetaminophen) [12]. Interspecies differences in P450 catalytic activities and regulation probably contribute to the imperfect ability of preclinical animal studies to identify human hepatotoxins [13].

Not all reactive metabolites are produced by P450s. Some reactive metabolites, such as acylglucuronides [14], are products of phase 2 metabolism. For example, glucuronide metabolites of diclofenac and valproic acid has been shown to covalently bind multiple proteins in the hepatocyte, and this covalent binding may contribute to hepatoxicity rarely associated with these drugs [15–17].

Enzymes involved in the safe elimination of reactive metabolites

Minor reactive metabolites are probably commonly produced during the metabolism of drugs. Fortunately, the liver usually has the ability to dispose of these metabolites before they can cause injury. The major safe elimination pathway for reactive metabolites involves conjugation to glutathione (GSH). Although GSH is synthesized in every cell in the body, the liver is the major site of its synthesis. Under usual conditions, the hepatocyte cytosolic concentration of GSH is quite high (~10 mM). GSH may conjugate to reactive metabolites spontaneously, but this reaction is usually catalyzed by the glutathione-*S*-transferases [18]. The resultant conjugates are generally nonreactive and readily excreted into bile or urine. GSH conjugates are pumped from the liver cell into bile by transporters, principally multidrug resistance-associated protein 2 (MRP2) (Fig. 28.2).

There are three families of glutathione transferases (GSTs): cytosolic, mitochondrial, and microsomal. The cytosolic GSTs are those most involved in drug metabolism and are divided into seven classes, designated alpha, mu, pi, sigma, theta, omega, and theta [19, 20]. Each class has several members designated by arabic numbers. For example, GSTM1 is the first of five members of the mu gene family.

The important role of GSH conjugation has led to the development of sophisticated methods to detect GSH conjugates in liver microsomes and whole animals [21]. The production of GSH conjugates from a drug generally means that reactive metabolites have been formed. However, in whole-animal studies, GSH conjugates may be undetectable if they enter bile and are eliminated in stool, or broken down by intestinal bacteria. In addition, not all reactive metabolites depend on GSH for safe elimination. One important class of reactive metabolites is the epoxides, which can be safely eliminated through the action of microsomal epoxide hydrolase [22]. In addition to functioning in the catalysis of detoxification reactions, it has recently been appreciated that GSTs and epoxide hydrolases play a role in intracellular signaling that may be linked to cell death pathways [23,24].

How reactive metabolites cause hepatotoxicity

There appear to be many potential ways in which toxic metabolites can injure hepatocytes, but the most common mechanisms appear to involve oxidative stress and covalent binding.

Table 28.1 Some characteristics of the main human liver P450s.

P450	Substrates	Inhibitors	Inducers
CYP1A2	Tacrine Theophylline Tolcapone[a] [135] Dihydralazine[a] [136] Flutamide[a] [137]	Fluvoxamine	Cigarette smoke Charcoal broiled foods Omeprazole
CYP2A6	Halothane[a] [138] Nicotine	8-Methoxy psoralen	None known
CYP2B6	Bupropion Carbamazepine[a] [139] Ticlopidine	None known	rif, phen, carb, pheno, SJW
CYP2C8	Paclitaxel Rosiglitazone	None known	rif, phen, carb, pheno, SJW
CYP2C9	Diclofenac[a] [140] Warfarin Tienilic acid[a] [141] Phenytoin Valproate	Fluvoxamine	rif, phen, carb, pheno, SJW
CYP2C19	Omeprazole Mephenytoin Diazepam Phenytoin[a] [142] Flutamide[a] [143]	Sulfinpyrazone Ticlopidine Fluvoxamine	rif, phen, carb, pheno, SJW
CYP2D6	Debrisoquine Metoprolol and other ß-blockers Amitriptyline and other neuroleptics Codeine Chlorpromazine[a] [144] Thioridazine[a] [144]	Fluoxetine and other SSRIs Quinidine	None identified
CYP2E1	Acetaminophen[a] [145] Ethanol Tolcapone[a] [135] Isoniazid[a] [146] Halothane [138]	Disulfram Ethanol	Ethanol Isoniazid
CYP3A4	Erythromycin Cyclosporine A Carbamazepine[a] [139] Midazolam/triazolam Lovastatin and other statins Saquinavir and other protease inhibitors Trazodone[a] [147] Nefazodone[a] [148] Troglitazone[a] [149] Nevirapine[a] [150]	Ketoconazole and other azoles Troleandomycin Rotinavir	rif, phen, carb, pheno, SJW

[a]Drugs metabolized to reactive metabolites that are implicated in hepatotoxicity.
carb, carbamazepine; rif, rifampin; phen, phenytoin, phenol, phenobarbital; SJW, Saint John's wort; SSRI, selective serotonin reuptake inhibitor.

Oxidative stress

The liver is the largest solid organ in the body, and its numerous metabolic functions require substantial energy. Energy is largely provided by adenosine triphosphate (ATP), which is derived from the reduction of molecular oxygen to water in mitochondria through a process termed oxidative phosphorylation. In the process of generating ATP and water, up to 5% of oxygen is converted to superoxide anion (O_2^-) and its metabolites, which are collectively termed reactive oxygen species (ROS).

ROS can also be produced outside of the mitochondria as a by-product of metabolism by cytochromes P450, particularly CYP2E1 [25] and CYP3A4 [26]. ROS can alter normal physiologic functions in the hepatocyte by reacting with proteins, DNA, or lipids [27–29]. For example, ROS can initiate lipid peroxidation. This is a self-propagating chain reaction whereby unsaturated fatty acids of membranes are broken down to volatile small molecules (such as F2-isoprostanes) that can be measured in breath [30,31].

ROS usually do not accumulate in hepatocytes because there exist multiple mechanisms for their deactivation to less harmful species, including reactions catalyzed by glutathione peroxidase, superoxide dismutase (SOD), and catalase. Moreover, as ROS deplete protective mechanisms, the cell mounts a coordinated "antioxidant response." This involves activation of NF-E2-related factor (NFR2), which mediates transcriptional activation of a cassette of genes that include those coding for GSH synthesis, GSTs, and certain uridine diphosphate glucuronosyltransferases (UGTs) [31].

The term "oxidative stress" has traditionally been used for the situation where the production of ROS exceeds the capabilities of antioxidant defenses, resulting in an accumulation of ROS [27]. However, it has recently become clear that in addition to the direct damaging effects of ROS through oxidation of proteins, lipids, and DNA, ROS can alter cell signaling pathways leading to cell death through either apoptosis or necrosis. For example, depletion of GSH, which occurs as a result of ROS, has been shown to sensitize hepatocytes to the injurious effects of certain cytokines, probably by inhibiting the transcription nuclear factor κB (NF-κB) [32]. ROS have also been shown to activate the transcription factor c-jun N-terminal kinase (JNK), which can result in activation of cell death pathways. It has therefore been proposed that the term "oxidative stress" be defined by these and related alterations in cell signaling typically but not exclusively observed in states of ROS accumulation [33].

Covalent binding

A variety of experimental evidence supports the view that covalent binding of reactive metabolites to proteins can alter their function, contributing to or causing hepatotoxicity [3,34–36]. For example, the location of covalently bound protein adducts within the acinus correlates well with the location of hepatocyte damage due to acetaminophen [37] and cocaine [38]. In addition, experimental manipulations that increase or decrease the rate of covalent binding (such as treatment with inducers or inhibitors of specific P450s) proportionately increase or decrease the sensitivity of the liver to toxicity [38–40]. However, the simple magnitude of covalent binding produced by a drug does not accurately predict hepatotoxicity [15,34]. For example, there exist structural analogs of acetaminophen that have relatively little hepatotoxic potential, but nonetheless covalently bind to hepatic proteins at rates comparable to, or actually higher than, observed with acetaminophen [41]. In addition, under certain experimental conditions, hepatocyte injury produced by cocaine can be prevented without influencing the extent of covalent binding to hepatocyte proteins [42]. It has therefore become clear that covalent binding to protein does not always result in toxicity. Indeed, covalent binding may in some instances represent an adaptive mechanism for the hepatocyte. For example, it has been speculated that certain cytosolic proteins identified as targets for acetaminophen covalent binding may function to protect the cell by inactivating reactive metabolites [43].

In view of the discrepancies between total covalent binding and toxicity, the idea has emerged that toxicity is caused by covalent binding to specific proteins critical to cell viability [44]. During acetaminophen hepatotoxicity, multiple enzymes important to the hepatocyte undergo covalent modification that results in the loss of catalytic activity [36]. The identity of specific proteins targeted by a given metabolite probably reflects several factors. First, if the metabolite is extremely reactive, it is likely to be very short lived; hence, binding can only occur to proteins that are located in close proximity to the enzyme that produced the metabolite. The closest protein to the metabolite when it is created is the enzyme that produced it. Hence, when a specific P450 is identified as the target for covalent binding, it is likely that this is the enzyme responsible for the generation of the reactive metabolite [45]. If the implicated metabolite is less reactive and longer lived, it may diffuse from the site where it was formed to bind to more distant proteins. Which specific proteins are affected also reflects the chemical nature of the metabolite and target protein. Acetaminophen, and the structurally similar but not hepatotoxic compound 3′-hydroxyacetanilide, produce comparable amounts of total covalent binding in the liver [41]. However, covalent binding with acetaminophen occurs largely in mitochondria, whereas AMAP forms adducts predominantly in other cellular compartments [46]. Specific binding to critical mitochondrial proteins may therefore account for the differences in hepatotoxic potential of acetaminophen

and AMAP. On the other hand, the selective binding to mitochondrial proteins may simply indicate that the reactive metabolite reached the mitochondria where it might initiate other processes responsible for toxicity.

Role of mitochondria as a target for drug-induced liver injury

The mitochondria are the cell's major source of energy by creating ATP. With complete loss of functioning mitochondria, the ATP-dependent sodium and potassium ion pumps at the plasma membrane cease to function, and the hepatocyte swells and ruptures in the process known as necrosis. Programmed cell death, or apoptosis, requires energy and therefore some functioning mitochondria are required. There is increasing evidence that mitochondria are critical targets during DILI and other types of adverse reactions to drugs [33,47,48].

As discussed above, loss of mitochondrial function could result from covalent binding of a reactive metabolite to key proteins involved in several critical processes. In addition, reactive metabolites could cause toxicity by damaging mitochondrial DNA [49]. Most mitochondrial proteins are encoded by genes present in the cell nucleus, however some vital mitochondrial proteins involved in oxidative phosphorylation are the products of genes contained within the mitochondria. Mitochondria are relatively deficient in DNA repair enzymes, and hence DNA mutations caused by reactive metabolites (or resulting from oxidative stress) can accumulate over time. For example, some antiviral drugs (fialuridine (FIAU) and azidothymidine (AZT) for example) are believed to have caused liver failure due to gradually accumulating mutations in mitochondrial genes [50,51].

Mitochondrial dysfunction can also occur as a consequence of depletion of mitochondrial glutathione [33,52]. Mitochondria are particularly susceptible to GSH depletion because they do not synthesize GSH and must import it from the cytosol. Mitochondria also lack catalase, and therefore place greater reliance on glutathione peroxidase to handle ROS. The activity of glutatione peroxidase activity is critically dependent on the concentration of GSH within the mitochondria, with a rapid fall in activity as GSH concentrations (usually 10–15 mM) fall below 2–3 mM. Greater than 90% depletion of mitochondrial GSH therefore significantly impairs the mitochondria's ability to safely dispose of ROS. Because ROS are constantly produced in mitochondria, even in totally healthy hepatocytes, depletion of mitochondrial GSH by reactive metabolites may be sufficient to cause hepatocyte injury and death through oxidative stress.

Mitochondria also play a central role in the initiation of apoptosis. It has been theorized that mitochondria evolved from a primitive bacterium that, when the earth's oxygen atmosphere began to emerge, entered and became part of early eukaryotic cells [53]. A bacterial origin would also account for why mitochondria have their own set of genes. According to the theory, the relationship between the bacterium and the eukaryotic cell was symbiotic. The bacterium's rudimentary machinery for oxidative phosphorylation provided the eukaryote with a means for survival in what would have otherwise been a toxic environment. The bacterium also benefited in most instances from the controlled environment afforded by the host cell. It has been further theorized that, in case the relationship ceased to be symbiotic, the bacterium retained or developed the ability to kill the cell and thereby "go it alone" [54]. According to this theory, as the bacteria evolved to become permanent residents in cells (i.e., mitochondria), these death mechanisms remained.

The mechanisms whereby mitochondria initiate apoptosis have been largely clarified. The critical event appears to be depolarization of the inner membrane of the mitochondria, termed mitochondrial permeability transition (MTP), that results from opening of pores in the inner membrane [55,56]. MTP results in a loss of the proton gradient required for the generation of ATP. If MTP occurs in all or most mitochondria there will be insufficient ATP generation to sustain vital physiologic functions. However, a further effect of MTP pore opening is swelling of the mitochondria and eventual rupture of the outer mitochondrial membrane. When the mitochondria ruptures, cytochrome *c* is released into the cytosol, causing activation of certain caspases that initiate apoptosis. Evidence suggests that MTP may be a common pathway for hepatocyte apoptosis resulting from diverse signals that may be involved in some forms of hepatotoxicity, including ligand binding to plasma membrane death receptors (FAS and tumor necrosis factor receptor (TNFr)), release of calcium from the endoplasmic reticulum, and release of lysosomal enzymes [56,57]. Apoptosis requires ATP, so the energy status of the hepatotocyte (i.e., how many mitochondria remain functional) appears to determine whether death will be by apoptosis or necrosis. Features of both necrosis and apoptosis can be present in a dying hepatocyte, termed "necrapoptosis" [58,59].

Progression versus recovery

Once liver injury has begun, it can either progress to liver failure or can subside with recovery (see Fig. 28.1). It was originally assumed that the critical variable here was how much damage was done by the reactive metabolite, such as the extent of critical covalent binding or extent of oxidative stress. Although this is clearly an important variable, it has recently become clear that there are many factors that can influence the outcome that are "down stream" of the events discussed so far. These factors can

both reverse toxicity or accelerate the death of injured or dying hepatocytes or even cause the death of healthy hepatocytes.

One factor that limits the progression of liver injury is increased tolerance to the hepatotoxin. For example, it has been shown that mice recurrently exposed to certain halogenated hydrocarbons develop hepatic necrosis after 1 week of treatment, but the liver injury can largely resolve despite continued exposure (Fig. 28.3) [60]. This indicates that the liver has the ability to reverse even severe hepatotoxicity through a process termed adaptation. Adaptation may account for why therapeutic dosing of acetaminophen is generally safe despite the fact that it causes alanine aminotransferase (ALT) elevations exceeding three times the upper limits of normal in one third of healthy adults [61]. It has also been shown that rats given gradually increasing doses of acetaminophen can develop complete tolerance to doses that would cause severe toxicity to treatment naïve rats [62]. This progressive tolerance also appears to occur in man; there has been one report of a narcotic/acetaminophen abuser who claimed to consume up to 65 g of acetaminophen daily yet had no clinical evidence of significant liver injury [62].

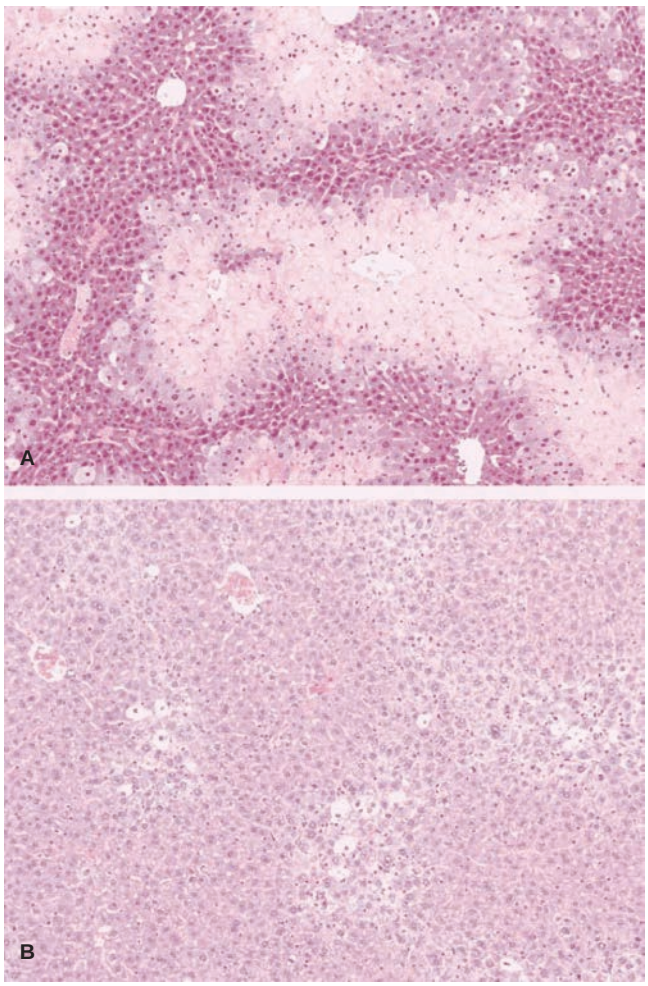

Figure 28.3 Adaptation to direct hepatotoxicity. Mice were exposed to recurrent doses of bromodichloromethane. (A) At 1 week, pericentral necrosis was observed in the mice. (B) Those that survived this initial injury had substantial recovery with absence of liver necrosis at 3 weeks, despite continued exposure to the toxicant. This is a dramatic example of the ability of the liver to adapt to hepatotoxins, which may reflect alterations in the expression of drug-metabolizing enzymes, transporters, or components of the innate immune response. (Reproduced from Torti et al. [60] with permission from Oxford University Press.)

Adaptation to hepatotoxicity can involve an altered regulation of genes involved in determining reactive metabolite accumulation. For example, when rodents are exposed to increasing doses of acetaminophen there is downregulation of the P450s involved in producing the reactive metabolite (*N*-acetyl-*p*-benzoquinone imine (NAPQI)) and an increase in hepatocyte GSH content [62]. In addition, it has been shown that during the recovery phase of acute exposure to acetaminophen or carbon tetrachloride, there is downregulation of certain basolateral uptake transporters (Na(+)-taurocholate cotransporting polypeptide (NTCP) and several organic anionic transporting polypeptides (OATPs)) and upregulation of basolateral and canalicular efflux transporters (including MRP3, MRP4, and MRP2) [63–66]. This appears to protect the cell by *preventing uptake* and *accelerating removal* of xenobiotics and potentially toxic bile acids. These effects could result from a combination of the antioxidant response and the acute phase reaction chiefly mediated by Nrf-2 activation and interleukin 6 (IL6), respectively [67,68]. In addition, regenerating (young) hepatocytes have reduced P450 activity and increased GSH levels and should therefore be less prone to toxic injury [69]. These mechanisms for adapatation are likely to be operative in patients. One human study demonstrated that after subfulminant liver injury, the regenerative hepatocytes contained increased levels of several transporters, including the major multidrug resistence transporter 1 (MDR1) [70].

Other factors that can determine progression or regression of injury involve mediators of inflammation controlled by the innate immune system [71]. The innate immune response, unlike the adaptive immune response, is not antigen-specific, has no memory, and can be immediately activated by pathogens. It is the coordinated and rapid release of certain cytokines and other biologic mediators that neutralize pathogens and, together with natural killer T cells and tissue macrophages, kill infected cells. Mechanisms involved in activation of the innate immune system in response to bacteria have been extensively studied. Various components of bacteria and viruses, termed pathogen-associated molecular patterns or PAMPs, activate toll-like receptors (TLRs) on mammalian cells that upregulate expression of pro-IL1β [72]. Pro-IL1β is not

active until cleaved by caspase 1, which is expressed when mammalian cells are injured or dying. Products of dying cells, termed damage-associated molecular patterns or DAMPs, activate receptor complexes termed inflammasomes, resulting in transcription of caspase 1 [73]. This two-step process makes sense since it permits the detection of pathogen infection anywhere the blood circulation may take the PAMPs but then focuses the inflammatory response where tissue damage is occurring. A recent finding is that DNA fragments resulting from hepatocyte necrosis can both activate TLRs and a certain inflammasome, resulting in the production of both IL-1β and caspase 1 [74]. Hence toxicity resulting in hepatocyte necrosis appears to be sufficient to activate a full innate immune attack on the liver.

The innate immune response is beneficial if it limits the spread of infection by killing and disposing of infected cells and pathogens. However, promotion of hepatocyte death by an innate immune response is not beneficial in the setting of toxic injury. Hence, it is not surprising that the elimination of various components of an innate immune response can reduce the degree of liver necrosis in response to acetaminophen [75,76]. Examples of components of the innate immune response that increase susceptibility to acetaminophen hepatotoxicity include interferon γ [77], macrophage inhibitory factor (MIF) [78], and tumor necrosis factor (TNF) [79]. However, the situation is complex since the loss of CD44, a lymphocyte surface protein involved in trafficking into tissues, appears to increase susceptibility to acetaminophen hepatotoxicity in both rodents and humans [80]. In addition, some cytokines reduce susceptibility to acetaminophen hepatotoxicity [81,82]. Whether an injury progresses or resolves may therefore depend on the balance of pro- and anti-inflammatory cytokines released in the liver; the factors that determine this balance during an episode of hepatotoxicity remain unclear.

The ability to downregulate the innate immune response may be particularly important in the liver [74, 75,83,84]. During evolution, some degree of hepatotoxicity probably occurred as a result of dietary consumption of naturally occurring hepatotoxic substances, such as natural insecticides made by plants, or fungal and bacterial products resulting from food spoilage. A reasonable hypothesis is that factors counteracting the innate immune response evolved in the liver to limit needless liver inflammation and hepatocyte injury as a result of recurrent encounters with these hepatotoxins.

It should be noted that most cytokines are produced in the liver by Kupffer cells and, during an innate immune response, other types of macrophages that are recruited to the liver. One study has suggested that the activation of inflammasones by DAMPs occurs in the sinusoidal endothelial cells [74]. This points out the potential limitations of studying hepatotoxicity mechanisms in isolated hepatocytes and emphasizes the need for more complex culture systems.

Other issues that may determine whether liver injury progresses or regresses have been identified. Soluble factors released from dying hepatocytes (such as calpain [85, 86]) may kill adjacent healthy hepatotcytes. In addition, it has been shown that liver injury caused by one predictable toxin can be "amplified" by pretreatments that hinder the liver's ability to regenerate [87].

Variation in susceptibility to predictable hepatotoxicity

Increased susceptibility to predictable hepatotoxicity could occur from any of the conditions outlined in Box 28.1. For example, some drugs either inhibit or increase (induce) the activity of certain drug-metabolizing enymes (see Table 28.1) and transporters. If safe pathways are induced or bioactivation pathways are inhibited, there should be less toxicity at a given dose of hepatotoxin. Alternatively, if safe pathways are inhibited and bioactivation pathways are induced, susceptiblity to toxicity should increase. However, the induction of metabolic pathways usually involves the activation of transcription factors that result in the transcription of multiple genes [88]. The deleterious effects of induction of the bioactivation pathway may therefore be offset by the simultaneous induction of safe elimination. An example where variation in susceptibility to toxicity can result from nongenetic factors is acetaminophen hepatotoxicity.

Increased susceptibility to acetaminophen hepatotoxicity

Chronic consumption of ethanol appears to increase susceptibility to acetaminophen hepatotoxicity [89]. Chronic ethanol consumption can increase CYP2E1 activity (see Table 28.1), and this provides an attractive explanation for incremental risks in ethanol consumers. However, early animal [90,91] and human [92] studies did not show increases in NAPQI formation when acetaminophen was given during or immediately after ingestion of ethanol. Indeed, these studies suggested that ethanol consumption actually reduces the rate of production of NAPQI, protecting the liver from toxicity. This is explained by the observation that the induction of CYP2E1 that occurs involves stabilization of the enzyme (reduced degradation), and that this occurs when ethanol is bound to the enzyme as substrate [93,94]. Prolonged intoxication therefore results in an accumulation of CYP2E1, but the enzyme activity is reduced because the induced CYP2E1 is inhibited by ethanol (Fig. 28.4). When ingestion is stopped, and ethanol is cleared from the liver, the accumulated CYP2E1

Box 28.1 Some potential reasons for increased susceptibility to predictable hepatotoxicity.

Decreased activity of safe elimination pathways
- Genetic: polymorphisms in phase 1 and 2 enzymes or transporters
- Nongenetic: drug interactions involving enzyme/transporter inhibition, nutrition, and inflammation

Increased activity of enzymes making reactive metabolites
- Genetic: gene duplication (CYP2D6)
- Nongenetic: induction of P450s

Reduced elimination of reactive metabolites
- Genetic: polymorphisms in elimination enzymes (e.g., glutathione transferases, epoxid hydrolase) or transporters (e.g., MRP2)
- Nongenetic: drug interactions involving enzyme/transporter inhibition, inflammation nutrition, and cofactor depletion (e.g., glutathione)

Variation in proteins and pathways targeted by reactive pathways
- Genetic: polymorphisms in proteins involved in target pathways (e.g., inherited defects in oxidative phosphorylation proteins)
- Nongenetic: drug effects (e.g., aspirin inhibition of oxidative phosphorylation), nutrition, and concomitant disease

Variation in the innate immune response
- Genetic: polymorphisms in cytokines and proteins involved in Kuppfer cells and lymphocyte function
- Nongenetic: inflammation and nutrition

Variation in ability to regenerate hepatocytes
- Genetic: polymorphisms in genes important in regeneration
- Nongenetic: effects of other drugs/xenobiotics, age, nutrition, and inflammation

Variation in ability to adapt to toxicity
- Genetic: polymorphisms in enzymes and transporters and proteins involved in their regulation or in innate immune response elements
- Nongenetic: effects of other drugs/xenobiotics, age, nutrition, and inflammation

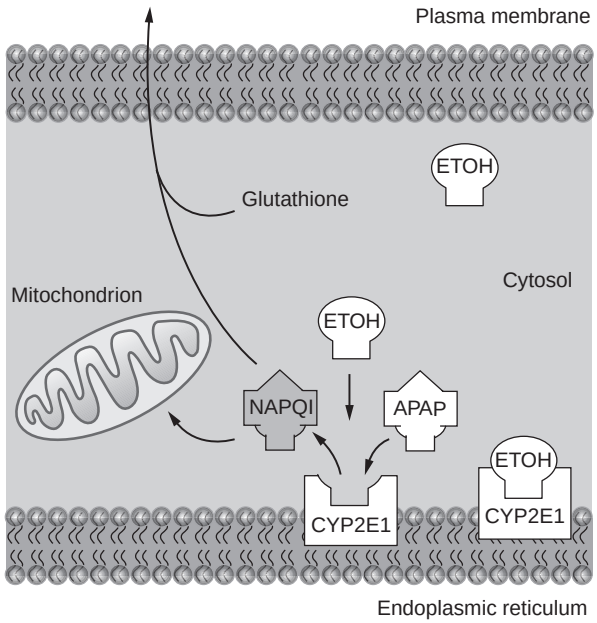

Figure 28.4 Effect of ethanol on acetaminophen toxicity. Acetaminophen is converted by cytochrome P450 2E1 (CYP2E1) to the reactive metabolite *N*-acetyl-*p*-benzoquinone imine (NAPQI), which then conjugates to glutathione and are safely excreted. If the production of NAPQI is rapid enough to deplete available cytosolic glutathione stores, NAPQI travels to mitochondria where it covalently binds to critical proteins and depletes mitchondrial glutathione, resulting in oxidative stress. Ethanol binds tightly to the substrate-binding site of CYP2E1, preventing acetaminophen from being metabolized to NAPQI. This accounts for the observation that acutely intoxicated rodents produce less NAPQI and are resistant to acetaminophen toxicity. However, the intracellular half-life of CYP2E1 is prolonged when bound to ethanol, so the enzyme accumulates in an inactive form during intoxication. When ethanol consumption ceases and ethanol is removed from the liver, the accumulated CYP2E1 becomes fully active and the rate of NAPQI formation increases until the CYP2E1 levels return to baseline (probably not more than 24 hours). This effect is very modest in social drinkers but can become significant when very large amounts of ethanol are consumed for prolonged periods. APAP, acetaminophen; ETOH, ethyl alcohol. (Reproduced from Thummel et al. [94] with permission from Nature.)

is no longer inhibited, and the aggregate CYP2E1 activity is increased above baseline levels [94]. However, stabilization against degradation is also reversed, resulting in a relatively rapid fall of enzyme activity to the preethanol exposure level. This results in a narrow window of susceptibility that probably lasts less than 24 hours [94]. This effect of inhibition followed by transient induction is also mimicked by some other substrates of CYP2E1, including isoniazid [95]. This may account for reports of enhanced susceptiblity to acetaminophen toxicity in patients treated with isoniazid [95,96].

Chronic alcoholics are also likely to have reduced hepatocyte concentrations of GSH, particularly mitochondrial GSH [97], limiting their ability to safely eliminate NAPQI once formed.

Another clinical situation that appears to increase susceptibility to acetaminophen toxicity is fasting [98]. This should result in reduced GSH levels, but should also cause depletion of the glucose available to make the UGT cofactor glucuronic acid, reducing the ability for safe elimination of acetaminophen by glucuronidation. It has also been proposed that liver hypoxia due to cardiopulmonary insufficiency can increase susceptibility to acetaminophen toxicity due to reduced glucuronidation capacity [99]. Patients with Gilbert syndrome have a reduced activity of the form of UGT that conjugates bilirubin (UGT1A1) and it has been reported that these patients may have increased susceptibility to acetaminophen toxicity. However, this seems unlikely since the major UGT involved in conjugation of acetaminophen is not UGT1A1.

Idiosyncratic hepatotoxicity

Understanding of the processes involved in the production of liver toxicity from reactive metabolites has greatly improved our understanding of variation in susceptibility to predictable liver toxins, particularly acetaminophen. Evidence that the mechanisms underlying predictable hepatotoxicity are also important in idiosyncratic hepatotoxicity has come from genetic studies. Susceptibility to idiosyncratic DILI from various drugs has been associated with genetic variation that leads to a reduced or increased function of transport proteins or in enzymes involved in bioactivation and detoxification [100]. This suggests that the mechanisms shown in Fig. 28.1 are relevant to understanding idiosyncratic toxicity. The rarity of idiosyncratic hepatotoxicity could be explained by interpatient variation in the multiple metabolic and transport functions as well as multiple mechanisms that may underlie a failure to adapt to the initial injury. The rarity of susceptible individuals could be explained if multiple susceptibility factors were required to manifest the toxicity.

One feature of idiosyncratic hepatotoxicity that is difficult to explain based on the mechanisms shown in Fig. 28.1 is the prolonged latency characteristic for this type of injury. Two theories have been proposed that directly link mechanisms of predictable toxicity to this latency. The first proposes that toxicity is initiated by a coincident episode of inflammation and the second proposes a cumulative, clinically occult injury.

Inflammatory stress hypothesis

It has been shown that rats or mice treated with a nonhepatotoxic dose of an inflammagen such as lipopolysaccharide (LPS) become susceptible to liver injury when treated with several drugs capable of causing idiosyncratic hepatotoxicity, including diclofenac and sulindac [101,102]. These observations support the idea that idiosyncratic hepatotoxicity might result from the same mechanisms as predictable hepatotoxicity (see Fig. 28.1), but that the threshold for hepatocyte injury is lowered by a concurrent mild infection, or occasional leak of bacterial products from the intestine [103]. The mechanisms whereby mild inflammation could initiate DILI are not clear, but this phenomenon has been reproduced in cultured human hepatocytes [104]. Certain cytokines released during inflammation alter the intracellular signaling pathways, and this can have many consequences, including a substantial alteration in expression of various liver enzymes and transporters [105]. Such sudden alterations could result in the increased production of a toxic metabolite initiating injury or could reduce the liver's ability to adapt to the injury. Also, partial activation of the innate immune system could result in an exaggerated injury where adaptation might otherwise have occurred.

Clinical support for the inflammation hypothesis is sparce, however. Although chronic hepatitis B may predispose patients to idiosyncratic hepatotoxicity from antituberculosis drugs [106], there are no data to suggest that the injuries occur with shorter latency in these patients. In addition, many drugs causing idiosyncratic hepatotoxicity display a characteristic latency interval that would be difficult to ascribe to random inflammatory events.

Progressive injury hypothesis

According to this hypothesis, injury to the hepatocyte begins soon after the start of drug dosing in susceptible individuals, but does not become clinically manifest until weeks or months later. This is easiest to understand with mitochondrial injuries, such as the depletion of mitochondrial DNA, which could gradually reduce the number of functioning mitochondria. There may be no clinical consequences apparent until mitochondrial function falls below a critical level. As hepatocytes begin to die, this would place more metabolic demand on the remaining but already compromised hepatocytes. This could result in what appears to be a sudden onset of severe liver injury after a prolonged latency. Support for the progressive injury hypothesis has come from a mouse model deficient in superoxide dismutase, an enzyme important in reducing oxidative stress in mitochondria. These mice are phenotypically normal but develop a delayed hepatotoxicity when treated with some drugs capable of idiosyncratic hepatotoxicity in man [107]. In addition, recent evidence supports the idea that genetic deficiency in SOD may increase susceptibility to idiosyncratic hepatotoxicity from multiple different drugs in patients [108].

Adaptive immune response

It is generally accepted that adaptive (as opposed to innate) immune mechanisms underlie the liver injury produced by some drugs. For example, liver injury due to halothane, phenytoin, and sulfonamides characteristically present with fever, rash, and eosinophilia – the classic clinical hallmarks of hypersensitivity [109]. This type of liver injury characteristically occurs within the first month of starting therapy with the drug, similar to the time required to become fully immunized to a vaccine. Reexposure after an episode of toxicity generally results in more rapid onset of the toxicity and greater severity of the injury, as would be expected with a hypersensitivity reaction.

There is also increasing evidence that adaptive immune mechanisms may be involved in idiosyncratic hepatotoxicity, even in the absence of clinical signs of hypersensitivity. For example, methyldopa-induced liver injury is not usually associated with peripheral eosinophilia, fever, or

rash, but recurs promptly and may be more severe upon rechallenge, consistent with an immune mechanism [110]. Tacrine-induced liver disease also has no hypersensitivity features [111] yet recurs promptly upon rechallenge, consistent with an immunologic mechanism. The idea that the adaptive immune system is involved in many forms of hepatotoxicity is also supported by lymphocyte proliferation studies. These studies are performed by isolating peripheral blood lymphocytes from patients who have experienced hepatotoxicity, and determining whether a subpopulation of the T lymphocytes proliferate upon exposure to the implicated drugs. A proliferative response implies that the drug has stimulated an adaptive, cell-mediated immunity. The test is often positive in adverse drug reactions resulting from hypersensitivity, but in one study [112], 56% of 95 patients with liver injury to diverse drugs demonstrated lymphocyte proliferation in response to exposure to the implicated drug. In contrast, proliferation was not observed in any of 35 control individuals who had been exposed to the same drugs without evidence of liver toxicity. In 70% of the patients with a positive test, there were no clinical signs suggestive of hypersensitivity. Although observations with lymphocyte transformation support a role for an adaptive immune response in DILI, these studies alone would also be consistent with an adaptive immune response as a result of, not the cause of, the liver injury.

The most convincing data to support a role for the acquired immune system in idiosyncratic DILI has come from genetic studies in patients who have experienced idiosyncratic DILI. Table 28.2 lists some identified associations between DILI susceptibility and human leukocyte antigens (HLAs), also called the major histocompatibility complex (MHC) antigens. These are proteins on the surface of certain cells (antigen-presenting cells) that hold and present antigens to the helper T cells. In the case of drugs, it has been assumed that the antigen is the reactive metabolite covalently bound to a liver protein. It should be noted that the HLA risk alleles listed in Table 28.2 are quite common in the population so only a small subpopulation of individuals with these risk alleles will develop DILI when treated with the listed drug. Some of the associations observed are very strong. For example, a person with the HLA-B*5701 allele is 80-fold more likely to develop DILI after treatment with the antibiotic flucloxacillin. This has suggested that HLA genotyping might be useful in screening patients for susceptibility prior to treatment with certain drugs, or using HLA genotyping to aid in the diagnosis of DILI due to certain drugs.

The immune system will not generally attack healthy cells just because they contain new antigens on their surface. As with the innate immune response, a second signal is necessary to mount an adaptive immune response. This "danger signal" was first proposed by Matzinger [113] and is consistent with the observation that vaccines only work when given with adjuvants that cause tissue injury at the site of injection. It appears that the DAMPs resulting from tissue injury (that mediate the second signal required for an innate immune response) also are capable of mediating the second signal required for the acquire immune response [114].

The involvement of an acquired immune response could account for the characteristic latency of idiosyncratic DILI and also provides another important locus for interpatient variation to account for the rarity of these events. A unified theory would be that an individual who develops idiosyncratic DILI would have to have the appropriate factors (see Box 28.1) to create sufficient amounts of a reactive metabolite to cause hepatocyte injury, to trigger an innate immune response, and to release DAMPs to provide the "danger signal." In addition, the individual must have a susceptibility HLA allele or adapation and resolution of injury will occur. Consistent with this hypothesis, susceptibility to DILI from ticlopidine has been recently associated with a polymorphism in CYP2B6 as well as with HLA-A*3303 [115]. In addition, susceptibility to flucloxacillin-induced liver injury has been associated with a polymorphism in the region of the pregnene X nuclear receptor (PXR) that activates transcription of a variety of drug-metabolizing enzymes and drug transporters [116]. This hypothesis would also explain why drugs that cause serious idiosyncratic DILI usually also cause much more frequent elevations in serum aminotransferases in clinical trials, and why the

Table 28.2 Some HLA associations with susceptibility to drug-induced liver injury.

Drug	Prevalence	Risk allele	Frequency	Relative risk	Reference
Augmentin	<0.001	HLA-DRB1*1501	0.15	4	Holden 2010 [154]
Flucloxacillin	<0.001	HLA-B*5701	0.04	81	Daly et al. 2009 [156]
Lapatinib	0.09	HLA-DRB1*0701	0.08	9	Spraggs 2010 [152]
Lumiracoxib	0.013	HLA-DRB1*1501	0.15	13	Singer et al. 2010 [153]
Ticlopidine	<0.001	HLA-A*3303	0.07	36	Hirata et al. 2008 [155]
Ximelagatran	0.08	HLA-DRB1*0701	0.08	4	Kindmark et al. 2008 [151]

episodes of severe DILI tend to occur with a latency characteristic of the transient ALT elevations [117]. For example, the anticoagulant ximelagatran was withdrawn from worldwide markets because of severe DILI, including liver failure. In clinical trials, about 10% of patients treated with ximelagatran developed ALT elevations that characteristically occurred between 1 and 6 months of treatment [118]. In most cases, the ALT elevations were transient, but rare cases of severe and fatal liver injury have been reported. In most instances, these severe events occurred within the latency period for ALT elevations, consistent with the idea that patients with severe injury arise out of the group with milder and transient liver injuries.

It should be noted that although an adaptive immune response to predictable liver injury is an attractive hypothesis to explain idiosyncratic hepatotoxicity, two observations do not support it. If the above hypothesis was correct, we would expect the initial liver injury to occur soon after starting treatment, but ALT elevations are characteristically delayed in clinical trials with drugs capable of causing idiosyncratic DILI. In addition, HLA allele associations should only be found with severe liver injuries and not with milder reversible ALT elevations. However, in the cases examined to date, the HLA associations exist with the minor ALT elevations as well as with the more severe liver injuries.

Hepatotoxicity not related to reactive metabolites

Although it is generally believed that reactive metabolites are the initiating events in most forms of DILI, this is not always the case. For example, ximelagatran has never been demonstrated to have reactive metabolites [114]. In some cases, the parent drug may directly interfere with crucial hepatocyte functions, resulting in toxicity. One example of this is interference with the homeostasis of bile acids, some of which can be toxic to cells, particularly to mitochondria [119]. The concentration of bile acids within the hepatocyte is governed by the rates of synthesis, uptake, and efflux of bile acids, which are usually tightly regulated. If a drug interferes with this homeostasis, toxicity could result. For example, it has been demonstrated that troglitazone and bosentan inhibit bile salt excretory protein (BSEP) (see Fig. 28.2) and this may contribute to the hepatoxicity observed with these drugs [120–123]. Glyburide has also been shown to inhibit BSEP, and this may explain why patients taking this drug appear to be at higher risk of developing liver toxicity from bosentan [123]. An interesting observation is that bosentan does not cause liver toxicity in the rat [120]. This may relate to the observation that whereas bosentan is a potent inhibitor of BSEP in both mouse and man, it is also a potent inhibitor of NTCP in just the rat [124]. Since NTCP transports bile acids into the hepatocyte, inhibition of both uptake and efflux in the rat may result in little change in hepatocyte concentrations of bile acids.

Pharmaceutical industry and preclinical drug testing

Idiosyncratic hepatotoxicity is the major single organ toxicity that results in abandonment of drug development programs and regulatory actions concerning drugs. Pharmaceutical companies are currently spending many millions of dollars to improve the ways drug candidates are screened for hepatotoxic potential. No consensus has yet been reached and practices vary.

One approach has been to try to "humanize" preclinical testing by using cultured human hepatocytes [125], mice that express human genes relevant to toxicity (such as human P450s and certain nuclear receptors) [126,127], or, recently, mice with stem cell-derived human livers [128]. There are potential problems with each of these approaches. Many important genes stop being expressed in cultured hepatocytes [129] and, as discussed above, cell types other than hepatocytes, such as Kuppfer cells and sinusoidal endothelial cells, may be important missing elements in current cell culture systems. A problem with humanized mice is that we do not yet know which are the relevant human genes to put into the mice. Putting a human liver into a mouse may also not represent a great advance since it is unlikely that the stem cells would be obtained from an individual susceptible to such a rare event as DILI.

Another approach taken is to screen compounds for the ability to form reactive metabolites. The rationale is that if the formation of a reactive metabolite is an essential step in idiosyncratic hepatotoxicity (see Fig. 28.1), understanding the many potential processes that culminate in liver injury are irrelevant if no reactive metabolite is made [21,130,131]. Although the concept of reactive metabolite screening is attractive, it is largely being abandoned in candidate drug selection. One problem is that most drugs generate reactive metabolites to some degree, and some safe drugs would be discarded unnecessarily [132]. For example, acetaminophen causes substantial covalent binding in the liver, as discussed previously. However, acetaminophen is quite safe when taken as directed.

