Pregnant women who contract hepatitis A are not at increased risk of severe disease from this infection (121), although the risk for premature labor may be increased in women who are seriously ill during the third trimester (122).

Hepatitis B

In patients with documented acute hepatitis B, pregnancy is not associated with increased mortality (123) or teratogenicity (124). Infection during gestation should not prompt termination of the pregnancy. Women exposed to hepatitis B during gestation may be vaccinated without any reported increase in congenital

anomalies (125); the vaccine is immunogenic in this setting (126).

Hepatitis E

This infection occurs both in epidemics and sporadically in many parts of the world (e.g., India, Pakistan, northern Africa, and Mexico). Women in the third trimester are more likely to have clinical disease than are other persons. The fatality rate in this group is as high as 25% (127,128,129). It can be difficult to distinguish fulminant hepatitis E from AFLP. Women in the third trimester of pregnancy should carefully consider the risks associated with travel to areas where this disease is endemic. Hepatitis E can cause acute hepatitis in the newborn and can be transmitted in utero to the fetus (127,129,130).

Hepatitis caused by herpes simplex virus and other viruses

When it occurs in the third trimester of pregnancy, hepatitis resulting from a primary systemic infection with herpes simplex virus is likely to be severe. Half of the reported cases of fulminant herpetic hepatitis have occurred in pregnant women (131). Affected patients may have a "viral" syndrome that includes fever and upper respiratory tract symptoms. Despite marked abnormalities in their aminotransferase levels and prothrombin time, these patients are usually anicteric at presentation. A vesicular eruption is diagnostically useful but may not yet be visible at presentation. Cultures and histology of liver biopsy specimens are helpful in the differential diagnosis, which should include severe liver disorders associated with pregnancy, such as AFLP and HELLP syndrome. Therapy with acyclovir is successful, and affected women need not be delivered of infants early. Acute infection with coxsackievirus B can cause a similar picture of acute hepatic failure (132).

Why hepatitis E and herpes simplex hepatitis are so much more severe and associated with such increased hepatic injury in the third trimester of pregnancy is unclear. Alterations in T-cell function have been reported in pregnancy and may be related to this enhanced susceptibility (133). Herpes simplex hepatitis is known to be more severe in certain immunocompromised states, such as chronic immunosuppression after transplantation.

Biliary Tract Disease and Pancreatitis

Pregnancy decreases gallbladder motility and increases the lithogenicity of bile (134). Pregnancy has long been considered a risk factor for the development of gallstones; epidemiologic studies confirm an association with an increased risk for gallstones, but only for a 5-year period after pregnancy. Thereafter, the risk drops back to that of the never-pregnant population (135). In adolescents with gallstones, a history of pregnancy is common (136). Ultrasonographic studies show that gallstones and biliary sludge may accumulate throughout gestation and resolve with a return to nonpregnant physiology (137,138). In a recent prospective study of 3,254 women, the cumulative incidence of new sludge, new stones, or progression of baseline sludge to stones

was 10.2%, by 4 to 6 weeks postpartum (vs. 5.1% by the first trimester). In the same study, 28 women (0.8%) underwent cholecystectomy within the first year postpartum (139).

Acute cholecystitis may occur in pregnancy. Operative cholecystectomy can be

performed during gestation, although it may increase maternal and fetal morbidity, particularly in the first trimester (140,141,142). In a large series of cholecystectomy in women, the procedure was only rarely performed during pregnancy (143), suggesting that acute cholecystitis, which is unresponsive to conservative medical management, is not a common occurrence during pregnancy. Recently, less invasive approaches to the problem of biliary lithiasis in pregnancy have been successful. Choledocholithiasis can be managed by endoscopic retrograde cholangiopancreatography with sphincterotomy (144,145). Laparoscopic cholecystectomy has also been reported to be successful in pregnancy (142,146), although the risk of morbidity may be increased (147).

Acute pancreatitis may complicate pregnancy. The serum amylase and lipase levels are normal during pregnancy, so abnormal values warrant attention (148). Pancreatitis usually occurs in the setting of cholelithiasis (149,150), and gallstones should be sought in any affected patient. Gallstone pancreatitis should be treated aggressively, either operatively (151) or endoscopically (144,152). Pancreatitis complicating pregnancy may be associated etiologically with AFLP or preeclampsia (153). Mild pancreatitis may occur in association with severe hyperemesis gravidarum, presumably as "refeeding pancreatitis." Familial hypertriglyceridemia, exacerbated by the physiologic hypertriglyceridemia of pregnancy, may present during pregnancy with pancreatitis (154). Hyperparathyroidism may be associated with pancreatitis in pregnancy (155,156).

A choledochal cyst may present during pregnancy, with abdominal pain, a mass, and jaundice (157). Such presentations may represent cases of congenital choledochal cyst exacerbated by the effects of pregnancy on biliary motility. Spontaneous rupture of a choledochal cyst (158) and of an apparently normal common hepatic duct (159) have been reported in pregnancy.

Hepatic Vein Thrombosis (Budd-Chiari Syndrome)

Both pregnancy and oral contraceptive therapy are associated with a hypercoagulable state (160). The frequency of hepatic vein thrombosis (Budd-Chiari syndrome) is increased in women using oral contraceptives (161). Reports from India suggest that it is also more common in pregnant women, usually manifesting immediately after delivery (162,163). Several reports have linked acute Budd-Chiari syndrome during pregnancy in western women with an underlying procoagulant state, such as primary antiphospholipid syndrome (164), anticardiolipin antibody (165), factor V Leiden mutation (166,167), or thrombotic thrombocytopenic purpura (168). The prognosis for pregnant women with this syndrome is ominous, as it is for pregnant women with idiopathic veno-occlusive disease. Liver transplantation has been used as a lifesaving measure (166,169), but such patients may survive with conservative measures, including delivery and anticoagulation. Recurrence has been reported in a patient whose anticoagulants were stopped when she became pregnant again (165). Nevertheless, subsequent successful, uncomplicated pregnancy has been reported for patients with a history of Budd-Chiari syndrome associated with oral contraceptives or an underlying myeloproliferative syndrome (170).

Drug-Induced Hepatic Injury

Because of concern about fetal teratogenicity, pregnant women in general take fewer drugs than those who are not pregnant. When they do take drugs, however, they run the same risk for adverse drug reactions as others. Potentially fatal hepatotoxicity has been reported in pregnant women undergoing

antiretroviral therapy for human immunodeficiency virus (HIV) infection (171). Acetaminophen overdose leading to death has been reported (172). On the other hand, no increased incidence of such adverse reactions during pregnancy has been documented. For example, 1,300 pregnant women took isoniazid for tuberculosis without ill effect (173).

Metastasis to the Liver

The liver is not palpable in normal pregnant women, and therefore, hepatomegaly detected on physical examination requires immediate evaluation. Patients with extensive tumor invasion of the liver may present with abdominal or back pain, rupture of the liver, or hepatic failure. The usual source is a common tumor, such as carcinoma of the colon (174,175) or pancreas (176). Gestational trophoblastic neoplasm (hydatidiform mole) can be a source of tumor spread to the liver. Breast cancer may also present with hepatomegaly during pregnancy. A patient presenting at 26 weeks of gestation with hypertension and thrombocytopenia, imitating HELLP syndrome, was found to have cholangiocarcinoma (177). It is possible that the modest immunosuppressive state associated with pregnancy promotes extensive tumor spread and growth.

Other Complicating Illnesses

Sepsis, particularly urinary tract infections, may be associated with jaundice in pregnant women (178),

as they are in the nonpregnant state. Echinococcal cysts of the liver have been reported during pregnancy (179,180).

Pregnancy in Women with Chronic Liver Disease

Monitoring of liver disease is necessary when its presence is known before pregnancy, and this requires cooperation between the obstetric team and hepatologists. Most patients with severe liver disease are not women of childbearing age or they are infertile because of the associated anovulatory state. Nevertheless, some of these women can become pregnant, and when they do, some special problems arise. On the other hand, most young women with chronic but nonsevere liver disease can have full-term pregnancies without any particular risk. However, there is the question of the effect of liver disease or its treatment on the fetus. Certain drugs should not be stopped during pregnancy because of the risk of relapse of the liver disease due to withdrawal of treatment. This is the case, for example, with immunosuppressive treatment of chronic autoimmune hepatitis and with penicillamine, which is used as a copper chelator in Wilson disease (see subsequent text). Other drugs, such as ribavirin used in the treatment of hepatitis C, are strictly contraindicated in pregnancy. In the case of ribavirin, the patient should be clearly informed of the need for effective contraception throughout treatment and during the 6 months thereafter.

Cirrhosis and Portal Hypertension

Worsening jaundice with progressive liver failure, ascites, and hepatic coma have been reported during the course of pregnancy in women with cirrhosis (181,182). Whether the exacerbation of hepatic dysfunction is caused by gestation or is merely coincident with it is unclear. What is clear, however, is that women with cirrhosis can often sustain pregnancy without any worsening of hepatic function (182). Published reports document an increased incidence of stillbirths and

premature delivery in such women (182,183,184).

The fertility of women with noncirrhotic portal hypertension, as seen in congenital hepatic fibrosis or portal vein thrombosis, is not diminished; therefore, pregnancy is encountered in this setting with some frequency (185,186). A worsening of preexisting portal hypertension may be anticipated because of the marked increase in blood volume and azygos flow that occurs during normal pregnancy. Variceal hemorrhage during pregnancy or labor has been reported (183,184,186,187). It is not clear whether the incidence of variceal hemorrhage in pregnant patients is higher than that in nonpregnant patients with known varices. Furthermore, a history of hemorrhage in one gestation does not predict the outcome of subsequent pregnancies (188). Sclerotherapy or endoscopic band ligation has been reported to be successful in pregnant women with variceal hemorrhage (185,189,190). Prevention of hemorrhage due to esophageal varices in women with known cirrhosis who desire pregnancy is based on classical treatment with β blockers and/or endoscopic ligature. An upper endoscopy is therefore usually performed before pregnancy. Prophylaxis with β blockers may be continued during pregnancy, but newborns should be monitored during the first days of life because of risks of hypoglycemia and bradycardia.

Specific Liver Diseases

Alcoholic liver disease

Alcoholic liver disease is often associated with infertility. However, most alcoholics do not have liver disease. Pregnancy in a fertile alcoholic woman can result in fetal alcohol syndrome in the infant, which includes typical facies, malformations, and developmental delay. Several such infants have been reported to have liver disease, with fatty liver and portal and perisinusoidal fibrosis suggestive of alcoholic liver disease (191). For the most part, however, liver disease or its treatment is not teratogenic. If they can succeed in getting pregnant, women with liver disease are not at increased risk of having children with congenital anomalies. On the other hand, they do have more maternal problems during pregnancy, and the risk of prematurity or stillbirth is greater.

Chronic hepatitis B

In general, pregnancy is well tolerated by women who are chronic carriers of the hepatitis B virus (HBV) (192); reactivation of the virus with exacerbation of disease during or after gestation is the exception rather than the rule (182,193). The placenta forms an excellent barrier against transmission of this large virus, and intrauterine infection with HBV is rare. It does occur, however, probably as a result of transplacental leakage, as in threatened abortion (194,195). The major problem for women who are chronic carriers of HBV is the risk of maternal-to-infant (vertical) transmission of infection at delivery. Transmission at birth is more likely if the mother is positive for

hepatitis B early antigen (HBeAg) (196) or has high circulating levels of HBV DNA (197). The rate of transmission may be lower if the delivery is by cesarean section (198). However, this is usually not indicated because appropriate immunoprophylaxis for the newborn with both HBV hyperimmune globulin and vaccine is efficient to interrupt transmission. Routine prenatal screening of all pregnant women for hepatitis B surface antigen (HBsAg) is now the standard of care (199). Infants born to infected mothers should be protected by the

recommended combination of vaccine and hepatitis B immunoglobulins at birth (199), although the emergence of mutant strains of the virus in such infants has been reported (200). Infants born to carriers of the HBV precore mutant who are positive for antibody anti-HBe and with high levels of HBV DNA in their serum are at risk for fulminant hepatitis B during the first 2 to 4 months after birth (201). Immunoprophylaxis should therefore be given to the infants of all mothers who are HBsAg positive, regardless of their HBe status. In women with very high HBV-DNA levels, vertical transmission of HBV can occur despite vaccination of the child. In eight such highly viremic HBsAg-positive women (HBV-DNA levels above 150pg/mL approximately equivalent to 1.2×10^9 geq/mL), a treatment with lamivudine (150 mg/day) during the last month of pregnancy decreased the HBV-DNA level and was associated with a reduction of the risk of child vaccination breakthrough (202). Hepatitis D (δ) virus can also be transmitted from mother to infant at birth (203).

Chronic hepatitis C

Uneventful pregnancy without worsening disease or fetal complications has been reported in women with hepatitis C (204). Several studies have demonstrated that aminotransferase levels decrease as the pregnancy progresses, whereas the HCV load, measured by polymerase chain reaction, increases during the course of gestation (205,206,207). Early evidence suggests that the hepatic histopathology may worsen during gestation (208). Whether pregnancy has any effect on the progression of this disease remains to be proved (209).

Transmission from mothers who are chronic carriers to their offspring may occur but appears to be much less efficient than the vertical transmission of hepatitis B (210). Rates of transmission were initially said to be proportional to the mother's viral burden, as indicated by the measurement of HCV RNA by polymerase chain reaction, and greatly enhanced transmission was supposed to occur in women coinfected with HIV, who have very high levels of viremia and rates of transmission ranging from 6% to 30% (211,212,213). More recent studies have not shown a correlation between a large viral load and increased maternal–infant transmission (205,207). Testing the newborn can be misleading. Early after birth, antibodies acquired from the mother result in positivity for HCV, and transient viremia can be seen in infants who later test negative. Cord blood can be negative for HCV RNA, although the infant is subsequently shown to be HCV RNA positive (205). An overall transmission rate of 5% according to testing performed 1 year after birth, regardless of the mother's HIV status, has been reported (205). No association with breast-feeding has been shown, and breast-feeding is not contraindicated (214,215). It may be prudent for mothers who are HCV infected and choose to breast-feed to consider abstaining from breast-feeding if their nipples are cracked and bleeding (215). The rate of transmission is not lower in infants delivered by cesarean section, and cesarean section is not recommended for women with chronic HCV infection alone (216). Hepatitis C acquired in infancy appears to have a benign course, although on biopsy some affected children have chronic hepatitis (210).

Hepatitis G/GB and hepatitis TT

It is unclear whether the hepatitis G/GB virus and the hepatitis TT virus are pathogenic. Both have been shown to be transmitted efficiently from mother to infant, with sustained infection in the offspring, in the absence of any liver disease (217,218,219).

Autoimmune hepatitis

A distinctive clinical characteristic of autoimmune hepatitis is the rapid and complete (or nearly complete) remission that occurs in response to immunosuppression with corticosteroids, given either alone or in combination with azathioprine. The disorder presents frequently in young women, many of whom become anovulatory in response to the active and severe hepatitis, which sometimes progresses to cirrhosis by the time of diagnosis. Women appropriately treated for this disease with corticosteroids and azathioprine regain their fertility, and successful pregnancies without any increase in fatality have been reported (220). The aminotransferase levels may decrease during the second and third trimesters of pregnancy, and some have advocated lowering doses of immunosuppressive drugs during gestation (221). Untreated patients may go into remission during pregnancy (222). The underlying disease may flare up after delivery, and women should be followed up carefully for the first 4 to 6 weeks postpartum, particularly if the immunosuppressive dose has been decreased. Worsening of the underlying disease or even initial presentation of autoimmune hepatitis has been reported during pregnancy (220). Azathioprine has not been reported to be teratogenic in this setting of low-dose therapy. Successful treatment of infertility in these patients, with in vitro fertilization/embryo transfer, has been reported (223).

Primary biliary cirrhosis

The effects of pregnancy on women with primary biliary cirrhosis have been reported to be variable although studies are scarce. Pregnancy may be associated with an increase in cholestasis that resolves after delivery, regression of cholestasis, or progression of disease

including the complications of portal hypertension (224,225,226,227). Ursodeoxycholic acid has been used for ICP with no reports of adverse effects and can be used in patients with primary biliary cirrhosis at the very least during the second and third trimester. In a recent report of nine pregnancies in six women with ursodeoxycholic acid–treated primary biliary cirrhosis, pregnancy was associated with improvement of liver function tests (228).

Wilson disease

Women with ovulatory failure secondary to Wilson disease regain their fertility, often quite rapidly, when treated. Either they or their physicians may be tempted to discontinue therapy during gestation, but, as in nonpregnant patients with Wilson disease, cessation of therapy can have devastating effects and should not be attempted (229,230). Successful pregnancy without teratogenicity has been reported in patients taking penicillamine or trientine (231,232,233,234). Zinc treatment has also been successful during pregnancy (235). Clearly, the major risk to the mother created by stopping therapy greatly outweighs the potential risk to the fetus, and therapy should be continued because successful pregnancy in treated women is the rule (231). Doses of penicillamine or trientine may be reduced during the last trimester (231).

Benign liver tumors (hepatic adenoma, focal nodular hyperplasia, hemangioma)

Hepatic adenoma associated with the previous use of oral contraceptive agents

has been reported to enlarge or rupture during subsequent pregnancy (236,237,238,239), and rupture is associated with high mortality (236). Successful surgical resection of a large hepatocellular adenoma performed at 13 weeks of gestation has been reported; the patient complained of increasing epigastric pain and the tumor (7 cm × 9 cm) was in the left hepatic lobe (240). A recent study of 216 women with focal nodular hyperplasia showed no association between oral contraceptive use and change in lesion size. Twelve women in this group became pregnant, with no change in lesion size or problems with pregnancy (241). An enlargement of a focal nodular hyperplasia associated with the previous use of oral contraceptive was however reported in one pregnant woman (242). The occurrence of liver hemangiomas during pregnancy has been reported (243). The results of a recent prospective study of 94 women (181 hemangiomas) suggests that endogenous and exogenous female sex hormones may play a role in the pathogenesis of liver hemangiomas, although significant enlargement occurs only in a minority of patients (244). These liver hemangiomas are rarely symptomatic and complications are exceptional.

Familial hyperbilirubinemia

The unconjugated hyperbilirubinemia of Gilbert syndrome is not exacerbated by pregnancy (245). In Dubin-Johnson syndrome, however, conjugated hyperbilirubinemia may worsen during gestation but returns to prepregnancy levels after delivery (246). Women with type II Crigler-Najjar syndrome have been reported to have uncomplicated pregnancies during phenobarbital therapy (247,248).

Porphyrias

Porphyrias, genetic disorders of heme metabolism that may be exacerbated by estrogenic hormones, occasionally cause problems for affected women and their fetuses during pregnancy. Porphyria cutanea tarda has rarely been reported to present initially during pregnancy (249). Acute attacks often complicate the course of pregnancy in patients with acute intermittent porphyria, variegate porphyria, or hereditary coproporphyria (250,251), and they may result in intrauterine growth retardation or, rarely, maternal death. On the other hand, many women with acute porphyria, particularly those with little clinical expression of the defect, weather pregnancy with no problems. Precipitation of an initial attack of acute intermittent porphyria by the nausea and vomiting of hyperemesis gravidarum, coupled with antiemetic therapy, has been reported (252).

Liver transplantation

Patients who have undergone transplantation regain their fertility promptly—within weeks of surgery. Young women should be counseled about the risks of becoming pregnant and encouraged to use effective contraception, preferably barrier methods, until their immunosuppressive regimen has been stabilized (253,254). A review of 136 pregnancies after liver transplantation reported to the National Transplantation Pregnancy Registry has shown that most are successful, with no birth defects in the offspring (255). The number of premature infants is increased, and women whose renal function is compromised do not do as well. Ten episodes of acute rejection occurred during pregnancy in this study, and as a result three women lost their grafts. Seven of the women died, three within a year of the pregnancy. The risk of teratogenicity with standard

immunosuppressive agents, including prednisone, azathioprine, cyclosporine, and tacrolimus, is low (256). It is preferable to delay pregnancy until the immunosuppressive regimen has been stabilized (i.e., 1 to 2 years after grafting). Surveillance for infection, such as that with cytomegalovirus, should be increased during gestation. If the results of liver tests become abnormal, then liver biopsy should be performed to establish the nature of the dysfunction. Increased monitoring of the

blood levels of cyclosporine and other immunosuppressive agents is necessary, both before and for several months after delivery (257). Such pregnancies should be considered high risk and managed together with experts in maternal–fetal medicine. Breast-feeding has been discouraged because of concerns about potential immunosuppression of the newborn, but many examples of successful breast-feeding without adverse effects have been reported (255).

Liver transplantation has been accomplished during pregnancy, with and without fetal wastage (255,258,259,260). Livers from living related donors have also been transplanted during pregnancy (261). Obviously, such heroic surgery must be considered with extreme care in this setting. If a condition prompting transplantation is caused (e.g., AFLP) or exacerbated (e.g., Budd-Chiari syndrome) by pregnancy, then prompt diagnosis, followed by termination of the pregnancy with maximum support for the mother, is the treatment of choice. Auxiliary partial orthotopic liver transplantation is an attractive alternative in the setting of liver disease that should resolve after delivery, with regrowth of the patient's native liver and atrophy of the transplanted liver (262).

Title: ***Schiff's Diseases of the Liver, 10th Edition***

Chapter 47
Liver Disease in Infancy and Childhood

Maureen M. Jonas
Antonio R. Perez-Atayde

Key Concepts

- Understanding the genetic and molecular control of liver development will elucidate hepatobiliary pathophysiology and provide a framework for understanding disorders of the liver and bile ducts that occur at all ages.
- Hepatobiliary disorders that occur in both adults and children, such as viral hepatitis and autoimmune hepatitis, share some features, but there may be important differences in epidemiology, natural history, clinical presentation, and therapeutic considerations.
- Characterization of the genetic defects in several forms of intrahepatic cholestasis illustrates the importance of normal hepatic excretory function, and may explain both severe cholestatic liver disorders in childhood as well as predisposition to liver and biliary tract diseases in some adults.
- Extrahepatic biliary atresia is the most common cause of end-stage liver disease and the most common indication for liver transplantation in the pediatric age-group. Early diagnosis is critical.
- Although some genetic diseases or inborn errors of metabolism cause significant liver disease during infancy and childhood, others may have manifestations beginning in or lasting into adulthood.
- As individuals with cystic fibrosis survive well into adulthood, it has become important to understand the chronic liver disease that develops in some of these patients and devise strategies that may be unique to this large group of patients with a multisystem disorder.

Embryology of the Hepatobiliary System

The hepatic diverticulum is seen as early as the 18th day of gestation (2.5-mm stage) as a thickening of the ventral floor of the distal foregut, the future duodenum. The liver diverticulum penetrates the adjacent mesoderm and capillary plexus known as the *septum transversum*. Cellular interactions between the endoderm and mesoderm result in rapid cell proliferation and the formation of hepatocytes, angioblasts, and sinusoids. By the third and fourth weeks of gestation the growing diverticulum enlarges and branches, projecting into the septum transversum. Division of this diverticulum into a solid cranial portion (hepatic parenchyma) and hollow caudal portion is evident by the 5-mm stage. The hepatic portion differentiates into proliferating cords of hepatocytes and intrahepatic bile ducts while the smaller cystic portion (pars cystica) forms the primordium of the gallbladder, common bile duct, and cystic duct.

The budding liver sequentially invades the vitelline veins and then the umbilical (placental) veins. The vitelline veins run from the gut-yolk sac complex to the heart. The caudal ends of the veins persist as the primitive portal veins and the cranial ends persist as the primitive hepatic veins. The hepatocytes grow as thick epithelial sheets intermingling between branching channels of the vitelline veins within the septum transversum to form a system of connecting liver cell plates,

whereas the proliferative angioblasts become the hepatic sinusoids. The sinusoids, present by 5 weeks' gestation, act as templates for the three-dimensional growth of the hepatic cords. The liver cell plates are initially three to five cells thick. Over time, they gradually transform to one-cell-thick plates, a process that is not complete until 5 years of age. Intrahepatic bile ducts begin to form at 6 weeks' gestation within the hilum of the liver and gradually reach the periphery at 3 months (1).

Although the pars cystica is initially hollow, epithelial proliferation obliterates the lumen early in its development. Therefore, the primitive gallbladder and common bile duct consist of solid chords of epithelial cells directly beneath the developing liver in the 6- to 7-mm embryo. Recanalization of the common bile duct and hepatic duct occurs subsequently, until at the 16-mm stage the proximal gallbladder and cystic duct are hollow. At the third month the gallbladder is fully hollow, and the intrahepatic and extrahepatic biliary structures are joined. Bile secretion into the duodenum starts by the fourth month.

In the third month the liver begins to store iron, and hematopoietic elements derived from the mesenchyme of the septum transversum localize within the lobules and portal tracts. The liver therefore becomes the major blood-forming organ of the embryo. This function is gradually transferred to the developing bone marrow so that by birth only an occasional focus of hematopoiesis remains in the liver.

During fetal life, the falciform ligament conducts the umbilical vein from the umbilicus to the liver. After birth this vein atrophies to form the ligamentum teres. In neonates and infants, the liver accounts for 5% of the total body weight, as compared with 2% in adults.

Development of Hepatobiliary Function

The fetus is supplied with a continuous flow of high-carbohydrate, low-fat, and high–amino acid nutrients through the placenta, but the newborn is fed in intervals with milk; a high fat, lower-carbohydrate diet. At weaning there is another shift to an adult-type diet, which includes more carbohydrates and less fat. The liver plays a central role in these adaptations through regulation of carbohydrate, fat, and protein metabolism. The adult pattern of metabolic pathways develops shortly after birth as the blood supply to the liver changes from one dominated by umbilical venous blood to one in which the hepatic artery plays an equally important role. This allows for the development of the functional zones within the liver, each with unique metabolic demands. Zone 1 (periportal) hepatocytes predominantly perform gluconeogenesis, β-oxidation,

cholesterol biosynthesis, bile acid secretion, ureogenesis, and sulfation of drugs, whereas zone 3 (pericentral) cells perform glycolysis, lipogenesis, ketogenesis, glutamine synthesis, and glucuronidation of drugs.

The liver plays an important role in the handling of dietary starches. Fetal glucose utilization approximately equals umbilical glucose uptake. At weaning, two factors allow for increase in hepatic glucose uptake. First is the presence of a high-capacity, low-affinity glucose transporter, GLUT2, which is insulin-independent. The second is glucokinase, which replaces hexokinase as the predominant glucose phosphorylation enzyme within the hepatocyte allowing for specific action upon glucose, and induction by insulin.

Throughout gestation the fetus actively stores some of the glucose as glycogen so that hepatic glycogen at birth is about twice the adult concentration at 40 to 60 mg/g of liver. Most of this stored glycogen is utilized in the immediate postnatal period. Reaccumulation begins in the second postnatal week, and glycogen stores typically reach adult levels by the third week. The role of this large store is the maintenance of blood glucose levels during the perinatal period, before other energy sources are available, and before the initiation of hepatic gluconeogenesis.

The rate-limiting enzyme involved in gluconeogenesis, phosphoenolpyruvate carboxykinase (PEPCK), rapidly rises after birth. PEPCK is a cytosolic enzyme primarily expressed in the periportal (zone 1) hepatocytes. Glucose-6-phosphatase catalyzes the final step in glucose release from the liver. This enzyme, located within the lysosomes, rises rapidly at term and is hormonally controlled.

Although the fetal liver is capable of synthesizing albumin, lipoproteins, enzymes, coagulation proteins, and a variety of carrier proteins after the third month of gestation, concentrations of these proteins are low in fetal plasma. Lipoproteins increase in the first week after birth to levels maintained until puberty. Albumin reaches adult levels after several months in a reciprocal relationship with the primary fetal protein, α-fetoprotein. Ceruloplasmin and complement factors increase to mature values during the first year. Transferrin levels are present in the low adult range at birth and slowly rise to normal adult levels thereafter.

Fat storage begins during fetal life. Synthesis of fatty acids by the fetal liver occurs despite low levels of acetyl CoA carboxylase, the rate-limiting step in fatty acid synthesis in the adult liver. The triacylglycerol that accumulated during fetal life is mobilized for local utilization after birth.

Bile acids are produced as early as the tenth week of gestation. Chenodeoxycholic acid is predominant. Although glycine is the most common conjugate in adults, in early life more than 80% of the bile acids are taurine-conjugated. In infants, the total bile acid pool size is small; at 32 weeks' gestation the fetus has a bile

acid pool one sixth that of an adult. In a premature infant, the intraluminal bile acid concentration may fall below the critical micellar concentration of 1 to 2 mmol/L. In addition, there is less effective intestinal reabsorption, inadequate canalicular secretion, and inefficient hepatic uptake of bile acids from the systemic circulation. The cumulative effects of the immature bile acid metabolism and homeostasis in newborns result in relatively inefficient absorption of dietary fats and fat-soluble vitamins, and a tendency toward cholestasis (2).

Hepatocytes are responsible for the excretion of numerous substances through bile, including bilirubin, drug metabolites, and heavy metals such as zinc and copper. Bile secretion starts at the beginning of the fourth month of gestation, and the presence of bile in the lumen of the intestine is responsible for the dark green color of meconium.

Bilirubin formation is 3 to 4 mg/kg per day in healthy adults and 6 to 8 mg/kg per day in healthy term infants. This difference is due to the greater relative red blood cell mass and shorter red blood cell life span in infants. Infants have lower levels of the conjugating enzyme, bilirubin glucuronyl transferase, and therefore have fewer diglucuronides than adults. When bilirubin conjugates enter the intestinal lumen, normal bacterial flora hydrogenate the carbon double bonds to produce urobilinogens, which are excreted. Neonates lack the bacteria *Clostridium ramosum* and *Escherichia coli* and are therefore more likely to absorb bilirubin from the intestine. Bilirubin can also be unconjugated by bacterial or tissue β-glucuronidase, and readily absorbed from the intestine.

Congenital Abnormalities in Hepatobiliary Structure

Situs Inversus and Heterotaxia

Situs inversus and heterotaxia result in left sided or ambiguous location of the liver within the abdominal cavity, respectively. Either may occur with other anomalies such as in the polysplenia/asplenia syndromes.

Vascular Anomalies

Although many variations have been described in hepatic artery anatomy, most do not have clinical significance except when the patient requires hepatic surgery.

Congenital absence of the portal vein (CAPV) is a rare but well-described anomaly (2a), and when seen with a spontaneously occurring mesocaval or other portosystemic shunt, is referred to as Abernethy malformation. CAPV may be associated with nodular regenerative hyperplasia of the liver (2) and the Goldenhar's syndrome (3). Children with this anomaly may have elevated serum ammonia, bile acids, and galactose concentrations, as the portosystemic shunt bypasses the detoxifying ability of the liver (4). Other anomalies of the portal vein are occasionally seen, in association with cardiac or urinary tract abnormalities.

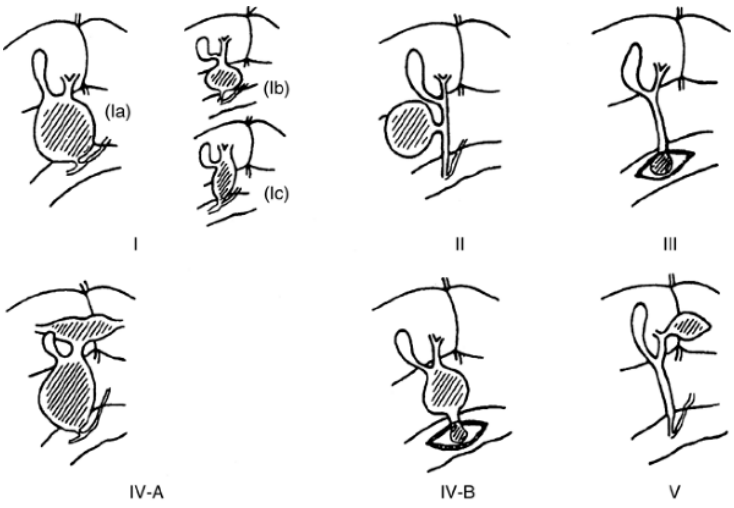
The presence of multiple serpiginous collateral veins surrounding a small or thrombosed portal vein has been referred to as *cavernous transformation of the portal vein*. This is an acquired rather than a congenital abnormality and is accompanied by portal hypertension since portal resistance is markedly elevated. It represents the body's effort to maintain hepatopetal portal flow in the face of occlusion of the extrahepatic portal vein. The causes of portal vein thrombosis include umbilical infection (omphalitis), perinatal catheterization of the umbilical vein, pancreatitis, surgical manipulation during splenectomy, and hypercoagulable states including deficiencies of protein C, protein S, or antithrombin III, and the presence of anticardiolipin antibodies or a factor V Leiden gene mutation. Children with cavernous transformation of the portal vein typically come to medical attention within the first decade with splenomegaly or bleeding from esophageal varices. The diagnosis is confirmed by ultrasonography of the extrahepatic portal area with Doppler interrogation. Endoscopic ligation or sclerosis of esophageal varices, portosystemic shunts, and mesenterico-left portal bypass (Rex shunt) are palliative measures. The natural history is such that over time there is a decrease in the frequency and intensity of the hemorrhagic manifestations. Liver histology is usually nondiagnostic with nonspecific findings, which may include fibrosis.

Biliary Tract Abnormalities

Choledochal cysts

Choledochal cysts are congenital malformations resulting in cystic dilatation of part or all of the extrahepatic biliary system. The incidence is estimated at 1 in 13,000 to 200,000 live births. They are found in women four times more frequently than in men, and are more prevalent in Asians, specifically the Japanese. The location of the cyst allows for classification into one of five anatomic types as described by Todani (Fig. 47.1) (5). Most are type I, diffuse enlargement of the common bile duct. The etiology of cyst formation is unclear, although there is growing evidence that the dilatation results from an anomalous junction of the common bile duct and the pancreatic duct resulting in a common channel up to 3.5 cm in length, from a normal of 5 mm. This long common channel may allow for the reflux of pancreatic proteases into the extrahepatic biliary tree resulting in cholangitis and stenosis. This hypothesis is supported by high levels of amylase within the cysts, but

the frequent documentation of prenatal choledochal cysts makes a malformation etiology more likely.



▪ **Figure 47.1** Types of choledochal cyst. (From Todani T, Watanabe Y, Narusue M, et al. Congenital bile duct cysts: Classification, operative procedures and review of thirty seven cases including cancer arising from choledochal cyst. *Am J Surg* 1977;134:263–269.with permission.)

Most patients present within the first decade of life. The classic triad of abdominal pain, jaundice, and palpable right upper quadrant mass occurs in less than 20% of patients. Other common symptoms are fever, nausea, and vomiting, with or without associated pancreatitis. Ultrasonography is the most valuable diagnostic test. Radionuclide scanning may demonstrate the accumulation of tracer within the cyst. Endoscopic retrograde cholangiopancreatography (ERCP) provides delineation of the biliary anatomy, but is not always necessary to confirm the diagnosis.

The high incidence of biliary malignancy, reported between 2.5% and 17.5% in Japanese patients, has led to the recommendation of cyst excision. Most tumors are adenocarcinomas, detected at a mean age of 35 years. The cause of the malignant transformation is not known, but may relate to the chronic reflux of pancreatic proteases and the mutagenic potential of secondary bile acids in a stagnant environment. The reconstruction varies on the cyst type, anatomy, and surgical preference; the most common procedures are hepaticoduodenostomy, hepaticojejunostomy, or jejunal interposition.

Gallbladder anomalies

Congenital absence of the gallbladder occurs in 1 in 7,500 to 1 in 10,000 individuals. Failure of development of the pars cystica is the likely etiology. As an isolated abnormality this is of little clinical significance although rarely symptoms develop because of calculi in the ductal system. In addition to extrahepatic biliary atresia (EBA), which may accompany agenesis of the gallbladder, other associations include imperforate anus, genitourinary anomalies, anencephaly, bicuspid aortic valve, and cerebral aneurysms. *Hypoplasia of the gallbladder* has been described. As many as one third of individuals with cystic fibrosis (CF) have small, poorly functioning gallbladders. There is also an association with EBA and trisomy 18. The incidence of *double gallbladder* is 0.1 to 0.75 per 1,000. The two cystic ducts may converge into a single duct forming a Y-shaped structure, or an accessory gallbladder may lie under the left lobe of the liver, draining into the left hepatic duct.

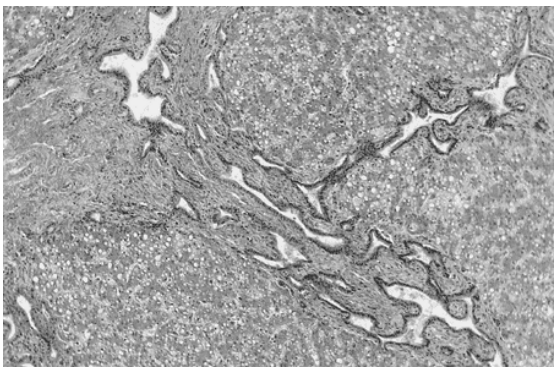
Extrahepatic biliary atresia—fetal form

EBA is usually considered an acquired condition, and is discussed in subsequent text in this chapter. However, there is an embryonic or fetal type that comprises approximately 35% of cases and may be a true congenital biliary tract anomaly (6). This form is characterized by earlier onset of cholestasis and absence of bile duct remnants. Ten percent to 20% of children with fetal-type biliary atresia have associated anomalies. The most common are various combinations that characterize the laterality sequence, such as polysplenia or asplenia, cardiovascular defects, abdominal situs inversus, intestinal malrotation, and vascular aberrations of the portal vein and hepatic artery. Intestinal malrotation alone is seen in 12%. There is speculation that the fetal form of biliary atresia has a different pathologic mechanism than the perinatal type, although this has not been proven.

Ductal plate abnormalities

At about the eighth week of gestation, the hepatic precursor cells that lie adjacent to the hilar portal vein vessels form a sleeve-like double layer of cells, which extends toward the periphery along the intrahepatic portal vein branches. This structure has been called the *ductal plate* (DP). Beginning at 12 weeks' gestation and extending into the postnatal period, the DP undergoes remodeling (7). Individual bile ductules are incorporated into the periportal mesenchyme that surrounds the portal vein branches. During successive periods of fetal life, DP remodeling leads to the formation of the intrahepatic biliary tree. The largest ducts are formed first, followed by segmental, interlobular, and finally the smallest bile ducts. Arrest or derangement in remodeling leads to the persistence of primitive bile duct configurations, or to what Jorgensen termed *ductal plate malformation* (DPM) (7). The occurrence of DPM at different generation levels of the developing biliary tree gives rise to different clinicopathologic entities, such as congenital hepatic fibrosis (CHF) and Caroli syndrome (8,9).

The most common DPM-associated disorder is autosomal recessive polycystic kidney disease (ARPKD) with CHF, which occurs with an incidence between 1 in 6,000 and 1 in 40,000 births. The cysts are rarely macroscopically visible. Microscopically, the portal tracts appear enlarged by connective tissue and contain tortuous and dilated bile duct structures (Fig. 47.2) and incompletely remodeled ductal plates, which are in continuity with the rest of the biliary system. The renal lesion is characterized by radially arranged tubular collecting duct cysts occupying most of the large, externally smooth renal mass. This disorder has been attributed to mutations in *PKHD1* on chromosome 6p12, which encodes a protein called *fibrocystin*. Fibrocystin is localized to the collecting ducts and biliary ducts.



▪ **Figure 47.2** Congenital hepatic fibrosis. Expanded portal tracts show persistence of the ductal plate and cystic and tortuous bile ducts. Incidental mild steatosis is also present.

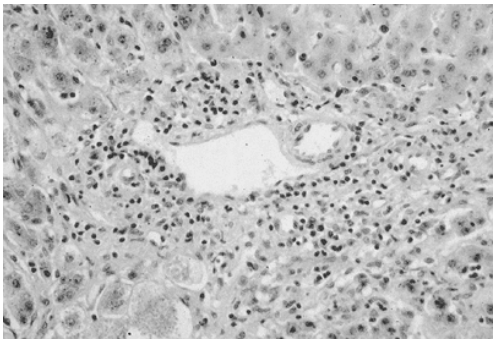
CHF may also be associated with other liver malformations such as von Meyenburg complexes (bile duct microhamartomas), as well as other renal lesions including autosomal dominant polycystic kidney disease, renal dysplasia, and nephronophthisis. Congenital dilatation resulting from DPM of the larger, segmental intrahepatic bile ducts is termed *Caroli disease*. When this lesion is combined with the changes of CHF, as is typically the case, the disorder is termed *Caroli syndrome* (see Chapter 43). Mutations in *PKHD1* have been found in 32% of adults with CHF/Caroli syndrome (10).

Infants with congenital hepatic fibrosis–autosomal recessive polycystic kidney disease (CHF-ARPKD) may have enlarged and severely dysfunctional kidneys. In this setting, hepatic fibrosis may be present, but is rarely an important clinical factor. In older patients, the most significant abnormality is portal hypertension due to the hepatic fibrosis and/or portal vein anomalies, such as duplication of intrahepatic branches. Hematemesis or melena may occur as early as 1 year, but more typically at 5 to 13 years of age. The biochemical parameters of hepatic synthetic function are typically normal, but there is a risk of cholangitis. Treatment may include portosystemic shunting for portal hypertension and aggressive antibiotic therapy for cholangitis. Approaches such as variceal sclerotherapy or pharmacologic management of portal hypertension have been used. In patients with chronic cholangitis and/or progressive hepatic dysfunction, liver transplantation may be indicated.

Bile duct paucity syndromes

Paucity of the intrahepatic bile ducts is defined as a ratio of interlobular ducts to

portal tracts of less than 0.9 (Fig. 47.3). Surgical biopsy or serial needle biopsies may be required to examine at least 20 portal tracts, the recommended sample for this diagnosis, but as few as 5 portal tracts in a percutaneous biopsy may be sufficient in the appropriate clinical setting. Syndromic paucity of the bile ducts, or Alagille syndrome (AS), discussed in subsequent text, is the most common disorder with this finding. Patients with nonsyndromic paucity of intrahepatic bile ducts typically present earlier than those with AS (11). Paucity of the bile ducts has been described in association with a variety of other conditions including Down's syndrome, hypopituitarism, CF, α_1-antitrypsin deficiency, Zellweger's syndrome, Ivemark's syndrome, and congenital infections. Inflammatory destruction of bile ducts occurs in graft versus host disease, chronic hepatic allograft rejection, primary sclerosing cholangitis (PSC), and drug toxicity (vanishing bile duct syndrome). Paucity of the bile ducts may lead to chronic cholestatic liver disease with biliary-type cirrhosis.



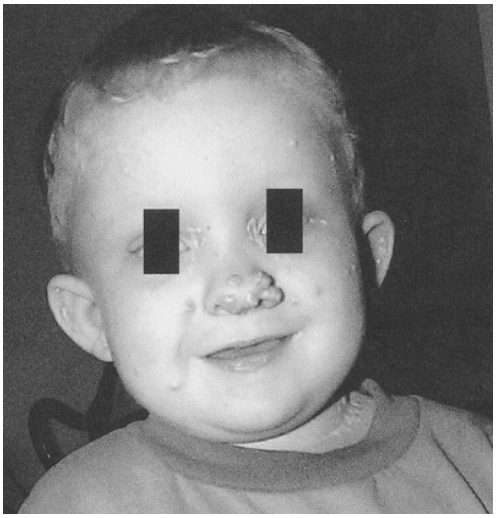
▪ **Figure 47.3** Intrahepatic paucity of bile ducts. Portal tract with absent bile duct in a patient with Alagille syndrome.

AS is also called *arteriohepatic dysplasia*, and is characterized by reduced interlobular bile ducts in association with cardiac, skeletal, ocular, facial, and less frequently renal, and neurodevelopmental abnormalities (12). Features of AS are listed in Table 47.1 (12,13). The prevalence of this autosomal dominant syndrome with highly variable penetrance is reported as 1 in 100,000 live births. Histologic evidence of bile duct paucity may not be present at birth; the ducts are thought to be lost over a number of months or even years. Jaundice is present in most symptomatic patients and presents as conjugated hyperbilirubinemia (serum levels between 4 and 10 mg/dL) in the neonatal period. Hepatomegaly is invariably present and pruritus can become severe by 6 months. Xanthomas develop in patients with chronic hypercholesterolemia and can become disseminated and disfiguring (Fig. 47.4). General management includes nutritional support with provision of fat-soluble vitamin supplements and symptomatic treatment for pruritus. Some of these symptoms may be improved by partial external biliary diversion (14). In some cases, the cardiac manifestations dominate the clinical presentation, and corrective surgery for peripheral pulmonic stenosis or other lesions may be needed. Progression to liver failure and cirrhosis requiring liver transplantation occurs in approximately 15% of cases, and account for approximately 2% of pediatric liver transplantations. In other cases, the cholestasis improves as the child approaches adulthood. Vascular anomalies, such as aneurysms and coarctation of the aorta, are reported in 9% of patients, and are responsible for up to 34% of the mortality caused by this syndrome (15). The genetic defect of AS has been found on chromosome 20p12, with a deletion or mutation of a single copy of the *Jagged 1* gene (16). Alterations of this gene interrupt the Notch signaling pathway that is crucial for cell-to-cell communication during differentiation. Notch signaling has an important role in the differentiation of biliary epithelial cells and is essential for their tubular formation during intrahepatic bile duct development (17).

Table 47.1. Features of Alagille Syndrome (12,13)

Feature	Percentage of patients
Bile duct paucity	85–100
Chronic cholestasis	91–96
Peripheral pulmonic stenosis	67–70
Tetralogy of Fallot	9–14
Butterfly vertebrae	51–87
Characteristic facies[a]	95–96
Posterior embryotoxon[b]	78–88
Growth retardation	50–87

[a]Facies consist of prominent forehead, moderate hypertelorism with deepset eyes, small pointed chin, saddle or straight nose.
[b]A defect in the anterior chamber of the eye in which there is a prominence of Schwalbe's ring (this is seen in 10% of the normal population).
Data from Alagille D, Estrada A, Hadchouel M, et al. Syndromic paucity of interlobular bile ducts (Alagille syndrome or arteriohepatic dysplasia): review of 80 cases. *J Pediatr* 1987;110:195–200 and Emerick K, Rand EB, Goldmuntz E, et al. Features of Alagille syndrome in 92 patients: frequency and relation to prognosis. *Hepatology* 1999;29:822–829.



• **Figure 47.4** Cutaneous xanthomas. The skin of this child with Alagille syndrome has numerous xanthomas that may be plaques or nodules with characteristic smooth surface. The lesions are characteristically yellow or pink.

Genetic/Metabolic Liver Disease

The liver is involved primarily or secondarily in many inborn errors of metabolism. This section will focus on those disorders that lead to acute or chronic

damage to the liver itself by one of three mechanisms: accumulation of toxic metabolites, failure to produce essential compounds, or sequestration of an abnormally synthesized product within the liver. In addition to nonspecific signs of liver disease, such as those seen in viral hepatitis or drug-induced liver injury, metabolic liver disease is often associated with other signs and symptoms that should suggest this diagnosis to the clinician (Table 47.2). Adequate liver sampling allows measurement of enzymatic pathways or substrate accumulation in addition to histologic examination. A specific diagnosis may allow effective therapy or provide an indication for liver transplantation. Genetic counseling is often indicated.

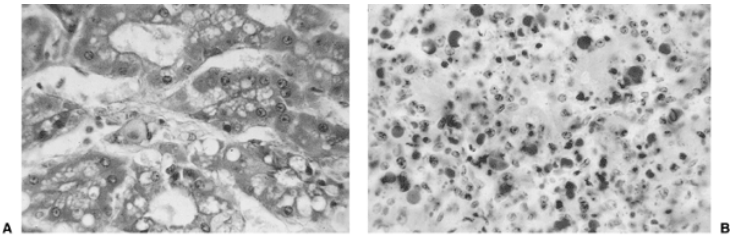
Table 47.2. Clinical Features Suggestive of Metabolic Liver Disease in Children

Coma with hyperammonemia
Hypoglycemia
Psychomotor retardation
Hepatosplenomegaly with or without liver dysfunction
Acidosis
Failure to thrive
Muscle weakness
Coagulopathy, particularly out of proportion to liver test abnormalities
Dysmorphic facial features
Cholestasis
Cardiac disease

Disorders of Carbohydrate Metabolism

Galactosemia

Galactose is normally converted to glucose through three separate enzymatic reactions involving galactokinase, galactose 1-phosphate uridyl transferase (GALT), and uridine diphosphate galactose 4-epimerase. The three known disorders are now designated transferase deficiency galactosemia, epimerase deficiency galactosemia, and galactokinase deficiency galactosemia. The overall frequency is approximately 1 in 40,000 live births. The most common severe defect involves a deficiency of GALT. The sequence of the human *GALT* gene has been established (18). Many patients are found to be compound heterozygotes. Inactivity of the transferase results in the accumulation of toxic metabolites including galactose 1-phosphate and galactitol. Early manifestations include lethargy, vomiting, acidosis, cataracts, failure to thrive, and jaundice. Urinary tract infection and/or sepsis, typically with gram-negative species, is also a common presenting problem. Hemolytic anemia and erythroid hyperplasia, occasionally severe and resembling erythroblastosis, occur in 40% of patients. Rapid recognition and treatment in the newborn period is critical because untreated disease is likely to result in severe neurologic injury. Most states have programs for newborn screening for galactosemia, but the diagnosis is confirmed with an enzymatic assay for GALT using red blood cells. Histopathologic findings in the liver include diffuse hepatocellular damage with marked steatosis, cholestasis, and pseudoacinar transformation (Fig. 47.5A,B). Treatment consists of strict elimination of galactose from the diet, which will normally reverse the hepatopathy. However, the long-term efficacy of dietary therapy may not be as successful due to difficulty in completely eliminating galactose from the diet and from endogenous conversion of glucose into galactose through reversal of the normal pathways for galactose metabolism. Long-term complications include growth failure, developmental delay, and ovarian failure despite vigilant adherence to a galactose-free diet (19).