Finally, there has been the broad application of current genomic technology to traditional preclinical toxicity testing [133]. This technology allows simultaneous quantitation of thousands of mRNAs (the "transcriptome"), proteins (the "proteome"), and endogenous metabolites (the "metabolome"). Some companies have treated rats

or human hepatocytes with known hepatotoxic and nontoxic drugs and examined time-dependent changes in the liver transcriptome, liver and serum proteome, and liver, serum, and urine metabolome. The goal is to find specific patterns that predict hepatotoxicity potential. Proteome and metabolome analyses have yet to become a standard part of preclinical testing. However, at least several companies have selected a set of mRNA transcripts that appear to correlate with certain forms of hepatotoxicity and are routinely measuring them, along with traditional serologic markers (like ALT) and pathologic evaluation, in the lead candidate selection process. In another recent study [134], florescent probes and automated confocal microscopy was used to assess the effects of a panel of drugs, both safe and those known to cause idiosyncratic DILI, on a variety of physiologic processes in cultured human hepatocytes.

It remains to be determined whether the application of genomic technology to new animal and culture models will reduce the risk of idiosyncratic hepatotoxicity for new drugs currently in the development pipeline.

Conclusions and future directions

The understanding of mechanisms underlying predictable liver toxicity, particularly acetaminophen-induced liver injury, has improved substantially in recent years. There has been identification of mechanisms that determine the extent of initial liver injury, and those involved in the balance between recovery and progression. It seems logical that variation in the activities of the proteins that underlie these mechanisms, which may reflect both genetic and nongenetic factors, will in part account for susceptibility to idiosyncratic hepatotoxicity. The recent finding of HLA allele associations with susceptibility to DILI from certain drugs has provided further support of an acquired immune component to at least some forms of DILI, and have provided plausible explanations for the characteristic latency. The data to date suggest that there are multiple mechanisms that can underlie idiosyncratic hepatotoxicity, and some may be relatively drug or drug class specific. However, it also seems likely that key components of susceptibility that lie in the "downstream" events, such as failure to adapt or progression of injury, may not be molecule specific. Fully elucidating these mechanisms will require studying many people who have actually experienced idiosyncratic hepatotoxicity. The Drug Induced Liver Injury Network, supported by the National Institute for Diabetes, Digestive and Kidney Diseases, and the Severe Adverse Events Consortium supported by the pharmaceutical industry, are creating a registry of such individuals, collecting genomic DNA, and have begun genetic studies. This will undoubtedly remain an exciting area of research.

PART VII

Genetic and Metabolic Disease

CHAPTER 29
Wilson Disease

Michael L. Schilsky[1] *& Anthony S. Tavill*[2]

[1]Yale New Haven Transplant Center, Yale University Medical Center, New Haven, CT, USA
[2]Case Western Reserve University, Cleveland Clinic, Cleveland, OH, USA

Key concepts

- Wilson disease is a genetic disorder in which copper accumulates in the liver and brain in excess of normal metabolic needs. The accumulation is based on an inherited defect in the hepatic biliary excretion of copper.
- The inheritance pattern is autosomal recessive. Homozygotes for this disorder, numbering about 1 in 30,000 of the population, inherit disease-specific mutations of both alleles of the gene for Wilson disease, *ATP7B*, on chromosome 13. The disease does not develop in heterozygotes with a mutation of a single *ATP7B* allele, and they do not require treatment.
- The diagnosis of Wilson disease is established by a combination of clinical and biochemical findings or by molecular genetic studies. Biochemical findings include most notably a decrease in levels of circulating ceruloplasmin, and a hepatic copper concentration above 250 mg/g dry weight of liver in most affected individuals. Clinical findings include the presence of corneal Kayser–Fleischer rings, stigmata of chronic liver disease, and neurologic findings.
- Molecular genetic studies demonstrating two disease-specific mutations of *ATP7B* may be used to establish a diagnosis of Wilson disease. Most patients are compound heterozygotes with two different mutations, but clinical and biochemical evaluation are needed to demonstrate phenotypic expression and to stage the disease.
- In most symptomatic patients, treatment with metal chelating agents is effective in stabilizing or reversing the disease. Asymptomatic patients may be treated with metal chelating agents or zinc salts. In all circumstances, lifelong pharmacologic treatment is required and results in excellent patient survival.
- Acute liver failure in Wilson disease or hepatic insufficiency unresponsive to medical therapy is best treated with orthotopic liver transplantation, which, by providing the liver with a normal physiologic capacity for copper excretion, is curative.

History

In 1912, while serving as a senior resident at the National Hospital for Nervous Diseases in London, Kinnier Wilson published his work "Progressive lenticular degeneration: a familial nervous disease associated with cirrhosis of the liver" as part of his dissertation for the Edinburgh MD degree [1]. Correctly, he speculated that the brain disease, characterized by extrapyramidal features, was caused by the liver disease. However, his concept of a "morbid toxin" produced by the cirrhotic liver, although strictly correct, could not have anticipated the much later insights into the role of the liver in copper metabolism and the vulnerability of certain areas of the brain to the toxic effects of excessive copper deposition. It was not until 33 years later that Glazebrook [2] detected a marked excess of copper in the basal ganglia of a patient dying of Wilson disease and surmised from the recognized accumulation of copper in the liver that the inability of the liver to excrete copper was the dysfunction responsible for the lenticular degeneration, a pathogenetic association later confirmed by other workers [3,4].

In 1902 and 1903 the first descriptions of corneal pigmented rings, now recognized eponymously as Kayser–Fleischer (K-F) rings, were based on observations in patients with neurologic disease [5,6]. Fleischer [7] was the first to associate three seminal features of Wilson diseases – namely, corneal pigmentation, neuropsychiatric disease, and hepatic cirrhosis – and another 10 years passed before the first hypothesis was proposed that the corneal pigmentation is caused by the pathologic deposition of copper [8,9]. Recognition of the value of a low serum ceruloplasmin concentration in the diagnosis of Wilson disease came from the observations of Scheinberg and Gitlin [10], who first reported this phenomenon in 96% of Wilson disease homozygotes. However, Sternlieb and Scheinberg [11] subsequently recognized that up to 20% of heterozygotes also have low

ceruloplasmin concentrations without any other clinical manifestations of Wilson disease. This observation and the presence of a normal ceruloplasmin in a small minority of Wilson disease homozygotes, and the lack of copper accumulation in patients with a defect in ceruloplasmin biosynthesis (aceruloplasminemia), argued against a direct pathogenetic role for ceruloplasmin in the accumulation of copper in tissues in cases of Wilson disease. With the understanding that the clinical features of Wilson disease are the result of copper toxicity in the various affected tissues of the body, the rationale for chelation therapy became apparent. The first chelation agent used for the treatment of Wilson disease in 1951 was British anti-lewisite (BAL), or dimercaptopropanol [12, 13]. This drug, which is lipophilic and therefore administered intramuscularly, provided the first effective therapy for a previously untreatable disorder. BAL was developed as a war time expedient as an antidote to arsenic gas. The principle on which its action was based depended on its two sulfydryl groups for the binding and inactivation of arsenic. Unfortunately BAL has a high incidence of toxic reactions, is painful for the recipient, and while also effective in the chelation of copper it has many toxic, adverse effects. As Walshe pointed out in his review of the pharmacologic treatment of Wilson disease [14], BAL, while offering significant progress, was limited in its application to copper toxicity by both toxicity and tachyphylaxis, thereby prompting the search for an oral copper chelator excreted through the kidneys.

John Walshe of Cambridge University, while working at the Boston City Hospital, introduced the first effective oral chelation therapy in the form of penicillamine and demonstrated its cupriuretic action and role in the symptomatic improvement of patients with life-threatening features of Wilson disease [15]. It was the incidental finding of the excretion of dimethylcysteine in the urine following the administration of penicillin that led Walshe to postulate that this breakdown amino acid product of the antibiotic (also known as D-penicillamine) might have copper chelating properties. That hypothesis was borne out in clinical practice, and with pharmaceutical industry collaboration the D-isomer of dimethylcysteine became the favored treatment for the copper overload of Wilson disease, with very promising benefits for both the hepatic and neurologic components of the disease. Sternlieb and Scheinberg [11] subsequently expanded the use of this drug to include the treatment of asymptomatic (or presymptomatic) patients with Wilson disease by showing its effectiveness in preventing disease progression.

Walshe [16] proceeded to develop another, safer chelating agent, triethylene tetramine dihydrochloride (trientine), which proved a valuable alternative agent in the treatment of those patients intolerant of the toxic effects of penicillamine. The development of trientine took place initially in Walshe's own laboratory before being taken up by industry and marketed as an orphan drug. It had powerful copper chelating ability with clinical benefits comparable to that of penicillamine but without the adverse effects of precipitating a lupus-like syndrome.

Walshe [17] was also instrumental in the initial human use of tetrathiomolybdate, currently an investigational drug in the United States and United Kingdom. Its mode of action is probably through tight binding of copper both in the intestine and the tissues, with the potential for reducing both its absorption from the intestine and its toxicity in the tissues.

The possibility of preventing the toxic accumulation of copper in Wilson disease by blocking the intestinal absorption of copper with oral zinc therapy was first considered by Schouwink [18]. Oral zinc therapy would not be regarded as appropriate for the management of newly diagnosed, symptomatic Wilson disease because it is ineffective in the removal of accumulated copper from the tissues and therefore it has not been licensed by the US Food and Drug Administration (FDA) for this purpose. Studies have shown, however, that it is a valuable alternative to chelation agents for long-term maintenance therapy based on its effectiveness in preventing copper reaccumulation [19,20].

A development that revolutionized the treatment of a subset of patients with Wilson disease presenting with acute liver failure was orthotopic liver transplantation [OLT), which effectively cures the disease [21]. The phenotypic reversion from a diseased to a normal state in transplant recipients demonstrates the central role of the liver in Wilson disease and copper metabolism.

The recognition of Wilson disease as an inherited disorder, defined by a complex of signs and symptoms, has evolved in less than a century to the point at which we are now able to define the molecular basis for the pathophysiology of this disorder. Milestones in this process, which culminated in the identification of the gene for Wilson disease, designated *ATP7B*, and the recognition of disease-specific mutations, are reviewed in subsequent text and outlined in Table 29.1.

Genetics

Although Wilson correctly recorded the familial nature of the disease, it was Hall in 1921 [22] who demonstrated its inheritance, later shown to be autosomal recessive [23]. Subsequently, the linkage of Wilson disease to the locus of the red cell *esterase-D* gene placed the gene for Wilson disease on the long arm of chromosome 13 [24], and additional studies further delineated its chromosomal localization [25,26].

A breakthrough in the understanding of the molecular basis of the defect of copper metabolism in Wilson disease was the discovery of the gene for Menkes disease,

Table 29.1 Milestones in the genetics of Wilson disease.

Year	Milestone	Reference
1912	Recognition of Wilson disease as an inherited disorder	Wilson 1912 [1]; Groth et al. 1973 [21]
1953	Pattern of inheritance described as autosomal recessive	Hall 1921 [22]; Bearn and Kunkel 1953 [23]
1985	Localization of disease locus to chromosome 13 by linkage with esterase D	Frydman et al. 1985 [24]
1986–1993	Localization of the responsible gene to a specific region in chromosome 13	Houwen et al. 1990 [25]; Bowcock et al. 1988 [26]
1992–1993	Identification of the gene for Menkes disease as a putative copper-transporting P-type ATPase	Vulpe et al. 1993 [27]; Chelly et al. 1993 [28]
1993	Identification of the gene for Wilson disease, *ATP7B*, and disease-specific mutations	Bull et al. 1993 [32]; Mercer et al. 1993 [29]; Petrukhin et al. 1993 [31]; Tanzi et al. 1993 [30]
1994 to present	Continued studies on disease-specific mutations and polymorphisms of *ATP7B*	Yamaguchi et al. 1993 [33]; Petrukhin et al. 1994 [34]

ATPase, adenosine triphosphatase.

another rare inherited disease of copper metabolism, and the identification of its gene product, ATP7A, a cation-transporting P-type adenosine triphosphatase (ATPase) involved in copper transport in many tissues [27–29]. The extrapolation of the copper-transporting P-type ATPase to the Wilson disease model led to the hypothesis that a mutation in the gene for a liver-specific copper transporter might be responsible for the association between the defective incorporation of copper into ceruloplasmin, failure of biliary secretion of copper, and accumulation of copper in the liver.

The isolation and identification of the gene for Wilson disease, designated *ATP7B*, followed closely the discovery of the gene for Menkes disease. The identification of the specific gene was accomplished almost simultaneously by three independent laboratories [30–33]. The detection of specific mutations unique to individuals with clinical and biochemically proven disease confirmed the identity of the responsible gene [30,31].

The *ATP7B* gene is contained within an approximately 80 kb region of DNA containing 22 exons (exon 22 being contained in a rare transcript); these encode an approximately 7.8 kb messenger RNA that is highly expressed in the liver [34]. Analysis of the gene sequence indicates that ATP7B belongs to a family of ATP-dependent metal transporters that are highly conserved through evolution [35]. A schema of the *ATP7B* gene showing specific regions of known homology to ATPases and metal transporters is shown in Fig. 29.1.

Screening for mutations of *ATP7B* has led to the identification of a large number (>300) of disease-specific mutations and polymorphisms of the gene [31,32,35–37]. Most of the mutations thus far identified are point mutations that result in amino acid substitutions. However, deletions, insertions, missense, and splice site mutations have also been reported. A summary of the mutations and polymorphisms of the gene can be found in the following website: http://www.wilsondisease.med.ualberta.ca/database.asp. When particular mutations are found frequently among members of a specific population or ethnic group, direct mutational analysis

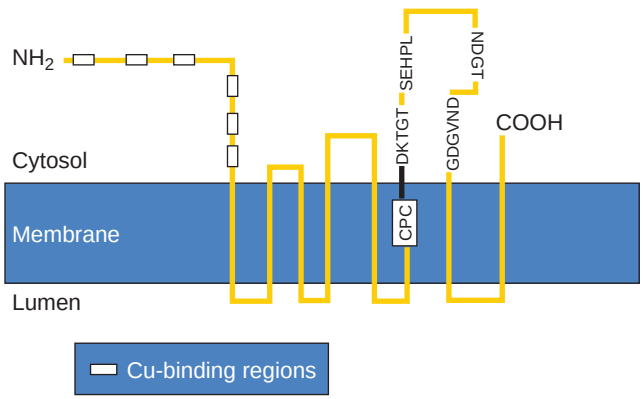

Figure 29.1 Predicted major structural features of the Wilson disease gene product (ATP7B). ATP7B, as a member of a class of heavy metal-transporting adenosine triphosphatases (ATPases), is predicted to contain the following structural features: cysteine-rich metal-binding regions near the amino terminus, a transduction and phosphatase domain, multiple transmembrane regions with one containing the amino acids cysteine-proline-cysteine (CPC), a phosphorylation domain (DKTGT), an ATP-binding region (NDGT), a hinge region (GDGVND), and a conserved domain for metal-transforming ATPase, critical for copper (Cu) transfer (SEHPL). (Adapted from Petrukhin et al. [34] and Cox [36]).

for these mutations is particularly useful and may expedite diagnosis. Haplotype analysis (polymorphism analysis of the region surrounding *ATP7B*) has proved useful for genetic screening of siblings of probands, though advances in DNA sequencing technology and its wider availability makes direct mutational analysis the testing of choice (see subsequent text). The most frequently observed point mutation, which results in a change from histidine to glutamine (H1069Q), is present in nearly 30% of patients of European descent [31,37]. In only a single population in Austria has the frequency of this mutation been reported to be higher (up to 65%) [38]. Most mutations are clustered about several transmembrane regions of the protein and in another region predicted to be involved in ATP binding. Some evidence indicates that mutations that result in a loss of the expression of the ATP7B protein may cause more severe phenotypic expression; however, not all studies support this conclusion. Another study suggests that expression of another gene, *APOE*, may modify the phenotype of Wilson disease. Polymorphisms in other genes involved in copper metabolism may also modify the disease phenotype, as suggested by studies of *MURR1* or *COMMD1* [39], a member of the commander family of proteins, the gene responsible for copper toxicosis in Bedlington terriers but whose function in copper export is not yet certain. XIAP (X-linked inhibitor of apoptosis) is another protein that is influenced by copper concentration that modifies the threshold for apoptosis [40]. Further investigations are ongoing that aim to correlate specific phenotypic presentations or manifestations of Wilson disease with *ATP7B* genotype and the expression of other potential modifying genes.

Pathophysiology

Copper is an essential cofactor for many enzymes and proteins and is important for the mobilization of tissue iron stores. The normal pathways for copper metabolism are outlined in Fig. 29.2. Ingested copper is extracted from the portal circulation by hepatocytes by the cell surface human copper transporter (hCTR1) [41]. Intracellular copper then interacts with low molecular weight ligands such as glutathione [42], metallothionein [43], and HAH1 [44], which serve as transfer or storage agents. It is subsequently used for cellular metabolic needs, incorporated into the secretory glycoprotein ceruloplasmin, or excreted into bile.

The passage of copper from hepatocytes to bile is critical for homeostasis of this metal because copper excreted into bile undergoes minimal enterohepatic recirculation [45]. The transport of hepatocellular copper to bile is thought to involve a vesicular pathway that is dependent

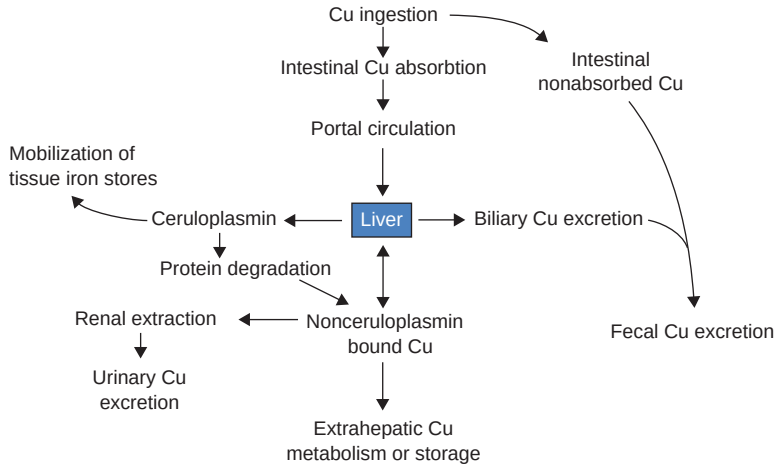

Figure 29.2 Copper (Cu) metabolism and pathophysiology of Wilson disease. Dietary copper is absorbed in the proximal small intestine, whereas nonabsorbed copper or copper bound within shed enterocytes passes into the feces. Absorbed copper is bound mainly to albumin in the portal circulation, from which it is avidly extracted by hepatocytes. Hepatocellular copper is bound to ligands and used for metabolic needs, transferred to endogenous chelators, incorporated into ceruloplasmin, or excreted into bile. Biliary copper does not undergo enterohepatic recycling and is therefore excreted in the feces. In Wilson disease, biliary copper excretion is reduced, and copper accumulates within hepatocytes. The incorporation of copper into ceruloplasmin is also impaired in Wilson disease; as a result, circulating levels of this protein are decreased in most patients. When cellular stores are overloaded or after a hepatocellular injury, the amount of copper released into the circulation is increased. Extraction of the excess of nonceruloplasmin-bound copper by the kidneys leads to an increase in urinary copper excretion and extrahepatic deposition of this metal. The dietary intake of copper is approximately 5 mg/24 h, with intestinal absorption varying between 25% and 60% of intake. Fecal excretion is approximately 4.9 mg/24 h, and urinary copper excretion and renal excretion do not usually exceed 50 μg/24 h (maximum 100 μg/24 h). In Wilson disease, nonceruloplasmin-bound copper is the precursor of the excessive copper deposited in the tissues.

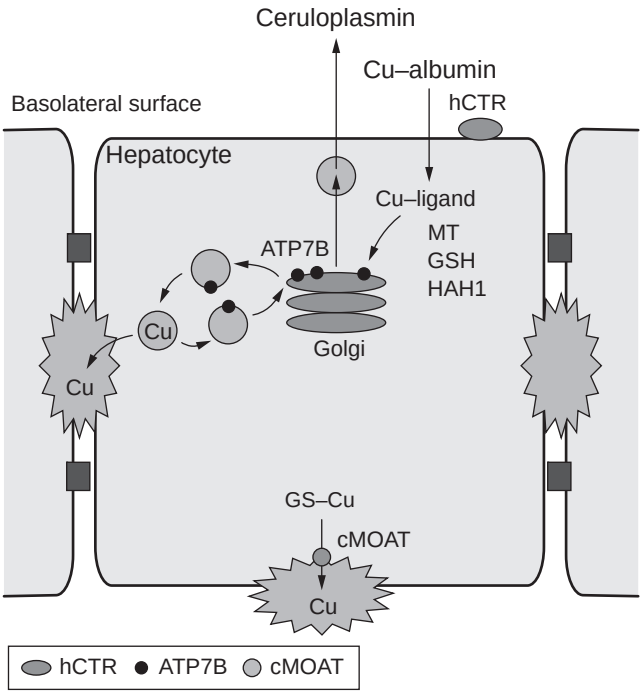

Figure 29.3 Cellular pathways of copper (Cu) metabolism. Newly absorbed copper, loosely bound to albumin, is transported across the plasma membrane of the hepatocyte, where it is transported by a variety of ligands to the Golgi apparatus. There, the ATP7B protein serves to transport it across the Golgi into ceruloplasmin for secretion into the circulation. Excretion into bile may occur by vesicular secretion, by transcanalicular association with glutathione (GSH) through the canalicular multispecific organic anion transporter (cMOAT), or by copper-transporting adenosine triphosphatase in the canalicular membrane. GS-Cu, copper glutathione; HAH1, human homolog of Atx1p, a copper chaperone; hCTR, human copper transporter; MT, metallothionein.

on the function of ATP7B. This protein appears to be present mainly in the *trans*-Golgi network of liver cells under basal conditions (Fig. 29.3) [46]. Interestingly, in recent studies of the homologous Menkes disease protein, ATP7A, this protein was observed to alter its intracellular localization in response to increases in the level of copper [47]. Although studies of ATP7B protein suggest that it also redistributes to a vesicular compartment in response to copper loading [46], how the redistribution affects the function of the protein remains to be determined. It is presumed that the vesicular pathway is critical for biliary copper excretion. However, other investigators suggest that ATP7B protein resides in a pericanalicular region and relocates directly to the canalicular membrane in response to increased cellular copper [48]. If the ATP7B protein is present at this site, it would be involved in the direct transfer of copper to bile. Whether the ATP7B protein resides in the canalicular membrane or whether copper is delivered through this site by vesicular transport, the absence or diminished function of ATP7B results in a decrease in biliary copper excretion, which is responsible for the hepatic accumulation of this metal in Wilson disease [4,49–51].

Ceruloplasmin is a serum glycoprotein that contains six copper atoms per molecule. It is synthesized predominantly in the liver. Copper is thought to be incorporated into apoprotein ceruloplasmin in the Golgi apparatus [52] and the copper-containing holoprotein secreted from the hepatocyte. Newly transported copper, which is used for ceruloplasmin biosynthesis, must also cross organelle membranes to enter into the protein biosynthetic pathway, a process that is dependent on ATP7B and is absent or diminished in most patients with Wilson disease. A reduction of the incorporation of copper into ceruloplasmin is believed to lead to a reduced circulating level of this protein in most patients with Wilson disease because the noncopper-containing apoprotein is less stable and undergoes more rapid degradation in vivo.

When copper accumulates beyond the cellular capacity for its safe storage, hepatocellular injury may result. Toxic effects of excess copper include the generation of free radicals, lipid peroxidation of membranes and DNA, inhibition of protein synthesis, and alterations in the levels of cellular antioxidants [53]. Recent data suggest that both hepatocellular necrosis and apoptosis may be triggered by copper-induced cell damage [54,55]. When copper-induced injury occurs, the functional status of the liver is determined by the delicate balance between injury, cell death, and the regenerative capacity of liver cells.

When the capacity of the liver to store copper is exceeded, or when hepatocellular damage results in the release of cellular copper into the circulation, levels of nonceruloplasmin-bound copper in the circulation become elevated. It is from this pool that the extrahepatic deposition of copper is thought to occur. The brain is the most critical extrahepatic site of copper accumulation, and copper-induced neuronal injury is responsible for the neurologic and psychiatric manifestations of Wilson disease and the characteristic changes on radiologic imaging studies of the brain.

Pathology

The evolution of pathologic changes in the tissues of patients with Wilson disease (see [53] for a review) follows the relative rates of accumulation of copper in the various body organs. Because the primary genetic defect resides in the liver and because the liver is the predominant storage organ for copper, it is not surprising that the earliest pathologic manifestations are hepatic in nature. As copper "spills" over to other organs from the liver, pathologic manifestations become evident in the brain, kidneys, eyes, red blood cells, and joints.

Hepatic pathology

Macroscopically, the liver may be only mildly enlarged in the early stages of life. Later, without treatment, the liver pathology progresses in most patients to fibrosis and cirrhosis. The nodular transformation of cirrhosis is a mixed macronodular–micronodular pattern, in which the nodules may vary in color depending on the degree of copper accumulation (Fig. 29.4A). The rate of pathologic change varies greatly between patients, and in some cases steatosis and fibrosis without cirrhosis may persist for decades [56].

At a microscopic level, the evidence of copper accumulation in early infancy may be subtle and nonspecific. Diffuse cytoplasmic copper accumulation may not be visible by immunohistochemical methods for detecting copper (e.g., rhodanine, rubeanic acid). This early stage of copper accumulation is associated with macrosteatosis, microsteatosis, and glycogenated nuclei,

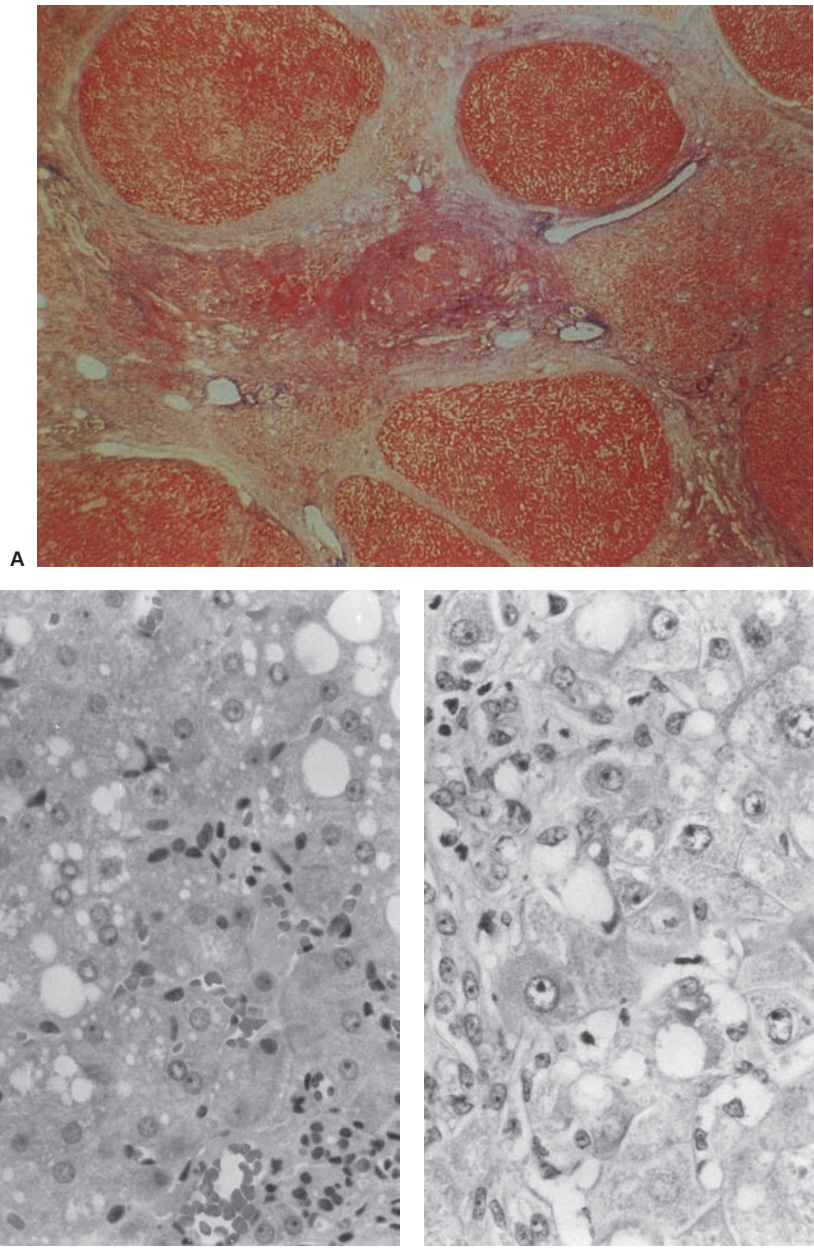

Figure 29.4 Light microscopic findings in liver in Wilson disease. (A) Masson trichrome stain of liver from a patient with established cirrhosis reveals broad bands of fibrosis intersecting variably sized nodules with varied staining characteristics. Original ×80. (B) Prominent microvesicular and macrovesicular steatosis and some inflammatory cells in a specimen from an asymptomatic patient with Wilson disease. Original ×250. (C) Hepatocellular ballooning and degeneration in a biopsy specimen from a patient with acute Wilsonian hepatitis. Original ×250.

features that may be seen in a variety of other conditions (Fig. 29.4B) [57]. Sternlieb [58] emphasized the almost ubiquitous presence of distinctive mitochondrial changes at this early stage of the disease. The ultrastructural abnormalities range from enlargement and separation of the inner and outer mitochondrial membranes, with widening of the intercristal spaces, to increases in the density and granularity of the matrix or replacement by large vacuoles. Pleomorphic changes may also be seen in distorted peroxisomes and endoplasmic reticulum, with nuclei showing glycogen inclusions. With progression of the disease, copper-associated protein is sequestered in lysosomes, appearing as electron-dense pericanalicular structures visible on light microscopy as granules detectable by copper immunohistochemistry (Fig. 29.5).

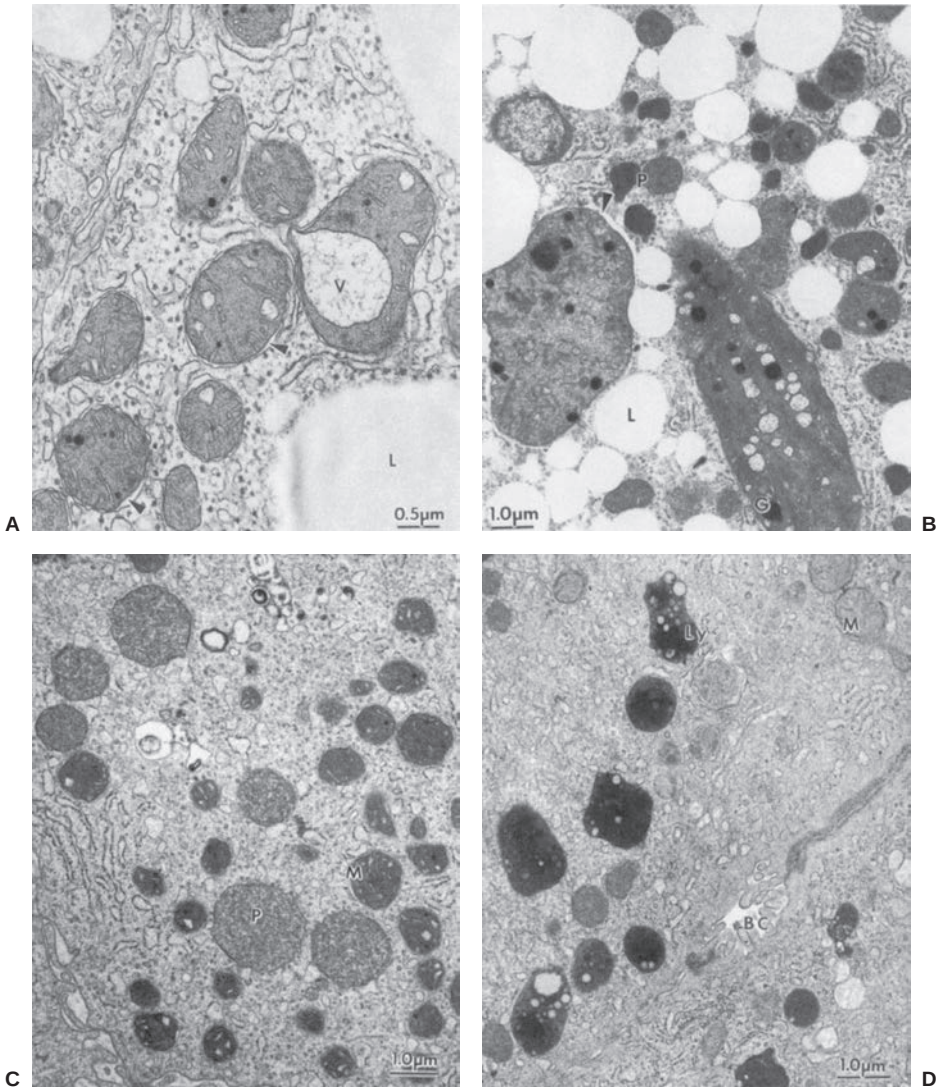

Figure 29.5 Electron micrographs of fine sections of liver biopsy specimens obtained from untreated patients with Wilson disease, showing portions of hepatocytes. (A) Ten-year-old asymptomatic girl with normal physical findings: aspartate aminotransferase, 76 IU/L; alanine aminotransferase, 55 IU/L; serum ceruloplasmin, 21.4 mg/dL; hepatic copper, 1,258 μg/g of dry tissue. Some of the mitochondria display vacuoles (V) with granular material. Note the separation of the inner from outer membrane (arrowheads), with the creation of an enlarged intermembranous space. L, lipid droplet. (B) Nineteen-year-old woman with a history of progressive fatigue, found to have Kayser–Fleischer rings 2 months after an episode of hemolytic anemia with jaundice: serum ceruloplasmin, 12.7 mg/dL; hepatic copper, 591 μg/g of dry tissue. The mitochondria are markedly pleomorphic, some displaying multiple, pathognomonic abnormalities: gigantism, increased matrical density, separation of inner from outer membrane (arrowhead), vacuoles, dilated cristae, crystals, and enlarged dense granules (G). P, peroxisomes. (C) Ten-year-old asymptomatic girl with a serum ceruloplasmin level below 1 mg/dL and a hepatic copper concentration of 1,029 μg/g of dry tissue. Mitochondria (M) display dilated cristae; the markedly enlarged peroxisomes (P) with grainy matrices are strikingly abnormal. (D) In a 20-year-old woman with severe neurologic Wilson disease, the hepatocellular cytoplasm appears virtually normal except for the abundance of electron-dense, peribiliary, lysosomal granules (Ly). BC, bile canaliculus; M, mitochondria.

If the condition is untreated or unrecognized, the initial stages of Wilson disease progress to an intermediate hepatic stage. This is characterized by periportal inflammation with mononuclear cellular infiltrates, erosion of the limiting lobular plates, lobular necrosis, and bridging fibrosis, features indistinguishable from those of chronic active hepatitis of many other causes [57]. Cirrhosis is virtually invariable at this stage of disease, with either a micronodular or a mixed macronodular–micronodular histologic pattern. Mallory bodies may be visible in up to 50% of biopsy specimens.

In patients presenting with acute liver failure, parenchymal necrosis with hepatocellular ballooning, apoptotic bodies, cholestasis, and collapse of the liver may predominate (Fig. 29.4C). In some of these individuals with acute liver failure, the liver has significant collapse and bridging fibrosis, but cirrhosis may not be present (M. Schilsky and J. Lefkowitch, personal observations, 2005).

A histochemical confirmation of copper deposition may be helpful; however, a negative result does not exclude copper overload. Rhodanine and rubeanic acid may show dense granular lysosomal copper deposition in hepatocytes at the stage of cirrhotic nodular regeneration. Staining at this stage often shows marked variability from nodule to nodule (Fig. 29.6). Paradoxically, the results of immunohistochemical staining for copper are usually negative in the earlier stages of the disease when the hepatocyte copper is diffusely distributed in the cytoplasm [59]. A more sensitive stain, Timms sulfide, is more effective in detecting cytoplasmic copper-binding proteins, although it is not routinely utilized. Overall, the opinion of most hepatopathologists is that histochemical copper stains should not be routinely used for the diagnosis of Wilson disease (see below) because of their lack of sensitivity [60].

Neuropathology

Macroscopically, most of the overt neuropathologic changes in advanced Wilson disease are concentrated in the lenticular nuclei. These show atrophy and discoloration, with cystic degeneration, pitting, and fissuring of the cut surfaces. Similar changes have been described in the thalamus, subthalamic region, and even the cerebral white matter [61].

Microscopically, the major pathologic changes occur in those parts of the central nervous system with the highest copper levels. Scheinberg and Sternlieb [61] calculated that the concentrations are highest in the thalamus, followed by the putamen and cerebral cortex. Neuroglial changes are the most distinctive in Wilson disease, with an increase in the number of astrocytes in the gray matter of the lenticular nuclei. Swollen glia may undergo cavitation and liquefaction, which create small cavities with an overall appearance of spongiform degeneration. Neuronal loss is accompanied by gliosis and astrocytosis and the production of glial fibrillary protein. The characteristic astrocytes seen within areas of lenticular degeneration are Alzheimer type I and II cells and, distinctively for Wilson disease, Opalski cells [62]. Opalski cells are large cells, up to 35 μm in diameter, with fine granular cytoplasm and slightly eccentric nuclei (single or multiple) that Scheinberg and Sternlieb [61] suggested originate from degenerating astrocytes. It is unclear at the present time whether the glial changes are secondary to the stimulation of metallothionein protein synthesis by copper in selective areas of the brain populated by protoplasmic astrocytes or whether the selective targeting of glial cells is related to other, as yet unidentified, factors.

Miscellaneous pathologic changes

Functional changes in the kidneys are often disproportionate to any observable changes on light microscopy.

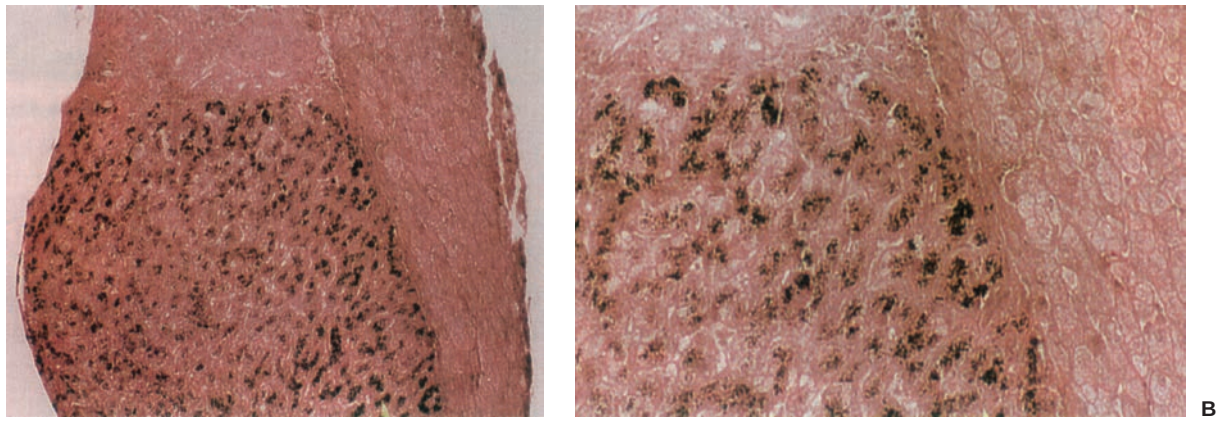

Figure 29.6 Liver section stained with rhodanine to show a lobule with heavy lysosomal copper deposition and the adjoining liver tissue with minimal copper staining. (A) Low power original ×110; (B) high power original ×200.

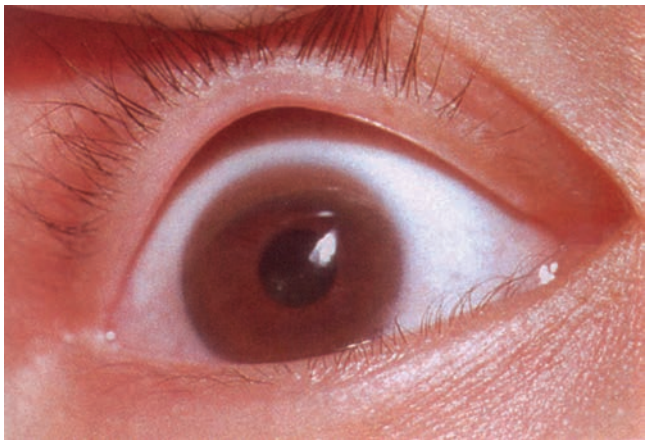

Figure 29.7 Kayser–Fleischer ring in a 17-year-old patient with neurologic symptoms of Wilson disease.

Proximal or distal tubular dysfunction leading to tubular proteinuria, bicarbonate loss, aminoaciduria, glycosuria, hyperphosphaturia, uricosuria, and hypercalciuria is common. Glomerular abnormalities, in the form of hypercellularity, basement membrane thickening, hyalinization, and fibrosis, have been described [61]. Penicillamine-induced immune complex nephropathy has been described. Bone pathology and periarticular abnormalities have been observed, accounting for osteoporosis, osteomalacia, spontaneous fractures, adult rickets, osteoarthritis, osteochondritis dissecans, chondrocalcinosis, and subchondral cyst formation [61]. Involvement of the spine and knee joints is the most common distribution of skeletal and articular abnormalities.

Ophthalmologic findings include K-F rings and sunflower cataracts. The K-F rings, most marked at the upper and lower poles of the cornea, are caused by the granular deposition of elemental copper on the inner surface of the cornea in the Descemet membrane (Fig. 29.7). The rings have a golden brown or green appearance on slit-lamp examination. The sunflower cataracts, with radiating centrifugal extensions, are associated with the granular deposition of copper in the anterior and posterior lens capsule. Both the K-F rings and sunflower cataracts are reversible with effective treatment.

Diagnosis

The diagnosis of Wilson disease should be considered in any person aged between 3 and 40 years with unexplained hepatic, neurologic, or psychiatric disease, although rare cases have been diagnosed in persons in the sixth, seventh, and even eighth decades of life [56]. In particular, this diagnosis must be excluded unequivocally in children or young adults who present with unusual extrapyramidal or cerebellar motor disorders, atypical psychiatric disease, unexplained hemolysis, or elevated liver enzyme levels or other manifestations of liver disease, with or without a family history of liver or neurologic disease. Failure to do so will lead to unnecessary and preventable demise. In most cases, the diagnosis can be made by a combination of clinical and biochemical testing. In practice, three levels of tests may be undertaken to confirm the diagnosis of Wilson disease (Table 29.2). The presence of K-F rings and a reduced serum concentration of ceruloplasmin are sufficient to establish the diagnosis. However, in the absence of K-F rings, it may be necessary to proceed to a liver biopsy for a quantitative copper determination to confirm the diagnosis.