▪ **Figure 47.5** Galactosemia. **A:** Pseudoacinar transformation of hepatocytes, fatty change and cholestasis is the usual triad of histologic findings. **B:** Oil-red-O on a frozen section reveals the extensive hepatocellular steatosis.

Hereditary fructose intolerance

Hereditary fructose intolerance (HFI) is the result of a genetic deficiency in the enzyme fructose 1,6-biphosphate aldolase (aldolase B). The pathophysiologic process is due to metabolic effects of the

accumulated fructose 1-phosphate. Sorbitol is interconverted to fructose and can therefore lead to a similar process. Signs and symptoms of long-term exposure to fructose include hepatomegaly, abnormal aminotransferase values, hepatic steatosis, poor feeding, vomiting, irritability, and poor growth (20). The classic features of acute metabolic disease and hypoglycemia are not always present, because many affected individuals evolve an eating behavior that avoids fructose. Therefore, HFI needs to be considered in children with unexplained hepatomegaly and steatosis. A high index of suspicion is crucial because the presenting signs and symptoms can be subtle. The histologic findings are similar to those of galactosemia. Aldolase B activity can be measured in liver tissue. Three different specific mutations in aldolase B account for a large number of affected individuals. Deoxyribonucleic acid (DNA) diagnostic assays (including allele specific oligonucleotide hybridization) using peripheral leukocytes may be utilized. Treatment involves strict avoidance of fructose, sorbitol, and sucrose. Partial adherence to this difficult diet can ameliorate many of the acute manifestations of this disease but not the chronic problems such as growth failure.

Table 47.3. Glycogen Storage Diseases

Type	Enzyme deficiency	Tissue involved	Synonym/notes
0	Glycogen synthetase	Liver, muscle	Aglycogenosis
Ia	Glucose-6-phosphatase (G6Pase)	Liver, kidney, intestine	Von Gierke's disease (hepatorenal glycogenosis)
Ib	Translocase (T_1) responsible for movement of glucose-6-phosphate across intracellular membranes	G6Pase activity is normal in homogenate made of frozen liver but is deficient in isotonic homogenate made of fresh (unfrozen) liver	
Ic	Translocase (T_2, the microsomal phosphate/pyrophosphate transport protein)		
Id	Translocase T_3		
IIa infantile IIb adult	Lysosomal acid α-glucosidase	In the fatal, classic form (IIa), glycogen concentration excessive in all organs examined; enzyme deficiency may be generalized; cardiac muscle in IIb normal but deficient in α-glucosidase activity	Pompe disease (generalized glycogenosis, cardiac glycogenosis)
III	Amylo-1,6-glucosidase ("debrancher" enzyme)	Liver, muscle, heart, etc., in various combinations	Limit dextrinosis (debrancher glycogenosis); Cori disease; Forbes disease

IIIa		Liver only	
IIIb		Generalized	
IV	Amylo-1,4→1,6-transglucosidase ("brancher enzyme")	Generalized (?)	Amylopectinosis (brancher glycogenosis); Andersen disease
V	Muscle phosphorylase deficiency	Skeletal muscles only	McArdle syndrome (liver and smooth muscle phosphorylase not affected)
VI	Liver phosphorylase deficiency	Liver; skeletal muscle normal	Hers disease
VII	Phosphofructokinase	Skeletal muscle, erythrocytes	Tarui disease
VIII	Hepatic phosphorylase kinase	Liver, brain, skeletal muscle normal; cerebral glycogen increased	Liver glycogenesis, X-linked
IX	Liver phosphorylase-*b*-kinase deficiency	Liver only; muscle tissue normal biochemically and microscopically	

Glycogen storage diseases

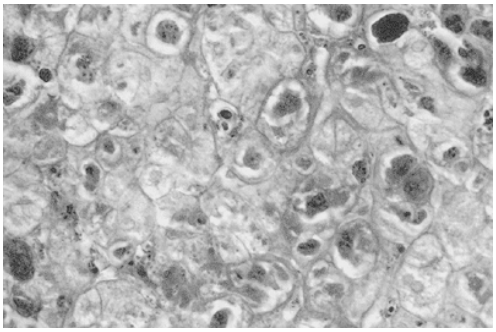
Glycogen, a polysaccharide molecule composed of D-glucose units, is found predominantly in liver and muscle. The glucose units are joined linearly by 1,4 linkages with 1,6 linkage branching at every fourth unit. The glycogen storage diseases (GSD) are disorders characterized by accumulation of glycogen in organ-specific patterns based on the deficient enzyme (Table 47.3).

Clinical manifestations of the various GSDs may result from inability to utilize glycogen stores, accumulation of glycogen within the liver and/or other tissues, and the toxic effects of certain abnormal types of glycogen. Forms of GSD that primarily affect the liver produce diffuse hepatomegaly and hypoglycemia, which

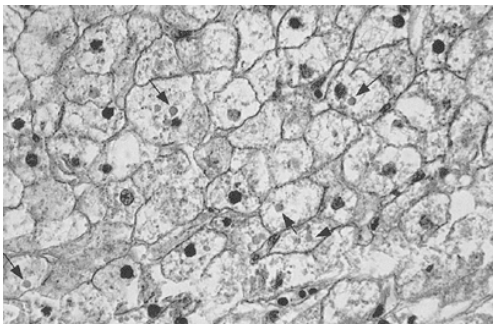
may be life-threatening. Fasting hypoglycemia is the hallmark of GSD due to an inability to utilize glycogen stores to produce glucose; type I is the most common. Forms of type I GSD (Table 47.3) include deficiency of glucose 6-phosphatase (von Gierke's disease, type Ia) and various deficiencies in glucose and glucose metabolite transport (glucose 6-phosphate transport, type Ib, microsomal phosphate transport, type Ic, microsomal glucose transport, type Id). GSD type Ib presents in a clinical manner identical to GSD type I, but these patients are often neutropenic with impaired neutrophil function (21); they are prone to recurrent bacterial infection, oral and intestinal mucosal ulceration, and bleeding. The striking limitation of glucose transport across the neutrophil cell membrane may account for impairment of neutrophil function. Cytokine therapy may correct the neutropenia.

A very different clinical presentation is observed in those disorders that lead to hepatic accumulation of toxic forms of glycogen. The best example of this is GSD type IV, deficiency of the glycogen branching enzyme. Glycogen that accumulates in this disease has long chains of glucose in a 1,4 linkage, resembling plant starch or amylopectin. This form of glycogen is relatively insoluble and presumed to be toxic. Liver biopsy reveals characteristic intracytoplasmic masses of periodic acid-Schiff (PAS) positive, diastase resistant material that enlarge and distort hepatocytes (Fig. 47.6). Progressive liver disease therefore becomes a major distinguishing feature of GSD type IV. Portal hypertension and hepatic failure may develop in early childhood.

Specific diagnosis depends on demonstration of the deficiency of enzyme activity in biopsy specimens. In these disorders, the liver biopsy should be processed for light and electron microscopic evaluation and a portion rapidly frozen for subsequent biochemical analysis. The light microscopic appearance of the liver in type I, the most common variety, demonstrates abundant accumulation of free glycogen in the cytoplasm and mild steatosis. Hepatocytes are markedly enlarged with clear cytoplasm, central nuclei, and compression of adjacent sinusoids (Fig. 47.7). Glycogenated nuclei are numerous in zone 1. Diagnosis of the specific type of GSD is critical for proper treatment and prediction of prognosis and potential complications. Specific enzymatic assays and DNA diagnostic tests are available in specialty laboratories for each of the disorders. Diagnostic assays can be performed on a number of tissues including liver, muscle, leukocytes, and fibroblasts.



▪ **Figure 47.6** Glycogenosis type IV (amylopectinosis). Large intracytoplasmic PAS+ diastase resistant inclusions enlarge and deform hepatocytes.



▪ **Figure 47.7** Glycogenosis type I. Diffusely enlarged hepatocytes have clear cytoplasms that impart a plant-like appearance. Hepatocellular megamitochondria (*arrows*) are usually present.

GSD can present at any age, and the prognosis is highly variable. Early reports of correction of many of the metabolic derangements of GSD type I by provision of nutrients directly into the systemic circulation by total parenteral nutrition (TPN) or by portacaval shunting gave important clues to its pathogenesis and therapy. Subsequently, it was demonstrated that maintenance of blood glucose levels greater than 70 to 90 mg/dL obviated most of the clinical manifestations of GSD type I (22). The presumed mechanism of action for this therapy is reduction of the stimulus for glycogenolysis and prevention of the abnormal compensatory metabolic pathways leading to lactate accumulation, lipid synthesis, purine synthesis, and subsequent hyperuricemia. The neutropenia of GSD type Ib is not corrected by glucose homeostasis.

Originally, maintenance of blood glucose was accomplished by continuous enteral feeding of infants with nasogastric or gastrostomy tubes. Alternatively, it has been shown that frequent daytime feedings (every 2 to 3 hours) of a high-starch diet can be combined with continuous nighttime tube feedings with the same effects. Frequent feeding of high-carbohydrate–containing foods and nocturnal administration of slow-release glucose polymers, such as uncooked cornstarch are utilized (22,23). This prevents the development of hypoglycemia and also

limits incorporation of excess dietary glucose into glycogen. However, as children become older, this regimen is more difficult to maintain and is altered to include daytime meals supplemented with raw cornstarch. Cornstarch undergoes slow degradation to glucose by α-amylase and, when given every 6 hours, steadily releases sufficient glucose into the system. This cornstarch supplementation can be combined with continuous nighttime feedings until the children are through the period of rapid growth and their glucose requirement decreases to the point that cornstarch supplements alone are sufficient for metabolic control.

As patients with GSD type I approach late adolescence, the tendency for hypoglycemia decreases and some investigators believe that less rigorous dietary therapy is required. However, treatment of the secondary complications of the disease with agents such as allopurinol for hyperuricemia or lipid-lowering agents for the prevention of cardiovascular disease and pancreatitis may be necessary. With prolonged survival due to improved therapy, an increasing number of patients are surviving into adulthood; this has led to recognition of late complications such as altered bone mineralization, renal disease, and endocrine abnormalities (24).

A long-term complication of GSD type I for which no definitive therapy has been established is hepatic adenoma (25,26). It is believed that adenomas develop because of chronic stimulation of the liver by glucagon and other trophic agents produced in response to chronic or recurrent hypoglycemia. Although some authors have reported regression of adenomas with aggressive dietary therapy, many patients who have received this treatment since infancy or early childhood are just now reaching adulthood and adenomas are a common finding in this group. Currently, a major challenge in the management of patients with GSD type I is the prevention, detection, and management of these lesions, as well as the development of a strategy for early detection of the rare transformation of adenomas into malignant lesions. In addition, a link between the hepatic adenomas and the normocytic anemia that often accompanies this disorder has been made. Hepcidin was found in abundance in the adenomas in GSD type Ia, and resection of the adenomas has resulted in normalization of the hematologic parameters and iron studies (27). Guidelines regarding monitoring of adenomas have been published, suggesting abdominal ultrasonography and measurement of serum α-fetoprotein and carcinoembryonic antigen every 3 months, as well as

computed tomography (CT) scan or magnetic resonance imaging in the case of growth or blurring of the margins of the lesions (28). Liver transplantation has been performed in patients having GSD, with some success (29). It is important to remember that these are systemic diseases that may have variable degrees of involvement of both skeletal and cardiac muscles.

Carbohydrate-deficient glycoprotein syndromes (glycosylation disorders)

The carbohydrate-deficient glycoprotein (CDG) syndromes are a group of newly recognized inborn errors of glycoprotein metabolism characterized by abnormal synthesis of *N*-linked oligosaccharides (30). The biochemical hallmark is a partial deficiency of the carbohydrate moiety of a wide range of secretory glycoproteins, including binding proteins, lysosomal enzymes, and coagulation factors. The clinical manifestations of the CDG syndromes, which include significant liver disease, are the direct embryologic and physiologic consequences of the abnormal *N*-linked glycosylation of cell structures.

CDG syndrome type I is a genetic multisystem disorder (31). The clinical picture is dominated by nervous system dysfunction, resulting in psychomotor retardation, seizures, ataxia, and stroke-like episodes (due to hypercoagulability). Also noted are an abnormal pattern of subcutaneous fat distribution (lipodystrophy and inverted nipples), feeding difficulties, retinitis pigmentosa, hypoalbuminemia/protein-losing enteropathy, pericardial effusion, and/or ascites. There is an age-dependent constellation of abnormalities in gonadal, thyroid and growth hormone, and insulin. Light microscopic findings in liver biopsy specimens include fibrosis and occasional cirrhosis and steatosis (32).

The CDG syndrome type I is clinically and biochemically distinct from type II, which is due to a deficient activity of the Golgi enzyme *N*-acetylglucosaminyltransferase II, and from other CDGs. The primary defect in CDG-I is the subject of ongoing study, although phosphomannomutase (PMM) deficiency appears to be the major cause (30). Biochemical diagnosis is based on documentation of misglycosylation, usually through detection of altered isoelectric forms of serum glycoproteins. The biochemical changes are easily observed by detecting altered isoelectric focusing of serum transferrin (carbohydrate-deficient transferrin). Serum antithrombin III and thyroxine-binding globulin (TBG) levels are low; these are useful screening probes for this disorder. Prenatal diagnosis is possible because PMM is active in amniocytes. No known treatment is available. Levels of intracellular mannose are limited and exogenous mannose can correct the defect in protein glycosylation in vitro; therefore some patients may benefit from including oral mannose in their regular diets.

Disorders of Lipid Metabolism

Wolman's disease and cholesteryl ester storage disease

Two distinct clinical syndromes, Wolman's disease and cholesterol ester storage disease (CESD), are

characterized by the massive intralysosomal accumulation of lipid (triacylglycerols and cholesteryl esters). The severe infantile-onset Wolman's disease and the milder late-onset CESD are caused by mutations in different parts of the lysosomal acid lipase gene, which is located on chromosome 10q24-q25. The diagnosis of these allelic disorders is made by demonstration of deficient lysosomal acid lipase activity in leukocytes or fibroblasts and an elevation of triglycerides and cholesterol ester levels in tissue. There is no specific therapy for these two disorders.

Wolman's disease (33) is characterized clinically by steatorrhea, failure to thrive, hepatosplenomegaly, and jaundice; the disease causes death usually within the first year of life. Stippled calcification of the adrenal glands is uniformly present either early in the course or in association with terminal liver failure. The disease has been reported in several ethnic groups and appears to be inherited as an autosomal recessive trait. There is diffuse cellular accumulation of triacylglycerol and cholesterol ester in lymph nodes, bone marrow, small intestine, liver, spleen, and adrenal glands. Deficiency of lysosomal acid lipase activity directed toward the hydrolysis of either triglyceride or cholesterol ester has been demonstrated. Grossly, the liver is yellow; frozen sections show lipid droplets in the parenchymal cells, some of which contain birefringent crystals under polarized light. Routinely processed liver biopsy reveals macrovesicular and microvesicular steatosis with empty crystalline profiles. Plasma lipids are generally normal. Diagnosis depends on liver biopsy and study of frozen sections with polarized light in addition to routine staining, analysis of tissue lipid, and demonstration of acid lipase deficiency. Death has occurred in all cases despite therapeutic trials of cholestyramine, adrenal steroids, clofibrate, cyclophosphamide, antibiotics, and thyroxine.

In patients with CESD, cholesteryl ester and triglyceride also accumulate in the liver and the intestinal mucosa; there is a marked decrease in lysosomal acid lipase activity against these substrates. The diagnosis can be confirmed by documenting deficiency of lysosomal acid cholesteryl hydrolase activity in fibroblasts (34). Although biochemical abnormalities are similar to those found in patients with Wolman's disease, patients with CESD have a normal life expectancy and present with hepatomegaly and hyperbetalipoproteinemia only, possibly due to a higher residual enzyme activity. Hepatomegaly is present at birth and increases with age. Grossly, the liver is similar in appearance to that in Wolman's disease, a brilliant orange-yellow color. Histologic findings on frozen section and routine light microscopy are also similar. By electron microscopy (EM), the larger vacuoles are seen to be surrounded by a single membrane, to contain angular images of cholesterol crystals, and to be secondary lysosomes. The epithelial cells of the intestinal mucosa are normal, but the lamina propria contains crystals of cholesterol ester and masses of foam cells around the lacteals. Suppression of cholesterol synthesis and apolipoprotein B production by 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors in combination with a diet excluding foods rich in cholesterol and triglycerides results in clinical improvement in some cases of CESD.

Gaucher's disease

Gaucher's disease, due to deficiency of acid β-glucosidase, is associated with widespread accumulation of glucosyl-ceramide laden macrophages, resulting in hepatosplenomegaly, marrow replacement causing skeletal disease, lung infiltration, and sometimes neurologic disease. There are several types, with different ethnic and geographic patterns. Hepatomegaly is seen in more than 50% of patients, but cirrhosis and portal hypertension are uncommon. Liver histology demonstrates the glycolipid-filled macrophages (Gaucher's cells) in the sinusoids, but hepatocytes are spared (35). This is probably due to biliary excretion of the glucocerebroside and the handling of glycolipids by mononuclear phagocytes, rather than hepatocytes. The diagnosis is confirmed by measurement of acid β-glucosidase in peripheral blood leukocytes. Enzyme replacement therapy is available, but responsiveness is variable. If cirrhosis is present, response to enzyme therapy is typically poor.

Niemann-Pick disease

The group of disorders classified under the eponym of Niemann-Pick disease (NPD) has been divided into two broad types: (a) A and B NPD are lysosomal storage disorders that result from deficient activity of acid sphingomyelinase (ASM); and (b) type C NPD is a lipidosis distinguished by a unique error in cellular trafficking of exogenous cholesterol. Both types are characterized by varying degrees of hepatomegaly, foam cells in the liver, bone marrow, and other tissues, and variably increased amounts of sphingomyelin, cholesterol, glycosphingolipids, and bis (monoacylglycero)-phosphate in the visceral organs.

Hereditary Tyrosinemia Type I

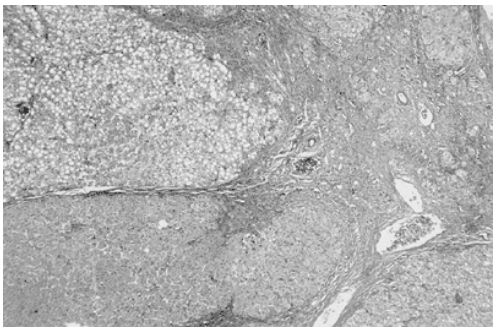
Transient neonatal hypertyrosinemia is a self-limiting condition primarily of premature infants, probably caused by an immaturity in tyrosine aminotransferase activity. Hypertyrosinemia also occurs with any severe hepatic injury, usually in association with high serum methionine levels. Hereditary tyrosinemia (HT) type I is an autosomal recessive disorder caused by deficiency of fumarylacetoacetate hydrolase (FAH), the last enzyme in the tyrosine degradation pathway. The

FAH gene has been mapped to chromosome 15 at q23-q25 (36) and cloned; more than 25 mutations have been associated with the phenotype of HT. Autosomal recessive inheritance has been suggested. The worldwide incidence is approximately 1 in 100,000 births. Because of a complex founder effect, there is an unusually high prevalence (1 in 1846) of HT in the province of Quebec, Canada, particularly in the Saguenay-Lac Saint Jean region.

Metabolites that accumulate proximal to the enzymatic block such as succinyl acetate, succinyl acetone, fumaryl acetoacetate, and maleylacetoacetate are highly reactive electrophilic toxic compounds, which bind to sulfhydryl groups, often leading to tissue injury. Many secondary enzymatic and biochemical defects occur in tyrosinemia because of the accumulation of these precursor compounds. For example, succinyl acetoacetate can inhibit enzymes such as porphobilinogen synthase, leading to the accumulation of 5-aminolevulinic acid and symptoms of acute intermittent porphyria.

There are two forms of HT, acute and chronic, which may occur in the same family. The acute form presents in infancy with severe liver dysfunction manifested by jaundice, hepatosplenomegaly, failure to thrive, anorexia, ascites, coagulopathy, and rickets. The disorder may actually begin in utero as evidenced by the presence of well-established cirrhosis with large regenerative nodules during infancy. The chronic form presents later in childhood with cirrhosis, renal tubular dysfunction, rickets, and hepatocellular carcinoma (HCC). Episodes of severe peripheral neuropathy occur in patients surviving infancy, leading to morbidity from severe pain and even mortality from respiratory failure.

Laboratory studies indicate significant compromise of hepatic synthetic function. Serum aminotransferase values are mildly to moderately elevated. Hypoglycemia is common, particularly in infants. Renal tubular dysfunction produces a Fanconi's syndrome with hyperphosphaturia, glucosuria, proteinuria, and aminoaciduria. Serum tyrosine and methionine concentrations are markedly elevated. Succinylacetone and succinylacetoacetate in the urine are typical and diagnostic of this disorder. Serum α-fetoprotein concentrations are often significantly elevated in affected infants and in cord blood, suggesting prenatal onset of liver disease. Histologic examination of the liver reveals fatty infiltration, iron deposition, varying degrees of hepatocyte necrosis, and pseudoacinar formation. Significant fibrosis may be present early in life with gradual evolution to multinodular cirrhosis, and the regenerative nodules mimic neoplasms in some patients (Fig. 47.8). HCC occurs frequently in older patients with cirrhosis. Livers of patients with HT often contain discrete nodules containing FAH activity. This mosaicism of enzymatic reactivity is due to somatic reversion to a normal genotype in these nodules. Molecular studies confirm correction of one of the disease-causing alleles in these nodules. These studies and other work in animal experiments suggest a strong selective advantage for FAH-expressing cells in an FAH-deficient liver. This information may be exploited in the future for gene therapy of HT.



▪ **Figure 47.8** Hereditary tyrosinemia. In this well-established cirrhosis, the regenerative nodules show variation in size and cytology. A nodule on the left has marked steatosis, whereas in the remainder of the specimen steatosis is absent.

The acute form of HT is usually fatal in the first year of life without therapy. Treatment with a diet restricted in phenylalanine, methionine, and tyrosine does not prevent progression of the liver disease or development of HCC. Liver transplantation reverses hepatic, neurologic, and most renal manifestations of the disease. Patients with cirrhotic nodules should be considered for transplantation because of the high risk of developing carcinoma. Treatment of HT has been revolutionized by the use of a metabolic inhibitor that acts early in the tyrosine degradation pathway (inhibiting 4-hydroxyphenylpyruvate dioxygenase) to prevent formation of the toxic intermediates succinyl acetoacetate (SAA) and succinyl acetone (SA). This inhibitor, (*2-[2-nitro-4-trifluoromethylbenzolyl]-1,3-cyclohexanedione*) *NTBC*, was first used in 1992 in five children with tyrosinemia. After 7 to 9 months, these patients had normal liver enzymes and coagulation studies, a decrease in α-fetoprotein levels, and no SA excretion. No toxicity was demonstrated. This report led to widespread clinical trials that largely reproduced the original experience, and more than 300 children with tyrosinemia have been treated, with subsequent stabilization of hepatic and renal function, improvement in growth and nutritional parameters, and delay or avoidance of liver transplantation. This drug has been licensed as nitisinone (trade name Orfadin). Although enthusiasm for this treatment has been somewhat tempered by the demonstration that NTBC administration corrects the hepatic and renal abnormalities in knockout mice deficient in FAH

activity but does not prevent all of the SA accumulation or the development of HCC, it is considered the standard of care for the treatment of HT, in addition to the dietary measures discussed in the preceding text (37). At present, the most prudent therapy for tyrosinemia is the institution of nitisinone and dietary therapy at the time of diagnosis. Close medical and radiographic monitoring is suggested for hepatic nodules that may herald early HCC, because a small percentage of children begun on therapy late in the course of disease have developed HCC despite treatment (38). Early liver transplantation is indicated in patients with severe neurologic crises.

Disorders of Bile Acid Metabolism

To date, several distinct inborn errors of bile acid biosynthesis have been recognized (39); these may be primary enzyme deficiencies or disorders that arise secondary to specific organelle dysfunction such as peroxisomal disorders. At present, two distinct major treatable disorders related to defective transformation of the steroid nucleus have been described: *Δ^4-3-oxosteroid 5β-reductase deficiency* and *3β-hydroxy-C_{27}-steroid dehydrogenase/isomerase deficiency*. The incidence of these defects is not known. In each, primary bile acid (cholic acid) synthesis is absent or markedly impaired, and urine, serum, and bile predominantly contain atypical bile acids. The cholestasis and liver injury are attributed to failure of synthesis of adequate amounts of the normal choleretic primary bile acids that are essential for the promotion and secretion of bile and/or the increased production of unusual primitive hepatotoxic bile acid metabolites. The unusual bile acids found in patients with defects in bile acid biosynthesis might cause cholestasis by inhibiting the canalicular ATP-dependent transport system for bile acids that constitute the rate-limiting step in the overall process of bile acid transport across hepatocytes.

The initial clue to the diagnosis is the finding of low serum concentrations of the primary bile acids in the presence of cholestasis. Impaired synthesis of bile salts may not be associated with either pruritus or elevated serum bile salt concentrations, because the normal end products are not synthesized. A high index of suspicion is required, because the presentation may be protean and diagnosis requires relatively specialized testing. Screening assays for these defects include gas chromatography and fast atom bombardment mass spectrometry of urine, serum, and/or bile. Confirmatory enzymatic and molecular assays exist for some of the defects.

Replacement bile acid therapy has been associated with reversal of hepatic injury and normalization of liver biochemical and histologic abnormalities (40). The rationale for bile acid therapy in inborn errors of bile acid biosynthesis is to replenish the bile acid pool and downregulate endogenous bile acid synthesis, thereby decreasing the production of toxic bile acid intermediates. Ursodeoxycholic acid (UDCA) presumably displaces toxic bile acids, improves bile flow, and offers cytoprotection.

Zellweger's (cerebrohepatorenal) syndrome is an example of a secondary defect in bile acid biosynthesis due to a primary defect in peroxisome development (41). Clinical manifestations include profound psychomotor retardation, hypotonia, a characteristic facies (narrow cranium, prominent forehead, hypertelorism, and epicanthic folds), cortical cysts of the kidney, and intrahepatic cholestasis. Hepatomegaly is usually present at birth and jaundice appears at 2 to 3 weeks of life. The hepatic histology includes hepatocellular damage with marked cholestasis, giant cell transformation, and pericellular fibrosis. Ultrastructurally, there is absence of peroxisomes (microbodies). Death occurs in most patients by 6 months of age. Diffuse micronodular cirrhosis is noted at autopsy.

A third type of genetic defect in bile acid metabolism is that of *bile acid transport defects*, which will be discussed subsequently in the chapter under the section on progressive familial intrahepatic cholestasis (PFIC).

Disorders of Bilirubin Metabolism and Excretion

Unconjugated hyperbilirubinemia is frequently encountered in infants. The causes are listed in Table 47.4. Normal hepatic clearance of bilirubin includes glucuronidation and carrier-mediated transport of bilirubin at the basolateral and canalicular membranes of the hepatocyte. Primary genetic abnormalities of these processes include Crigler-Najjar and Gilbert's syndromes that result from defects in glucuronidation (42) and Dubin-Johnson syndrome that results from a defect in canalicular excretion of conjugated bilirubin.

Gilbert's syndrome is the most benign of these disorders and probably represents a relatively common genetic phenotype. Between 2% and 10% of individuals have Gilbert's syndrome, which is the result of an alteration in the promoter for the bilirubin uridine diphosphophate glucuronyl transferase (*UDP-GT*) gene. The altered promoter is transcriptionally less active and leads to a relative deficiency of the enzyme. Clinically, this translates into a condition characterized by mild indirect hyperbilirubinemia (typically <5 mg/dL) without associated hemolysis or hepatocellular or canalicular injury. This may manifest as jaundice during times of stress and fasting. In addition, Gilbert's syndrome may explain many cases of prolonged "physiologic" jaundice in the newborn period (43). This entity has not been associated with any specific morbidity or

mortality. The liver biopsy reveals normal morphology. Gilbert's syndrome does not require treatment.

Table 47.4. Causes of Unconjugated Hyperbilirubinemia in Infants

Hemolytic diseases
Isoimmune (ABO or Rh incompatibility)
Congenital spherocytosis
Hereditary elliptocytosis
Red blood cell enzyme defects (e.g., glucose-6-phosphaste dehydrogenase)
Disorders of bilirubin conjugation or transport
Crigler-Najjar syndrome types 1 and 2
Gilbert's syndrome
Dubin-Johnson syndrome
Enclosed hematoma
Polycythemia
Diabetic mother

Twin–twin transfusion
Hypothyroidism
Sepsis
Intestinal obstruction
Breast milk jaundice

Crigler-Najjar syndrome has two forms, types I and II. Type I is the more severe, the result of a complete absence of bilirubin UDP-GT activity. This disease presents in the newborn period with severe indirect hyperbilirubinemia, necessitating continuous phototherapy and/or exchange transfusions. Analysis of bile reveals no bilirubin conjugates. Kernicterus is a serious potential complication for children with Crigler-Najjar syndrome type I and can occur at any age. Specific DNA testing can confirm the diagnosis of Crigler-Najjar type I, and can be utilized for prenatal testing. Phototherapy is the mainstay of therapy. Tin-mesoporphyrin, a synthetic heme analog with inhibitory activity against heme oxygenase, may decrease bilirubin production in affected individuals (44), but large-scale long-term studies have not yet been performed. Liver transplantation can be curative, although risk-benefit decisions for this approach can be complex (45). Preliminary reports of hepatocyte transplantation for this disorder have been disappointing. Gene therapy may ultimately be an attractive means of curing this disease.

Crigler-Najjar type II is the result of genetic abnormalities in the bilirubin *UDP-GT* gene that lead to partial activity. Hyperbilirubinemia of less than 10 mg/dL is usually observed and is typically responsive to cytochrome P-450–inducing compounds such as phenobarbital. Long-term treatment with phenobarbital is generally not recommended because it results in a cosmetic improvement but is associated with potential neurodevelopmental complications.

Dubin-Johnson syndrome is the genetic deficiency in the *cMOAT/MRP2* gene, which encodes the canalicular transporter of conjugated bilirubin (46). The disease is manifest by relatively mild conjugated hyperbilirubinemia (3 to 8 mg/dL) with no evidence of significant hepatocellular or canalicular injury. The liver, however, accumulates a dark green or black pigment within the pericanalicular cytoplasm of zone 3 hepatocytes. The pigment is coarsely granular and imparts a black discoloration to the gross liver. Analysis of urinary coproporphyrins reveals a preponderance of the isoform I. Like Gilbert's syndrome and Crigler-Najjar type II, this is a disease that is not associated with significant morbidity or mortality and as such does not require treatment.

Disorders of Fatty Acid Oxidation

Normal fatty acid metabolism in the liver is a highly complex process, which involves transport into hepatocytes and mitochondria and a series of distinct enzymatic steps that generate energy from fatty acid oxidation (FAO). During prolonged fasting, when glucose supplies are depleted, fatty acids are mobilized from adipose tissue, taken up by liver and muscle, and oxidized stepwise to acetyl-CoA, providing an important source of energy for cardiac and skeletal muscles. Abnormalities in fatty acid metabolism can lead to acute liver injury, as a result of both energy deprivation and the accumulation of highly toxic intermediary metabolites. At least 22 different clinical entities have been ascribed to distinct abnormalities in FAO (47). Clinical presentations include a "Reye's-like" syndrome with hypoglycemia, fatty liver, and coma; sudden, unexplained death; or skeletal- or cardiomyopathy with mild or severe liver disease. The typical case presents with elevated serum aminotransferase values and variable degrees of coagulopathy with normal bilirubin. Nonketotic hypoglycemia is a hallmark feature. Some form of stressor that includes fasting typically precedes the onset of symptoms. Both clinical manifestations and biochemical abnormalities may be intermittent. Isolated deficiency of mitochondrial long-chain fatty acid β-oxidation in the fetus may be associated with severe illnesses in heterozygote women during pregnancy. These include acute fatty liver of pregnancy (48); the hypertension/hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome; and hyperemesis gravidum.

Diagnostic testing is complex, and includes both nonspecific screening assays as well as more specific enzymatic and molecular tests. Initial evaluation includes assays of plasma carnitine, acylcarnitines, free fatty acids, and urine organic acids and acylglycines. An important diagnostic tool is tandem mass spectrometry, which can identify diagnostic abnormal acylcarnitines in most disorders using random plasma samples or filter paper blood spot cards. This technique has been adapted for expanded newborn screening. Most diagnostic assays must be performed during illness, as many

of the metabolites will clear with treatment. These preliminary assays are followed by specific enzymatic assays in fibroblasts, with DNA diagnostic confirmatory tests, when possible (49).

Long-term treatment is directed at halting fat catabolism. This can be achieved by intravenous administration of 12 to 15 mg/kg per minute of glucose. The principle of long-term treatment is to avoid reliance on FAO by preventing prolonged fasting and using low-fat diets supplemented, if necessary, by carbohydrate snacks. The benefits of carnitine administration and specific dietary fat restrictions or supplementation are controversial. If a diagnosis cannot be made before the development of irreversible hepatic injury, liver transplantation may be considered, but care must be taken to ensure that there is no evidence of systemic disease that would not be addressed by hepatic replacement.

Primary Mitochondrial Hepatopathies

The liver is a major target organ in inherited defects of mitochondrial oxidative phosphorylation. Neonatal and early childhood hepatic failure have been associated with defective activity of respiratory chain complexes and oxidative phosphorylation (50), but liver disease of varying severity and at different ages has also been reported (51). Neonatal liver failure occurs in association with deficiency of complex IV (cytochrome *c* oxidase) and of complexes I and III. Evidence of synthetic failure is prominent with hypoglycemia, hypoproteinemia, hyperbilirubinemia, hyperammonemia, and coagulopathy. Lethargy, hypotonia, vomiting, and poor feeding are also seen. Prenatal onset is suggested in some patients by the occasional occurrence of fetal hydrops and congenital ascites. An important diagnostic feature in these patients is lactic

acidosis and an elevated molar ratio of plasma lactate to pyruvate (normal <20:1). Histologic features of the liver include microvesicular and macrovesicular steatosis, often with increased mitochondrial density giving an oncocytic appearance to the hepatocytes. Cholestasis, bile ductular proliferation, fibrosis, or even cirrhosis may be present. Activities of mitochondrial respiratory chain enzymes can be measured in affected tissues.

Because heteroplasmy for mitochondrial DNA (mtDNA) mutations is not uniform in all tissues, patients may present exclusively with liver disease or with variable involvement of other organ systems (52). Most commonly, this includes varying degrees of neuromuscular involvement, including hypotonia, cardiomyopathy, ophthalmoplegias, diabetes mellitus, deafness, nephropathy, intestinal pseudo-obstruction, and pancreatitis. This issue is important, because patients may undergo successful liver transplantation only to have later onset of severe neuromuscular or cardiac disease (53). The spectrum of respiratory chain disorders is sufficiently broad that some patients are now being recognized with a more chronic course or onset later in infancy or childhood. Alpers' disease is one such disorder; it is characterized by progressive neuronal degeneration and cirrhosis of the liver in childhood.

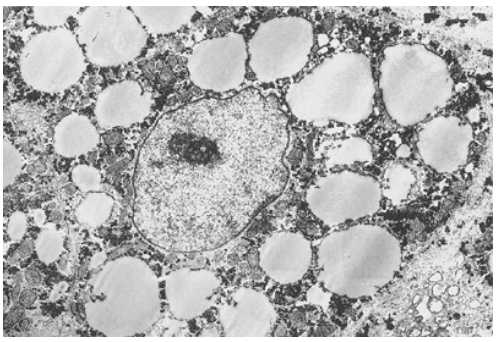
Point mutations, deletions, and rearrangements in mitochondrial or nuclear DNA have been detected in patients with neonatal liver failure caused by respiratory chain defects (52). Some children with severe liver disease have been found to have the mtDNA depletion syndrome in which there is a generalized reduction of otherwise normal mtDNA molecules in affected organs. Autosomal recessive, maternal, and possibly X-linked modes of inheritance have been observed or proposed. The prognosis for patients with acute liver failure secondary to mitochondrial disorders is extremely poor. There is no proven medical therapy, although supplementation with mitochondrial cofactors such as coenzyme Q10 and antioxidants theoretically, may be beneficial. Liver transplantation has been successful in patients whose disease is restricted to the liver.

Mitochondrial injury—Reye's syndrome

Reye's syndrome (RS) is a systemic illness characterized by acute liver disease and hyperammonemic encephalopathy (54). RS had a peak incidence in the 1960s and 1970s; only rare cases have been reported since 1985 (55). Although the cause of this disease was never fully elucidated, the stereotypic presentation after routine childhood viral illnesses, such as varicella and influenza, and the association with aspirin ingestion, raised the possibilities of immune-mediated and/or toxic pathogenesis. The reasons for the decreasing incidence of RS are not clear, but may in part be due to the avoidance of aspirin administration to children with viral illnesses.

This disorder shares many features with mitochondrial hepatopathy, and indeed, abnormal mitochondria are an important ultrastructural feature. The microvesicular steatosis characteristic of this disorder indicates a mitochondrial energy-generation defect. Children with RS develop vomiting within a few days of the antecedent illness; the vomiting is not due to gastrointestinal upset, but more likely to the earliest stages of encephalopathy. In the mildest cases, the vomiting is associated with minimal neurologic changes such as lethargy, and resolves spontaneously or with intravenous glucose. In the more severe cases, vomiting is followed quickly by progressive obtundation and the stages of metabolic coma. aspartate aminotransferase (AST) and alanine aminotransferase (ALT) values are typically moderately to markedly elevated. Prolonged

prothrombin time is common, but in contrast to fulminant hepatitis jaundice is not noted. Hyperammonemia is usually found at presentation; the average value is approximately 350 g/dL, but the level does not correlate with the severity of the encephalopathy.



▪ **Figure 47.9** Microvesicular steatosis. Ultrastructutal appearance of hepatocyte with microvesicular steatosis. The nucleus remains at the center and fat vesicles are numerous, small and uniform.

The liver is enlarged but not firm; it is characterized histologically by extensive accumulation of microvesicular fat, but inflammation, necrosis, and cholestasis are absent. EM reveals marked microvesicular steatosis (Fig. 47.9) and characteristic mitochondrial changes with swelling of matrix, dissolution of cristae and intramatrical granules, and ameboid shapes. The hepatopathy resolves over the first several days of the illness, and the prognosis is determined by the central nervous system component of the illness. Treatment is directed at maintaining metabolic homeostasis with glucose administration, and minimizing intracranial hypertension with maneuvers such as hyperventilation and mannitol infusion.

There are pediatric disorders that may mimic RS, with liver disease and encephalopathy. Children who present sporadically with vomiting, lethargy with progressive coma, and biochemical evidence of hepatocellular injury may have systemic viral infections with multisystem involvement, toxin exposure, or inborn errors of metabolism. The genetic/metabolic disorders that are most likely to be confused with RS are FAO defects and urea cycle defects. These should be suspected in very young children, or in those who have had recurrent episodes of hepatopathy and encephalopathy, especially if preceded by periods of fasting or other metabolic stress.

Mitochondrial injury—copper overload

The mitochondrion is a major intracellular target for copper toxicity. Accumulation of copper in the hepatic mitochondria leads to oxidative stress (increased free radical generation) with subsequent lipid peroxidation and oxidative alterations of

thiol-containing proteins. Oxidant damage in hepatic mitochondria also leads to deletions in mtDNA in young adults with Wilson disease (52). Therefore, dysfunction of hepatic mitochondrial electron transport may be an important factor in the pathogenesis of liver dysfunction and liver failure in copper overload states. Treatment to reduce oxidative stress (e.g., antioxidants) may protect the mitochondria from injury.

Wilson disease, the most common genetic disorder associated with copper overload and mitochondrial injury, is discussed in Chapter 35. Wilson disease should be considered in any child with an unexplained hepatic, neurologic, or psychiatric illness. The clinical presentation is highly variable. Although patients as young as 2 years have presented with liver disease, symptoms are rarely evident before 5 years of age. Younger children, identified by family screening or after evaluation of abnormal liver biochemical tests, are often asymptomatic. Patients younger than 20 years tend to present predominantly with hepatic manifestations. Kaiser-Fleischer rings are often absent in younger patients presenting only with liver disease.

Several non-Wilsonian copper overload syndromes have been described in children. The best described is *Indian childhood cirrhosis* (ICC). A unique familial form of liver disease, ICC, confined primarily to the Indian subcontinent, affects Hindu children (primarily boys) below 3 years (56). It is characterized by a striking accumulation of copper-associated granules within hepatocytes. Affected children present insidiously with hepatomegaly, abnormal stools, and behavioral changes, such as increased appetite, excessive irritability, and disturbed sleep patterns. Jaundice is uncommon; ceruloplasmin levels are normal. ICC is progressive and results in hepatocellular failure and death. Investigators who believe that ICC is a primary dietary copper toxicity cite the widespread use of brass cooking utensils among middle-class Indian families and the increased rate of absorption and storage of copper in infants compared with adults. Those who favor an inborn error of metabolism as the cause of ICC cite the 25% to 30% recurrence rate within families and other epidemiologic studies reporting a strong genetic component. Children older than 3 years rarely, if ever, develop typical ICC in spite of a similar environment and diet. Therefore, immaturity of hepatocytes during that critical phase of high dietary intake makes them prone either to accumulate copper excessively or fail to excrete it through the bile. In composite, ICC may represent a genetic disorder that requires an environmental influence to be manifest. The liver biopsy reveals hepatitis reminiscent of alcoholic liver disease with marked ballooning of hepatocytes, Mallory hyaline, and neutrophilic infiltrate. Copper-binding

protein accumulates in hepatocytes. The process progresses to venosclerosis and pericellular fibrosis, leading to cirrhosis. Preliminary therapeutic studies of D-penicillamine have led to clinical, functional, and histologic improvement (57). In contrast to Wilson disease, therapy can apparently be discontinued after 2 years without reaccumulation of copper in the liver.

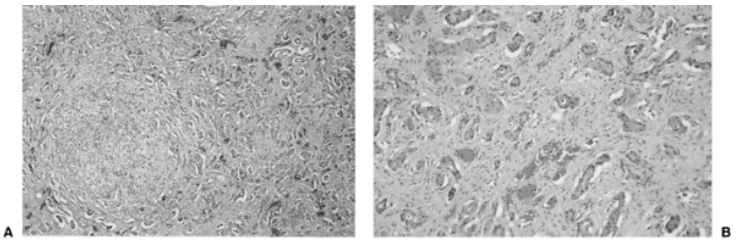
α_1-Antitrypsin Deficiency

α_1-Antitrypsin deficiency is an important genetic liver disease in children. In some pediatric centers, it is the most common genetic disease requiring liver transplantation. This disorder is discussed in detail in Chapter 37.

Cholestatic jaundice occurs in approximately 10% to 15% of infants with the protease inhibitor ZZ (PIZZ) phenotype. Patients rarely present with signs of advanced liver disease. Another 40% to 50% of homozygous infants show asymptomatic abnormal liver biochemical test results in the first months of life. Giant cell hepatitis is a typical histologic finding in the neonate. Bile ductular proliferation may be observed initially; occasionally, paucity of bile ducts is found later. The periodic acid-Schiff positive and diastase-resistant α_1-antitrypsin inclusions within periportal hepatocytes are hallmarks of the disorder but are not prominent before 4 months of age. The outcome of neonatal liver disease related to α_1-antitrypsin deficiency is variable. In most infants, jaundice clears by 4 months of age. Patients may present with cirrhosis later in childhood and are at risk for HCC. There is no specific treatment for α_1-antitrypsin deficiency. Liver transplantation is curative for patients progressing to end-stage liver disease; the recipient assumes the Pi type of the donor organ.

Neonatal Hemochromatosis

Neonatal hemochromatosis (NH) has also been called *neonatal iron storage disease* (58). This disorder, characterized by marked hepatic and extrahepatic hemosiderosis, is a form of neonatal liver failure that is characterized by an early in utero onset. Whether this disease represents a single pathophysiologic entity or is a common pathologic end-point of a number of diseases that lead to in utero liver failure is not known. NH is unrelated to hereditary hemochromatosis or the *HFE* gene that is often defective in that disease. NH does not appear to be the result of a primary abnormality in fetal iron metabolism. Infants with NH have very high mortality unless prompt treatment and/or liver transplantation is undertaken.



▪ **Figure 47.10** Neonatal hemochromatosis. **A:** Marked and diffuse interstitial fibrosis with pseudoacinar transformation of hepatocytes. A regenerative nodule is present at the lower left. **B:** At higher magnification the interstitial fibrosis (interstitial cirrhosis) is better seen.

The initial clinical presentation of NH can be subtle. The findings of cholestatic jaundice with coagulopathy and/or ascites at birth should prompt diagnostic evaluations. Supporting biochemical features include thrombocytopenia, hypoalbuminemia, hypoglycemia, hyperammonemia, and high iron saturation and serum ferritin levels. Diagnosis is dependent on documentation of hepatic insufficiency and extrahepatic siderosis with no other apparent etiology of the liver failure.

Extrahepatic siderosis can be demonstrated by either biopsy of a minor salivary gland or magnetic resonance imaging of the pancreas and/or heart. Analysis of both these studies requires assessment by a specialist experienced in the special applications of these diagnostic tests. Liver histology, when available, reveals nonspecific findings with marked diffuse hepatocellular damage, significant hepatocellular loss with parenchymal collapse, and well-established pericellular fibrosis or cirrhosis (Fig. 47.10A,B).

Immediate referral of infants with NH to a center experienced in liver transplantation in infants is advised. Medical therapy consists of a combination of antioxidants (vitamin E in the form of tocopheryl polyethylene glycol succinate, selenium, and *N*-acetyl cysteine), membrane stabilizers (prostaglandin $E_{1\alpha}$), and an iron chelator (deferoxamine). The efficacy of medical therapy alone has been questioned, but it

appears at a minimum to stabilize infants in preparation for liver transplantation, which has been successful in very small infants with NH (59). Recurrence of the disease post-transplant has not been reported.

The inheritance of NH is complex and in many circumstances is associated with a recurrence rate in siblings that exceeds that expected for either an autosomal recessive or dominant pattern. For these reasons, ascertainment of a diagnosis of NH is of critical importance for family counseling and for monitoring subsequent pregnancies. Recently, an alloimmune etiology for this disorder has been hypothesized, and, on the basis of the hypothesis, high-dose immunoglobulin has been provided during subsequent pregnancies to 15 women who had previously delivered affected infants. A highly significant difference in outcome and survival was demonstrated in the newborns compared with those from prior pregnancies (60).

Progressive Familial Intrahepatic Cholestasis

Progressive familial intrahepatic cholestasis PFIC is a heterogeneous group of disorders with some common features: Jaundice due to intrahepatic cholestasis beginning anywhere from infancy to late childhood, severe pruritus, growth failure, and a genetic pattern most consistent with autosomal recessive inheritance. Patients with PFIC present with pruritus and jaundice early in life. A subset of infants has a phenotype indistinguishable from that of NH (discussed in preceding text) (61). Initially the jaundice may be episodic, but the biochemical cholestasis persists and eventually the patient becomes permanently icteric. In some types of PFIC, the biochemical profile differs from that of other forms of cholestasis in that serum γ-glutamyl transpeptidase (GGT), which may be two to three times the normal initially, becomes normal. Serum cholesterol levels are usually normal as well. The hepatic histology early in the course may show hepatocanalicular cholestasis, giant cell transformation, and ballooning of hepatocytes around terminal hepatic venules. Paucity of interlobular bile ducts and bile duct epithelial degeneration are prominent findings. With progression, fibrosis is initially centrilobular and later causes central to portal bridging. A characteristic pattern consists of diffuse pericellular fibrosis, severe cholestasis, and pseudoacinar transformation of hepatocytes (62).

Complications include fat-soluble vitamin deficiencies, growth retardation, delay in sexual maturation, infections related to cholestasis, cholelithiasis, and chronic pancreatitis. HCC may develop in children with advanced cirrhosis, even before 3 years of age.

Three distinct types of PFIC have been described so far. Type 2 is mentioned in the preceding text under the section on bile acid metabolism disorders, because it has been found to be due to an inborn error in canalicular bile salt transport.

Low serum γ-glutamyl transpeptidase and cholesterol levels help to differentiate PFIC types 1 and 2 from other chronic cholestatic disorders in children. PFIC type 1, previously known as *Byler's disease*, is a syndrome in which chronic, unremitting cholestasis develops early in life. The gene *ATP8B1* encodes a protein called *FIC1*. It was mapped to the same locus as that for benign recurrent intrahepatic cholestasis (BRIC) at chromosome 18q21-q22, and has been cloned (63). *ATP8B1* encodes for a P-type ATPase that may be involved in ATP-dependent aminophospholipid transport. Although the genetics of FIC1 disease are complex, various mutations have been detected in patients affected with PFIC-1, BRIC, and a unique geographic form, Greenland familial cholestasis (64). *ATP8B1* is expressed in several epithelial tissues, particularly intestine and bile duct cells, but not in hepatocytes. Manifestations of the deficiency in these other tissues are being elucidated. Progression to cirrhosis and liver failure usually occurs by 3 to 4 years of age but may develop in the neonatal period.