Molecular testing is currently available for Wilson disease. There are two types of testing that may be employed. Haplotype analysis that looks for familial inheritance of polymorphisms around the *ATP7B* gene can be considered for use in screening the siblings of affected persons, however direct mutational analysis is now available and is the preferred testing technique. Newer methodology has made the molecular screening of the entire coding region of *ATP7B* less cumbersome and time consuming, although some targeting of specific exons with higher frequencies of mutations makes sense, particularly in individual populations in which specific mutations are present at higher frequency. There is a need to identify disease-specific mutations of the gene to firmly

Table 29.2 Diagnostic tests in Wilson disease.

Level 1[a]	Level 2[a]	Level 3
Low serum ceruloplasmin[1]	Liver copper concentration[2]	
Slit-lamp examination for K-F rings	–	Ultrastructural studies of hepatocytes
Raised serum-free copper level[3]	24-hour urine copper[4]	Molecular genetic studies for Wilson disease

[a]Normal values: (1) 20–50 mg/dL; (2) <250 μg/g dry weight; (3) <10 μg/dL; (4) <50 μg/24 hours. Values in Wilson disease: (1) <20 mg/dL; (2) >250 μg/g dry weight; (3) >25 μg/dL; (4) >100 μg/24 hours.
K-F, Kayser–Fleischer.

establish the diagnosis in the absence of pathognomonic biochemical abnormalities. Although molecular studies may detect the disease, it may still be useful to fully characterize all patients with standard clinical and biochemical testing to better understand the degree of disease involvement, as well as to provide confirmation of the diagnosis. Given the current relatively high cost and complexity of this testing, molecular testing is not useful as a screening test for Wilson disease in the population at large. However, for patients in whom there is difficulty in determining the diagnosis by clinical and biochemical testing, and for family screening, molecular testing should prove extremely useful.

Concentration of ceruloplasmin

A test to determine the serum concentration of ceruloplasmin is routinely available in all clinical laboratories. It is most useful, when measured by means of enzymatic methods, to determine oxidase activity, because this best reflects the copper content of the protein, although immunologic assays are frequently utilized. The normal range is 20–50 mg/dL. About 95% of homozygotes with Wilson disease have values of less than 20 mg/dL. Up to 5% of all homozygotes and up to 15–50% of persons with liver disease may have normal levels, which is defined as concentrations above 20 mg/dL [61,63]. In some cases, normal levels are present in patients with active liver disease, probably as a consequence of acute-phase responses in the liver or estrogen supplementation. Homozygotes rarely have serum concentrations exceeding 30 mg/dL. Low serum concentrations of ceruloplasmin may also be observed in hypoproteinemic states, such as protein-calorie malnutrition, nephrotic syndrome, protein-losing enteropathy, and other forms of severe decompensated liver disease, and in up to 20% of asymptomatic heterozygous carriers of the gene for Wilson disease. Rarer causes of serum ceruloplasmin deficiency include hereditary aceruloplasminemia and Menkes disease.

Concentration of circulating copper not bound to ceruloplasmin

The total concentration of copper in plasma or serum represents ceruloplasmin-bound copper plus nonceruloplasmin-bound ("free") copper, which is bound mainly to albumin, peptides, or amino acids. Because the former is reduced in proportion to the degree of hypoceruloplasminemia, the total copper may be low in the face of a typically raised free copper concentration. To calculate the latter, the plasma ceruloplasmin copper concentration (approximately the ceruloplasmin level in mg/dL multiplied by 3) is subtracted from the total copper concentration (in μg/dL). The value for total plasma copper ranges from 80 to 120 μg/dL and the value for nonceruloplasmin-bound copper is usually 10% of the total value (8–12 μg/dL). In Wilson disease, levels of nonceruloplasmin-bound copper are typically above 25 μg/dL in symptomatic patients before treatment. Recently a direct assay for nonceruloplasmin copper in serum was introduced, but it is not yet widely available [64].

Slit-lamp detection of Kayser–Fleischer rings

It is essential that all patients in whom Wilson disease is suspected undergo a slit-lamp examination, performed by an experienced ophthalmologist, for the detection of K-F rings. These rings are present in patients with neurologic disease, with only rare exceptions, but they may be absent, particularly in younger patients with hepatic manifestations only (see Fig. 29.7). Another finding that may suggest Wilson disease is the presence of sunflower cataracts, also best observed by slit-lamp examination.

Urinary excretion of copper

The copper excreted in urine is derived from the free copper circulating in plasma, which represents filterable, nonceruloplasmin-bound copper. The rate of excretion may exceed 100 μg/24 h in symptomatic patients. In patients presenting with chronic liver disease, the urinary copper level is elevated above normal levels but may not reach diagnostic levels of more than 100 μg/24 h. False-positive increases in urinary copper level may be seen in the face of significant proteinuria and urinary loss of ceruloplasmin, and rarely in other liver diseases where copper storage is increased or in acute liver failure. A provocative test for urinary copper excretion with the use of the chelating agent penicillamine has been studied in children [65] but may be no better than changing the threshold of urinary copper excretion to 40 μg of copper in 24 hours [66]. When urinary excretion of copper is tested, it is crucial that a metal-free container be used and that the adequacy of the collection be monitored by correlation with volume excreted or with creatinine excretion.

Concentration of copper in the liver

Normal concentrations of copper in the liver rarely exceed 50 μg/g dry weight of liver. Most patients homozygous for Wilson disease have levels above 250 μg/g, whereas the concentration of copper in the liver of heterozygotes, although commonly elevated above normal, typically does not exceed 250 μg/g [61]. The hepatic copper concentrations may also be elevated in other liver diseases, particularly chronic cholestatic diseases such as primary biliary cirrhosis and primary sclerosing cholangitis. However, these disorders are usually readily distinguishable from Wilson disease on the basis of serologic and histologic criteria.

A recent study by Ferenci et al. [67] suggested that in some individuals confirmed to have Wilson disease by molecular studies, hepatic copper content does not reach 250 μg/g dry weight of liver. On the basis of these results, these investigators proposed a lower threshold for considering Wilson disease: 70 μg copper/g dry weight liver. However, no data are presented in this study on heterozygotes in whom hepatic copper may easily exceed this threshold. Therefore, the previous cutoff of 250 μg copper/g dry weight liver may better differentiate heterozygotes and homozygotes with Wilson disease, but this should not be the sole criterion for excluding the diagnosis if there is appropriate histology or clinical signs of disease. In patients for whom the diagnosis remains uncertain despite extensive clinical and biochemical evaluation, molecular studies will help in confirming or refuting the diagnosis of Wilson disease.

Liver biopsy specimens for a quantitative copper determination should be obtained with a (Tru-Cut or Jamshidi) needle and placed dry in a copper-free vessel. About 1 cm of a 1.6 mm diameter core of liver should be dried overnight at 56°C in a vacuum oven or, alternatively, frozen immediately before being shipped to a laboratory specializing in microchemical analysis for copper. The remainder of the specimen can be fixed in the usual manner for histopathologic examination. In asymptomatic patients, the hepatic copper level is higher than that in patients with established cirrhosis. Specimens with extensive fibrosis and fewer parenchymal cells may yield copper concentrations that are nondiagnostic, and therefore the result of hepatic copper quantification should be correlated with the histologic, clinical, and biochemical data. If the diagnosis of Wilson disease is considered after specimens are processed, liver tissue can be removed from paraffin and copper quantitation performed after extraction of the paraffin and drying of the specimen. These specimens are often smaller, and larger errors in the estimation of tissue copper may occur if too little of the specimen remains for analysis.

Molecular genetic studies

The identification of the gene for Wilson disease has enabled the molecular genetic diagnosis of this disorder. There are now numerous disease-specific mutations of the gene described; however, the most common mutation is present in only 15–30% of most populations [37,38]. This makes most patients compound heterozygotes, possessing different mutations on each allele of *ATP7B*. Direct de novo analysis for the presence of disease-specific mutations is now possible, given the advances in DNA sequencing and screening technology. The ability to establish the diagnosis by this methodology depends on distinguishing disease-specific mutations from polymorphisms of the gene and is further limited by the fact that some of the noncoding regions of the gene, which may also affect gene expression, are not analyzed. It is also possible to screen family members of an affected person by haplotype analysis. This process involves inspecting the patterns of polymorphisms of the DNA in the region surrounding the Wilson disease gene to determine whether mutant regions present in the affected person have been inherited by family members [31]. Future developments in DNA analysis should make it possible to screen for disease-specific mutations in an even more cost-effective manner, so that de novo population screening will one day prove practical. At present, genetic testing should be used for screening families and used in concert with standard clinical and biochemical testing as discussed above.

Ultrastructural studies

In cases in which indeterminate hepatic copper concentrations make it difficult to distinguish between heterozygotes and homozygotes, ultrastructural analysis for the pathognomonic mitochondrial abnormalities described by Sternlieb [58] may be helpful. The performance of these studies requires proper specimen handling and the assistance of pathologists skilled in electron microscopy, obviously with forethought to process the specimen appropriately for such analysis.

Clinical manifestations

Patients with symptomatic Wilson disease most frequently present with liver disease or neurologic/psychiatric symptoms. Affected persons detected by family screening are often asymptomatic (also termed *presymptomatic*). The failure to initiate specific treatment for Wilson disease or the disruption of ongoing treatment results in progression to hepatic insufficiency, neuropsychiatric disease, and ultimately hepatic failure and death.

The clinical spectrum of liver diseases associated with Wilson disease is broad (Box 29.1). Younger patients identified by family screening or serial evaluations of isolated biochemical abnormalities are most often asymptomatic. Some patients present with chronic liver disease indistinguishable from other forms of chronic active hepatitis, with or without specific symptoms. In patients with cirrhosis and hepatic insufficiency, jaundice, ascites, edema, or other stigmata of chronic liver disease, including hepatic encephalopathy, may be observed. When untreated, the liver disease progresses to cirrhosis with hepatic insufficiency, liver failure, and death. Some patients, most often in their second decade of life, present with acute hepatitis and an associated nonimmunopathic hemolytic anemia, which without the life-saving intervention of OLT is frequently fatal (see below). Among patients

Box 29.1 Clinical presentations of Wilson disease.

- Asymptomatic (presymptomatic)
- Hepatic disease
- Asymptomatic with only biochemical abnormalities
- Chronic active hepatitis
- Cirrhosis with hepatic insufficiency and associated signs and symptoms
- Acute hepatitis with or without hemolytic anemia
- Neurologic signs and symptoms
- Dystonia with rigidity and contractures
- Tremors
- Dysarthria and dysphonia
- Gait disturbance
- Choreiform movements
- Psychiatric symptoms
- Range from neuroses to psychoses
- Renal disease
- Aminoaciduria
- Nephrocalcinosis
- Hematologic disease
- Hemolysis

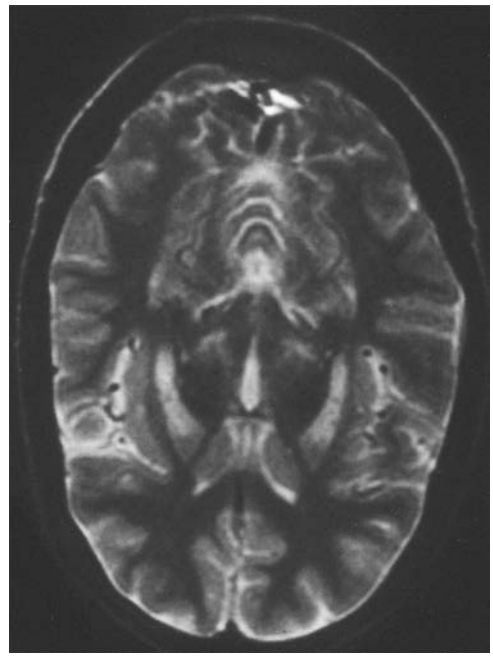

Figure 29.8 Magnetic resonance image of the brain of a 21-year-old woman with dysarthria, dysphagia, slurred speech, and tremors caused by Wilson disease. Note the hyperintensity in the region of the basal ganglia.

presenting with Wilsonian acute hepatitis, the female to male ratio is almost 2 : 1 [68].

Patients in whom the first presenting symptoms of Wilson disease are either neurologic or psychiatric are frequently older than those who present with hepatic symptoms. Most patients with central nervous system involvement are believed to have significant liver disease at the time of presentation. However, hepatic histology is not generally available for these patients because the diagnosis is often established on the basis of a decreased ceruloplasmin level and the presence of K-F rings. Neurologic disease may be manifested as motor abnormalities with parkinsonian characteristics of dystonia, hypertonia and rigidity, chorea or athetosis, tremors, and dysarthria [69]. Disabling muscle spasms can lead to contractures, dysarthria, dysphonia, and dysphagia. At this stage of disease, magnetic resonance imaging or computed tomography of the brain may be useful in delineating changes in the basal ganglia (Fig. 29.8).

Wilson disease infrequently presents with abnormalities of other organ systems. Changes induced by copper toxicity in the kidneys include nephrocalcinosis, hematuria, and aminoaciduria [61] and those in the skeletal system include arthritis, arthralgias, and premature osteoarthrosis [61]. Myocardial copper accumulation can cause cardiomyopathy and arrhythmias [70,71], although these are rarely manifested clinically. A more indolent form of hemolytic anemia unassociated with acute hepatitis may occasionally be seen [72].

The diagnosis of Wilson disease in the setting of acute hepatitis deserves special mention because of several unique features. In this setting, acute hepatitis is associated with a nonimmunopathic hemolytic anemia with unconjugated hyperbilirubinemia and markedly elevated serum and urinary levels of copper. Most of these patients are in the second decade of life, and K-F rings may not yet be apparent. Paradoxically, levels of serum alkaline phosphatase are frequently depressed [73–75], and this feature led to the observation that a ratio of alkaline phosphatase to bilirubin of less than 2 might be diagnostic of Wilsonian acute hepatitis [75,76]. We and others have observed some patients with Wilsonian acute hepatitis in whom this ratio was above 2 [68]. However, when an alkaline phosphatase : bilirubin ratio of <4 and aspartate aminotransferase (AST) to alanine aminotransterase (ALT) ratio of >2.2 are used in combination, a nearly 100% identification of Wilson disease can be made in patients with acute liver failure [77].

Treatment

The therapeutic options in Wilson disease include pharmacologic treatment and OLT. The aim of medical therapy is to abolish symptoms, if present, and prevent the worsening or progression of disease. Successful therapy may be gauged by clinical improvement or stabilization and by the normalization of biochemical parameters

Table 29.3 (a) Treatment and (b) follow-up management in Wilson disease (WD) patients.

(a)

Medical therapy for WD treatment	Chemical form	Route of administration
British antilewisite (BAL)	Dimercaptopropanol	Intramuscular
Penicillamine	Dimethylcysteine	Oral
Trientine	Trientine dihydrochloride	Oral
Zinc salts	Zinc sulfate, zinc gluconate, zinc acetate	Oral
Tetrathiomolybdate (experimental)	–	Oral

(b)

Maintenance therapy for WD	Oral maintenance dose (adult)	Comments	Monitoring of efficacy and compliance
Penicillamine	750–1,000 mg in three to four divided doses	Monitor for lupus-like reactions and marrow suppression; requires supplemental pyridoxine, and dose reduction for surgery and pregnancy	Nonceruloplasmin Cu <10 μg/dL Urine Cu >250 μg/24 h
Trientine	750–1,000 mg in three to four divided doses	Monitor for sideroblastic anemia; requires dose reduction for surgery and pregnancy	Nonceruloplasmin Cu <10 μg/dL Urine Cu >250 μg/24 h
Zinc salts	150 mg in three divided doses	Occasional gastric intolerance	Nonceruloplasmin Cu <10 μg/dL Urine zinc >1,000 μg/24 h Urine Cu <150 μg/24 h

Cu, copper.

of liver function and copper metabolism. Serial liver biopsies have no role in the management of Wilson disease. Repeated liver biopsies should be performed only to exclude concurrent illness or as part of an experimental treatment protocol. Liver transplantation should be reserved for patients with severe hepatic insufficiency or liver failure occurring in the context of acute hepatitis or end-stage liver disease. Transplant recipients subsequently have a normal donor phenotype with respect to copper metabolism, and with rare exception, they do not require further therapy specific to Wilson disease.

Pharmacologic treatments for Wilson disease include chelating agents and zinc salts (Table 29.3). Chelating agents (e.g., penicillamine, trientine, BAL, and tetrathiomolybdate) remove copper from potentially toxic sites within cells and detoxify and/or excrete the remaining copper. Zinc salts act mainly by blocking the intestinal absorption of dietary copper, but also stimulate the biosynthesis of endogenous chelators in the liver, such as metallothioneins, that help detoxify the remaining metal [43].

The treatment of asymptomatic patients and maintenance therapy for previously symptomatic patients are identical (Table 29.3). Patients with hepatic insufficiency or chronic active hepatitis evident only on biochemical testing or histologic examination of the liver should be considered symptomatic, and treated with chelation therapy for adequate copper removal before their medications are changed or the doses of chelator reduced for maintenance therapy (see subsequent text). The largest experience for long-term treatment is still with penicillamine, whereas trientine and zinc salts are alternative agents with fewer potential side effects. Both these alternative agents, previously used only for penicillamine-intolerant patients, should now be considered for the initial therapy of asymptomatic patients and for long-term use as maintenance therapy. Regardless of the specific agent chosen, monitoring for efficacy and patient compliance is crucial.

Chelation therapy is indicated as the primary therapy for symptomatic patients with hepatic or neurologic/psychiatric disease. As mentioned in the preceding text, the greatest experience thus far is with penicillamine.

Figure 29.9 Progeric change (appearance of premature aging) in the skin of the neck, characteristic of patients on long-term penicillamine treatment.

The reported incidence of penicillamine-induced side effects varies greatly [61,78], although worsening of neurologic symptoms has been observed in about 10% of symptomatic patients during the early phase of penicillamine therapy. Whether this worsening would have occurred with the use of alternative agents is uncertain and awaits the systematic evaluation of alternative agents as the primary treatment for neurologically affected patients. Late, dermatologic effects of penicillamine include progeric changes in the skin, often visible around the neck (Fig. 29.9), and the cheloid-like lesions of elastosis perforans serpiginosa, which may appear anywhere on the body (Fig. 29.10). Trientine has proved to be an effective treatment for penicillamine-intolerant patients [79], and experience is growing in the utilization of this agent as a first-line therapy for hepatic and neurologic disease [79–82]. Zinc salts may be used as an alternative initial therapy for patients who cannot tolerate penicillamine or trientine. Although it has been reported that zinc is an effective treatment for symptomatic patients, it may be delayed in its effective onset of action and therefore chelation agents are preferable in this setting.

Figure 29.10 The cheloid-like lesions of elastosis perforans serpiginosa on the elbow of this penicillamine-treated patient may appear on different areas of the body.

Once clinical and biochemical stabilization has been achieved, typically within 2 to 6 months of the initiation of treatment for most patients, but somewhat longer for more severely affected persons, maintenance therapy should be considered. Tetrathiomolybdate, first used to treat animals with copper toxicosis, is currently an experimental agent undergoing evaluation as an initial treatment for patients with neurologic symptoms. Initial reports on the use of tetrathiomolybdate in this setting suggest no worsening of neurologic symptoms and a rapid reduction in circulating nonceruloplasmin-bound copper during the first 8 weeks of therapy [83]. However, studies directly comparing the efficacy of this agent with trientine did not show statistically significant differences in neurologic and speech scores over a 4-year observation period [84].

BAL, the first available treatment for Wilson disease, is now rarely used, and only as adjunctive therapy for patients with neurologic/psychiatric symptoms refractory to chelation therapy with penicillamine or trientine alone [85]. This drug, used in conjunction with oral therapy with penicillamine or trientine, is administered intramuscularly in an oil base. As a lipophilic compound, BAL has the theoretical advantage of possibly crossing the blood–brain barrier more easily. The main drawback of BAL therapy is the difficulty and discomfort involved in administering it and the lack of objective parameters outside clinical evaluation to determine its efficacy.

The dietary consumption of foods with a high copper content should be avoided during the initial phases of treatment. These include organ meats such as liver, in addition to nuts, shellfish, and chocolate. During the maintenance phase of therapy, liberalization of the diet is permitted.

OLT should be considered for patients with Wilsonian acute liver failure and for those with severe hepatic insufficiency unresponsive to medical therapy [68]. Two different series that retrospectively reviewed the data on OLT for patients with Wilson disease found 1-year survival rates after transplantation to be about 80% [68,86], and, more recently, 1-year patient survival was found to be about 87% [87]. In this last report, acute renal insufficiency was observed more often in patients who underwent transplantation for acute liver failure secondary to Wilson disease than in those who underwent

transplantation for acute liver failure of other causes. The acute renal insufficiency resolved without long-term renal damage. During the acute phase of acute liver failure, when toxic copper complexes are being released into the circulation, plasmapheresis, exchange transfusion, and albumin dialysis have been utilized in an effort to further reduce copper-induced toxicity. These interventions may be helpful in reducing comorbidity and stabilizing the patient, but they have not precluded the need for OLT. Neurologic symptoms may improve after transplantation [68,88]. However, it is our opinion that transplantation should not be used for patients with neurologic symptoms in the absence of hepatic failure, especially given the current shortage of donor organs. After the perioperative period of OLT, with rare exceptions, no further specific therapy for Wilson disease is necessary.

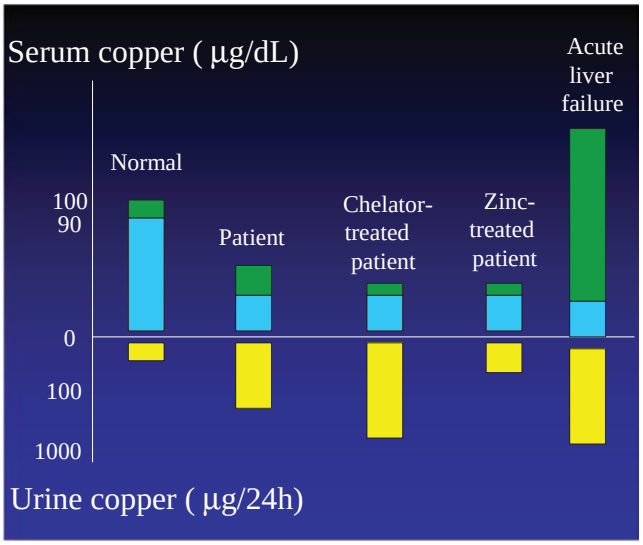
Living donor transplantation has been performed for acute liver failure secondary to Wilson disease in a few children and in some adults as well. Partial grafts from heterozygous parents have been successful, with good organ function in both donor and recipient [89].

The treatment of pregnant women with Wilson disease and persons with Wilson disease who must undergo surgical interventions deserves special mention. The goal of treatment in pregnant patients is to maintain adequate disease control in the mother, reduce her risk for bleeding, and prevent interference with wound healing and the possibility of teratogenicity. Pregnancies have been successful in patients taking penicillamine, trientine, or zinc [90–94]. For patients being maintained on chelation therapy, the dosage of penicillamine or trientine should be lowered whenever possible early in the course of the pregnancy. The suggested dosage is 500 mg/day, and monitoring during each trimester is advised. Zinc therapy can be maintained uninterrupted at full dosage during pregnancy and postpartum [94]. Dose reduction during pregnancy is recommended as the medications D-penicillamine and trientine have known teratogenicity. Furthermore, the reduction in dosage helps prevent impaired collagen cross-linking due to copper depletion in lysyl oxidase.

When patients with Wilson disease maintained on chelating agents must undergo surgery, the dose of their medication should be reduced preoperatively and perioperatively to avoid interference with wound healing. The dosage of penicillamine or trientine can be reduced to 250–500 mg daily during this time and rapidly advanced to a maintenance dosage once wound healing has taken place. No adjustment of the dosage is required for patients on zinc therapy, either perioperatively or postoperatively.

We cannot overemphasize that the key to the long-term success of pharmacotherapy for Wilson disease is patient adherence to the use of medications. This can be monitored by history and clinical examinations to detect any changes in the symptoms or signs of liver or neurologic disease, pill counts, screening for biochemical evidence of hepatic dysfunction, measurement of urinary copper or zinc excretion, periodic slit-lamp examinations, and, importantly, biochemical testing for nonceruloplasmin-bound copper. This last test is the standard by which pharmacotherapeutic doses should be determined and is the single best parameter for gauging the adequacy of treatment. Nonceruloplasmin-bound copper is a derived number, estimated from the difference between the total serum copper content and the copper content of ceruloplasmin, determined by its oxidase activity (approximately three times the value for ceruloplasmin in mg/dL). In healthy persons and appropriately treated patients, the value for nonceruloplasmin-bound copper should be 8–12 μg/dL or less. In untreated, inadequately treated, and noncompliant patients, this value is frequently elevated above 25 μg/dL (Fig. 29.11).

The interpretation of the results of urinary copper excretion must take into account the mode of treatment, ability to collect a complete sample, avoidance of contamination, and appropriate analysis of copper content. During the early phase of treatment with chelating agents, values for urinary copper excretion are frequently greater than 1,000 μg/24 h. These decline to about



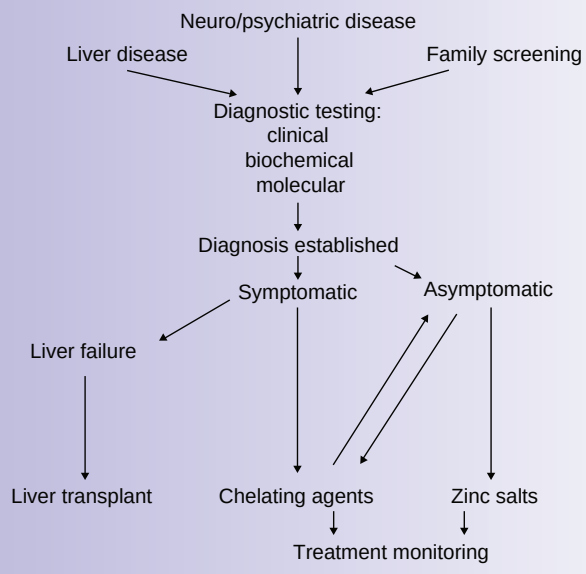


Figure 29.11 Copper parameters in normal, untreated, and treated Wilson disease. In normal patients ceruloplasmin accounts for ~90% of serum copper. In untreated Wilson disease, the percent of copper not bound to ceruloplasmin in the circulation is increased, as is the urine copper. In patients treated with copper chelators, the nonceruloplasmin-bound copper is reduced and the urine copper is increased. In zinc-treated patients, the nonceruloplasmin-bound copper is reduced and the urine copper typically is less than 100 μg/24 h. In acute liver failure, nonceruloplasmin-bound copper and urine copper are markedly increased. Ceruloplasmin-bound copper: blue; nonceruloplasmin-bound copper: green.

250–500 μg/24 h over time, and despite the continuous use of chelation agents, the values for urinary copper excretion tend to remain at about this level (Fig. 29.11). Values below 250 μg/24 h suggest noncompliance with therapy, overtreatment, or an incorrect diagnosis from the outset.

The values for 24-hour urinary copper excretion in patients on zinc therapy are not significantly elevated because zinc acts to prevent copper absorption [95]. However, a rise in urinary copper excretion to above 125 μg/24 h may indicate noncompliance or inadequate therapy, and, if so, they are likely to be accompanied by an increase in the nonceruloplasmin-bound copper level. Urinary and plasma levels of zinc may also be used to monitor compliance with zinc therapy.

The prognosis for patients who comply with pharmacotherapy for Wilson disease is excellent, even if cirrhosis or chronic hepatitis is present at the time of diagnosis [96]. Patients with neurologic or psychiatric symptoms of Wilson disease may continue to recover for months to years after the initiation of treatment. In some patients with neurologic disease or hepatic insufficiency, symptoms or biochemical abnormalities persist but stabilize with treatment. At present, the best way to determine whether and to what extent a patient's disease is reversible is to await a response to treatment.

Management protocol of Wilson disease

Multiple choice questions

29.1 What clinical and biochemical tests help diagnose Wilson disease?

- **a** Ceruloplasmin.
- **b** Slit-lamp examination for Kayser–Fleischer rings.
- **c** 24-hour urine copper.
- **d** Liver copper content.
- **e** Molecular testing for ATP7B mutations.
- **f** All of the above.

29.2 Which of the following is not true for patients with acute liver failure due to Wilson disease?

- **a** Serum and urine copper are extremely elevated.
- **b** Hemolytic anemia is caused by nonimmune-mediated mechanisms.
- **c** Transplantation is indicated for these patients.
- **d** Advanced fibrosis or cirrhosis is always present in the liver of the patient.
- **e** Exchange transfusion, albumin dialysis, plasmapheresis, or other methods aimed at copper removal from the circulation may help stabilize a patient awaiting transplantation.
- **f** Living donor transplant using a parent as a donor is never possible for these patients.

29.3 Which of the following treatments are not useful as a treatment for Wilson disease?

- **a** D-penicillamine.
- **b** Trientine.
- **c** Zinc.
- **d** Desferrioxamine.
- **e** Liver transplant.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 30
Hemochromatosis and Iron Storage Disorders

Bruce R. Bacon & Robert S. Britton
School of Medicine, Division of Gastroenterology and Hepatology, Saint Louis University, St Louis, MO, USA

Key concepts

- An increase in systemic iron levels is the consequence of: (i) inherited excessive intestinal absorption of dietary iron (hereditary hemochromatosis); (ii) ineffective erythropoiesis or chronic liver disease; or (iii) parenteral iron administration. Excessive intracellular deposition of iron ultimately results in tissue and organ damage.
- Hereditary hemochromatosis (HH) constitutes several inherited disorders characterized by an increased intestinal absorption of iron with its subsequent accumulation in tissues. Most (approximately 90%) patients with HH have mutations in the *HFE* gene, and *HFE*-related HH is one of the most common inherited disorders among whites, with a frequency of about one in 250.
- Two independent mutations of the *HFE* gene are principally responsible for *HFE*-related HH. These mutations result in a change of cysteine to tyrosine at amino acid 282 (C282Y) and of histidine to aspartic acid at amino acid 63 (H63D) of the HFE protein. Approximately 95% of persons with *HFE*-related HH are homozygous for the C282Y mutation. Population studies indicate that the penetrance of the C282Y mutation is incomplete, and genetic modifiers may be involved. Some compound heterozygotes with copies of both the C282Y and H63D mutations have a clinically significant degree of iron overload.
- Mutations in the iron-related genes encoding for hemojuvelin, hepcidin, ferroportin, transferrin receptor 2 (TFR2), divalent metal transporter 1, and ferritin result in non-*HFE*-related HH.
- The pathogenesis of nearly all forms of HH involves an inappropriately low expression of the iron-regulatory hormone hepcidin, which acts to decrease the export of iron from absorptive enterocytes and reticuloendothelial cells. Hepcidin is highly expressed in hepatocytes, and it is proposed that HFE protein, TFR2, and hemojuvelin all play a role in the hepatic iron-signaling pathway that regulates hepcidin expression. The C282Y mutation causes functional inactivation of the HFE protein, leading to low hepcidin expression with a resultant increase in duodenal iron absorption.
- In *HFE*-related HH, the excess iron is preferentially deposited in the cytoplasm of parenchymal cells of various organs and tissues, including the liver, pancreas, heart, endocrine glands, skin, and joints. Damage can result in micronodular cirrhosis of the liver and atrophy of the pancreas (primarily islets). Hepatocellular carcinoma, usually in the presence of cirrhosis, is another consequence of excess iron deposition in the liver. Symptoms are related to damage of the involved organs and include liver failure (from cirrhosis), diabetes mellitus, arthritis, cardiac dysfunction (arrhythmias and failure), and hypogonadotropic hypogonadism.
- The diagnosis of iron overload includes serum iron studies (elevated transferrin saturation, elevated serum ferritin levels), genetic testing, and sometimes liver biopsy to assess the hepatic iron concentration and degree of liver injury. In cases of *HFE*-related HH, liver biopsy is usually not indicated if the patient has normal liver enzyme levels and a serum ferritin level below 1,000 ng/mL. Because regular phlebotomy therapy prevents or reverses the accumulation of excess iron and prevents the complications of HH, it is important to identify persons with this inherited disorder early in the disease process.

History

The first medical description of a patient with hemochromatosis was by Trousseau [1] in the French pathology literature in 1865 (Table 30.1). Twenty-four years later, the German pathologist von Recklinghausen [2] was the first to use the term *hemochromatosis*; he thought that the pigmentation ("chrom") in the tissues of patients with the disorder was caused by something circulating in their blood ("hemo"). In 1935, Joseph Sheldon [3], a British geriatrician, published a monograph describing the 311 cases of hemochromatosis that existed in the world literature up to that time. Sheldon concluded that hemochromatosis is an inherited disorder in which tissue injury and damage result from excess iron deposition. He drew accurate conclusions without the techniques of modern molecular medicine available today. The situation was somewhat confused by MacDonald [4], a pathologist at the Boston City Hospital, who believed that hemochromatosis was a nutritional disorder, possibly because he

HH, hereditary hemochromatosis; HLA, human leukocyte antigen.

saw many alcoholic patients who happened to be of Irish descent. It is now known that the prevalence of homozygosity for *HFE*-related hereditary hemochromatosis (HH) is high in the Irish population, approaching 1 in 70 persons [5]. In 1976, Marcel Simon et al. [6] definitively showed that classic hemochromatosis is inherited as an autosomal recessive disorder, with linkage to the human leukocyte antigen (HLA) region of the human genome; the gene for hemochromatosis is located on the short arm of chromosome 6. It took another 20 years until the research group at Mercator Genetics successfully identified and cloned the hemochromatosis gene by means of a positional cloning approach using DNA samples from well-documented patients with hemochromatosis in the United States [7]. In 1996, Feder et al. [7] identified *HFE*, a novel major histocompatibility complex (MHC) class I-like gene; homozygosity for a single missense mutation (C282Y) of *HFE* was found in 83% of the patients who were studied. Quickly, several other groups reported their findings in series of patients with hemochromatosis, and homozygosity for the C282Y mutation was found in about 85–90% of typical patients [8]. This discovery has yielded significant benefits in clinical medicine and hepatology, including more accurate diagnosis of *HFE*-related HH, improved family screening, and evaluation of the role of *HFE* mutations in other liver diseases. Additionally, there has been a wealth of new information about the cellular and molecular mechanisms of iron homeostasis, including the discovery of the iron-regulatory hormone hepcidin. In this chapter, we highlight the new advances in the area of HH and other iron storage disorders, interdigitating these discoveries with the classic pathologic and clinical features seen in these patients.

Classification of iron overload syndromes

Many terms have been used in the past to describe HH, such as idiopathic, primary, and familial. The term *hereditary hemochromatosis* should be reserved to describe inherited disorders of iron metabolism that lead to tissue iron loading (Box 30.1). The most common form of this disease, *HFE*-related HH, is caused primarily by homozygosity for the C282Y mutation in the *HFE* gene. However, other heritable forms of iron overload have also been recognized (non-*HFE*-related HH). These include: (i) autosomal recessive forms of HH characterized by rapid iron accumulation and caused by mutations in the genes for hemojuvelin and hepcidin (also called juvenile hemochromatosis) [9,10]; (ii) an autosomal dominant form of HH caused by mutations in the ferroportin gene [11,12]; (iii) an autosomal recessive form of HH resulting from mutations in the gene for transferrin receptor 2 (*TFR2*) [13]; and (iv) rare forms of HH resulting from mutations in the *divalent metal transporter 1* (*DMT1*) gene [14] or in the regulatory region of ferritin messenger RNA [15]. Some other types of iron overload may have a heritable component but the genes involved have not yet been identified. For example, African iron overload is a familial disorder of iron loading prevalent in sub-Saharan Africa that is exacerbated by the ingestion of iron-rich home-brewed beer [16]. The degree of iron loading can be similar to that in *HFE*-related HH, but the cellular and lobular distribution of iron is different. In addition, a rare disorder termed congenital alloimmune (neonatal) iron overload is characterized by severe neonatal liver injury in association with parenchymal iron accumulation and extrahepatic siderosis [17,18].

Box 30.1 Classification of iron overload syndromes.

Hereditary hemochromatosis

- *HFE*-related:
  - C282Y/C282Y
  - C282Y/H63D
  - Other *HFE* mutations
- Non-*HFE*-related:
  - Hemojuvelin (*HJV*) mutations (autosomal recessive)
  - Hepcidin (*HAMP*) mutations (autosomal recessive)
  - Ferroportin (*SLC40A1*) mutations (autosomal dominant)
  - Transferrin receptor 2 (*TFR2*) mutations (autosomal recessive)
  - Divalent metal transporter 1 (*SLC11A2*) mutations (rare)
  - Ferritin regulatory mutations (rare)
- Miscellaneous:
  - African iron overload
  - Congenital alloimmune (neonatal) iron overload (rare)

Secondary iron overload

- Anemia caused by ineffective erythropoiesis:
  - Thalassemia major
  - Sideroblastic anemias
- Congenital dyserythropoietic anemias
- Congenital atransferrinemia:
  - Aceruloplasminemia
- Liver disease:
  - Alcoholic liver disease
  - Chronic viral hepatitis B and C
  - Porphyria cutanea tarda
  - Nonalcoholic steatohepatitis
  - After portacaval shunt
- Miscellaneous:
  - Excessive iron ingestion

Parenteral iron overload

- Red blood cell transfusions
- Iron–dextran injections
- Associated with long-term dialysis

Several noninherited syndromes of iron overload are known. In secondary iron overload, an underlying disorder causes an increase in iron absorption; examples are disorders of ineffective erythropoiesis and liver disease [19]. Parenteral iron overload is an iatrogenic disorder in which blood transfusions or iron–dextran injections are given to patients who are anemic [20].

In *HFE*-related HH, it has become clear from population studies that not all individuals who have the C282Y/C282Y genotype become iron loaded. This observation indicates that there are many nonexpressing C282Y homozygotes in the population [21–23] and has led to a four-category description of *HFE*-related HH: (i) genetic predisposition with no other abnormality; (ii) iron overload (approximately 2–5 g) but without symptoms or tissue damage; (iii) iron overload with early symptoms (i.e., lethargy, arthralgias); and (iv) iron overload with organ damage, particularly cirrhosis.

HFE-related hereditary hemochromatosis

Since the work of Simon et al. in the mid-1970s [6], it has been known that the major gene for HH is located on the short arm of chromosome 6 in the HLA region of the genome. In 1996, investigators at Mercator Genetics used a positional cloning approach to identify *HFE* as the responsible gene [7]. *HFE* codes for a novel MHC class I-like protein that requires interaction with β_2-microglobulin (β_2M) for normal presentation on the cell surface [7]. Structural homology with other MHC class I proteins and X-ray crystallographic studies indicate that HFE protein has a large extracellular domain with three α-loops, a single transmembrane region, and a short cytoplasmic tail [7,24]. In the original work by Feder et al. [7], two missense mutations were identified in *HFE*, one resulting in a change of cysteine to tyrosine at amino acid 282 (C282Y) and the second causing a change of histidine to aspartate at amino acid 63 (H63D). Other *HFE* mutations have been identified, but their frequency is low and their clinical impact is limited. Feder et al. [7] reported that 148 (83%) of 178 patients with typical phenotypic HH were homozygous for the C282Y mutation while eight (4%) patients were compound heterozygotes, with one allele containing the C282Y mutation and the other allele containing the H63D mutation. These findings were confirmed by subsequent studies that showed that 60–100% (mean value, 84%) of patients with typical phenotypic HH were homozygous for C282Y [8]. Of interest, approximately 6% of these patients had a clinical syndrome phenotypically similar to that of patients with typical HH but were negative for either *HFE* mutation [8]. Some of these patients may have had mutations in known iron-related genes or in as yet unidentified genes involved in iron metabolism.

HFE gene and protein

The *HFE* gene is expressed at relatively low levels in most human tissues [7]. However, unlike other classic MHC class I genes, *HFE* is rarely expressed in lymphopoietic and hematopoietic cells [7]. Little is known of the regulation of *HFE* gene expression. In contrast to the expression of genes for other MHC molecules, *HFE* expression is not induced in cultured cells by various cytokines. Sequences known to confer transcriptional regulation by cellular metal ion content have not been identified in the *HFE* gene. Furthermore, sequences homologous to iron-responsive elements (IREs) have not been identified in either the 3′- or 5′-untranslated region of *HFE* mRNA. However, several splice variants of human *HFE* mRNA have been identified. An HFE transcript lacking exons 6 and 7 has been detected (by means of reverse

transcription followed by polymerase chain reaction) in human duodenum, spleen, breast, skin, and testicle [25]. Because this transcript does not include the sequences encoding the transmembrane and cytoplasmic domains, it is predicted to encode a secretory form of HFE protein. HFE splice variant transcripts lacking exon 2 and/or a portion of exon 4 have been identified in a human liver cell line, a colon carcinoma cell line, and an ovarian cell line [26]. Deletion of exon 2 is predicted to eliminate the α_1-loop of HFE protein, whereas deletion of a portion of exon 4 is predicted to affect the α_3-loop. The levels of protein expression and physiologic roles of the splice variant HFE transcripts are not yet known.

The *HFE* gene encodes a 343-amino acid protein consisting of a 22-amino acid signal peptide, a large extracellular domain, a single transmembrane domain, and a short cytoplasmic tail [7]. HFE protein is widely expressed in several organs including the liver, placenta, and gastrointestinal tract (i.e., epithelium of esophagus, stomach, duodenum, small intestine, and colon) [27]. The extracellular domain of HFE protein consists of three loops (α_1, α_2, and α_3), with intramolecular disulfide bonds within the second and third loops. The structure of HFE protein is therefore similar to that of other MHC class I proteins. The two common *HFE* mutations, C282Y and H63D, are in the extracellular domain. Crystallographic studies demonstrate that the α_1- and α_2-loops of HFE protein form a superdomain consisting of antiparallel β-strands topped by two antiparallel α-helices [24]. The groove between the antiparallel α-helices is analogous to the peptide-binding groove in antigen-presenting MHC class I proteins. Several lines of evidence, however, suggest that HFE protein does not participate in antigen presentation. The groove between the α-helices in HFE protein is physically narrower than that in antigen-presenting MHC class I molecules, so that the ability to bind peptides is precluded. Indeed, N-terminal sequencing performed on acid eluates from HFE protein found no evidence of peptide binding [24]. HFE protein, like other MHC class I molecules, is physically associated with β_2M. This association has been demonstrated in the human duodenum and placenta [27], and in cultured cells [28–30].

C282Y mutation of *HFE*

The C282Y mutation results in the substitution of tyrosine for cysteine at amino acid 282 in the α_3-loop and abolishes the disulfide bond in this domain [7]. Loss of the disulfide bond was predicted to interfere with the interaction of β_2M with HFE protein [7]. Indeed, C282Y mutant protein expressed in cell culture systems demonstrates diminished binding with β_2M and decreased presentation at the cell surface in comparison with wild-type HFE protein [28,29]. The C282Y mutant protein is retained in the endoplasmic reticulum and middle Golgi compartments, fails to undergo late Golgi processing, and is subject to accelerated degradation [29]. However, some C282Y mutant protein in patients with HH reaches the cell surface, as detected by immunohistochemistry, although at reduced levels [31]. Definitive proof that this mutation can cause HH was provided when knock-in of the C282Y mutation in mice resulted in iron overload [32].

The C282Y mutation is present in most, but not all, patients with a clinical diagnosis of HH. The proportion of patients with HH who are homozygous for C282Y varies in different populations. In the United States, Britain, Australia, Canada, and France, approximately 85–90% of patients with a clinical diagnosis of HH are homozygous for C282Y [8], but a lower frequency (60%) has been reported in Italy [33]. Conversely, population studies have revealed that the clinical features of HH do not develop in many C282Y homozygotes [21–23]. This observation suggests incomplete penetrance of the C282Y mutation and raises the possibility that other genes involved in iron homeostasis may act as modifiers of the HH phenotype [34,35].

The prevalence of the C282Y mutation is greatest in whites of European ancestry. In this population, the carrier frequency ranges from 10% to 15% [5,8,17,18]. In other ethnic populations, the C282Y mutation is less common and is always associated with the ancestral white haplotype [36,37]. Such studies suggest that the C282Y mutation occurred once on an ancestral (possibly Celtic) haplotype that spread from northern Europe to other regions of the world [38,39]. The observation that the haplotype containing the C282Y mutation extends for approximately 7 megabases suggests that the mutation arose during the last 2,000 years [40]. It has been proposed that the C282Y mutation, associated with increased iron absorption and the accumulation of body iron stores, provided a selective advantage to a population in which the availability of dietary iron was limited or in which intestinal parasitic infections caused a loss of iron.

H63D mutation of *HFE*

The most common *HFE* mutation in the general population is a missense mutation that results in the substitution of aspartate for histidine at amino acid 63 (H63D) of the HFE protein [7]. The H63D mutation is found at a frequency of 15–40% in white populations [8], but homozygosity for H63D appears to increase the risk for iron loading only slightly [41]. However, the frequency of compound heterozygosity for the H63D and C282Y mutations is greater in patients with iron overload than that predicted for the general population [7,8]. It is estimated that the risk for iron loading of the C282Y/H63D compound heterozygote is nearly 200-fold lower than that for the C282Y homozygote [42]. The population

distribution of the H63D mutation differs somewhat from that of C282Y. The highest frequencies of H63D are found in European countries bordering the Mediterranean, the Middle East, and the Indian subcontinent [39]. The H63D mutation has been found on many haplotypes, which suggests that this less consequential mutation may have arisen historically multiple times and in different populations. Because the haplotype comprising the H63D mutation is shorter (approximately 700 kb) than that of the C282Y mutation, it is thought to be evolutionarily older [40].

Other mutations of *HFE*

HFE mutations other than C282Y and H63D have been identified in isolated patients with iron overload [43,44]. These include missense mutations (e.g., S65C, G93R, I105T, Q127H), splice site mutations (e.g., IVS3+1 G/T, IVS5+1 G/A), frameshift mutations (e.g., V68ΔT, P160ΔC), and nonsense mutations (e.g., R74X, E168X, W169X). Each symptomatic patient carrying one of the missense mutations has carried the C282Y or H63D mutation on the other allele. The two identified splice site mutations cause altered mRNA splicing and exon skipping, resulting in abnormal variants of HFE protein. The frameshift and nonsense mutations result in the production of truncated forms of HFE protein. The relative contribution of *HFE* mutations other than C282Y or H63D to the overall incidence of *HFE*-related HH is small.

Experimental disruption of the *Hfe* gene in mice

Transgenic methodology has provided important information about the functional consequences of *Hfe* gene disruption in the whole animal. Four different murine models have been generated: an exon 4 knock-out [45], an exon 3 disruption/exon 4 knock-out [32], an exon 2–3 knock-out [46], and a C282Y knock-in (32)[32]. These mice manifest increases in hepatic iron levels [32,45,46], transferrin saturation (TS) [45], and intestinal iron absorption [46]. No immunologic consequences of *Hfe* disruption have been observed in mice [46]. Like patients with *HFE*-related HH, these mice demonstrate relative sparing of iron loading in reticuloendothelial (RE) cells [32,45]. Interestingly, iron loading in mice that are homozygous for the C282Y mutation is less severe than that in *Hfe* knock-out mice, which indicates that the C282Y mutation is not a null allele [32]. Strain differences determine the severity of iron accumulation in *Hfe* knock-out mice, supporting the concept that there are genetic modifiers of the HH phenotype [35,47].

Determinants of duodenal iron absorption

An increase in intestinal iron absorption is a key characteristic of HH [48–50], and, therefore, understanding the pathogenesis of HH requires a review of the determinants of duodenal iron absorption. Because there are no significant physiologic mechanisms to regulate iron loss, iron homeostasis is dependent on tightly linking body iron requirements (approximately 1 mg/day) with intestinal iron absorption. Nearly all absorption of dietary iron occurs in the duodenum, where iron may be taken up either as ionic iron or as heme [50]. The absorption of both forms of iron is increased in patients with HH. Uptake of heme occurs by an as yet unidentified transporter. Absorption of ionic iron across the enterocytes occurs in two stages: uptake across the apical membrane and transfer across the basolateral membrane (Fig. 30.1). Before uptake, ionic iron requires reduction from the ferric to the ferrous state. This is accomplished by the ferric reductases (such as Dcytb), which are expressed on the luminal surface of duodenal enterocytes [51]. The ferrous iron crosses the apical membrane using the transporter DMT1 [52,53]. Iron taken up by the enterocyte may be stored as ferritin (and excreted in the feces when the senescent enterocyte is sloughed) or transferred across the basolateral membrane to the plasma. This latter process occurs through the transporter ferroportin [54–56]. The basolateral transfer of iron requires oxidation of iron to the ferric state by the ferroxidase, hephaestin [57]. In addition to increased uptake of iron from the diet, patients with *HFE*-related HH demonstrate increased basolateral transfer of iron from the enterocytes to the plasma, and this may be a driving force behind the increased intestinal iron absorption observed in *HFE*-related HH [49]. Some studies on patients with *HFE*-related HH [58–60] and *Hfe* knock-out mice [61,62] have demonstrated increased expression of mRNAs encoding DMT1 and ferroportin. However, not all investigators have observed upregulation of DMT1 and ferroportin expression in patients with HH [63,64] or in *Hfe* knock-out mice [65,66]. In *Hfe* knock-out mice, these discrepancies may be due to differences in mouse strain [47] or age [67].

Several biologic factors influence the rate of dietary iron absorption. Reduction in body iron stores, increased erythropoietic activity, decreased blood hemoglobin content, and decreased blood oxygen saturation increase the absorption of iron from the diet [50]. In contrast, the presence of systemic inflammation decreases dietary iron absorption. All these factors are thought to act by influencing the levels of hepcidin, an iron-regulatory hormone.

Dysregulation of hepcidin in hereditary hemochromatosis

Hepcidin is a 25-amino acid peptide, first identified in urine and plasma as an antimicrobial peptide [68–70]. However, its role in influencing systemic iron status has become paramount, and it is now considered to be the principal iron-regulatory hormone [71,72]. The first

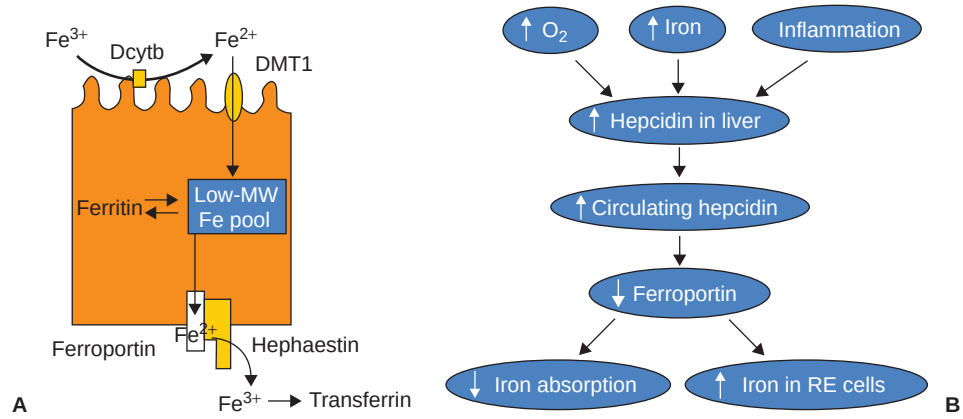

Figure 30.1 Iron absorption and the role of hepcidin. (A) Absorption of dietary ionic iron across the duodenal villus enterocyte occurs in two stages: uptake across the apical membrane and transfer across the basolateral membrane. Ferric reductases (such as Dcytb) are expressed on the luminal surface of duodenal enterocyte and are required for the reduction of ferric to ferrous iron, which then crosses the apical membrane via divalent metal transporter (DMT1). Iron taken up by the enterocyte is thought to enter a low molecular weight (MW) iron pool and is then stored as ferritin or transferred across the basolateral membrane to the plasma. On the basolateral surface of the enterocyte iron is oxidized to the ferric state by hephaestin, a ferroxidase and transported via ferroportin. Ferric iron is then bound to transferrin in the circulation. (B) Hepcidin expression by the liver is upregulated by increased iron, inflammation, or increased oxygen availability. The functional activity of ferroportin is decreased by hepcidin by binding to it and causing its internalization and degradation. In reticuloendothelial (RE) cells, this results in iron sequestration while in duodenal enterocytes it leads to decreased basolateral iron transfer and, therefore, decreased dietary iron absorption. Patients with hereditary hemochromatosis have low hepcidin expression with a consequent increase in iron absorption.

evidence that hepcidin is involved in iron homeostasis came from the observation that liver hepcidin mRNA expression is increased in mice with dietary iron loading [70]. The fortuitous discovery that knock-out of the hepcidin gene in the mouse led to a HH-like phenotype established the critical role of hepcidin as a negative regulator of intestinal iron absorption [73,74]. It was later discovered that hepcidin mutations are responsible for one form of juvenile hemochromatosis [10]. Factors regulating intestinal iron absorption (i.e., iron status, erythropoietic activity, hemoglobin levels, oxygen content, and inflammation) also regulate liver hepcidin expression (see Fig. 30.1). In each of these situations, intestinal iron absorption varies inversely with liver hepcidin expression. For example, animals with dietary iron overload [70] or systemic inflammation [75] have higher hepatic hepcidin mRNA levels, whereas animals subjected to hypoxia or hemolytic anemia have lower mRNA levels [76]. Hepcidin is an acute-phase reactant and plays a central role in the hypoferremia of inflammation (i.e., anemia of chronic diseases) [75,77]. Hepcidin acts to decrease the functional activity of the iron exporter ferroportin by binding to it and causing its internalization and degradation [78]. In the duodenal enterocyte, this leads to decreased basolateral iron transfer and, therefore, decreased dietary iron absorption.

Dysregulation of hepcidin expression is thought to play a key role in the pathogenesis of HH. Bridle et al. [79] demonstrated that patients with *HFE*-related HH have low hepatic expression of hepcidin, as do *Hfe* knock-out mice, despite excess hepatic iron stores [79–81]. In addition, urinary hepcidin levels are low in patients with HH caused by mutations in *HFE*, *TFR2*, and *HJV* [75,82–85]. Therefore, it is proposed that low circulating levels of hepcidin in these forms of HH cause increased ferroportin-mediated efflux of iron from both RE cells (resulting in iron sparing) and duodenal enterocytes (resulting in increased iron absorption).

Iron-dependent regulation of hepcidin in hepatocytes is mediated by bone morphogenetic protein 6 (BMP6) [86,87]. BMP6 binds to specific receptors on hepatocytes, and this triggers SMAD-dependent activation of hepcidin expression. Selective inhibition of BMP signaling abrogates iron-induced upregulation of hepcidin [87]. Interestingly, hemojuvelin is a BMP co-receptor, facilitating the binding of BMP6 to its receptor [86].

The molecular mechanisms by which HFE and TFR2 influence iron-dependent regulation of hepcidin remain unclear [13,86–88]. Mutations of *TFR2* cause a rare form of HH in humans [13] and *Tfr2* mutant mice have a HH phenotype [89]. Despite hepatic iron loading, hepcidin expression is low in patients with *TFR2*-related HH [85] and in *Tfr2* mutant mice [90]. This suggests that TFR2 protein is necessary for the appropriate transduction of the signal between body iron status and hepcidin expression [13,88]. Likewise, HFE protein may also modulate the BMP6 signaling pathway within hepatocytes because inactivating mutations of HFE result in low hepcidin expression and iron overload [96]. HFE protein binds avidly to the classic TFR1 [91], but it is not yet clear

whether this interaction plays a part in the signaling pathway to hepcidin.

Non-*HFE*-related hereditary hemochromatosis

Although *HFE* mutations account for the vast majority of HH, other forms of HH have been recognized and are generally grouped together as non-*HFE*-related HH (see Box 30.1) [92]. Mutations in two different genes, *HJV* and *HAMP*, cause forms of juvenile HH. The *HJV* gene encodes hemojuvelin, a glycosylphosphatidylinositol-anchored protein that has substantial expression in hepatocytes. More than 25 disease-causing mutations have been described in *HJV* [9]. As a co-receptor of BMP6, hemojuvelin is involved in regulating the hepcidin pathway, and patients with *HJV*-associated HH [84] and *Hjv* knock-out mice [93,94] have a low hepcidin expression that is responsible for increased iron absorption. Inactivating mutations of the *HAMP* gene (that encodes hepcidin) also produce a form of juvenile HH [10].

Two distinct types of ferroportin mutations cause autosomal dominant HH [95,96]. The first type of mutation results in ferroportin inactivation, while the second type interferes with the interaction between ferroportin and hepcidin (but ferroportin retains its iron export capability). Inactivating ferroportin mutations cause a cellular distribution of iron loading that differs from that of *HFE*-related HH because iron is retained primarily in RE cells rather than hepatocytes [97]. Moreover, TS values tend to be lower than those in *HFE*-related HH. Individuals with the second type of ferroportin mutation fail to respond to hepcidin and therefore demonstrate a more classic HH phenotype. In both forms of ferroportin-related HH (unlike other types of HH), hepcidin expression is elevated rather than decreased [97].

Mutations in the *TFR2* gene produce an autosomal recessive type of HH that is clinically similar to *HFE*-related HH [13]. It is not yet known how these uncommon mutations of *TFR2* result in iron overload, but it is possible that they cause abnormal iron signaling to hepcidin within hepatocytes, the predominant site of *TFR2* expression [88].

DMT1 mediates iron uptake at the intestinal brush border and across the membrane of acidified endosomes in cells such as erythyroid precursors [98,99]. A single patient with severe hypochromic microcytic anemia and iron overload has been reported to carry a homozygous mutation (E399D) of DMT1 [14]. Cell biology studies suggest that E399D DMT1 protein has a partial loss of function that may limit iron availability to erythyroid precursor cells. The resulting anemia may subsequently stimulate dietary iron absorption, mediated by the partially functional DMT1 in enterocytes [100]. This may explain the distinguishing iron overload seen in this patient, along with microcytic anemia.

Ferritin, which is composed of H and L subunits, plays an important role in iron storage and intracellular iron distribution. Synthesis of both ferritin subunits is controlled by an iron-regulatory protein, which binds to the IRE in the 5′-untranslated region of the H- and L-ferritin mRNAs [101]. Kato et al. [15] identified a single point mutation (A49U) in the IRE motif of H-ferritin mRNA in four members of a Japanese family affected by dominantly inherited iron overload. When the mutated H-ferritin mRNA is expressed in cultured cells, there is an increase in iron uptake, suggesting that the A49U mutation may be responsible for tissue iron deposition.

Hereditary hemochromatosis

Clinical features

In older series of patients with typical phenotypic HH, a number of symptoms and physical findings generally associated with the disorder have been delineated (Boxes 30.2 and 30.3). Symptoms include fatigue, malaise, abdominal pain, arthralgias, and impotence. Physical findings include hepatomegaly, skin pigmentation, diabetes, and cardiac abnormalities [102–104]. All physicians should be aware of this constellation of symptoms and findings, but most patients who now come to medical attention have few of these signs or symptoms.

Box 30.2 Symptoms in patients with hereditary hemochromatosis.

Asymptomatic

- Abnormal serum iron study results on routine screening chemistry panel
- Evaluation of abnormal liver test results
- Identified by family screening
- Identified by population screening

Nonspecific, systemic symptoms

- Weakness
- Fatigue
- Lethargy
- Apathy
- Weight loss

Specific, organ-related symptoms

- Abdominal pain (hepatomegaly)
- Arthralgias (arthritis)
- Diabetes (pancreas)
- Amenorrhea (cirrhosis)
- Loss of libido and impotence (pituitary, cirrhosis)
- Congestive heart failure (heart)
- Arrhythmias (heart)

Box 30.3 Physical findings in patients with hereditary hemochromatosis.

Asymptomatic
- No physical findings
- Hepatomegaly

Symptomatic

Liver
- Hepatomegaly
- Cutaneous stigmata of chronic liver disease
- Splenomegaly
- Liver failure: ascites, encephalopathy

Joints
- Arthritis
- Joint swelling

Heart
- Dilated cardiomyopathy
- Congestive heart failure

Skin
- Increased pigmentation

Endocrine
- Diabetes
- Testicular atrophy
- Hypogonadism
- Hypothyroidism

More recent series in which patients were identified by family studies, abnormal iron study results on routine screening chemistry panels, or population surveys indicate that most patients are asymptomatic, even on specific questioning about the symptoms of HH [105,106]. When symptoms are present, they are the same as those described above, with fatigue and arthralgias being the most common. Therefore, in the face of abnormal iron study results, clinicians should not expect to see the usual symptoms or findings of "classic" HH but should recognize that many C282Y homozygotes are asymptomatic. Alcohol and chronic hepatitis C are potentiating factors in the development of hepatic fibrosis in patients with *HFE*-related HH [107–109].

Diagnosis

Once the diagnosis of HH is being considered for a patient after either an evaluation of the symptoms and findings listed in Boxes 30.2 and 30.3, or a workup for abnormal results of screening iron studies or a family study, then a definitive diagnosis is relatively straightforward [107–109]. The fasting TS ((serum iron level divided by transferrin level or total iron-binding capacity) × 100) and the serum levels of ferritin and liver enzymes should be determined (Table 30.2). It is important that the TS be obtained in the fasting state because the serum iron level varies diurnally, and many breakfast cereals that are highly fortified with iron can raise the serum iron level shortly after ingestion. An elevated TS (≥45%) is recognized as the most common early phenotypic marker of HH; some patients who are homozygous for the C282Y mutation have elevated TS with a normal ferritin level. The sensitivity and specificity of these tests are difficult to determine when young persons are being evaluated (in whom increased iron stores may not have developed) or when patients have co-morbidities, such as chronic

Table 30.2 Diagnostic criteria for *HFE*-related hereditary hemochromatosis.

Measurements	Normal subjects	Patients with *HFE*-related HH
Blood (fasting)		
Serum iron (μg/dL)	60–180	180–300
Serum transferrin (mg/dL)	220–410	200–300
Transferrin saturation (%)	20–50	45–100
Serum ferritin (ng/mL):		
Men	20–200	150–6,000
Women	15–150	120–6,000
***HFE* mutation analysis**	wt/wt	C282Y/C282Y (homozygote) C282Y/H63D (compound heterozygote)
Liver		
Hepatic iron concentration:		
μg/g dry weight	300–1,500	1,500–30,000
μmol/g dry weight	5–27	27–550
Liver histology (Perls' Prussian blue stain)	0, 1+	2+ to 4+

wt, wild type.

liver disease (in which values may be falsely elevated). For example, serum ferritin levels are elevated in more than 50% of patients with alcoholic liver disease [110,111], nonalcoholic steatohepatitis (NASH) [107], or chronic viral hepatitis [112–114] in the absence of HH. Furthermore, other inflammatory disorders (e.g., inflammatory arthropathies) and various neoplastic disorders (e.g., lymphoproliferative disorders) may cause ferritin levels to rise without any increase in iron stores. Therefore, many results of serum iron studies can be false-positive or false-negative, and reliance on these laboratory values alone may cause significant problems in the diagnosis. The use of *HFE* mutation analysis significantly improves diagnostic accuracy in these challenging patients.

When evaluating the results of *HFE* genotyping obtained from screening family members or from population studies, it is valuable to remember that the C282Y mutation has incomplete penetrance. This is highlighted by the results of two large North American population studies comprising approximately 100,000 and 41,000 primary care patients [22,23]. In these two populations, a substantial proportion (27% and 60%, respectively) of female C282Y homozygotes had a TS of less than 45% or 50%, respectively, while the values were smaller (16% and 25%) for male C282Y homozygotes with a TS of less than 50%. Similarly, more than 40% of female C282Y homozygotes (43% and 46%) in these populations had serum ferritin levels in the normal range (<200 ng/mL), while the corresponding values in male C282Y homozygotes were 12% and 24% (serum ferritin levels of <300 or 250 ng/mL, respectively). Therefore, for C282Y homozygotes without increases in TS or ferritin level (termed nonexpressing C282Y homozygotes), it seems likely that many will not develop a clinically significant degree of iron overload in their lifetimes. Periodic follow-up measurements of serum ferritin levels at about 5-year intervals may be warranted in such individuals, with initiation of phlebotomy therapy if the values rise above normal.

In the past, if either a fasting TS or a ferritin level was elevated in an otherwise uncomplicated patient, a liver biopsy was performed to establish or disprove the diagnosis of HH. Perls' Prussian blue staining was used for histochemical iron analysis, and the hepatic iron concentration was also measured, with subsequent calculation of the hepatic iron index (HII). In current practice, if a patient has an abnormal result on iron studies, *HFE* mutation analysis is performed; if the patient is found to be a C282Y homozygote or a compound heterozygote (C282Y/H63D), and has normal liver enzymes and a serum ferritin level below 1,000 ng/mL, then a liver biopsy is not required before commencing phlebotomy treatment. Accordingly, as genetic testing has become more widely available and better understood, fewer liver biopsies are being performed. Four reports from France, United States, and Australia have shown that if the parameters mentioned earlier are used, no patient with significant fibrosis will be missed even if a liver biopsy is not performed [109,115–119]. An algorithm for the evaluation of possible *HFE*-related HH is shown in Fig. 30.2.

On the other hand, if a patient has elevated liver enzymes or a ferritin level above 1,000 ng/mL, a liver biopsy may be performed, and the typical findings of *HFE*-related HH should be recognized. Iron deposition occurs preferentially within the hepatocytes in the periportal region (acinar zone 1) of the hepatic lobule; the gradient of iron deposition decreases toward the pericentral region (acinar zone 3) (Fig. 30.3). With high levels of iron loading, Kupffer cell aggregates (siderotic nodules), iron deposition in bile duct epithelial cells, and increased fibrosis are found in the portal tracts. In other liver diseases associated with increased iron deposition (e.g., alcoholic liver disease, NASH, chronic viral hepatitis), the distribution of iron is usually panlobular, with increased amounts of iron found in sinusoidal lining cells (Kupffer cells) and hepatocytes. The histologic evaluation of iron staining – with a recognition of the pattern seen in *HFE*-related HH as opposed to that associated with secondary iron overload – provides important complementary information to the clinician caring for a patient with liver disease and abnormal iron study results. It has been reported that a non-HH pattern of iron distribution reliably predicts the absence of homozygosity for C282Y or the compound heterozygous state [118]. Conversely, the HH pattern of iron deposition can be seen in other forms of liver disease in the absence of C282Y homozygosity [118].

The HII was introduced in a classic paper by the Brisbane group in 1986 [119]. It is based on the concept that in patients with HH the hepatic iron concentration increases progressively with age, whereas in HH heterozygotes or in patients with various forms of liver disease with secondary iron overload, it does not. The HII was originally introduced as a means of differentiating HH homozygotes from both HH heterozygotes and patients with alcoholic liver disease and secondary iron overload, but it quickly came to be used as a surrogate test for HH homozygosity. The HII is calculated by dividing the hepatic iron concentration (in μmol/g dry weight of liver) by the patient's age (in years). In several studies, patients with homozygous HH had an HII above 1.9. Now that investigations have been performed with *HFE* mutation analysis used as the "gold standard" for the diagnosis of *HFE*-related HH, it is clear that many patients who are C282Y homozygotes have an HII below 1.9 [116]. Therefore, with the availability of genetic testing, the determination of the hepatic iron concentration and HII has little diagnostic value for *HFE*-related HH.

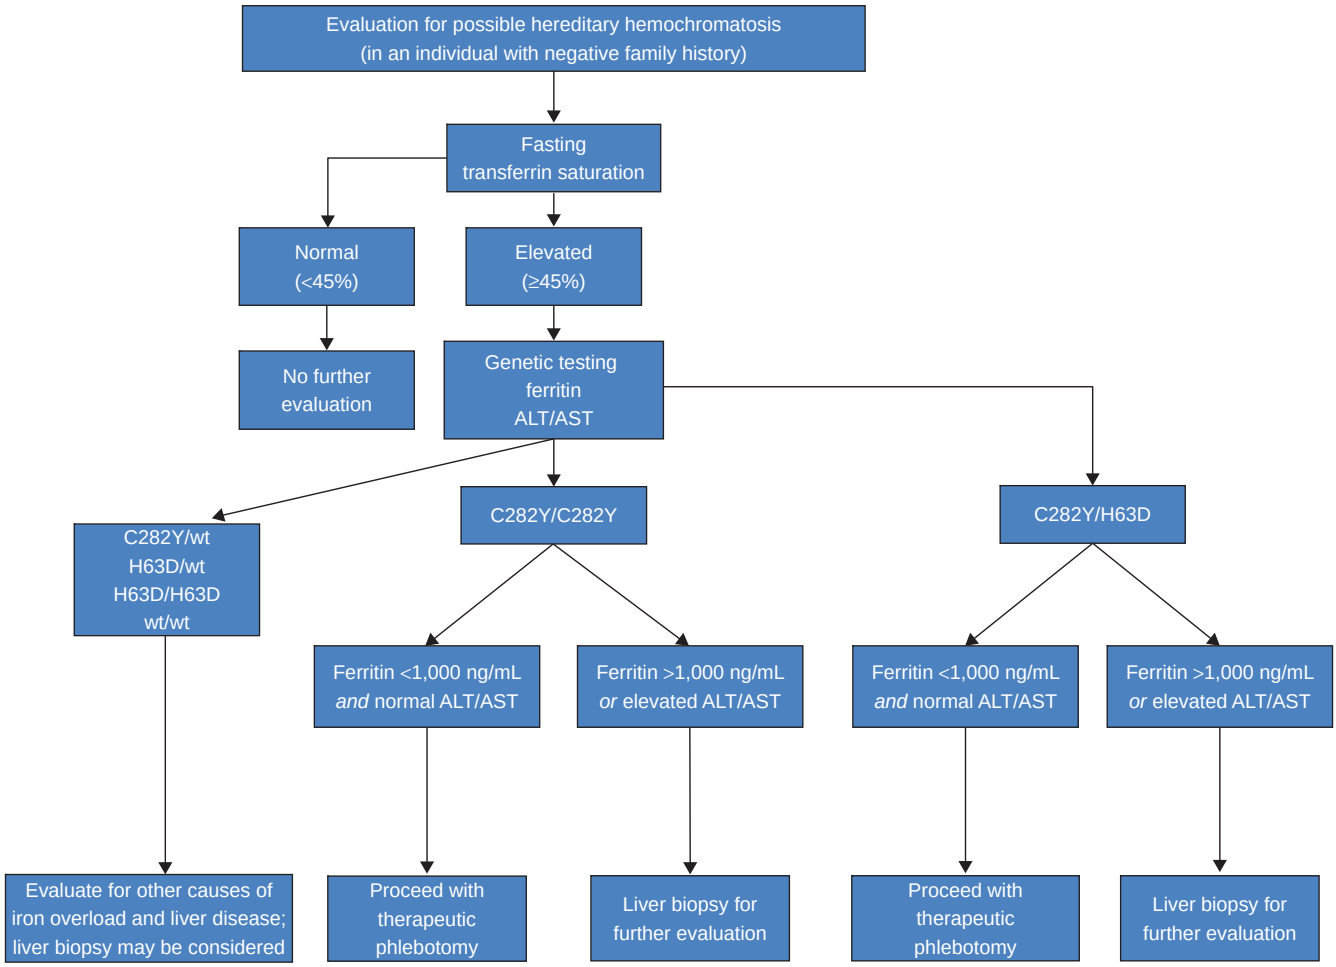

Figure 30.2 Algorithm for the evaluation of possible *HFE*-related hereditary hemochromatosis in a person with a negative family history. ALT, alanine aminotransferase; AST, aspartate aminotransferase; wt, wild type.

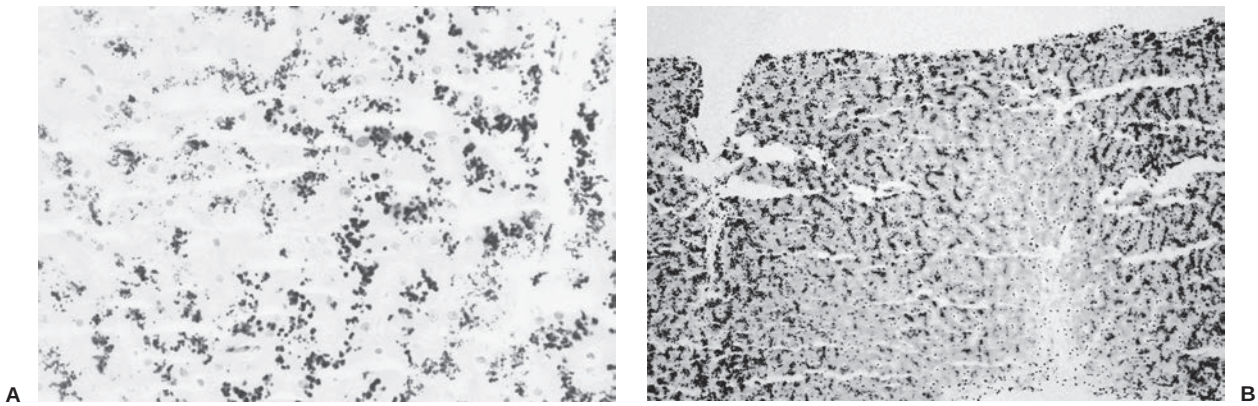

Figure 30.3 Liver biopsy specimen from a patient with *HFE*-related hereditary hemochromatosis stained for storage iron with Perls' Prussian blue stain. The hepatic iron concentration was elevated to 9,840 μg/g dry weight. Iron deposition is found preferentially in hepatocytes (A; original ×400) in the periportal region (acinar zone 1) of the hepatic lobule, with a decrease in the gradient toward the pericentral region (acinar zone 3) (B; original ×200). (Courtesy of Dr Elizabeth M. Brunt.)

Treatment

The treatment of HH remains relatively straightforward [107–109]. Once the diagnosis has been established by standard iron studies, genetic testing, or liver biopsy, treatment should be initiated with routine therapeutic phlebotomy. Patients should be encouraged to undergo weekly therapeutic phlebotomy with removal of 500 mL (1 U) of whole blood, which represents approximately 200–250 mg of iron, depending on the hemoglobin level. Some patients can tolerate the removal of 2 or even 3 U of blood per week, but 1 U per week is comfortable for most patients. Occasionally, older patients may only be able to tolerate the removal of 0.5 U every other week. Therapeutic phlebotomy should be performed until iron-limited erythropoiesis develops, which is identified by the failure of the hemoglobin level and hematocrit to recover before the next phlebotomy. It is reasonable to monitor the TS and ferritin levels periodically (every 3 months) to predict the return to normal iron stores and encourage patients who are undergoing phlebotomy. Phlebotomy should be continued until the serum ferritin level is less than 50 ng/mL and the TS is less than 50%. It is not necessary for patients to become iron deficient, just depleted of their excess iron stores. Usually, in otherwise uncomplicated patients, each unit of blood removed reduces the serum ferritin level by about 30 ng/mL. This can be a useful way of predicting the depletion of iron stores. Once standard therapeutic phlebotomy has been completed, patients require maintenance phlebotomy. Because in most patients approximately 2–3 mg of iron is absorbed per day in excess of their needs, they can be maintained in normal iron balance if 1 U of blood (200–250 mg of iron) is removed from them every 3 months.

With treatment, patients generally have an improved sense of well-being, and pain/fullness in the right upper quadrant is reduced (Box 30.4). If liver enzyme abnormalities are present, they will normalize with treatment.

Box 30.4 Response to phlebotomy therapy in hereditary hemochromatosis.

- Reduction of tissue iron stores to normal levels
- Improved survival if condition is diagnosed and treated before the development of cirrhosis and diabetes
- Improved sense of well-being and energy levels
- Improved cardiac function
- Improved control of diabetes
- Reduction in abdominal pain
- Decrease in skin pigmentation
- Normalization of elevated liver enzymes
- Reversal of hepatic fibrosis (approximately 30% of cases)
- No reversal of established cirrhosis
- No (or only minimal) improvement in arthropathy
- No reversal of testicular atrophy

Also, if patients require management of diabetes, the need for insulin or oral agents may decrease with successful phlebotomy therapy. On the other hand, testicular atrophy, arthropathy, and established cirrhosis generally are not reversible. Patients with established cirrhosis are still at risk for the development of hepatocellular carcinoma [102,120–122], and they should be screened periodically (every 6 months) with abdominal imaging and measurement of α-fetoprotein levels.

Family and population screening

Once a proband with *HFE*-related HH has been identified, family screening is necessary [107–109,123]. It is recommended that all first-degree relatives undergo *HFE* mutation analysis. In the past, HLA haplotyping was recommended as a surrogate genetic test, but with the availability of *HFE* mutation analysis, HLA typing is no longer recommended. Both the C282Y and H63D mutations should be analyzed. If a family member is found to be a C282Y homozygote or a compound heterozygote (C282Y/H63D), then therapeutic phlebotomy may be initiated if serum parameters indicate iron overload, such as an elevated ferritin level or TS. Individuals who are C282Y heterozygotes (C282Y/wt), H63D homozygotes (H63D/H63D), or H63D heterozygotes (H63D/wt) are not at risk for progressive iron overload. The issue of screening children by genetic testing raises questions of possible genetic discrimination and stigmatization [123]. These issues are not yet resolved at a societal level, but it may be useful to have the spouse of a proband undergo genetic testing to predict the genotype in a child [124]. Because C282Y and H63D are such common mutations, occurring in approximately 35% of persons singly or in combination, the chance that the spouse will have a mutation of *HFE* is approximately 1 in 3. If the spouse is homozygous for wild-type *HFE*, then the children do not require genetic testing because they are obligate heterozygotes and are not at increased risk for excess iron storage. In children who are C282Y homozygotes or compound heterozygotes, ferritin levels should be measured yearly and phlebotomy instituted when ferritin levels become elevated.

After the original discovery of *HFE*, it was thought that population screening using genetic testing might be ideal for *HFE*-related HH. Some of the reasons favoring screening are that C282Y homozygosity is common in white populations, there is a long latent phase before the development of disease manifestations, and treatment is simple and effective [21–23,125,126]. More than 15 studies have used *HFE* genotyping in population studies, and it has become evident that the C282Y mutation has incomplete penetrance, both in terms of serum iron parameters (i.e., TS and ferritin) and clinical impact (i.e., signs, symptoms, and morbidity) [22,23,125]. Incomplete

penetrance of the C282Y mutation raises serious concerns about the cost-effectiveness of large-scale population screening, as does the issue of genetic discrimination about health and life insurance [127,128]. Alternative screening approaches such as targeted screening of high-risk groups (e.g., patients with diabetes) and workplace screening may prove efficacious [129,130]. At the present time, general population screening is not recommended and the most cost-effective methods of early detection of *HFE*-related HH appear to be family screening and evaluation of potential cases by primary care physicians with a high index of clinical suspicion [128,131].

Analysis of *HFE* mutations in patients with liver disease

Clinicians must frequently determine whether a patient has liver disease with abnormal parameters of iron metabolism or *HFE*-related HH with elevated liver enzymes. Abnormal results of blood iron studies are common in patients with a variety of liver diseases. These are generally associated with hepatocellular types of liver disease rather than the cholestatic syndromes. Approximately 50% of patients with alcoholic liver disease [110, 111], NASH [132,133], or chronic viral hepatitis (B and C) [112–114] have abnormalities in serum iron parameters. Typically, these abnormalities are limited to an elevated serum ferritin level, but some patients may also have an elevated TS. The hepatic iron concentration is typically normal or slightly elevated, and if the HII is calculated, it is usually normal. *HFE* mutation analysis has been applied to groups of patients with alcoholic liver disease, chronic hepatitis C virus (HCV), NASH, and porphyria cutanea tarda (PCT).

It has been known for more than 20 years that results of iron studies are frequently abnormal in patients with alcoholic liver disease [110,111]. Patients with acute alcoholic hepatitis can present with ferritin levels above 1,000 ng/mL and a TS above 100%. These values return to normal with abstinence and recovery from alcoholic hepatitis. Parameters of iron metabolism can also be abnormal in patients with chronic alcoholic liver disease. When *HFE* mutations are examined in patients with chronic alcoholic liver disease, the prevalence of C282Y or H63D is not greater than that in the control population [134, 135]. Additionally, the absence of a relationship between *HFE* mutations and hepatic iron levels in patients with alcoholic liver disease suggests that the abnormal iron parameters (whether blood studies or hepatic iron concentration) are caused by factors other than *HFE* mutations [134].

A relationship between the hepatic iron concentration and the response to treatment with interferon monotherapy of patients with chronic HCV has been reported [136,137]. Studies in the 1990s demonstrated a higher hepatic iron concentration in patients with chronic HCV who did not respond to treatment with interferon monotherapy than in those who did [136–139]. This concept led to the use of therapeutic phlebotomy to deplete iron stores before initial interferon therapy or retreatment with interferon. Iron depletion results in reduced levels of serum alanine aminotransferase (ALT) but does not significantly improve the rate of sustained virologic response (HCV RNA levels undetectable after 6 months without therapy) [140–143]. In addition, hepatic iron concentration is not an independent predictor of response to combined therapy with interferon and ribavirin [144]. In a long-term study in patients with HCV who failed to respond to interferon, phlebotomy combined with a low iron diet decreased ALT activity, histologic inflammation and fibrosis, and the hepatic levels of 8-hydroxy-deoxyguanosine (a marker of DNA damage) [145]. These results suggest that iron depletion can slow the progression of liver damage in HCV and may reduce the risk for developing hepatocellular carcinoma.

Other studies have suggested that the effect of an increased hepatic iron concentration may be synergistic with that of HCV in causing hepatic fibrosis [146–149]. Studies in which *HFE* mutation analysis was performed in patients with HCV, like those carried out in patients with alcoholic liver disease, showed no difference in the prevalence of C282Y or H63D mutations in comparison with a control population [141,147,148,150–152]. Some studies have reported that the presence of *HFE* mutations (especially C282Y) in patients with HCV is associated with an increase in fibrosis and cirrhosis [141,147,153], but other studies have not confirmed this association [149,151,152,154]. Further investigation is needed to determine the potential role of *HFE* mutations and iron in HCV-induced liver injury and to confirm that long-term iron removal by phlebotomy decreases the progression of hepatic fibrosis and the incidence of hepatocellular carcinoma in patients with HCV.

Results of serum iron studies are often abnormal in patients with NASH [132,133,155–158] and stainable hepatic iron may also be present. A number of investigations have assessed the prevalence of *HFE* mutations in NASH and the potential role of hepatic iron in disease severity. In several studies, it has been observed that patients with NASH have a higher prevalence of the C282Y mutation (usually heterozygotes) [157–160], but this is not always the case [161]. Not all patients with NASH with elevated hepatic iron levels have the C282Y mutation, indicating that other factors are involved. Some studies also observed an increase in hepatic fibrosis in patients with NASH who carry the C282Y mutation [157,158]. While two reports found an association of increased hepatic iron with the development of fibrosis in NASH [157,158], other investigations have not found this

Table 30.3 Prevalence of *HFE* mutations and hepatitis C virus in patients with porphyria cutanea tarda.

Country	No. of patients	Percentage with C282Y/C282Y	Percentage with at least one C282Y mutation	Percentage with at least one H63D mutation	Percentage HCV antibody-positive	Reference

association [159,161,162]. Regardless of iron levels and *HFE* mutations, several small trials indicate that phlebotomy therapy decreases ALT levels in patients with NASH [163–166], but the potential beneficial effects on hepatic histopathology have not been systematically evaluated.

In PCT, the role of abnormal iron stores in disease progression has been known for many years [167,168]. In addition, some patients with PCT also have chronic HCV, and alcohol consumption is known to be another risk factor. Studies from the United States, Europe, and Australia have shown that 16–49% of patients with PCT have at least one C282Y mutation in *HFE* and 6–19% are C282Y homozygotes (Table 30.3) [169–175]. The situation is different for Italian patients with PCT, in whom the prevalence of the C282Y mutation is not increased; rather, the prevalence of the H63D mutation is elevated [176]. Therapeutic phlebotomy is beneficial in PCT, inducing a reduction in liver enzyme abnormalities and regression of the skin lesions [167,168]. Patients should also be counseled about abstaining from alcohol, and if they have HCV they should be offered a course of antiviral therapy once their excess iron stores have been depleted.

In summary, all patients with PCT should undergo *HFE* mutation analysis and HCV testing, and phlebotomy therapy is definitely beneficial. For patients with alcoholic liver disease, the role of *HFE* mutation analysis seems to be limited because *HFE* mutations do not appear to contribute to the iron abnormalities seen in these patients. For patients with chronic HCV and NASH, it is reasonable to request *HFE* mutation analysis if the parameters of iron metabolism are abnormal (elevated ferritin level or TS), but the relationships between *HFE* mutations and abnormal iron parameters are not as clear as those in PCT. In patients with HCV or NASH, phlebotomy may be beneficial in decreasing ALT activity and ameliorating liver damage, but additional long-term studies of iron depletion are needed to further assess the possible beneficial effects on the development of cirrhosis and hepatocellular carcinoma.