Molecular transporters of bile acids are found on both the canalicular and basolateral hepatocyte membranes. Canalicular excretion of bile salts is mediated by the bile salt excretory protein, bile salt export pump (BSEP), encoded by the gene *ABCB11* or ATP-binding cassette B11. A primary genetic defect in BSEP, which maps to 2q24, leads to a disorder called *progressive familial cholestasis type 2* (*PFIC-2*). This defect results in progressive cholestasis characterized by severe pruritus, markedly elevated serum bile acid concentration, normal serum cholesterol concentration, and normal GGT values (42). Biliary bile acid concentrations are extremely low. Liver histology early in the course of the disease may reveal giant cell transformation and ductular proliferation. Cirrhosis and end-stage liver disease may evolve relatively quickly. Differentiation of this disease from PFIC-1 may be difficult, but it is critically important because primary defects in canalicular transport of bile acids may be cured by liver transplantation, although PFIC-1 may not. Defects in the basolateral transport of bile salts have not been definitively identified, although this is suspected to be the cause of a relatively rare form of cholestatic liver disease characterized by isolated elevations of serum bile salts and severe pruritus.

There is a third variant of PFIC, *PFIC-3*, in which patients have high serum GGT values and low concentrations of phospholipids in bile. These children develop severe liver disease characterized by diffuse hepatocellular damage, cholestasis, inflammation of portal tracts, bile ductular proliferation, and fibrosis. Immunohistochemical techniques have revealed the absence of canalicular staining for a gene called *MDR3*

or *ABCB4*, which encodes a phosphatidylcholine flippase, in liver tissue from affected patients. Genomic DNA analysis has demonstrated several mutations in the *MDR3* gene, in this disorder (65). In addition to the severe, progressive cholestatic disorder of childhood caused by mutations in this gene, a link between PFIC-3 and intrahepatic cholestasis of pregnancy has been established. Heterozygous women carrying fetuses affected with distinct nonsense or missense mutations in *MDR3* were found to have typical recurrent episodes of cholestasis during pregnancy (66). A similar link was recently reported in adults with symptomatic gallstone disease (67), demonstrating the role of this transporter in the maintenance of normal ratio of cholesterol to phospholipid in bile.

PFIC is generally refractory to medical therapy, although UDCA has proven of benefit in some forms. Prompt surgical management with partial diversion of the bile flow may arrest progression of hepatic fibrosis and improve pruritus, growth and school attendance (68). Liver transplantation is reserved for patients who have cirrhosis.

Miscellaneous Familial Cholestatic Syndromes

A number of familial, presumably genetic, syndromes of childhood intrahepatic cholestasis have been described in ethnic populations. Whether they are variants of one disorder, expressed in geographically different kindreds, or clinically similar but genetically distinct diseases, has not been elucidated in most instances.

"Norwegian cholestasis" has been reported in patients of Norwegian extraction and is characterized by lymphedema of the lower extremities and recurrent bouts of intrahepatic cholestasis that begin within the first 3 months of life (69). North American Indian cholestasis is restricted to a tribe of native North Americans from northwest Quebec (70). The disease often presents with neonatal cholestasis, with the striking feature of telangiectasias of the cheeks ("papermoney skin"). Greenland Eskimo cholestasis, also limited to a well-defined ethnic group, presents at birth or within the first 3 months of life with permanent jaundice and pruritus (71). A unique missense mutation in the *ATP8B1* gene has been implicated (64), linking this disorder to PFIC-1 and BRIC.

The types and features of the various forms of PFIC and other genetic cholestasis disorders are listed in Table 47.5.

Viral Hepatitis

Viral hepatitis is extensively discussed in Part V, Chapters 26, 27, 28, 29, 30 and 31. Although the prevalence of viral hepatitis is much lower in children than in adults, it is important to identify infected children to interrupt horizontal and community transmission, detect liver disease, intervene to minimize progression, and design a strategy for immunization when available. This requires understanding of risk factors important in children. The natural history of some kinds of viral hepatitis in children may be more benign than infection acquired in adulthood, but childhood cases contribute disproportionately to the overall disease burden in some instances. Identification of appropriate pediatric candidates for treatment and definition of optimal therapy in these children represent a unique challenge. Because viral hepatitis is covered in other sections of the book, only selected aspects of special pertinence to the pediatric population will be discussed here.

Hepatitis A

Outbreaks of hepatitis A virus (HAV) have been traced to day care centers, where unsanitary practices involving infants and children have been implicated in viral transmission. The severity of disease caused by HAV infection is inversely correlated to age; icteric HAV infection occurs in approximately 10% of children younger than 5 years, but in up to 80% of adults. Severe liver dysfunction such as coagulopathy, marked cholestasis, and encephalopathy, is rare in childhood, but more common in adolescents and adults.

Hepatitis A vaccines are licensed for children 2 years of age and older. Routine HAV vaccination is currently recommended for children in the United States who live in "endemic" areas (rates of HAV infection twice the national average, i.e., >20 cases per 100,000 population), and should be considered for those living in areas of "intermediate" incidence (rates of HAV infection 10 to 20 cases per 100,000 population) (72). This has proven to be a cost-effective strategy (73). Otherwise, the indications are the same as for adults: Anticipated travel to an HAV-endemic area, underlying chronic liver disease, or in the control of an outbreak. In children younger than 2 years in whom vaccine efficacy and safety have not been adequately determined, immunoglobulin is recommended if needed to prevent infection. Intramuscular immunoglobulin is efficacious and safe, but may interfere with the immunologic response to several live-virus vaccines including mumps, measles, rubella (administered individually or in combination) and varicella. Accordingly, mumps, measles, and rubella immunization should be delayed by 3 months and varicella vaccination by 5 months after the administration of immunoglobulin.

Postexposure prophylaxis is recommended for susceptible personal contacts of an HAV-infected child, such as a household member (72). In addition, day care staff and attendees in close contact with an HAV index

case should receive passive immunization. Administration of immunoglobulin is not routinely indicated for exposures arising in the school setting.

Table 47.5. Genetic Disorders Associated with Intrahepatic Cholestasis During Infancy and Childhood

Genetic disorder	Associated findings	GGT	Pruritus	Serum bile acid concentration	Inheritance	Chromosomal location	Gene defect
Alagille syndrome	Cardiac, vertebral, facial, growth abnormalities	High	Yes	High	Autosomal dominant	20p12	*JAG1* (encodes Jagged 1)
Bile acid synthesis defects[a]	None		No	Low	Autosomal recessive	Unknown	(see subsequent text)
PFIC-1	Diarrhea	Low	Yes	High	Autosomal recessive	18q21-q22	*ATP8B1* (encodes FIC1)
PFIC-2	Growth failure	Low	Yes	High	Autosomal recessive	2q24	*ABCB11* (encodes BSEP)

PFIC-3	Later presentation	High	Yes	High	Autosomal recessive	7q21.1	*ABCB4 (MDR3)*
Norwegian cholestasis	Lymphedema	High	NR	NR	Autosomal recessive	Unknown	Unknown
North American childhood cholestasis	Telangiectasia of the cheeks	High	NR	NR	Autosomal recessive	Unknown	Unknown
Greenland cholestasis	Thrombocytosis, subcutaneous bleeding	NR	Yes	NR	Autosomal recessive	18q21-q22	*ATP8B1* (specific mutation)

[a]Bile acid synthesis defects include 3β-hydroxy-C27-steroid dehydrogenase/isomerase deficiency, Δ^4-3-oxosteroid 5-β-reductase deficiency, oxysterol 7α-hydroxylase deficiency, and others.
GGT, γ-glutamyl transpeptidase; PFIC, progressive familial intrahepatic cholestasis; NR, not reported; BSEP, bile salt export pump; MDR3, multidrug resistance gene.

Hepatitis B

Children at risk for hepatitis B virus (HBV) infection are neonates born to infected mothers, children who live in subpopulations with high endemicity (such as groups of immigrants from HBV-endemic areas), children adopted from these areas, and adolescent intravenous drug users. In the United States, children and adolescents comprise approximately 15% to 20% of new HBV infections annually. The clinical course and natural history of HBV infection is variable and depends on the age at which infection occurs. HBV infection during the perinatal period, infancy, and early childhood is rarely symptomatic, whereas adolescents and adults commonly develop symptoms. HBV acquisition during infancy results in the development of a chronic carrier-state in more than 90% of cases, characterized by persistence in serum of hepatitis B surface antigen (HBsAg), high-level HBV DNA and minimal biochemical or clinical evidence of liver disease. In contrast, acute HBV infection gradually resolves without chronic sequelae in more than 90% of infected adults. Although the precise mechanisms that underlie these age-related differences in the natural history of HBV infection are unknown, experimental evidence suggests that immune tolerance to viral antigens may play an important role.

Children who are candidates for treatment are those with serologic evidence of HBV infection for at least 6 months. The criteria include detectable serum HBsAg, HBeAg, and/or HBV DNA (in case of HBeAg negative HBV infection), and consistently abnormal ALT values. A liver biopsy should be obtained before the start of therapy to provide evidence of chronic hepatitis, to stage the disease, and to rule out other processes. In most studies performed before the high prevalence of HBeAg negative infections was appreciated, seroconversion from HBeAg to anti-HBe was used as the primary outcome variable for response to therapy. Therapeutic trial results must be compared to the "background rates" of spontaneous seroconversion. Other treatment responses that are frequently reported include decrease in serum HBV DNA to levels undetectable by non-polymerase chain reaction (PCR) assays, and normalization of ALT values.

There are two licensed medications for treatment of chronic HBV in adults and children in the United States:Interferon α (IFN-α) and lamivudine.

IFN-α induces sustained viral remission (disappearance of serum HBV DNA and HBeAg) in 25% to 40% of children with chronic hepatitis B (74). IFN-α is generally well tolerated by children; the most common adverse event described is a flu-like syndrome characterized by fever, headaches, chills, and myalgias, which generally resolve within the initial 2 to 3 doses. Other reported side effects include bone marrow suppression, neuropsychiatric disorders (depression and anxiety), fatigue, diarrhea, anorexia, and weight loss (75).

A randomized, double blind, placebo-controlled multicenter trial of lamivudine for 52 weeks in children with chronic HBV has been done (76). Twenty-three percent of children who received lamivudine cleared HBV DNA and lost HBeAg from serum compared with 13% of the placebo group ($P < 0.05$). Of those children who responded to the first year of treatment, 82% had sustained response at 6 months, although they had received no further treatment. As with IFN, children with higher ALT values and higher histology activity index scores at baseline had greater likelihood of virologic response (77). Prior receipt of IFN did not affect the response rate. Lamivudine did not interfere with growth, and side effects were the same in the lamivudine and placebo groups. Lamivudine treatment in adults has been complicated by the development of viral resistance, and the same has been true in children. The HBV in 19% of children had developed resistance to lamivudine after 1 year. As lamivudine is so well tolerated, many patients, including those with advanced liver disease in whom IFN is contraindicated, may be considered for treatment. It has been suggested that the medication should be continued until HBeAg disappears from the serum, anti-HBe appears, or, if neither occurs, HBV DNA becomes persistently undetectable. This strategy has not been validated in children. Although as an oral medication with a satisfactory safety profile lamivudine is an attractive medication for children, the optimal duration of therapy has not yet been defined. Newer agents such as pegylated IFN and other nucleoside analogs have not yet been studied in children with chronic HBV infection.

Although infants and children who are long-term HBV carriers have little clinical and histologic evidence of liver disease, they are at high risk to develop cirrhosis and HCC. Because children have minimal liver disease, they often do not benefit from currently available antiviral therapy. Although screening strategies to detect early HCC are evolving, periodic determinations of serum α-fetoprotein and serial abdominal sonography, as recommended for adults, seem reasonable approaches for children with chronic HBV infection.

HBV infection can be effectively prevented after exposure by the administration of hepatitis B immunoglobulin (HBIG). This preparation is indicated in the prevention of perinatal transmission from HBV-infected women, and should be given to their

neonates in the first hours of life. Completion of immunoprophylaxis in this setting is accomplished with active immunization with one of the two licensed HBV vaccines. Following

the initial failure of immunization strategies, which targeted high-risk individuals, vaccination is now recommended for all newborns, all preadolescent children, and adults at high risk (78,79). The vaccine is safe and effective in children, including premature infants (80,81). Concerns about mercury exposure in neonates and young children caused by thimerosal (used as vaccine preservative) prompted the development of preservative-free formulations.

Hepatitis C

In the United States, the estimated prevalence of hepatitis C virus (HCV) infection in children aged 18 years or younger is 0.1% to 0.2%, as compared with 1.8% in adults (82). Because HCV is a parenterally transmitted pathogen, children at risk include neonates born to HCV-infected mothers and recipients of transfusions of blood and blood products before 1992. The routine screening of blood for HCV has resulted in a dramatic decline in transfusion-associated infection, and perinatal exposure has become the major mode of transmission to children. The general incidence of transmission from HCV-viremic mothers is approximately 5% (83,84,85); active untreated human immunodeficiency virus (HIV) coinfection raises this risk substantially (86,87). Risk factors that may increase the likelihood of perinatal transmission include prolonged rupture of amniotic membranes and the use of internal fetal scalp monitors (83). There is as yet no evidence to indicate breast feeding as an additional risk. Current recommendations regarding perinatal HCV transmission are indicated in Table 47.6. HCV antibodies present in newborns are typically derived from the maternal serum, so testing after 15 months of age is indicated for the detection of HCV infection in these children.

Table 47.6. Guidelines Regarding Perinatal Hepatitis C Virus Infection

RECOMMENDED (supported by data)
Targeted testing of pregnant women who have risk factors for HCV
Aggressive treatment of HIV in coinfected pregnant women
Testing of infants for anti-HCV when they are 12 to 15 months of age
SHOULD BE CONSIDERED (suggested by data)
Avoid internal fetal scalp monitoring during labor
Deliver infant within 6 hours of rupture of membranes
NOT RECOMMENDED (no data to support)
Universal testing of pregnant women
Elective cesarean delivery
Avoidance of breast-feeding
Immunoglobulin administration to newborns

HCV, hepatitis C Virus; HIV, human immunodeficiency virus.

The natural history and pathobiology of HCV infection in infants and children is incompletely understood, but HCV infection leads to chronic liver disease in some children. It is generally mild, although aggressive liver disease with fibrosis and even cirrhosis can occur. Extrahepatic manifestations such as cryoglobulinemia, membranoproliferative glomerulonephritis, and vasculitis commonly seen in adults are seldom reported in children. Histologic findings of chronic hepatitis C in children are similar to those in adults (88,89).

If, when, and how to treat children with chronic hepatitis C is at present uncertain and controversial (90). Spontaneous viral remission may occur in the first couple of years after infection, but only in a minority of cases. Liver disease may progress silently in some children. Therefore, it is reasonable to consider treatment for children infected with HCV. The combination of IFN and ribavirin has been licensed for children aged 3 years and above. The use of multiple treatment regimens in mostly small and uncontrolled clinical trials of IFN-α in children with chronic hepatitis C makes direct comparison to adult data difficult. However, it is clear that children may have sustained virologic response to treatment at rates that are at least comparable to those in adults. The safety and efficacy of the combination of pegylated IFN and ribavirin are currently being evaluated in a large pediatric trial.

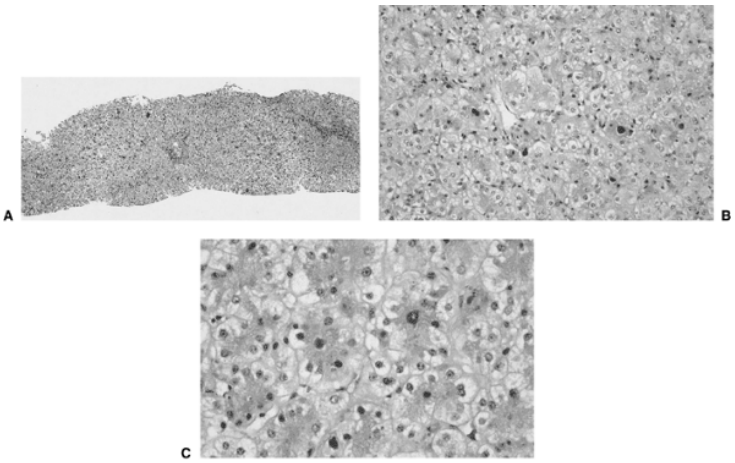
Epstein-Barr Virus

Epstein-Barr Virus (EBV) is a DNA virus that is transmitted primarily by close person-to-person contact with infected secretions, particularly saliva. After initial replication in epithelial cells of the oropharynx, EBV disseminates throughout the reticuloendothelial system by propagating in B lymphocytes. Liver involvement is common in childhood EBV infection; it may be manifested by hepatosplenomegaly, liver tenderness, modestly elevated aminotransferase values, and, occasionally, jaundice. The course of liver disease is usually mild and self-limited but occasionally can be severe and protracted, particularly in immunocompromised hosts. Fulminant hepatitis due to EBV infection is rare. Although liver biopsy is generally not indicated in EBV infection, it should be considered in severe cases with atypical features. Characteristic histologic findings that support the diagnosis of EBV include varying degrees of portal and lobular inflammation and sinusoidal infiltration by mononuclear cells (91). Management of EBV hepatitis is usually supportive although short courses of prednisone may be indicated in select children with severe or prolonged illness. Antiviral agents have no proven benefit in the treatment of EBV infection in immunocompetent patients.

Other Viruses Associated with Hepatitis

Other human herpesviruses, including cytomegalovirus (CMV) and human herpesvirus (HHV) types 1, 2, and 6, may be associated with liver disease, predominantly in neonates and infants (92). The clinical course of these infections can be severe in neonates and immunocompromised children. Parvovirus B19 is a small single-strand DNA virus that causes erythema infectiosum and has been associated with hydrops fetalis and aplastic anemia. Although liver involvement is seldom seen in these conditions, parvovirus B19 infection has been implicated in multisystem disease (93) and fulminant liver failure in children (94), and acute hepatitis in adults. Infections with paramyxoviruses, such as mumps and measles, very occasionally involve the liver and usually in the context of generalized disease. Coxsackie virus and echoviruses are

enteroviruses, they occasionally cause neonatal liver failure (95).



▪ **Figure 47.11** Total parenteral nutrition effect. **A:** At low power, this needle biopsy reveals centrilobular ballooning of hepatocytes. **B:** Centrilobular hepatocytes show pseudoacinar transformation and cholestasis. A terminal hepatic vein is seen at the center. **C:** At higher magnification the pseudoacinar transformation and canalicular cholestasis are better seen.

Liver Disease Associated with Parenteral Nutrition

There are three distinct but overlapping hepatobiliary syndromes associated with TPN discussed comprehensively in Chapter 13. Gallbladder sludge and gallstones may occur at any age but are rarely symptomatic. Older children and adults may develop hepatic steatosis or steatohepatitis. In infants, the typical complication is cholestasis or cholestatic hepatitis (96). It is characterized histologically by predominantly centrilobular hepatocellular damage with ballooning, cholestasis, varying degrees of steatosis, portal mixed inflammatory infiltrate with bile duct proliferation, and portal and pericellular fibrosis (Fig. 47.11A–C). The incidence of cholestasis associated with parenteral nutrition varies from 7% to 50%. The frequency increases with younger gestational age, lower birth weight, and longer duration of parenteral nutrition. Most cases occur from 2 to 10 weeks after starting TPN, and 90% of infants develop cholestasis after 13 weeks (97). TPN-associated liver injury in infants is characterized by hepatomegaly and jaundice. The most widely accepted laboratory indicator is a rising conjugated bilirubin level in a patient who has received TPN for at least 2 weeks. The ALT peaks between the second and fourth week of continuous TPN and then declines, whereas the bilirubin and alkaline phosphatase (AP) continue to increase and remain elevated for the duration of TPN. Patients who cannot be fed enterally and require continued TPN despite cholestasis may develop cirrhosis. Extreme short bowel syndrome may shorten

this period to as early as 6 months. Infants with necrotizing enterocolitis have a sevenfold increased risk for cholestasis. In fact, end-stage liver disease has replaced catheter-related sepsis and malnutrition as the leading cause of death in TPN-dependent infants with short bowel syndrome. HCC has been reported even in noncirrhotic patients (98,99).

A single etiology for TPN-associated cholestasis has not been identified. Factors that have been associated with TPN-related liver disease include immaturity of the enterohepatic circulation, perinatal insults, toxins, nutrient deficiency, contaminants, substrate imbalance, absence of enteral intake, and infection.

When biochemical evidence of cholestasis or hepatocyte injury is found, other causes of liver disease should be excluded. Avoidance of TPN, when possible, is the best approach. In cases where its use is mandatory, it is important to utilize enteral alimentation as soon as possible, even if only for partial or minimal feeding. Dosages of trace elements such as copper and manganese that are excreted through the biliary tree should be adjusted in TPN solutions for patients with cholestatic liver disease. Discontinuation of TPN before development of frank cirrhosis results in substantial improvement in the histologic changes in the liver.

Autoimmune Hepatobiliary Disease

Autoimmune Hepatitis

Although autoimmune hepatitis (AIH) is the subject of Chapter 31, there are some special features and types of AIH that are of special relevance to the pediatric population (Table 47.7). Type 1 or "classic" AIH, associated with presence in serum of smooth muscle antibody (SMA) and/or antinuclear antibody (ANA), more commonly affects women and has a pediatric incidence peak between 10 and 20 years of age (100). Type 2 AIH is characterized by liver–kidney microsomal-1 (anti-LKM-1) antibody in serum (101). Children with type 2 AIH tend to be younger, and there is no clear gender predilection. The liver disease at presentation is more likely to be severe or advanced in type 2 AIH; this disorder may even present as fulminant hepatitis (102). A genetic disorder called *autoimmune polyglandular syndrome* or *AIPGS type 1*, is a disease of immune dysregulation. Affected children have some immunodeficiencies, manifest by chronic mucocutaneous candida infections, and some autoimmune endocrinopathies, such as hypothyroidism and adrenal insufficiency. AIH occurs in approximately 25% of cases of AIPGS type 1 (103). A fourth type of AIH seen in childhood is associated with Coombs positive hemolytic anemia, and is histologically characterized by giant cells (104). ANA, SMA, and LKM antibodies are not found in this type. Rarely, "seronegative AIH" is encountered, in which the histologic features of AIH are recognized, no other causes of liver disease are identified, but none of the typical autoantibodies are identified. Minocycline, pemoline, and other drugs sometimes used in children or adolescents have been associated with the development of AIH (105,106,107).

Table 47.7. Types of Autoimmune Hepatitis in Childhood

Autoimmune hepatitis	Autoantibodies	Associated features
Type 1	ANA, ± ASMA	Female preponderance Other autoimmune disorders
Type 2	Anti-LKM-1	Genders equal Younger children Other autoimmune disorders
Seronegative	None	Other autoimmune disorders?
Drug-associated	ANA	Exposure to minocycline or pemoline
After liver transplantation	ANA	Recurrent or de novo after transplantation
With AIPGS-1	None (occasionally anti-LKM)	Autoimmune endocrinopathies Mucocutaneous candidiasis
Giant cell hepatitis with hemolytic anemia	None	Coomb's positive hemolytic anemia
Overlap syndrome	ANA, ± ASMA	PSC

ANA, antinuclear antibody; ASMA, antismooth muscle antibody; Anti-LKM, liver/kidney microsomal antibody; AIPGS-1, autoimmune polyglandular syndrome type 1; PSC, primary sclerosing cholangitis.

Primary Sclerosing Cholangitis

The chronic fibrosing inflammation of the intra- and extrahepatic bile ducts called *sclerosing cholangitis* has been characterized as either primary or secondary. Secondary sclerosing cholangitis may be due to choledocholithiasis, postoperative stricture, toxin-induced bile ductular injury, or in association with other disorders such as acquired immunodeficiency syndrome and Langerhans-cell histiocytosis (108). The cause of PSC (see Chapter 23) is unknown. The association between PSC and inflammatory bowel disease, as well

as the occasional presence in serum of autoantibodies such as antineutrophil cytoplasmic antibody (ANCA) strongly suggests an immunologic cause. Although adults, particularly men, are most commonly affected, PSC has been reported in the adolescent, childhood, and neonatal age-groups, with or without concurrent inflammatory bowel disease (109).

The clinical presentation of PSC is widely variable. Neonates with jaundice resembling that of biliary atresia have been described. Older children can be asymptomatic or present with nonspecific symptoms such as fatigue, vague abdominal pain, and/or pruritus. Cirrhosis and portal hypertension may be the earliest indicators. PSC should be considered in any patient with inflammatory bowel disease, especially ulcerative colitis, who exhibit physical or biochemical evidence of hepatobiliary dysfunction. Although cholangiography may be diagnostic if macroscopic bile ducts are involved, it is not unusual early in childhood to have only microscopic or "small duct" PSC, detected only by examination of liver biopsy specimens. An "overlap syndrome" with features of both AIH and PSC has been noted in children (110), as in adults. A longitudinal cohort study of 52 children with PSC (81% with inflammatory bowel disease) demonstrated that 35% had an overlap syndrome with AIH (111). In this pediatric population, the median survival without liver transplantation was only 12.7 years, indicating that PSC may be a rapidly progressing chronic liver disease in children, as in adults.

Acquired Disorders of the Biliary Tract

Extrahepatic Biliary Atresia

EBA, although not a common disorder, is the most common pediatric indication for liver transplantation. EBA is an inflammatory and progressive destruction of the extrahepatic bile ducts resulting in fibrosis, biliary cirrhosis, and eventual liver failure (6,112). The cause of EBA is unknown, but the most common form is felt to be acquired rather than congenital. Infections, intrauterine and perinatal, metabolic disorders, genetic predisposition, and environmental exposures have been implicated in various studies (6). Current surgical intervention and medical management have dramatically improved the prognosis for this disease since its discovery in 1817. Although EBA was once a universally fatal disease, the developments of the hepatoportoenterostomy (Kasai) procedure and liver transplantation have made it a survivable condition (113).

The most consistent clinical feature of EBA is cholestatic jaundice that appears in the second or third week of life, although some infants may be jaundiced from birth. Hypopigmented or acholic stools are strongly suggestive of this diagnosis. An enlarged and hard liver may be evident at the time of presentation. Congenital anomalies such as splenic malformations, intestinal malrotation, and cardiovascular defects have been associated with the fetal or embryonal form of EBA, as described earlier in this chapter.

The evaluation of an infant suspected of having biliary atresia is essentially the same as that for an infant with neonatal cholestasis (see subsequent text). Frequently, the jaundiced infants will have a mixed hyperbilirubinemia with elevated

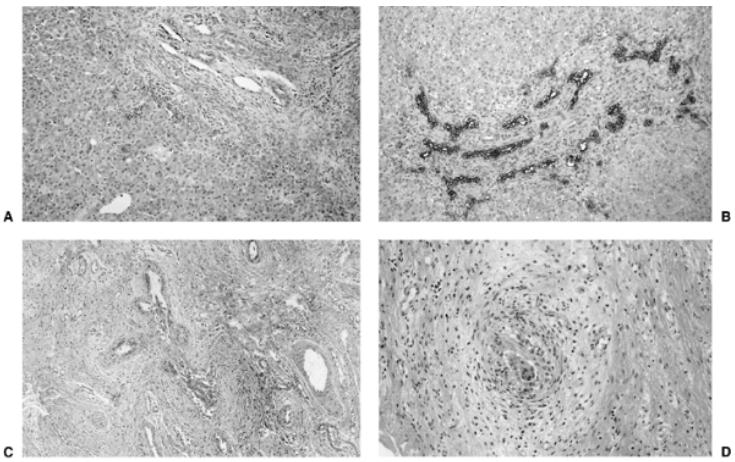
serum AP, γ-glutamyl transpeptidase (GGTP), and aminotransferase values. The absence of a gallbladder on fasting sonography should raise suspicion of EBA, although some affected infants will have a gallbladder. Radionuclide scans are often used to determine biliary patency. Failure of excretion of radioisotope is an indication for liver biopsy and cholangiogram. Bile ductular proliferation and cholestasis are typical histopathologic findings; variable degrees of portal inflammation, occasional giant cell formation, and portal fibrosis are noted (Fig. 47.12A,B). The diagnosis of EBA is confirmed by cholangiogram, usually intraoperative, but sometimes by ERCP. The resected porta hepatis reveals an active destructive and fibrosing extrahepatic cholangitis (Fig. 47.12C, D).

The bile drainage procedure is a hepatoportoenterostomy or "Kasai procedure," after Dr Morio Kasai who developed the surgery in 1968. In this surgery, the scar tissue within the porta hepatis is excised, and a loop of bowel is attached in an attempt to reestablish bile flow from the liver. Recognition of EBA and the timely establishment of biliary drainage through the portoenterostomy are critical. After 3 months of age, the liver injury may be severe enough to make portoenterostomy very unlikely to be of value. Therefore, awareness of EBA and early referral for diagnostic evaluation are essential. In one third of infants treated with portoenterostomy, jaundice never resolves, and hepatic injury progresses rapidly. In approximately another one third, jaundice resolves over several months, but cirrhosis is already established, or develops over the next several years (114). In these children, liver transplantation is the only other treatment option, although supportive measures such as fat-soluble vitamins and choleretic agents are often employed.

Cholelithiasis

Cholelithiasis or gallstones are more common in children than previously thought. Increased awareness and improved detection with techniques such as sonography have played a role in the recognition of gallstone disease as a potentially important pediatric problem (115).

The incidence of cholelithiasis is unknown; this is largely because many infants and children with gallstones are asymptomatic. When symptoms do occur, they are similar to those in adults.



▪ **Figure 47.12** Extrahepatic biliary atresia. **A:** There is marked portal expansion with fibrosis, mixed inflammatory infiltrate, and marked bile ductular proliferation. There is no significant hepatocellular damage. **B:** Immunohistochemical stain for cytokeratin 19 highlights the marked bile ductular proliferation. **C:** Sections of the porta hepatis demonstrate an active destructive and fibrosing cholangitis. **D:** This extrahepatic bile duct remnant shows mixed inflammation, necrosis of the wall, and early periductal fibrosis.

Several conditions have been associated with gallstone formation in children. Hemolytic disease, TPN, short bowel syndrome, CF, and adolescent pregnancy are responsible for most cases. Complications of cholelithiasis include cholecystitis, cholangitis, and perforation; all are more common in adults. Pancreatitis, due to obstruction of the pancreatic duct by a stone or stones in the common bile duct, is the most common complication in children.

Therapy depends on several factors including severity of symptoms, if any, type of gallstone, etiology, and patient factors. As in adults, this may range from expectant management in asymptomatic patients to cholecystectomy for those who have clinically apparent biliary colic, cholangitis, cholecystitis, or an episode of pancreatitis. Endoscopic sphincterotomy with or without stone retrieval is used in the management of bile duct stones. Dissolution therapy using oral bile acids is not effective for pigment stones, which represent most childhood gallstones. Lithotripsy has not been adequately studied in children.

Cholecystitis

Both calculous and acalculous cholecystitis occur in children. Physical examination, laboratory findings, and recommended treatment are similar to those in adults.

Hydrops of the Gallbladder

A massively dilated gallbladder without evidence of gallstones or inflammation is termed *hydrops of the gallbladder* (116). The exact cause of hydrops is unknown, but there is frequently an antecedent or concurrent illness. Acute hydrops of the gallbladder has been reported in association with streptococcal infections, Kawasaki syndrome, and Henoch-Schönlein purpura. Patients vary in age from newborns to adolescents. Symptoms include right upper quadrant abdominal pain and an enlarged, tender, palpable gallbladder. Differentiation between gallbladder hydrops and cholecystitis may be difficult. The best means of diagnosis is ultrasonography, which will reveal a distended and thin-walled gallbladder with no stones, normal

bile ducts, and no evidence of inflammation such as a thickened gallbladder wall. Spontaneous recovery is typical and surgical intervention is usually not necessary.

The Syndrome of Neonatal Hepatitis

Neonatal hepatitis is a syndrome of symptoms, signs, and hepatic histology that includes many types of neonatal liver disease of infectious, genetic, toxic, and metabolic etiologies (117) (Table 47.8). Many of these have already been discussed, and others are discussed in subsequent text because they are specifically pertinent to the differential diagnosis of the syndrome of neonatal hepatitis. The term *neonatal hepatitis* is often used interchangeably with "neonatal cholestasis" because of the prominent conjugated hyperbilirubinemia in most of these disorders. The designation *idiopathic* neonatal hepatitis describes the neonatal liver disease for which no specific etiology can be ascertained. The incidence ranges from 1 in 4,800 to 1 in 9,000 (118). Idiopathic neonatal hepatitis/cholestasis and EBA account for 60% to 70% of all cases of neonatal cholestasis (119).

Table 47.8. Disorders Associated with Neonatal Hepatitis/Cholestasis

ANATOMIC ABNORMALITIES
- Extrahepatic biliary atresia
- Choledochal cyst
- Bile duct stenosis
- Neonatal sclerosing cholangitis
- Spontaneous perforation of common bile duct
- Cholelithiasis
- Masses or neoplastic lesions

IDIOPATHIC NEONATAL HEPATITIS/CHOLESTASIS
- Infections
  - Viral
    - Cytomegalovirus
    - Herpesviruses (simplex, herpes-6 virus)
    - Rubella virus
    - Hepatotropic viruses (A, B, C, D, E)
    - Human immunodeficiency virus
    - Enteroviruses
    - Adenovirus
    - Parvovirus
  - Bacterial
    - Syphilis
    - Bacterial sepsis, urosepsis
    - Listeriosis
    - Tuberculosis
  - Parasitic
    - Toxoplasmosis
- Familial intrahepatic cholestasis syndromes
  - Alagille syndrome
  - Nonsyndromic paucity of the interlobular bile ducts
  - Progressive familial intrahepatic cholestasis (several types)
  - Miscellaneous familial cholestatic syndromes
- Metabolic disorders
  - Disorders of carbohydrate metabolism
    - Galactosemia
    - Hereditary fructose intolerance
    - Glycogen storage disease type IV
    - Carbohydrate-deficient glycoprotein syndrome
  - Disorders of amino acid metabolism
    - Tyrosinemia
  - Disorders of lipid metabolism
    - Wolman's disease
    - Cholesteryl ester storage disease
    - Niemann-Pick disease
  - Disorders of bile acid synthesis
    - 3-β-Hydroxysteroid 5-C_{27} steroid dehydrogenase isomerase deficiency
    - Δ^4-3-oxosteroid 5 β-reductase deficiency
    - Oxysterol 7α-hydroxylase deficiency
  - Peroxisomal disorders
    - Zellweger's syndrome (cerebrohepatorenal syndrome)
  - Mitochondrial hepatopathies
  - Miscellaneous metabolic disorders
    - α_1-Antitrypsin deficiency
    - Cystic fibrosis
    - Neonatal hemochromatosis

CHOLESTASIS ASSOCIATED WITH TOTAL PARENTERAL NUTRITION
- Miscellaneous
  - Vascular disorders of the liver
  - Drug hepatotoxicity
  - Inspissated bile syndrome

Ischemia
Endocrine disorders
Chromosomal disorders
Neonatal lupus erythematosus
Neonatal histiocytosis

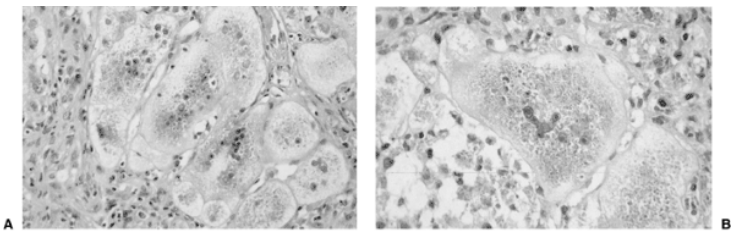
Giant Cell Hepatitis

Giant cell hepatitis is a general term applied when there is extensive or diffuse transformation of hepatocytes into multinucleated giant cells (Fig. 47.13A,B). Giant cell transformation is a common response of the infantile liver to heterogeneous insults. It is not a specific diagnosis and may be associated with a variety of different disorders. The origin and mechanisms of giant cell formation are not clear. They are primarily the result of syncytial fusion of ballooned, degenerated hepatocytes.

Causes of Neonatal Hepatitis/Cholestasis

Congenital infections

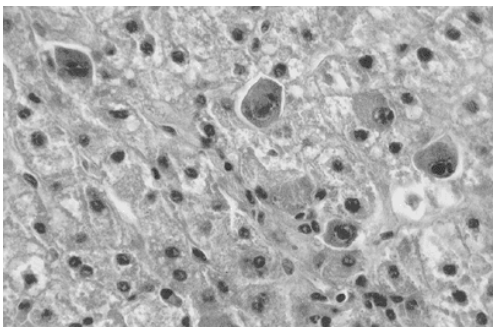
Numerous agents, viral, bacterial, and protozoal, have been implicated in congenital infections associated with hepatitis.



▪ **Figure 47.13** Giant cell hepatitis. **A:** Diffuse giant cell transformation of hepatocytes, cholestasis, and mild lymphocytic infiltrate. **B:** At higher magnification a multinucleated giant hepatocyte reveals cytoplasmic distention with numerous bile granules.

Cytomegalovirus

CMV, a herpesvirus, is the most common cause of congenital infection (120). Clinically apparent disease occurs in only 10% to 15% of infected infants. Signs in the newborn include intrauterine growth retardation, microcephaly, periventricular intracranial calcifications, psychomotor retardation, deafness, and thrombocytopenia. Hepatosplenomegaly with conjugated hyperbilirubinemia and mild elevation of aminotransferase levels are common. Hepatic calcifications may be noted. Hepatic histologic findings include giant cell hepatitis, cholangitis, fibrosis, and persistent extramedullary hematopoiesis. The diagnosis is confirmed by the characteristic viral cytopathic changes (Fig. 47.14) in the bile duct epithelium, hepatocytes, or Kupffer cells. Cytopathic changes may not be present in the liver of neonates; the diagnosis in newborns may be suggested by detection of CMV in a buffy coat preparation, or immunoglobulin M (IgM) antibody to CMV. Treatment of congenital CMV infection includes the use of ganciclovir and CMV immunoglobulin. The liver injury usually resolves if the patient survives the neurologic damage.



▪ **Figure 47.14** Cytomegalovirus (CMV) hepatitis. Characteristic CMV cytopathic changes are seen in several transformed hepatocytes. There is cytomegaly and an intranuclear inclusion surrounded by a halo. Nucleoli appear displaced by the intranuclear viral inclusion.

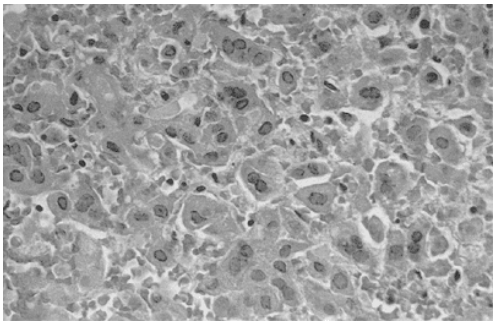
Herpes simplex virus

Herpes simplex virus ([HSV]-1 and -2) may be transmitted vertically, either in utero or perinatally, as the result of ascending infection or contact with cervicovaginal secretions (121). Approximately 90% of congenital herpes infections are due to HSV-2. Primary maternal infection, especially late in gestation, prolonged rupture of membranes, prematurity, and skin trauma such as fetal scalp monitoring are factors that increase the risk of neonatal HSV disease. Perinatal HSV infection is manifested by three syndromes, skin, eye, mouth disease; central nervous system disease; and disseminated HSV disease. Hepatitis is often part of the disseminated disease (122) and it is usually severe with jaundice, hepatomegaly, coagulopathy, and gastrointestinal bleeding. Liver histologic findings include multifocal lytic-type necrosis with characteristic intranuclear inclusions within viable hepatocytes at the periphery of the necrotic areas (Fig. 47.15). Diagnosis is confirmed by isolation of virus from the skin or mucous membranes, immunohistochemistry, and by detection of viral DNA utilizing PCR. Prognosis is ominous without treatment. Early parenteral administration of acyclovir decreases both morbidity and mortality.

Rubella

Congenital infection with rubella occurs transplacentally, and more severe consequences result from infection earlier in gestation. Children with congenital rubella have ophthalmologic, cardiac, and neurologic abnormalities; mental retardation; and sensorineural deafness. Hepatic involvement is frequent (123), and may range from an early presentation with jaundice,

hepatosplenomegaly, and transient cholestasis to a late anicteric hepatitis. Hepatosplenomegaly is a consistent feature and may persist until the end of first year or even later. The diagnosis of neonatal infection is confirmed by isolation of the virus from nasopharyngeal or other body fluids, demonstration of rubella IgM antibody at birth, or a postnatal increase in the infant's IgG titer with stable or decreasing maternal IgG titer. The widespread use of rubella vaccine has resulted in a marked decrease in the incidence of congenital rubella.



▪ **Figure 47.15** Herpes simplex virus hepatitis. Numerous hepatocytes with characteristic cytopathic changes are seen. These include multinucleation, glassy intranuclear inclusions, and margination of chromatin.

Enteroviruses

Transmission of the nonpolio enteroviruses (Coxsackie, echoviruses, and others) may occur during the prenatal, intrapartum, or perinatal period. In 60% of cases there is a history of viral-like syndrome with fever during the last 2 weeks of pregnancy. Infants appear healthy in the first days of life before they develop fever, lethargy, poor feeding, and diarrhea. Hepatitis and jaundice are the most frequent manifestations. In most cases, the course is benign and self-limited. However, progressive hepatic failure with markedly elevated aminotransferase levels, disseminated intravascular coagulation, and massive hepatic necrosis have been reported with infections of Coxsackie group B, echovirus types 6, 11, 14, and 19. Therapy is supportive.

Hepatotropic viruses

HAV is not a common cause of neonatal hepatitis. However, a newborn may become infected if the mother has acute hepatitis during the last 2 weeks of pregnancy. In infants, the infection may be asymptomatic or present as a gastroenteritis-like syndrome. One report documents a premature infant who developed hepatic necrosis during the course of acute hepatitis A. No specific treatment is available. Mothers who are either long-term carriers of hepatitis B or have acute infection during the third trimester of pregnancy may transmit the virus to their infants. Infants born to HBsAg-positive mothers demonstrate serologic or clinical evidence of HBV infection, 1 to 4 months postnatally. Although most perinatally infected neonates are asymptomatic, there are occasional cases of acute icteric hepatitis and even fulminant hepatitis. HCV can be transmitted perinatally. HCV infection in the newborn is usually asymptomatic. Some infected infants, however, may have mild to moderate aminotransferase elevation. Perinatal transmission of hepatitis D is possible, although uncommon (124). Vertical transmission of hepatitis E virus (HEV) has been described. In one report, 6 of 8 babies born to mothers infected with hepatitis E in the third trimester had clinical, serologic, or virologic evidence of HEV infection (125). Most of them had anicteric hepatitis, but one was icteric at birth. Two of them died within 24 hours and one was found to have massive hepatic necrosis.

Human immunodeficiency virus

Hepatosplenomegaly is a common early manifestation of HIV infection in infants, seen in more than 90% of pediatric cases. Cholestatic hepatitis has been reported as the first manifestation of HIV infection as early as 5 months of age (126).

Syphilis

Hepatitis and hepatosplenomegaly are manifestations of early congenital syphilis (127). Jaundice may be the predominant feature. Fulminant hepatitis has been associated with death in a few patients. Characteristic histologic findings are centrilobular mononuclear infiltrates with portal and interstitial fibrosis. Other histologic patterns may be seen, such as neonatal hepatitis with giant cell transformation, nonspecific hepatitis with portal inflammation and portal fibrosis, or even completely normal histology in the presence of heavy infiltration by treponemes. Extramedullary hematopoiesis is seen in both liver and spleen. The treatment is penicillin administered parenterally. Aminotransferase levels may remain elevated for months after treatment. Although treatment may arrest or eradicate the infection, the prognosis depends on the damage done prior to initiation of therapy.

Bacteremia

Bacteremia (128) and urosepsis (129) are well-documented causes of jaundice in the newborn period and jaundice may be the earliest manifestation of sepsis. Hepatomegaly occurs in 40% to 60% of patients, although aminotransferase levels are normal or mildly elevated. The most commonly reported

agent is *E. coli*. Genitourinary evaluation is mandatory although anatomic urinary abnormalities are infrequent. Histologic examination of the liver reveals periportal inflammation, Kupffer cell hyperplasia, moderate cholestasis, and clusters of neutrophils ("minimicroabscesses") within the lobule. The pathogenesis of bacterial sepsis-associated cholestasis is not clear. Hepatocellular damage and enhanced hemolysis causing overload of the immature hepatic function are among the factors considered. Bacterial endotoxin has been implicated in the pathogenesis of hepatocellular injury. It is speculated that the lipid moiety inhibits the activity of Na^+, K^+-ATPase, which interferes with the bile flow at the canalicular level.

Listeria

Direct bacterial infections of the hepatic parenchyma are very uncommon in the newborn infant. The exception is septicemia caused by *Listeria monocytogenes*, in which hepatic manifestations are always present. Listeria is acquired transplacentally or at delivery from infected cervicovaginal secretions. Two histologic forms have been described: Diffuse hepatitis or, more commonly, demarcated areas of necrosis or microabscesses that contain pleomorphic gram-positive bacilli (130).

Toxoplasmosis

Toxoplasma gondii is an obligate intracellular protozoan parasite that can cross the placenta and infect the fetus. Congenital infection occurs primarily as a result of acute maternal infection during pregnancy, by either ingestion of cysts in undercooked meat or direct contact with feces of infected animals such as cats or kittens. The minority of cases result from reactivated disease in pregnant immunosuppressed women, especially those infected with HIV. Severe clinical disease is observed in fetuses infected in the first trimester, whereas those infected in the second and third have mild or subclinical disease at birth. Treatment of acute infection during pregnancy with spiramycin has been shown to decrease the incidence of vertical transmission. Most infants have subclinical disease. Clinical manifestations, when they occur, include microcephaly or hydrocephalus, intracranial calcifications, chorioretinitis, seizures, psychomotor retardation, thrombocytopenia, hepatosplenomegaly, and jaundice. Hepatitis may be the only clinical sign of disease. Hepatic microcalcifications may be detected on plain abdominal radiographs. Liver histology may reveal a nonspecific giant cell hepatitis, but more frequently shows focal areas of necrosis and endothelial cells containing the parasite. The enzyme-linked immunosorbent assay (ELISA) detecting toxoplasma IgM antibody has high sensitivity and specificity. Pyrimethamine and sulfadiazine are synergistic and are the most commonly used drugs in the treatment of infants with documented infection.

Familial intrahepatic cholestasis syndromes

Familial intrahepatic cholestasis syndromes are generally included in the differential diagnosis of the neonatal hepatitis syndrome, because presentation is often in the first months of life. Although they are grouped together arbitrarily because they have similar features, many of these disorders are not completely characterized, and the pathogenetic mechanisms may be unrelated. Some of these disorders have been discussed in the preceding text; these include inborn errors of bile acid metabolism or transport, the three types of PFIC, and Alagille syndrome.

Cholestasis associated with total parenteral nutrition

As discussed in the preceding text, cholestasis and a clinical picture indistinguishable from the neonatal hepatitis syndrome are common in infants who receive TPN.

Miscellaneous causes of neonatal hepatitis syndrome

Vascular disorders of the liver

Vascular disorders are an unusual cause of the neonatal hepatitis syndrome, but they may present with conjugated hyperbilirubinemia, and elevated aminotransferase and AP levels. Two major categories of vascular disorders, hemangiomas and vascular malformations, have been distinguished, on the basis of the cellular biology and natural history of the lesions. Infantile hemangioendotheliomas may also present with jaundice. These vascular tumors are discussed in subsequent text as tumors of the liver in childhood.

Other vascular disorders, such as veno-occlusive disease and Budd-Chiari syndrome are rarely described in neonates, although veno-occlusive disease has been reported in a breast-fed infant whose mother was drinking herbal tea.

Drug hepatotoxicity

Neonatal cholestasis has been reported with chloral hydrate, pancuronium bromide, and erythromycin estolate. Di-2-ethylhexyl phthalate, a plasticizer found in the tubing for extracorporeal membrane oxygenation (ECMO) has been implicated in the pathogenesis of cholestasis seen in infants supported with ECMO. Isolated reports describe infantile hepatitis caused

by halothane and phenobarbital.

Inspissated bile syndrome

Inspissated bile syndrome is a term that was first used to describe conjugated hyperbilirubinemia in fetal erythroblastosis. The liver histology in those infants was similar to that of neonatal hepatitis. Rh-incompatibility and CF are currently the most common causes of inspissated bile syndrome.

Endocrine disorders

Congenital hypothyroidism is associated with neonatal jaundice in approximately 20% of cases. Jaundice may be the presenting symptom and is prolonged if the hypothyroidism is left untreated. Hyperbilirubinemia is usually unconjugated. In contrast, conjugated hyperbilirubinemia has been reported in newborns with hypopituitarism (131,132) and septo-optic dysplasia. Signs of hypopituitarism in the neonatal period include hypoglycemia, jaundice, hepatomegaly, and micropenis in males. Prompt recognition and hormone replacement therapy result in resolution of cholestasis, although delay in treatment may result in progression to significant permanent hepatic injury, and even cirrhosis. It is speculated that cholestasis develops secondary to lack of the trophic hormones, such as growth hormone and cortisol, which modulate bile acid synthesis and flow. Cholestasis has also been reported in infants with primary adrenal insufficiency.