Other iron storage disorders

Secondary and parenteral iron overload

Disorders of erythropoiesis and some forms of chronic liver disease can cause increased iron absorption and deposition in tissues (see Box 30.1). In these disorders, the iron overload is said to be secondary because the increased absorption of dietary iron is a consequence of an underlying condition [19,177,178]. A common factor in the iron-loading anemias is refractory anemia, characterized by hypercellular bone marrow and ineffective erythropoiesis. These conditions, which include β-thalassemia and the sideroblastic anemias, can be associated with clinical and pathologic consequences similar to those seen in *HFE*-related HH. In patients with disorders of erythropoiesis who undergo blood transfusions, the iron burden can be increased rapidly by the combined effects of increased iron absorption and the transfusion of iron (in hemoglobin). Therefore, iron toxicity to the liver, heart, and pancreas may develop many years earlier than in patients with *HFE*-related HH [179]. To minimize iron-induced toxicity in patients with iron-loading anemias, intensive chelation therapy with desferrioxamine or other chelators is required; this is started at the time when a commitment to long-term transfusion is made [19].

Parenteral iron overload is iatrogenic and results from transfusions of red blood cells, injections of iron–dextran, or long-term dialysis [19,20]. Parenteral iron deposition is initially confined to cells of the RE system, including the Kupffer cells of the liver. When transfusions are required

in disorders of erythropoiesis, parenchymal and RE iron overload can coexist. With long-term parenteral iron overload, iron also accumulates in the parenchyma, presumably through the uptake of iron released from RE cells. The degree of structural and functional damage to the liver and endocrine organs generally parallels the degree of parenchymal iron overload. Sensitive magnetic resonance imaging (MRI) techniques are now available that accurately measure hepatic iron concentration noninvasively [180–182], and these may be particularly useful for ongoing assessment of chelation efficacy in patients with disorders of erythropoiesis.

African iron overload and congenital alloimmune iron overload

The iron overload that occurs in people living in sub-Saharan Africa is now considered to be the result of a non-*HFE*-related genetic trait that can be exacerbated by dietary iron loading [16]. Some persons with African iron overload consume an iron-rich beverage made from fermented maize, but iron overload also occurs in persons who do not drink it. The distribution of accumulated iron in African iron overload is different from that in *HFE*-related HH in that the ratio of the splenic iron concentration to hepatic iron concentration is higher in African iron overload. In addition, iron-loaded Kupffer cells are prominent in African iron overload, whereas the Kupffer cells are relatively spared in *HFE*-related HH. Nevertheless, both African iron overload and *HFE*-related HH can result in portal fibrosis and cirrhosis, and the risk for hepatocellular carcinoma is increased [183]. Associations of African iron overload with diabetes mellitus, peritonitis, scurvy, and osteoporosis have been described [16]. It has been reported that non-*HFE*-related iron overload may occur in African-Americans [184–186], but further investigations are needed to determine the genetic basis, prevalence, and clinical consequences of this condition.

Congenital alloimmune iron overload (also known as neonatal iron overload) is a rare disorder (fewer than 250 cases are reported in the literature) in which severe liver disease is associated with parenchymal iron loading, relative sparing of Kupffer cells, and extrahepatic siderosis [17,18,187]. Most cases have a fatal outcome, and treatment with desferrioxamine or an antioxidant cocktail has not been effective [188]. Some successful orthotopic liver transplantations have been performed in infants with neonatal iron overload, but long-term survival after this procedure has been disappointing [188]. Some cases show evidence of autosomal recessive inheritance, but without mutations in the genes for *HFE*, β_2M, heme oxygenase, TFR1, or ferritin [17]. Neonatal iron overload recurs within sibships at a rate higher than that predicted for simple Mendelian autosomal recessive inheritance, suggesting the role of a maternal factor [17]. Immunomodulation with intravenous high-dose immunoglobulin during pregnancy lessens the severity of disease, strongly suggesting that recurrent neonatal iron overload is an alloimmune condition causing liver injury [18,187].

Conclusions

With the discovery of *HFE* and other genes involved in iron homeostasis, our understanding of the normal physiology of iron absorption and the pathophysiology associated with mutations of these genes has been dramatically enhanced. *HFE* mutation analysis has greatly improved the ability to diagnose *HFE*-related HH accurately, to perform careful family screening, and to evaluate patients with liver disease and abnormal results of iron studies. Interestingly, population studies have revealed that many C282Y homozygotes do not have clinically significant iron overload, suggesting the influence of modifier genes. With a better understanding of the genes that modulate iron homeostasis, the reasons for the phenotypic variability of C282Y homozygotes may be discovered. Mutations in the iron-related genes encoding for hemojuvelin, hepcidin, ferroportin, TFR2, DMT1, and ferritin result in non-*HFE*-related HH. The pathogenesis of nearly all forms of HH involves an inappropriately low expression of hepcidin, an iron-regulatory hormone that acts to decrease the export of iron from duodenal enterocytes and RE cells. As a consequence of this low hepcidin expression, patients with HH having phenotypic expression have increased absorption of dietary iron and an elevated TS. Timely phlebotomy treatment of patients with *HFE*-related HH prevents cirrhosis and other iron-induced toxicity.

Multiple choice questions

30.1 **Which of the following molecules interacts with ferroportin to regulate iron absorption by enterocytes?**

a Hemojuvelin.
b Hepcidin.
c Hephaestin.
d Transferrin receptor 2.
e Hemopexin.

30.2 **In which of the following clinical scenarios would a liver biopsy be recommended?**

HFE genotype	Ferritin (ng/mL)	ALT (IU/mL)
a. C282Y/H63D	800	25
b. C282Y/C282Y	608	12
c. C282Y/wt	645	35
d. C282Y/C282Y	1,586	68
e. H63D/wt	253	38

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 31

Alpha-1 Antitrypsin Deficiency

David H. Perlmutter

Department of Cell Biology and Physiology, University of Pittsburgh School of Medicine and Children's Hospital of Pittsburgh of UPMC, Pittsburgh, PA, USA

Key concepts

- Homozygous protease inhibitor phenotype ZZ (PIZZ) α_1-antitrypsin (α_1-AT) deficiency, which has an incidence of one in 2,000 to one in 3,000 live births, is the most common genetic cause of liver disease in children. It is also causes more chronic liver disease and hepatocellular carcinoma in adults than previously appreciated. It is the most frequent genetic cause of chronic obstructive pulmonary disease (COPD)/emphysema.
- α_1-AT is an approximately 55 kDa secretory glycoprotein that inhibits destructive neutrophil proteases, elastase, cathepsin G, and proteinase 3. Plasma α_1-AT is predominantly derived from the liver, and its level increases 3–5-fold during the host response to tissue injury and inflammation. It is the archetype of a family of structurally related circulating serine protease inhibitors termed serpins.
- Although COPD is predominantly caused by a loss-of-function mechanism in which uninhibited proteolytic activity destroys the connective tissue backbone of the lung, liver disease is caused by a gain-of-toxic function mechanism attributable to the toxic effects of polymerized/aggregated mutant α_1-AT molecules retained within the endoplasmic reticulum (ER) of liver cells.
- Screening studies by Sveger in Sweden have shown that only 8% of the PIZZ population have clinically significant liver disease in the first 30 years of life. These results provide the basis for the concept that genetic and/or environmental modifiers determine whether a homozygote develops clinically significant liver disease. One series of studies has suggested that a subgroup of PIZZ individuals are predisposed to liver injury because of an inefficient degradation of mutant α_1-ATZ within the ER.
- Altered migration of the abnormal α_1-AT molecule in isoelectric focusing gels is the basis of the diagnosis of α_1-AT deficiency.
- Management of α_1-AT deficiency-associated liver disease is mostly supportive. Liver replacement therapy has been used successfully for severe liver injury.
- Although clinical efficacy has not been demonstrated, many patients with emphysema due to α_1-AT deficiency are being treated by means of intravenous and intratracheal aerosol administration of purified plasma α_1-AT. An increasing number of patients with severe emphysema are undergoing lung transplantation.
- Advances in understanding how cells degrade mutant α_1-ATZ and how cells activate protective signaling responses when mutant α_1-AT accumulates in the ER have led to novel concepts for pharmacologic strategies.

Incidence

The incidence of homozygous protease inhibitor phenotype ZZ (PIZZ) α_1-antitrypsin (α_1-AT) deficiency is highest among people of Scandinavian and northern European descent at one in 1,600 to one in 2,000 live births [1]. Although the incidence of the homozygous deficiency state in North American white populations was originally reported to be one in 6,700 live births [2], more recent studies have demonstrated an incidence of one in 2,000 to one in 3,000 [3].

Clinical manifestations

Liver disease

Liver involvement is often first noticed at the age of 1–2 months because of persistent jaundice. Conjugated bilirubin levels in the blood and serum transaminase levels are mildly to moderately elevated. The liver may be enlarged. Such infants are usually admitted to the hospital with a diagnosis of neonatal hepatitis syndrome and undergo a detailed diagnostic evaluation [4]. Infants may also be initially evaluated for α_1-AT deficiency because

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.
© 2012 John Wiley & Sons, Ltd. Published 2012 by John Wiley & Sons, Ltd.

of an episode of gastrointestinal bleeding, bleeding from the umbilical stump, or bruising [5]. A small number of affected infants have hepatosplenomegaly, ascites, and liver synthetic dysfunction in early infancy. An even smaller number have severe fulminant hepatic failure in infancy [6]. A few cases are recognized initially because of a cholestatic clinical syndrome characterized by pruritus and hypercholesterolemia. The clinical features among these infants resemble those of extrahepatic biliary atresia, but histologic examination shows a paucity of intrahepatic bile ducts.

Liver disease associated with α_1-AT deficiency may be discovered in late childhood or early adolescence, when the patient is seen with abdominal distension due to hepatosplenomegaly or ascites or with upper intestinal bleeding caused by esophageal variceal hemorrhage. In some of these cases, there is a history of unexplained prolonged obstructive jaundice during the neonatal period. In others, there is no evidence of any previous liver injury, even when the neonatal history is carefully reviewed.

α_1-AT deficiency should be considered in the differential diagnosis for any adult who has chronic hepatitis, cirrhosis, portal hypertension, or hepatocellular carcinoma of unknown origin. An autopsy study in Sweden showed a higher risk of cirrhosis among adults with α_1-AT deficiency than was previously suspected, and indicated that α_1-AT deficiency has a strong association with primary liver cancer [7]. This study raised the possibility that the risk of clinical liver disease is as high as 25% among men in the fifth and sixth decades of life (Box 31.1).

The only prospective data on the course of α_1-AT deficiency-associated liver injury are from the Swedish nationwide screening study conducted by Sveger [1]. In this study, 200,000 newborn infants were screened and 127 PIZZ individuals were identified. Fourteen of the 127 had prolonged obstructive jaundice and nine of the 14 had severe liver disease, as indicated by clinical and laboratory criteria. Another eight of the 127 PIZZ infants had mildly abnormal serum bilirubin or serum transaminase levels or hepatomegaly. Approximately 50% of the rest of the 127 only had abnormal transaminase levels [8]. Published results of follow-up studies of the original cohort of 127 PIZZ children at 26 years of age [9] showed marginal elevations in serum transaminase levels in 4–9% with no evidence of liver dysfunction. Issues not addressed by the Sveger study are whether 26-year-olds with α_1-AT deficiency have persistent subclinical histologic abnormalities, despite a lack of clinical or biochemical evidence of liver injury, and whether liver disease will eventually become clinically evident during adulthood.

It is still not clear what clinical manifestations or abnormal laboratory test results can be used to predict a poor prognosis for patients with α_1-AT deficiency-associated liver disease. Results of one study suggested that persistence of hyperbilirubinemia, hard hepatomegaly, early development of splenomegaly, and progressive prolongation of prothrombin time were indicators of poor prognosis [10]. In another study, elevated transaminase levels, prolonged prothrombin time, and a lower trypsin inhibitor capacity correlated with a worse prognosis [11]. However, this author and his colleagues have found that some children with α_1-AT deficiency-associated liver disease can lead relatively normal lives for years after the development of hepatosplenomegaly and mild prolongation of prothrombin time. In a review of 44 patients with α_1-AT deficiency seen in the specialty practice at St Louis Children's Hospital, 17 patients had cirrhosis, portal hypertension, or both [12]. Nine of the 17 patients with cirrhosis or portal hypertension had a prolonged, relatively uneventful course for at least 4 years after the diagnosis of cirrhosis or portal hypertension. Two of these patients eventually underwent liver transplantation, but seven were leading relatively healthy lives for as long as 23 years after being diagnosed as having severe α_1-AT deficiency-associated liver disease. Patients with a prolonged stable course could be differentiated from those with a rapidly progressive course on the basis of overall life functioning but not on the basis of other more conventional clinical or biochemical criteria. Therefore, prediction of poor prognosis for α_1-AT deficiency-associated liver disease and for the timing of liver transplantation depends more on the overall functioning of the child than on histologic findings or laboratory data.

It is not clear whether heterozygotes for the Z allele of α_1-AT are predisposed to liver disease. Early studies of liver biopsy collections suggested that there was a relation between heterozygosity and the development of liver disease [13]. A retrospective study at the Mayo Clinic showed a higher prevalence of heterozygosity for α_1-ATZ in liver transplant recipients than in the general

Box 31.1 Liver disease associated with α_1-antitrypsin deficiency.

Clinical features

- Prolonged jaundice in an infant
- Neonatal hepatitis syndrome
- Mild elevation of transaminase levels in a toddler
- Portal hypertension in a child or adolescent
- Severe liver dysfunction in a child or adolescent
- Chronic hepatitis in an adult
- Cryptogenic cirrhosis in an adult
- Hepatocellular carcinoma in an adult

Diagnostic features

- Diminished serum levels of α_1-antitrypsin
- Abnormal mobility of α_1-antitrypsin in isoelectric focusing (PIZ)
- Periodic acid–Schiff-positive, diastase-resistant globules in liver cells

population, including a group of patients without another explanation for liver disease [14]. However, both these studies were biased in ascertainment and did not include concurrent prospective controls. Results of a cross-sectional study of patients with α_1-AT deficiency in a referral-based Austrian university hospital, who were reexamined with the most sophisticated and sensitive assays available, suggested that liver disease in heterozygotes can be accounted for, to a great extent, by infections with hepatitis B or C virus or by autoimmune disease [15]. Although this author suspects that liver disease can be caused by genetic and/or environmental modifiers in some heterozygotes, because of lack of clarity on this issue it is always wise to search for other causes of clinical liver disease in heterozygotes for the α_1-ATZ allele.

Liver disease has been described for several other allelic variants of α_1-AT. Children with compound heterozygosity type PISZ are affected by liver injury in a manner similar to that of PIZZ children [1,8,9]. There are several reports of liver disease in α_1-AT deficiency-type PIMMalton [16,17]. This is a particularly interesting association because the abnormal PIMMalton α_1-AT molecule has been shown to undergo polymerization and retention within the endoplasmic reticulum (ER) [17]. Liver disease has been detected in single patients with several other α_1-AT allelic variants, such as PIMDuarte [18], PIW [19], and PIFZ [20], but it is not clear whether other causes of liver injury for which there are more sophisticated diagnostic assays, such as infection with hepatitis C and autoimmune hepatitis, have been completely excluded in these cases.

Lung disease

The association between α_1-AT deficiency and the premature development of chronic obstructive pulmonary disease (COPD) is well documented [21]. Cigarette smoking markedly accelerates this destructive lung disease, reduces the quality of life, and markedly shortens the longevity of these persons [22]. There is still, however, wide variability in the incidence and severity of destructive lung disease within the α_1-AT-deficient population [3]. There are even PIZZ individuals who smoke but do not have any symptoms of lung disease or pulmonary function abnormalities or do not experience them until the seventh or eighth decade of life. Although results of one study have suggested the possibility that a subtle degree of hyperinflation can be detected with pulmonary function testing in infants with α_1-AT deficiency [23], results of other studies did not show any significant difference between the pulmonary function of PIZZ individuals aged 13–30 years and that of age-matched controls [24,25]. Clinical symptoms of COPD in α_1-AT-deficient individuals do not begin until the third decade of life. The usual initial symptoms are shortness of breath, wheezing, cough, sputum production, and frequent chest infections [21].

There is still limited information about the incidence of liver disease among persons with α_1-AT deficiency and emphysema. In one recent study of 22 PIZZ patients with emphysema, there was an elevated transaminase level in ten patients, and cholestasis was present in one patient [26]. Liver biopsies were not performed in this study and may be necessary for the accurate determination of the extent of liver injury in these patients.

Alpha-1 antitrypsin structure, function, and physiology

Alpha-1 antitrypsin gene structure

Alpha-1 antitrypsin is encoded by a 12.2 kb gene on chromosome 14q31-32.3 [27]. There is a sequence-related gene approximately 12 kb downstream. Because there is no evidence that it is expressed, the downstream gene is considered a pseudogene. The gene is composed of five exons and four introns (Fig. 31.1) [28]. Exon I_C, the 5′ portion of exon II, and the 3′ portion of exon V are noncoding regions. The first intron is 5.3 kb long, contains a short open reading frame, an Alu family sequence, and a pseudotranscription initiation codon. Apparently, the short open reading frame does not code for protein. The α_1-AT messenger RNA expressed in the liver is 1.4 kb long [29]. In macrophages, the α_1-AT mRNA is slightly longer [29]. There are three forms of α_1-AT mRNA in macrophages, depending on transcription initiation sites in two upstream exonic structures (exons I_A and I_B) [29,30].

Alpha-1 antitrypsin protein structure

Alpha-1 antitrypsin is a single-chain, approximately 55 kDa polypeptide with 394 amino acids and three asparagine-linked complex carbohydrate side chains [31]. There are two major serum isoforms depending on the presence of a biantennary or triantennary configuration of the carbohydrate side chains. α_1-AT is the archetype of a family of structurally related proteins called serpins (serine protease inhibitors), which includes antithrombin III, α_1-antichymotrypsin, C1 inhibitor, α_2-antiplasmin, protein C inhibitor, heparin cofactor II, plasminogen activator inhibitors I and II, and protease nexin I [31]. A serpin-like structure is also found in several cellular proteins, trophic factors, and circulating carrier proteins, such as corticosteroid- and thyroid hormone-binding globulin.

Many studies of the structural characteristics of α_1-AT have shown that it is essentially composed of two central β-sheets surrounded by a small β-sheet and nine α-helices. The dominant structure is the five-stranded, β-pleated sheet called the A sheet (Fig. 31.2). A mobile

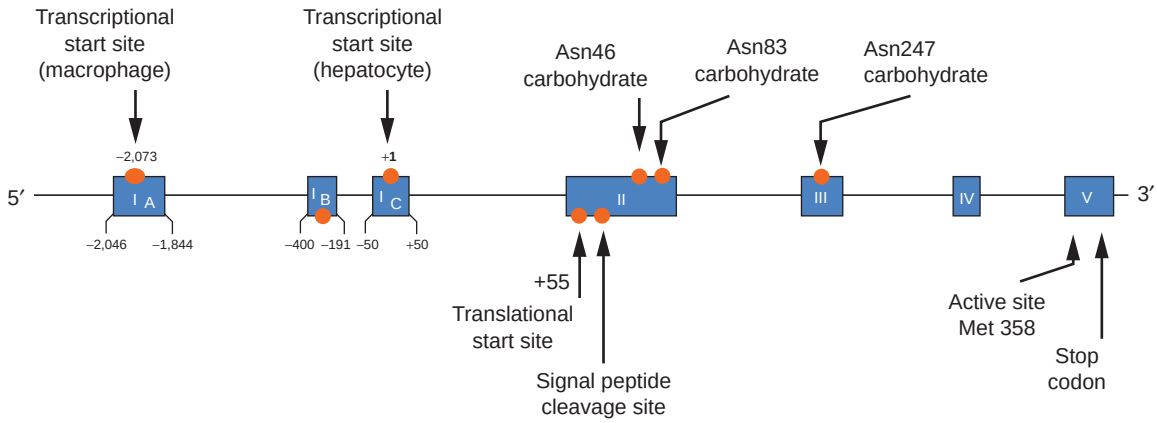

Figure 31.1 Structure of the α_1-antitrypsin gene (not to scale).

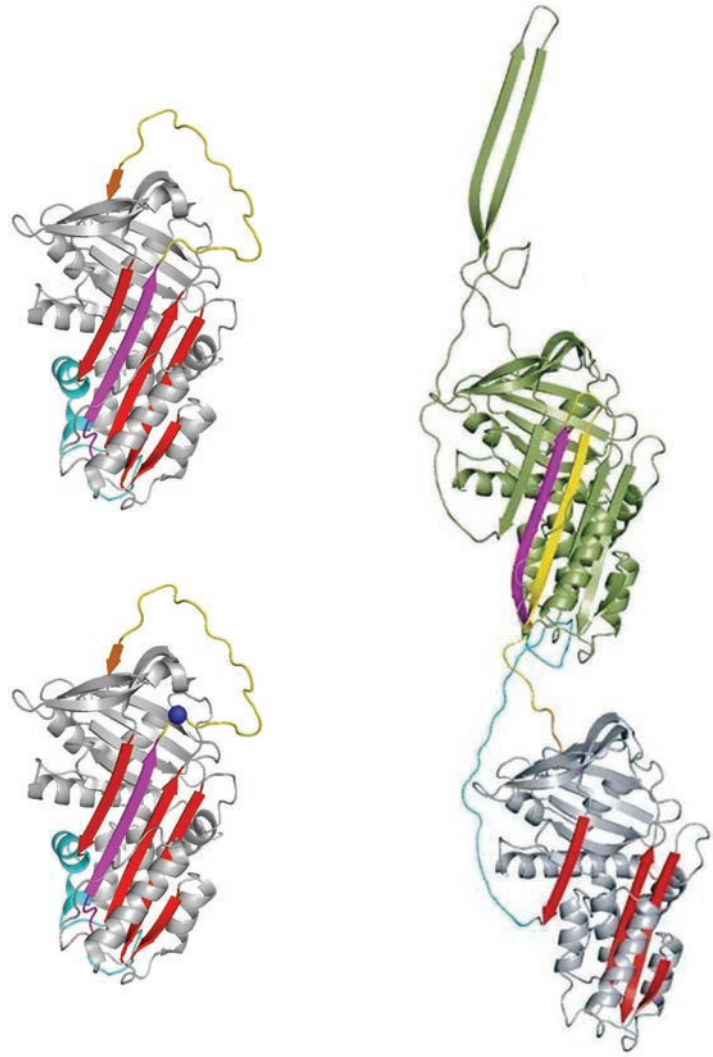

Figure 31.2 Ribbon diagrams of the normal α_1-antitrypsin molecule (A), mutant α_1-ATZ molecule (B), and polymerized α_1-ATZ molecule (C) according to the new domain swapping model. The position of the lysine substitution for glutamate 342 that characterizes the α_1-ATZ molecule is shown as a dark blue ball. That position lies within strand s5A, which is shown in pink. The reactive site loop, which becomes strand s4a, is shown in yellow. This color scheme makes it possible to see the swap of strand s4a and s5a together from the bottom α_1-ATZ molecule into the top molecule of the polymer structure. Strands s4a and s5a of the top molecule are shown in green, presumably being swapped into another α_1-ATZ molecule. The hydrophobic linker region is shown in teal blue. (Adapted from Yamasaki et al. [100] with permission from Nature.)

reactive center loop rises above a gap in the center of the A sheet [31,32].

Protease inhibitor system for classification of structural variants of α_1-antitrypsin

Variants of α_1-AT in humans are classified according to the PI phenotype system, as defined by agarose electrophoresis or isoelectric focusing of plasma in polyacrylamide at acid pH [33]. The PI classification system assigns a letter to variants according to migration of the major isoform. For example, the most common normal variant migrates to an intermediate isoelectric point, designated M. Persons with the most common severe deficiency have an α_1-AT allelic variant that migrates to a high isoelectric point, designated Z (Fig. 31.3). Even greater polymorphic variation of α_1-AT has been detected by means of restriction fragment length and direct DNA sequence analysis. With these techniques, in addition to isoelectric focusing, investigators have identified more than 100 allelic variants [34].

Normal allelic variants

The most common normal variant of α_1-AT is termed M1 and is found in 65–70% of whites in the United States [2].

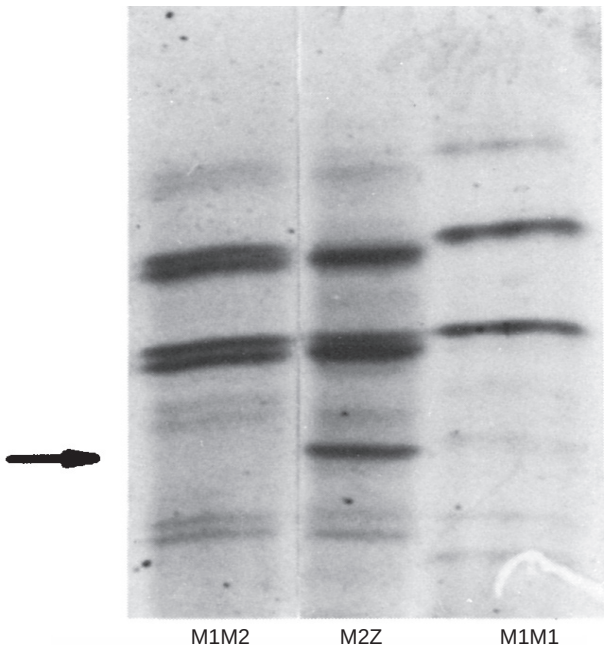

Figure 31.3 Isoelectric focusing of human serum samples for the diagnosis of α_1-antitrypsin deficiency. Serum samples from a person with the normal M1M2 variant, from an M2Z heterozygote, and from a person with the normal M1M1 variant were subjected to isoelectric focusing with the anode at top and cathode at bottom. Migration of the Z allele is indicated by the arrow. (Courtesy of J. A. Pierce, St Louis, MO. Reproduced from Perlmutter [164] with permission from Elsevier.)

There are many rare normal allelic variants with allelic frequencies of less than 0.1%. For each of these variants, serum concentration and functional activity of α_1-AT are within the normal range.

Null allelic variants

Alpha-1 antitrypsin variants in which α_1-AT is not detectable in serum are called null allelic variants (Table 31.1). The inheritance of a null allelic variant with another null variant or a deficiency variant is associated with premature development of emphysema. There is no evidence for liver injury in persons with null variants who were examined in detail [34]. Potential molecular mechanisms for the null phenotype have been identified by DNA sequence analysis of a number of null variants [34–37]. They include deletion of all α_1-AT coding exons, substitutions that result in stop codons, frameshift mutations, and single base substitutions. In at least three cases, the frameshift mutation resulted in an abnormal truncated protein that is retained in the ER ($null_{HongKong}$, $null_{Clayton}$, $null_{Saarbrucken}$) [35–38].

Dysfunctional variants

α_1-$AT_{Pittsburgh}$ is the most well-characterized dysfunctional variant [39], which was identified in a 14-year-old boy who died of an episodic bleeding disorder. A single amino acid substitution, Met to Arg at residue 358, converted α_1-AT from an elastase inhibitor to a thrombin inhibitor. The episodic nature of the illness was attributed to changes in the synthesis of the mutant protein during the host response to acute inflammation and tissue injury, the acute phase response. The α_1-AT $M_{Mineral\ Springs}$ and $null_{Ludwigshafen}$ probably are other examples of dysfunctional variants [37,40].

Deficiency variants

Several variants of α_1-AT that are associated with a reduction in serum concentrations have been described and are called deficiency variants (Table 31.2). Some of these variants are not associated with clinical disease, such as the S variant [18,41]. Other deficiency variants are associated only with emphysema, such as $M_{Heerlen}$, $M_{Procida}$, and P_{Lowell} [34]. In two persons with M_{Malton} and one with M_{Duarte}, hepatocyte α_1-AT inclusions and liver disease have been found with emphysema [16–18]. In one person with the α_1-AT S_{Iiyama} variant, emphysema and hepatocyte inclusions were reported, but this patient did not have liver disease [42]. The most common deficiency variant, the Z variant, is associated with emphysema and liver disease, as discussed later.

Alpha-1 antitrypsin function

Alpha-1 antitrypsin is an inhibitor of serine proteases in general, but its most important targets are neutrophil

Table 31.1 Null variants of α_1-antitrypsin.

	Clinical disease				
Variant	**Defect**	**Site**	**Liver**	**Lung**	**Cellular defect**
$Null_{GraniteFalls}$	Single base deletion	Tyr160	–	+	No detectable RNA

elastase, cathepsin G, and proteinase 3, proteases released by activated neutrophils. Several lines of evidence suggest that inhibition of neutrophil elastase is the major physiologic role of α_1-AT. First, persons with α_1-AT deficiency are susceptible to premature development of emphysema, a lesion that can be induced in experimental animals by means of the instillation of excessive amounts of neutrophil elastase [43]. These observations have led to the concept that destructive lung disease may result from perturbations of the net balance of elastase and α_1-AT within the local environment of the lung [44]. Second, the kinetics of association for α_1-AT and neutrophil elastase are more favorable, by several orders of magnitude, than those for α_1-AT and any other serine protease [45]. Third, α_1-AT constitutes more than 90% of the neutrophil elastase inhibitory activity in the one body fluid that has been examined – pulmonary alveolar lavage fluid [44].

α_1-AT acts competitively by allowing its target enzymes to bind directly to a substrate-like region within its reactive center loop. The reaction between enzyme and inhibitor is essentially of second order, and the resulting complex contains one molecule of each of the reactants. A reactive site peptide bond within the inhibitor is hydrolyzed during the formation of the enzyme–inhibitor complex. The complex of α_1-AT and serine protease is a covalently stabilized structure resistant to dissociation by denaturing compounds, including sodium dodecyl sulfate and urea. The interaction between α_1-AT and serine protease is suicidal in that the modified inhibitor is no longer able to bind with or inactivate the enzyme. There is also a profound alteration in the structure of the enzyme, including disruption of the catalytic site, such that the enzyme becomes inactive and subject to proteolytic destruction [46]. Studies have shown that the irreversible trapping of target enzyme is mediated by a profound conformational change in α_1-AT, such that the cleaved reactive-loop binding-enzyme inserts into the gap in the A sheet. Carrell and Lomas [47] likened the inhibitory mechanism to a mousetrap: The active inhibitor circulates in the metastable, stressed form and then springs into the stable, relaxed form to lock the complex with its target protease.

The net functional activity of α_1-AT in complex biologic fluids may be modified by several factors. First, the reactive site methionine may be oxidized and thereby rendered inactive as an elastase inhibitor [48]. In vitro, α_1-AT is oxidatively inactivated by oxidants released by activated neutrophils and alveolar macrophages of cigarette smokers [49,50]. Second, the functional activity of α_1-AT may be modified by proteolytic inactivation. Several members of the metalloproteinase family, including collagenase and *Pseudomonas* elastase, and the thiol protease family can cleave and inactivate α_1-AT [51]. Studies have shown that the pathogenesis of bullous pemphigoid may involve uninhibited neutrophil elastase activity at the dermal–epidermal junction because α_1-AT is cleaved and inactivated by matrix metalloproteinase 9 (MMP-9)–gelatinase B in the skin [52,53]. Third, DNA, which is often released from neutrophils at sites of inflammatory activation and phagocytosis, can impair the cathepsin G inhibitory activity of α_1-AT [54].

Although α_1-AT from the plasma or liver of persons with PIZZ α_1-AT deficiency is functionally active [55], there may be a decrease in its specific elastase inhibitory capacity. Ogushi et al. [56] showed that the kinetics of association with neutrophil elastase and the stability of complexes with neutrophil elastase were significantly decreased for α_1-AT isolated from PIZZ plasma. There was no decrease in the functional activity of α_1-AT in individuals homozygous for the S variant.

Results of several studies have indicated that α_1-AT protects experimental animals from the lethal effects of tumor necrosis factor [57]. Most of the evidence from these studies indicates that this protective effect is due to inhibition of the synthesis and release of platelet-activating factor from neutrophils [58], presumably through the inhibition of neutrophil-derived proteases. The antiapoptotic effect of α_1-AT on vascular smooth muscle cells [59] also probably involves the inhibition of extracellular matrix degradation by neutrophil-derived proteases.

Results of several studies indicate that α_1-AT has functional activities other than the inhibition of serine protease. The carboxyl-terminal fragment of α_1-AT, which can be generated during the formation of a complex with serine protease or during proteolytic inactivation by oxidants, thiolproteinases, or metalloproteinases, is a potent neutrophil chemoattractant [60]. The chemotactic response is equivalent to that elicited by formyl-methionyl-leucyl-phenylalanine. The carboxyl-terminal fragment of α_1-AT is also responsible for an increase in synthesis of α_1-AT in human monocytes and macrophages when these cells are incubated with exogenous neutrophil elastase [61]. In each case, the biologic effect is mediated by the interaction of a pentapeptide neodomain within the carboxyl-terminal fragment of α_1-AT and a novel cell surface receptor, the serpin–enzyme complex (SEC) receptor [62–64]. This mechanism may also be responsible for the neutrophil chemotactic effect of α_1-AT polymers [65], an effect that could explain the excessive neutrophil infiltration that characterizes the lungs of patients homozygous for the polymerization-prone α_1-ATZ.

Several studies have suggested that α_1-AT inhibits human immunodeficiency virus 1 (HIV-1) [66,67]. This effect appears to involve inhibition of viral entry and does not require protease inhibitory activity. A synthetic

peptide from the region around the reactive site of α_1-AT has more potent anti-HIV activity but it was not proven that this peptide region mediates the effect of the intact protein [68].

There have been several reports that α_1-AT alters immune and inflammatory activities through effects on white blood cells that are distinct from its protease inhibitory activites, but investigation of the responsible mechanisms has produced confusing results [2,68,69].

Biosynthesis of α_1-antitrypsin

The predominant site of synthesis of plasma α_1-AT is the liver. This is most clearly shown by conversion of plasma α_1-AT to the donor phenotype after orthotopic liver transplantation [70]. α_1-AT is synthesized in human hepatocellular carcinoma cells as a 52 kDa precursor, undergoes post-translational, dolichol phosphate-linked glycosylation at three asparagine residues [71], and undergoes tyrosine sulfation [72]. It is secreted as a 55 kDa native single-chain glycoprotein with a half-time for secretion of 35–40 minutes.

Tissue-specific expression of α_1-AT in human hepatocellular carcinoma cells is directed by structural elements within a 750-nucleotide region upstream of the hepatocyte transcriptional start site in exon I_C. Within these regions are structural elements that are recognized by nuclear transcription factors, including hepatocyte nuclear factor 1α (HNF-1α), HNF-1β, hepatocyte nuclear factor 1α (HNF-1α), HNF-4, and HNF-3 [73]. HNF-1α and HNF-4 appear to be particularly important for the expression of the human α_1-AT gene in liver cells and intestinal epithelial cells [74]. Two distinct regions within the proximal element bind these two transcription factors. Substitution of five nucleotides at positions 77 to 72 disrupts binding of HNF-1α and dramatically reduces expression of the human α_1-AT gene in the liver of transgenic mice [75]. Substitution of four nucleotides at positions 118 to 115 disrupts the binding of HNF-4 but does not alter expression of the human α_1-AT gene in the liver of adult transgenic mice. The latter mutation does reduce expression of human α_1-AT in the liver during embryonic development.

Plasma concentrations of α_1-AT increase three- to fivefold during the host response to inflammation or tissue injury [76]. The source of this additional α_1-AT has always been considered the liver; therefore, α_1-AT is known as a *positive hepatic acute-phase reactant*. Synthesis of α_1-AT in human hepatocellular carcinoma cells (e.g., HepG2, Hep3B) is upregulated by interleukin 6 (IL6) but not by IL1 or tumor necrosis factor [77]. Plasma concentrations of α_1-AT also increase during pregnancy and during treatment with estrogens or androgens [78].

α_1-AT is also synthesized and secreted in primary cultures of human blood monocytes and bronchoalveolar and breast milk macrophages [79]. Expression of α_1-AT in monocytes and macrophages is influenced by products generated during inflammation, such as bacterial lipopolysaccharide [80] and IL6 [77]. Expression of α_1-AT in monocytes and tissue macrophages is also regulated by a feed-forward mechanism that is triggered by its functional activity. This regulatory mechanism was elucidated when it was discovered that synthesis of α_1-AT by monocytes increased when neutrophil elastase was added to the incubation medium [61]. This effect was later attributed to the formation of elastase–α_1-AT complexes that could interact with a specific cell surface receptor [62]. The effect on α_1-AT synthesis could be elicited by synthetic peptides corresponding to a domain in the carboxyl-terminal fragment of the α_1-AT molecule that is exposed only after the structural rearrangement that accompanies complex formation or proteolytic modification. This class of receptor molecules was called SEC receptors because the receptors recognize the highly conserved domains of other SECs, such as antithrombin III–thrombin, α_1-antichymotrypsin–cathepsin G, and, to a lesser extent, C1 inhibitor–C1s and tissue plasminogen activator–plasminogen activator inhibitor I complexes, as well as that of α_1-AT–elastase complexes [62,81]. Substance P, several other tachykinins, and bombesin bind to the SEC receptor through a similar pentapeptide sequence [82], indicating that expression of α_1-AT can be upregulated at sites of tissue inflammation by neuropeptides and peptide hormones as well as by cytokines. Although the pharmacologic and physiologic characteristics of the SEC receptor still appear to be distinct the receptor has not been purified and its primary structure has not been determined.

α_1-AT mRNA has been isolated from several tissues in transgenic mice [83], but in many cases it has not been possible to determine whether this mRNA is in ubiquitous tissue macrophages or other cell types. α_1-AT is synthesized in enterocytes and Paneth cells, as indicated by the results of studies with intestinal epithelial cell lines, ribonuclease protection assays of human intestinal RNA, and in situ hybridization analysis in cryostat sections of human intestinal mucosa [84]. Expression of α_1-AT in enterocytes increases markedly during differentiation from crypt to villus, in response to IL6, and during inflammation in vivo. α_1-AT is also synthesized by pulmonary epithelial cells [85,86]. Synthesis of α_1-AT in pulmonary epithelial cells is less responsive to regulation by IL6 than by a related cytokine, oncostatin M [86]. Moreover, there is evidence that HNF-1β, and not HNF-1α, HNF-4, or HNF-3, plays a predominant cell-specific role in transcription of the α_1-AT gene in pulmonary epithelial cells [87].

Clearance and distribution of α_1-antitrypsin

The half-life of α_1-AT in plasma is approximately 5 days [2,34]. It is estimated that the daily production rate of α_1-AT is 34 mg/kg body weight, 33% of the intravascular pool of α_1-AT being degraded daily. There is a slight increase in the rate of clearance of radiolabeled α_1-ATZ compared with that of PIM α_1-AT when infused into PIMM individuals, but this difference does not account for the decrease in serum levels of α_1-AT in persons with the deficiency [2,34]. The low-density lipoprotein receptor-related protein (LRP) family probably plays a major role in the clearance and catabolism of α_1-AT when it is in complex with neutrophil elastase [88]. The SEC receptor may be involved in the clearance and catabolism of both complex and modified forms of α_1-AT [81,89], but this has not yet been tested in vivo. The mechanism of clearance of native α_1-AT is not yet known [90].

α_1-AT diffuses into most tissues and is found in most body fluids [44]. Its concentration in lavage fluid from the lower respiratory tract is approximately equivalent to that in serum. α_1-AT is also found in feces, and increased fecal concentrations of α_1-AT correlate with the presence of inflammatory lesions of the bowel [91]. In each case, it is assumed that α_1-AT is derived from serum. However, local sites of synthesis, such as macrophages and epithelial cells, may make important contributions to the α_1-AT pool in these tissues and body fluids.

Mechanism for deficiency of α_1-antitrypsin in PIZZ individuals

The mutant α_1-ATZ molecule is characterized by a single nucleotide substitution that results in a single amino acid substitution, Lys for Glu342 [92,93]. There is a selective decrease in the secretion of α_1-AT, the abnormal protein accumulating in the ER [94,95]. The defect is not specific to liver cells because it also affects extrahepatic sites of α_1-AT synthesis, such as macrophages [94] and transfected cell lines [96,97]. Site-directed mutagenesis studies have shown that this single amino acid substitution is sufficient to produce the cellular defect [98]. Once translocated into the lumen of the ER, the mutant α_1-AT protein is relatively inefficient in traversing the remainder of the secretory pathway because it is abnormally folded. Only 10–15% of newly synthesized α_1-ATZ reach the extracellular fluid in cell line models or the blood and body fluids in vivo.

Several studies have provided evidence that the substitution of glutamate 342 by lysine in the α_1-ATZ variant decreases the stability of the molecule in its monomeric form and increases the likelihood that it will form polymers [99]. Studies by Lomas and Carrell showed for the first time polymers of α_1-ATZ in the ER of liver cells in biopsy specimens from patients with α_1-AT deficiency [99]. A recent study by Yamasaki et al., which elucidated the crystal structure of a stable serpin dimmer, has provided the basis for an interesting new model in which a domain swapping mechanism explains the formation of polymers and insoluble aggregates of α_1-ATZ [100]. The model predicts that the final step in the folding of the serpin molecule is the incorporation of strand s5a into the central β-sheet A. The substitution of lysine for glutamate 342 that characterizes the ATZ molecule lies within strand s5a and this substitution further disrupts the usual intramolecular interactions with Lys290 on strand s6a and Thr203. Because of these effects, the region, which is destined to form strand s5a in the α_1-ATZ protein, becomes flexible and unstructured in a way that favors domain swapping of strand s5a together with the reactive center loop/strand s4a between adjacent α_1-ATZ molecules. Presumably domain swapping between adjacent α_1-ATZ molecules leads to progressive linear polymerization. Finally, the unfolding event that leads to domain swapping is predicted to expose a 30-residue helical linker region. Because this linker is hydrophobic it is possible to envision lateral association between linear polymers that would produce the tangled aggregates seen by Lomas and Carrell in the ER of liver cells in AT deficiency [99]. This model provides explanations for several phenomena that have been somewhat mysterious in the past: (i) how the α_1-ATZ molecule transitions from a relatively normally folded but still polymerogenic intermediate into polymers and insoluble aggregates; (ii) how a small number (10–15%) of α_1-ATZ molecules are kinetically capable of folding into a conformation that can traverse the secretory pathway; and (iii) how the accumulation of polymeric α_1-ATZ in the ER does not activate the unfolded protein response (see below) because the structure of the polymer closely resembles the relaxed conformation of the normally folded monomer.

Polymers have also been found in the plasma of patients with the PIS_{Iiyama} α_1-AT variant and the PIM_{Malton} α_1-AT variant [101,102]. The mutations in α_1-AT PIS_{Iiyama} (Ser53 to Phe) [42] and α_1-AT PIM_{Malton} (Phe52 deletion) [17] affect residues that provide a ridge for the sliding movement opening the A sheet. According to the domain swapping model of Yamasaki et al., these mutations would be expected to slow the final folding step from a polymerogenic intermediate with an exposed strand 5A to the native state with the strand incorporated in β-sheet A. It is interesting that the hepatocytic α_1-AT globules have been found in a few patients with these two variants. Recent observations suggest that the α_1-ATS variant also undergoes polymerization [103] and that this may account for its retention in the ER, although to a milder extent than that for α_1-ATZ [41].

Polymerization also appears to occur for other serpins in clinical deficiency states, including antithrombin deficiency [104] and C1 inhibitor deficiency [105]. A striking example of this phenomenon is the familial dementia associated with Collins bodies. Studies by Davis et al. [106] have shown that these neuronal inclusion bodies contain a polymerized mutant neuroserpin.

Several studies have suggested that polymerization is the cause of retention of α_1-ATZ in the ER of liver cells. The most powerful of these are studies showing partial correction of the secretory defect by the insertion of a second mutation into the α_1-ATZ protein that suppresses polymerization [107–109]. However, these studies do not exclude the possibility that there is an abnormality in folding that is distinct from the tendency to polymerize and is also partially corrected by the second, experimentally introduced mutation. More recent studies cast some doubt on the concept that polymerization is the cause of ER retention. First, naturally occurring variants of α_1-AT, in which the carboxyl terminal tail is truncated – including a double mutant with the substitution that characterizes the Z allele together with the substitution that results in carboxyl terminal truncation – are retained in the ER of liver cells although they do not form polymers [38]. Second, only a minor proportion (approximately 18%) of the intracellular pool of α_1-ATZ at steady state in model cell lines is in the form of polymers [38,110]. Moreover, because the remainder of α_1-ATZ in the ER in vivo is in the form of heterogeneous soluble complexes with multiple ER chaperones [110], the principles by which purified α_1-ATZ polymerizes in vitro are probably not applicable to what happens in live cells in vivo. Taken together, the extant data suggest that polymerization is not the cause by which α_1-ATZ is retained in the ER of liver cells but rather is the result of its retention. Nonetheless, the polymerogenic properties of the Z mutant are still likely to be critical determinants in the pathobiology of liver disease.

To understand how alteration in the folding of α_1-AT might result in retention within the ER, we must consider what is known about the biology of protein secretion. Most newly synthesized secretory proteins are translocated into the lumen of the ER together with membrane proteins. Before being transported to their final destination, these nascent secretory and membrane polypeptide chains undergo a series of post-translational modifications, including glycosylation, formation of disulfide bonds, oligomerization, and folding. Folding is facilitated by interaction with resident ER proteins, termed molecular chaperoness. One family has been referred to as the polypeptide chain-binding protein family and includes several heat-shock proteins, GRP78/BiP and GRP94, protein disulfide isomerase, ERp57, and Erp72 [111]. Lectins including the calcium-binding phosphoproteins calnexin and calreticulin as well as OS9, also have molecular chaperone activity within the ER [112].

It is still not clear, however, whether the mechanism by which the secretory proteins are transported out of the ER involves one of three possible alternatives: (i) the protein encodes a transport signal by which it is recognized for selective removal from the ER and is concentrated as cargo in a departing vesicle; (ii) the protein encodes a signal for retention in the ER and restricts it from entering a departing vesicle; or (iii) the protein lacks both transport and retention signals and enters, by means of bulk flow, the budding vesicles at its prevailing concentration in the ER. Several cargo receptors, which direct transport out of the ER, have been identified, but so far we know of only a select group of secretory protein ligands governed by this mechanism. Nyfeler et al. recently provided evidence that the lectin ER Golgi intermediate compartment 53 kD protein (ERGIC-53) is an export receptor for α_1-AT [113]. Most importantly, ERGIC-53 failed to recognize mutant α_1-ATZ [113]. This could mean that polymerization/aggregation prevents α_1-ATZ from being presented to ERGIC-53 or that the altered folding pathway of α_1-ATZ prevents an essential ligand domain from being available to bind to ERGIC-53. The implications of these observations, together with those of the domain swapping model for polymerization/aggregation of α_1-ATZ from Yamasaki et al. [100], will be critical in conceptualizing novel therapeutic strategies in the future.

Pathogenesis of liver injury in PIZZ individuals

Liver damage in the classic form of α_1-AT deficiency is caused by accumulation of mutant α_1-AT molecules in the ER of liver cells, constituting a gain-of-toxic-function mechanism. Experimental results with transgenic mice provide the most compelling evidence for the gain-of-toxic-function mechanism and completely exclude the possibility that liver damage is caused a loss-of-function mechanism that might involve "proteolytic attack" as a consequence of diminished serum α_1-AT concentrations. Transgenic mice carrying the mutant Z allele of the human α_1-AT gene develop periodic acid–Schiff (PAS)-positive, diastase-resistant intrahepatic globules and liver injury early in life [114,115]. Because there are normal levels of α_1-AT and presumably other antielastases in these animals, as directed by endogenous murine genes, the liver injury cannot be attributed to proteolytic attack.

It has been difficult to reconcile the accumulation theory with the observations of Sveger [8,9], who showed that only a subset of α_1-AT-deficient persons sustain clinically significant liver damage. These observations have therefore led to the concept that modifiers, either genetic

or environmental, predispose a subgroup of homozygotes to liver disease and/or protect the remainder of the population from liver disease. Furthermore, we have theorized that these putative modifiers affect the pathways responsible for the disposal of mutant ATZ and/or the protective signaling pathways that are activated by accumulation of ATZ in the ER [116]. This theory envisions "secondary" alterations that are subtle, in the sense that they are clinically silent when inherited or acquired by a host who has not inherited the mutation of ATZ. Furthermore, the modifiers are likely to be heterogeneous among patients and their families because this would explain the rather remarkable diversity in natural history of liver disease that has been observed. One study [117] has provided substantiation for this theory by showing a delay in intracellular disposal of ATZ after gene transfer into cell lines from homozygotes with known liver disease (susceptible hosts) compared with cell lines from homozygotes who had no evidence of liver disease (protected hosts) (Figs 31.4 and 31.5).

Because the pathways for degradation of the α_1-ATZ that is retained in the ER are obvious candidates for putative modifiers of liver disease by the gain-of-toxic function mechanism, we and others have sought to characterize the pathways. Early studies in both yeast and mammalian cell lines showed that the proteasome participates in the degradation of mutant α_1-ATZ [118–121]. In fact, degradation of mutant α_1-ATZ by the proteasome was one of the original observations that led to the recognition of the ER-associated degradation (ERAD) pathway. ERAD is a pathway by which proteins in the lumen or membrane of the ER are targeted for degradation by retrograde translocation into cytoplasm where ubiquitination and proteasomal degradation take place (reviewed in [111]). We know now that there are different types of ERAD for luminal and membrane proteins and there may even be further subspecialization for different types of luminal proteins, but the exact chaperones and proteins that recognize α_1-ATZ and mediate its transport into the cytoplasm are not yet elucidated. It is even possible that transport of α_1-ATZ from the ER to cytoplasm involves proteasome-mediated "extraction" or "dislocation" [122]. Studies using a cell-free microsomal translocation system suggest that α_1-ATZ degradation by the proteasome occurs by both ubiquitin-dependent and -independent mechanisms [119].

Nevertheless, there was evidence from these studies of the proteasomal pathway in mammalian cell lines, of cell-free microsomal translocation systems, and of yeast that this pathway could not completely account for the disposal of ATZ. Autophagy was first implicated in AT deficiency when a marked increased in autophagosomes were observed in fibroblast cell lines engineered for the expression of ATZ [123]. Increased autophagosomes were observed in the liver of PiZ mice and in liver biopsy specimens from patients [123].

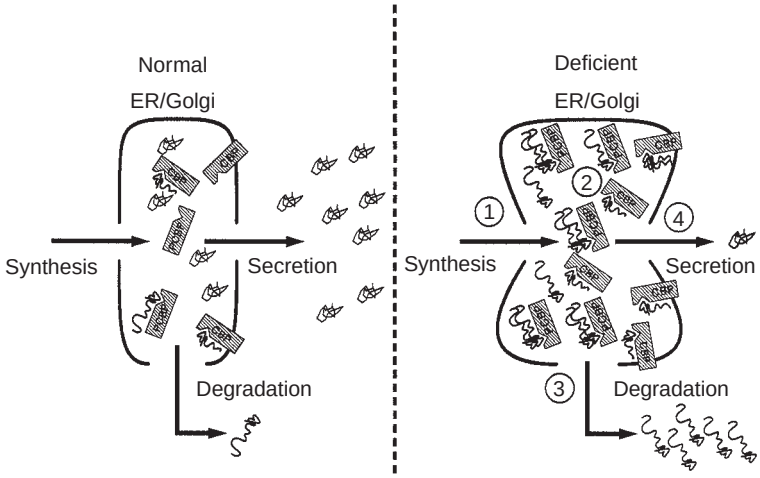

Figure 31.4 Conceptual model for liver injury in α_1-antitrypsin (α_1-AT) deficiency. Polypeptide chain-binding proteins (PCBP) and membrane-associated calcium-binding proteins (CBP) are shown as hatched bars. The α_1-AT molecules that are unfolded or misfolded are shown as long wavy lines, and those that are maturely folded are shown as condensed masses. (A) In the normal state, α_1-AT enters the secretory pathway (endoplasmic reticulum, ER) unfolded. Interaction with PCBP or CBP facilitates folding into a mature state and allows dissociation from the PCBP or CBP in a form competent for secretion. A relatively minor proportion of the α_1-AT molecules that do not fold into the mature state are directed into a pathway for degradation in, or through, the ER. (B) In a person with α_1-AT deficiency, only a minor proportion of the mutant α_1-AT molecules achieve the mature, folded state that allows secretion. There is a net accumulation of α_1-AT molecules in the ER and an increase in α_1-AT molecules directed into the pathway for degradation. Further intracellular accumulation of α_1-AT, which is potentially hepatotoxic, could result from increased synthesis of α_1-AT (1), abnormalities in interaction with PCBP or CBP (2), abnormalities in degradative enzymes (3), or abnormalities in bulk flow that allow secretion (4) of 10–15% of the newly synthesized mutant α_1-ATZ molecules.

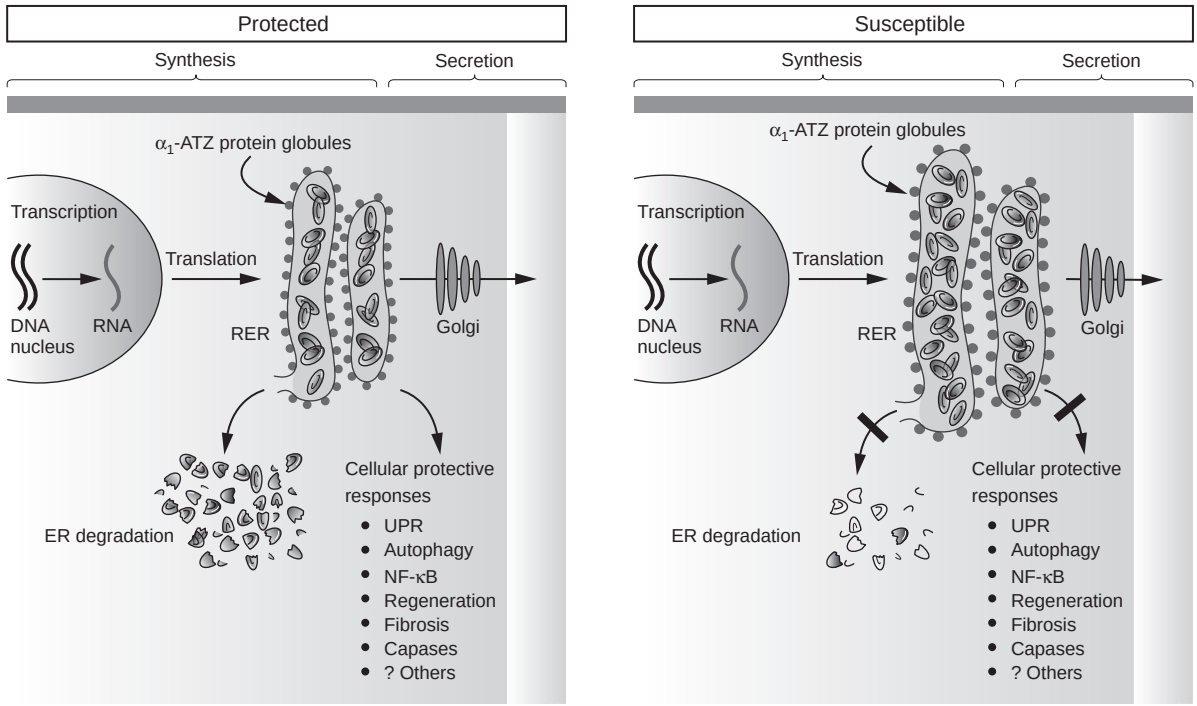

Figure 31.5 Difference in endoplasmic reticulum (ER) degradation of α_1-ATZ protein in protected and susceptible hosts. The blocks in ER degradation and cellular response pathways in susceptible hosts are represented by small dark bars. DNA, deoxyribonucleic acid; NF-κB, nuclear factor κB; RER, rough endoplasmic reticulum; RNA, ribonucleic acid; UPR, unfolded protein response; ?, not proven.

Autophagy is a catabolic process by which the cell digests its internal constituents to generate amino acids in response to nutrient starvation and other stress states. It also appears to play a role in homeostasis, cell growth, and cell differentiation. It begins with the formation of a membranous platform around a targeted region of the cell. This platform becomes a double-membrane vesicle as it envelopes cytoplasm together with parts of or entire subcellular organelles. Eventually this autophagosome fuses with the lysosome for degradation of its contents.

Thus, the presence of abundant autophagosomes in the liver in AT deficiency and its models raised the possibility that autophagy could be involved in degrading the mutant ATZ that is retained in the ER. Indeed the initial study went on to show that the disposal of ATZ was partially abrogated by chemical inhibitors of autophagy, including 3-methyladenine, wortmannin, and LY-294002 [123]. However, because these drugs have other cellular effects and therefore cannot be considered specific for autophagy, we sought to provide genetic evidence that autophagy participated in the disposal of ATZ. For this we engineered an embryonic fibroblast cell line (MEF) from an ATG5-null mouse for expression of ATZ [124]. The results showed a marked delay in degradation of ATZ in the ATG5-null compared to the wild-type MEFs. Furthermore in the ATG5-null cell line it became possible to observe massive accumulation of ATZ with very large inclusions throughout the cytoplasm. Therefore, in addition to providing definitive evidence that it contributes to the disposal of ATZ, these studies suggested that autophagy plays a "homeostatic" role in the AT-deficient state by preventing toxic cytoplasmic accumulation of ATZ through piecemeal digestion of insoluble aggregates.

A study by Kruse et al. [125] using a completely different strategy also demonstrated the importance of autophagy in the disposal of ATZ. This group expressed human ATZ in a library of yeast mutants and screened for mutants that were impaired for degradation of ATZ. One of the mutants corresponded to the yeast homolog of mammalian ATG6. In the absence of this ATG6 homolog or the homolog of ATG16 there was a marked delay in the disposal of human ATZ. These studies were particularly revealing because a delay in the degradation of ATZ was most apparent in the autophagy-deficient yeast strains when ATZ was expressed at high levels. At lower levels of expression, ATZ was degraded at a rate not signicantly different from that in wild-type yeast. These results are consistent with the notion that at lower levels of expression ATZ in the ER is predominantly soluble and can be degraded by the proteasome, whereas at higher levels of expression it is more likely to undergo transition to insoluble polymers/aggregates that require autophagy for disposal.

Kruse et al. also discovered that a mutant subunit of fibrinogen that forms insoluble aggregates in the ER of liver cells in an inherited form of fibrinogen deficiency depends on autophagy for disposal [126]. This type of fibrinogen deficiency has been associated with a chronic liver disease characterized by distinct fibrillar aggregates in the ER of liver cells. These results substantiate the concept that chronic liver disease can be caused by accumulation of an aggregation-prone protein in the ER and that autophagy is specialized for the disposal of aggregation-prone proteins that accumulate in the ER.

The presence of increased hepatic autophagosomes in AT deficiency could potentially indicate that there is some defect in the clearance of autophagosomes rather than an increase in the formation of autophagosomes. We have recently investigated this issue by monitoring LC3 isoform conversion in a cell line model with inducible expression of ATZ. The results indicate that ATZ expression is sufficient to elicit LC3 conversion and that conversion is further accentuated by the presence of lysosomal inhibitors (N. Maurice and D. H. Perlmutter, unpublished results). Thus, at least within the context of a cell line model, accumulation of ATZ in the ER results in increased formation of autophagosomes and increased autophagic flux without a defect in clearance.

Several lines of evidence suggest that there are one or more other pathways that contribute to disposal of ATZ. A pathway that depends on a tyrosine phosphatase activity has been described [127]. The studies of Kruse et al. indicated that ATZ could be transported to the trans-Golgi and then targeted to the lysosome of yeast [125] but a comparable pathway has not be described in mammalian cells.

Modifiers that affect the function of any of these pathways could increase susceptibility to liver disease according to our theory. Indeed, a single nucleotide polymorphism (SNP) in the downstream flanking region of ER mannosidase I has been implicated in early-onset liver disease among AT-deficient individuals [128]. Because ER mannosidase I plays a role in ERAD, a polymorphism that affects its function would be a prime candidate for a modifier of liver disease in AT deficiency. However, further epidemiologic studies are needed to determine if this SNP is truly affecting liver disease susceptibility and further cellular studies are needed to identify how it alters ATZ accumulation. A SNP in the upstream flanking region of the AT gene itself has also been implicated in liver disease susceptibility [129]. There is no reason to believe that this SNP would affect the disposal of ATZ. The logical explanation for the effect of this polymorphism would be to increase expression of ATZ, but the published results did not substantiate that notion. Furthermore, the study could have led to an entirely different conclusion with a legitimate alternate way of classifying one of the patient groups.

According to our theory for the pathogenesis of liver disease in AT deficiency, modifiers would also be predicted to alter the functioning of cellular signaling pathways that might be activated to protect the cell from aggregated proteins. To address this we began a series of studies designed to determine what signaling pathways were activated when ATZ accumulated in the ER. We reasoned that this would require cell line and mouse model systems with inducible rather than constitutive expression of ATZ because the latter would potentially permit adaptations that could obscure the primary signaling effects. A series of studies using these kinds of systems have shown that the autophagic response and the nuclear factor κB (NF-κB) signaling pathway, but not the unfolded protein response, are activated when ATZ accumulates in the ER [124,130]. Activation of the autophagic response was shown by investigating the liver of a novel mouse model with hepatocyte-specific inducible expression of ATZ, the Z mouse, bred onto the GFP-LC3 mouse background. LC3 is an autophagosomal membrane-specific protein, so the GFP-LC3 mouse makes green fluorescent autophagosomes. Green fluorescent autophagosomes appear in the liver of the GFP-LC3 mouse only after 24 hours of starvation. In the Z × GFP-LC3 mouse green fluorescent autophagosomes are seen merely by allowing hepatocyte expression of the ATZ gene to be induced [130]. GFP+ autophagosomes are not seen in the liver of the Saar × GFP-LC3 mouse, which has hepatocyte-specific inducible expression of the AT Saar variant that accumulates in the ER but does not polymerize. Thus, autophagy is activated when ATZ accumulates in the ER and the autophagic pathway then plays a critical role in disposal of ATZ and in preventing massive intracellular aggregates.

Activation of NF-κB is another hallmark of the cellular response to ATZ accumulation [130]. One of the most interesting aspects of the NF-κB signaling pathway under these circumstances is that it is associated with a rather limited set of downstream transcriptional targets [131]. Indeed the most significant change in expression that could be attributable to NF-κB is downregulation of Egr-1, a transcription factor that is essential for hepatocyte proliferation and the hepatic regenerative response [132]. Our most recent studies have indicated that the downregulation of Egr-1 in the liver of the Z mouse when ATZ expression is induced is directly attributable to the action of NF-κB (A. Mukherjee and D. H. Perlmutter, unpublished results). Furthermore, the complex of proteins that assembles to form NF-κB when ATZ accumulates in the ER has a profile that is entirely distinct from that which forms when cells are treated with tumor necrosis factor (TNF) or tunicamycin

(A. Mukherjee and D. H. Perlmutter, unpublished results). Finally, mating of the PiZ mouse to a mouse model with conditional hepatocyte-specific deficiency of NF-κB activity shows more severe inflammation, fibrosis, steatosis, dysplasia, and more hepatocytes with globules (A. Mukherjee, T. Hidvegi and D. H. Perlmutter, unpublished results), indicating that NF-κB signaling is intended to protect the liver from the effects of ATZ accumulation. Together, the data on NF-κB suggest that it plays a particularly important role in the effects of ATZ on cell proliferation, survival, and ultimately the predisposition to hepatic carcinogenesis in AT deficiency.

The absence of the unfolded protein response (UPR) is also noteworthy [130]. For one, it means that activation of autophagy and NF-κB in cells that accumulate mutant ATZ is independent of the UPR, another distinct characteristic of the cellular response in the AT deficiency state. With what is known about the mechanism by which the UPR is initiated it has always been relatively easy to understand how polymerized and aggregated would not elicit the UPR. Results of recent structural studies by Huntington and colleagues provide an explanation for why soluble monomeric ATZ does not get recognized by the UPR apparatus. Those results suggest that the monomeric ATZ intermediate adopts a conformation that resembles the wild-type molecule [100] and therefore would not be recognized as unfolded.

Genomic analysis of liver from the Z mouse has identified other changes in gene expression that are attributable to the cellular response to ATZ [131]. One of these changes, upregulation of the regulator of G signaling 16 (RGS16), may represent a mechanism by which autophagy is activated in the liver in AT deficiency. We have found that the RGS16 response is characteristic and specific for ATZ. Because RGS16 anatagonizes Gαi3, and Gαi3 plays a role in inhibiting hepatic autophagy [133], we have hypothesized that increased RGS16 when ATZ accumulates in the ER leads to reversal of the inhibition of autophagy that would otherwise pertain in resting hepatocytes. There is still relatively limited information about how RGS16 is upregulated and where in the cell it acts to antagonize Gαi3.

Together the results of the foregoing studies indicate that degradation of α_1-ATZ is a complex process that may involve more than one pathway and at least several sequential steps in each pathway. Furthermore, signaling pathways that are presumably designed to protect the cell from the toxic effects of aggregated proteins are activated by accumulation of α_1-ATZ in the ER. Theoretically, each of these pathways or its individual steps may be affected in an α_1-AT-deficient patient who is "susceptible" to liver disease; that is, there may be heterogeneity among susceptible hosts in the mechanism by which ER degradation is delayed.

Mechanism of liver injury

There is still relatively little information about the mechanism by which ER retention of α_1-ATZ leads to liver cell injury. In transgenic mice that express the human α_1-ATZ gene, there are focal areas of liver cell necrosis, microabcesses with an accumulation of neutrophils, regenerative activity in the form of multicellular liver plates, and focal nodule formation during the neonatal period [134]. Nodular clusters of altered hepatocytes that lack α_1-AT immunoreactivity are also found during the neonatal period. With aging, there is a decrease in the number of hepatocytes containing α_1-ATZ globules; there is also an increase in the number of nodular aggregates of α_1-AT-negative hepatocytes and the development of perisinusoidal fibrosis [134]. Within 6 weeks, there are dysplastic changes in these aggregates. Adenoma occurs within 1 year, and invasive hepatocellular carcinoma occurs between 1 and 2 years of age [135]. The histopathology of α_1-ATZ transgenic mice is remarkably similar to that of hepatitis B virus surface antigen in transgenic mice and is particularly interesting because hepatitis B virus is retained in the ER or the ER–Golgi intermediate compartment of hepatocytes, often called *ground-glass hepatocytes* [136]. It is still unclear why liver injury in the transgenic mouse model of α_1-AT deficiency is somewhat milder and less fibrogenic than that in children with α_1-AT deficiency-associated liver disease. It is possible that strain-specific factors condition the response to injury, just as there are apparently host-specific factors that affect the response to injury in α_1-AT-deficient infants [117].

A series of studies showing the presence of hepatic mitochondrial injury in α_1-AT deficiency [137] have raised the possibility that liver damage is mediated by oxidative mechanisms. Mitochondrial damage was evident in both cell line and transgenic mouse models of α_1-AT deficiency including mitochondrial depolarization and activation of caspase 3. Treatment of the PIZ mouse model with cyclosporin A, an inhibitor of mitochondrial depolarization, resulted in less histologic damage and complete reversal of mortality associated with the experimental stress of starvation [137].

Rudnick et al. examined the proliferation of hepatocytes in the PIZ mouse model [138], and the results have led to a new theory for the mechanism by which α_1-AT deficiency is predisposed to hepatocellular carcinoma. This study showed that there was increased hepatocellular proliferation in the liver at baseline. The increase was 5–10-fold above that in controls and highly significant statistically; it represented a relatively low number of BrdU-positive hepatocytes (2–3% detected over 72 hours of continuous labeling). These data indicate that liver injury in the mouse model is relatively mild and

appropriately corresponds to the smoldering and slowly progressing liver disease seen in most α_1-AT-deficient patients. Four other important observations were made. First, the increase in proliferation was proportional to the number of hepatocytes with globules containing the retained α_1-ATZ. This suggested that the globule-containing hepatocytes were producing a regenerative signal or signals. Second, the proliferating hepatocytes were almost entirely the ones devoid of globules. This suggested that retention of α_1-ATZ inhibits cell proliferation and that cells with a lesser accumulation of α_1-ATZ have a selective proliferative advantage in the damaged liver. Third, both globule-containing and globule-devoid hepatocytes proliferated when the PIZ mice were subjected to partial hepatectomy. This suggested that the block in proliferation of globule-containing hepatocytes is relative; that is, that they would proliferate if the stimulus were as powerful as the one generated after partial hepatectomy. Fourth, although globule-containing hepatocytes were more likely than globule-devoid hepatocytes to be undergoing cell death [139] there were still many globule-containing hepatocytes in the liver of α_1-AT-deficient patients that had not undergone death. This suggested that the globule-containing hepatocytes were "sick but not dead."

These observations constitute the basis for a new paradigm for the pathogenesis of hepatic cancer in α_1-AT deficiency and, perhaps, other chronic liver diseases. Globule-devoid hepatocytes, which are probably progenitors or at least young cells with less time to accumulate the mutant protein, have a selective proliferative advantage in the liver of the deficient individual. They are chronically stimulated in "trans" by signals that are generated by globule-containing hepatocytes that are "sick but not dead." The cancer-prone state is then engendered by having cells that are unable to die at the appropriate time and cells that are chronically dividing in the inflamed milieu. This paradigm is consistent with what has been found in the liver of the Z#2 mouse model of α_1-AT deficiency [135]. Most of the liver (>90%) becomes α_1-AT-negative as the mouse ages. This probably represents the selective proliferation of the globule-devoid hepatocytes, the progenitor cells. Adenomas and then carcinomas arise in these regions in more than 80% of the mice. This paradigm also appears to apply to the predilection for hepatic cancer in several other forms of chronic liver disease [140]. The origin of the globule-devoid hepatocytes has not been determined but these cells are known to have a lesser proportion of polymerized/aggregated α_1-ATZ than the globule-containing hepatocytes [141]. Therefore we have speculated that these cells are younger and engendered with a selective proliferative advantage when in the presence of the globule-containing hepatocytes.

Diagnosis

The diagnosis of α_1-AT deficiency is established by means of serum α_1-AT phenotype determination in isoelectric focusing or by means of agarose electrophoresis at acid pH. Serum concentrations can be used for screening, with follow-up PI typing of any values below normal (85–215 mg/dL). A retrospective study of all pediatric patients who had both serum concentrations and PI typing done at one center indicated that the serum concentration determination had a positive predictive value of 94% and a negative predictive value of 100% for homozygous α_1-AT deficiency [142]. However, because of the inherent limitations of retrospectively defining a patient population for the analysis, the results of the study are not necessarily applicable to each diagnostic situation that might be encountered. It is wise to get a phenotype together with the serum level in most cases of neonatal hepatitis or unexplained chronic liver disease in older children, adolescents, and adults. Serum concentrations of α_1-AT may be helpful, when used with the phenotype, to differentiate persons homozygous for the Z allele from SZ compound heterozygotes, both of whom may develop liver disease. In some cases, phenotype determinations of parents and other relatives are necessary to insure the distinction between ZZ and SZ allotypes, a distinction important for genetic counseling. Serum concentrations of α_1-AT are occasionally misleading. For example, serum α_1-AT concentrations may increase during the host response to inflammation, even in homozygous PIZZ individuals, and give a falsely reassuring impression.

The distinctive histologic feature of homozygous PIZZ α_1-AT deficiency, PAS-positive, diastase-resistant globules in the ER of hepatocytes, substantiates the diagnosis (Fig. 31.6). The presence of these inclusions should not

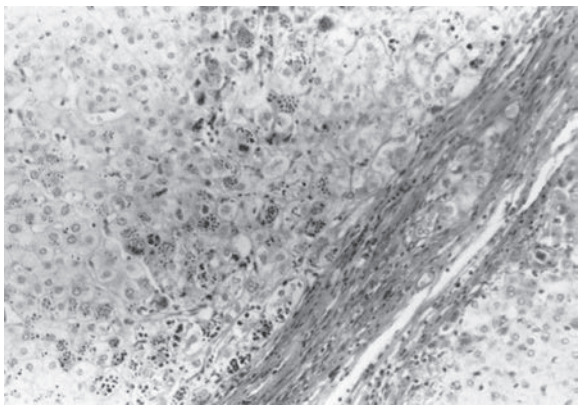

Figure 31.6 Histologic appearance of liver biopsy specimen of a patient with homozygous PIZZ α_1-antitrypsin deficiency. Micrograph shows periodic acid–Schiff (PAS)-positive, diastase-resistant globules in hepatocytes, especially periportal ones, adjacent to a broad band of fibrous tissue. PAS, diastase, original ×40. (Courtesy of Dr C. Coffin, St Louis, MO.)

be interpreted as confirming the diagnosis of α_1-AT deficiency. Similar structures are occasionally found in PIMM individuals with other liver diseases [143]. The inclusions are eosinophilic, round to oval, and 1–40 μm in diameter. They are most prominent in periportal hepatocytes but may also be present in Kupffer cells and cells of biliary ductular lineage [144]. There may be evidence of variable degrees of hepatocellular necrosis, inflammatory cell infiltration, periportal fibrosis, or cirrhosis. There may also be evidence of bile duct epithelial cell destruction, and occasionally there is a paucity of intrahepatic bile ducts.

Treatment

The most important principle in the treatment of patients with α_1-AT deficiency is avoidance of cigarette smoking, which markedly accelerates the destructive lung disease associated with α_1-AT deficiency, reduces the quality of life, and significantly shortens the longevity of these patients [2].

There is no specific therapy for α_1-AT deficiency-associated liver disease. Therefore, clinical care largely involves supportive management of symptoms caused by liver dysfunction and the prevention of complications. Progressive liver dysfunction and failure in children have been managed with orthotopic liver transplantation, with survival rates approaching 90% at 1 year and 80% at 5 years [145]. Approximately 70–80 patients with this deficiency undergo liver transplantation in the United States annually. Nevertheless, a number of PIZZ individuals with severe liver disease, even cirrhosis or portal hypertension, may have a relatively low rate of disease progression and lead a relatively normal life for extended periods. With the availability of living related donor transplantation techniques, it may be possible to treat these patients expectantly for some time. Children with α_1-AT deficiency, mild liver dysfunction (elevated transaminase levels or hepatomegaly), and without functional impairment may never need liver transplantation.

Numerous studies have shown that a class of compounds called chemical chaperones can reverse the cellular mislocalization or misfolding of mutant plasma membrane, and lysosomal, nuclear, and cytoplasmic proteins [146]. These compounds include glycerol, trimethylamine oxide, deuterated water, and 4-phenylbutyric acid (PBA). This author and his colleagues have found that glycerol and PBA mediate a marked increase in the secretion of α_1-ATZ in a model cell culture system [147]. Oral administration of PBA was also well tolerated by PIZ mice (transgenic for the human α_1-ATZ gene) and consistently mediated an increase in blood levels of human α_1-AT, reaching 20–50% of the levels present in PIM mice and healthy humans. However, in a pilot study in patients with α_1-AT deficiency, PBA did not mediate an increase in serum levels of α_1-AT [148]. However it was not clear whether this was because the patients could not tolerate the doses necessary to have chemical chaperone activity. It is important to note that the mechanism of action of chemical chaperones has not been elucidated, but in some cases it may involve histone deacetylase inhibitory activity that mimics the changes in the transcriptional program of the cell during stress states [146].

Recently the emergence of drugs that enhance the function of endogenous degradation pathways [149–152] has raised the possibility that these drugs might be considered in patients with AT deficiency. Drugs that enhance proteasomal activity [149] or the ERAD pathway [150] should certainly be further investigated. By enhancing the degradation of soluble forms of mutant α_1-ATZ this strategy may reduce the load of α_1-ATZ in the ER in such a way that it prevents the high levels of accumulation that drive the formation of insoluble polymers and aggregates. Drugs that enhance autophagy would also be very appealing in that they would target the insoluble forms of α_1-ATZ that appear to be integral to hepatic fibrosis and carcinogenesis. Several US Food and Drug Administration (FDA)-approved drugs that have recently been shown to enhance the autophagic disposal of aggregation-prone proteins that cause neurodegenerative diseases [151,152] are currently being investigated in cell line and mouse models of α_1-AT deficiency. Ultimately it would be ideal to investigate these drugs together with small molecules that alter the conformation of the mutant α_1-ATZ in such a way that insoluble α_1-ATZ is destroyed in the liver and soluble α_1-ATZ is secreted, thereby preventing both liver and lung disease in α_1-AT deficiency. The recently described domain swapping mechanism for the polymerization of α_1-ATZ [100] provides a basis for believing that only relatively minor changes in the kinetics of folding and degradation would be needed to facilitate secretion of the soluble forms of α_1-ATZ.

Patients with COPD associated with α_1-AT deficiency have undergone replacement therapy with α_1-AT purified from recombinant plasma and administered intravenously or by means of intratracheal aerosol [34]. This therapy is associated with improvement in α_1-AT serum concentrations and in α_1-AT and neutrophil elastase inhibitory capacity in bronchoalveolar lavage fluid without significant side effects. Although results of initial studies have suggested that there is a slower decline in forced expiratory volume in patients undergoing replacement therapy, this occurred only in a subgroup of patients, and the study was not randomized [153]. It is not clear why there has not been a more impressive clinical response to date. This could mean that therapy is instiuted only for patients with established and

progressive COPD, too late in the course for clinical efficacy. It is also possible that replacement therapy is unable to reverse unregulated longstanding pericellular proteolysis [154] or even that the loss-of-function mechanism does not completely account for the lung damage. Protein replacement therapy is not used for patients with liver disease because there is no information to support the notion that deficient serum levels of α_1-AT are mechanistically related to liver injury.

A number of patients with severe emphysema from α_1-AT deficiency have undergone lung transplantation in the last 10 years. The latest data from the St Louis International Lung Transplantation Registry show that 91 patients with emphysema and α_1-AT deficiency had undergone single or bilateral lung transplantation by 1993. The actuarial survival rate among patients in this category who underwent transplantation between 1987 and 1994 was approximately 50% for 5 years. Lung function and exercise tolerance were significantly improved [155].

Replacement of α_1-AT by means of somatic gene therapy has been discussed in the literature [34]. This strategy is potentially less expensive than replacement therapy with purified protein and can alleviate the need for intravenous or inhalation therapy. Again, this form of therapy will be useful only in ameliorating COPD because liver disease associated with α_1-AT deficiency is not caused by deficient levels of α_1-AT in the serum or tissue. Of course, it would be helpful to know whether replacement therapy with purified α_1-AT, as it is currently applied, is effective in ameliorating COPD in this deficiency before embarking on clinical trials involving gene therapy. There are still major issues that must be addressed before gene therapy becomes a realistic alternative [156]. Several novel types of gene therapy – such as repair of mRNA by means of trans-splicing ribozymes and chimeric RNA/DNA oligonucleotides, triplex-forming oligonucleotides, small fragment homologous replacement, or RNA silencing [157] – are theoretically attractive alternative strategies for the management of liver disease in α_1-AT deficiency because they would prevent the synthesis of mutant α_1-ATZ protein and ER retention.

Studies have shown that transplanted hepatocytes can repopulate the diseased liver in several mouse models, including a mouse model of a childhood metabolic liver disease called hereditary tyrosinemia [158,159]. Replication of the transplanted cells occurs only when there is injury or regeneration in the liver because the transplanted hepatocytes have a selective proliferative advantage in the presence of the hepatocyte that are damaged by the metabolic abnormality [159]. These results provide evidence that it may be possible to use hepatocyte transplantation techniques to manage hereditary tyrosinemia and, perhaps, other metabolic liver diseases in which the defect is cell autonomous. For example, α_1-AT deficiency involves a cell-autonomous defect and we already know that the globule-devoid hepatocytes have a selective proliferative advantage [138] and thus it would be an excellent candidate for this strategy.

A recent study described a novel approach that depends on the latest advances in viral-mediated gene transfer and gene repair technology together with the selective proliferative advantage of relatively healthy hepatocytes on a background of damaged hepatocytes to correct a mouse metabolic defect [160]. Adeno-associated virus 8 was used to carry a wild-type sequence for repairing the mutant gene in a mouse model of hereditary tryrosinemia. With correction of the metabolic defect the transduced hepatocytes had a selective proliferative advantage. This approach would also be applicable for α_1-AT deficiency.

Genetic counseling

Restriction fragment length polymorphisms detected with synthetic oligonucleotide probes [161] and family studies [162] allow prenatal diagnosis of α_1-AT deficiency. Nevertheless, it is not clear how prenatal diagnosis of this deficiency should be used and how families should be counseled about the diagnosis. The data reviewed earlier indicate that 85–90% of individuals with α_1-AT deficiency do not have evidence of liver disease at 18 years of age and that nonsmoking PIZZ individuals may not develop emphysema or even pulmonary function abnormalities until 60–70 years of age. These data could support a counseling strategy in which amniocentesis and abortion are discouraged. The only other data on this subject come from two studies with conflicting results. Results of one study suggested that the incidence of significant liver disease among siblings at risk is 78% [162]. The results of the other suggested that the incidence is 21% [11]. These studies, however, were retrospective and heavily influenced by bias in ascertainment of patients. The issue will not be resolved until it is studied prospectively, as, for example, in the Swedish population [1].

Population screening

Results of several studies have suggested that population screening for α_1-AT deficiency would be efficacious. First, there is evidence that knowledge of and counseling about the consequences of α_1-AT deficiency are associated with a reduced rate of smoking among affected adolescents [163]. Second, although there was initially some evidence for adverse psychologic effects, more recent results have indicated that there are no significant negative

psychosocial consequences in adults who were informed about their deficiency in a follow-up study after neonatal screening in Sweden [163]. These data should give new momentum to reconsider screening programs for α_1-AT deficiency.

This is the original description of a defect in the degradation of α_1-ATZ in the ER that predisposes a subgroup of persons with α_1-AT deficiency to liver disease.

Yamasaki M, Li W, Johnson DJD, Huntington JA. Crystal structure of a stable dimer reveals the molecular basis of serpin polymerization. *Nature* 2008;455:1255–8.
This study describes the structure of a stable serpin dimer and provides evidence that polymerization of serpins involves a domain swapping mechanism. The mutation that characterizes the disease-associated Z allele lies within the domain that is swapped. This new model for polymerization of α_1-ATZ has enormous implications for the pathobiology of liver disease.

Multiple choice questions

31.1 The histologic hallmark of the liver disease associated with α_1-AT deficiency is which of the following?

a Steatosis.
b Congo red-positive amyloid fibrils in hepatic macrophages.
c PAS-positive, diastase-resistant globules in hepatocytes.
d Peroxisomal proliferation.

31.2 Alternative strategies for treatment of severe liver disease due to α_1-AT deficiency include which of the following?

a Liver transplantation.
b Monthly infusions of purified α_1-AT.
c Sodium benzoate to scavenge ammonia.
d *N*-acetylcysteine.

Answers to the multiple choice questions can be found in the Appendix at the end of the book.

These multiple choice questions are also available for you to complete online.

CHAPTER 32

Nonalcoholic Fatty Liver Disease

Stephen H. Caldwell, Curtis K. Argo & Abdullah M. S. Al-Osaimi

Division of Gastroenterology and Hepatology, Department of Internal Medicine, University of Virginia Health System, Charlottesville, VA, USA

Key concepts

- Nonalcoholic fatty liver disease (NAFLD) is one of the most common liver disorders worldwide. It is defined as liver fat exceeding 5–10% by weight and exists as a spectrum from steatosis (which is usually stable) to steatohepatitis or nonalcoholic steatohepatitis (NASH) (cellular ballooning, necroapoptosis, inflammation, and fibrosis) which progresses to cirrhosis in 15–20%. Progression is often associated with lower (even normal) aminotransferases and loss of steatosis – advanced cases may present as "cryptogenic cirrhosis." Cirrhotic complications and hepatocellular cancer occur at a slightly slower rate of progression compared to hepatitis C cirrhosis but NASH-related cirrhosis is an increasing indication for liver transplantation.
- Obesity with insulin resistance, type 2 diabetes, hyperlipidemia, and metabolic syndrome are major risk factors. Nonobese patients with fatty liver often have central obesity, insulin resistance, and physical deconditioning on exercise testing ("metabolic obesity") although some may have primary lipoprotein disorders or possibly toxin exposure (toxin-associated steatohepatitis). Ethnic variation in NAFLD is due to the *PNPLA3* (patatin-like phospholipase 3) gene, which influences the relation of steatosis to obesity and insulin resistance.
- Hepatic fat accumulation results from de novo lipogenesis from carbohydrate substrate, uptake of circulating fatty acids from lipolysis in adipose tissue, and uptake of very low-density lipoprotein-derived low-density lipoprotein remnants or circulating dietary chylomicron remnants. Lipid peroxidation, a branching chain reaction attack mediated by free radicals, is the most consistent mechanistic finding in NASH. Malondialdehyde and lipofuschin are common end products. Excessive free fatty acids alter permeability of mitochondria (cytochrome c) and lipophagic lysosomes (cathepsin), both of which result in the activation of apoptotic cell death pathways. Disturbed cytoskeleton metabolism (keratin 18 degradation) probably contributes to cellular ballooning and necrotic cell death. Oxidative injury to the phospholipid monolayer of small fat droplets (and associated PAT proteins) contributes to endoplasmic reticulum injury and likely impairs the disposal of fatty acids which might otherwise proceed through incorporation into fat droplet triglyceride.
- The diagnosis of steatosis can be made noninvasively by conventional imaging such as ultrasound, computed tomography or magnetic resonance (MR) imaging, although quantification and accuracy at levels less than 20% triglyceride require MR spectroscopy (or modifications of conventional MR). The diagnosis of NASH requires an adequate biopsy sample, which also allows determination of fibrosis stage. Noninvasive markers of NASH are emerging and may soon provide alternatives, especially as means of following progression or response to therapy. These include measures of elasticity and blood markers of collagen metabolism and keratin fragments as indices of cell death.
- Survival in NAFLD is influenced by its association with the metabolic syndrome. The risk of liver-related death is increased, as is the risk of cardiovascular disease and non-liver cancers. The dominant course in a given patient is difficult to predict. This constellation of abnormalities presents the clinician with significant challenges. For example, conventional therapies for type 2 diabetes (angiotensin-converting enzyme inhibitors or aspirin) may be problematic in patients with portal hypertension due to fluid retention. Anticoagulant therapy in patients with coronary disease (stents), metabolic syndrome, and underlying cirrhosis is another challenging area.
- Exercise and dietary changes are key elements of treatment and may result in histologic improvement. Conditioning exercise with (or without) weight loss can reduce liver fat. Alterations in dietary composition (type of sweeteners and polyunsaturated fats) also influence disease expression. Voluntary adoption of such lifestyle changes can improve histology and introduces confounding variables in pharmacologic studies. This requires consideration of other end-points in treatment trials, including anthropometric indices and measures of insulin signaling, hepatic fat, physical conditioning, and systemic markers of fibrosis and cell death.
- A number of randomized and controlled pharmacologic trials are now available. From these, the thiazolidinediones can reduce steatosis, inflammation, and ballooning but cause weight gain, carry possible vascular risk with some agents, and have less effect on fibrosis. Higher dose vitamin E, possibly in combination with cytoprotective agents, appears promising but requires further study and carries concerns of long-term safety. Statins and fibrates appear ineffective but further study of these agents is needed. As an alternative in some patients, bariatric surgery improves liver histology along with parameters of the metabolic syndrome but carries significant risk if cirrhosis is already present. Long-term follow-up suggests a slight increase in fibrosis can also be seen.