Chromosomal disorders

Both neonatal hepatitis syndrome and EBA have been reported in association with trisomy 17-18 syndrome (trisomy E) and trisomy 21 (Down's syndrome). The mechanism is unknown.

Transient myeloproliferative disorder, an acute leukemia-like disorder that may affect neonates with Down's syndrome, has been associated with diffuse hepatic fibrosis and obstructive jaundice (133). Histologically, there is excessive extramedullary hematopoiesis with myelodysplasia, numerous dysplastic megakaryocytes, hepatocellular damage, hemosiderosis, and pericellular fibrosis (134). The prognosis is poor.

Neonatal lupus erythematosus

Cholestasis and hepatosplenomegaly have been reported in infants with neonatal lupus erythematosus (135). Hepatic histology may demonstrate giant cell transformation, extramedullary hematopoiesis, and ductular proliferation. Paucity of interlobular bile ducts has also been reported. It is speculated that maternal autoantibodies that pass to the fetus transplacentally are involved in the pathogenesis of the liver injury. Cholestasis usually resolves by 9 months.

Tumors of the Hepatobiliary System in Children

Tumors of the hepatobiliary system are uncommon in children and comprise approximately 1% to 4% of all childhood solid tumors. They are most common in young children, and usually found in the right hepatic lobe. Benign lesions such as hemangioma, adenoma, focal nodular hyperplasia (FNH), and mesenchymal hamartoma outnumber the malignant tumors, hepatoblastoma, HCC, and embryonal sarcoma. In general, liver tumors are asymptomatic and are discovered during routine examination as an abdominal mass.

Hemangiomas and hemangioendotheliomas, which arise from vascular endothelium, are the most common benign tumors of the liver in children (136). These lesions are generally asymptomatic but larger or numerous tumors can be associated with hepatomegaly, abdominal pain, bruit, and/or jaundice. Heart failure from arteriovenous shunting within the liver or thrombocytopenia from sequestration of platelets within the tumor, termed *Kasabach-Merritt syndrome*, is sometimes seen. True hemangiomas exhibit rapid growth then slow involution, whereas vascular malformations grow in proportion to the growth of the child and fail to regress. Multiple hepatic hemangiomas are usually associated with cutaneous hemangiomas or diffuse neonatal hemangiomatosis involving the brain, lungs, and gastrointestinal tract. They commonly present within the first 6 months. Hepatic hemangiomas invariably regress late in infancy, but they may be life threatening during the proliferative phase with a mortality of 30% to 80%. Pharmacologic therapy with corticosteroids and IFN-α-2a has been used for symptomatic hepatic hemangiomas, large asymptomatic lesions, and extensive multiple hemangiomas which might cause congestive heart failure (137). The response rate to corticosteroids has ranged from 18% to 70% whereas that to interferon has been reported to be as high as 85%. Hepatic arteriovenous malformations (AVM) are less common than hemangiomas and may have similar clinical presentations. Combined embolization and resection is advised for symptomatic AVMs, because they do not regress with time.

Infantile hemangioendothelioma is the most common liver tumor in the first year of life (138). In 87% of cases it is detected before the age of 6 months. Complete resection of the tumor, if possible, is the treatment of choice.

Hepatic adenomas are usually large, encapsulated solitary masses, most often found in young women. Although liver adenomas have been linked to estrogen use in adults, glycogen storage disease is the more important condition associated with this lesion in children (139). Although these are hepatocellular

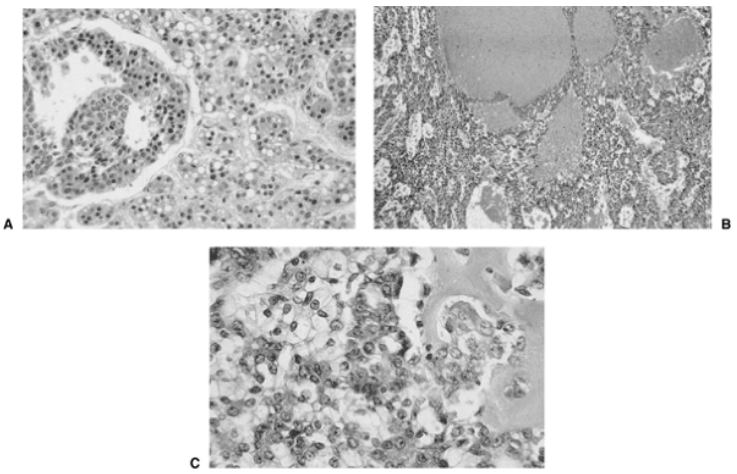
neoplasms, the serum α-fetoprotein level is typically normal. The large nodules seen in galactosemia and tyrosinemia are more accurately designated as nodular hyperplasia, because they occur in the presence of cirrhosis.

FNH is a small, unencapsulated and generally solitary lesion that occurs most commonly in young girls or women but may be noted in either gender and at any age, including infancy and childhood.

Mesenchymal hamartomas (140) are large and multilobulated and cystic tumors. They are asymptomatic, unless the size of the mass is large, causing abdominal pain or jaundice from compression. Histologically, these tumors are comprised of a meshwork of hepatocytes, bile duct epithelia, and mesenchymal cells, intermixed with cystic dilatations within a dense fibrous stroma. The prognosis is usually excellent although malignant transformation into embryonal sarcoma has been reported rarely. Excision is the treatment of choice.

Malignant liver tumors in the pediatric age-group include hepatoblastoma and HCC (140). Hepatoblastomas are single, lobulated, often calcified masses that are usually discovered during infancy. Tumor cells histologically resemble fetal and embryonal hepatocytes and occasionally have mesenchymal components (Fig. 47.16A–C). These tumors may occur in association with Beckwith-Weideman syndrome, hemihypertrophy, and familial adenomatous polyposis. Serum α-fetoprotein levels are almost universally elevated in children with these tumors. Prognosis is fair, with overall survival rates of

approximately 50% depending on the stage of the disease. The lungs and contiguous abdominal spread are common sites for metastasis. Treatment should be aimed at complete resection with pre- and postoperative chemotherapy. Liver transplantation has been successfully used in cases where complete tumor resection cannot be accomplished.



▪ **Figure 47.16** Hepatoblastoma. **A:** Epithelial hepatoblastoma with embryonal (*left*) and fetal (*right*) components. Fetal hepatocytes closely resemble the normal counterparts. **B:** In embryonal areas, peliosis is frequently observed. **C:** Mixed epithelial mesenchymal hepatoblastoma with fetal, embryonal, and mesenchymal components. The mesenchymal component is composed of osteoid-forming malignant cells (*right*).

Childhood HCC arise in association with cirrhosis but can be seen in the absence of underlying liver disease. The incidence is exceedingly high in HT (141). The prognosis is generally poor unless total excision of early tumors is possible. Fibrolamellar HCC occurs in the pediatric age-group, and is not associated with cirrhosis.

The Liver in Cystic Fibrosis

CF, an autosomal recessive multiorgan disorder, is the most common lethal inherited disease affecting the white population, occurring in 1 of 2,000 live births.

The abnormal gene is on the long arm of chromosome 7 and encodes for the cystic fibrosis transmembrane conductance regulator (CFTR). CFTR, a cyclic adenosine monophosphate (cAMP)-dependent chloride channel located in the apical membrane of secretory epithelial cells, promotes efflux of chloride. Several hundred mutations that encode for CFTR proteins with impaired ability to transport chloride ions have been identified. The ubiquity of CFTR throughout the body accounts for the multiorgan involvement that characterizes this disorder. The primary organs affected are the lungs, pancreas, gastrointestinal tract, and liver. In the liver, CFTR is expressed primarily on the apical surface of the biliary epithelium. Largely because of prolonged patient survival and greater awareness, the recognition of liver disease in CF appears to be increasing. Liver disease is not universal; the incidence does not rise progressively but seems to peak during adolescence. However, it is rare for liver disease to have its onset after 20 years of age. Although the reasons for this decline are unclear, two hypotheses have been offered: (a) liver disease increases mortality selectively so that individuals without liver disease are more likely to survive into adult life, or (b) a cohort effect 10 to 15 years earlier than the prevalence studies artificially inflated the likelihood of liver disease, and current adolescent population. Symptomatic liver disease has been documented in 20% of patients with CF and in up to 50% in some series; this can be the presenting or the dominant feature. Pathologic evidence of liver disease, however, is found at autopsy in more than 75% of patients, and is often focal. Cirrhosis complicates CF in 1.4% of patients, with a peak frequency of 2.7% in those 16 to 20 years of age (142). Cirrhosis now accounts for virtually all nonpulmonary causes of death in patients with CF.

The factors that initiate, accentuate, and perpetuate the development of liver disease in patients with CF have not been identified. A 3:1 male preponderance of liver disease is seen in patients with CF (143). Although liver disease is most common in patients with steatorrhea, it may occur in those with intact pancreatic exocrine function (144). Genotype analysis has not revealed a specific mutation in the *CF* gene that correlates with the existence of liver disease. One study has suggested an association with particular histocompatibility antigens, thereby implicating a possible role for altered immune responses in patients with CF and liver disease (145). A more recent study demonstrated an association of a specific polymorphism of glutathione S-transferase with liver disease in patients with CF (146).

The etiology of the hepatobiliary lesions in CF has not been fully elucidated. The description of the gene product cystic fibrosis transmembrane regulator in the apical domain of bile duct epithelial cells (147) suggests that altered ductular secretion results in concentrated viscous bile with subsequent plugging and inflammation.

Several forms of liver disease are seen in patients with CF. Neonatal cholestasis occurs in 2% to 20% of affected infants and may persist for several months. It is generally attributed to viscous bile with sludging. Hepatic steatosis is common, but its cause has not been clearly elucidated. Micronodular cirrhosis is evident in only 2% to 5% of patients and may be multifactorial in etiology. Focal biliary cirrhosis, a lesion virtually unique to CF, is seen in up to 10% to 20% of individuals. Focal biliary cirrhosis begins with accumulation of amorphous material in intrahepatic ducts, which causes focal obstruction, edema, and chronic inflammation. Subsequently, bile duct proliferation and fibrosis evolve into biliary cirrhosis. This lesion occurs most often without signs or symptoms until portal hypertension and its complications ensue. Results of standard biochemical tests may be normal or nearly normal. Patients with CF also have a high incidence of biliary tract disease, including hypoplastic gallbladders, gallstones and/or sludge, common bile duct strictures, common bile duct obstruction from severe pancreatic fibrosis, and a cholangiopathy indistinguishable from PSC.

The optimal method for detection of liver disease in CF has not been established, but several studies have documented the utility of serial ultrasonography in discovery of abnormalities such as steatosis, heterogeneity in echotexture, nodularity, and evidence of portal hypertension, often in the absence of biochemical abnormalities.

Because of pancreatic insufficiency and steatorrhea, most patients with CF should receive supplements of fat-soluble vitamins. However, infants with cholestasis or older patients with severe liver disease may require these supplements in higher dosages because of the additional fat malabsorption associated with low intestinal luminal bile salt concentrations. Because taurine deficiency has been demonstrated in some patients with CF as a result of excessive losses, some authors recommend that supplemental taurine be provided to patients with CF treated with UDCA on the basis of theoretical concern of excessive consumption of this conjugating amino acid induced by large amounts of the unconjugated bile acid. However, in clinical trials, no significant effect of taurine supplementation was documented. Other than the supportive role of nutritional management for chronic liver disease, no other specific dietary therapies are known.

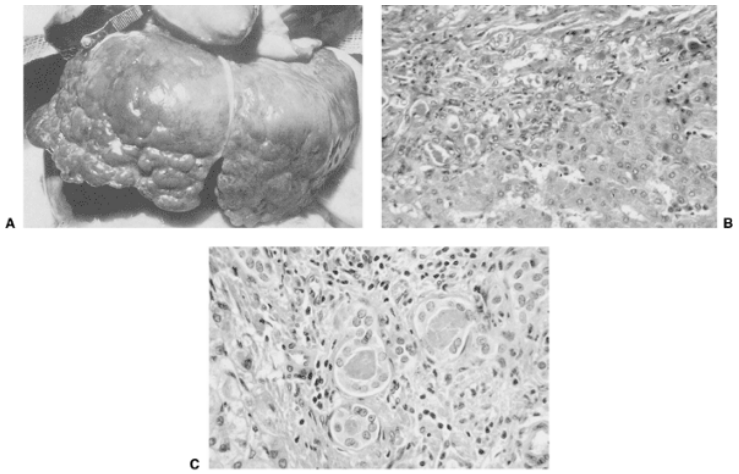
Although the precise pathogenetic effects of the CFTR defect are unknown, it results in the production of thick, tenacious secretions in affected organs, including the hepatobiliary system. Secretion of thick, viscous bile results in impaired bile flow and consequent sludge and potential gallstone formation. Over time, these abnormalities in bile lead to persistent

focal microscopic or macroscopic obstructions in the intrahepatic biliary tree causing a chronic inflammatory infiltrate, bile duct proliferation, and fibrosis with extension and coalescence; the resulting lesion is called *focal biliary cirrhosis* (142) (Fig. 47.17A–C). Focal biliary cirrhosis may be asymptomatic and associated with normal liver biochemical studies, but it appears to be progressive.

Well-established biliary cirrhosis may present as hepatomegaly, splenomegaly, variceal bleeding, or abdominal pain or enlargement. The pathogenesis seems to be an extension of the factors that cause focal disease. The true incidence is undefined. End-stage CF-associated liver disease may be indistinguishable from other forms of severe liver disease.

Other conditions, including reversible focal or diffuse hepatic steatosis, neonatal cholestasis, inspissated bile syndrome, and biliary tract anomalies such as microgallbladder, cystic duct atresia, and bile duct stenosis are also seen. In older patients, a radiographic picture indistinguishable from that of PSC has been reported.

The evaluation of liver disease in children with CF is dictated by the clinical presentation and may include ultrasonography or other imaging modalities such as ERCP. Other causes of liver disease should be excluded. There are several potential, albeit conceptual, approaches to the treatment and ultimate prevention of CF-associated liver disease.



▪ **Figure 47.17** Cystic fibrosis. **A:** Gross appearance of the so-called focal biliary cirrhosi with focal nodularity of the right and left lobes. **B:** Microscopically, portal tracts are expanded with fibrosis, mixed inflammatory infiltrate and bile duct proliferation. Ductal cholestasis is observed. **C:** Bile ducts are distended and contain inspissated pink bile, a feature characteristic of the disease.

Because the presumed underlying pathogenesis focuses on abnormal hyperviscid secretions with bile stasis with the intrahepatic accumulation of hydrophobic, hepatotoxic bile acids, this suggests a rationale for an attempt to decrease the viscosity of bile or to replace or displace hepatotoxic bile acids. UDCA has shown promise in studies of patients with CF-associated liver disease (148). UDCA therapy has been associated with an improvement in biochemical parameters and nutritional status. It is doubtful that the improvement in liver function is solely a function of either an induced choleresis or a change in the hydrophobic/hydrophilic balance of the biliary bile acid pool; UDCA may have some as yet undescribed direct effect at the level of the hepatocyte or biliary epithelial cell. UDCA in pharmacologic concentrations increases intracellular calcium concentrations and stimulates chloride efflux through opening of chloride channels in biliary cells. UDCA may exert a membrane-stabilizing effect on biomembranes exposed to cytotoxic bile acids. However, its long-term benefit, particularly in preventing cirrhosis, remains to be determined.

Management of CF-related liver disease also depends on clinical manifestations and includes assessment of appropriate caloric intake and pancreatic enzyme supplementation. Intervention for variceal bleeding, using sclerotherapy or shunts, has been extensively utilized in patients with CF and cirrhosis. Liver transplantation alone, when possible, may lead to an improvement in both the pulmonary function and nutritional status of CF patients with end-stage liver disease (149). However, the optimal timing of transplantation for an individual patient requires careful thought. Candidacy is influenced by several factors, including lung disease. In the post-transplant period, medication doses must be carefully monitored; patients with CF often need higher doses of drugs because of poor absorption and altered drug metabolism.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is a spectrum of disorders that encompasses simple hepatic steatosis and the more serious nonalcoholic steatohepatitis (NASH) that can progress to cirrhosis (see Chapter 39). These increasingly recognized disorders have become one of the most common causes of chronic liver disease in both adults and children. Although the prevalence of NAFLD in childhood is not clear, it has become apparent that it is much more common than originally thought. The major association with NAFLD is obesity, and as the prevalence of obesity in childhood and adolescence increases, fatty liver is recognized with greater frequency. Factors that are associated with progression of liver disease have not been fully determined, but it has become clear that the pathogenesis of NASH is a "two hit" process that includes disturbed lipid homeostasis, resistance to the effects of insulin and subsequent hyperinsulinemia, and local toxic effects of triglyceride on hepatocytes. In adults, steatohepatitis is commonly related to consumption of alcohol, obesity, exposure to hepatotoxic drugs, and diabetes mellitus, but obesity probably plays the most important role in children. Steatohepatitis is usually a clinically silent disease that is commonly discovered when liver test abnormalities are discovered incidentally. However, the clinical spectrum of disease is wide with findings of advanced liver disease occasionally evident at the time of diagnosis. The frequency of progression to cirrhosis is not known.

There appears to be a phenotype of children with NASH that resembles the "typical adult patient": A preteen, asymptomatic obese child (males predominate) who may have hyperlipidemia. In one series (150) of children with steatohepatitis and no evidence of inherited, infectious, autoimmune, endocrinologic, toxicologic, or iatrogenic causes, all 14 patients (10 boys; mean age 13.5 years) were obese (121% to 222% of ideal body weight). Nine patients initially had transient abdominal pain, two had hepatomegaly, and one was identified by incidental laboratory evaluation. Bilirubin levels were normal in all. Five patients had elevated serum cholesterol, and 10 of 12 patients in whom nonfasting triglycerides were measured had elevated levels. All patients had normal nonfasting serum glucose values. All had hepatic imaging studies demonstrating diffuse fatty change.

Although no directly comparative studies have been done, fibrosis may be more common at the time of diagnosis of NAFLD in children and adolescents. One report describes some degree of fibrosis in all 14 children with NASH discovered on a retrospective clinicopathologic review (150). In a study of 17 children, fibrosis was found in 9 (151); one group reports 75% prevalence of fibrosis in 24 children with NASH (152); and another reports fibrosis in 50% of 43 children with biopsy-proven NAFLD (153). It is possible that patient selection for liver biopsy may be more stringent in the pediatric age-group; so far there are no studies that report a large series of biopsies in unselected obese children with ALT or ultrasonographic abnormalities. In any case, instances of advanced liver disease and cirrhosis (152,154) have been described during childhood and adolescence. NAFLD and NASH must be recognized as potential causes of serious liver disease in this population.

Risk factors for progression of liver disease due to NAFLD have been identified in adults. These include age, diabetes mellitus, obesity, and AST:ALT ratio of greater than 1 (155,156,157). Age may be a less consistent risk factor as more cases are being recognized in the pediatric age-group. No risk factors have been confirmed in children or adolescents to date. The higher rate of NAFLD in males may be associated with gender differences in leptin production in obese adolescents.

Laboratory abnormalities in steatohepatitis are mild and nonspecific, and the diagnosis is one of exclusion. Disorders such as Wilson disease, glycogen storage disease, CF, and other metabolic defects may be associated with hepatic steatosis, but usually have other recognizable features. Hepatic steatosis may be suggested by abdominal ultrasonography or computerized tomography but should be confirmed histologically. Liver biopsy specimens will reveal varying degrees of panlobular, macrovesicular steatosis with inflammation and bridging fibrosis. The degree of steatosis, fibrosis, and inflammation does not correlate with symptoms or signs.

Weight loss leads to improvement in or resolution of liver dysfunction, but may be difficult to achieve. The possible contribution of lipid peroxidation causing mitochondrial injury in steatohepatitis might suggest the use of supplemental antioxidants.

Approach to Pediatric Patients with Hepatobiliary Signs or Symptoms

Abnormal "Liver Enzymes"

Persistent aminotransferase abnormalities in children require diagnostic evaluation, because some disorders require specific therapy, whereas others have implications for future health of the patient or family members. The diagnostic approach to abnormal ALT values depends on the age of the patient, exposure history, physical findings, and family history. As in adults, the degree of aminotransferase elevation may not correlate with the amount of liver damage and is often of little prognostic value. Work-up is essentially the same as in adults. Injury or inflammation of cardiac or skeletal muscle also causes increased AST and ALT values. Other causes of elevated aminotransferase values include celiac disease and the presence of a macroenzyme of AST. In the latter, the AST will range from 60 to 1100 IU/L but ALT is normal.

Elevation in GGT is most commonly associated with obstruction or inflammation of bile duct epithelial cells. Although marked elevation of GGT suggests a significant bile duct injury or reduced bile flow, GGT can be paradoxically normal with certain bile acid enzyme or canalicular transport defects such as PFIC-1 and PFIC-2 (see preceding text). Some medications, especially anticonvulsants, induce synthesis of GGT and cause increased serum concentrations. It is not necessary to discontinue these medications for GGT elevations, if other evidence of drug-induced liver injury is absent.

Serum AP activity is less helpful in the assessment of liver disease in children, as it may be elevated for reasons unrelated to hepatic function such as bone injury or growth. Benign elevation of serum AP is an important condition to consider when faced with unexpected elevation in the range of above 1,000 IU/mL. The typical clinical setting is that of an infant or toddler with an apparent viral gastroenteritis in whom AP is measured (158). These very high levels tend to resolve spontaneously over several weeks, although familial persistent elevation of AP is described. In this setting, the serum AP usually comprises primarily the bone isoenzyme. Treatment for this condition is reassurance and avoidance of unneeded, expensive, and invasive tests. Isolated abnormalities in serum AP of the liver isoenzyme are occasionally encountered in infiltrative processes of the liver, namely metastatic disease or granulomatous hepatitis, or as an early indicator of PSC in a child with underlying inflammatory bowel disease.

Hepatomegaly

The liver span will increase as the child grows older but should not exceed 10 cm in childhood. Although the liver span is the

most precise measure (159), palpation of the liver edge is the more conventional method. A liver palpable 2 cm below the right costal margin is considered normal during infancy and 1 cm below the costal margin is acceptable throughout childhood. A liver edge palpable below the xiphoid is atypical and may be another indicator of generalized hepatomegaly. Hepatomegaly may be a transient finding during systemic viral illnesses, such as infectious mononucleosis, but persistent hepatomegaly is an indication for further evaluation. This evaluation would include measurement of aminotransferase and AP values, and some sort of imaging study, such as an ultrasonography. The latter will also detect abnormal echotexture suggestive of fat, fibrosis, or infiltration, as well as space-occupying lesions such as masses or cysts.

Hyperammonemia

The clinical presentation of hyperammonemia is broad and nonspecific. In the newborn period, patients most often present with irritability, fretfulness, and vomiting. Findings on physical examination may likewise be nonspecific with hypotonia, hyperventilation, or apparent respiratory distress. Often, in infants with metabolic disorders, a change in diet or metabolic stress will precipitate an episode of hyperammonemia. A combination of clinical characteristics and plasma amino acid values is used to characterize the patient's underlying condition. Unless the physician suspects a metabolic cause for the clinical symptoms and obtains a measurement of serum ammonia, the infant may succumb within days to progressive acidosis, obtundation, and multiorgan failure.

Hyperammonemia may also occur in older children. As in the newborn period, initial symptoms are variable, but typically include vomiting and/or an altered mental state. Neurologic manifestations are progressive, beginning with increased irritability and confusion, which is followed by combativeness, and only later do patients experience seizures, apnea, or loss of consciousness. Causes of hyperammonemia in children are listed in Table 47.9.

Table 47.9. Causes of Hyperammonemia in Children

Urea cycle disorders
Organic acidemias
Fatty acid oxidation disorders
Disorders of pyruvate metabolism
Transient hyperammonemia of the newborn
Reye's syndrome
Valproic acid hyperammonemia
Congenital absence of the portal vein with portosytemic shunt

Acute Hepatic Failure

Hepatic failure is a well-defined clinical syndrome in adults, comprising the acute onset of encephalopathy, coagulopathy, and evidence of hepatic dysfunction without preexisting liver disease. However, a specific definition is lacking for pediatric patients who may not fulfill all the adult criteria. In particular, encephalopathy in its early stages is difficult to define in infants and children, and when it can be identified may appear late in the course. Therefore, a working definition for children is evidence of liver injury and an uncorrectable coagulopathy in the absence of underlying chronic liver disease. Causes of acute hepatic failure in children are listed by age-group and type of disease in Table 47.10. The diagnostic evaluations for some of these disorders have already been discussed, and for others the principles are the same as in adults. Essential requirements for the management of acute liver failure in children are the same as those in adults.

Table 47.10. Age-Related Differential Diagnosis of Acute Hepatic Failure in the Pediatric Population

Early (<1 wk) perinatal period
Infectious
Herpes simplex virus (HSV)
Echovirus
Parvovirus
Hepatitis B (mutants)
Adenovirus
Metabolic
Neonatal iron storage disease
Respiratory chain defects (disorders of oxidative phosphorylation)
Late perinatal period
Metabolic
Tyrosinemia
Fructosemia[a]
Galactosemia
Zellweger's syndrome
Inborn errors of bile acid biosynthesis (2,35)
α_1-Antitrypsin deficiency
Infectious
EBV
Human immunodeficiency virus
Leptospirosis

HAV
Vascular
Congenital heart disease, myocarditis
Asphyxia
Seizure
Budd-Chiari syndrome
Others
Leukemia
Neuroblastoma
Hepatoblastoma
Hemophagocytic lymphohistiocytosis (familial erythrophagocytic lymphohistiocytosis)
Infants and older children
Infectious (HAV, HBV, HCV, HDV, EBV, CMV, HSV, non-A, non-B, non-C, leptospirosis, togavirus, bacterial sepsis)
Drugs (valproic acid, acetaminophen, pemoline, isoniazid, salicylates)
Toxins (carbon tetrachloride, *Amanita phalloides*, iron overload)
Metabolic (hereditary fructose intolerance, Wilson disease, mitochondrial DNA depletion)
Vascular (shock, myocarditis, sequelae of cardiac surgery, sickle cell anemia)
Other (leukemia, TPN-associated, erythropoietic protoporphyria, autoimmune hepatitis, neuroblastoma, choledochal cyst)
Adolescents
Infectious (HAV, HBV, HCV, HDV, EBV, CMV, HSV, non-A, non-B, non-C, leptospirosis, bacterial sepsis, treponemal infection)
Drugs and toxins (acetaminophen, pemoline, TMP-SMX, drugs of abuse [glue sniffing, cocaine, ecstasy])
Metabolic (Wilson disease, fatty liver of pregnancy)
Neoplastic (lymphoma, leukemia, hepatocellular carcinoma)
Vascular insufficiency (pericarditis, myocarditis, hypoperfusion and hypoxemia)
Miscellaneous disorders (chronic hepatitis, fulminant presentation) (90)
[a]After introduction of sucrose- or fructose-containing feedings.
EBV, Epstein-Barr virus; HAV–HDV, hepatitis A through hepatitis D viruses; CMV, cytomegalovirus; TPN, total parenteral nutrition; TMP-SMX, trimethoprim-sulfamethoxazole.

Complications and Management of Chronic Cholestasis in Children

Some complications are common to all cholestatic disorders: Reduction in intraluminal bile acids resulting in malabsorption of fat and lipid-soluble vitamins; retention of the constituents of bile such as bile acids, bilirubin, and cholesterol, resulting in pruritus and xanthomas; and progressive hepatocellular damage leading to portal hypertension and liver failure. The management of cholestasis is first directed toward specific treatment of the underlying disorder when possible.

Steatorrhea, almost always present in children with severe cholestasis, is a major cause of malnutrition. The combination of long-chain triglyceride malabsorption and inadequate intake may lead to essential fatty acid deficiency. Bile acids are necessary for effective intraluminal long-chain triglyceride absorption as well as for the micellar solubilization of lipid-soluble vitamins (A, D, E, K). In addition, vitamin A and E esters require hydrolysis by pancreatic or intestinal esterases that are bile acid–dependent. Therefore, supplements of preparations with medium-chain triglyceride and fat-soluble vitamins at least two to four times the recommended dietary allowances are necessary. Signs of deficiency as well as toxicity of these vitamins should be monitored periodically by measuring serum vitamin A, E, and 25-hydroxy vitamin D levels, calcium, phosphorus, and prothrombin time. The ratio of serum vitamin E to total serum lipids is more reliable in assessing vitamin E status because elevated lipid levels during cholestasis allow vitamin E to partition into the plasma lipoproteins, artificially raising the serum vitamin E concentration. Prevention and treatment of vitamin E deficiency in chronic cholestasis is best accomplished with a water-soluble formulation of vitamin E, D-α-tocopheryl polyethylene glycol succinate (TPGS), a prodrug in which vitamin E linked to polyethylene glycol is passively absorbed by the intestinal epithelium. This preparation has been shown to increase the absorption of other lipid-soluble chemicals. Hyperlipidemia, xanthomas, and pruritus associated with cholestasis may cause significant morbidity in children, as in adults with chronic cholestasis. Pruritus can be severe and debilitating; it may respond to nonabsorbable anion exchange resins, such as cholestyramine and colestipol, UDCA, phenobarbital, or rifampin as single agents or in combination.

Liver Transplantation in Children

Liver transplantation is reviewed in Part XII of the book. It has become an important therapeutic option for children with chronic or fulminant liver disease, or inborn errors of metabolism (160). Now, with an increasing donor pool, advances in medical and surgical care, and earlier referral to transplantation centers, children are healthier at the time of transplantation and therefore better able to tolerate the surgery with shorter hospital stays.

The indications for orthotopic liver transplantation in children are listed in Table 47.11. Children with metabolic diseases provide a unique challenge. Their illnesses rarely meet the standard criteria for transplantation based on chronic liver disease. In addition, hepatic transplantation in patients with metabolic defects that involve, but are not limited to, the liver (e.g., mitochondrial disorders, some types of GSD) may interrupt the progressive liver disease, but patients often succumb to their condition due to the systemic nature of the diseases.

Survival rates range from 60% to 90%,5 years following liver transplantations in children. Factors that negatively impact survival include age less than 1 year, weight less than 10 kg, care in the intensive care unit (ICU) before transplantation, and a diagnosis of fulminant hepatic failure.

Vascular complications are the most common cause of early postoperative allograft loss and are more likely to occur if the patient weighs less than 10 kg, receives a reduced size graft, develops hypotension during or shortly after the procedure, or has a hypercoagulable state. Hepatic artery thrombosis (HAT) is three to four

times more frequent in children than in adults and occurs most often within the first 30 days following transplantation. Although HAT itself does not lead to hepatic infarction, it commonly causes ischemic injury to the biliary tract. Biliary complications develop in approximately 10% of liver transplant recipients.

Table 47.11. Indications for Liver Transplantation in Children

Biliary tract disorders
Extrahepatic biliary atresia
Alagille syndrome
Caroli syndrome
Genetic/metabolic disorders
α_1-Antitrypsin deficiency
Hereditary tyrosinemia
Cystic fibrosis
Glycogen storage disease
Wilson disease
Neonatal hemochromatosis
Urea cycle defects
Fulminant hepatic failure
"Non-A through E"
Hepatitis B
Drug hepatoxicity
Wilson disease
Autoimmune hepatitis
Chronic hepatitis
Idiopathic neonatal hepatitis
Autoimmune hepatitis
Cirrhosis
Cryptogenic
Total parenteral nutrition-associated cholestasis
Tumor
Hepatoblastoma
Hepatocellular carcinoma

Members of the herpesvirus family cause most of the early and severe viral infections in children after liver transplantation. Patients who are seronegative for CMV and receive an organ from a seropositive donor are at greatest risk for development of either CMV or EBV infection. The clinical manifestations of EBV infection may include a mononucleosis-type syndrome, hepatitis simulating rejection, and extra-nodal lymphoproliferative disease, especially involving the bowel. Post-transplant lymphoproliferative disease (PTLD) is a potentially fatal abnormal proliferation of B-lymphocytes and can occur in any immunosuppressed host. PTLD is seen in up to 15% of all EBV naïve children who are organ transplant recipients. In general, with these considerations, liver transplantation surgery in children should be done at centers that have significant experience with these young patients.

Chapter 48
Liver Abscesses

David Kershenobich
Marco A. Olivera-Martínez

Key Concepts

- A liver abscess is a space-occupying suppurative cavity in the liver resulting from invasion and multiplication of microorganisms, entering directly from an injury, through blood vessels or by the way of bile ducts. The most common forms of liver abscesses are amebic, pyogenic, or mixed in origin.
- The invasive process of *Entamoeba histolytica* in the liver is driven by the motility of the parasites. The parasite relies on a dynamic actomyosin cytoskeleton and on surface adhesion molecules for dissemination in the tissue.
- Emerging new risk factors for amebic liver abscesses include the use of immunosuppressive drugs, sexual lifestyles, human immunodeficiency virus (HIV) infection, traveling to endemic areas, and population migration.
- Risk factors for pyogenic liver abscess (PLA) include aggressive treatment of liver and pancreas malignancies, stent placements, sphincterotomy, embolization, ethanol injection, or radiofrequency ablation.
- Distinguishing between amebic or pyogenic liver abscess is crucial because treatment and prognosis are different. Differential diagnosis relies on clinical history, and laboratory and imaging findings.

A liver abscess is a space-occupying suppurative cavity in the liver resulting from the invasion and multiplication of microorganisms, entering directly from an injury, through the blood vessels or by the way of the bile ducts. The most common forms of liver abscesses are amebic, pyogenic, or mixed in origin. Approximately 60% are solitary and mainly located in the right lobe, as a result of the streaming pattern of portal blood flow secondary to the fact that the right lobe is supplied predominantly by the superior mesenteric vein, and because most of the hepatic volume is in the right lobe. When multiple abscesses are present, pyogenic or mixed abscesses are the most probable types. A detailed clinical history is useful in identifying the risk factors that suggest a possible etiology. Emerging new risk factors include the use of immunosuppressive drugs for neoplastic disease or for organ transplantation, sexual lifestyles, human immunodeficiency virus (HIV) infection, history of traveling to endemic areas, and the population migration phenomena (1).

Amebic Liver Abscess

Epidemiology

Entamoeba histolytica infection is the principal cause of liver abscess in the world, especially in tropical and subtropical regions. It is more prevalent in developing countries; it can be spread from person to person, when polluted water is used to keep vegetables and fruits sold by street vendors fresh. The greatest risk is associated with cyst passers, especially if they are food handlers.

Landmark advances in epidemiology of amebiasis include the recognition that there are two distinct species, *E. histolytica* which is the cause of dysentery, colitis, and liver abscess, and *Entamoeba dispar* which is a nonpathogenic form of ameba (2) and recent technologic advances exploring the genome of the different strains of *E. histolytica* that ultimately may lead to the development of vaccines (3).

Specific probes derived from the analysis of repetitive deoxyribonucleic acid (DNA) sequence in the *Entamoeba* genome analysis have demonstrated possible candidates to distinguish between *E. histolytica* and *E. dispar*, such as transposable elements common in primitive eukaryotes that harbor non–long-terminal-repeat (non-LTR) retrotransposons (also called *long interspersed repetitive elements* [*LINEs*]) (4) or short interspersed repetitive elements known as EhSINE1 (5).

Genotyping of *E. histolytica* has revealed an extensive genetic diversity among *E. histolytica* isolates preventing at present an association of a single genotype with hepatic disease (6). The HM-1 strain of *E. histolytica*, which was isolated from a dysenteric patient in Mexico more than 30 years ago, and those isolated in India and Bangladesh still cause disease in experimental animals and have been used for nearly all immunologic, biochemical, and molecular biologic studies of amebae (7).

Pathogenesis

The invasive process is driven importantly by the parasite's motility. The parasite relies on a dynamic actomyosin cytoskeleton and on surface adhesion molecules for dissemination in the tissues. Myosin II is essential for *E. histolytica* intercellular motility through intestinal cell monolayers and for its motility in the liver, while galactose-binding lectins, mainly galactose/*N*-acetylgalactosamine (Gal/GalNAc), modulate the distribution of trophozoites in the liver and their capacity to migrate in the hepatic tissue (8). Gal/GalNAc acts as a major cell surface antigen that activates target epithelial cells and triggers subsequent disease pathology and parasite survival. Lectin-stimulated cells show an immediate rise in Ca^{+}, which in turn activates cyclic nucleotides and other protein kinases, leading to activation of mitogen activated protein kinase (MAPK) cascade. Activation of MAPK pathway is implicated in events such as apoptosis, proliferation, cytoskeleton rearrangements, and permeability changes (9).

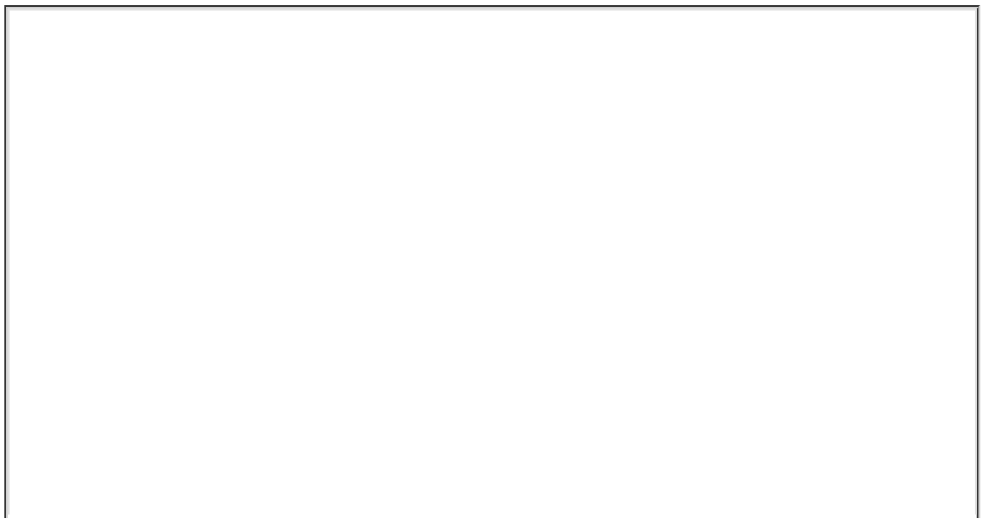
Initial steps in tissue invasion include the release of proteases by trophozoites, which are capable of degrading extracellular matrix components. *E. histolytica* is a cytotoxic effector cell with an extraordinary capacity to lyse the surrounding cells. The inflammatory response (mainly neutrophils and macrophages) initiated by amebic invasion may further contribute to tissue damage by added lysis of parenchymatous cells (10). When ameba is inoculated in the liver significant areas of apoptosis develop within the amebic liver abscess (ALA) (11).

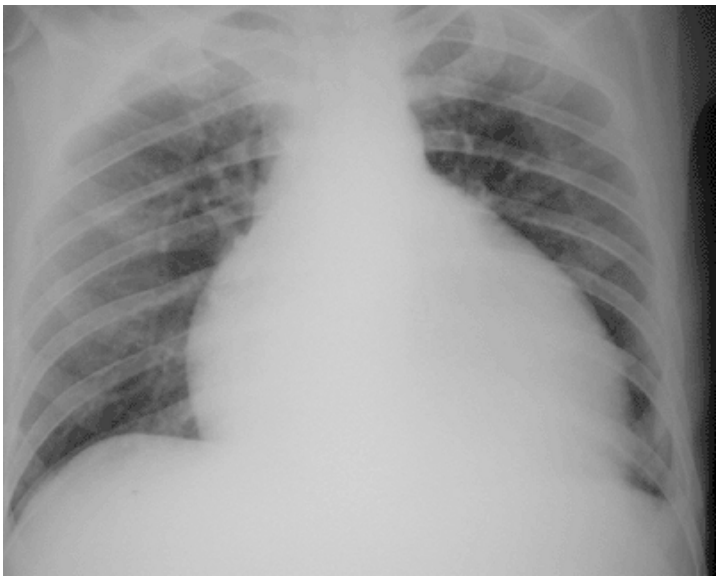
The sequencing of the genome of *E. histolytica* has allowed a reconstruction of its metabolic pathways, many of which are unusual for a eukaryote. On the basis of the genome sequence, it appears that amino acids may play a larger role than previously thought in energy metabolism, with roles in both adenosine triphosphate (ATP) synthesis and nicotinamide adenine dinucleotide (NAD) regeneration (12). *E. histolytica* uses a complex mix of signal transduction systems to sense and interact with the different environments and encounters. The analysis of its genome has revealed almost 270 putative *E. histolytica* protein kinases (13).

Clinical Manifestations

ALA is found more frequently in men between 20 and 40 years of age, but can occur at any age. Gender differences in abscess formation in adults have been related to alcohol consumption. Identification of risk factors including a history of travel to or residency in endemic areas several weeks or even months before, must be identified. Almost always the patients present with a constant, dull, and intense right upper quadrant abdominal pain that exacerbates with movement and frequently radiates to the scapular region and right shoulder. Patients have fever between 38°C and 40°C, chills, and sweating. Very frequently they give a history of malaise and nausea in the previous 2 weeks and moderate weight loss. Some patients have cough and chest pain. Most of them do not have coexistent dysentery, although a past history of diarrhea or dysentery is present in approximately 50% of cases. At physical examination, the patient appears pale and wasted, with painful hepatomegaly, point tenderness over the liver, below the ribs, or in the intercostal spaces. When the abscess is located in the left lobe, the patient may have epigastric tenderness. Ventilation in the right lung is frequently restricted, respiratory sounds are reduced, and jaundice is infrequent. Alarm signs include abdominal rebound tenderness, guarding, absence of bowel sounds, and pleural or pericardial rub. The abscess may extend to the peritoneum, abdominal organs, great vessels, pericardium (Fig. 48.1), pleura, bronchial tree, and lungs (14,15). Common differential diagnoses include pyogenic liver abscess (PLA), primary hepatic carcinoma, liver metastases (Fig. 48.2), or hydatid cysts. The clinical presentation of an ALA among high-risk groups such as patients with HIV or other immunosuppressed individuals is similar to that described for the remaining patients (16). Neonates present with

nonspecific clinical and laboratory findings mimicking fulminant neonatal sepsis (17).

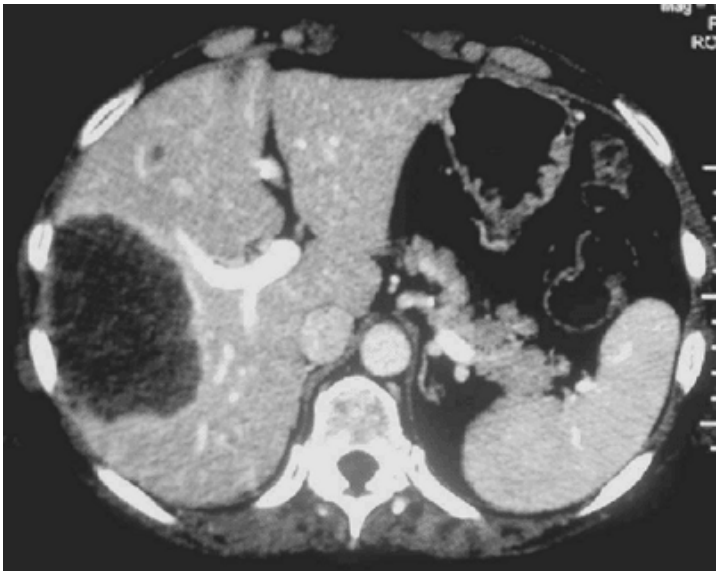




▪ **Figure 48.1** Amebic liver abscess ruptured into the pericardium.

Diagnosis

Leukocytosis (>15 × 10^9 cells/L), with neutrophilia, increased erythrocyte sedimentation rate, slight anemia, and elevated alkaline phosphatase levels are common. Serum antibodies to *E. histolytica* are detected in more than 90% of patients. An indirect hemagglutination (IHA) with a cutoff value of 1:512 is considered diagnostic. The enzyme immunoassay (EIA) with a sensitivity of 99% and specificity greater than 90% is also commonly used. In those patients in whom an aspirate is obtained, either for diagnostic or therapeutic purposes, the material should also be sent for Gram's staining and culture (18).



▪ **Figure 48.2** Liver metastases of colorectal cancer. No specific

characteristics can differentiate it from primary neoplasia, or pyogenic or amebic liver abscess.

Imaging studies are very important in the workup of patients with suspected ALA and have reduced the delay in diagnosis. Ultrasonography is the initial screening choice. The abscess appears as an hypoechoic round or oval lesion with well-defined margins. More advanced imaging techniques such as tomography or magnetic resonance (MR) are indicated for differential diagnosis. Chest x-ray may reveal elevation of the right diaphragm, atelectasis, and pleural effusion (19).

Therapy

The drug of choice is metronidazole at an oral dose of 1g twice daily for 10 to 15 days in adults and 30 to 50 mg/kg daily for 10 days divided in three doses in children; when given intravenously the dosage is 500 mg every 6 hours for adults and 7.5 mg/kg every 6 hours for children for 10 days. Other nitroimidazoles include tinidazole or ornidazole at a dose of 2 g orally daily for 10 days. Secondary drugs include chloroquine 1 g/day for 2 days orally followed by 500 mg/day for 2 to 3 weeks. In children the dose is 15 mg/kg PO daily for 2 to 5 days followed by 5 mg/kg daily for 2 weeks. Percutaneous drainage may be necessary in nonresponders to antiameba therapy to rule out a pyogenic abscess or when less than 1 cm of rim liver tissue remains around a liquefied abscess.

Vaccination

Studies in experimental animals, using *E. histolytica* galactose-and *N*-acetylgalactosamine-inhibitable surface lectin either for systemic application or oral administration are ongoing. Research has focused on how to fuse surface lectin to the B subunit of cholera toxin, attenuated salmonella, or *Yersinia enterocolitica* for antigen delivery (20).

Pyogenic Liver Abscess

Epidemiology

The incidence of PLA is 0.007% to 2.2% of hospital admissions, 11 per 1 million in general population, and between 0.29% and 1.47% in autopsy series. PLA varies among different geographic regions influenced by the local prevalence of bacterial, parasitic, and helmintic infections, age of the population, and the presence of chronic debilitating diseases. Benign or malignant biliary tract disease, diverticulitis, and Crohn’s disease are the most common predisposing factors. The frequency of PLA has increased as a complication of more aggressive treatment of liver

or pancreatic malignancies—stent placement, sphincterotomy, embolization, ethanol injection, or radiofrequency ablation. In the past, PLA was primarily a complication of ruptured appendix (21). Accordingly, the age of presentation has moved forward from the second and third decades of life to the sixth and seventh (21,22). Advances in imaging techniques and new antibiotics, have decreased the morbidity and mortality of PLA (22,23).

Pathogenesis

Abscess formation, a host defense strategy to contain the spread of infection, is promoted by a combination of factors that impair phagocytosis and the clearance of microorganisms. Neutrophils and platelets attached to the endothelial surface, and endotoxin produced by gram-negative bacteria contribute to tissue injury by releasing proinflammatory cytokines and reactive oxygen species. When bacteria reach the liver, endotoxin stimulates the proliferation of Kupffer cells that engorge, and produce toxic mediators that modulate microvascular response. After adhesion, diapedesis through cell junctions follows. The inflammation thus produced causes obstruction of the sinusoidal lumen and secondary obstruction of the blood flow. These phenomena inhibit sodium and potassium ATP activity, impair the generation of energy for bile excretion, and promote biliary stasis. The sinusoidal diameter is reduced and hence the velocity of the blood flow decreases; as the number of obstructed sinusoids increases and hydrostatic pressure rises, hepatic ischemia develops (24).

The source of infection determines to a certain degree the localization and number of abscesses. If infection reaches the liver through the portal system, several abscesses may develop, mostly confined to the right lobe. The left lobe is usually involved in septic thrombosis of the portal vein. When bacteria reach the liver through arterial circulation, several small abscesses develop, equally distributed in both lobes. Forty percent of patients with PLA have multiple liver abscesses (25,26).

Clinical Manifestations

An early clinical diagnosis requires a high index of suspicion: Fever, malaise, right upper quadrant abdominal pain, nausea, and vomiting for more than 2 weeks are the most common presentations (21,27). Abdominal pain in patients with PLA is similar to that found in patients with ALA (25). Other symptoms, anorexia, jaundice, and painful hepatomegaly are less prevalent in PLA as compared to ALA (26,28,29,30). Jaundice predicts a complicated clinical course but has no impact on mortality. Approximately 60% have an underlying debilitating condition or have had a recent interventional procedure (e.g., biliary stent placement, ethanol injection). PLA should be suspected in elderly patients, in those taking steroids, or in patients with right-sided pulmonary abnormalities of unknown origin (30,31).

Diagnosis

When PLA is diagnosed, prognostic factors associated with increased mortality include low albumin, anemia, high blood urea nitrogen (BUN) and creatinine, prolonged prothrombin time, polymicrobial infection, pleural effusion, high acute physiological assessment and chronic health evaluation (APACHE) II score, disseminated intravascular coagulation, and septic shock. Multiple abscesses carry a high mortality risk independent of other risk factors (23). Regarding PLA in patients with cancer, morphology and topography are not different from noncancer patients (25).

Distinguishing Characteristics

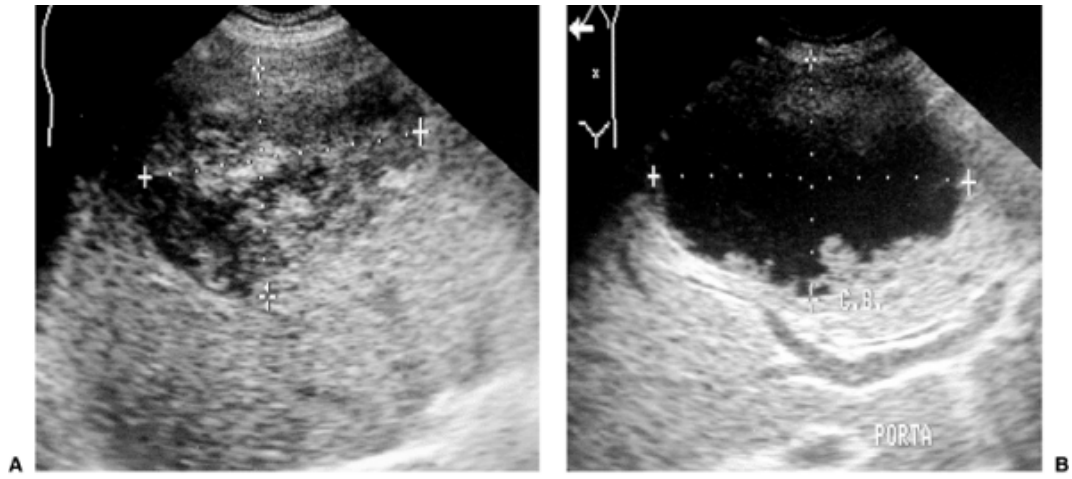
Distinguishing PLA from ALA is crucial because treatment and prognosis are different. Detection of PLA relies on laboratory and imaging findings (Table 48.1). Abdominal ultrasonography and computed tomography (CT) scan have

sensitivities greater than 95% in detecting abscess formation (23,27). PLA and ALA have similar imaging characteristics (Figure 48.3) (28).

Patients with PLA are older than those with ALA, and more likely to have debilitating diseases; this might explain the lower concentration of albumin found in patients with PLA. Abnormal chest findings are more prevalent in patients with PLA (28).

Table 48.1. Diagnostic Differences Between Amebic Liver Abscess and Pyogenic Liver Abscess

Amebic liver abscess	Pyogenic liver abscess
Leukocytosis >15 × 10^9	Leukocytosis >15 × 10^9
Serum antibodies to *E. histolytica* >1:512	Serum antibodies to *E. histolytica* negative
Aspirated pus shows no microorganisms	Aspirated pus shows bacteria
Jaundice uncommon (<8% of patients)	Jaundice common in presentation
Abnormal chest finding in physical examination uncommon	Abnormal chest findings in physical examination common
Younger patients (usually 20 to 40 yr)	Older patients (usually 60 to 70 yr)
Previously healthy	Presence of debilitating disease (cancer)



▪ **Figure 48.3** Pyogenic liver abscess. **A:** Initial ultrasound showing debris inside the abscess cavity. **B:** Liquefied pus inside the abscess.

Laboratory Findings and Microbiology

These data include leukocytosis, anemia, elevated alkaline phosphatase, positive C-reactive protein, and negative *E. histolytica* antibodies. Other findings are increased total bilirubin, low albumin level, and prolonged prothrombin time.

Microbiology studies are the gold standard in establishing the diagnosis of PLA. Specimens of pus and blood should be obtained for culture under strict anaerobic and microaerophilic techniques. Gram's stain guides the selection of the antibiotic regime, pending the result of culture. One third of PLAs are caused by aerobic bacteria, one third by anaerobes, and one third by a mixture of aerobic and anaerobic bacteria. Enteric gram-negative rods are the most frequent isolates in either blood or pus aspirated from the abscess. In children, *Staphylococcus aureus* is the most frequent organism. Only 50% of anaerobic PLA are diagnosed by culture, because of defective sampling or suboptimal laboratory techniques, but this should not delay the initiation of antibiotics. A combination of antibiotics against different microorganisms is the treatment of choice (21).

Bacteriology of PLA is evolving, in some areas of the world specific bacteria have been isolated. *Klebsiella pneumoniae* is being found in PLA in the Asian population in America, suggesting either an epidemiologic transition or the continued prevalence of an endemic infection in a specific ethnic group (22,25,26,28). Resistant bacteria and fungi are opportunistic infections in patients with debilitating conditions (31). Isolation of fungi is frequent in patients with manipulated biliary stents or with intermittent cholangitis treated with broad-spectrum antibiotics. Immunocompromised individuals can develop PLA with other microorganisms such as *Salmonella* (30).

Imaging

Ultrasonography is the screening test of choice. CT scan can detect collections as small as 0.5 cm in diameter and allows therapeutic interventions (e.g., needle aspiration/drainage). The presence of aggregates of multiple small abscesses

suggests the coalescence into a larger abscess (cluster sign) and indicates a PLA (21). MR using serial gadolinium-enhanced gradient-echo images can help in differentiating PLA from other focal lesions (32). MR cholangiogram can be useful in planning possible resectional therapy. All of these modalities are able to demonstrate loculation and consistency of the contained pus to make therapeutic decisions.

Therapy

Antibiotic therapy choices involve combining broad-spectrum antibiotics: Third-generation cephalosporin plus clindamycin or metronidazole; broad-spectrum penicillin plus aminoglycosides; and second-generation cephalosporin plus aminoglycosides. Treatment should be started immediately after specimens have been obtained for culture without waiting for definitive results. Imipenem, aztreonam, piperacillin, tazobactam, ticarcillin, clavulanate, and quinolones are active against almost all aerobic gram-negative bacilli (21). Antibiotics should be given before, during, and after drainage and surgical procedures. Parenteral therapy for 2 to 3 weeks followed by oral antibiotics for 4 to 6 weeks is recommended. For a solitary abscess less than 5 cm in diameter, confirmed by aspirate and

with available antimicrobial sensitivity, resolution can be achieved with antibiotics alone (33,34). For PLA greater than 5 cm with thick and viscous pus, or for those large multiloculated abscesses, surgical drainage may be necessary (35).

Aspiration and Drainage

Under imaging guidance, PLA can be aspirated and drained. Drainage is most effective when well liquefied pus is completely evacuated. If the abscess is not well liquefied or has a thick wall, it is impossible to remove the pus completely. In such cases, most of the drainable pus is removed by needle aspiration, after which, antibiotic therapy is necessary to treat the residual abscess. Needle aspiration should be performed with an 18-gauge fine-walled needle. In multiloculated abscess, the needle tip should be inserted into the various loculi to evacuate pus as completely as possible. Percutaneous needle aspiration is considered unsuccessful when patients fail to improve clinically or radiologically after the second aspiration. Factors affecting drainage include accessibility, number, and size of the abscesses as well as the patient's general condition. Abscesses most accessible to percutaneous drainage are the posterior right lobe deep-seated lesions, those that adhere to the abdominal wall, and peripheral abscesses of the right lobe (36).

Surgery

Surgical therapy is necessary for multiple macroscopic or multiloculated abscesses, or for those in the left lobe, after percutaneous drainage failure. Surgical drainage may be required in the presence of ascites or renal failure, evidence of clinical deterioration, persistent jaundice, or concomitant steroid therapy; or when abscesses are not accessible to radiologic manipulation; and in the case of a ruptured abscess (34,35).

Endoscopic Drainage

In patients with stones or strictures of the bile duct and abscess formation in

continuity with the biliary system, endoscopic therapy provides biliary drainage, promoting abscess drainage (37).

Title: ***Schiff's Diseases of the Liver, 10th Edition***

Chapter 49
Parasitic Diseases

Michael A. Dunn

Key Concepts

- Liver parasites span a wide range of complexity, from intracellular protozoa to visible multicellular helminths with highly evolved life cycles. Different species mature and reproduce within hepatocytes, reticuloendothelial cells, the portal venous system, and the bile ducts.
- Well-adapted parasites cause minimal acute injury to the host organ as they generate enormous numbers of progeny that pass into the blood or bile with the potential to infect other hosts. Examples include the malaria parasites, the schistosome worms, and the bile duct flukes.
- When a parasite enters a species or an organ to which it is poorly adapted, acute or severe injury is likely: *Echinococcus* tapeworms, well adapted to canine-herbivore or canine-rodent life cycles, cause severe cystic liver disease in accidental human hosts. The protozoan *Entamoeba histolytica* and the roundworm *Ascaris*, both well suited to the human intestinal lumen, cause acute injury when they invade the liver parenchyma or bile ducts, respectively.
- Successful parasites have evolved to evade or to accommodate the effects of the defenses and immunologic responses of healthy hosts. Hosts with abnormal or compromised responses are at risk for severe disease manifestations, such as the reactivation of subclinical *Leishmania* infection with development of advanced visceral leishmaniasis in human immunodeficiency virus (HIV)-infected persons.

Protozoal Diseases

Malaria, one of the world's most serious and widespread infectious diseases, is intimately involved with the liver during its pre-erythrocytic and exoerythrocytic stages of development. Visceral leishmaniasis is a cause of severe debility and hepatosplenomegaly in the tropics and a growing concern for immunosuppressed persons in temperate climates.

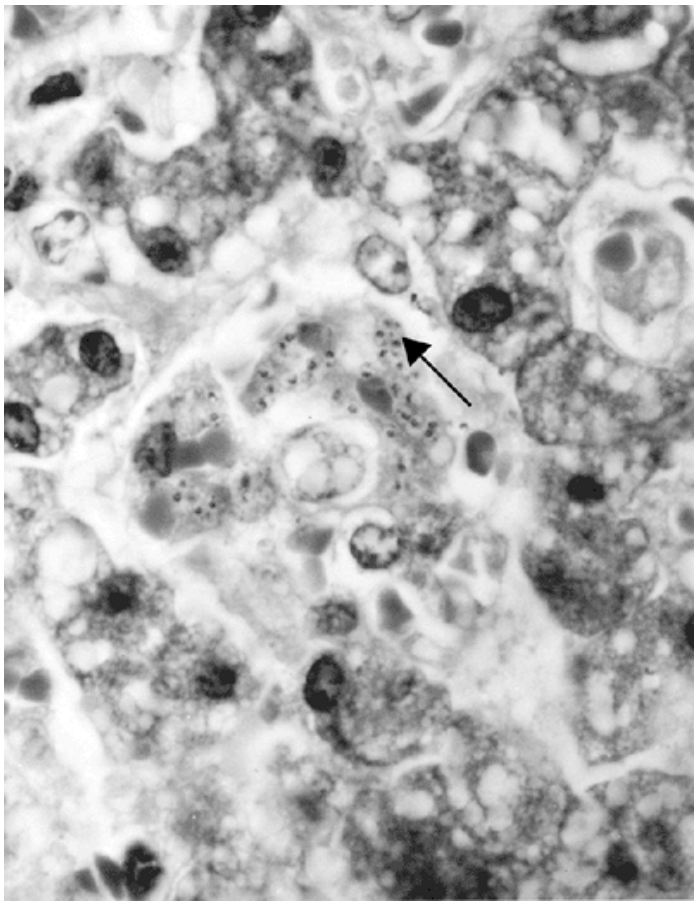
In addition to these obligatory intracellular parasites, *Entamoeba histolytica*, an extracellular protozoan cause of liver abscess, is considered in Chapter 48.

Malaria

Malaria, the world's most prevalent fatal parasitic disease, is caused in humans by intracellular protozoa of four species, *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, and *Plasmodium malariae*. All are transmitted by mosquito bite, and involve the entry of mosquito-borne sporozoites into hepatocytes, where a pre-

erythrocytic stage of the parasite multiplies and is subsequently released to invade erythrocytes. Malaria continues to kill 2 million persons a year and frustrate eradication efforts because of the parasite's capacity to develop drug resistance. There is, therefore, great interest in defining the events within the liver that may account for complete protection of animals with a vaccine directed against genetically attenuated sporozoites (1). Protection of immunized animals appears to depend both on antibody-mediated recognition of a sporozoite surface protein that binds to liver extracellular matrix proteoglycans, and cell-mediated responses to attenuated

parasites that enter hepatocytes but fail to multiply (2).



▪ **Figure 49.1** Visceral leishmaniasis. Dot-like organisms (*arrow*) are present in several hypertrophied Kupffer cells (hematoxylin-eosin, ×1,000). (Armed Forces Institute of Pathology [AFIP] Negative 87-5647.)

The cyclical fevers, hemolysis, vascular stasis, shock, and multiple organ failure of severe malaria are the clinical end results of synchronized multiplication and release of the parasite's erythrocytic stage. Kupffer cells take up released hemoglobin degradation products known as malarial pigment, which appears as dark cytoplasmic granules in liver specimens from persons with a history of malaria. Humans with intact host defenses normally recover from acute episodes of malaria. The highest risk for severe illness and death is with *P. falciparum* infection. Falciparum malaria often produces clinical and laboratory evidence of multiple organ dysfunction. In two reviews, 60% of 106 patients (3) and 20% of 91 patients (4) showed modest

elevations in serum bilirubin, aspartate aminotransferase, or alkaline phosphatase levels. Severe liver injury in malaria has only infrequently been reported in patients with heavy *P. falciparum* infections, commonly associated with acute renal failure and encephalopathy. In a report from India, seven such patients presented with the acute onset of jaundice, asterixis or impaired sensorium, bleeding with prolonged prothrombin and partial thromboplastin times, and aminotransferase elevations at fourfold the normal (5). *P. falciparum* infection was evident in their blood smears. The three survivors responded to intravenous quinine and supportive care that included lactulose and bowel cleansing. One of the four patients who died had submassive hepatic necrosis; focal steatonecrosis was present in postmortem liver specimens from the other three. As with earlier similar reports, it is unclear to what extent liver injury contributed to morbidity in these patients. The key message remains, however, that a clinical presentation suggesting acute hepatic failure in persons at risk for malaria infection should prompt consideration of this readily diagnosed and treatable illness.

Leishmaniasis

Visceral leishmaniasis, or kala-azar, is an infection of the reticuloendothelial cells of the liver, spleen, bone marrow, and other organs with an intracellular protozoan parasite, *Leishmania*. Common throughout the tropics, visceral leishmaniasis has been increasingly recognized elsewhere as a potential problem for immunosuppressed persons with human immunodeficiency virus (HIV) disease or after organ transplantation (6). As an experimental disease model, leishmanial infection provides an opportunity to study liver inflammation and fibrosis with the same methods that have advanced our knowledge of these important processes in other diseases, such as hepatic schistosomiasis.

Infections with different species of *Leishmania* cause visceral, cutaneous, and mucocutaneous patterns of disease. Visceral leishmaniasis, involving the liver, normally results from infection of children and young adults with *Leishmania donovani*. In the Indian subcontinent, the parasite is transmitted by sandflies that have bitten infected humans. Elsewhere—in South America, southern Europe, Africa, the Middle East, and China—*L. donovani* transmission to humans by sandflies is primarily enzootic, involving canine and rodent reservoir hosts. Visceral involvement with *Leishmania tropica*, a species that normally causes cutaneous disease, was described in eight American veterans of the 1991 Persian Gulf War (7), and two more recent cases of visceral disease due to *L. donovani* were reported in American soldiers exposed to infection in Afghanistan (8). Other than infection from the bite of sandflies in endemic areas, clinical studies suggest that *Leishmania* can be transmitted by blood transfusion or needles shared for drug abuse, by sexual contact, or by transplantation of infected organs (9,10,11,12).

After bloodstream infection and uptake of the parasite by reticuloendothelial cells, its amastygote stage, shown in Figure 49.1, multiplies within Kupffer cells and macrophages, infects new cells, and triggers cellular and humoral host responses. Most immunocompetent persons respond to infection with a successful T helper cell 1 (Th) 1-type cell-mediated defense that prevents clinical disease and suppresses, but may not

eliminate, the infection (13). Such a cellular response, akin to that seen in tuberculoid leprosy or successfully contained initial *Mycobacterium tuberculosis* infection, involves the same T4 cells and cytokines—interferon-γ, interleukin (IL)-2, and IL-12—that are critical for dealing with other intracellular organisms. The potential importance of inducible synthesis of nitric oxide as an effective mechanism for Th 1–mediated killing of the parasite was suggested by a report of high

susceptibility of Syrian hamsters, which are deficient in nitric oxide generation, to severe visceral disease after *L. donovani* infection, despite their ability to mount a prominent and otherwise complete Th 1 cytokine response (14). Humoral antibody responses, also regularly present, do not appear to modify the course of leishmanial infection, nor do the Th 2–type cellular responses seen in persons who develop clinically severe disease.

Pathologic examination of liver specimens shows findings that parallel the predominant host response: In persons with minimal disease and few parasites visible in liver specimens, epithelioid granulomas, including fibrin-ring granulomas similar to those described in Q fever, may be present (15). Numerous parasites multiplying within activated Kupffer cells and macrophages, appearance of myofibroblasts, deposition of intralobular collagen, and effacement of the space of Disse with connective tissue all accompany an ineffective response in persons with overt disease (16,17). A pattern of severe intralobular liver fibrosis as a predominant finding was described by Rogers (18) in 1908 as a "peculiar cirrhosis" in Indian patients with visceral leishmaniasis. So-called Rogers' cirrhosis, however, shows normal liver architecture and no regenerative nodules.

The major clinical manifestations of visceral leishmaniasis include fever, weight loss, hepatomegaly, splenomegaly, lymphadenopathy, pancytopenia, and hypergammaglobulinemia. All organs with reticuloendothelial cells may be involved, including the entire gastrointestinal tract. Laboratory abnormalities may include modest elevations in serum aminotransferase and alkaline phosphatase levels and depressed albumin levels, as well as skin test anergy to common delayed hypersensitivity antigens. Although hepatic and splenic enlargement from cellular infiltration may be truly massive and intralobular liver fibrosis may be pronounced, overt ascites is uncommon, and the very rare occurrence of either hepatocellular failure (19) or of clinically evident portal hypertension suggests another etiology. Persons with advanced disease are at risk of death from intercurrent infections or severe malnutrition. Conversely, malnutrition, immunosuppressive therapy, or an immunosuppressive disease such as HIV infection can precipitate the development of overt visceral leishmaniasis in previously healthy persons with latent infections acquired as long as 20 years earlier (20,21).

Severe HIV-associated visceral leishmaniasis has been described in reports from Spain, a *Leishmania* endemic area, as well as from nonendemic countries such as France and Germany (11,21,22,23). Visceral leishmaniasis should be sought as a treatable cause of fever, hepatosplenomegaly, and rapid deterioration in HIV-infected persons with even a remote positive travel history or risk factors for non–sandfly-transmitted blood-borne infection. Intracellular parasites may be seen in liver or intestinal biopsy specimens obtained during the evaluation of HIV-infected persons for persistent fever or diarrhea (24). Most such patients have CD4 cell counts less than 400/mm^3, consistent with the importance of an intact Th 1 cellular response for dealing with leishmanial infection. This relationship supports the suggestion that visceral leishmaniasis in HIV-infected persons should be considered as an acquired immunodeficiency syndrome (AIDS)-defining illness (11,23). Most HIV-positive patients with visceral leishmaniasis respond well to antimonial therapy; however, relapse after cessation of treatment is common, so that long-term suppressive therapy with fluconazole, ketoconazole, or pentamidine is often used (23).

Visceral leishmaniasis may also become manifest in immunosuppressed liver, heart and kidney transplant recipients (12,25); in one report, the donor liver was considered the likely source of parasite infection (12). Reduction of the immunosuppressive regimen to the minimum needed to support graft function, combined with initial antimonial and long-term suppressive antiparasitic therapy, is

the recommended management.

The diagnostic procedure for visceral leishmaniasis with the highest accuracy, close to 100%, is the examination and culture of a needle splenic aspirate. In nonendemic areas where the experience levels to safely perform splenic aspiration are lacking, examination and culture of bone marrow and liver biopsy specimens are more often performed. Either method provides a 50% to 80% yield. Polymerase chain reaction–based detection of leishmanial DNA in peripheral blood has now been reported to match the diagnostic accuracy of bone marrow aspiration (26,27). The mainstays of therapy for visceral leishmaniasis are pentavalent antimonial compounds; in the United States, the Centers for Disease Control drug service provides sodium stibogluconate as an investigational drug. Its use by daily intramuscular or intravenous administration for 3 weeks or longer is safe and generally effective. Second-line antileishmanials include pentamidine, amphotericin B, allopurinol, and ketoconazole and related azole compounds. A new drug-delivery strategy of incorporating amphotericin B into liposomes or lipid complexes appears to greatly enhance its efficacy: 5-day courses of lipid-complexed amphotericin B at total doses of 5 to 15 mg/kg were

remarkably effective in patients who had not responded or relapsed after antimonial therapy (28).

Although the clinical manifestations of visceral leishmaniasis resolve with antiparasitic therapy, it remains unclear, especially in persons with underlying immunologic deficits, whether the infection is ever truly eliminated or only suppressed below detectable limits (29). The successful use of highly active antiretroviral therapy (HAART) in HIV-infected patients, for example, is thought to be responsible for recent major decreases in the incidence of clinically overt visceral leishmaniasis in France and Spain, although HIV-infected persons with inapparent leishmanial infection remain at lifelong risk for the occurrence of clinical illness (30,31).

Visceral leishmaniasis has attracted investigative interest because of its association with severe intralobular liver fibrosis, which appears to be fully reversible after treatment of the infection (16). When experimental animal systems for the study of liver fibrosis in visceral leishmaniasis are defined, we may gain information of comparable significance to that which has already been gained for the cellular inflammatory immunopathology of this disease.

Helminthic Liver Diseases

Schistosomes are blood flukes that are well adapted to long survival as male and female adults in the venous circulations of human hosts. Human disease involves host responses to the deposition of schistosome eggs in tissues.

Fascioliasis is caused by flukes that primarily infect sheep and other herbivores. When humans are infected, a biphasic liver disease results from maturation of the parasite as it migrates through the liver parenchyma followed by an extended life span in the bile ducts.

Clonorchiasis and opisthorchiasis are biliary infections by trematode flukes that are well adapted to humans. Asymptomatic or minimally symptomatic for many years in most infected persons, these infections are of major concern because of their potential for the development of cholangiocarcinoma.

Table 49.1. Imaging Characteristics in Helminthic Liver Diseases

Infection	Imaging methods	Findings	Reversibility
Schistosomiasis	Ultrasonography	Portal fibrosis	Years to permanent
Fascioliasis, acute	Computed tomography	Serpiginous linear subcapsular abscess tracts	Months
Fascioliasis, chronic	Ultrasonography, computed tomography, cholangiography	Dilated ducts, visible adult worms	Months to years
Clonorchiasis and opisthorchiasis	Ultrasonography, computed tomography, cholangiography	Dilated irregular ducts, stones, associated cholangiocarcinoma	Years to permanent
Cystic and alveolar echinococcosis	Ultrasonography, computed tomography, magnetic resonance imaging	Cysts with variable wall calcification, complex internal structures, and daughter cysts	Years to permanent
Ascariasis	Ultrasonography, computed tomography, cholangiography	Dilated ducts obstructed by worms	Months

Echinococcosis is a potentially life-threatening cystic liver disease caused by the infection of humans as accidental intermediate hosts of three species of canine cestode tapeworms.

A relatively uncommon complication of intestinal infection with the nematode roundworm *Ascaris lumbricoides* is biliary ascariasis, which manifests as biliary colic, cholangitis, or pancreatitis induced by the migration of one or more of these large (up to 20 cm) adult worms into the ductal system (32,33,34). Biliary ascariasis usually occurs in children or in adults with an abnormal, open ampullary orifice produced by preexisting biliary tract disease or after surgical or endoscopic sphincterotomy (35). *Ascaris* worms in the ductal system are readily visualized on ultrasonography or computed tomography. If the worms do not spontaneously clear from the duct after antihelminthic treatment with mebendazole or an alternative agent, they may be removed endoscopically (32,35). Chronic biliary ascariasis has been implicated in the development of Oriental cholangiohepatitis, as discussed later for clonorchiasis and opisthorchiasis.

Abdominal imaging methods may show characteristic findings in helminthic liver diseases, as summarized in Table 49.1. The laboratory diagnosis of helminthic infections, as shown in Table 49.2, relies primarily on demonstrating eggs in the stool when the parasite's life cycle involves egg excretion by the human host. Serologic examinations, especially enzyme-linked immunosorbent assay (ELISA) methods, have become established for most infections as diagnostic adjuncts; serologic diagnosis is especially helpful when positive in the acute stage of fascioliasis and in echinococcosis, situations in which fecal egg excretion does not take place. Eosinophilia is such a regular accompaniment of most helminthic infections that its occurrence should prompt their diagnostic consideration, and its persistence after presumed parasitologic cure may signal treatment failure.

Table 49.2. Diagnosis of Helminthic Liver Diseases

Infection	Stool examination for eggs	Serology
Schistosomiasis	Method of choice in active infection, may be supplemented with rectal mucosal biopsy	ELISA available
Fascioliasis, acute	Negative	ELISA highly sensitive and specific, serial testing useful to monitor response to therapy
Fascioliasis, chronic	Often positive but egg production may be intermittent	ELISA method useful in addition to stool examination
Clonorchiasis, opisthorchiasis	Method of choice in active infection, stool PCR may be useful in mass screening	ELISA available; limited utility
Echinococcosis	Negative	IHA or ELISA positive in 90% of cases, serial testing useful to monitor response to therapy
Ascariasis	Method of choice	Not applicable

ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction; IHA, indirect hemagglutination assay.

Schistosomiasis

Schistosomes are trematode flukes, which infect more than 200 million persons worldwide. Schistosomiasis has attracted more study and effort than all the other parasitic liver diseases combined. Few other diseases of any cause have posed the intensity and breadth of challenges in molecular biology, immunology, economic development, pharmacology, and surgical therapy that have been overcome and that remain for this disease (36).

Disease mechanisms

Schistosomes begin their life cycles with the passage of eggs by adult females that live, paired with male worms, in the mesenteric or vesical venous beds. Viable eggs erode through the intestinal or bladder mucosa, are passed in feces or urine, hatch in water, and infect an intermediate snail host. Snails shed free-swimming ceracariae, the infectious stage for humans, which have the ability to penetrate human skin and transform into immature worms. The worms mature over a period of approximately 6 weeks as they traverse the venous, pulmonary, and systemic circulations and localize in their species-specific target vessels to form male–female copulating adult worm pairs and initiate egg production that may continue for decades (37).

Five species of schistosomes, listed in Table 49.3, develop to maturity in humans. The great majority of schistosomal liver disease is caused by infections with *Schistosoma mansoni* in Africa and South America and *Schistosoma japonicum* in Asia. Although portal-tract egg deposition, granuloma formation, and fibrosis have been reported in persons infected with *Schistosoma hematobium* (38), these findings are minor compared with urinary tract egg deposition and disease. *Schistosoma mekongi* and *Schistosoma intercalatum* have limited geographic distributions in Asia and Africa, respectively.

Table 49.3. Human Schistosomes

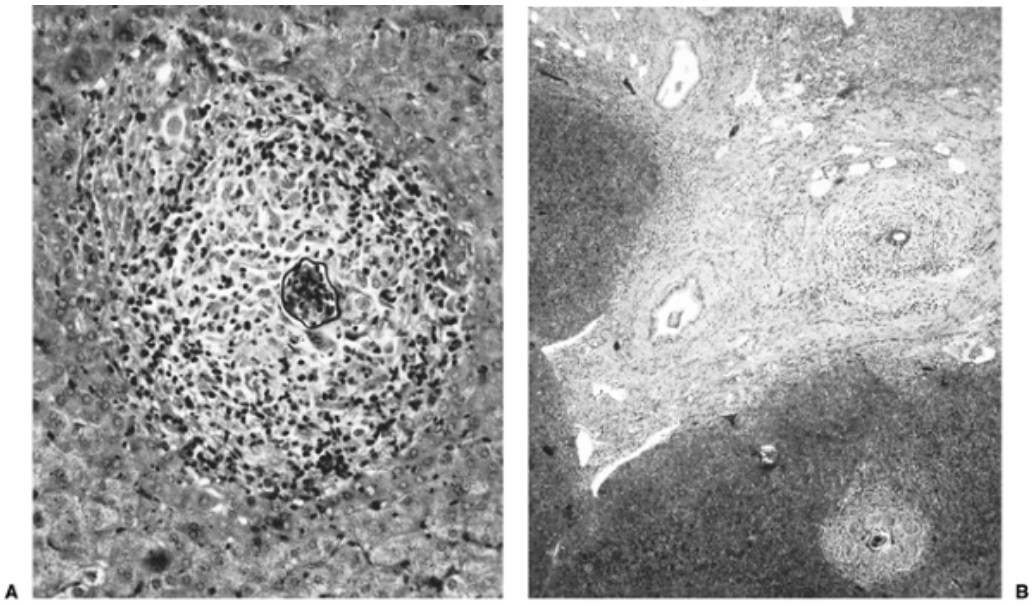
Species	Geographic range	Preferred vascular bed	Main target organs
Schistosoma mansoni	Middle East, Africa, Central and South America	Mesenteric	Liver, colon
Schistosoma japonicum	Far East	Mesenteric	Liver, small intestine, colon
Schistosoma hematobium	Middle East, Africa	Vesical	Bladder, ureters
Schistosoma mekongi	Southeast Asia	Mesenteric	Liver, small intestine, colon
Schistosoma	Central Africa	Mesenteric	Colon, less

intercalatum			severe liver and small intestinal disease

The preferential homing and predilection of maturing schistosomes of all species other than *S. hematobium* to concentrate in the mesenteric venous system, and of the latter species to concentrate in the vesical plexus, is central to the pattern of subsequent injury that their infections produce. Immature worms make several passes through the circulation before remaining at their preferred location (39). The mechanism that signals this remarkable preference for specific vascular beds is unknown. One potential localizing signal was suggested by the finding that human portal serum, but not peripheral blood, contains material of molecular weight greater than 1,000 that stimulates cell proliferation in immature *S. mansoni* worms (40).

Mature worm pairs in the mesenteric veins continuously produce large numbers of viable eggs that are carried to the intestine or the liver. Eggs deposited in the vessels of the intestinal mucosa may remain trapped within inflammatory granulomas, or erode into the

lumen and be excreted. Liver disease in schistosomiasis results from the entrapment of eggs that lodge in portal venules (41). Eggs in the liver remain viable for approximately 3 weeks and secrete products that elicit a characteristic initial response, the schistosome egg granuloma, as shown in Figure 49.2A. In some persons with heavy infections, the end result of hepatic schistosomiasis is severe portal fibrosis, as shown in Figure 49.2B. Advanced schistosomal hepatic fibrosis gives a gross appearance of greatly enlarged fibrotic portal tracts, described by Symmers (42) in 1904 as resembling clay pipestems thrust through the liver, and now termed Symmers' pipestem fibrosis.



▪ **Figure 49.2 A:** A *Schistosoma mansoni* egg granuloma in the liver. The schistosome egg has lodged in a portal venule, with formation of an epithelioid granuloma (hematoxylin-eosin, ×250). (AFIP Negative 79-16805.) **B:** Hepatic schistosomiasis. The large area of scarring would correspond grossly to pipestem portal fibrosis. A *Schistosoma mansoni* egg granuloma is at the *lower right* margin of the field (hematoxylin-eosin, ×60). (AFIP Negative 79-16808.)

Schistosomiasis has become a valuable model disease, in both clinical and experimental animal studies, for advancing our understanding of the key processes of hepatic inflammation and fibrosis (43,44,45). Important control points and mechanisms of immune regulation and collagen gene expression are more clearly defined in schistosomiasis than in other chronic liver diseases. The antigenic products secreted by living schistosome eggs first elicit a predominant Th 1–type cellular response, marked by an influx of mononuclear cells and formation of highly cellular egg granulomas, with initiation of increased collagen formation. Over time, from several weeks to months depending on the specific experimental model or human infection, a modulation of the initial cellular reaction takes place as egg deposition continues, with a diminution of the intensity of inflammation and a shift to a predominantly Th 2–type cellular response with prominent eosinophilic infiltration of granulomas and continuing deposition of fibrous tissue. Of the mediators associated with the Th 2 response, IL-13 appears to have strong potential as a pivotal mediator of fibrogenesis, based on studies in *S. mansoni* infected gene knockout mice that fail to express either IL-13 or its receptor complex (45). In humans, there appears to be a genetic component of susceptibility of infected persons to severe fibrotic disease. One report suggested an association between schistosomal hepatosplenomegaly and human leukocyte antigen (HLA) alleles A1 and B5 (46). In another study, a codominant gene with an allele frequency of 0.16 in a heavily infected community in Sudan was associated with severe schistosomal hepatic fibrosis. The gene, located on chromosome 6, was closely linked to the interferon-γ receptor gene (47). In general, however, the most important single determinant of the severity of disease in hepatic schistosomiasis appears to be the intensity of egg deposition in the liver over time (37).

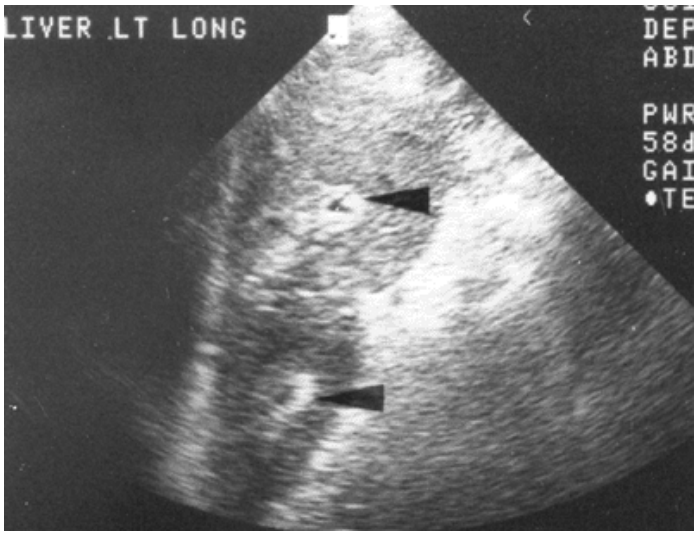
Hepatic fibrosis

Synthesis, deposition, remodeling, and turnover of collagen types I and III and basement membrane–associated collagen components, as well as that of fibronectin

and accompanying matrix substances such as glycosaminoglycans, are greatly increased in hepatic schistosomiasis, as are the plasma levels of multiple markers of collagen deposition. Experimental schistosomiasis has been an especially useful model for the study of the specific inflammatory cytokines proposed to have an influence on fibrogenesis (45).

In schistosomiasis, cells in granulomas and in adjacent fibrotic portal tracts show the appearance of stellate cells known to produce collagen and other connective tissue components in other chronic liver diseases. The potential interactions between granuloma macrophages, cytokines, and stellate cells appear to parallel those described in other experimental model systems (48). As disease progresses from initial egg deposition to advanced fibrosis, portal tracts become less prominently involved with inflammatory cells, and prominent cellular infiltrates diminish and disappear. Portal tracts in persons with Symmers fibrosis are markedly expanded with broad, dense-appearing bands of relatively acellular, mature fibrous tissue, as shown in Figure 49.2B.

Because normal liver architecture is preserved in hepatic schistosomiasis, reversal of portal-tract inflammation and fibrosis should allow resolution of the disease and restoration of normal function. Reversal of fibrosis has been well described after the cure of early *S. mansoni* and *S. japonicum* infections in mice (49,50). Murine schistosomiasis is one of the best-studied examples of the increased activity of two competing processes, collagen biosynthesis versus collagenolysis, in inflammatory fibrotic liver disease (51,52,53). In this model system, cure of infection with cessation of new egg deposition in the liver appears to allow collagenolysis to predominate over continued collagen synthesis, with resolution of fibrosis. It is unclear, however, to what extent the advanced dense portal collagen deposition associated with chronic human hepatic fibrosis might be subject to the same outcome. Two lines of evidence suggest that even dense pipestem fibrosis may be reversible, at least in part. First, rabbits infected with *S. japonicum* provide an animal model of dense portal collagen deposition that resembles human pipestem fibrosis morphologically and biochemically and shows slow reversibility of fibrosis over a 40-week period after cure of the infection (54). Second, serial ultrasonographic examination of persons with schistosome infection has become a standard method of assessing pipestem hepatic fibrosis in population-based treatment studies (55,56,57,58). The ultrasonographic appearance of pipestem fibrosis is shown in Figure 49.3. Ultrasonography in persons with acute nonfibrotic liver diseases may show a modest degree of portal-tract expansion that cannot be distinguished from early schistosomal fibrosis (59), and the imaging method is not reliable for assessing fibrosis in persons with schistosomiasis and coexisting conditions such as chronic viral hepatitis (60). Taking these precautions into account, multiple reports now clearly document the partial or complete resolution over several years of the ultrasonographic findings of pipestem fibrosis after parasitologic cure of *S. mansoni* or *S. japonicum* infection (61,62,63,64,65). In children and in adults treated after relatively short durations of infection, ultrasonographic resolution is more likely to be complete and accompanied by reversal of hepatomegaly and splenomegaly as assessed on physical examination.



▪ **Figure 49.3** Hepatic schistosomiasis. Ultrasonography shows echogenic deposits of pipestem portal fibrosis at *arrowheads*. (Courtesy of Colonel Michael P. Brazaitis, Department of Radiology, Walter Reed Army Medical Center.)

Clinical manifestations

The cercariae of all schistosomes, including those that die on skin penetration in humans, such as the avian schistosome species, may cause a hypersensitivity dermatitis, swimmer's itch. A potentially fatal acute illness, Katayama fever, is a serum sickness–like syndrome triggered by the onset of tissue egg deposition in heavy infections (36). The cardinal characteristic manifestations of advanced hepatic schistosomiasis are related to portal fibrosis and the development of presinusoidal portal hypertension, with passive congestion of the portal system, hepatomegaly, potentially marked splenomegaly, and the enlargement of collateral vessels such as esophageal and gastric varices. Patients classically present with a history of one multiple variceal bleeding episode, accompanied by prominent splenomegaly, no ascites, and normal or nearly normal indices of synthetic liver function and other biochemical laboratory values. It has become increasingly evident from careful longitudinal study of the populations of endemic areas, however, that the greatest health and economic impact of chronic schistosomiasis may

not be its dramatic end state with variceal bleeding, but retardation of growth and development, malnutrition, and generalized debility in heavily infected children and adults (66,67). Growth retardation in children with schistosomiasis is specifically associated with the infection rather than other potential causes and is only partially overcome after parasitologic cure (66).

The prominent splenomegaly of persons with hepatic schistosomiasis is caused both by infiltration with inflammatory cells and by passive congestion. The spleen is firm, normally nontender on palpation, and may be the site of sufficient sequestration to produce clinically important reductions in red blood cells, leukocytes, and platelets, as well as significant discomfort attributed to the bulk of the enlarged organ. Symptomatic splenomegaly may persist after the cure of infection, so that simple splenectomy is one of the most common surgical procedures in endemic areas. Segmental splenectomy, with removal of the bulk of an enlarged organ and preservation of a functional remnant of approximately normal size, is safe and

effective in experienced hands when hypersplenism in schistosomiasis requires surgical therapy (68). When variceal bleeding is an additional concern, portal variceal disconnection may be added (69), although as discussed in the subsequent text, optimal therapy to prevent recurrent variceal bleeding in schistosomiasis is far from clear. Massive splenomegaly may suggest the presence of follicular lymphoma of the spleen, the only malignant tumor clearly associated with hepatic schistosomiasis. Follicular lymphoma was reported to occur in 1% of *S. mansoni*–infected Brazilian patients who required splenectomy (70).

Bacterial infections associated with schistosomiasis include pyogenic liver abscesses, predominantly caused by *Staphylococcus aureus* (71) and chronic *Salmonella* bacteremia (72). Liver abscesses tend to occur in persons with early schistosome infections, perhaps coincident with the effects of initial egg deposition and the initial formation of highly cellular and vascular egg granulomas, as noted in the preceding text. Chronic *Salmonella* bacteremia appears related to the sequestration of living bacteria in the integument of adult worms and may be permanently cured only after elimination of the parasitic infection. HIV and schistosome infections now coexist in a growing number of persons as the HIV epidemic spreads through areas endemic for schistosomiasis. No clear-cut clinical interaction of these diseases, with their profound cellular immunologic disturbances, has been reported so far in persons with both infections (73).

Schistosomiasis and viral hepatitis

The accepted clinical findings of hepatic schistosomiasis—normal liver architecture and cellular function in the presence of portal fibrosis and portal hypertension—are present only in a minority of schistosome-infected persons who require hospitalization for liver disease. Because testing for the markers of hepatitis B and C infections has become widespread, it is evident that regions with a high prevalence of *S. mansoni* and *S. japonicum* infections also tend to have high endemicity for chronic viral hepatitis (74,75,76,77). In most populations studied, there is no higher occurrence of coinfection with schistosomiasis and hepatitis B or C than would be expected by their independent prevalence (78,79). An increased risk for acquiring both infections has been reported, however, in persons with schistosomiasis who required transfusions, and a major increase in the risk for hepatitis C infection has now become evident as the unintended consequence of mass treatment programs for schistosomiasis prior to 1980 that used injections with inadequately sterilized nondisposable syringes and needles (80). For example, in communities in Egypt with an overall prevalence of anti-hepatitis C virus (HCV) of 15% to 20%, up to 50% of persons in age groups with a history of such mass parenteral therapy are now anti-HCV positive (81). The intensive viral transmission attributed to these mass parenteral treatment programs, with formation of a large reservoir of chronic HCV infection, is thought to be responsible for the high current prevalence and transmission rates of hepatitis C in these areas (81).

In persons who develop both hepatic schistosomiasis and chronic viral hepatitis, severe illness is common. Most of the subset of persons living in schistosomiasis endemic areas who are hospitalized for variceal bleeding, management of ascites, or decompensated hepatocellular failure do, in fact, have both schistosomiasis and chronic viral hepatitis, frequently with cirrhosis (74,75,82,83). Whether comorbidity involves specific interactions of the pathologic mechanisms of both diseases or is simply a summation of their effects is unclear. Two comparisons of the extent of pathologic findings of chronic hepatitis C in liver biopsy specimens from persons with and without schistosomiasis suggested more severe histologic activity of chronic hepatitis in dually infected persons in one report (84), but not in the other (85). When acute hepatitis C infection occurred in health care providers with preexisting

chronic *S. mansoni* infection, they showed uniform inability to clear viremia and accelerated histologic progression of chronic hepatitis C compared with the course of hepatitis C infection in their colleagues without schistosome infection (86). Persons with coexisting *S. mansoni* infection and chronic hepatitis C appear less likely than others to respond to interferon therapy (87,88) and *S. mansoni*–infected persons respond less consistently to hepatitis B vaccination (89,90), although vaccination should be a high priority in schistosome-endemic areas to prevent as

much comorbidity as possible. Antiviral therapy for chronic hepatitis B or C should be considered for persons who have been cured of active schistosome infection and who would otherwise meet treatment criteria, bearing in mind that the predominant HCV genotype transmitted in Egypt is type 4 (88).

Diagnosis

Detection of schistosome eggs in the stool is the most useful diagnostic method for documenting active infection. Quantitative studies have shown generally strong relationships between the extent of fecal egg output, the host's worm burden, and the extent of pathology in both *S. mansoni* and *S. japonicum* infections (37,41). Stool examinations for eggs become negative after parasitologic cure of infection. Some persons with active untreated *S. japonicum* infections causing significant morbidity may also show few or no eggs on stool examination (66). Low-power examination of fresh rectal mucosal biopsies may show schistosome eggs that were not apparent in stool specimens. Serologic ELISA methods to detect the antibody to parasitic antigens show excellent sensitivity and are of value in population surveys, but may not be helpful in assessing the activity of infection in an individual patient (91). Of the standard abdominal imaging methods, ultrasonography, as discussed earlier, is by far the most practical for field application and appears to be of better diagnostic utility than computed tomography scan (92) or magnetic resonance imaging (93) for assessment of the extent of portal fibrosis.

Medical therapy

Praziquantel is an effective drug against all human schistosomes, producing parasitologic cures in approximately 90% of persons (37). It is orally administered, preferably in three doses of 20 mg/kg body weight given over 8 hours for a total of 60 mg/kg. Single-dose therapy of 40 and 50 mg/kg has been used in some community mass treatment programs for *S. mansoni* and *S. japonicum* infections, respectively (37). Praziquantel is approved by the U.S. Food and Drug Administration (FDA) for use in schistosomiasis. Gastrointestinal irritation is the major side effect of this generally well-tolerated drug. Another drug effective for *S. mansoni* infection is oxamniquine, used in mass treatment programs in Africa and South America.

Mass treatment programs have become a central element in the efforts of many countries to combat schistosomiasis. For *S. mansoni* infection, a community-based strategy of mass chemotherapy followed by periodic surveillance with stool examinations and prompt treatment of any reinfections has reduced morbidity and promoted resolution of ultrasonographic evidence of portal fibrosis (61,63,64). Reducing new transmission by largely eliminating the contamination of water with shed parasite eggs underlies this approach. Although promising results have also been achieved in some *S. japonicum*–endemic areas (62,65), adults in other treated communities show persistence of hepatosplenomegaly and fibrosis even with decreased prevalence of infection (94). The existence of numerous animal reservoirs of *S. japonicum* in other communities, coupled with the inability of stool examinations to detect all *S. japonicum* reinfections, suggests that in these locations, frequent mass retreatment would be more effective than surveillance by

stool examination for reinfection (66,94). In addition, parasitologic cure followed by prompt reinfection might produce a rebound of the relatively severe inflammatory and fibrotic events that accompany acute infection rather than the persistence of a modulated, relatively less damaging long-term response (66). In such a situation, it may be especially important to maintain effective mass retreatment once a decision has been made to begin community-based therapy.

There are no clinical data to suggest that specific therapy promotes any greater degree of resolution of schistosomal liver fibrosis in humans beyond what would normally be expected after the cure of active infection, as discussed in the preceding text. However, administration of the immunomodulating Th 1 cytokine interferon-γ to schistosome-infected mice, or promotion of its release by the inhibition of IL-4, diminishes liver collagen deposition (95,96). Schistosomes, along with all other multicellular parasites, continue to defy efforts to produce an effective antiparasitic vaccine. However, a combined antigen–cytokine vaccination concept may help limit parasite-induced host injury: Sensitization of mice with *S. mansoni* eggs administered together with IL-12 appears to prime the animals to respond with markedly diminished liver fibrosis when they are subsequently challenged with a schistosome infection (97).

Surgical therapy

Four major factors contribute to portal hypertension, increased collateral blood flow, and variceal enlargement in schistosomiasis (98,99). They include portal fibrosis that produces presinusoidal obstruction of portal inflow; arterialization of abnormal vessels within the portal fibrous tissue that promotes increased hepatic arterial inflow; cellular infiltration of the spleen that adds to passive congestion to produce marked splenomegaly and increased splenic blood flow; and poorly understood functional disturbances that diminish splanchnic resistance and promote a hyperdynamic splanchnic circulation.

Nearly every form of medical and surgical therapy for bleeding varices has been advocated in schistosomiasis. Solid information to support evidence-based

treatment decisions remains as elusive in schistosomiasis as it is for other causes of variceal bleeding. The results at 4 to 10 years of an important randomized trial of proximal splenorenal shunt, distal splenorenal shunt, and splenectomy with esophagogastric devascularization in schistosomiasis have been reported (100) and critically reviewed (101). Bleeding recurred in one fourth of patients in each surgical treatment group, with slightly more variceal bleeding after splenectomy-devascularization. Occurrence of mortality and hepatic encephalopathy, both approximately 40%, was much greater after proximal shunting than after either distal shunting, with 15% mortality and 15% encephalopathy, or splenectomy-devascularization, with 7% mortality and no encephalopathy. Taking into account the study's reported limitations, the data support the current reliance on splenectomy-devascularization in many centers as the preferred surgical option for variceal bleeding refractory to endoscopic therapy. The procedure may involve either total or segmental splenectomy as discussed earlier. As endoscopic control of variceal bleeding with band ligation and sclerotherapy becomes more effectively practiced and widespread, surgical therapy for bleeding varices is likely to become increasingly limited to devascularization in persons who require splenectomy for other indications, as discussed in the preceding text.

The benefits and potential problems of endoscopic sclerotherapy of bleeding varices are similar for schistosomiasis and other liver diseases (102,103,104,105). Growing experience with endoscopic band ligation of varices in schistosomiasis has been encouraging (106,107). A randomized study of band ligation versus sclerotherapy in

40 Brazilian patients reported similar high efficacy and safety for both procedures, with better patient acceptance of band ligation, and a trend toward fewer sessions required for variceal eradication with band ligation (106).

Two controlled secondary prevention trials of propranolol in patients with schistosomiasis and variceal bleeding have shown decreased recurrence of bleeding (108,109). One of these reports from Sudan, which evaluated sustained-release propranalol at a single daily dose of 160 mg, showed a 40% reduction in mortality after 2 years (109). β-Blockade appears to be a useful adjunct for secondary prevention of variceal bleeding in schistosomiasis, in line with its value in other liver diseases, and to merit consideration for evaluation in primary prevention.

The general movement toward medical, endoscopic, and nonshunting surgical therapy for variceal bleeding in schistosomiasis shares common ground with the same trends and uncertainties that apply to other liver diseases. Key considerations in schistosomiasis include the frequent occurrence of marked splenomegaly that has attracted interest in evaluating the potential benefits of complete or partial splenectomy, as well as concern about encephalopathy after shunting. Shunted patients require lifelong vigilant prevention of reinfection to avoid iatrogenic pulmonary egg deposition and the development of schistosomal-induced cor pulmonale. Pulmonary hypertension is a known problem even in nonshunted persons with hepatic schistosomiasis, potentially related to incomplete hepatic clearance of vasoactive compounds and mediators (110).