Schiff's Diseases of the Liver, Eleventh Edition. Edited by Eugene R. Schiff, Willis C. Maddrey and Michael F. Sorrell.
© 2012 John Wiley & Sons, Ltd. Published 2012 by John Wiley & Sons, Ltd.

Nonalcoholic fatty liver disease (NAFLD) is an umbrella term that includes a range of conditions including nonalcoholic steatohepatitis (NASH); both of these terms were coined two or more decades ago [1,2]. This disease is now recognized worldwide as a potentially serious condition, which can progress to cirrhosis, liver failure, and hepatocellular cancer [3]. The spectrum of severity from very mild to very severe reflects the normal role of the liver in systemic lipid metabolism – capable of lipid synthesis from carbohydrate substrates, fat storage, and importantly lipoprotein secretion, but also subject to significant lipid-induced injury.

Terminology and diagnostic criteria

Although criteria and the name itself continue to be debated, the term NASH is widely accepted as the more severe form of NAFLD (Box 32.1) [4]. NAFLD or liver steatosis is technically defined as fat exceeding 5–10% of the liver *by weight* although it is usually estimated as fat identifiable in more than 5–10% of hepatocytes by light microscopy [5]. While NASH has become a well-known term, fatty liver without evidence of progressive injury or significant ethanol exposure (see below) is less clear and it is variably referred to as simple steatosis, pure fatty liver, or nonalcoholic fatty liver (NAFL) (Fig. 32.1). In this chapter, we have elected to use the term non-NASH fatty liver (NNFL) for this condition, which carries a better prognosis than NASH [6]. The diagnosis of either NASH or NNFL is a clear example of a "clinicopathologic" diagnosis (dependent on both clinical and histologic parameters).

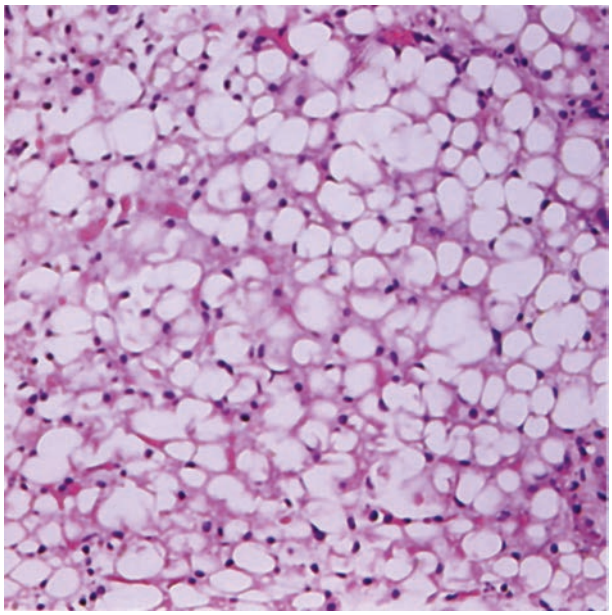

Figure 32.1 Non-NASH fatty liver (NNFL). The patient is a 47-year-old female with mild obesity, hepatomegaly, minimal past ethanol exposure, and an idiopathic, neurodegenerative disease. The biopsy showed only minimal inflammation and no fibrosis. No inciting agents were identified to explain the liver condition. NNFL is variably referred to as simple steatosis, pure steatosis, and NAFL in publications. Hematoxylin and eosin (H&E), original ×200.

Box 32.1 Definitions and terms.

- *Nonalcoholic fatty liver disease (NAFLD):* indicates the presence of fatty infiltration of the liver, defined as fat exceeding 5–10% of weight and frequently taken as >5–10% macrosteatotic hepatocytes in biopsy specimens. Microsteatosis is an underappreciated aspect because of limitations of routine staining techniques. The term NAFLD includes the term NASH
- *Nonalcoholic steatohepatitis (NASH):* a type of NAFLD with inflammation, ballooned hepatocytes, necroapoptosis (cell death), and fibrosis, usually beginning around the central vein, which may progress to cirrhosis
- *Non-NASH fatty liver (NNFL):* nonalcoholic fatty infiltration with no or minimal inflammation, and no fibrosis. We use this term to include what others have referred to as simple steatosis, nonalcoholic fatty liver (NAFL), pure steatosis, and bland steatosis. This form of fatty liver is more stable over time
- *"Primary" NAFLD or NASH:* a term occasionally encountered in the literature. It usually indicates typical NAFLD or NASH associated with central obesity and often type 2 diabetes mellitus but without a specific, additional etiology. The likelihood that many cases of "secondary" NAFLD or NASH represent unrecognized or exacerbated "primary" NAFLD or NASH makes the term less useful
- *"Secondary" NAFLD or NASH:* NAFLD or NASH associated with a specific, nonalcohol-related problem such as a drug- or toxin-induced cause
- *Toxin-associated steatohepatitis (TASH):* NAFLD or NASH associated with a specific toxin or medication. Toxins implicated to date include petrochemical exposure in the oil industry and severe vinyl chloride exposure. Medications that have been associated with fatty liver include methotrexate and tamoxifen
- *"Presumed" NASH or NAFLD:* a number of epidemiologic studies have utilized a presumptive diagnosis of NAFLD or NASH based on abnormal liver enzymes, negative viral studies, and echogenic or 'bright' liver on ultrasonography consistent with fatty infiltration

Clinical criteria of nonalcoholic steatohepatitis

By definition, the criteria for NASH require the presence of steatosis and cell injury and the exclusion of alcohol as an etiology. The acceptable level of alcohol consumption is variable but can be conservatively taken as daily alcohol intake not exceeding 20 g/day in males and 10 g/day in females – levels below the risk level (30 g/day in males and 20 g/day in females) [7–9]. These cutoffs leave an unresolved gray area where a patient prone to NASH may consume alcohol close to the threshold or have significant past exposure. These issues are further discussed below.

Histologic criteria of nonalcoholic steatohepatitis

The term NASH indicates more severe cellular injury compared with NNFL. Important histologic features of NASH include lobular and/or portal inflammation, ballooned hepatocytes often containing Mallory–Denk bodies, and fibrosis (usually sinusoidal in a pericentral vein or zone 3 distribution) (Figs 32.2 and 32.3) [10,11]. Fat droplets are typically mixed macro-, medio-, and microvesicular (Fig. 32.4). Other characteristic findings include foci of necrosis, occasional apoptotic bodies, lipogranulomas, and glycogenated nuclei. Age-related patterns of injury are reported: a portal-dominant pattern is characteristic of pediatric NASH [12]. Substantial concordance between observers is evident for the extent of steatosis, and the distribution and severity of fibrosis [13]. Balloon degeneration has been more controversial but recent characterization of these cells as keratin deficient and containing small fat droplets associated with dilated endoplasmic reticulum (ER) may lead to refined clinical characterization [14,15]. The degree of fibrosis has been organized into a staging system [16]. Other refinements in histology include the NASH activity index (NAI) and NAFLD activity score (NAS) by Kleiner et al. (see below).

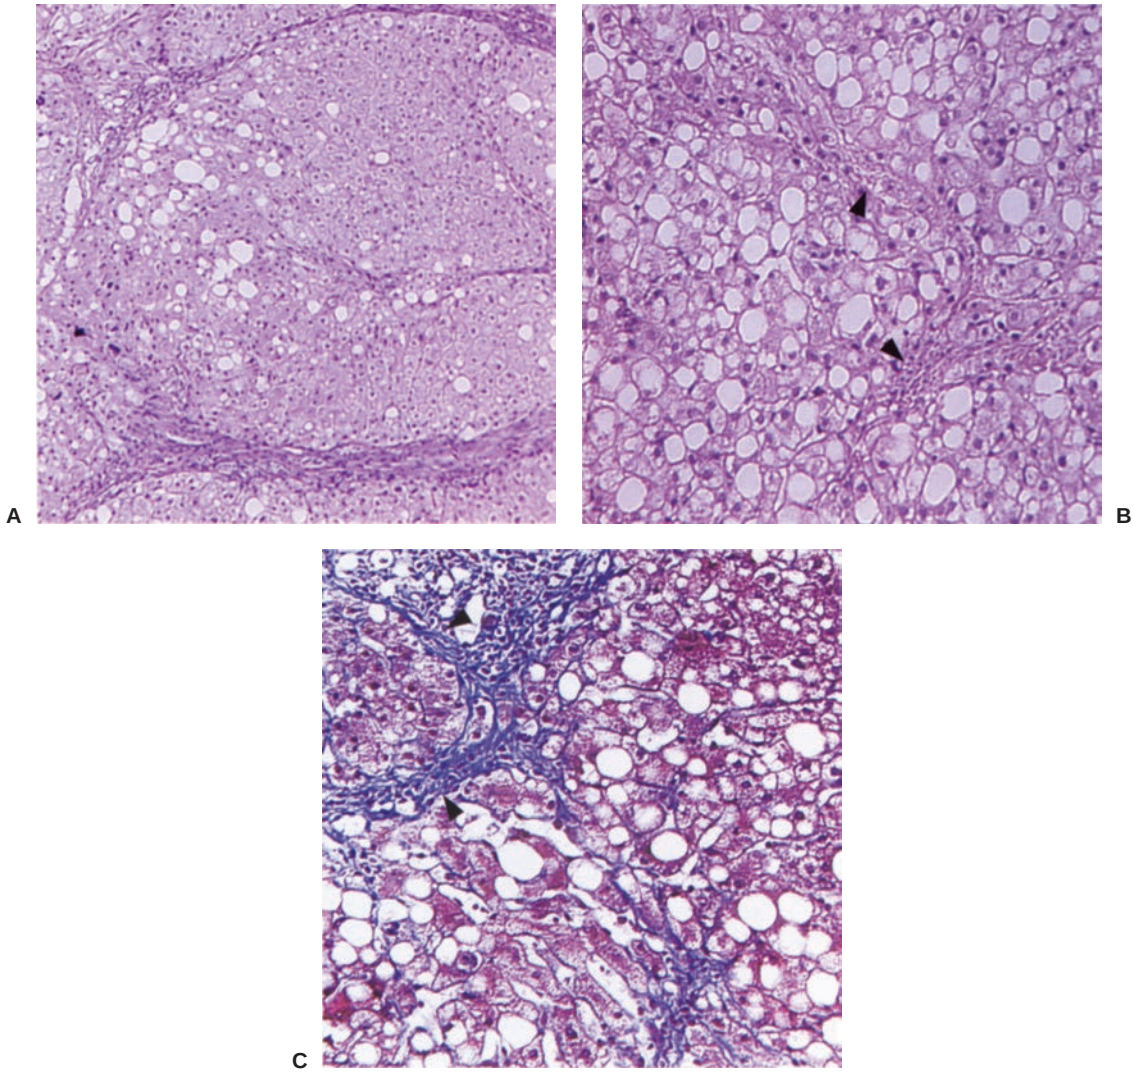

Figure 32.2 (A) Nonalcoholic steatohepatitis (NASH) with cirrhosis from a 65-year-old female with moderate obesity and type 2 diabetes. She did not have complications of portal hypertension. The presence of macrovesicular steatosis, inflammation, and cirrhosis allowed the diagnosis of NASH with cirrhosis (stage 4). H&E, original ×100. (B) Early stage 3 (bridging fibrosis) with H&E stain (original ×200). (C) The same biopsy accentuating the presence of bridging with a Masson trichrome stain (original ×200). The latter two specimens are from the first patient's 40-year-old son who had mild liver enzyme abnormalities and mild (mostly truncal) obesity (BMI = 30 kg/m^2) without diabetes. NASH with fibrosis, mildly apparent on the H&E stain (B), is accentuated with trichrome staining (C) which demonstrated bridging consistent with stage 3. These slides also illustrate a familial pattern seen in about 20% of patients.

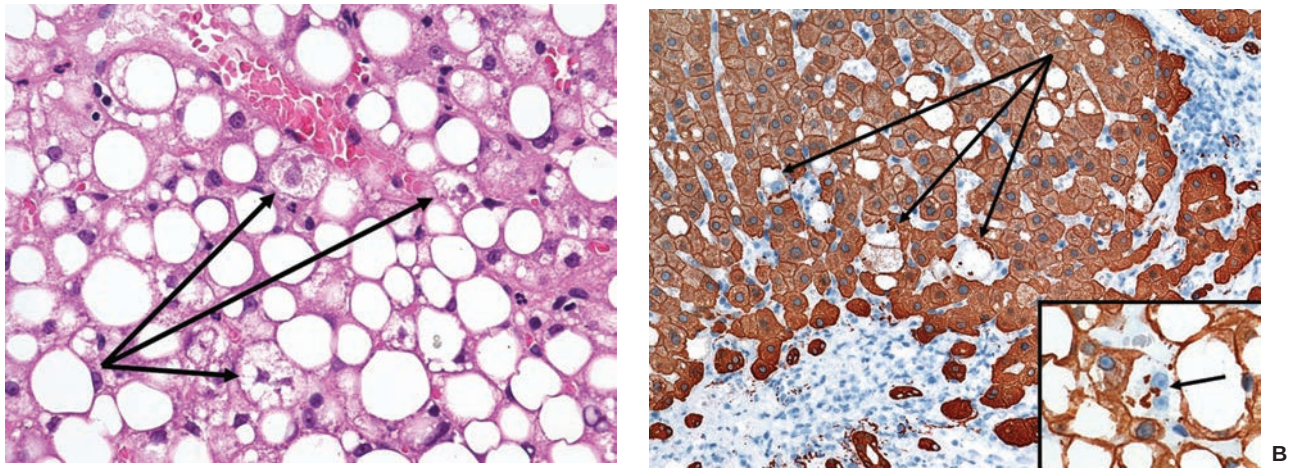

Figure 32.3 Hepatocellular ballooning and Mallory–Denk bodies. (A) The arrows indicate ballooned hepatocytes with Mallory–Denk bodies evident as perinuclear material in two of the cells by H&E staining. (B) With antikeratin8/18 immunohistochemistry, ballooned hepatocytes are "empty" of keratin (arrows) but the Mallory–Denk bodies are accentuated as dark brown-staining masses. (Courtesy of Dr Carolyn Lackner.)

Presumed nonalcoholic fatty liver disease

In epidemiologic studies, the diagnosis of "presumed NAFLD" may be made on the basis of noninvasive testing. In general, such studies have utilized abnormal transaminases in the absence of other known liver disease and/or liver ultrasound to make the diagnosis of fatty liver. The relationship between the diagnosis of presumed NAFLD and the histologic activity, stage, and prognosis is unreliable. Indeed, this constitutes one of the major limitations of these studies.

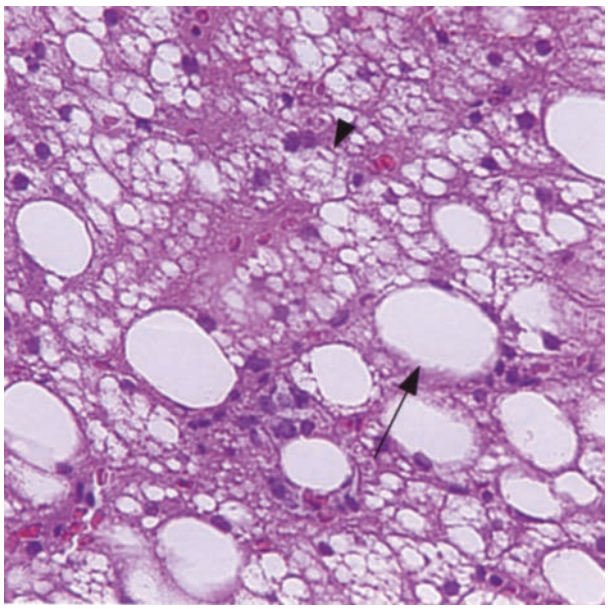

Figure 32.4 Micro- and macrovesicular steatosis in nonalcoholic steatohepatitis. The arrowhead indicates a cell with small droplets of fat in addition to the more apparent and typical large droplet, macrovesicular, steatosis (arrow). Special stains or fixation techniques, such as osmium tetroxide fixation (not shown), can be used to accentuate the often overlooked microvesicular component. H&E, original ×400.

Cryptogenic cirrhosis

While diverse causes are recognized, NASH can progress to a late stage with loss of steatosis which is sometimes called "cryptogenic cirrhosis" (Fig. 32.5) [17–19]. Typical patients are 60 years old with only mild liver enzyme elevation and more often are or were obese and diabetic compared with control groups (Fig. 32.6) [20–29]. A *history* of obesity must be specifically sought due to nutritional changes characteristic of advancing cirrhosis – especially loss of body fat [30]. Histologically, residual cellular ballooning and glycogenated nuclei serve as clues to prior NASH from studies in patients undergoing serial biopsy [31]. Loss of steatosis may be due to altered blood flow, decreased sinusoidal permeability, and impaired lipoprotein delivery as the liver becomes fibrotic or to more fundamental changes in hepatocyte metabolism related to the proliferation of progenitor cells [32–34]. In a series of patients undergoing transplantation for cryptogenic cirrhosis, definitive features of NASH were evident in 17 of 30 patients and minor features were seen in an additional ten patients [35]. The incidence of steatosis and steatohepatitis after transplantation for cryptogenic cirrhosis further supports this relationship [36–38]. A proposed classification is shown in Box 32.2.

Focal steatosis and focal fat sparing

In a series of patients with fatty liver detected radiographically, focal steatosis was evident in approximately 15% and focal sparing (usually of the caudate lobe) was seen in 9% [39]. Variation in blood flow is thought to explain both and altered insulin exposure is a suspected factor [40,41].

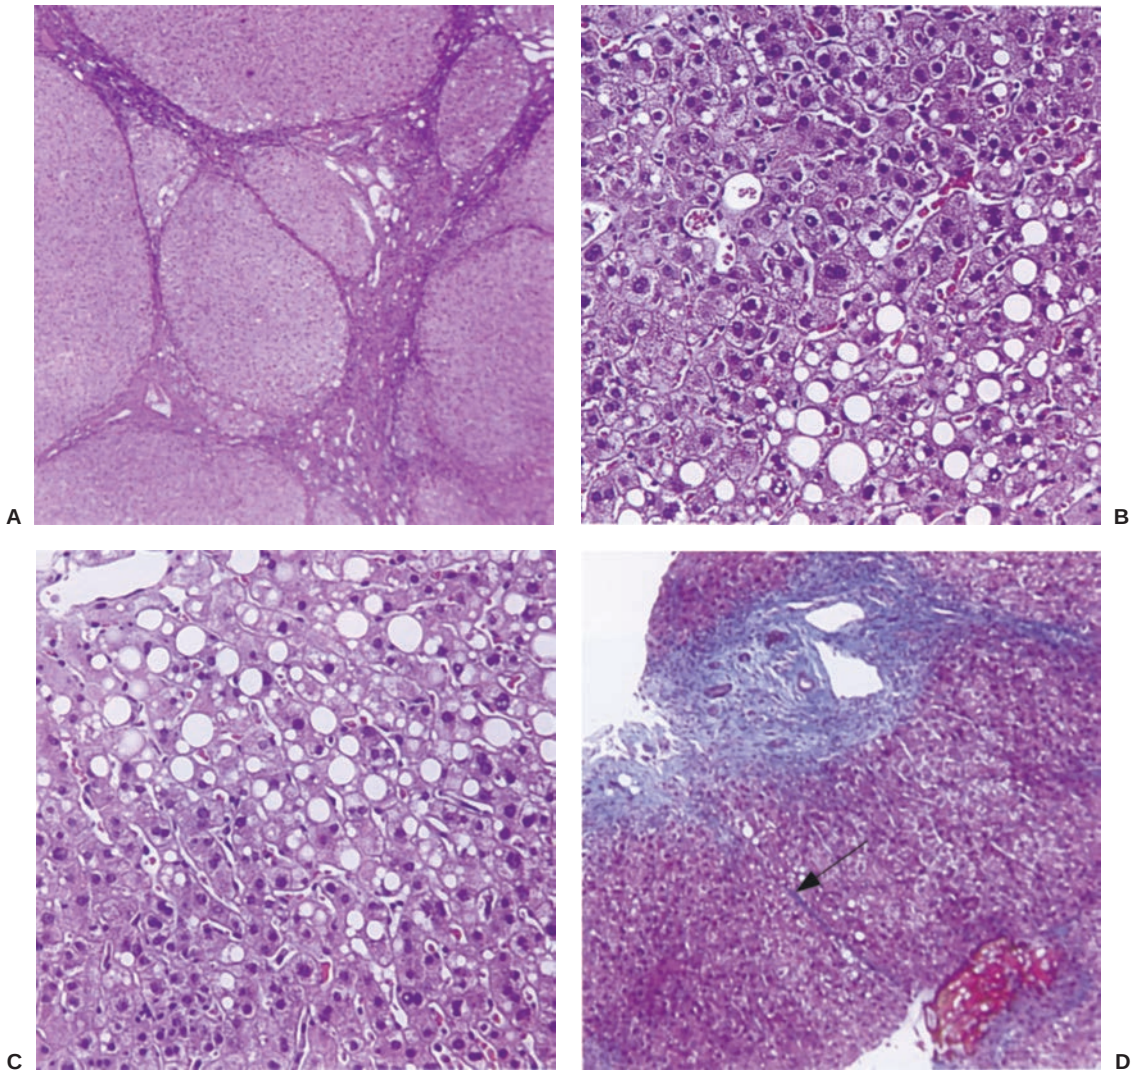

Figure 32.5 Development of nonalcoholic steatohepatitis following transplantation for cryptogenic cirrhosis. (A) Explanted liver from an obese, diabetic male showing "bland" cirrhosis. H&E, original ×40. (B) Two years later a repeat biopsy for abnormal liver enzymes revealed steatosis. H&E, original ×200. (C) The steatosis was persistent and associated with mild inflammation at 3 years. H&E, original ×200. (D) Four years after transplantation the patient developed ascites and a repeat biopsy showed early cirrhosis with bridging and diminished fatty infiltration. The arrow indicates a fibrous band. H&E, original ×100.

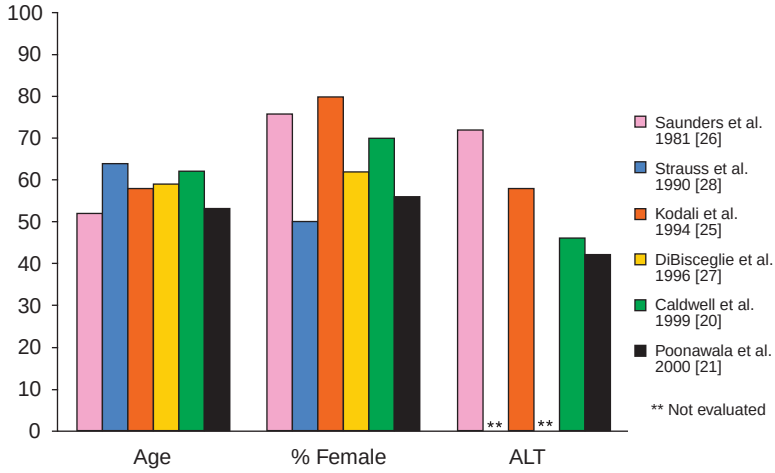

Figure 32.6 Past series of cryptogenic cirrhosis patients. Previous case series have shown a predominance of females, onset in sixth or seventh decade, and mildly abnormal alanine aminotransferase (ALT) levels. The *y* axis represents age in years, percent females, or mean serum ALT. Series are included in the references cited in the text.

Box 32.2 Proposed classification of cryptogenic cirrhosis.

- Class 1: Cirrhosis with features of steatohepatitis
  - 1a: NASH with cirrhosis
  - 1b: Cirrhosis with features of NASH
  - 1c: Bland cirrhosis with NASH risk factors (obesity, hyperlipidemia, diabetes)
- Class 2: Cirrhosis with features of autoimmune disease
- Class 3: Cirrhosis with features of viral hepatitis
- Class 4: Cirrhosis with features of alcoholic liver disease (i.e., history of lifelong significant alcohol consumption)
- Class 5: Cirrhosis with features of biliary disease
- Class 6: Bland cirrhosis with no specific histologic or historical diagnostic features

Adapted from Argo and Caldwell [64] and Caldwell [473].

Histologically, the lesions vary from simple steatosis to frank steatohepatitis.

Historical perspective

Early observations

A long recognized association between the liver and fat storage is revealed in the origin of the Latin word for liver *ficatum* and the corresponding modern Greek term *sycoti*, both of which derived from the common name for fattened animal livers, *iecur ficatum* and *hepar sykoton* (D. Tiniakou, personal communication). A scientific appreciation of fatty liver emerged in the nineteenth century when Virchow classified various types of fatty infiltration of the liver [42]. The color, shape, and firmness of fatty liver were described and fat globules were proven to be within hepatocytes [43]. Morgan, in the 1870s, described an association of fatty liver with obesity and overeating [44]. This was extended many years later by Zelman who reported liver fibrosis and cirrhosis in obese patients without significant alcohol consumption [45]. The concept resurfaced in the 1970s in patients who had undergone intestinal bypass for morbid obesity [46].

The ethanol conundrum

Cutoffs for classification as "*non*-alcoholic" versus "alcoholic" steatohepatitis (NASH versus ASH) remain unresolved. Clearly, there are patients with NASH and related cirrhosis without a history of ethanol exposure (teetotalers). Prior to this recognition, a common experience was nicely summarized by Ludwig in his original description of NASH [2]:

> . . . we have encountered patients who did not drink, who had not been subject to bypass surgery, and who had not taken drugs that may produce steatohepatitis, yet had in their liver biopsy specimens changes that were thought to be characteristic of alcoholic liver disease. In these instances, the biopsy evidence sometimes caused clinicians to persevere unduly in their attempts to wrench from the patient an admission of excessive alcohol or to obtain a confirmation of such habits from relatives of the patients. Thus, the misinterpretation of the biopsy in this poorly understood and hitherto unnamed condition caused embarrassment to the patient and physician.

Nonetheless, about 10% of patients classified as having NASH actually have had significant lifetime exposure to ethanol when a more structured history is obtained [47]. Intuitively, synergy between ASH and NASH seems likely because obesity is a risk for more severe alcohol-related liver disease [48]. However, studies suggest *moderate* consumption either reduces or does not worsen histology in NASH – an effect possibly mediated by changes in insulin signaling [49–51]. Conventional histologic features do not reliably distinguish ASH from NASH, with the exception of glycogenated nucleii (increased in NASH) [52]. Immunohistochemical stains may help but are not established [53]. Proposed laboratory tests have largely fallen short [54] although aminotransferase ratios may provide guidance: the aspartate aminotransferase (AST) to alanine aminotransferase (ALT) ratio is typically <1 in early or mild NASH, >1 and <2 in more severe NASH, and >2 in more severe ASH (see section below on laboratory findings). For these reasons, a gray area is likely to persist and a careful history remains the common means of assessing alcohol consumption.

Hepatogenous diabetes

Complicating the relationships between insulin resistance and NAFLD is the relationship between cirrhosis and diabetes referred to as "hepatogenous diabetes" [55]. A number of papers have established an increased prevalence of diabetes in cirrhosis of various etiologies [56]. Impaired insulin sensitivity is postulated to explain this [57]. The role of abnormal cirrhosis-related skeletal muscle metabolism has yet to be fully investigated [58].

Epidemiology and prevalence

Nonalcoholic fatty liver disease is one of the most common liver disorders [3,59–63]. The prevalence of NAFLD (including both NNFL and NASH) is as high as 38% depending on criteria and region studied [64,65]. In 150 consecutive patients with abnormal liver enzymes for at least 6 months, 42% had fatty liver while 15% had hepatitis C [66]. In 81 patients with abnormal liver enzymes and a negative serologic workup, 50% of the patients had steatosis and 32% had steatohepatitis [67].

Box 32.3 Conditions associated with nonalcoholic fatty liver.

Metabolic factors
- Metabolic syndrome:
  - Obesity (especially truncal or central obesity)
  - Type 2 diabetes mellitus or hyperinsulinemia
  - Hypertension
  - Hyperlipidemia (especially hypertriglyceridemia)
- Polycystic ovary disease

Genetic/metabolic conditions associated with fatty infiltration of the liver
- Lipodystrophies
- Mitochondrial diseases
- Weber–Christian disease
- Wilson disease

Toxin-associated steatohepatitis
- Medications:
  - Methotrexate
  - Amiodarone
  - Tamoxifen
  - Nucleoside analogs
- Work-related toxins:
  - Carbon tetrachloride
  - Percholorethylene
  - Ethyl bromide
  - Petrochemicals
  - Vinyl chloride

Parenteral nutrition and malnutrition
- Total parenteral nutrition
- Kwashiorkor
- Celiac disease

NAFLD accounts for about one third of cases of chronic liver disease in primary care [68]. Obesity, type 2 diabetes, and hyperlipidemia are the most constant conditions associated with steatosis and are predictors of more severe histologic disease [69,70]. An overview of conditions associated with NAFLD is shown in Box 32.3.

Obesity

There is a 4.6-fold increased risk of fatty liver in obese patients compared with nonobese patients by ultrasound imaging [8]. In an autopsy study, steatosis was found in approximately 70% of obese versus 35% of lean patients, and steatohepatitis was found in 18.5% of obese versus 2.7% of lean patients [71]. In a compilation of 12 studies of 1,620 patients undergoing bariatric surgery (body mass index (BMI) usually >35 kg/m^2), histology revealed steatosis (NNFL) in 85–90%, NASH in 25–30%, and unexpected cirrhosis in 1–2% (Fig. 32.7) [72]. In a series of consecutive obese patients with abnormal liver enzymes approximately 30% had at least septal fibrosis and 10% had cirrhosis [73]. However, the relationship between obesity and fatty liver is significantly influenced by both ethnicity and the degree of physical conditioning (see below).

Insulin resistance and type 2 diabetes mellitus

Insulin resistance is very common in NAFLD [74–76]. It can be demonstrated in major insulin targets including adipose tissue (persistent lipolysis), muscle (diminished glucose disposal), and liver (failure to suppress glucose release). The progression to overt diabetes depends on pancreatic islet cell vitality but it is thought that steatosis usually precedes this development in susceptible populations [77]. However, as with obesity, ethnicity significantly influences these relationships (see below). In general, it is estimated that up to 75% of type 2 diabetic patients have fatty infiltration [78,79]. Liver injury worsens with the degree of abnormal glucose metabolism, and the existence of diabetes in patients with NAFLD more than doubles the prevalence of cirrhosis from 10% to 25% [80,81].

Hyperlipidemia

The prevalence of NAFLD in different forms of hyperlipidemia remains uncertain. One study using noninvasive imaging showed that two thirds of patients with

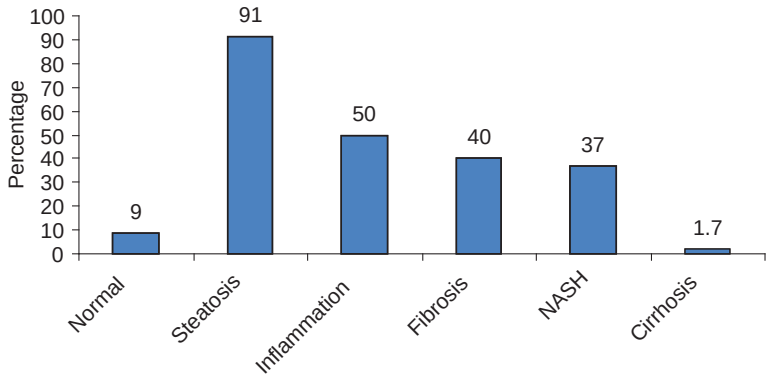

Figure 32.7 Liver histology in a series of severely obese patients (BMI >35 kg/m^2). Only 9% had normal histology while 1–2% had previously unidentified cirrhosis. Approximately 90% had steatosis and one third of these met criteria for nonalcoholic steatohepatitis (NASH) with varying degrees of fibrosis in 40%. (Data from Machado et al. [72].)

hypertriglyceridemia and one third with hypercholesterolemia had fatty liver [82]. This is probably an underestimation as hyperlipidemia is reported in up to 92% of NASH patients, although a wide range has been noted [83]. Postprandial lipid profiles as opposed to fasting profiles may be especially relevant [84]. The complexity of these relationships is reflected in the mechanistic role of lipoproteins in NASH, ethnic variation in lipid metabolism, overlapping risks of NASH and atherosclerotic vascular disease, and suspected heterogeneity in lipid phenotypes in NAFLD.

Metabolic syndrome

Steatosis and central adiposity are independent risk factors for the metabolic syndrome, united by underlying insulin resistance and lipotoxicity [85,86]. An unexplained elevation of liver enzymes, attributable to NAFLD, is seen in 7% of individuals with metabolic syndrome defined by the Adult Treatment Panel III criteria (Box 32.4) [87,88]. However, the prevalence of NAFLD in the general population, the prevalence of metabolic syndrome among patients with NAFLD, and the frequency of normal liver enzymes even with histologic disease suggest that the prevalence of NAFLD in metabolic syndrome is much higher although influenced by genetic/ethnic factors (discussed below) [89,90]. While closely related, it is evident that fatty liver in itself does not cause metabolic syndrome but constitutes a feature of this syndrome [91].

Normal body mass index

Nonalcoholic fatty liver disease has been well documented in patients with normal BMI [5]. Such individuals are characterized by visceral adiposity, hyperinsulinemia, and physical deconditioning [92]. These findings are consistent with the concept of "metabolic obesity" in patients with a lower BMI and NAFLD and the role of body fat distribution and physical deconditioning in the development of this disorder [93–95].

Box 32.4 Adult Treatment Panel III clinical features of the metabolic syndrome.[a]

- Abdominal obesity:
  - Men: waist circumference >102 cm (>40 inches)
  - Women: waist circumference >88 cm (>35 inches)
- Triglycerides: ≥ 150 mg/dL
- High-density lipoprotein cholesterol:
  - Men: <40 mg/dL
  - Women: <50 mg/dL
- Blood pressure: ≥130/≥85 mmHg
- Fasting glucose: ≥110 mg/dL

[a] Although specific criteria are noted, this syndrome can also be viewed as a continuum.

Pediatric patients

Nonalcoholic fatty liver disease is a potentially serious problem in children, where it is also associated with obesity and the metabolic syndrome [96,97]. Severity varies but fibrosis and cirrhosis were described in 18 of 24 patients in one series [98]. Recently acquired rather than longstanding obesity increases the risk of fatty infiltration. Male preponderance and prominent portal tract injury are characterisitic [99]. Ethnic influences are similar to adult disease, with a greater risk among children of Hispanic or northern European compared with those of African-American descent [100].

Nonalcoholic steatohepatitis in other liver diseases

Nonalcoholic fatty liver disease coexists with and influences other liver diseases [101]. Steatosis mediated by core protein metabolism and microsomal triglyceride transfer protein (MTTP) is associated with hepatitis C (especially genotype 3) and probably accelerates progression [102,103]. Many hepatitis C virus (HCV) patients have coexisting risk factors for NASH, suggesting a synergistic effect in some [104]. Obesity, insulin resistance, and steatosis negatively influence response to antiviral therapy [105]. Occult hemochromatosis and iron loading has also been suggested as a factor in the progression of NASH [106]. However, hyperferritinemia in NAFLD correlates more closely with insulin resistance than with iron overload or *HFE* gene mutations and can be reversed with weight loss [107]. Steatosis has also been recognized as a potential factor in the progression of primary biliary cirrhosis (PBC) [108]. Histologic features of autoimmune hepatitis are sometimes seen with NASH. It is likely that this represents two separate diseases although weight gain with steroid therapy may explain an association.

Genetic factors

Ethnic variation

The prevalence of NAFLD varies among high-risk groups depending on ethnicity (Fig. 32.8) [109–111]. People of Hispanic descent in the United States have a higher prevalence, while people of primarily African-American descent have a lower than expected prevalence relative to rates of obesity and diabetes compared with people of Asian or northern European descent. The findings reflect ethnic differences in the distribution of body fat and lipoprotein metabolism [112–114]. Importantly, ethnic variation reveals a dissociation between fatty liver,

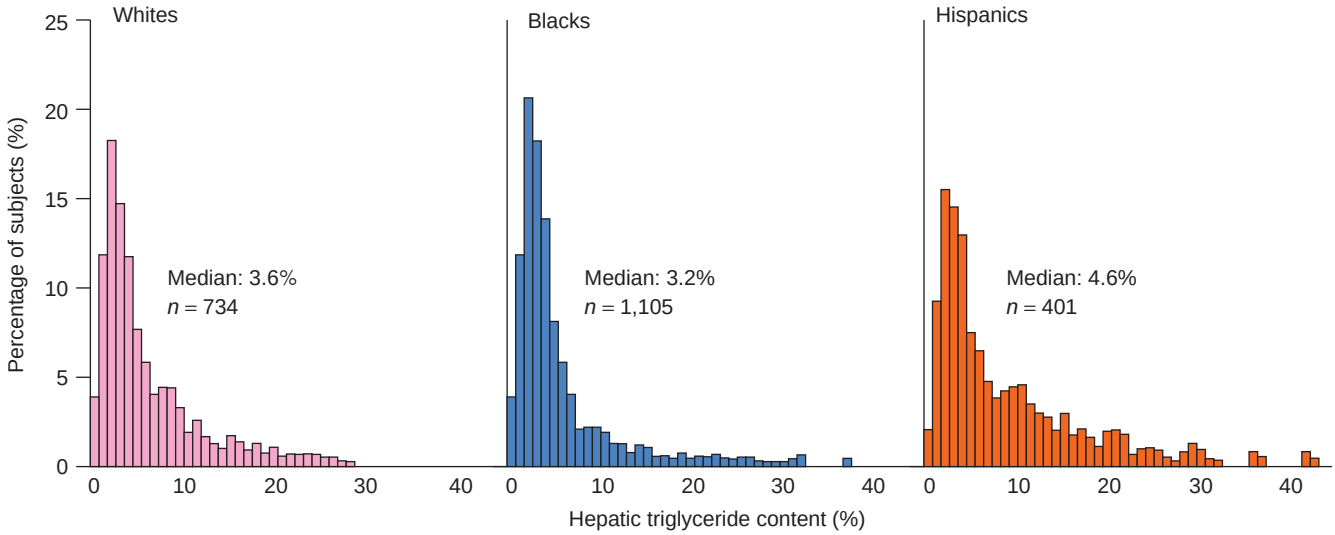

Figure 32.8 Distribution of hepatic triglycerides content by ethnicity as assessed by ^{1}H-magnetic resonance spectroscopy. The distribution of hepatic triglycerides content was skewed toward lower levels in blacks and slightly higher levels in Hispanics. (Reproduced from Browning et al. [111] with permission from Wiley.)

hyperlipidemia, and insulin resistance. Although liver fat generally correlates to intraperitoneal fat, African-Americans have lower intraperitoneal fat, lower liver fat, and lower blood triglycerides despite similar levels of insulin resistance as Hispanic-Americans [115]. Similar ethnic variation has been described in cryptogenic cirrhosis [116].

Familial factors

A high prevalence of afflicted first-degree relatives is seen in NASH [117–119]. There is an association with obesity, diabetes, and cryptogenic cirrhosis within kindreds. The findings likely represent a combination of both genetic risk and common health habits. The demonstration of insulin resistance among relatives of type 2 diabetics and impaired skeletal muscle mitochondrial metabolism in their offspring supports a strong genetic component [120, 121]. Moreover, a prospective study using spectroscopy among siblings and parents of overweight probands with and without fatty liver detected fatty liver in 17% of siblings and 37% of parents in the group without fatty liver compared to 59% and 78%, respectively, in the group with fatty liver [122].

Genetic variation

Given the complexity of organ injury in NASH, it is not surprising that a number of associations have been identified in genes regulating fat and glucose metabolism, oxidative stress, the mitochondrial antioxidant system, keratins, and cytokine activity [123,124]. A gene coding for a phospholipase-like protein called PNPLA3 (patatin-like phospholipase 3) or adiponutrin has been identified as a major predictor of steatosis within different ethnic groups [125]. PNPLA3 may function primarily in the transfer of fatty acids between lipids. The gene is highly conserved and appears to be regulated in part by dietary fat [126]. Apolipoprotein C3 variants may also influence the risk of steatosis, together with fasting and postprandial triglyceride clearance possibly mediated by altered chylomicron metabolism [127]. Polymorphisms in transcription factor 7-like 2 (TCF7L2) and MTTP influence NASH risks through postprandial lipidemia, adipokine secretion, and metabolism of oxidized low-density lipoprotein (LDL) [128,129]. A synergistic association between angiotensinogen and transforming growth factor β1 (TGF-β1) genotypes has also been described in patients with more severe NASH [130].

Clinical and laboratory findings

Symptoms and signs

Typical signs and symptoms and laboratory findings are summarized in Box 32.5. Fatigue and right upper quadrant discomfort (often positional) are common but an absence of more specific symptoms was noted in 48–100% of patients in a compilation of studies [131]. Discomfort may be mistaken for gallstone disease. Hepatomegaly is usually due to steatosis but may be due to glycogenosis in diabetic patients [132]. Clinical findings of obesity

Box 32.5 Symptoms, signs, and laboratory features of nonalcoholic fatty liver disease.