Fascioliasis

Fasciola hepatica is a trematode bile duct fluke with a worldwide distribution in sheep and cattle (111). The leaf-shaped male and female adult worms reach a size of approximately 2 cm and may remain viable in the bile ducts for more than a decade. They produce eggs that pass in feces, hatch in water, and infect a snail as an intermediate host. Snails release a cercarial stage of the parasite that contaminates aquatic plants ingested by sheep, cattle, or humans. When ingested, transformed metacercariae penetrate the intestine, traverse the peritoneal cavity and liver capsule, and burrow through the liver parenchyma for 1 to 3 months while maturing, finally entering the bile ducts to become mature adults and complete the cycle. Heavy infection of sheep and cattle, called *liver rot*, is an important economic cause of livestock loss in areas where animals regularly consume aquatic vegetation. Humans with fascioliasis generally give a history of eating watercress or drinking potentially contaminated water. Human fascioliasis is prevalent in developing countries with humid climates and largely agrarian populations and is less frequently seen in Europe and North America. In the Nile Delta of Egypt, there is a positive association between *Fasciola* and *S. mansoni* infections (112).

Acute fascioliasis is a febrile illness, typically of up to 3 months duration, presenting with right upper quadrant discomfort and hepatomegaly. As immature flukes continue their course through the liver parenchyma, they leave behind a track of coagulation necrosis infiltrated by an intense eosinophilic inflammatory response. In sheep with experimental fascioliasis, the ability of the parasite to keep moving ahead of the host inflammatory response appears to allow it to literally outrun what would otherwise be an effective host defense (113). The resulting tracks show a characteristic appearance of yellow–white serpiginous subcapsular cords at laparoscopy (114). On computed tomography, the tracks appear as tortuous linear arrays of small, 1- to 3-cm abscess-like lesions (115).

In acute fascioliasis, fever, leukocytosis, and right upper quadrant pain are each present in approximately two thirds of patients. In 20 patients reported from

Spain, 19 had eosinophilia in the 15% to 65% range (111). Atypical manifestations of acute fascioliasis may result when penetration of the ductal system causes hemobilia or discrete abscess formation (116). Immature flukes that fail to migrate into the liver can produce ectopic masses or abscesses in many locations, most commonly appearing as subcutaneous nodules with an eosinophilic infiltrate surrounding the degenerating parasite tissues. In addition, a syndrome of eosinophilic pleuritis and pericarditis without direct parasitic involvement of these structures may accompany acute fascioliasis (111).

After bile duct penetration by mature flukes, egg production initiates chronic fascioliasis. Host responses to adult worms are limited to local inflammation, ductal epithelial proliferation, and fibrous thickening of the duct wall. *Fasciola* produces proline, a key precursor of collagen, as a major nitrogen excretion product. Animal experiments suggest that high local concentrations of proline in fascioliasis may promote ductal hyperplasia and fibrosis (117). Large numbers of adult flukes in the ductal system may precipitate episodes of acute biliary obstruction and cholangitis (111). In addition to visualization of the adult flukes, dilated ducts may be seen by ultrasonography, computed tomography, or cholangiography.

Fever and right upper quadrant abdominal pain in acute fascioliasis, or biliary symptoms in chronic infection, coupled with a consistent dietary history, suggest the possibility of fascioliasis. Eosinophilia and consistent imaging findings as discussed in the preceding text strongly support the diagnosis. Serologic testing for antibody to the parasite was refined by development of an ELISA method using a purified preparation of a *Fasciola*-specific protease, cathepsin L1, as antigen (118). The assay detected 20 of 26 persons with fascioliasis, with no false positive tests in persons with other helminth infections. An alternative approach using a crude *Fasciola* worm antigen preparation achieved 97% sensitivity; high specificity of this method required identification of immunoglobulin G (IgG)4 subclass antibody (119). Antibody levels slowly decrease after successful treatment (120). Stool examination for eggs is useful only in chronic disease and may be negative when egg output is intermittent.

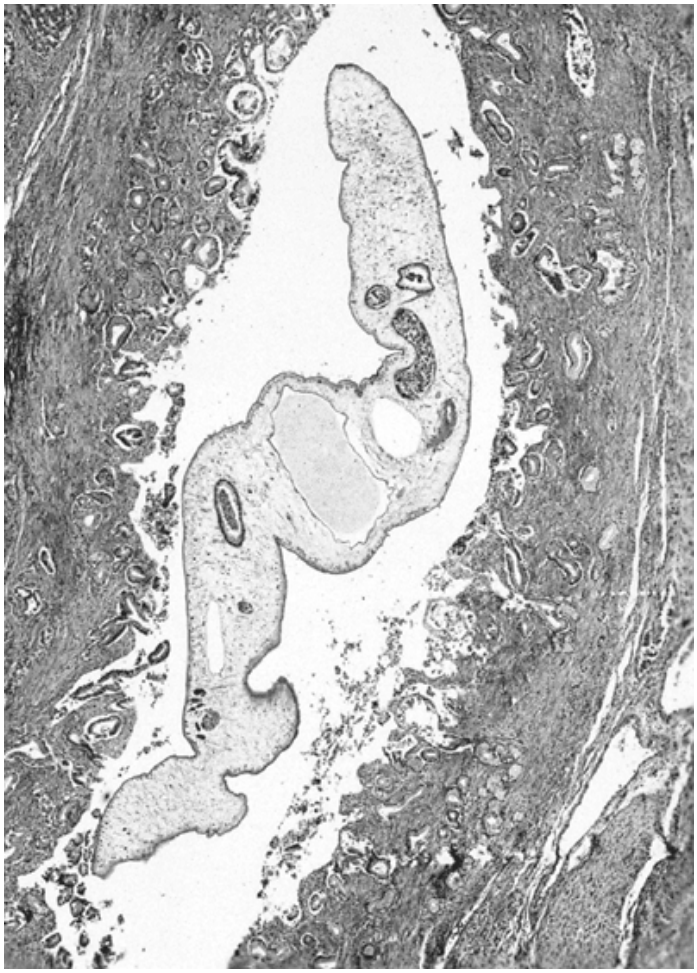
Bithionol has been the most widely used antihelminthic compound for fascioliasis. It is given in courses of 10 to 30 days for acute and chronic infections (111). Gastrointestinal irritation is common; rash, leukopenia, and hepatotoxicity are less frequent; and retreatment may be attempted for nonresponders to an initial course of therapy. Triclabendazole, a benzamidazole compound widely used in veterinary practice, appears to be more effective and less toxic than bithionol in humans with fascioliasis (121). Limited quantities of bithionol are available in the United States from the Centers for Disease Control and Prevention parasitic drug service as an investigational drug. Triclabendazole, the preferred agent, may now be imported for investigational human use in the United States with FDA approval of an expedited individual use request. A 3- week course of oral metronidazole therapy was recently reported to be effective in Iranian patients who had not responded to triclabendazole (122).

Clonorchiasis and Opisthorchiasis

Clonorchis sinensis, *Opisthorchis viverrini*, and *Opisthorchis felineus* are bile duct flukes acquired by humans who eat raw fish containing the parasite's infective metacercaria stage. Human hosts excrete eggs that hatch in water and pass through snail and fish stages to infect new humans and animals. With a size of approximately 1 cm and a ventral sucker that permits attachment to the intrahepatic bile duct epithelium, male and female adult flukes have life spans of 10 years or more. *C. sinensis* infects persons in China and elsewhere in east Asia; approximately one fourth of Chinese immigrants to New York City have active infection (123). *O.*

viverrini has a more limited range in Thailand, Laos, and Cambodia but shows very high prevalence in northeast Thailand, where one third of the population is infected (124). *O. felineus* infects cats and humans in limited areas of Russia and eastern Europe.

Most infected persons have relatively light parasite burdens of 100 or fewer worms. For *O. viverrini* infection, there is a strong quantitative relationship between the number of eggs excreted per gram of stool and a host's burden of adult worms, as determined at autopsy (125) or by retrieval of worms in stool after parasitologic cure of infection (126). A new polymerase chain reaction (PCR)-based fecal test as an alternative for microscopic stool examination may facilitate the screening of large populations (127). Study of the intensity of infection in population-based samples has provided strong evidence to support the linkage of bile duct fluke infection with chronic biliary tract abnormalities and with the ultimate development of cholangiocarcinoma, a leading cause of cancer deaths in endemic areas. In surveys using ultrasonography, the intensity of infection is strongly correlated with the occurrence of gallbladder enlargement and wall irregularity, biliary sludge, and enhanced portal-tract echogenicity (128). For cholangiocarcinoma in northeastern Thailand, a locality-adjusted odds ratio of 14.1 was found for male residents with the highest intensity of *O. viverrini* infection; 4% of the surveyed male population with more than 6,000 eggs/g feces reportedly had the malignancy (129).



▪ **Figure 49.4** Clonorchiasis. A dilated intrahepatic bile duct contains an adult worm cut in cross section. The ductal epithelium shows adenomatous

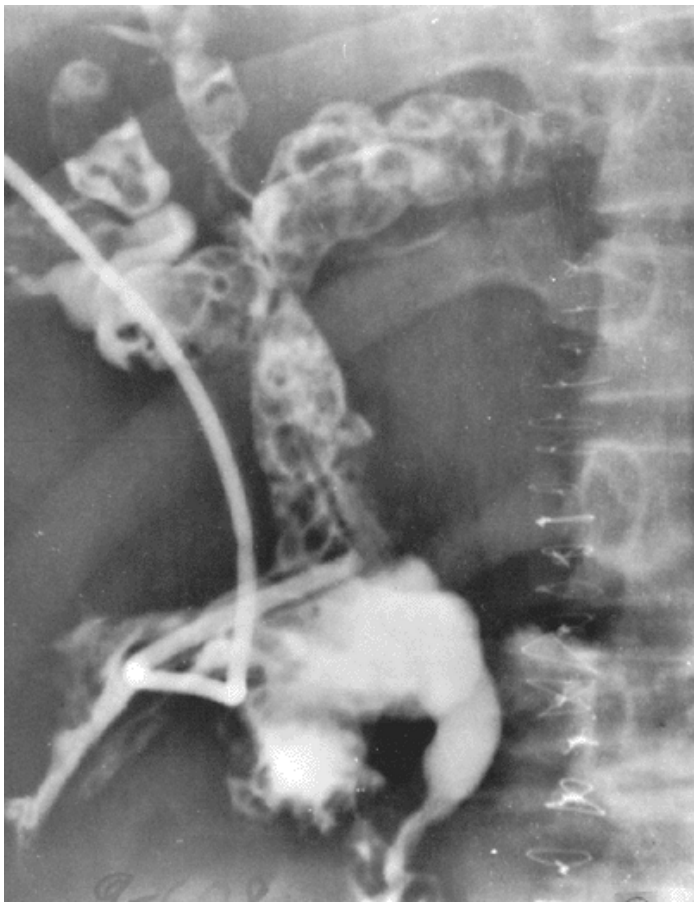
hyperplasia (hematoxylin-eosin, ×40). (AFIP Negative 72-11587.)

The bile ducts that harbor adult *Clonorchis* or *Opisthorchis* worms can show dilatation, irregular thickening, and adenomatous epithelial hyperplasia, as shown in Figure 49.4. Some of these changes may be reversible, especially after treatment of light or early infection. Ten months after eliminating *O. viverrini* infection with praziquantel treatment, repeated ultrasonographic study of 72 persons showed resolution of gallbladder enlargement, improved gallbladder contractility, and decreases in visible sludge and portal-tract echogenicity (130). However, repeat endoscopic cholangiography at an average interval of 32 months in persons treated for *C. sinensis* infection showed some improvement in the appearance of the intrahepatic ducts and loss of the filling defects caused by the presence of adult worms but no changes in measured duct enlargement or the presence of duct wall irregularities (131). Adenomatous hyperplasia of the papilla in chronic clonorchiasis can produce radiographic duct abnormalities indistinguishable from those of cholangiocarcinoma (132).

The development of cholangiocarcinoma may reflect the interaction of multiple processes. For example, *O. viverrini*–infected persons with ultrasonographic biliary abnormalities were shown to have increased activity of cytochrome P-450 2A6, an enzyme that promotes activation of carcinogenic nitrosamines (133). Similarly, administration of dimethylnitrosamine to *C. sinensis*–infected hamsters resulted in development of cholangiocarcinomas that did not occur in uninfected animals or in infected animals not exposed to the carcinogenic compound (134). Although the morbidity associated with biliary fluke infection before the development of cholangiocarcinoma appears to be slight in most persons, the outlook is very poor in those who present with the tumor, similar to that for the same disease in nonendemic areas (135). With currently available information, it seems appropriate to continue efforts to persuade residents of areas with high prevalence of infection and cholangiocarcinoma to modify their dietary habits, and to eliminate existing infection with praziquantel, an easily administered and effective curative drug (124). Screening and parasitologic cure of immigrants to Western countries, who are at high-risk for infection, is also warranted.

Oriental cholangiohepatitis is a chronic illness marked by episodes of cholangitis with formation of multiple pigment stones, irregular bile duct dilatation with disproportionate severity in the extrahepatic ductal system, and formation of multiple strictures (136,137). Its geographic range corresponds roughly to that of the bile duct flukes and *Ascaris* infection. Figure 49.5 shows a cholangiogram from a patient with

this condition and associated clonorchiasis. In many patients with severe distortion of the ductal system, recurrent episodes of cholangitis appear to be self-perpetuating in the absence of active parasitic infection. Helminth infection should be sought and eliminated in persons with the disease. In addition, recurrences due to obstructing stones may be more easily managed in patients who have had placement of a Roux-en-Y jejunal conduit for biliary access (138).



▪ **Figure 49.5** Oriental cholangiohepatitis associated with clonorchiasis. The cholangiogram shows a dilated, distorted intrahepatic ductal system with contrast material outlining numerous filling defects that represent adult *Clonorchis sinensis* flukes. (AFIP Negative 96-22949.)

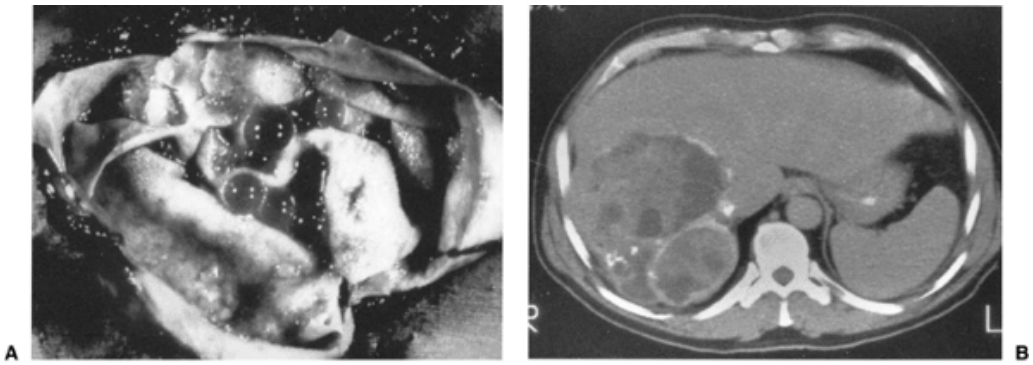
Echinococcosis

Echinococcosis, or hydatid disease, develops in humans when they become accidental hosts for a cystic intermediate stage of one of three canine tapeworms, *Echinococcus granulosus*, *Echinococcus multilocularis*, or *Echinococcus vogeli*. Humans become infected by eating food contaminated with eggs excreted by domestic or wild dogs or other canines such as foxes, coyotes, and wolves (139,140). The parasite normally multiplies as a larval scolex stage within cysts in the solid organs of herbivores or rodents that have consumed excreted eggs. Consumption of the cyst-containing viscera of these animals by new canines completes the cycle.

Hydatid disease most often affects humans in contact with sheep-herding dogs infected with *E. granulosus*. The resulting cystic hydatid disease has a worldwide distribution. *E. multilocularis* infection, concentrated mainly in the arctic and subarctic regions of the Northern Hemisphere, causes human alveolar hydatid disease. *E. vogeli*, the cause of human polycystic hydatid disease, has a very limited range in Central and South America (141).

Hydatid liver cysts caused by *E. granulosus*, as shown in Figure 49.6, are most often asymptomatic. They are fluid-filled structures delimited by a parasite-derived

membrane, as shown in Figure 49.7A, which contains germinal epithelium that buds viable scoleces, shown in Figure 49.7B. Imaging by ultrasonography, computed tomography (as shown in Figure 49.6), or magnetic resonance may demonstrate the formation of daughter cysts, cyst wall calcification, and compression and fibrous reaction of the surrounding liver parenchyma, and in complicated disease, communication of the cyst with the biliary system or external leakage of cyst material. The cysts formed in *E. multilocularis* infection are less well delimited. They tend to invade the liver parenchyma and seed adjacent organs and structures with scoleces and daughter cysts (142). The polycystic hydatid disease of *E. vogeli* infection shows well-delimited multiple cysts (141).



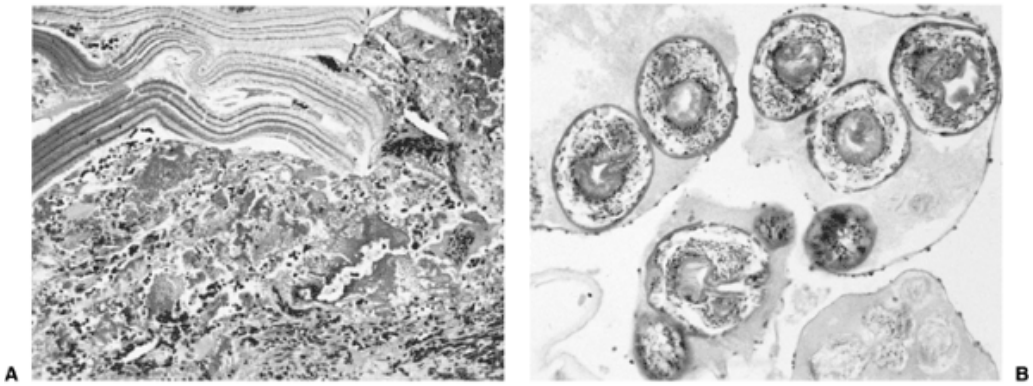
▪ **Figure 49.6 A:** Hepatic hydatid cyst of *Echinococcus granulosus*, opened to show folds of the pale thickened germinal membrane associated with translucent budding daughter cysts. (AFIP Negative 95-82642.) **B:** Hepatic hydatid cyst of *Echinococcus granulosus*. A computed tomographic image shows a large cyst in the posterior right lobe of the liver with a complex internal structure similar to the cyst shown in (A) and areas of wall calcification. (AFIP Negative 92-84646.)

Cystic hydatid disease now most often presents as a hepatic mass with a typical appearance on abdominal imaging, coupled with confirmatory serologic testing by indirect hemagglutination or ELISA, which is positive in approximately 90% of hydatid cysts (140). As discussed in the preceding text, no fecal eggs are present in human hosts. Eosinophilia is usually present. Biliary or peritoneal extension or pulmonary cystic disease is usually easily recognized; however, ectopic cysts in the kidney, spleen, brain, orbit, heart, and bone may produce unusual findings. Uncommon presentations of hydatid disease include segmental portal hypertension due to splenic vein compression by a cyst in the splenic hilum, with adjacent perihilar varix formation (143), and rupture of a hepatic cyst causing inferior vena cava thrombosis (144).

Until recently, most hydatid cysts came to clinical attention because of symptomatic enlargement, so that their management by surgical excision was a straightforward decision. Palliative resections for the spreading, poorly contained cysts of *E. multilocularis*–induced alveolar hydatid disease were often inadequate to deal with this frequently lethal disease.

Now that many hydatid cysts are detected as incidental findings during abdominal imaging and newer forms of medical and surgical therapy for hydatid disease are being reported, therapeutic options are at once more promising and more

challenging.



▪ **Figure 49.7 A:** Hepatic hydatid cyst of *Echinococcus granulosus*. Laminated membrane, top, and debris within the cyst (hematoxylin-eosin, ×160). (AFIP Negative 82-12615.) **B:** Hepatic hydatid cyst of *E. granulosus*, showing viable scoleces cut in cross section (hematoxylin-eosin, ×250). (AFIP Negative 82-12530.)

After initial evaluation of the benzimidazole antihelminthic compound mebendazole, a related compound, albendazole, has become the current standard for medical therapy of hydatid disease (145,146,147,148). Albendazole has strong scolicidal activity for *E. granulosus* and *E. multilocularis* and superior absorption, bioavailability, and distribution into hydatid cysts compared with mebendazole (145). Albendazole was reported to be an effective preoperative adjunct for disrupting the viability of *E. granulosus* and *E. multilocularis* cysts and improving resectability in the latter disease (142,146,147). Albendazole was studied as primary therapy in 59 persons with hepatic *E. granulosus* cysts of diameter 10 cm or less: After 3 to 7 years, cysts had fully resolved in 24 patients, decreased in size in another 24, not changed in 9, and recurred after initial resolution in 2 (148). In another series of 19 patients treated with a combination of albendazole and praziquantel for 2 to 6 months, the combination was reported to produce more rapid and complete resolution than that seen in 22 patients treated earlier by the authors using albendazole alone (149); however, the results of combination therapy in this report were similar to those reported by others for albendazole alone. In an extensive series of 929 cysts in 448 persons treated with mebendazole or albendazole with up to 14 years follow-up, approximately 1 in 4 cysts recurred after initial resolution or regression (150). Recurrence was greatest within 2 years of resolution. Albendazole, approved for use in the United States, is generally administered two to three times daily with food at doses ranging from 10 to 50 mg/kg per day, for 12 to 24 weeks or longer, with or without intervening rest periods (145,146,147,148). Toxicity includes variable alopecia and, in many patients, minor elevations in aminotransferase levels as well as transient pain perceived at the location of a cyst on initiation of treatment. Elevation of aminotransferase levels more than four times normal or leukopenia requires discontinuing albendazole.

Traditional surgical therapy for hepatic *E. granulosus* cysts at laparotomy includes isolation by packing; careful aspiration of cyst fluid to avoid spillage of viable scoleces or anaphylaxis; injection of the cyst with hypertonic saline, alcohol, or dilute silver nitrate to kill the scolices if the aspirated fluid is crystal clear; and

resection of either the cyst alone or both the cyst and its pericystic rim of compressed liver tissue (151,152). Aspiration of turbid cyst fluid suggests a biliary communication so that injection with potential sclerosants is avoided. The use of percutaneous drainage, described in the subsequent text, for an increasing proportion of patients with relatively simple cysts, has left the remaining patients who now come to open surgery as a population with relatively greater aggregate complexity and technical challenge than those of earlier surgical series.

Laparoscopic evacuation (153) and ultrasound-guided percutaneous drainage (154,155,156,157,158) are reported to be safe and effective for treating uncomplicated cystic hydatid disease. Percutaneous drainage has become the first-line management for cystic hydatid disease in many centers. The most extensive current experience is with an ultrasound-guided four-step process of puncture; aspiration; injection with hypertonic saline, silver nitrate, or other scolicidal solution; and re-aspiration (PAIR) method, with one or more days of subsequent percutaneous catheter drainage for

large cysts. Patients normally receive a several day preprocedure course of oral albendazole, and are given antihistamine and steroid coverage for the procedure to minimize anaphylaxis in the event of cyst leakage at puncture, followed by continued albendazole for 2 months after the procedure. Advantages of the PAIR technique include minimal disability and early return to full activity, with a 1- to 2-day length of hospital stay compared to a typical 2-week stay after open cyst evacuation. In contrast to primary medical therapy without aspiration and drainage, the PAIR technique has the advantages of a much shorter duration of 2 months of adjunctive albendazole therapy postprocedure, compared with up to 6 months or more for albendazole as primary treatment, as well as a minimal recurrence rate compared with recurrence of 25% of cysts treated medically alone (150). PAIR and laparoscopic cyst evacuation in experienced centers have both shown low morbidity, with anaphylaxis being the most significant problem in the 1% to 2% range, which is generally easily managed in pretreated patients, and the potential for bleeding or duct injury common to all liver punctures.

Patients with alveolar hydatid disease due to *E. multilocularis* have an infection whose biologic behavior resembles that of a malignant tumor as its complex cystic structures invade the liver parenchyma and spread by direct extension to adjacent sites. Albendazole therapy is administered in an effort to stabilize unresectable disease, or as an adjunct to liver resection, which may cure early localized disease. Alveolar hydatid disease may require multiple surgeries in an attempt to deal with severe complications such as hepatic vein compression and thrombosis, and secondary sclerosing cholangitis. Similar major problems occur much less frequently in cystic hydatid disease. Liver transplantation for patients with end-stage alveolar or cystic hydatid disease often presents a technical challenge related to extensive prior surgery, but transplantation may produce a good long-term outcome in patients whose disease has progressed beyond the point of cure or control by other methods (159,160).

Chapter 50
Bacterial and Systemic Infections

Stuart C. Gordon

Key Concepts

- Involvement of the liver with various bacterial, fungal or rickettsial infections may be a primary disorder or part of a multisystemic disorder. These infections often mimic other conditions, therefore a high degree of clinical suspicion is often needed to establish the diagnosis of nonviral hepatic infection.
- Cholestasis and hyperbilirubinemia can occur after gram-positive or gram-negative bacteremia, even in the absence of fever or positive blood cultures, and is often an overlooked entity. Endotoxin-mediated cytokine release is the likely cause of septic jaundice.
- The possibility of a nonviral hepatic infectious disorder should be suspected when a patient with a fever has a cholestatic biochemical profile (predominant alkaline phosphatase elevation out of proportion to the aminotransferase derangement). Occupational and travel history may provide diagnostic clues, and results of specific serologic tests or biopsy of the liver may lead to the institution of appropriate therapy.
- Although in the past many nonviral hepatic infectious diseases were diagnosed retrospectively with serologic titers or microbiologic cultures, currently polymerase chain reaction (PCR) (candidiasis, tuberculosis, tularemia, leptospirosis, Q fever) is increasingly used to facilitate early diagnoses.

A variety of bacterial, fungal, and rickettsial infections affect the liver, either as the result of direct hepatocellular or biliary invasion or through the production of toxins. In addition, systemic infectious processes frequently cause jaundice or nonspecific liver biochemical abnormalities through mechanisms that are less defined. The jaundice of bacterial pneumonia has been long recognized (1,2), and both jaundice and aminotransferase abnormalities have been associated with other systemic infections, including appendicitis (3), bacteremia in infants (4,5), and other extrahepatic infections (6,7). Most descriptions of liver dysfunction during systemic infection were reported several decades ago, whereas recent research has focused on the mechanisms of the jaundice of sepsis. Reports of the hepatobiliary manifestations of specific infectious agents come from around the world; newly recognized manifestations, diagnostic modalities, and treatment regimens shed new light on the clinical relevance of these conditions. Anecdotal case reports emphasize the need for clinicians to consider the possibility of such infectious agents and entities when encountering unusual cases of hepatitis or cholestasis.

Bacterial Infection and Jaundice

The observation that extrahepatic bacterial infection can cause jaundice has been attributed to Garvin (8). Osler (9) in 1892 found that in patients with pneumonia, jaundice might occur. The syndrome of septic jaundice is highly variable and may range from nonspecific

biochemical cholestasis to deep jaundice. Sepsis as a cause of jaundice in the hospitalized patient is often an overlooked entity (10). A disproportionate elevation of serum bilirubin in comparison with serum alkaline phosphatase and aminotransferase levels should suggest underlying sepsis, even in the absence of fever or leukocytosis (11). Accordingly, early medical or surgical intervention may reduce morbidity and mortality (11).

In more than one third of patients with sepsis, hyperbilirubinemia associated with bacteremia with or without an increase in serum alkaline phosphatase level may occur 1 to 9 days before the initial positive blood culture result is obtained. Although gram-negative bacteria, especially *Escherichia coli*, have been implicated as the predominant causative agent in most series, infection with nonhepatic gram-positive organisms, especially *Staphylococcus aureus* (12,13) also have been cited.

The mechanisms by which bacterial infection causes cholestasis and jaundice are not clear, but endotoxemia appears to be the likely cause. Lipopolysaccharide (LPS), or endotoxin, is contained within the outer membranes of gram-negative bacteria and is a potent inducer of cytokines. Endotoxemia may occur in the absence of documented sepsis (14), and increased levels of tumor necrosis factor α and other cytokines occur in alcoholic hepatitis and in jaundice associated with total parenteral nutrition. Accordingly, endotoxin-mediated cytokine release may be the basis for the jaundice of many disorders, including sepsis (15,16).

Early studies showed a reduction in bile flow and biliary excretion after administration of endotoxin to isolated, perfused rat liver. Pretreatment with dexamethasone, which blocks endotoxin-mediated release of the cytokines tumor necrosis factor α and interleukin-1, largely prevented this reduction in bile flow (11,17). The cholestasis of sepsis has long suggested an impaired hepatocyte transport of bile acids and organic anions. Studies have shown that canalicular bile acid and organic anion transport are markedly impaired in endotoxemia (18). Therefore, endotoxemia severely impairs the transport of organic anions at both the sinusoidal and canalicular membrane. Because of impaired hepatic organic anion transport, both bile acid–dependent and bile acid–independent

components of bile flow decrease with the administration of endotoxin. Li et al. (19) recently demonstrated that LPS administration decreases organic anion transport mRNA levels in mice, and that this decrease is mediated through toll-like receptor 4 (TLR4).

The jaundice of sepsis was historically described as occurring in pediatric patients, but its presence in adults is increasingly observed. Marked elevations in direct and total serum bilirubin concentrations occur in bacteremic adults (20,21). In a review of 100 consecutively enrolled adult and pediatric patients with positive results of blood cultures (4), 54% had elevated serum bilirubin levels, and 34% had values of 2.0 mg/dL or greater. The condition may be more prevalent among patients with preexisting liver disease, whereas only 6% of patients without preexisting hepatobiliary disease had jaundice in another series (22).

The molecular pathogenesis and pathophysiology of cholestasis has been reviewed (23,24). Secretion of bile depends on the adequate functioning of many membrane transport systems in both hepatocytes and cholangiocytes, and various molecular defects in hepatocellular membrane transporters are associated with cholestatic liver disease in humans. At present, ursodeoxycholic acid (ursodiol) is used in many cholestatic liver diseases, presumably because it replaces toxic hydrophobic bile salts in serum, liver, and bile. At present, however, ursodiol has no accepted role in the cholestasis of sepsis. A better understanding of the molecular mechanisms involved in cholestatic syndromes should unfold the potential for newer therapies (23).

Specific Bacterial Infections

Salmonella Hepatitis (Typhoid Fever)

Both *Salmonella typhi* and *Salmonella paratyphi* cause the acute systemic disease enteric fever. It has been estimated that 16 million cases occur per year, with at least 600,000 deaths, making typhoid fever a major public health problem in less developed regions of the world (25). Although clinical hepatitis is unusual (probably fewer than 25% of all cases), liver involvement is present in almost all cases (26).

The term *salmonella hepatitis* refers to liver injury caused by infection with either *S. typhi* or *S. paratyphi*, and the disease has been documented in both endemic and nonendemic areas. Among the 150 cases of salmonella hepatitis reported to date, most occurred in patients with typhoid infection. The disease affects people of all ages, and those with immune deficiency are particularly at risk. Among persons with human immunodeficiency virus (HIV) infection, the most commonly isolated serotypes are *Salmonella enteritidis* and *Salmonella typhimurium* (25). Alcoholism has been identified as a predisposing factor for severe forms of *S. enteritidis* infection in cases in which no other underlying disease has been evident (27,28,29).

The mechanism by which the organism causes hepatitis is not established. It may be related to either direct hepatic damage from endotoxin or the inflammatory process or to immune mechanisms. In a rodent

model of Salmonella infection, the organism invaded and multiplied extensively in hepatocytes. Thereafter destruction of infected hepatocytes by inflammatory phagocytes was followed by a release of bacteria into the extracellular space. The findings suggested that lysis of infected hepatocytes by phagocytic cells was an important early-defense strategy against liver infection with *S. typhimurium* (30). Similar mechanisms of infection occurred with *Francisella tularensis* and *Listeria monocytogenes* (see subsequent text). There is also evidence to suggest that the severity of the hepatitis in typhoid fever correlates with the virulence of the infecting organism (31,32).

The liver histology of salmonella hepatitis is nonspecific. Ballooning degeneration with vacuolation has been reported. Reticulum endoplasmic dilatation, mitochondrial alterations, and biliary canaliculus injury have been described. Occasionally, *S. typhi* organisms are found in the liver cells, as are lobular aggregates of Kupffer cells, lesions known as *typhoid nodules* (33,34). Such nodules simulate granuloma formation and represent hyperplasia of the reticuloendothelial system. This hyperplasia reportedly causes hepatic enlargement in patients with enteric fever (35).

The clinical presentation of salmonella hepatitis resembles that of viral hepatitis, but certain features help in differentiating the two diseases. In particular, high fever (often >40°C) and bradycardia (inappropriate response of heart rate to degree of fever) seem to be more common among patients with salmonella hepatitis. In addition, the biochemical profile is markedly different from that of viral hepatitis and suggests the presence of an infiltrative process rather than hepatitis. In a comparison of 27 cases of salmonella hepatitis with acute viral hepatitis, El-Newihi et al. (36) found that patients with salmonella hepatitis were more likely to have a disproportionately increased serum alkaline phosphatase level and that serum aminotransferase values were far lower than with acute viral hepatitis. Also unlike viral hepatitis, salmonella hepatitis was associated with fever and a left shift of white blood cells (37). Jaundice is unusual, and many cases of salmonella hepatitis are anicteric. In untreated patients, jaundice may be delayed appearing in the second to the fourth week of the illness. Among patients with jaundice, and presumably more severe disease, glomerulonephritis (characterized by increased blood urea nitrogen and serum creatinine levels, proteinuria, and urinary sediment red cell casts) has been more common (38,39). In the more severe cases, in addition to glomerulonephritis, complications include liver abscess, cholangitis, encephalitis or neuropsychiatric manifestations, myocarditis, or bleeding diathesis. Disseminated intravascular coagulation with extensive gangrene of the extremities and rhabdomyolysis has been described (27).

Establishing a diagnosis of salmonella hepatitis may be difficult in developing countries, because the manifestations are similar to those of other forms of acute hepatitis, including viral hepatitis, leptospirosis, and malaria. The biochemical profile described earlier helps to differentiate the various entities. The alanine aminotransferase (ALT) to lactate dehydrogenase (LDH) (ALT/LDH) ratio usually is less than 4.0 in salmonella hepatitis. A ratio greater than 5.0 is reported in acute viral hepatitis, and a ratio less than 1.5 occurs in cases of central zonal injury, such as hepatic ischemia or acetaminophen injury (36).

Prompt diagnosis and early intervention with appropriate antibiotics assure a good prognosis. Because of

salmonella resistance to the so-called first-line antibiotics (chloramphenicol, trimethoprim-sulfamethoxazole, and amoxicillin), antibiotic sensitivity testing is advised. A 5-day course of fluoroquinolone is the therapy of choice for uncomplicated enteric fever. Some experts have advocated the addition of intravenous dexamethasone (40). Because the organism can enter the bile and reside in the gallbladder, shedding for long periods can cause the chronic carrier state. Follow-up stool cultures are advised for all patients with typhoid fever to ensure that they are not carriers, and long-term fluoroquinolone therapy may help eradicate the carrier state (35). The prognosis for salmonella hepatitis is excellent; death has occurred among patients with malnutrition and immunodeficiency.

Tuberculosis

There has been a renewed interest in tuberculous infection of the liver because of the increasing incidence of extrapulmonary tuberculosis related to acquired immunodeficiency syndrome. In such cases, *Mycobacterium avium-intracellulare* is often the cause of liver dysfunction (see Chapter 51). Classically, however, hepatic tuberculosis (infection with *Mycobacterium tuberculosis*) as a part of miliary disease may occur in as many as 80% of all patients dying of pulmonary tuberculosis (41). The original description of hepatic tuberculosis classified the disease as (a) miliary, a part of generalized disease, or (b) local, with focal involvement of the liver. The terms that have led to confusion over the years included tuberculous pseudotumor, atypical hepatic tuberculosis, tuberculous cholangitis, and tuberculous liver abscess (42).

One classification scheme (42) separates hepatic tuberculosis into three categories: Miliary, granulomatous, and localized hepatic. The miliary form, which is part of generalized miliary disease, usually does not involve the liver. Granulomatous disease, that is, hepatitis due to tuberculosis, is defined by the finding of typical caseating granulomas at liver biopsy and response to appropriate antimicrobial therapy. Finally,

localized hepatic tuberculosis is further classified into disease that is either (a) without bile duct involvement (e.g., solitary or multiple hepatic nodules or tuberculous abscess) or (b) with bile duct involvement due to either compression of the bile duct by lymph nodes or actual involvement of the ductal epithelium by the tuberculous process. Therefore, the term *hepatobiliary tuberculosis* refers to a distinct clinical entity of localized hepatic disease with characteristic clinical features.

The portal of entry of *M. tuberculosis* organisms into the biliary tract and the liver is the hematogenous route or, less commonly, the portal vein or lymphatic vessels (43). Therefore disease that is isolated to the liver is considered rare, even in the absence of documented disease elsewhere; often inactive pulmonary tuberculosis is found at autopsy. One variant form of hepatic tuberculosis without active pulmonary or miliary disease is the so-called "nodular form," which presents as an isolated liver tumor or abscess (44,45). In most cases, the clinical presentation is that of neoplasm, with solitary liver lesions of variable size and imaging features, raised alkaline phosphatase values, weight loss, and so on, in the absence of known previous tuberculosis. In one recent series, PCR assay of the liver tissue in five cases established the etiologic diagnosis of *M. tuberculosis*, with postoperative histologic diagnoses only showing chronic granulomatous inflammation. Such cases underscore the difficulty in reaching the correct diagnosis of hepatic tuberculosis, the value of PCR technology in establishing this diagnosis, and the need for a high index of suspicion (44).

The clinical manifestations of hepatobiliary tuberculosis are those of the extrahepatic disease; hepatic involvement usually produces no symptoms (46). Nevertheless, cases of fulminant hepatic failure have been reported, among both immunosuppressed and immunocompetent persons (47,48). In one summary of cases of gastrointestinal tuberculosis in California, patients with hepatic involvement usually had right upper quadrant pain or fever of unknown origin (49). Nonspecific abdominal pain may be present in patients with chronic tuberculosis, whereas fever and weight loss are common in cases of tuberculous abscess. The most common physical finding is hepatomegaly, which probably occurs in most cases (46,50). A disproportionately increased serum alkaline phosphatase level is a consistent finding (51), which suggests the presence of an infiltrative hepatic process, whereas nonspecific aminotransferase elevations do not aid in diagnosis (52). The presence of jaundice suggests biliary involvement, and the biochemical profile may simulate that of extrahepatic biliary obstruction (53).

An unusual manifestation of tuberculosis involves the development of portal hypertension caused by the compression of the portal vein by tuberculous lymph nodes, followed by the rupture of esophageal varices and hematemesis (54). Isolated pancreatic tuberculosis may manifest in a manner very similar to that of a pancreatic neoplasm, including a mass lesion of the pancreatic head (55). Similarly, gallbladder tuberculosis is reportedly increasing in incidence and may manifest as biliary colic and acute cholecystitis (56).

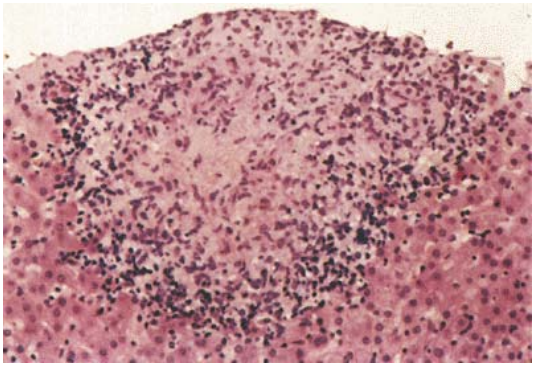
Another unusual but increasingly reported variant of hepatobiliary tuberculosis is obstructive jaundice caused by the involvement of the bile duct, pancreas, or gallbladder. Compression of the biliary tree by involved lymph nodes or possibly by direct involvement of the biliary epithelium or rupture of a caseating granuloma into the lumen of the bile duct may cause jaundice and biochemical cholestasis. Intrahepatic bile duct obstruction may result from granulomatous involvement, often as part of miliary tuberculosis. The entity of bile duct tuberculosis (57) may manifest as bile duct dilatation and common hepatic duct strictures. Biliary cytologic findings from endoscopic cholangiography may yield the diagnosis (58). Such patients have painless jaundice and weight loss that mimics malignant disease of the pancreas or cholangiocarcinoma, and dilated bile ducts are found at imaging studies. Experience with therapeutic biliary stenting has been variable, and in unsuccessful cases, percutaneous biliary drainage decompresses the obstruction (59,60).

Imaging studies may help rule out other conditions. Plain radiographs may show hepatic calcifications in patients with chronic tuberculosis, and both ultrasonography and computed tomography (CT) may show complex masses, either solitary or multiple. Such masses, common in patients with tuberculous liver abscesses, cannot be differentiated from malignant tumors and necessitate aspiration or biopsy for further investigation. One patient with cirrhotic hepatitis C and end-stage renal disease presented with multiple hyperechoic hepatic lesions on ultrasound, without pulmonary involvement (61). Blind percutaneous liver biopsy may be useful in the diagnosis of

the miliary form, whereas direct-guided biopsy with laparoscopy results in a higher diagnostic yield. At laparoscopy, a cheesy white appearance of irregular nodules, often resembling malignant tumor, has been described (42,62). Although the finding of caseating granuloma is highly suggestive of tuberculosis (Fig. 50.1), similar pathologic findings occur in brucellosis, coccidioidomycosis, and Hodgkin's disease. Caseation is commonly associated with tuberculosis, but in some series it occurs less frequently. The finding of acid-fast bacilli at biopsy occurs infrequently, fewer than 35% of cases, and the yield of a positive culture result for *M. tuberculosis* itself is even less common.

Molecular techniques establish the diagnosis of hepatic tuberculosis. Akcan et al. (63) and Alcantara-Payawal et al. (64) reported very high sensitivity (overall assay positivity of 88% in one series) with

low false-negativity among control patients, from a PCR assay on the liver tissue of patients with infection.



▪ **Figure 50.1** Tuberculosis. Caseating hepatic granuloma in a patient with fever of unknown origin.

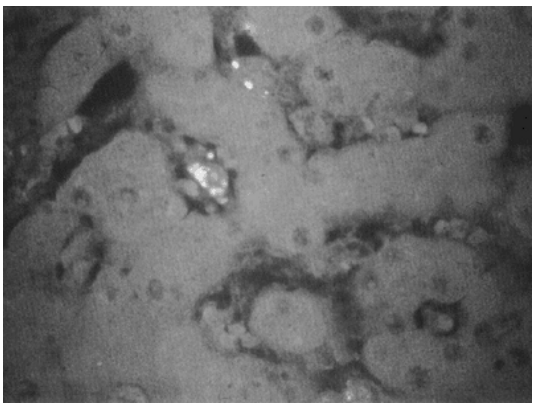
The management of hepatic tuberculosis involves the use of at least four antituberculous drugs, usually including isoniazid, rifampicin, pyrazinamide, and ethambutol (65). Although therapy traditionally lasts at least 6 months, multidrug resistant organisms require alternative chemotherapies, and there is a genuine need for new agents. It is anticipated that implementation of the recently developed molecular assays for *M. tuberculosis* will serve to assess response to therapy and allow individualized treatment duration.

Legionnaires Disease

Although most forms of pneumonia may cause derangements in liver function, Legionnaires disease, pneumonia characterized by multisystemic involvement, is particularly likely to cause abnormal results of liver tests. In one large review (66) both aminotransferase levels (up to 15 times the upper limit of normal) and alkaline phosphatase levels (up to 9 times the upper limit of normal) accompanied the pneumonia. Fifteen percent of patients also had hyperbilirubinemia. Therefore, the finding of markedly abnormal liver biochemical values in the presence of obvious pneumonia may be a clue to the appropriate diagnosis. The organism can be found with direct immunofluorescence or other techniques (Fig. 50.2) (67). Deranged liver biochemistries may represent the main manifestation (68).

Brucellosis

Three species of Brucella affect humans: *Brucella melitensis*, *Brucella abortus*, and *Brucella suis*. Brucellosis is an occupational disease that affects food handlers, and organisms enter the body through the skin or oropharynx and spread to regional lymph nodes. The disease can also be airborne and transmitted to personnel in microbiology laboratories.



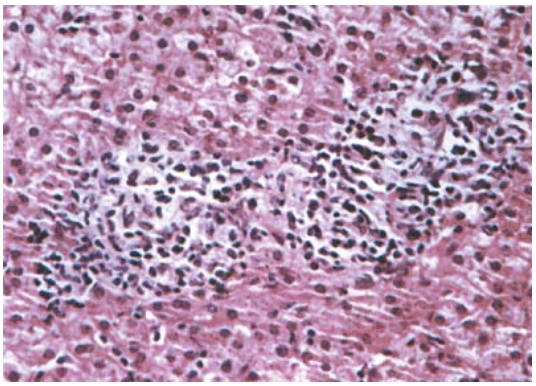
▪ **Figure 50.2** Legionella pneumophila serogroup 3. Antigenic material within sinusoidal lining cells in the liver (direct immunofluorescence, 512×). (Courtesy of John Watts, MD.)

The involvement of the liver in human brucellosis may occur with infection by both *B. melitensis* and *B. abortus*. The incidence of liver disease in brucellosis depends on the definition. Colmenero et al. (69) proposed that the concept of hepatic complication of systemic brucellosis be reserved for patients with obvious hepatic dysfunction, including jaundice or abscess. Defined in these terms, only 2.4% of 530 patients with *B. melitensis* infection had hepatic complications, whereas the presence of hepatic granuloma in the absence of overt hepatitis may be more common. In a study of 905 patients with brucellosis, Ariza et al. (70) found 16 cases of chronic hepatosplenic suppurative brucellosis (14 in the liver and 2 in the spleen) among 15 patients. One half of the patients had previous remote brucellosis. Although hepatic abscess formation after acute infection is unusual, mild nonspecific liver enzyme abnormalities may be detected in approximately 50% of patients with brucellosis. In addition to hepatic involvement, spontaneous bacterial peritonitis can occur in the absence of obvious hepatic involvement (71,72). Febrile and fatal hepatitis with hepatic abscess and endotoxic shock has been described (73).

Carazo et al. recently described the imaging features in cases of hepatosplenic brucelloma, and noted that on ultrasound, the lesion appears iso- or hypoechogenic with the liver, with focal calcifications. Contrast-enhanced CT scans showed predominantly solid masses with irregular borders, rarely with transdiaphragmatic lung invasion (74).

Histologic examination of the liver in brucellosis usually shows nonspecific portal and lobular inflammation, and small noncaseating granulomas are often associated with reactive hepatitis (Fig. 50.3). The finding of granuloma is constant when the duration of the

disease is less than 100 days but is infrequent after this time (75). The predominant biochemical derangement in clinically apparent disease is an increase in serum alkaline phosphatase level. This finding suggests the presence of an infiltrative process. The organism can be isolated from the blood in acute states, but cultures may take 3 weeks to turn positive. Agglutinating antibodies generally appear after the second week of illness, and the diagnosis usually is established by the demonstration of increasing titers. Therefore, the presence of acute infection may be established by isolation of the microorganism or by appropriate serologic findings. These diagnostic criteria may not be helpful, however, for chronic forms of the disease, which may have evolved over long periods.



▪ **Figure 50.3** *Brucella melitensis*. Nonspecific lymphoplasmacytic inflammatory infiltrate in patient with brucellosis (hematoxylin and eosin, 510×). (Courtesy of John Watts, MD.)

The more serious form of the disease therefore involves hepatic abscesses, and imaging studies show large calcium densities within the liver. Many such patients had known brucellosis many years earlier and were free of symptoms before the development of the abscess. However, even among patients without previous brucellosis, the finding of hepatic calcium deposits when the patient first arrives for evaluation strongly suggests that this entity represents a local reactivation of a previous undocumented brucellosis, as in tuberculosis (70). In the United States, the manifestation of brucellosis among children as hepatosplenic abscess may cause diagnostic confusion, particularly among immigrants and travelers from countries where brucellosis is endemic (76).

Unlike patients with acute brucellosis, patients with hepatic abscess (chronic hepatosplenic suppurative brucellosis or "brucelloma") tend not to have either leukopenia or relative lymphocytosis, and biochemical abnormalities are minor (68,75). The differential diagnosis includes neoplasm, hydatid disease, pyogenic or amebic abscess, and other granulomatous infections, including tuberculosis and histoplasmosis (77). Such patients often have had very low titers of agglutinating antibody that have delayed appropriate diagnosis.

The drugs administered for therapy for acute infection are tetracycline and rifampicin. In cases of chronic suppurative disease, percutaneous or surgical drainage should be performed (70,78).

Tularemia

Infection with *F. tularensis*, the causative agent of tularemia, occurs after exposure to jackrabbits and hares, the main animal reservoir in North America and Europe. Hunters are at risk and may acquire the disease from tick or deer-fly bites in the summer months. In Sweden, the lemming is responsible for this disease ("lemming fever"), whereas in Russia the water rat and muskrat may spread tularemia. The disorder usually affects the lungs, and the usual manifestation is a flu-like syndrome occurring between 1 and 10 days after exposure. Liver involvement is rare, and when it does occur, only modest aminotransferase abnormalities are found (79). Tularemia also manifests as obstructive jaundice with fever, suggesting the presence of cholangitis. A cholestatic biochemical profile may cause a diagnostic dilemma in such cases (80).