Symptoms
- Asymptomatic (48–100%)
- Fatigue (~70%)
- Right upper quadrant pain (up to 50%)
- Occasional neurologic deficits (possibly part of systemic lipotoxicity)
- Obstructive sleep apnea
- Polycystic ovarian syndrome-related complaints

Signs
- Hepatomegaly
- Acanthosis nigricans
- Palmer erythema and spider angiomata (with development of cirrhosis)

Laboratory features
- Elevated aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels (usually <2 times upper limit of normal)
- Elevated γ-glutamyltransferase (GGT) level
- Mildly elevated alkaline phosphatase level
- Antinuclear antibody (ANA) positive (~30%)
- Increased serum immunoglobulin A (IgA) level in about 20%
- Elevated iron indices in 20–60% (usually without actual hemochromatosis)
- Hyperuricemia

and metabolic syndrome include diabetes, hyperlipidemia, hypertension, vascular disease, polycystic ovary syndrome, and sleep apnea [133–135]. Changes in body composition due to aging and cirrhosis may mask a history of prior obesity [30]. A relationship between hypercoagulability in metabolic syndrome and steatohepatitis is increasingly recognized [136–138]. Acanthosis nigricans may be present especially in children, but also in adults. The presence of a "buffalo hump" may indicate more severe histologic disease. Palmer erythema or spider angiomata suggest the presence of cirrhosis. A subacute form of NASH with unexplained sudden decompensation has also been recognized [139].

Common laboratory findings

Many patients present with abnormal ALT and/or AST, detected on screening or in treatment for weight loss, hypertension, diabetes, or hyperlipidemia. AST and ALT levels average 55 and 74 IU/L, respectively [140]. AST is partly mitochondrial in origin (mAST) [141]. An AST : ALT ratio of <1 suggests mild disease, while values >1 often indicate fibrosis [142]. However, patients with advanced disease, including cirrhosis, may have normal aminotransferases [143]. This results in part from diminished inflammation as fibrosis progresses (see below). In addition, obesity in the general population has resulted in a spuriously rising "normal" reference range – an issue that has yet to be uniformly resolved [144,145]. Antidiabetic and antilipidemic medications also influence this relationship in both directions.

Other laboratory abnormalities

Autoantibodies such as antinuclear antibody are seen in about one third of NASH patients [146]. Abnormal iron indices are seen in 20–60% of patients but usually are not associated with genetic hemochromatosis, although ferritin elevation may be a marker for more severe disease [147,148]. Hyperuricemia may be present as in metabolic syndrome. Low platelets warrant an additional search for hypersplenism and cirrhosis [149]. Similar to alcoholic steatohepatitis, elevation of serum immunoglobulin A (IgA) may be seen [150]. Thyroid dysfunction has been suggested as an association in some patients.

Tests of insulin resistance, dyslipidemia, and physical conditioning

The HOMA (homeostatic model assessment) and QUICKI (quantitative insulin sensitivity check index) are used to estimate insulin resistance although these tests have limitations [151]. Both utilize mathematical manipulation (derived from euglycemic clamp testing) of fasting insulin and glucose levels. The addition of free fatty acid levels to the QUICKI improves its accuracy [152]. Lipoprotein profiles in NAFLD are incompletely defined. The VAP (vertical analytic profile) panel and nuclear magnetic resonance-based techniques may be useful to define lipid particle size. Although not widely available, measures of exercise capacity by bicycle ergometry to determine oxygen utilization (VO_{2peak}) may also be useful to discern "metabolic obesity" and correlate to the degree of insulin resistance [153].

Noninvasive markers of liver injury and fibrosis

See the section on the role of liver biopsies below.

Findings of lipodystrophy

Fatty liver is common in the lipodystrophies [154]. These disorders, congenital or acquired, are possibly more prevalent than commonly thought. A familial form of partial lipodystrophy with NAFLD and cirrhosis is reported among females with the acquired variety [155]. Typical features include diabetes, elevated triglycerides, and focal or diffuse loss of subcutaneous fat. Histologic NASH was observed in eight of ten patients who had improvement with leptin replacement [156].

Lipodystrophy related to antiretroviral therapy is discussed further below.

Findings suggestive of mitochondrial disease

Mitochondrial abnormalities in the liver suggest that systemic mitochondrial disease may be present and influenced by genetic mitochondrial heteroplasmy [157, 158]. Cryptogenic cirrhosis is seen in mitochondrial disease and insulin resistance is a feature of the MIDD syndrome (maternally inherited diabetes and deafness) and Madelung disease (both associated with mitochondrial DNA mutations) [159–161]. Similar hepatic mitochondrial DNA mutations have been identified in NASH [162]. Symptoms suggestive of systemic mitochondrial disease include depression, ophthalmoplegia, neurodegenerative diseases, deafness, lipomatosis, and gut dysmotility [163].

Weber–Christian disease

Nodular panniculitis with fat necrosis, especially over the lower extremeties, is the most distinguishing features of Weber–Christian disease. Steatohepatitis suggests a systemic disorder of fat metabolism [164]. Immunosuppression has been reported to be effective therapy indicating an autoimmune component [165].

Liver imaging

Liver imaging plays an important role in the clinical evaluation of NAFLD (Fig. 32.9) and in epidemiologic studies of the disease [166]. However, conventional techniques are unable to grade or stage NASH and are insensitive to hepatic fat that is less than 20% by weight [167,168]. Cross-sectional imaging is also used to assess fat distribution (visceral versus peripheral fat) by determining the fat area at specific levels such as L4–5 [169,170]. Ultrasonography detects steatosis by echogenicity and sound attenuation with defined criteria [171]. Ultrasonic elastography measures liver stiffness as a marker of fibrosis. Sensitivity and specificity for stage 3–4 fibrosis is 91% and 75%, respectively (>7.9 kPa) but failure to acquire a signal increases with a BMI of >30 kg/m^2 [172].

Unenhanced computed tomography (CT) relies on attenuation differences between the liver and spleen [173]. A "liver : spleen ratio" (in Hounsfield units) of <1 is consistent with steatosis. Sensitivity and specificity for fatty liver were 84% and 99%, respectively, for a spleen minus liver value of ≥10 Hounsfield units in one study [174]. Conventional spin-echo magnetic resonance imaging (MRI) is insensitive in detecting steatosis. However, refinements including "in–out of phase imaging" improve fat detection [175]. Improved signal processing (using the Dixon technique) provides quantitative estimates expressed as percentage triglyceride content. Magnetic resonance proton spectroscopy is the most accurate means of quantifying steatosis (Fig. 32.10) [176]. In one study, the correlation between fat measured in liver biopsies and proton spectroscopy was 0.9 (P <0.001) [177]. ^{31}P spectroscopy is capable of measuring adenosine triphosphate (ATP), lipid peroxidation, and the phospholipid content of the liver [178,179].

Role of liver biopsy

Liver biopsy remains the standard for confirming the diagnosis, staging fibrosis, grading activity, and judging response to treatment. Clinically, biopsy is often deferred until failure of a conservative course of exercise and diet unless the evaluation indicates more advanced disease

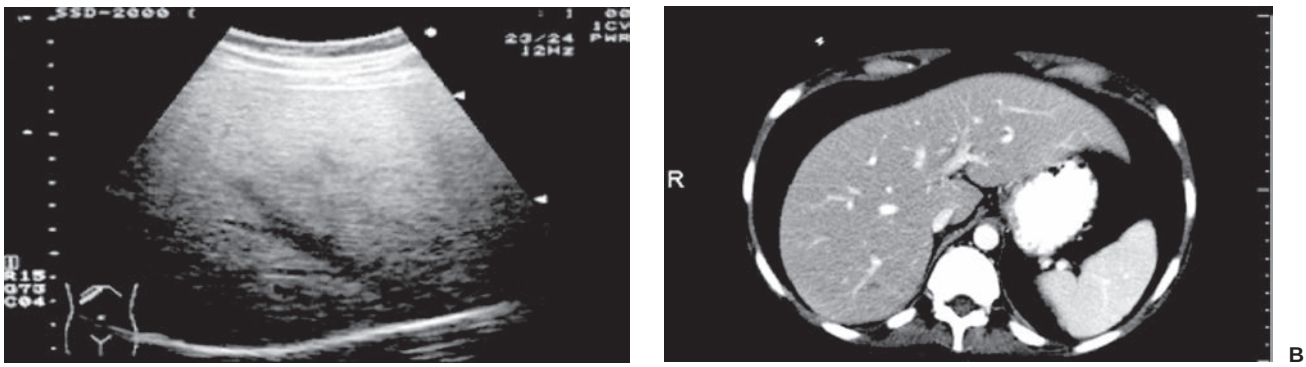

Figure 32.9 Radiologic imaging of NAFLD. (A) Sonographic appearance of NAFLD demonstrating a heterogeneous appearing echotexture with findings of "bright liver" in the parenchyma. (B) Computed tomography (CT) appearance of NAFLD showing a relatively hypodense liver compared to the spleen (liver:spleen ratio <1).

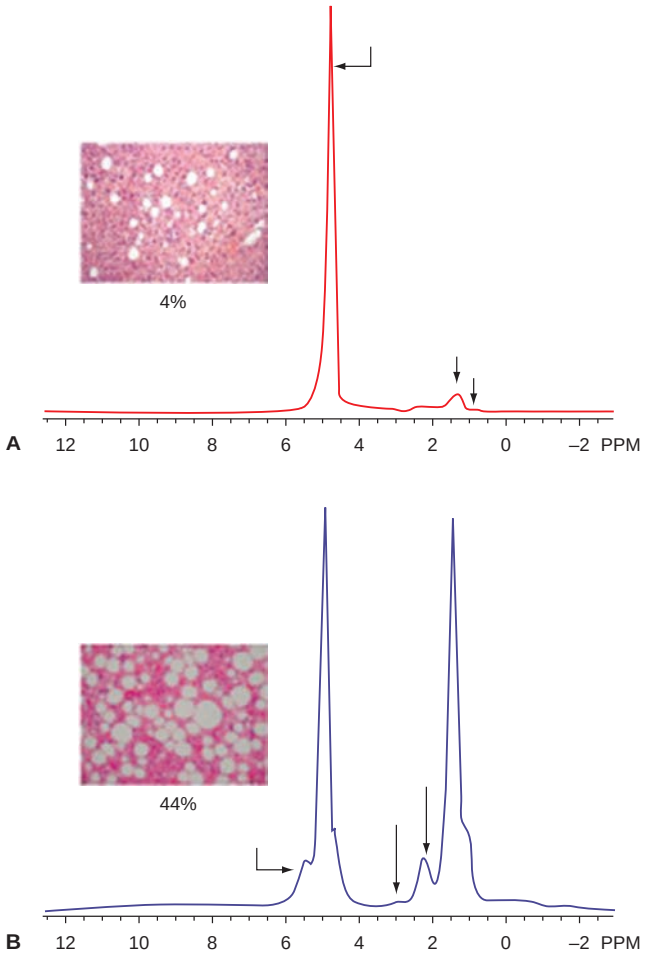

Figure 32.10 Magnetic resonance proton spectroscopy to measure hepatic fat content. (A) A patient with lower triglyceride content (4%) with a strong water signal and relatively weak methyl and methylene signal from triglyceride. (B) A patient with high triglyceride content (44%) evident by the sharp peak from the methyl and methylene groups. Small peaks can provide an estimation of the amount of unsaturated fatty acids. (Reproduced from Browning [176] with permission from Elsevier.)

or when there is a question of medication-induced injury. Limitations and risks inherent to biopsy have led to study of noninvasive "surrogate" markers.

Noninvasive surrogates

Clinical predictors of histology (Box 32.6) should be regarded cautiously due to the high number of exceptions; they most consistently include age (>40–50 years), the degree of obesity, the degree of diabetes or insulin resistance, features of the metabolic syndrome, family history of liver disease, aminotransferase elevation, and an AST : ALT ratio >1 [180–182]. Of note, the use of statins and some antidiabetic agents may spuriously change the AST : ALT ratio, thus limiting the use of this simple test. Other blood markers include indices of collagen metabolism (fibrosis), markers of cell death (M30 keratin 18 fragments), adipocytokine indices of insulin resistance (adiponectin and resistin), and markers of oxidative injury [183–185]. Clinical and laboratory variables have been combined into composite scores but none have gained uniform acceptance [186].

Box 32.6 Predictors of more severe histology in nonalcoholic steatohepatitis (NASH).

- Age >40–50 years
- Degree of obesity
- Hypertension
- Overt diabetes mellitus
- Hypertriglyceridemia
- Elevated ALT
- Elevated AST
- AST : ALT ratio >1
- Elevated serum IgA level
- Family history of NASH or cryptogenic cirrhosis

ALT, alanine aminotransferase; AST, aspartate aminotransferase; IgA, immunoglobulin A.

Limitations of liver biopsy

The limitations of biopsy include risk, patient inconvenience, performance in obese patients, and sampling error. Although always warranting careful caution, complications with liver biopsy are low and available techniques offer improved safety [187]. Sampling error is well recognized with all types of liver biopsy and may represent regional variation within the liver [188]. Fibrosis staging error is reduced by obtaining a specimen >2 cm in length (1.5 mm diameter) with a minimal length of 1.5 cm core using a 15–16 gauge needle [189].

Biopsy scoring

Composite scores provide a useful means of globally evaluating the biopsy (Table 32.1). Key parameters were combined into the NASH activity index (NAI) and the more commonly used NAFLD activity score (NAS) [190–191]. The NAI ranges from 0 to 12 and accounts for steatosis, necroinflammatory activity, and hepatocyte injury, each of which is scored from 0 to 4. The NAS uses a scale of 0 to 8 to score steatosis (0–3), lobular and/or portal inflammation (0–3), and cellular ballooning (0–2). Fibrosis stage is staged separately between 1 and 4, where 3 is bridging fibrosis and 4 is cirrhosis. Limitations of these systems include the imprecise and narrow ballooned cell scores and the stages of fibrosis intermediate between bridging fibrosis and cirrhosis ("incomplete" cirrhosis).

Table 32.1 Histology scoring systems in nonalcoholic fatty liver disease (NAFLD).

	Steatosis	Inflammation (lobular)	Hepatocyte injury (ballooning)	Maximum score	Fibrosis
NASH grade and stage (Brunt)	0–3 0 = none 1 = <33% 2 = 33–66% 3 = >66%	0–3 0 = no foci 1 = 1–2 foci/mpf 2 = 3–4 foci/mpf 3 = >4 foci/mpf	0–2 0 = absent 1 = present in z3 2 = marked in z3	8	0–4 0 = none 1 = sinusoidal 2 = sinusoidal and periportal 3 = bridging fibrosis 4 = cirrhosis
NAI (NASH activity index) (Promrat)	0–4 0 = <5% 1 = 5–25% 2 = 25–50% 3 = 50–75% 4 = >75%	0–4 0 = no foci 1 = <1 foci/2 mpf 2 = 1 foci/1–2 mpf 3 = 1–2 foci/mpf 4 = >2 foci/mpf	0–4 0 = absent 1 = only z3, <50% of CVs 2 = only z3, >50% of CVs 3 = Both z2 and z3 (1/3 to 2/3) 4 = All zones (>2/3)	12	0–4 0 = none 1 = perisinusoidal 2 = perisinusoidal and periportal 3 = bridging fibrosis 4 = cirrhosis/regeneration
NAS (NAFLD activity score CRN revision) (Kleiner)	0–3 0 = <5% 1 = 5–33% 2 = 33–66% 3 = >66%	0–3 0 = no foci 1 = <2 foci/mpf 2 = 2–4 foci/mpf 3 = >4 foci/mpf	0–2 0 = absent 1 = few ballooned cells 2 = many/prominent ballooning	8	0–4 0 = none 1 = perisinusoidal or periportal 1A = mild, z3, perisinusoidal 1B = moderate, z3, perisinusoidal 1C = portal/periportal 2 = perisinusoidal and portal/periportal 3 = bridging fibrosis 4 = cirrhosis

CRN, xxx; CVs, central veins; mpf, medium power field (defined as ×20 ocular); NASH, nonalcoholic steatohepatitis; z2, zone 2; z3, zone 3.

Better understanding of pathophysiology will likely lead to refinements of composite scoring.

Natural history and prognosis

Mortality in NAFLD is influenced by underlying histology and co-morbidities associated with the metabolic syndrome [192,193]. Although cardiovasacular disease is a leading cause of death (see below), obesity is a risk for cirrhosis-related death [194,195]. In type 2 diabetes, although cardiac deaths exceed liver-related deaths (19.5% versus 6.4%), the O/E ratio (observed/expected deaths) is higher for cirrhosis than for heart disease (2.67 versus 1.81) [196]. Nonhepatic cancer is another prominent cause of death in this group. Although it remains unclear which of these (vascular, cancer, or cirrhosis) is dominant in a given patient, serial biopsy studies and longer follow-up in cohort studies over the past 20 years have improved our understanding [197].

Clinical course based on the initial biopsy

In a retrospective study of adults, the overall and cirrhosis-related mortality was increased compared to crude death rates when steatosis was accompanied by inflammation, fibrosis, or ballooned cells (i.e., NASH) [198]. In contrast, NNFL appears to be relatively stable over time [6,199]. Older age (>40–50 years), higher BMI (>30 kg/m^2), diabetes, and abnormal aminotransferases are consistent predictors of more severe histology on the initial biopsy [70,74,200–202]. The diverging course between NASH and NNFL indicates that NASH usually begins as such rather than progressing from an initial stage of NNFL [203].

Histologic progression over time

Although serial biopsy studies have limitations due to variable technique, criteria, and incomplete data, existing studies offer essential observations [204–207]. Over 5–6

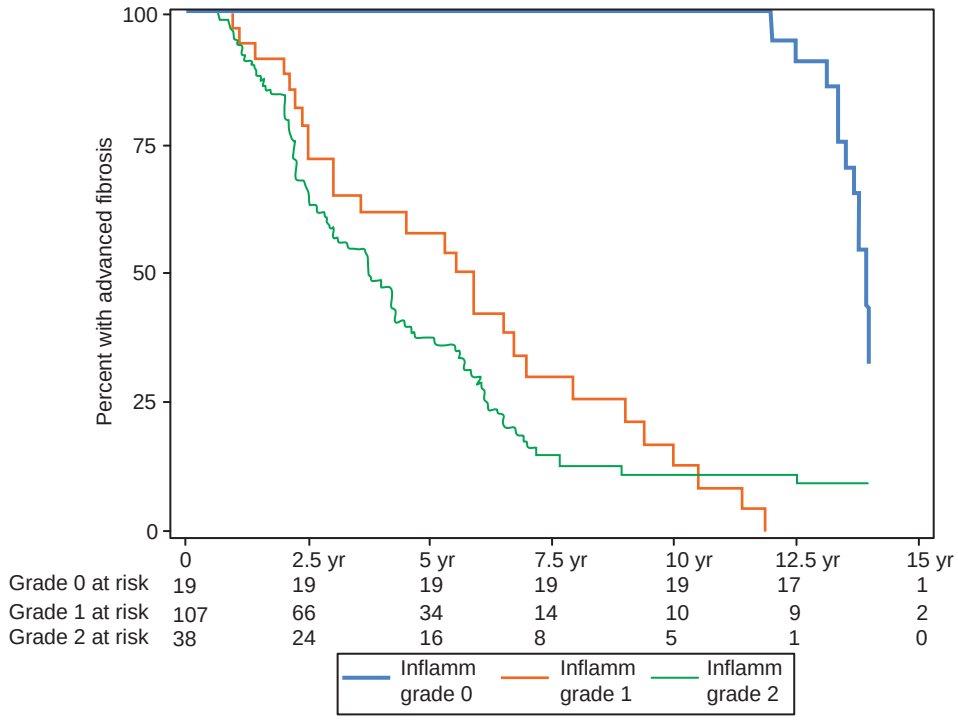

Figure 32.11 Histologic progression in nonalcoholic steatohepatitis. Kaplan–Meier curves showing the differences in progression to stage 3 or 4 fibrosis between patients with inflammation on the initial biopsy versus those without inflammation. (Reproduced from Argo et al. [208] with permission from Elsevier.)

years, histologic improvement can be seen but worsening fibrosis occurs more frequently than improvement (38% versus 21%) [208]. The risk of progression is associated with older age and the presence of inflammation on the initial biopsy (Fig. 32.11). One third of patients develop bridging fibrosis or cirrhosis.

Long-term mortality in nonalcoholic fatty liver disease

Based on four long-term cohort studies, the overall mortality from the initial diagnosis over 10–15 years is 10–12%, being significantly higher in NASH versus NNFL (Table 32.2) [209–212]. Over the same period, the

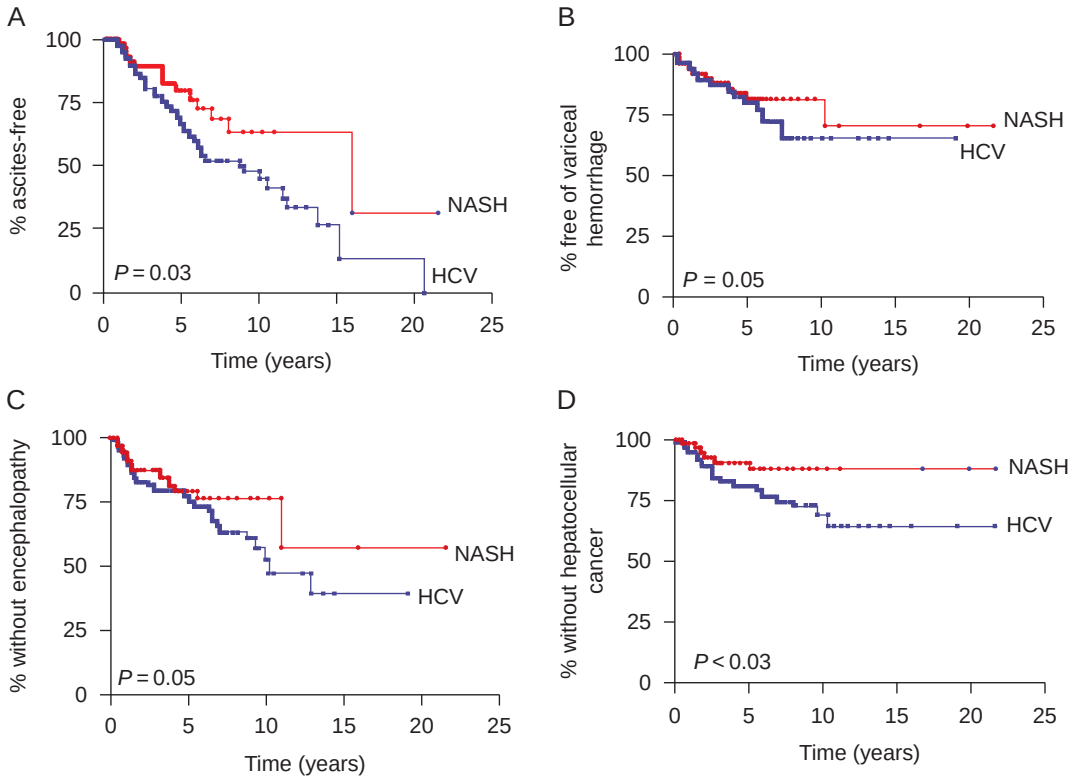

Figure 32.12 Comparison of complications in nonalcoholic steatohepatitis (NASH) cirrhosis versus cirrhosis due to hepatitis C (HCV). The course is similar in the two diseases but slightly slower in NASH cirrhosis. The figure depicts the hazard of developing (A) ascites, (B) variceal hemorrhage, (C) encephalopathy, and (D) hepatocellular cancer, and are shown as "time to failure" via the Kaplan–Meier method. (Reproduced from Sanyal et al. [214] with permission from Wiley-Blackwell.)

risk of decompensated cirrhosis was 5–10% and for hepatocellular cancer it was 1–2%. The leading causes of death overall were coronary artery disease (10%), extrahepatic malignancy (5%), and cirrhosis-related death (2%) – expressed as a percentage of the original cohort. Cirrhosis deaths exceeded cardiac deaths among NASH patients in one study [213]. These circumstances present clinical challenges as it is increasingly likely that patients with metabolic syndrome suffer from both coronary disease and cirrhosis – two conditions with often conflicting management strategies.

Prognosis of nonalcoholic steatohepatitis-related cirrhosis

Once cirrhosis develops, the risk of developing a major complication of portal hypertension is reported to be 17%, 23%, and 52% at 1, 3, and 10 years, respectively, indicating a progressive condition [213]. In a study comparing 152 NASH–cirrhosis patients with 150 patients with cirrhosis from hepatitis C, the number of patients free of a given complication (bleeding, ascites, encephalopathy, hepatocellular cancer) over 10–20 years revealed that patients with NASH–cirrhosis were similar to those with hepatitis C-related cirrhosis but progressed at a slightly slower rate (Fig. 32.12) [214].

Cryptogenic cirrhosis

A close association between NASH and cryptogenic cirrhosis is evident in different populations, in post-transplantation studies, and in "look-back" histologic studies (see above as well) [17–37]. About one half present with a major complication of portal hypertension. Although there is confusion in nomenclature between NASH–cirrhosis and cryptogenic cirrhosis, these conditions constitute an increasingly common indication for liver transplantation, estimated at 5–10% of liver transplants [215].

Hepatocellular cancer

Epidemilogic studies show an increased risk of hepatocellular cancer (HCC) in both obese and diabetic patients [216,217] and case series confirm progression of NASH to cirrhosis to HCC [17,218,219]. HCC is especially common in NASH–cirrhosis and it tends to be diagnosed at a later stage possibly due to inadequate surveillance [220,221]. While NASH–cirrhosis or obesity-related

cryptogenic cirrhosis constitute the primary associations, HCC is reported in NNFL, suggesting that steatosis alone is a risk [222–224]. HCC screening is recommended in NASH–cirrhosis or cryptogenic cirrhosis although optimal schedules are uncertain. Tumorogenesis in this setting may represent unique cancer biology. Molecular events include proliferation of progenitor cells observed in human and experimental NAFLD [225].

Experimental and animal models

Small animal models

Experimental models, usually in rodents, have been reviewed extensively [226]. Classic models include the ob/ob mouse, which has a congenital deficiency of leptin, the FA/FA rat, which has an impaired leptin receptor, and the methionine-choline deficient (MCD) diet rodent. While often helpful, the models often have limitations such as absence of insulin resistance in the MCD models [227]. Recent studies have focused on dietary manipulations such as trans fat or fructose content or high fat with toxin exposure and others have utilized the zebra fish as a model of fat metabolism [228–230].

Large animal steatosis

Fatty liver is seen in cows, hens, cats, and some pigs [231,232]. It is a common disorder in cats [233]. Seasonal variation in steatosis is seen in wild deer [234]. Palmipedes (migratory geese) develop fatty liver before migration and utilize fat as a preferred source of energy for muscle metabolism [235]. This has been exploited in the production of foie gras wherein geese are fed a corn-based diet resulting in an increase in liver size in as little as 2 weeks from 100 to 800 g. Mixed micro- and macrosteatosis is evident with increased susceptibility to accidental mycotoxin exposure [236]. Steatosis involves increased synthesis and altered very low-density lipoprotein (VLDL) secretion [237,238]. These relationships illustrate the role of the liver in the evolution of adipose and energy metabolism and thermoregulation [239].

Pathogenesis

Nonalcoholic fatty liver disease and especially NASH can be viewed as conditions within the spectrum of the metabolic syndrome and systemic lipotoxicity [240]. Steatosis and oxidative injury known as the "two hit" hypothesis encapsulates the consistent role played by oxidative injury [241]. A cascade of events leads eventually to cellular ballooning, cell death, organ fibrosis, and cirrhosis. Although fat necrosis may occur from the direct release of fat from swollen hepatocytes in NAFLD [242], cell injury results predominantly from the indirect effects of intracellular lipid peroxidation and the toxicity of fatty acids on organelles (Fig. 32.13).

Local cellular factors

Steatosis

Steatosis exists when fat stores exceed 5–10% of the organ by weight [5,243]. Fat is derived from the uptake of plasma fatty acids (nonesterified fatty acids (NEFAs)) released by lipolysis of adipose tissue, the uptake of VLDL-derived LDL remnants or circulating dietary chylomicron remnants, and from de novo lipogenesis (DNL) from carbohydrate precursors [244]. Both triglycerides (mostly as unsaturated fatty acids) and free fatty acids (mostly as saturated fatty acids) are increased in steatosis [245]. The disposal of fatty acids proceeds by several routes: incorporation into triglyceride in cytoplasmic lipid droplets, export as lipoproteins such as VLDL, oxidation especially via mitochondrial β-oxidation, or formation of phospholipids as membrane components. Recycling through autophagy is another key aspect (see below). The regulation of these pathways depends on energy homeostasis influenced by peroxisome proliferators-activated receptor (PPAR) activity and the adrenergic nervous system [246–248]. The transcription factors sterol regulatory element binding protein (SREBP), governed by insulin and dietary fatty acids, and carbohydrate response element binding protein (CREBP), governed by glucose levels, regulate lipid metabolism [249–251]. SREBP and CREBP stimulate nuclear transcription of the enzymes responsible for fatty acid synthesis and their incorporation into triglyceride in lipid droplets or exported as VLDLs.

De novo lipogenesis from carbohydrates

Adenosine triphosphate-dependent synthesis of the 16-carbon palmitic acid begins with translocation of carbohydrate-derived acetyl-coenzyme A (acetyl-CoA) subunits which pass through the mitochondrial membrane to the cytosol as citrate. Acetyl-CoA carboxylase (ACC) then activates the formation of malonyl-CoA from acetyl-CoA. Importantly, ACC is activated by insulin and inactivated by epinephrine, glucagons, and long chain fatty acids (the end-product). Through a series of repetitive cytosolic condensations catalyzed by fatty acid synthase (FAS), molecules of malonyl-CoA are assembled into palmitic acid. As a control, malonyl-CoA inhibits fatty acid β-oxidation by blocking carnitine, which shuttles fatty acids into the mitochondrion. Once formed, palmitic acid undergoes elongation in the ER to longer chain fatty acids or desaturation and esterification to glycerol to form mono-, di-, and triglycerides. The latter is incorporated in the ER via MTTP into VLDLs for export in

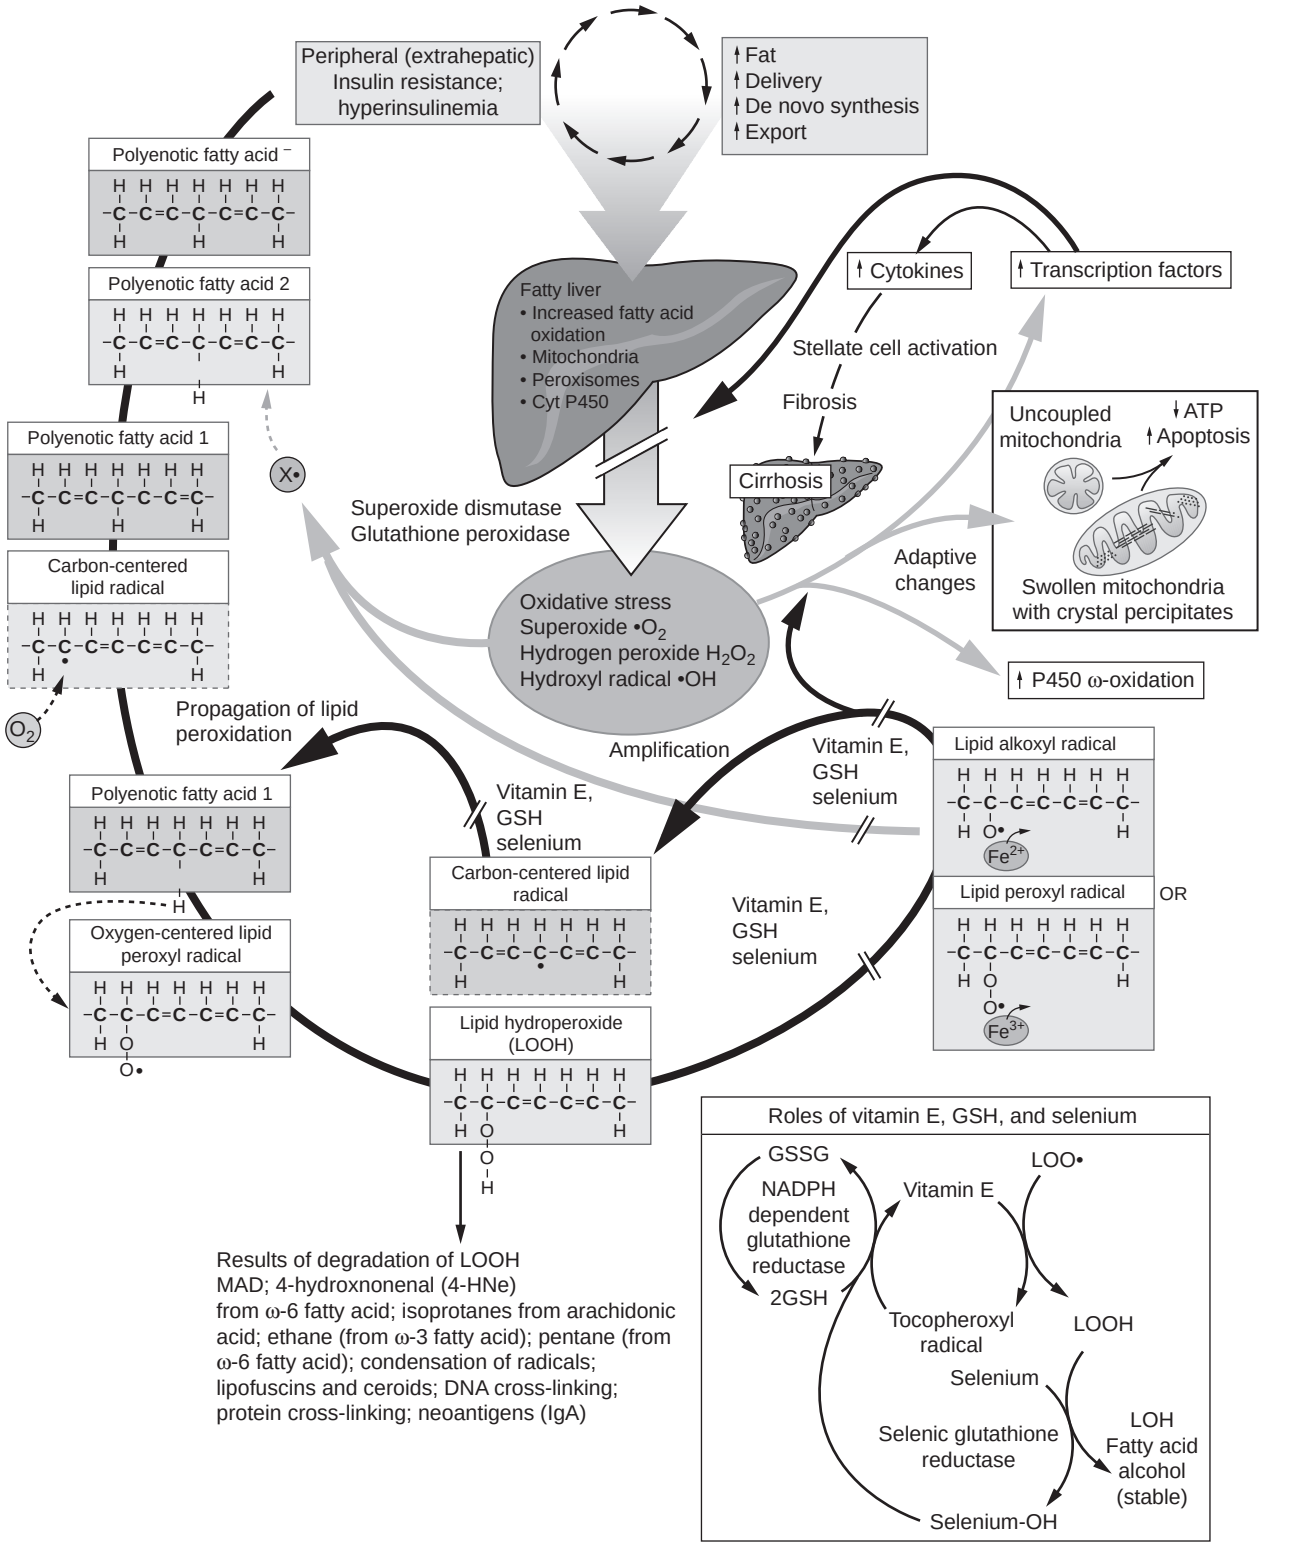

Figure 32.13 Lipid peroxidation and cell injury. (A) Lipid peroxidation is a branching chain reaction stimulated by free radical attack (super oxide, hydroxyl radical) on lipid constituents. Unsaturated fatty acids are especially susceptible and lose an electron to the radical. This produces a *carbon-centered lipid radical* which reacts with oxygen to form an *oxygen-centered lipid peroxyl radical*. This reacts with a second fatty acid to form another lipid free radical (propagation) and a *lipid hydroperoxide*. The latter is unstable and, in the presence of iron and another fatty acid, reacts to form yet another lipid radical (amplification). Lipid hydroperoxide degrades to malondialdehyde (MDA), ethane, or pentane or reacts with other radicals to form a stable pigment (lipofuscins). It may also cross-link with DNA or cellular proteins impairing their function. Lipid radicals are neutralized through combination with tocopherols (vitamin E). (*Continued*)

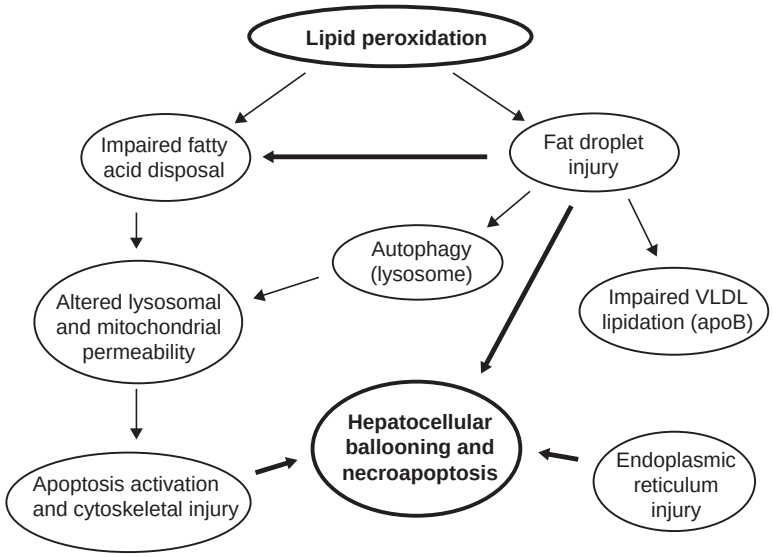

Figure 32.13 (*Continued*) The latter is then restored by shuffling the radical groups to glutathione (GSH) via selenium. ATP, adenosine triphosphate; GSSG, oxidized gluatathione, IgA, immunoglobulin A; LOH, fatty acid alcohol; NADPH, nicotinamide adenine dinucleotide phosphate (reduced form). (B) Cell injury appears to result from a cascade of events initiated by lipid peroxidation, which triggers lipid droplet dysfunction, endoplasmic reticulum "stress," autophagosome formation, and mitochondrial dysfunction. Fatty acids cause activation of apoptosis through changes in lysosome and mitochondrial permeability. Caspases (apoptosis pathway) contribute to cytoskeletal injury and ballooning and Mallory–Denk body formation. Necroapoptotic cell death stimulates fibrotic pathways amplified by systemic factors such as cytokines. VLDL, very low-density lipoprotein.

association with apolipoprotein B100 [252]. Triglyceride synthesis in human NAFLD results from the uptake of adipose-derived NEFAs (59%), DNL (26%), and dietary fat (15%) based on nutrition studies with radiolabeled precursors [253].

Lipid composition (lipidomics)

Variation in fat droplet size and density reflects different types of component fatty acids [254,255]. Incorporation of NEFA into droplet triglyceride depends on the activity of diacylglycerol acyltransferase 1 (Dgat1) [256]. Lipidomic analysis shows a stepwise increase from normal to NASH in the triacylglycerol to diacylglycerol ratio, indicating a relative increase in triacylglycerol in more advanced disease [257]. The ratio of n6 : n3 polyunsaturated fatty acid is higher in NASH possibly due to the diminished triacylglycerol content of eicosapentanoic acid and docosahexanoic acid. Free fatty acids were not different but phosphatidylcholine was decreased in NNFL and NASH, while the free cholesterol to phosphotidylcholine ratio was increased. Ceramide, a toxic lipid intermediary, has been detected more in obese patients with fatty liver versus those without although its role is uncertain [258].

Lipoproteins

Although lipid trafficking and lipoprotein metabolism are important factors [259], no dominant pattern of fasting lipoproteins is established in NAFLD. In some cases, primary lipoprotein disorders might constitute a separate and/or overlapping entity. VLDL secretion is increased in human NAFLD but plateaus at a hepatic triglyceride content of 10%, indicating limited compensation for increased uptake of NEFAs. The secretion of apolipoprotein B100, a component of VLDL, is insufficient and may promote the secretion of a larger VLDL particle with greater triglyceride content [260,261]. Differences in ApoA1 (a component of high-density lipoprotein) are also described [262]. The role of *postprandial* lipid metabolism and intestinal chylomicrons is an emerging area [263].

Lipid peroxidation

The most enduring finding that distinguishes NASH from NNFL is lipid peroxidation (see Fig. 32.13) [264–267]. This process is evident as the accumulation of oxidative by-products such as 4-HNE (4-hydroxynonenal), MDA (malondialdehyde), nitrotyrosine, and 8-hydroxydeoxyguanine, and systemically as adducts of oxidized phospholipids and 11-HETE (hydroxyeicosatetraenoic acid), a by-product of arachidonic acid oxidative injury [185,268]. Lipid peroxidation is a branching, chain reaction attack on unsaturated fatty acids that produces another free radical and a lipid hydroperoxide [269–271]. It is sparked by superoxide radicals derived especially from mitochondrial oxidative-phosphorylation in the electron transport chain. The superoxide radical is metabolized via superoxide dismutase to hydrogen peroxide, which in the presence of Fe^{2+}

(Fenton or Haber–Weiss reaction) decays to hydroxyl radicals. Hydroxyl radicals catalyze peroxidation of fatty acids damaging membranes, cellular proteins, and DNA [272]. Oxidation of the phospholipid monolayer of fat droplets (including PAT proteins (perilipin-adipose differentiation protein-tail interacting protein)) and constituents of the ER may be particularly relevant to cellular ballooning, impaired disposal of fatty acids, and hepatic insulin resistance [265,273–275]. The speed of these pathologic reactions in vivo, whether in seconds, minutes, hours, days or longer, is uncertain.

Lipid droplets, VLDL lipidation, and lipophagy