Early diagnosis and management of tularemia probably account for the rarity of hepatic dissemination, but hepatic tularemia may also manifest as a solitary hepatic abscess early in the course of disease (81). Histologic examination of the liver in cases of tularemia shows multiple focal areas of coagulative necrosis with a surrounding chronic inflammatory infiltrate (82). The diagnosis can be established serologically with demonstration of agglutinating antibodies. Enzyme-linked immunosorbent assay (ELISA) tests are available, but a PCR test for *F. tularensis* should enable rapid confirmation of the clinical diagnosis of tularemia (83). Treatment consists of streptomycin or gentamicin.

Listeriosis

L. monocytogenes is an organism found mostly in rodents. It is widely distributed in nature, including soil and plant material. It usually causes meningoencephalitis or pneumonitis, although hepatic involvement is reported. The liver disease of listeriosis is more common in neonates, but in adults, it may manifest as signs and symptoms of viral hepatitis, usually with high fever (84). Patients are often immunosuppressed or have underlying malignant disease (85). The onset may be gradual over several weeks or immediate fulminant hepatitis. Aminotransferase levels may be high, and jaundice may be present. The presence of high fever and leukocytosis tends to differentiate this condition from viral hepatitis, and the diagnosis is confirmed by the isolation of the organism from blood or cerebrospinal

fluid. The disease may also manifest as a liver abscess, in which case the diagnosis is established by culturing aspirated abscess material (86).

Melioidosis

Melioidosis is endemic to northeastern Thailand but is also found throughout Southeast Asia and northern Australia. It is a potentially fatal infection caused by the bacterium *Burkholderia pseudomallei* (formerly *Pseudomonas pseudomallei*). The organism is ubiquitous in many parts of the tropics, and is found in damp soil and freshwater. The usual mode of acquisition is through inhalation or through minor skin abrasions. The mortality may be high, averaging 45%, and in cases of acute septicemia, death occurs within the first 3 days after hospital admission. The disease has protean manifestations, and histopathologically it mimics tuberculosis and catscratch disease. Early diagnosis and proper antibiotic therapy (parenteral ceftazidime was provided for 4 weeks in the report of Ben et al. (87)) are crucial.

Melioidosis may present with pulmonary infection, tonsillitis, localized abscess or fulminant septicemia (87). Liver involvement in melioidosis is common, but the increase in aminotransferase and serum bilirubin values is similar to that among patients with other forms of bacteremia. Visceral organ abscesses are common and usually involve the spleen, liver, and kidney. Granulomas may be found. The sonographic appearance of these multiple, small, discrete abscesses is target-like, and larger multiloculated abscesses are common (88). The differential diagnosis of melioidosis includes other forms of liver abscess, tuberculosis, and other bacterial causes of sepsis. Immunohistochemistry plays a useful diagnostic role, and polyclonal antibodies applied to formalin-fixed, paraffin-embedded tissue help establish the diagnosis earlier than the traditional but less reliable culture techniques (89).

Spirochetal Infections

Leptospirosis

Professor Weil of Heidelberg first made the classic description of febrile headache, jaundice with renal failure, and severe muscle pain, which is now known as *Weil disease*. Yet only a small percentage of patients infected by spirochetes of the genus *Leptospira* have this most severe of manifestations, and most descriptions of liver pathology in this disease come from autopsy series. Early recognition, with administration of appropriate antibiotics, has resulted in a very low incidence of hepatic manifestations.

Leptospirosis has a worldwide distribution. It results from direct or indirect exposure to the urine of infected animals, usually rodents. The most common serotypes are *Leptospira icterohaemorrhagiae*, carried by rats, and *Leptospira canicola*, carried by dogs. The organism enters the body through wounds on the skin and through intact mucous membranes and can directly penetrate the skin. Therefore the disease often results from occupational exposure, as among persons who work in sewers, mines, and construction sites and among food workers who may be exposed to rodent-infested environments. Leisure activities that include swimming, white-water rafting, or fishing in rivers or ponds contaminated with infected urine from wild animals also have resulted in leptospiral infection (90). In Thailand, risk factors include walking through water, applying fertilizer or plowing wet fields (91). Eating uncooked rice has been reported as a risk factor because of contamination with rat urine (90).

Although usually considered a disease of developing nations, cases occur in the United States and may cause a diagnostic dilemma. Among immunosuppressed HIV-infected patients, homelessness in large cities may result in exposure to rodent urine and resultant urban leptospirosis (92). The usual manifestations are acute fever and a

flu-like illness, often with cough and chest pain, that occur after a 7- to 10-day incubation period. The abdominal pain of the acute phase may simulate surgical abdomen and may manifest as biliary colic. At a recent triathlon in Illinois, which included swimming in a freshwater lake, two athletes had clinically suspected acute cholecystitis and underwent cholecystectomy. An immunohistochemical test for leptospirosis applied to these gallbladders showed bacterial antigens and intact bacteria (93). Central nervous system symptoms of headaches and confusion may occur in the acute stage.

A second phase occurs during the second week of illness. The patient may have a milder recurrence of the aforementioned symptoms. This is the so-called icteric stage and may be caused by the effects of an activated immune system (90,94). Muscle pain may become severe, especially in the lower extremities. Marked conjunctival congestion (suffusion) occurs within the first few days of the illness and may persist into the second stage. Jaundice may or may not be present at this stage. Renal function worsens during this second phase, and a progressive increase in serum creatine kinase level reflects the presence of myositis.

The third, or convalescent, stage starts in the third week with progressive improvement in mental status and renal function and relief from jaundice. The so-called classic Weil disease is actually a recurrence of the fever after termination of the first stage of the illness, and the initial biphasic course is bypassed. Hepatic involvement is usually self-limited, and "microcirculatory abnormalities" (95) have been implicated as a cause of high bilirubin values. One recent report from Japan (96) described a case of simultaneous hepatitis E

infection and leptospirosis, with prolonged cholestasis and jaundice lasting several months.

Doxycycline may be effective prophylaxis of leptospirosis (97). Once the disease has developed, early intensive care and administration of doxycycline may be lifesaving (98), and therefore early diagnosis is important. During the first phase, leptospires can be isolated from the cerebrospinal fluid and blood; in the second phase, they are isolated from the urine. Dark-ground microscopic examination of plasma has been found to be a simple and rapid form of early diagnosis of leptospirosis with hepatorenal involvement (99). PCR based on the *flaB* gene of *Leptospira* has been found to be an efficient tool for the rapid detection and identification of *Leptospira* from clinical specimens (100).

Syphilis

Syphilis is a multisystemic disease caused by the spirochete *Treponema pallidum* subsp. *pallidum*, and is a microaerophilic gram-negative bacterium. Like tuberculosis, syphilis, once a disease affecting primarily homosexual men, has been increasingly reported among heterosexuals in the urban areas of the United States. The disease spans several stages, from congenital involvement to tertiary disease, and derangements in liver function may occur in all stages. In the congenital form of the disease, liver manifestations generally occur between the ages of 2 and 15 years, with hepatic gummas. Biochemical hepatitis with jaundice may occur, and therefore a wide differential diagnosis can produce a diagnostic dilemma. A positive result of an ELISA test for immunoglobulin G (IgG) antibodies against treponemal antigen and the fluorescent treponemal antibody (FTA)-immunoglobulin M (IgM) help establish the correct diagnosis.

In a 1917 paper on the subject (101), jaundice was reported to occur in as many as 12% of cases of secondary syphilis, probably owing to inflammation of hepatocytes. The pathologic findings generally include lymphocytic and neutrophilic infiltrates in the portal tracts; pericholangiolar inflammation has also been described. Spirochetes are infrequently seen (10% in one series); identification of treponemes in the liver is even less common. Therefore, direct hepatotoxicity by the organism is probably a less likely pathogenesis of hepatitis than are immune-mediated mechanisms. Invasion of the portal venous system through the rectal portal entry in homosexual men with primary anal or rectal lesions may explain a reportedly higher frequency of syphilitic hepatitis in this population.

The clinical manifestations may be subtle in an anicteric patient, who may have anorexia, weight loss, and hepatomegaly. The initial signs and symptoms may include pruritus and proteinuria (102,103). The rash of secondary syphilis usually is present, whereas the primary chancre usually is no longer present. In the absence of jaundice, biochemical cholestasis with a disproportionately increased serum alkaline phosphatase level may provide a clue to the diagnosis (104,105,106). Syphilitic hepatitis may coexist with nephrotic syndrome due to syphilitic membranous glomerulonephritis (107). However, because many of the reported cases of presumed syphilitic hepatitis occurred before the advent of viral hepatitis serologic tests, Veeravahu (105) suggested that the evidence to implicate *T. pallidum* as a liver pathogen in early syphilis is not convincing. Nevertheless, the occurrence of acute cholestatic syphilitic hepatitis in the era of viral hepatitis testing has been described (108).

Additional laboratory studies of the syphilitic hepatitis of secondary-stage disease include a hemagglutination test for *T. pallidum* and an FTA absorption (FTA-ABS) test. Liver imaging studies may reveal focal liver lesions as large as 3 cm in diameter. In an unusual case from France, Maincent et al. (109) reported a case of tertiary hepatic syphilis that manifested as multinodular hepatic metastasis. This case shows that the entity of hepatic syphilis may manifest in a variety of misleading ways.

Liver involvement in cases of tertiary syphilis usually is discovered at the postmortem examination. The gummas of the liver may resemble metastatic disease at autopsy or may resemble cirrhosis because of the nodular configuration of the liver in the later stages. Hepar lobatum refers to the lobulation of the liver because it appears to be divided into several smaller lobes by deep furrows. The lobulation originates from the resorption of gummas in the tertiary stages of the disease (110). Focal liver lesions with filling defects on CT scans may similarly mimic metastatic disease in a patient with weight loss. Diagnostic liver biopsy is therefore essential (109) (Fig. 50.4). Appropriate intervention with proper antimicrobial therapy may reduce the size of the liver lesions.

The incidence of primary and secondary syphilis, as noted in the preceding text, has increased in the United States in recent years, especially among HIV-positive individuals (111). Regarding the involvement of the liver, the last large review of syphilitic hepatitis that was described in the medical literature was 30 years ago (112)

until the recent report of seven such cases among HIV-infected patients (113). These individuals presented with rash and predominant alkaline phosphatase elevations, with symptomatic and biochemical improvement following antibiotic therapy. The authors noted that high rapid plasma reagin (RPR) titers were more likely to be present if $CD4^+$ cell counts were higher. These cases emphasize the importance of entertaining the diagnosis of syphilitic hepatitis as a cause of otherwise unexplained high alkaline phosphatase levels among HIV-infected patients.

Lyme Disease

One of the less recognized manifestations of multisystemic Lyme disease is hepatitis, yet hepatic involvement appears to be common. It has been suggested that Lyme disease resembles syphilis, in that a spirochete organism causes both diseases (in the case of Lyme disease, a zoonosis, the tick-borne *Borrelia burgdorferi*), and both diseases may develop as an acute or chronic multisystemic inflammatory disease (114). The mechanism by which liver injury occurs is not known. Direct invasion of the liver by the organism and immune-complex deposition have been proposed. In one case of Lyme disease–related hepatitis in a human, the organism was found in the liver with Dieterle staining, and the patient's condition improved with doxycycline therapy. This result suggests that borrelial invasion may cause direct hepatocyte damage (115).

Lyme disease has both an early, acute stage and a chronic phase (116). Involvement of the liver is more common in the early stage. Histologic examination shows portal inflammation, ballooning of hepatocytes, considerable mitotic activity, hyperplasia of Kupffer cells, prominent microvesicular fat, and sinusoidal mononuclear and neutrophil cell infiltration (115). Clinically, in addition to other features of erythema chronicum migrans, hepatosplenomegaly and biochemical hepatitis may persist for several weeks. The acute phase may manifest as a febrile illness with jaundice and mixed hepatitic and cholestatic abnormalities (117).

In a review of the cases of 115 patients with erythema migrans, the characteristic rash of early Lyme disease, approximately one third of the patients were found to have abnormal serum ALT values. Among those with early disseminated Lyme disease, two thirds of the patients had abnormal liver biochemical values (118). The investigators concluded that liver function test abnormalities are common among patients with erythema migrans but that these abnormalities are generally mild and improve with antibiotic therapy. Zaidi and Singer recently reviewed biochemical abnormalities of the liver in patients with Lyme disease (118a).

Rickettsial Infections

Q Fever

The causative rickettsia of Q fever is *Coxiella burnetii*. It was first described in Australia in the 1930s after an outbreak of an undiagnosed febrile illness among workers at an abattoir in Brisbane; the Q represents query. The source of infection is infected sheep, goats, or cattle, and the infection may be transmitted through contact with unpasteurized milk or contact with livestock. The organism has been identified in ticks, and the disease has a worldwide distribution. Liver involvement is common.

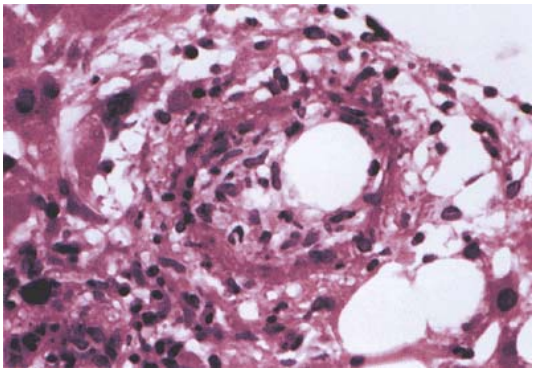
The typical presentation of Q fever is a febrile, flu-like illness with pneumonitis. The usual epidemiologic risk factors of exposure to sheep, cattle, and goats may be lacking in many cases, and often the disease goes undiagnosed (119). Hepatitis is common (120), and the disease may manifest as hepatitis in the absence of pulmonary manifestations (121). In a report of 63 sporadic cases of Q fever in an urban adult population in Spain (122), approximately 50% of patients had accompanying hepatitis.

Three main hepatic manifestations of Q fever have been proposed: A clinically acute hepatitis-like illness without respiratory involvement (the most common form of hepatic involvement); an incidental finding of increased liver biochemical values in a patient with known acute Q fever; or fever of unknown origin with characteristic hepatic granulomas (123,124,125). After an incubation period of 14 to 26 days, patients have a fever and flu-like symptoms, often with a dry cough.

Bradycardia may be present. Liver biochemical abnormalities are common but nonspecific and may manifest as anicteric hepatitis. In an appropriate setting, the disease mimics several other conditions, including other fungal infections of the liver, other granulomatous diseases, drug reactions, and so on. A 70-year-old man with cancer presented with low-grade fever and fatigue following a vacation in the Canary Islands, an area endemic for Q fever. His illness progressed to jaundice and fatal liver failure; the following year, after considering the diagnosis, an indirect microimmunofluorescence test for *C. burnetii* IgG and IgM antibodies were strongly positive, therefore confirming acute Q fever (126).

The classic doughnut granuloma of Q fever—a central clear space in the center of the granuloma—is not pathognomonic for the disease and may be seen in Hodgkin's disease and infectious mononucleosis (Fig. 50.5). The granulomas have been shown to disappear over a period of 3 months after appropriate antibiotic therapy (127). The granuloma is a dense fibrin ring surrounded by a central lipid vacuole and is composed of neutrophils, monocytes, eosinophils, and occasional multinucleated giant cells. Kupffer cells are hypertrophied and there may be a lymphocytic portal inflammation with erosion of the limiting plate (128).

The disease may be prolonged, may affect children exposed to farm animals (129), and one third of patients may have jaundice. The diagnosis is established when an increase in complement fixation is detected or the result of an immunofluorescent antibody titer to *C. burnetii* is positive (123). PCR can be used to amplify *C. burnetii* DNA from tissue (130,131). Tetracycline is considered the treatment of choice, although the less effective erythromycin may be an appropriate alternative in the treatment of children. A recently developed vaccine may be efficacious in persons at high risk (132).



▪ **Figure 50.5** Section shows classic doughnut granuloma. The characteristic lesion of Q fever is a doughnut granuloma similar to that shown here (hematoxylin and eosin, 780×). (Courtesy of John Watts, MD.)

Ehrlichiosis

Ehrlichiosis is a rickettsial infection that occurs in animals and humans, and is caused by microorganisms of the genus *Ehrlichia*. The pathogenesis and comparative pathology and immunohistology of ehrlichiosis have been reviewed (133). Human infection with *Ehrlichia canis*, a tick-borne infection common among dogs, was first reported in 1987. Recent molecular characterization, however, has suggested that taxonomic reorganization will more accurately define the Ehrlichia species. Therefore, *Ehrlichia chaffeensis* causes human granulocytic ehrlichiosis, and the major tick vector is a member of the genus *Ixodes* (134).

Involvement of the liver in human ehrlichiosis is largely anecdotal, but it can be a multisystemic disease with intense cholestasis. In one case following a documented tick bite, a 56-year-old man had multisystemic disease with sepsis and renal failure complicated by deep jaundice. Liver biopsy showed intense bile stasis and intense neutrophilic infiltration of bile ducts that suggested extrahepatic bile duct obstruction with cholangitis. A rickettsial immunofluorescent antibody panel confirmed the presence of ehrlichiosis, and the patient responded to a course of chloramphenicol (135). A tetracycline such as doxycycline also is reported to be effective.

In a review of eight cases of ehrlichiosis managed at an Arkansas medical center, seven patients had raised aminotransferase levels that suggested biochemical hepatitis, and three patients had jaundice with a peak bilirubin level of 13.8 mg/dL. All eight patients were treated with and responded to doxycycline, including one patient who had multiple-organ failure but eventually recovered. The authors concluded that in the appropriate clinical setting, ehrlichiosis should be considered a cause of elevated liver enzyme values (136).

Rocky Mountain Spotted Fever

Infection with the tick-borne *Rickettsia rickettsii* causes the multisystemic disease that is occasionally associated with an increased alkaline phosphatase level and jaundice (137). Zaidi and Singer recently reviewed the gastrointestinal and hepatic manifestation of Rocky Mountain Spotted Fever (118a).

Tick-Borne Diseases

The prevalence of tick-borne diseases has been increasing in the United States as a result of greater outdoor activity and migration of the population into rural areas (118a).

The eight most common tick-borne diseases include Lyme disease, ehrlichiosis, Rocky Mountain spotted fever, tularemia, Colorado tick fever, tick-borne relapsing fever, Q fever, and babesiosis; many of these entities have been considered separately in this chapter. Table 50.1 summarizes the gastrointestinal and hepatic manifestations of tick-borne diseases. With the exception of Colorado tick fever and babesiosis, most of these infections may cause a form of acute hepatitis and should be considered in areas of endemicity. Ehrlichiosis is most likely to cause cholestasis and jaundice, whereas Q fever, Lyme disease, ehrlichiosis and, to a lesser extent, tularemia, may cause granulomatous hepatitis.

Table 50.1. Laboratory and Clinical Manifestations of Tick-Borne Liver Infections

Manifestation	Lyme disease	Ehrlichiosis	RMSF	Tularemia	Colorado tick fever	TBRF	Q fever	Babesiosis
Anorexia	+	++	+	+	+	+	+	+
Nausea	+	++	++	++	++	+++	++	+
Vomiting	+	++	++	++	++	+++	++	+
Abdominal pain	+	++	++ to +++	++	+	++	+	+
Diarrhea	+	++	++	++ to +++	+	+ to ++	++	+
Hepatomegaly	R	+ to ++	+	+ to ++	R	+	+	+
Splenomegaly	+	+ to ++	+	+ to ++	R	R to +	+	+
Jaundice	+	+++	+	+	+	+	+	+ to ++
Elevated bilirubin level	+	+++	+ to ++	+	+	+	+ to ++	++ to +++
Elevated ALT level	++	++++	++ to +++	++	+	++	++[a]	+

[a]Elevated alkaline phosphatase level is the predominant abnormality.
ALT, alanine aminotransferase; R, rare; RMSF, rocky mountain spotted fever; TBRF, tickborne relapsing fever; +, uncommon; ++ common; +++, very common; ++++, almost always present.

Fungal Infections

Histoplasmosis

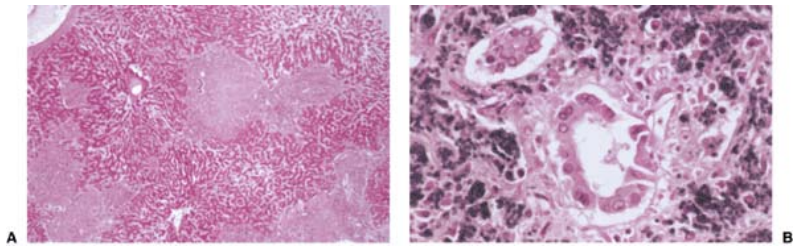
Histoplasmosis has a worldwide distribution, including the central and northeastern United States, Central and South America, India, and the Far East. It is the most common cause of fungal infection in the Ohio River Valley of the United States. It is usually transmitted after inhalation of the organism *Histoplasma capsulatum*, which is particularly associated with bird droppings, especially those of chickens. In most cases, exposure to the fungus is asymptomatic, and documentation of previous exposure is in the form of delayed-type cutaneous sensitization.

Although liver involvement is common in cases of disseminated histoplasmosis, in which case the infection may travel from the lungs to involve other organs, the disease may also present as an isolated liver mass or as an infiltrative liver disorder. A 39-year-old HIV-negative alcoholic man from New Delhi presented with a 3-month history of weakness associated with fever and jaundice. Laboratory studies showed anemia, leukocytosis, and marked alkaline phosphatase elevation. A pharyngeal culture was positive for *H. capsulatum*, and a liver biopsy

showed granulomas consisting of macrophages and giant cells. Multiple periodic acid-Schiff (PAS) positive ovoid fungal bodies were seen causing a swelling of the Kupffer cells consistent with the diagnosis of hepatic histoplasmosis, and treatment with amphotericin B was started with clinical improvement. This case, with a negative chest x-ray, demonstrates the potential for isolated liver involvement in cases of histoplasmosis (138).

Hepatic involvement with histoplasmosis may manifest as fever of unknown origin and cause a considerable diagnostic dilemma (139). It may also manifest as unexplained biochemical cholestasis with fatigue and weight loss, which can mimic neoplasia or even cholangitis (140). The disease occurs among persons without HIV infection, but immunosuppression in the form of chronic glucocorticoid therapy may be present. Liver biochemical abnormalities in many cases may be nonspecific, and biopsy may be needed for the correct diagnosis. Thrombocytopenia may be present and necessitate a transjugular approach to biopsy. Hepatic lesions may include diffuse granulomas distributed throughout the liver or parenchymal infiltration with macrophages filled with the organism, seen with fungal staining. One report described a rare case that presented as a solitary right-sided liver lesion invading the diaphragm (141).

A review of the pathologic spectrum of cases of gastrointestinal histoplasmosis showed that 10% of 52 patients had histologic evidence of liver disease, most commonly portal lymphohistiocytic inflammation (Fig. 50.6). Discrete hepatic granulomas were found in fewer than 20% of livers that were involved (142).



▪ **Figure 50.6** Elderly diabetic man who lived in an area endemic for histoplasmosis had fever and hepatomegaly. **A:** Confluent portal granulomas in a patient with hepatic histoplasmosis (hematoxylin and eosin). **B:** Special stain shows uniform, oval, yeast-like cells morphologically typical of *Histoplasma capsulatum* (hematoxylin and eosin, methenamine silver). (Courtesy of Laura Lamps, MD.)

Early diagnosis may be lifesaving, so this infection requires diagnostic consideration. Management is the same as that of other disseminated fungal infections and usually includes intravenous amphotericin B. The use of newer antifungal agents has not been described.

Another case of an unusual manifestation of hepatic histoplasmosis involved a 56-year-old "university lecturer" from Canada with a 10-year history of disabling fatigue, and a 6-month history of anorexia, weight loss and abnormal liver biochemistries, primarily alkaline phosphatase elevations. A liver biopsy showed non-caseating granulomas with multinucleated giant cells, and screening serologies were positive for *H. capsulatum*. His only risk factor was having lived in Indiana from his youth. Additional studies confirmed Addisonian crisis. After appropriate antifungal therapy, his fatigue and constitutional symptoms improved (143).

Candidiasis

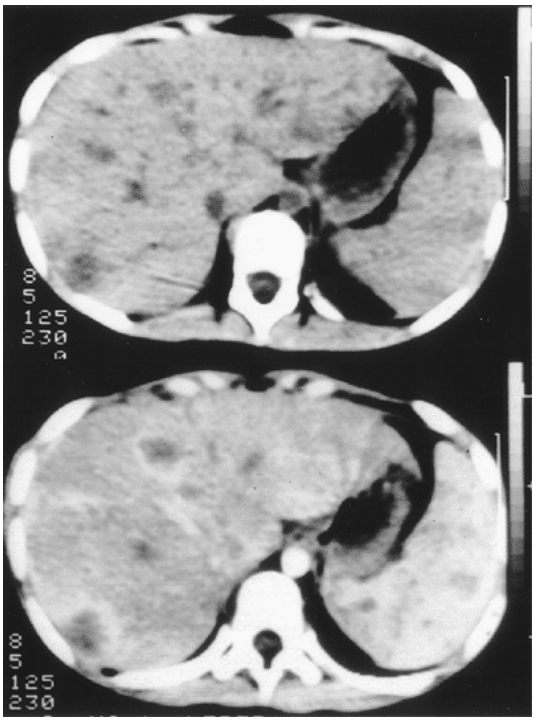
Caused by infection with the fungi of the genus *Candida*, the clinical spectrum of candidal liver disease is varied. The most common species causing human infection is *Candida albicans*, although other species also cause disease. Liver involvement in systemic candidiasis often goes unrecognized, and hepatic lesions may be found incidentally at autopsy. Therefore the entity of focal hepatic candidiasis may be part of the syndrome of hepatosplenic candidiasis or, more appropriately, chronic disseminated candidiasis (144), because other organ systems may be involved. Although systemic disease is presumed, results of blood cultures may be negative, and appropriate diagnosis requires a high degree of clinical suspicion.

The typical patient has leukemia and fever, jaundice, and biochemical cholestasis after induction chemotherapy–associated neutropenia. After the nadir of neutropenia, the serum alkaline phosphatase level begins to increase, suggesting the presence of an infiltrative or infectious process. The pathogenesis of the disease probably relates to mucosal damage of the colonic mucosa at the time of neutropenia. Local invasion and subsequent entry of the Candida organisms into the portal circulation result in liver infection (145). Results at CT and ultrasonography are often normal in the early stage of neutropenic fever, whereas as the neutrophil count returns to normal, imaging studies may show focal liver lesions with a bull's-eye appearance (145,146,147,148) (Fig. 50.7). These lesions may be absent on images, however, even with jaundice. In such cases, diagnostic laparoscopy with local anesthesia may show discrete focal yellowish-white punctate lesions scattered throughout the liver surface (149) (Fig. 50.8). Direct-guided biopsy (Figs. 50.9, 50.10 and 50.11) may establish the diagnosis and allow for appropriate antifungal therapy.

Cholangitis with common bile duct stenosis secondary to *Candida* colonization of the biliary tract was recently

described in a patient on long-time mechanical ventilation. Cholangiography revealed bead-like deformity consistent with sclerosing cholangitis. Microbiologic analysis of aspirated bile confirmed Candidiasis (150).

Although the diagnosis of hepatic candidiasis required histologic findings previously, confirmation by culture (not possible in formalin-fixed samples), or immunofluorescence, or PCR testing now allows for a sensitive and specific diagnosis, and further permits *Candida* species identification. Kirby et al. (151) described a typical case of hepatosplenic candidiasis in which PCR was positive for candida DNA in both the sera and liver biopsy. The authors noted the importance of identifying species, because *candida* shows species-specific antifungal resistance patterns, that is, some resistant to fluconazole and others to amphotericin.



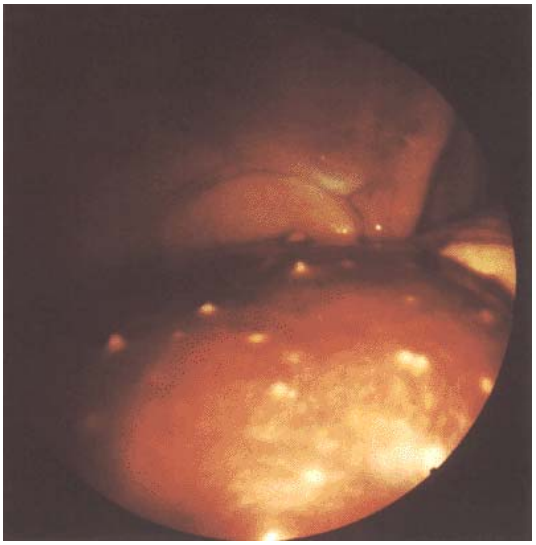
▪ **Figure 50.7** Computed tomography scan of an 8-year-old girl with leukemia undergoing chemotherapy who had a fever. Images before (top) and after (bottom) administration of contrast material reveal numerous areas of low attenuation throughout the liver and spleen. Rim enhancement of the lesions after injection of contrast material is caused by inflammation. Open biopsy of the hepatic lesion proved the diagnosis of hepatic candidiasis. (Courtesy of Ali Shirkhoda, MD.)

P.1391

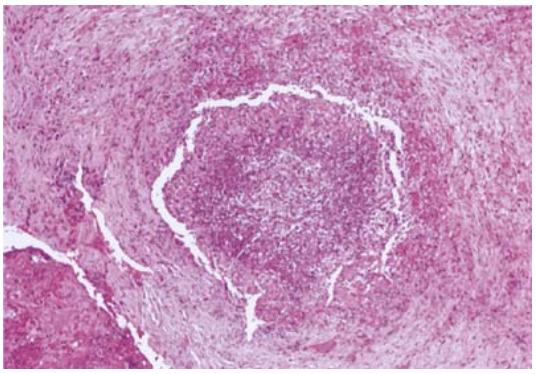
Optimal therapy for hepatic candidiasis has not been established, in part because of the rarity of the condition, the paucity of controlled trials, and the absence of established end points of treatment. A relapse of the infection may be related to either premature discontinuation of therapy or inadequate antifungal treatment of patients with chemotherapy-induced neutropenia (144). Furthermore, the hepatic lesions of chronic disseminated candidiasis may transiently disappear during neutropenia, and therefore antifungal therapy should not be discontinued on the basis of radiologic findings alone (152). The original therapy for this infection consisted of amphotericin B, yet prolonged treatment with amphotericin B may cause renal toxicity and often fails to eradicate infection. Some experts have advocated the addition of other antifungal agents or the addition of liposomal formulations (153,154), which may be better targeted to enter the liver. Pappas et al. recently reviewed the treatment of candidiasis (155). Both fluconazole and caspofungin are as effective as and less toxic than amphotericin B, and can

P.1392

be given orally (153,156). As illustrated in the recent case report by Kirby et al. (151), identification of the specific *candida* species may guide appropriate therapy, such as an oral azole, therefore obviating the need for prolonged parenteral amphotericin treatment. The heightened awareness of the entity of hepatic candidiasis in the patient with neutropenic leukemia undergoing chemotherapy has highlighted the importance of factors that promote its development, including intravenous catheters and broad-spectrum antibiotics; furthermore, there has been the suggestion that prophylactic antifungal agents may prevent systemic fungal disease, but results are conflicting (157,158).



▪ **Figure 50.8** A 60-year-old woman with leukemia had fever and jaundice after induction chemotherapy. Computed tomography scan shows no significant pathologic process. At laparoscopy, however, the liver was diffusely infiltrated with small discrete lesions of focal candidiasis.

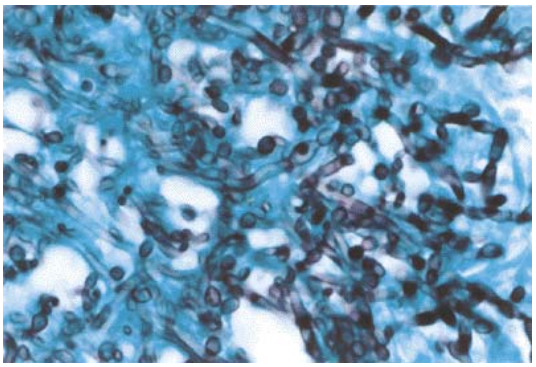


▪ **Figure 50.9** Focal hepatic candidiasis. Same patient as in Fig. 50.8 is shown here. Centrally necrotic granuloma is surrounded by a thick fibrous capsule (hematoxylin and eosin, 80×). (Courtesy of John Watts, MD.)

▪ **Figure 50.10** Focal hepatic candidiasis. Gross wedge biopsy specimen of liver shows necrotic granuloma encapsulated by fibrous tissue with central cavitation. This cavitation results in the bull's-eye lesion often seen on imaging studies. (Courtesy of John Watts, MD.)

Actinomycosis

Actinomycosis is a chronic, progressive, suppurative disease caused by actinomycetes of the genus *Actinomyces*, notably *Actinomyces israelii*, *Actinomyces bovis*, and *Actinomyces naeslundii*. Infection often occurs in the mouth (cervicofacial) area, thorax, abdomen, or uterus (pelvic). Early management of dental sepsis is believed to have prevented the cervicofacial form of the disease, which is thought to cause infection by local proliferation of organisms (159).



▪ **Figure 50.11** Focal hepatic candidiasis. Grocott-stained section shows numerous yeast-like cells and mycelial elements of *Candida* in the center of a granuloma (80×). (Courtesy of John Watts, MD.)

The involvement of the liver is rare, but primary hepatic actinomycosis is an important differential diagnosis to hepatocellular carcinoma in endemic areas, and may present as a solid liver mass. In a recent review of 57 cases reported in the literature, the mean age of patients was 43 years (range, 4–65 years) with a male predominance. Most patients presented with fever, abdominal pain and weight loss, typically with a subacute presentation of up to 18 months. Leukocytosis was common, as was serum alkaline phosphatase elevations (160).

Hepatic actinomycosis had been reported to occur in 15% of abdominal cases (5% of all cases). In a review of 11 cases of actinomycosis of the liver from Japan (161), investigators found that in six cases (55%), partial hepatectomy had been performed because of involvement of liver tumors and that five patients had liver abscess. The authors concluded that hepatic actinomycosis should be considered in the differential diagnosis of pyogenic liver abscess and space-occupying lesions of the liver.

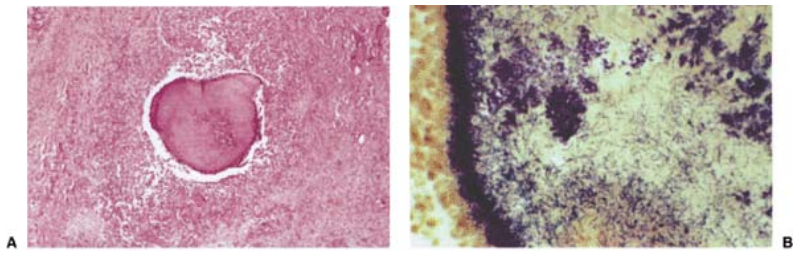
The hepatic disease probably is caused by spread through the portal vein caused by a mucosal injury due to ulcer, inflammatory bowel disease, or surgery. Local aggregates of Actinomyces organisms are often associated with other bacteria, such as coliforms, and these other bacteria may be involved in the pathogenesis of the infection. The hallmark of the infection is the formation of inflammatory masses containing granules (Fig. 50.12) (162,163).

The CT scan appearance may be a multiloculated low-attenuation lesion with low intensity on the T1-weighted sequence at magnetic resonance imaging (high intensity on the T2-weighted sequence) with surrounding edema. A peripherally thickened and irregular inner wall may suggest the presence of an abscess (164). Angiography may show a hypervascular hepatic mass mimicking hepatic neoplasm in the arterial phase (166,167). These radiographic features are nonspecific, however, and there is debate regarding how best to establish the diagnosis.

Establishment of the correct diagnosis may be prolonged, as noted in the preceding text, because cases may

manifest as nonspecific subacute presentations including fever of unknown origin (162,165) or inflammatory pseudotumors (163), which have the gross appearance of malignant lesions. This manifestation emphasizes the need to search for bacteria in such lesions. Often such patients have underlying sepsis due to chronic abdominal abscesses. The histologic examination of tissue samples (168) is needed to establish the appropriate diagnosis. In one case (169) a positive blood culture established the correct diagnosis, but a recent review of hepatic actinomycosis (170) observes that percutaneous or surgical interventions for tissue samples were more likely to be diagnostic than

positive peripheral blood cultures for *A. israelii*. In rare instances, the lesion may infiltrate the diaphragm and right lung (162).



▪ **Figure 50.12 A:** Microcolony of Actinomyces organisms (sulfur granule) surrounded by acute suppurative inflammation (hematoxylin and eosin, 80×). **B:** High-power Brown-Brenn stained section of a sulfur granule, which is composed of gram-positive filamentous bacteria. The diagnosis of actinomycosis was confirmed with direct immunofluorescence (not shown) (780×). (Courtesy of John Watts, MD.)

Most patients respond to prolonged intravenous penicillin G, alone or in combination with clindamycin or ciprofloxin, often for several months (160). Lack of response to such therapy may necessitate surgical drainage. Alternative regimens include erythromycin and tetracycline. One recent report described a 53-year-old immunocompetent male with hepatic actinomycosis who failed to respond to intravenous antibiotic and underwent right posterior hepatic segmentectomy, with successful resolution of infection and without evidence of recurrence (171).

Coccidioidomycosis

The disease known as *San Joaquin Valley fever* is caused by the dimorphic fungus *Coccidioides immitis*. It is endemic in the Southwest region of the United States, Central America, and Mexico and is characterized by a respiratory infection and fever after an incubation period of 7 to 28 days. The route of infection follows inhalation of the fungus, and the disease may then spread from the primary lung focus to involve the liver. Extrapulmonary disease is rare, but case reports clearly show that both liver and biliary involvements are manifestations of coccidioidomycosis.

A 26-year-old man from New Delhi had right upper quadrant pain, and ultrasonography revealed a solitary right lobe liver abscess. Aspiration of the abscess revealed pure growth of coccidioidomycosis, which was confirmed with culture (172). In the United States, 8 of 1,347 (0.59%) patients who underwent liver transplantation at a California medical center had coccidioidomycosis, showing that this organism can cause a serious and in some cases fatal infection after liver transplantation and that the incidence of this disease appears to be increasing (173).

The usual clinical features are those of nonspecific anicteric hepatitis, often with biochemical cholestasis, in a person who has recently traveled to Mexico or the American Southwest. It commonly presents as a hepatopulmonary syndrome with eosinophilia (174). Biopsy of the liver shows granulomatous hepatitis (174,175). In rare instances, obstructive jaundice may relate to granulomatous involvement of the bile duct epithelium. Ramirez et al. (176) reported the case of a 43-year-old man from Arizona who had fever and abdominal pain followed by jaundice and a cholestatic biochemical profile with no obvious lung involvement. The bilirubin level reached 7.4 mg/dL, and endoscopic cholangiography showed an irregular stricture involving the common bile duct and intrahepatic biliary tree necessitating placement of a biliary stent. Biopsy of the lymph node performed at laparotomy showed granuloma with spherules, and complement fixation antibody testing confirmed the presence of coccidioidomycosis. Endoscopic retrograde cholangiopancreatography after successful therapy (fluconazole and intravenous amphotericin B) showed resolution of the stricture.

Among 37 immunosuppressed patients who received liver transplants who later moved to Arizona, the incidence of new coccidioidal infection was 2.7%, suggesting that coccidioidomycosis was not frequent in this population (177). Nevertheless, among patients with end-stage liver disease listed for transplantation in this same region of Arizona, the incidence of new coccidioidal infection was 4.2%, compared with 0.04% in the same county in the general population. The authors suggested that treatment might alleviate some of the

symptoms of coccidioidomycosis originally attributed to disease of the liver (178).

Other Infections

Neisseria

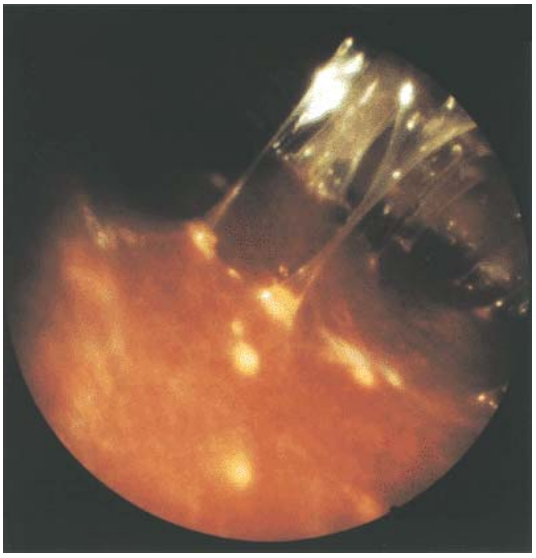
Nonspecific aminotransferase abnormalities occur in disseminated gonococcal infection (179,180). Cervical and pelvic gonorrhea may be associated with violin-string adhesions between the liver capsule and the peritoneal wall, known as Fitz-Hugh-Curtis syndrome. However, such adhesions are not pathognomonic for Neisseria infection, and may occur after other infections, including hepatic candidiasis (Fig. 50.13) (149).

Chlamydia

A similar syndrome of perihepatitis occurs with infection with *Chlamydia trachomatis* (181), which may also cause prolonged fever and liver granuloma (182).

Campylobacter

Mild liver dysfunction as well as acute hepatitis–like biochemical values may occur after infection with *Campylobacter* organisms (183). The organism has been isolated from bile during episodes of cholecystitis in association with gallstones (184).



▪ **Figure 50.13** Perihepatic adhesion (Fitz-Hugh-Curtis syndrome) may occur in conditions other than gonorrhea. After therapy for hepatic candidiasis, a follow-up laparoscopy showed violin-string adhesions from the focal lesions to the peritoneal wall. Such adhesions may result in marked right upper quadrant pain.

Shigella

Anecdotal case reports include a case of cholestatic hepatitis following infection with *Shigella sonnei* (185) and anicteric hepatitis associated with *Shigella flexneri* infection (186).

Yersinia

Cases of granulomatous hepatitis and cholestasis have been reported in association with disseminated yersinia infections (187).

Catscratch Disease

Hepatosplenic catscratch disease often manifests as fever of unknown origin in children who have had contact with an immature cat. The disease occurs when *Bartonella henselae* causes necrotizing granuloma in the liver or spleen or both. Fleas have also been suggested as vectors for this organism, because catscratches may be absent in some cases. Abdominal pain is common and occasionally is severe. Abdominal ultrasonography shows microabscesses in the liver or spleen. Positive serologic results for *B. henselae* establish the diagnosis. Several antibiotic regimens have proved effective (188). Among HIV-infected patients, a syndrome of peliosis hepatis (bacillary angiomatosis) is caused by *B. henselae* infection. Serologic assays, indirect immunofluorescence, and PCR assays may assist in diagnosis (189); prolonged antibiotic regimens with erythromycin, doxycycline, or macrolides have proved effective in various series (190,191).

Chapter 51

Hepatobiliary Manifestations of Human Immunodeficiency Virus

Neeraj Saraf
Cem Cengiz
James S. Park
Douglas T. Dieterich

Key Concepts

- Liver disease has assumed a far greater importance as a cause of morbidity and mortality in patients infected with human immunodeficiency virus (HIV) because of their increased life expectancy as a result of antiretroviral therapy (ART).
- Hepatobiliary disease in HIV-infected patients can be divided into two groups: Those with severe immunosuppression, who commonly have opportunistic infections, and those with suppressed HIV viral loads and minimal immunosuppression.
- Because of shared modes of transmission, coinfection with hepatitis B virus (HBV) and hepatitis C virus (HCV) is common. HCV-related liver disease is an important cause of morbidity and mortality. HIV accelerates the natural history of HCV infection. Combination therapy with pegylated interferon and ribavirin is effective in treating these patients.
- Hepatotoxicity associated with ART is a major cause of morbidity in HIV-infected patients. Steatosis and HIV-associated lipodystrophy are emerging as distinct entities causing liver disease in this group of patients.
- HIV infection was earlier considered a contraindication to liver transplantation. In recent years, liver transplantation is emerging as a cornerstone in the management of end-stage liver disease in HIV-infected patients.

Since its recognition more than two decades ago, the natural history of infection with human immunodeficiency virus (HIV) has undergone a vast change, from a disease associated with high mortality, to a chronic illness that may last for decades without significant morbidity. With the introduction of antiretroviral therapy (ART) in 1996, HIV-infected patients have experienced dramatically prolonged survival, resulting in patients falling sick from comorbidities unrelated to HIV. Liver disease has become one of the most important factors affecting survival, quality of life, and health care costs among HIV-infected patients. HIV-infected patients experience an array of hepatic manifestations (Table 51.1).

Given the shared epidemiologic risks, patients with HIV are commonly coinfected with hepatotropic viruses, and in particular coinfection with hepatitis C virus (HCV) which is now the leading cause of liver disease in HIV-infected patients in developed nations. Hepatotoxicity associated with ART also contributes significantly to liver disease in HIV-infected patients. In recent years, with the effective use of ART, opportunistic infections have assumed a lesser role in contributing to liver disease, although they are still an important cause of morbidity in developing countries. Steatosis and HIV-associated lipodystrophy are now being considered as distinct entities in this group of patients. Hepatic manifestations of HIV-infected patients without significant immunosuppression result from coinfection as with other hepatotropic viruses. The natural history, pathogenesis, and management of the hepatitis viruses in the presence of HIV infection are discussed in the subsequent text.

Table 51.1. Major Causes of Liver Injury in HIV-Infected Patients

DRUGS
- ART: NRTI, NNRTI, PI
- Antimicrobial agents:
  - Antituberculosis (INH, rifampin)
  - Macrolides (clarithromycin, azithromycin)
  - Antifungal (ketoconazole, itraconazole, fluconazole)
  - Antipneumocystis (TMP-SMX, pentamidine, dapsone)

INFECTIONS
- Viral (HAV, HBV, HCV, HDV, GBV-C, CMV, HSV, VZV, EBV)
- Mycobacterial (*Mycobacterium avium*, *Mycobacterium tuberculosis*, other mycobacteria) Fungal (cryptococcus, histoplasma, coccidioides, candida)
- Protozoan (pneumocystis, toxoplasma, microsporidia, cryptosporidium)

BILIARY TRACT INFECTIONS
- HIV cholangiopathy
- Acalculous cholecystitis

NEOPLASMS AND VASCULAR LESIONS
- Kaposi sarcoma
- Lymphoma
- Peliosis hepatis

STEATOSIS WITH LIPODYSTROPHY
- HCV/HIV coinfection
- Drug-associated (PI and NRTI)

ART, antiretroviral therapy; NRTI, nucleoside reverse transcriptase inhibitors; NNRTI, non-nucleoside reverse transcriptase inhibitors; PI, protease inhibitor; INH, isonicotonic acid hydrazide; TMP-SMX, trimethoprim-sulfamethoxazole; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; GBV-C, hepatitis G virus; CMV, cytomegalovirus; HSV, herpes simplex virus; VZV, varicella-zoster virus; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus.

Hepatitis B Virus

Because of common epidemiologic risks of transmission including sexual and parenteral exposures, coinfection of hepatitis B virus (HBV) with HIV is common. Coinfection rates vary by risk factors, geographic region, and endemicity, being the highest among men who have sex with men (6% to 10%) in developing countries (1,2,3). As a consequence, up to 80% of HIV-infected patients have serologic markers of present or past HBV infection (hepatitis B surface antibody [anti-HBs] or hepatitis B core antibody [anti-HBc] positive) and 10% to 15% are chronic HBV carriers (hepatitis B surface antigen [HBsAg] positive) (2,3,4). Decreased response to HIV-ART and a higher risk of hepatic decompensation was observed in HBV/HIV-coinfected patients compared with those of HIV-monoinfected patients (5). Chronic liver disease because of viral hepatitis has emerged as one of the leading causes of mortality and morbidity in HIV-infected patients in the post-ART era (6).

Immune Dysfunction in Human Immunodeficiency Virus and Hepatitis B Virus Coinfection

Immune dysfunction related to HIV infection affects the natural history of HBV infection, reflecting the fact that the immune response plays a key role in viral clearance and the hepatic damage associated with HBV infection (7). Cytotoxic CD8+ lymphocytes recognize HBV antigens in the context of human leukocyte antigen (HLA) class I antigen exposed on the surface of infected hepatocytes and destroy them. During clearance of virally infected cells, CD8+ lymphocytes, with CD4+ help, mediate destruction of infected hepatocytes with resultant transaminitis and histologic damage (8). As the CD4+ lymphocytes are crucial for effective CD8+ cell-mediated immunity (CMI), depressed CD4+ cell number and function caused by HIV-mediated destruction will modify the natural history of HBV infection. This is illustrated by the finding that increased risk of chronic infection appears to be inversely correlated with the CD4+ cell count and is likely a result of the inability to promptly and vigorously respond to HBV antigen (9). The importance of the CD4+ cells in the control of HBV is also illustrated by the finding that improvement of HIV-infected patient's immune response with ART may induce spontaneous e antigen (hepatitis B e antigen [HbeAg]) to e antibody (hepatitis B e antibody [HbeAb]) seroconversion of their chronic HBV infection (9). On the other hand, ART-induced immune reconstitution may also be associated with acute hepatitis, presumably because of increased recognition and destruction of HBV-infected hepatocytes (7,10). Decreased anti-HBV immune surveillance resulting from HIV also results in heightened HBV replication, manifested by higher levels of HBV-DNA, higher rates of reactivation of HBV infection, increased HBeAg titer, and a lower rate of spontaneous HBeAg seroconversion (9,11). Despite higher serum HBV-DNA levels, hepatic necro-inflammation tends to be milder in HBV/HIV-coinfected individuals (12) that is in agreement with the postulated immune-mediated pathogenicity of HBV. However, the enhanced replication levels of HBV in HIV-coinfected patients may result paradoxically in the progression of liver fibrosis and increased mortality (11). Consistent with this observation, several clinical studies have shown that the risk of end-stage liver disease is significantly increased in HIV-infected patients with chronic hepatitis B, especially those with low CD4 cell counts (1,2,3,4,5). The diminished immune responses in HIV-infected individuals may enhance a persistent HBV coinfection through covalently closed circular DNA (cccDNA) that

replicates in the cytosol of infected hepatocytes (8). The

term "occult HBV infection" was recently coined to define the presence of HBV DNA in the serum or liver of patients without HBsAg (13). The results of previous studies of occult HBV infection in HIV-infected patients are controversial. Earlier studies have shown high rates of occult infections (14,15). However, recent studies have found very low level (<1%) of such occult HBV infections (16,17). Therefore, the prevalence and potential impact of occult hepatitis B infections are still unclear in the setting of HIV infection.

Treatment

The goals of HBV therapy in patients with HIV/HBV coinfection are suppression of HBV DNA, seroconversion from HBeAg to anti-HBe, normalization of transaminases, and improvement of liver histology. Guidelines for HIV-negative individuals recommend that treatment should be considered for patients with detectable serum HBV DNA above 10^5 copies/mL in HBeAg-positive patients (17a). A lower threshold may be appropriate for HBeAg-negative patients and those with decompensated cirrhosis (thresholds of 10^4 and 10^3 copies/mL, respectively) (17a). At this time, recommendations for the treatment of HBV in the setting of coinfection with HIV should be taken individually and on the basis of consideration of several aspects, including some related to the HIV infection (17a). Drugs approved for the treatment of chronic HBV infection are interferon (IFN), peginterferon α-2a, lamivudine, adefovir dipivoxil, and entecavir. Moreover, other compounds, such as tenofovir disoproxil fumarate and emtricitabine, approved for HIV therapy, also show strong anti-HBV activity. Although not approved for use against HBV, these drugs are often used in HIV-infected patients. Because HBV virions use a reverse transcription step in its life cycle, similar to HIV, nucleoside reverse transcriptase inhibitors (NRTIs) have been used to treat HBV-infected patients. The first NRTI to be used was zidovudine (formerly called *azidothymidine* [AZT]), but when administered in combination with IFN, AZT was no more efficacious than when administered with IFN alone (8). Greater success has been achieved with lamivudine, a potent inhibitor of the reverse transcriptase of HIV and HBV. U.S. Food and Drug Administration (FDA) has approved lamivudine for the treatment of chronic HBV infection (100 mg/day), as well as for the treatment of HBV infection as a component of an ART regimen (300 mg/day). However, the use of lamivudine is limited by the development of a high resistance rate because of a mutation in the (tyrosine, methionine, aspartate, aspartate) YMDD motif of the HBV-DNA polymerase gene (18). In patients with HBV infection alone, resistance ranges from 24% in the first year of treatment to 67% by year 4 (18); in HIV/HBV-coinfected patients, resistance is more frequent, with 47% resistant to lamivudine at year 2 and 90% at year 4 (19). Among patients with the YMDD mutation, many have a rebound in HBV viremia with a subsequent diminished clinical response to lamivudine therapy, aminotransferase flares, and occasional fatal liver failure (20,21). Emtricitabine, a close analog of lamivudine, has been approved for the treatment of HIV infection in the United States and is also active against HBV infection (22). Emtricitabine induces a rapid and sharp reduction in HBV-DNA levels (mean -3·4 $\log_{10}$ in 2 months) at doses of 25 to 300 mg/day (22). Suppression of HBV replication is maintained over 48 weeks of treatment in more than one-half of patients (22). However, not enough data are available on its use in HBV/HIV-coinfected patients. Famciclovir, an acyclic guanine derivative, suppresses HBV replication modestly, but in combination with

lamivudine, shows synergistic antiviral effect (23). Famciclovir-resistant HBV mutations different from lamivudine mutations have been documented during famciclovir monotherapy.

Adefovir dipivoxil is the bioavailable prodrug of adefovir, a nucleotide analog of adenosine monophosphate that was under development for HIV treatment until its use was halted because of nephrotoxicity at doses higher than 30 mg (24). As with lamivudine, the approved HBV infection treatment dose (10 mg/day) is lower than the HIV treatment dose (30 mg/day). Adefovir suppresses HBV DNA replication by 3.52 to 3.91 $\log_{10}$ copies/mL from baseline (25); normalizes transaminase levels in up to 70% of patients with HBeAg-negative chronic hepatitis (24); and causes HBeAg seroconversion in 23% of HBeAg-positive patients (24). Adefovir is also effective in lamivudine-resistant patients (26) and HIV-coinfected patients (27). The use of adefovir may lead to resistance too. The mutations, rtAsn236Thr and rtAla181Val, have been shown to be selected in 3·1% of HBV-monoinfected individuals treated with adefovir monotherapy after 3 years of follow-up (28,29). Tenofovir disoproxil fumarate is a nucleoside analog closely related to adefovir approved for the treatment of HIV. It is not yet approved for treatment of HBV, but reports demonstrate efficacy against both wild-type and lamivudine-resistant HBV strains, even in the presence of lamivudine-resistance mutations (30,31). Increased dosing intervals are also recommended for patients with abnormal renal function to avoid rare renal toxicity (32). A number of studies showed the potent effect of tenofovir in patients with HIV and HBV coinfection, particularly patients who had developed lamivudine resistance (31,33,34). A recent study by van Bommel et al. compared adefovir, 10 mg/day versus tenofovir, 300 mg/day in patients with lamivudine resistance (35). The tenofovir group, that included both HIV seronegative and coinfected patients, had a significantly earlier

response to treatment and a greater mean HBV DNA $\log_{10}$ drop (5.5 vs. 2.8 log) at week 48 than the adefovir group. In addition, all 35 of the patients treated with tenofovir achieved undetectable viral loads at week 48 compared with only 44% of patients taking adefovir. There was also a better serologic response in the group treated with tenofovir with 11 of the patients seroconverting to anti-HBe and 5 of these patients having HBsAg loss corresponding to a cure of their infection (35). There have not been reports of nephrotoxicity in patients on tenofovir therapy for HBV. In clinical studies assessing the efficacy of tenofovir against HBV in HBV/HIV-coinfected patients, HBV DNA levels declined on average 4 $\log_{10}$ with less than 25% of anti-HBe serocoversion, despite most patients carrying lamivudine-resistance mutations in both lamivudine-experienced and naïve patients (31,33,34,35,36,37). Tenofovir may be more potent than adefovir in controlling HBV in patients also infected with HIV (38). At 48 weeks, the mean change in HBV-DNA levels from baseline was -4·4 $\log_{10}$ in the group treated with tenofovir and -3·21 $\log_{10}$ in the group treated with adefovir (38). Nephrotoxicity mediated by renal tubular damage in HIV patients treated with ART has been reported (39). Entecavir, another nucleoside analog, was recently approved by the United States regulatory authorities for treatment of HBV infection (40). Entecavir is active against wild-type and lamivudine-resistant HBV in vitro and in vivo (41). The drug is specific for HBV and lacks any anti-HIV activity and it may be a better choice of therapy for HBV/HIV-coinfected patients who do not need HIV therapy because it does not promote evolution of HIV-resistant virus. Virologic responses to entecavir are seen in patients with lamivudine-resistant HBV, although they tend to be lower than in lamivudine-naive patients. Although

a number of resistance mutations were found in vitro, clinical resistance to entecavir requires multiple mutations in HBV polymerase in vivo, including those linked to lamivudine resistance (42). Therefore, entecavir doses of 0.5 mg/day are recommended in drug-naive patients, and doses of 1.0 mg/day daily are recommended for patients with lamivudine-resistant HBV strains (17a). A recent international trial with 68 HBV/HIV-coinfected patients with 88% lamivudine-related mutations demonstrated at least a 2 $\log_{10}$ copies/mL HBV viral load drop from baseline after 24 weeks of treatment (43).

Recently, the FDA approved peginterferon α-2a for the treatment of chronic hepatitis B infection in patients positive and negative for HBeAg with a higher HBeAg seroconversion rate than that of lamivudine (32% vs. 19%, respectively) (44,45). Peginterferon is more effective in HBeAg-positive patients than HbeAg-negative patients (32% vs. 19%, respectively). Although treatment of HBV with peginterferon has a reasonable success rate in immunocompetent patients, its value in HBV-infected patients with HIV is not known. As mentioned, immunosuppressed HIV-infected patients have higher levels of HBV DNA, lower pretreatment transaminases levels and less hepatic inflammation (4,5,12). These are all predictors of poor response to IFN treatment against HBV. Earlier studies showed that HIV-positive patients are approximately one-fifth as likely to respond to a 12-week course of IFN, clearing HBeAg in less than 10% of patients (46). This is especially true in patients with low CD4 cell counts. However, therapy with IFN may decrease the incidence of HBV cirrhosis regardless of HIV status (47). IFN is contraindicated in patients with decompensated cirrhosis because of the risk of serious bacterial infections and bone marrow suppression (17a). IFN appears to be safe in patients with compensated cirrhosis, although there is a risk of hepatic decompensation with prolonged therapy (17a).

New compounds are currently being tested for the treatment of HBV infection. Unlike the other analogs, Telbivudine (LdT) does not possess anti-HIV activity, it is expected to be approved by the FDA in 2006. Diaminopurine dioxolone (DAPD) and clevudine (L-FMAU) are nucleoside analogs in early clinical investigation that are active against wild-type and lamivudine-resistant HBV. Elvucitabine (β-L-FD4C), another L-deoxycytidine analog, is also a potent antiviral against HBV and HBV in animal models.

As HBV cure is a rare event, maintenance of therapy with long-term nucleoside/nucleotide analogs may be required in most cases. The role of combination therapy in the treatment of HBV is unclear at this time; however, emtricitabine (or lamivudine) plus tenofovir or emtricitabine plus adefovir may be good first choices in HBV/HIV-coinfected patients requiring ART (17a). For HBV/HIV-infected patients not requiring ART, entecavir or peginterferon may be reasonable options. In cases of no clear indication for anti-HBV treatment, the inclusion of active drug(s) against HBV in the ART regimen may be considered to avoid hepatic flares in the context of immune reconstitution (17a).

Hepatitis D Virus

Hepatitis D virus (HDV, delta agent) is a defective RNA virus that requires concurrent infection with HBV (coinfection) or chronic HBV carriage (superinfection) to produce hepatic disease. HDV superinfection causes a more severe liver disease than HBV infection alone, with progression to cirrhosis in 70% to 80% of immunocompetent patients (48). The incidence of this virus is low in the homosexual population, but up to 70% of parenteral drug users carry HDV, many of whom are also HIV-positive (49). Evolution towards cirrhosis tends to be

faster, and the outcome is generally much worse in these multiple coinfected patients

than in individuals with monoinfections (48). HDV is directly cytopathic to hepatocytes, and disease appears to be worsened by immunosuppression, although some observational studies have failed to show an influence of HIV on the clinical course of HDV infection (49). This may be because of the small number of patients studied. HIV infection does not appear to alter the efficacy of IFN treatment for HDV infection; however, the long-term response is poor in both groups even with lamivudine (50). Finally, coinfection with HCV rarely responds to combination therapy with IFN plus ribavirin when delta virus is present (49,50).

Hepatitis A, E, and G Virus

The prevalence, morbidity, and mortality of Hepatitis A virus (HAV) infection are not altered by HIV infection. Despite this, vaccination of HIV-infected patients is recommended, particularly for homosexual patients who are at a higher risk of transmission through person-to-person sexual contact. The presence of chronic HCV appears to increase the risk for fulminant liver disease caused by acute HAV infection, so coinfected patients are excellent candidates for HAV vaccination (51). Hepatitis E virus (HEV), a waterborne or fecal orally transmitted virus, usually causes an acute self-limited disease. A study showed an increased incidence of HEV in HIV-infected patients from a nonendemic area, but without clinical significance (52). A putative hepatotropic virus, hepatitis G virus (GBV-C), is present in approximately 20% to 40% of the HIV-infected patients compared with less than 3% in the general population (53). The presence of GBV-C also does not alter CD4+ cell count or plasma HIV-1 RNA levels in coinfected patients. Although GBV-C does not cause clinical disease, HIV replication is inhibited by GBV-C, translating clinically into an increased survival of HIV-infected patients also infected with GBV-C (54). This virus seems to be a lymphotropic virus that may downregulate cytokines responsible for HIV replication. Another putative hepatotropic virus, transfusion-transmitted virus (TTV) is highly prevalent and replicates to a greater degree in HIV-infected patients, although the significance remains unknown (55). The prevalence of SEN virus and its implications among HIV-infected individuals remain unstudied.

Hepatitis C Virus

In the United States and other developed nations at least 2% of the population is infected with HCV (56). Among all HIV-infected patients in the United States, approximately 16% are coinfected with HCV (57). In addition to both being major health issues, there are many similarities between HIV and HCV infection. Both viruses possess a single strand RNA genome and result in subclinical chronic infection. Each virus is able to evade the host's immune system because of high genetic variability, and the replication rate of both viruses is extremely high. With the introduction of ART, there has been a dramatic improvement in survival of HIV-infected patients (58,59,60). In one year HIV virus can be suppressed to undetectable levels in 70% to 80% of patients. With longer survival patients with HIV infection/disease now increasingly fall sick from comorbid diseases, chief among them being HCV infection. HCV is not classified as an opportunistic infection in HIV-infected patients, but as HIV can accelerate HCV-induced liver disease, it may actually mimic an opportunistic infection (61). Chronic HCV increases both morbidity and mortality in HIV-infected patients. Although overall

mortality of HIV-infected patients has declined, the relative mortality because of liver disease has increased. A 5-year study of a cohort of HIV patients in the ART era found an increased mortality in HIV/HCV-coinfected patients versus HIV-monoinfected patients, with a mortality of 6.7 versus 2.3/100 person years (P = 0.05). Hospitalization of the coinfected group was also more common compared with the HIV-monoinfected group (62). A large French cohort study of more than 17,000 HIV-infected patients compared mortality in pre-ART era to ART era. Although there was a decline in mortality from all causes from 2% to 0.9%, an increase in deaths related to cirrhosis and hepatocellular carcinoma (HCC) from 6.5% to 10% was observed. Coinfection of HCV-infected patients with HIV is common because of shared modes of transmission. The prevalence HCV coinfection varies according to the risk for HIV acquisition; amongst intravenous drug users up to 95% are HCV positive (57,63) and amongst hemophiliacs 73% are HCV positive (57). On the other hand in those belonging to low-risk categories for HCV infection including men who have sex with men, heterosexual persons with exposure to HIV, and health care workers, the prevalence of coinfection is much lower at about 3.5% (57). Vertical transmission of HCV may be increased up to threefold in presence of HIV.

Impact of Human Immunodeficiency Virus and Antiretroviral Therapy on Hepatitis C Virus

In addition to influencing the transmission rate of HCV, HIV also significantly affects the natural history of HCV-related liver disease. In comparison with HBV infection, hepatic damage resulting from HCV infection

is predominantly caused by direct viral toxicity with lesser contribution from the host immune response. Cell-mediated immunity, particularly Th 1 clones play a role in viral clearance through recognition of multiple core epitopes of HCV on virally infected hepatocytes (64,65,66). Given this role, the decline in CD4+ cells associated with progressive HIV infection permits greater HCV replication. In addition to suppressing an active cell-mediated response to HCV, coinfection with HIV also appears to alter the quality of that response. When $CD3^+/CD30^+$ cells are infected with both HCV and HIV, their cytokine production is skewed towards an anti-inflammatory Th 2 response rather than the protective Th 1 response seen when cells are infected with HCV alone (67). Viral escape from cytotoxic CD8+ lymphocytes may also result in enhanced viral replication. Similar to HIV, viral evolution is seen through accumulation of mutations resulting from the high replication rate of this virus in the face of selective pressure from lymphocytes directed against HCV antigens. The HCV hypervariable region, which is a major target of cell-mediated immunity and humoral mechanisms, exhibits greater heterogeneity in HIV-infected patients (68). HCV viral loads are higher in plasma (69,70) and liver (71) in HIV/HCV-coinfected patients compared with HCV-monoinfected patients because of greater HCV replication reflecting the immunosuppressed state. There is a more rapid progression to cirrhosis, end-stage liver disease and HCC in coinfected patients (72,73,74,75,76). Other factors associated with more rapid HCV-related fibrosis are low CD4+ counts, alcohol use, and a higher age at initial HCV infection. However, many of these studies confirming a more rapid progression of liver disease in HIV/HCV-coinfected patients were carried out in the pre-ART era. A number of studies have attempted to assess whether ART affects HCV replication and progression. Although ART causes hepatotoxicity, it is also possible that ART-induced immune restoration might attenuate the increased risk of cirrhosis associated with

coinfection. Earlier studies suggest that protease inhibitors (PIs) did not inhibit HCV replication (77), and the lowering of HIV viral load by ART did not affect HCV viral load (78). One study (79) has shown that ART may retard the progression to fibrosis. In 182 coinfected patients the progression to fibrosis was slower in those on ART, which included a PI, as compared with those who did not receive a PI. The estimated 15-year rate of progression to cirrhosis was 5% versus 18% ($P < 0.001$). In another report it was seen that use of PI-based ART was associated with lower risk of bridging fibrosis or cirrhosis, whereas nevirapine (NVP) was associated with greater risk of disease (80). In a recent study addressing the role of ART in coinfected patients, out of 210 coinfected patients, 64% had received ART within 2 years of liver disease assessment. Of these, 33% had no fibrosis and 23% had bridging fibrosis or cirrhosis. Significantly lower hepatic necroinflammatory scores (mean-3, range 0 to 9 of 18) were observed among persons who received ART longer ($P = 0.02$) and who had HIV RNA suppression ($P < 0.01$). This study suggests that ART use was not protective against fibrosis, although individuals with longer cumulative exposure to ART and HIV RNA suppression had significantly less necroinfammatory activity (81). Identification of noninvasive markers of fibrosis (liver enzymes, albumin, and hyaluronic acid) may help in identifying individuals at greatest risk for cirrhosis (82). Some degree of steatosis has been observed in up to 40% of patients with HCV/HIV coinfection. Patients with steatosis are more likely to have greater hepatic fibrosis and more severe HCV-related liver disease. Obesity, hyperglycemia, and use of stavudine (d4T) have been identified to be modifiable risk factors for steatosis in this population (83). HCC in HIV has a more aggressive course with a higher frequency of infiltrating tumors and extranodal metastases at presentation, portal invasion and reduced survival (84,85). Progression from initial HCV infection to HCC is more rapid in coinfected patients, probably because of a more rapid progression to cirrhosis. Despite a more rapid rate of liver disease progression, the impact of coinfection with HIV on mortality is unclear. Although some studies report a higher liver related mortality (86), others have not shown any effect on survival (87,88). In the ART era, longer follow-up will be necessary to show a difference in mortality in the two groups.

Impact of Hepatitis C Virus on Human Immunodeficiency Virus

HCV may act as a cofactor for HIV disease progression by several mechanisms. The state of permanent immune activation provided by chronic HCV infection can favor HIV transcription within infected cells and cause more rapid destruction of CD4 T lymphocytes (68). Moreover the immune response to ART may be slowed down in the presence of HCV infection (89). Data regarding the influence of HCV on the natural history of HIV diseases is conflicting. The Swiss cohort study with 1,157 patients demonstrated that the risk of HIV progression to clinical acquired immunodeficiency syndrome (AIDS) or death was independently associated with HCV seropositivity (90). On the other hand, in an urban United States cohort (91) of 1,955 patients, HCV infection did not substantially alter the risk of death, clinical AIDS, or the response to ART. Various other studies have also shown mixed results (92,93,94). HCV may also negatively influence HIV disease by resulting in increased liver toxicity and higher treatment discontinuation (95,96).

Diagnosis

All patients with HIV should be screened for HCV. The method of screening is

important as the enzyme-linked immunosorbent assay-2 antibody test (anti-HCV ELISA-2) can result in an estimated 3% to 4% false-negative rate (57,97) in coinfected patients because of impaired HCV antibody production with immunosuppression, a rapid decline in antibody titer, and a possible interaction between the two viruses. Screening with HCV RNA should be done in coinfected patients by either the more sensitive qualitative tests or by quantitative methods using target amplification or signal amplification techniques. The role of liver biopsy in treatment decision has been controversial in HIV/HCV-coinfected patients. Given the effect of HCV on morbidity and mortality, the complexities of therapy for both HIV and HCV infection, and the current limitations of noninvasive markers, liver biopsy continues to play an important role in the evaluation of HCV infection in the setting of HIV coinfection.

Management

Given the impact of HIV-induced immunosuppression on natural history of HCV disease, infection with HCV should be treated as any other opportunistic infection. The goals of treatment of HCV in the presence of HIV are viral eradication, slowing the progression of liver disease, and better tolerance of anti-HIV medication. The adverse effects of anti-HCV therapy and drug interactions must be weighed with the benefits of treatment. The various treatment options and evidence supporting their use are discussed in the subsequent text.

Interferon monotherapy: IFN inhibits virus-induced cytopathic effects, induces natural killer cells and cytotoxic T lymphocytes, and has a role in chemo-attraction of these cell lines to the liver. It stimulates major histocompatibility complex (MHC) Class 1 expression and acts to polarize the adaptive immune response to a Th 1 milieu. In HIV-coinfected patients the end of treatment response to IFN monotherapy has been found to be similar to HCV-monoinfected patients, but sustained virologic responses (SVRs) are rare (98,99). Histologic response has also been observed with IFN monotherapy. Di Martino et al. (100) compared the histologic response to IFN in patients with coinfection and those with HCV alone in a cohort of 79 patients. The rate of histologic improvement (2 point drop in Knodell score on paired liver biopsies) was similar in the two cohorts, but the SVR was much lower in the coinfected group (6% vs. 30%). Treatment with IFN did not significantly change CD4 counts or the HIV RNA levels.

Interferon and ribavirin: Ribavirin is a guanidine analog that has an immunomodulatory action; it increases the production of Th 1 cytokines and decreases the production of Th 2 cytokines. Combination therapy with standard IFN and ribavirin in naive monoinfected HCV patients achieves an SVR of 17% to 29% in patients with genotype 1 and 65% to 67% in genotype 2 and 3. In HIV/HCV-coinfected patients, combination therapy appears to be well tolerated and SVR rates are better than those with IFN alone. The American Foundation for AIDS Research Study DCRI 010 (101), in a randomized controlled trial in HIV/HCV coinfection used therapy with IFN-2b at 3 MIU three times weekly combined with either initial or 16-week delayed ribavirin at 800 mg/day in 106 patients. The response at week 12 was 23% in the combination group compared with 5% in IFN and placebo group (P = 0.016), proving that even in coinfection the addition of ribavirin improves initial response. However, the difference in SVR between the two groups was not statistically different (11% vs. 5%). In the Hepatitis Resource Network study HRN-002, a controlled trial of 155 coinfected

patients showed that daily IFN in combination with ribavirin was more effective in obtaining an SVR than a standard IFN regimen given thrice weekly (19% vs. 8.6%, *P* < 0.001). In this study, early virologic response (EVR) was a strong predictor of SVR (102).

Pegylated interferon and ribavirin: The use of standard IFN has now been largely replaced by peginterferon, and treatment with peginterferon in combination with ribavirin is now the standard of care in managing HIV/HCV-coinfected patients. In the largest study so far, the AIDS Pegasys Ribavirin International Coinfection Trial (APRICOT) (103), a total of 868 subjects with HCV and HIV coinfection were assigned to receive one of three regimens: Peginterferon α-2a (180 μg/week) plus ribavirin (800 mg/day); peginterferon α-2a plus placebo; or IFN-α-2a (3 million IU thrice a week) plus ribavirin. Baseline characteristics were well-matched between the three groups. The overall rate of SVR was significantly higher in the group receiving peginterferon and ribavirin than in that receiving standard IFN and ribavirin (40% vs. 12%, *P* < 0.001), or peginterferon plus placebo (40% vs. 20%, *P* < 0.001). SVR in genotype 1 was 29% in group 1, which is higher than the previous studies. Genotypes 2 and 3 were treated for 48 weeks and achieved a SVR of 62% in the group treated with peginterferon and ribavirin. In the group treated with peginterferon and ribavirin, a baseline HCV viral load of more than 800,000 IU/mL led to a significantly lower

SVR rate in genotype 1 as compared with those with viral load less than 800,000 IU/mL (18% vs. 61%), but not in genotypes 2 and 3 (63% vs. 61%). Multivariate logistic regression analysis identified genotype non-1 and HCV RNA level less than 800,000 IU/mL, as independently associated with higher SVR. Age, race, liver histology, CD4+ counts, and ART did not influence SVR rates. In the peginterferon and ribavirin group, the HIV viral load decreased by 0.7 log 10, which supports the concept that IFN leads to decline in HIV viremia. In the AIDS Clinical Trials Group (ACTG) study (104), a total of 66 patients were randomly assigned to receive 180 μg of peginterferon α-2a weekly for 48 weeks along with ribavirin escalating from 600 to 1,000 mg/day. Sixty-seven patients were given 6 million IU of standard IFN thrice a week for 12 weeks followed by, 3 million IU three times a week for 36 weeks along with the same dose of ribavirin. At the primary end point, week 24, viral response was better in the peginterferon rather than the IFN group (44% vs. 15%; *P* < 0.001). Treatment with peginterferon and ribavirin was associated with a significantly higher rate of SVR than treatment with standard IFN and ribavirin (27% vs. 12%, *P* = 0.03). In the group given peginterferon and ribavirin only 14% of patients with HCV genotype 1 had a SVR, as compared with 73% in other genotypes. Independent factors associated with higher SVR were genotype non-1 infection, no prior intravenous drug use, and an undetectable HIV RNA at baseline.

Although a slower decline in HCV RNA level is seen in coinfected patients after standard therapy is initiated with peginterferon and ribavirin, the stopping rule at week 12 that is recommended for HCV-monoinfected patients seems to be equally valid in HIV-positive patients (103,104,105). In the ACTG trial (104), of the 106 subjects in whom HCV RNA levels were measured at week 12, 43 (41%) had an EVR. Twenty-two of them (51%) had a SVR; in contrast none of the 63 patients who did not have an EVR achieved a SVR (negative predictive value 100%). Similarly, in the APRICOT

(103) study only 2% of the patients who did not have an early response went on to have an SVR (negative predictive value 98%). When an EVR was defined as one occurring at week 24, the results were similar. In a large French randomized controlled trial of 412 HIV/HCV-coinfected patients, the RIBAVIC study (105), 48 weeks of weekly peginterferon in combination with 800 mg/day ribavirin was compared with thrice a week standard IFN and ribavirin treatment. SVR was achieved in 20% of IFN patients versus 27% of peginterferon patients (P = 0.047). However, the peginterferon therapy was superior to standard IFN therapy only in genotype 1 or 4 (17% vs. 6%; P = 0.01), but not in genotypes 2 and 3 (44% vs. 43%; P = 0.88). Similar to the APRICOT and ACTG studies, the week 12 EVR had a high negative predictive value of 99%. In a smaller randomized controlled trial (106), 95 patients were randomly assigned to receive either peginterferon at 100 µg (<75 kg) to 150 µg (>75 kg) once weekly or standard IFN 3 million IU thrice a week, each combined with ribavirin 1,200 mg/day (>75 kg), 1,000 mg/day (60 to 74.9 kg), and 800 mg/day (<60 kg). Treatment was given for 48 weeks in genotype 1 and 4, and for 24 weeks in genotype 2 or 3. The peginterferon plus ribavirin group had a higher SVR in genotypes 1 and 4 as compared with the IFN plus ribavirin group (38% vs. 7%; P = 0.007). However, in genotypes 2 and 3 there was no significant difference in SVR between the two groups (53% vs. 47%; P = 0.73). This and the RIBAVIC (105) studies suggest that the peginterferon and ribavirin treatment has superior SVR rates only in genotype 1, and not in genotypes 2 and 3. This study used a higher dose of ribavirin and showed SVR of 38% in genotype 1. This is higher than those reported in other studies, suggesting that HIV/HCV-coinfected patients may have a higher SVR with a higher dose weight–based ribavirin regime. In summary, therapy with peginterferon and ribavirin is superior to standard IFN and ribavirin, and achieves overall SVR rates of up to 40% (Fig. 51.1). The difference is more marked with genotype 1 as compared with genotypes 2 and 3.

Adverse Effects of Therapy

Common side effects of IFN and ribavirin therapy include fatigue, influenza-like symptoms, hematologic abnormalities, gastrointestinal disturbances, and neuropsychiatric symptoms. Both standard interferon and peginterferon have similar side effect profiles and discontinuation rates. In the APRICOT (103) study the rate of premature discontinuation was 12% in the peginterferon plus ribavirin group. The dose of peginterferon was reduced in 34% because of neutropenia and thrombocytopenia. The dose of ribavirin was reduced in 16% because of anemia. Similarly, in the ACTG (104) trial the treatment discontinuation rate was 12%, whereas in the RIBAVIC (105) study the discontinuation rate was 17% and serious side effects were seen in 32% cases. There are specific toxicities observed in this population as a result of having a concomitant chronic illness, drug

interactions, and higher susceptibility to the usual side effects of antiviral therapy. A clinically significant interaction is seen between IFN and AZT, leading to anemia from bone marrow suppression. The more profound anemia seen during HCV therapy in coinfected patients is a combined effect of hemolytic anemia caused by ribavirin and the failure of the suppressed marrow to compensate for the loss of red blood cells. Anemia in this setting can be managed by reducing

the dose of ribavirin and avoiding AZT wherever possible. Erythropoetin is effective in treating anemia in coinfected patients undergoing anti-HCV therapy and has an efficacy similar to monoinfected patients (107,108). Recent studies have not found a difference in neutropenia in patients receiving IFN plus ribavirin with or without concomitant AZT (101,103). Moreover, neutropenia does not lead to a higher rate of infection in this group of immunosuppressed patients (102). Ribavirin enhances the phosphorylation of didanosine (ddI) resulting in an increased risk of mitochondrial toxicity, pancreatitis, lactic acidosis, and fulminant hepatic failure (109). As a result the FDA has issued a black box warning for the use of ribavirin and ddI. Toxicity may also be seen with other NRTI particularly those with a high affinity for the mitochondrial enzyme DNA polymerase γ. d4T, zalcitabine (ddC), and ddI should be avoided. A reasonable approach would be to avoid combining these drugs with ribavirin and to use a less hepatotoxic agent like lamivudine, tenofovir, or abacavir. Liver enzymes, amylase and lactate should be monitored monthly while using the drugs. Liver decompensation during the treatment is also a complication of anti-HCV therapy in the coinfected patients. The rate of hepatic decompensation in this group of patients with cirrhosis is 7.8% to 10.4% (103,105). In the APRICOT study four factors were found to be associated with decompensation: Increase in total bilirubin, increase in alkaline phosphatase (ALP), fall in hemoglobin and use of ddI for HIV therapy. Therefore, coinfected patients with cirrhosis should be closely monitored during anti-HCV treatment and ddI should be avoided wherever possible. Active psychiatric illness, and active alcohol and drug use, are other barriers to anti-HCV treatment in coinfected patients (110). Current treatment with peginterferon and ribavirin is generally well tolerated with adverse events similar to those observed in HCV-monoinfected patients. Benefits of the treatment must be weighed against the risks of therapy, and the treatment should be individualized in this group of patients. Judicious use of erythropoietin, granulocyte colony stimulating factor (GCSF), and antidepressants can improve tolerance to treatment and outcome of therapy.

Approach to Management of Human Immunodeficiency Virus/Hepatitis C Virus Coinfection

The 2002 National Institutes of Health (NIH) Consensus Development Conference on the management of HCV recommends treatment of HIV/HCV coinfection on a case-by-case basis (56). Several factors should be considered when deciding to start anti-HCV or anti-HIV therapy in coinfected patients (Fig. 51.2).

P.1410

HIV therapy with ART may slow the progression of HCV-induced liver fibrosis, moreover, immune reconstitution associated with PIs can help reduce the HCV viral load, and therefore, initiating ART therapy may improve the efficacy of anti-HCV therapy and should be a priority in managing the coinfected patient. On the other hand, chronic HCV infection is an independent risk factor for ART-induced hepatotoxicity. It has been shown that prior treatment of HCV infection decreases the rate of severe hepatotoxicity with ART. In a study evaluating 66 patients pretreated with anti-HCV therapy, and 39 patients without HCV treatment, the rate of discontinuation of ART was significantly higher in the untreated group as compared with those who were previously treated for HCV ($P < 0.01$) (111). Anti-HCV therapy should be initiated in all patients with elevated transaminases, stable HIV disease (HIV RNA <50,000), high CD4 counts (>350 cells/μL), and no opportunistic infections. Favorable HCV genotypes (2 and 3), advanced stage of fibrosis, and compensated liver disease also influence the decision to start anti-HCV treatment. Individuals with active alcohol and substance abuse, and prior severe neuropsychiatric illness should not be treated. In patients with low CD4 counts (<200), high HIV RNA levels and presence of opportunistic infections, HIV treatment takes priority. Treatment in patients with normal transaminases should be on the basis of the presence of significant liver fibrosis on biopsy. Patients with CD4 counts between 200 and 350 cells/μL, should be treated with caution (112). In contrast with HCV-monoinfected patients, HIV/HCV-coinfected patients with all genotypes should be treated with peginterferon and ribavirin for a period of 1 year. Patients with advanced fibrosis and cirrhosis should be treated for a year in order to delay the clinical and histologic progression of diseases. Maintenance therapy with peginterferon may also be considered in such patients even if HCV clearance is not achieved. In the recent ACTG trial (104) it was found that in subjects without a virologic response at week 24 who underwent liver biopsies, over one third had histologic evidence of improvement,

P.1411

suggesting a role for maintenance therapy. Patients with decompensated liver disease should not be treated with anti-HCV therapy, given the high risk for treatment-related side effects. Management in these patients is focused on symptomatic treatment, and referral for liver transplantation. In a retrospective cohort study (113), survival of 1,037 HCV-monoinfected and 180 HCV/HIV-coinfected patients with cirrhosis after first hepatic decompensation was analyzed. Out of these, 386 (37%) HCV-monoinfected patients and 100 (56%) coinfected patients died during follow-up. The median survival time of HIV-infected and HIV-noninfected patients was 16 and 48 months respectively ($P <$

0.01). HIV coinfection reduces the survival of patients with HCV-related end-stage liver disease, and this factor should be taken into account for proper timing of liver transplantation in these patients.

Hepatotoxicity Associated with Antiretroviral Therapy

Drug toxicity secondary to antiretroviral (ARV) and other agents as well as their interactions is a major concern in the treatment of HIV seropositive patients. Although asymptomatic and reversible in most cases, ART has been reported to cause severe (i.e., grade 3 or 4 inflammation; alanine aminotransferase [ALT] or aspartate aminotransferase [AST] >5–10, and >10 times the upper limit of normal [ULN], respectively) liver injury requiring cessation of therapy in up to 30% of patients (114,115,116,117,118). ARV drug-specific factors such as hepatic metabolism, intrinsic effects, and interaction with the other drugs as well as patient-related factors including age, preexisting liver disease like chronic viral hepatitis, alcohol abuse, concomitant use of potentially hepatotoxic drugs,

and opportunistic infections may all contribute to the risk of liver toxicity. There are different mechanisms through which ARVs exert their toxic effects in the liver.

Hepatotoxicity Associated with Nucleoside Reverse Transcriptase Inhibitors

NRTIs are competitive inhibitors of viral reverse transcriptase terminating chain elongation of viral DNA. They have been associated with grade 3 or 4 hepatotoxicity in 5% to 6% of the patients in several cohort studies (115,119). However, very rarely they lead to steatosis, lactic acidosis, and liver failure with varying mortality rates (120,121,122,123). The underlying mechanism of liver injury attributed to NRTIs is associated with mitochondrial toxicity because of their inhibition of mitochondrial DNA polymerase-γ (124). This leads to impaired oxidative phosphorylation and fatty acid oxidation, which in turn results in hyperlactatemia and microvesicular steatosis. The degree of hepatotoxicity seems to be correlated with their potential to cause mitochondrial damage. Therefore, ddC, d4T, and ddI are the most common drugs in this group causing severe liver injury with life-threatening lactic acidosis in approximately 1% of the subjects (121,122,123,12). However, most patients have asymptomatic chronic hyperlactatemia. Hepatotoxicity typically occurs sometime after 3 months. Apart from the liver injury, mitochondrial toxicity is also manifested clinically as myopathy, neuropathy, and pancreatitis (126). Abacavir differs from the rest of the group in that although much safer in regard to lactic acidosis and subsequent liver injury, it is associated with a life-threatening hypersensitivity reaction manifesting within the first 2 weeks of initiation, which may also include liver dysfunction (126,127,128).

Hepatotoxicity Associated with Non-Nucleoside Reverse Transcriptase Inhibitors

Non-nucleoside reverse transcriptase inhibitors (NNRTIs) also inhibit HIV reverse transcriptase without nucleotide chain incorporation. Some of the previous studies raised concern that serious hepatic events are more common in patients treated with NNRTI-based (NVP in particular) regimens than NRTI or PI-based regimens (115,129,130). However, a recent analysis of hepatotoxic events from four cohorts (Amsterdam, CHORUS, ICONA, and TARGET) including 5,133 patients revealed that there was no consistent risk of long-term liver toxicity attributable to a specific ARV drug (131). In addition, another recent comprehensive review of 17 clinical trials and cohort studies between 1991 and 2001 derived from the FDA database demonstrated that the risks of developing grade 3 or 4 change with NVP or efavirenz-based therapies were similar to those associated with other ARV drugs (132). Similarly, serious clinical (symptomatic) hepatotoxicity was detected in 5% of those treated with NVP. NVP rarely causes a hypersensitivity reaction characterized by rash, eosinophilia, and fulminant hepatitis within the first 6 weeks of treatment that may be fatal (133,134). This type of reaction has been identified more often in women with relatively higher CD4 counts. Therefore, a warning has been issued by the manufacturers notifying the risk of hepatotoxicity, which is approximately 12-fold higher in women with CD4 count of more than 250 cells/mm^3 or men with CD4 counts of more than 400/mm^3. NVP should not be taken as HIV prophylaxis after needle stick exposure. The data also showed an increased risk of severe hepatotoxicity with NNRTIs in patients with concomitant chronic hepatitis B or C as well as in patients with elevated baseline transaminases

greater than 2.5 times the ULN (131,132,135). Overall, NNRTIs continue to be used because of their greater efficacy and tolerability.

Hepatotoxicity Associated with Protease Inhibitors

PIs interfere with the formation of viral reverse transcriptase. Some clinical studies have indicated that among all PIs, the use of full-dose ritonavir is associated with a higher risk of severe hepatotoxicity compared with other PI-based regimens and is the single most important predictor of grade 3 or 4 liver injury (115,118,136). However, recent data suggest that ritonavir associated liver toxicity is comparable to other PI-based regimens at lower doses to boost the levels of other PIs, like lopinavir or indinavir (137,138,139). Similar to NNRTIs, chronic hepatitis B or hepatitis C coinfection is associated with an increased risk of severe hepatotoxicity, particularly in patients not receiving full-dose ritonavir (115,116,118,129,136,140,141). On the other hand, most HCV-coinfected patients do not develop severe hepatotoxicity (139). Immune reconstitution that is an increase in CD4 count as a result of ART and subsequent acute hepatotoxicity with viral seroconversion has been suggested as a mechanism of PI-associated liver injury (142,143). But, this theory fails to explain ART-associated hepatotoxicity observed in subjects without viral hepatitis.

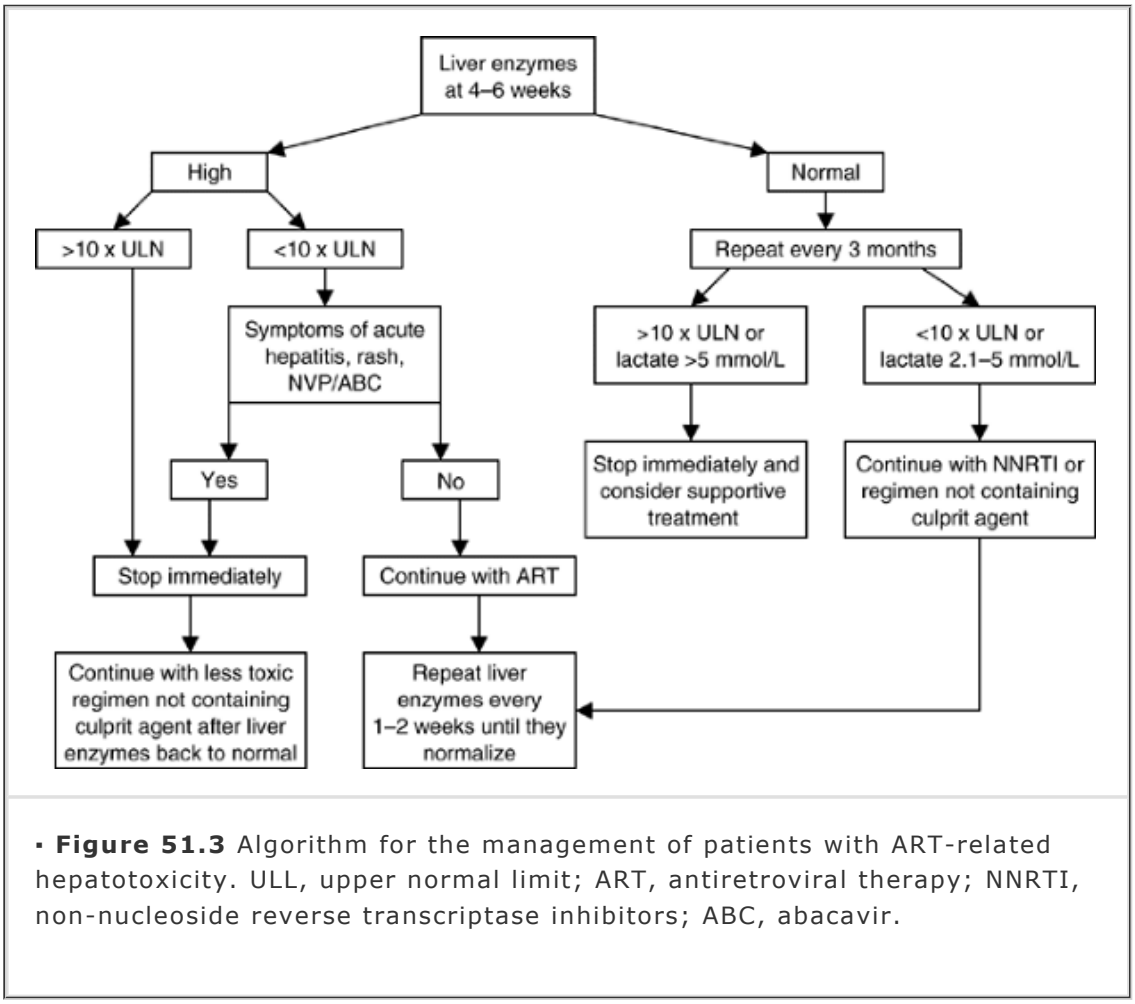
Clinically, the use of PIs may be associated with lipoatrophy, truncal-abdominal fat deposition, hyperlipidemia, insulin resistance (IR), and subsequent fatty liver (144). Indinavir may cause a hypersensitivity reaction whereas saquinavir and nelfinavir are more likely to act as direct hepatotoxins. In addition, indinavir and atazanavir are associated with asymptomatic indirect hyperbilirubinemia similar to Gilbert's disease as a result of their inhibition of uridine diphosphate (UDP)-glucuronosyl transferase activity.

Evaluation and Management of Patients with Hepatotoxicity

The most useful and analytic approach to a patient with drug-related toxicity is suggested by Nierenberg (145) addressing five specific questions: (i) Has this type of adverse reaction been observed previously? (ii) Was the timing appropriate? (iii) Does the problem improve with discontinuation of therapy with the drug? (iv) Does the problem recur with reexposure to the potential culprit? (v) Were the other likely causes of hepatitis excluded? Therefore, the possibility of ARV hepatotoxicity in a given patient should be assessed initially using this algorithm. Patients undergoing ART should have baseline liver function tests, screening for hepatitis A, B, C and also precise recording of alcohol consumption. Liver enzymes should be repeated at 4 to 6 weeks following initiation of ART and at least every 3 months thereafter if the values are within normal limits. Therapy must be completely withheld in case of liver enzyme elevation (LEE) within the first 4 to 6 weeks in patients undergoing treatment with NVP or abacavir because of the possibility of hypersensitivity reaction. Beyond 3 or more months, LEEs accompanied by nausea, vomiting, abdominal pain, fatigue, weight loss, and serum lactate levels between 2.1 to 5 mmol/L should prompt the physician to stop NRTI therapy or to replace it with a non-NRTI agent. In the absence of symptoms, serum lactate level greater than 5 mmol/L mandates withdrawal of all ART immediately, and to consider supportive treatment with vitamin B_1 (thiamine), B_2 (riboflavin), carnitine, coenzyme Q10, and/or vitamin C. In

patients without symptoms of acute liver failure or hyperlactatemia, the presence of LEEs less than or equal to 10 times the ULN requires repeating liver enzymes every 1 to 2 weeks until they improve or normalize as ART continues. However, LEEs exceeding 10 times the ULN, even in the absence of symptoms evoking liver failure warrant prompt withdrawal of ART. ART-induced hepatotoxicity is more likely if the regimen contains d4T, ddI, AZT, NVP or PIs, and no other cause of injury such as alcohol intake, concomitant drug toxicity, or hepatitis with other hepatotropic viruses (e.g., HAV, cytomegalovirus [CMV], herpes simplex virus [HSV] or Epstein-Barr virus [EBV]) is detected. A new regimen containing less hepatotoxic drugs like abacavir, lamivudine, or tenofovir may be considered after normalization of liver enzymes. An algorithm summarizing the approach to a patient with ART-associated hepatitis is depicted in Figure 51.3.

There are a variety of medications contributing to liver toxicity when taken together with ART. Among them, hydroxyurea in combination with NRTIs and particularly d4T/ddI, may cause acute liver failure with hepatic necrosis. As all PIs are metabolized in the liver by cytochrome P-450 (CYP450) system, concomitant medications that are also metabolized by CYP450 (e.g., isotonicotonic acid hydrazide [INH], rifampin, macrolides, ketoconazole) and PIs may potentiate hepatotoxicity of each other. In addition, caution is recommended when using statins in the treatment of PI-related hyperlipidemia as they may also contribute to hepatotoxicity. And finally, ddI and d4T, which have the greatest risk of mitochondrial toxicity, should not be coadministered with ribavirin in HIV/HCV-coinfected patients as ribavirin raises the intracellular levels of these agents increasing the frequency of hepatotoxicity.



▪ **Figure 51.3** Algorithm for the management of patients with ART-related hepatotoxicity. ULL, upper normal limit; ART, antiretroviral therapy; NNRTI, non-nucleoside reverse transcriptase inhibitors; ABC, abacavir.

Steatosis and Lipodystrophy in Human Immunodeficiency Virus–Infected Patients

The risk factors of steatosis in non-HIV population such as obesity, diabetes, and alcohol are also valid in HIV patients. Moreover, NRTIs such as d4T, ddC, zidovudine, and ddI may lead to severe microsteatosis along with lactic acidosis in these patients through the impairment of mitochondrial β-oxidation as mentioned previously. In vitro studies have demonstrated that PIs induce inhibition of adipocyte maturation as well as apoptosis and increase lipolysis (146,147,148). PIs have also been associated with hyperlipidemia, IR and consequent hepatic steatosis. IR and the incidence of lipoatrophy are significantly increased in HIV/HCV-coinfected patients compared with those with HIV alone (149). In addition, IR is also significantly associated with steatosis and fibrosis in this group of patients and has an important role in histologic progression of the disease (150). Hepatic steatosis was observed in 40% of HIV/HCV-coinfected patients in a more recent study published by the Johns Hopkins group (151). Although, ART did not seem to have a significant impact on the prevalence of steatosis in their cohort of patients, exposure to d4T was associated with a more than fivefold higher risk of steatosis. These data also suggest that hepatic steatosis is associated with more severe HCV-related liver disease in HIV/HCV-coinfected patients than has been shown previously for HCV-monoinfected patients. PIs and NRTIs acting synergistically are primarily responsible for HIV-related lipodystrophy (HIVLD). Further, several large cohort studies found a

correlation between the duration of therapy with PIs or NRTIs and the development of HIVLD (153,154,155). There is no definite therapy for HIV-related lipodystrophy. In several studies, metformin decreased IR and visceral adipose tissue (156,157). Among the currently available therapies, thiazolidinediones seem to be the best option as they increase insulin sensitivity and subcutaneous adipose tissue while decreasing visceral adipose tissue (158,160). Switching from a PI regimen to another regimen offers very little clinical benefits (160,161,162).

Liver Infections in Human Immunodeficiency Virus–Infected Patients with Severe Immunosuppression

As HIV infection has turned into a well-controlled chronic disease with relatively preserved CD4 counts

after the introduction of ART, the incidence of opportunistic infections has declined substantially. However, severely immunosuppressed HIV patients are susceptible to a variety of opportunistic infections involving the liver. These may be seen in 33% to 78% of autopsy series including patients with AIDS (163,164), and in liver biopsy of almost 90% of HIV seropositive patients with abnormal liver function tests (165). A thorough clinical and diagnostic workup is warranted, which may include liver biopsy with appropriate cultures and staining, provided that less invasive tests are not conclusive.

Viral Infections

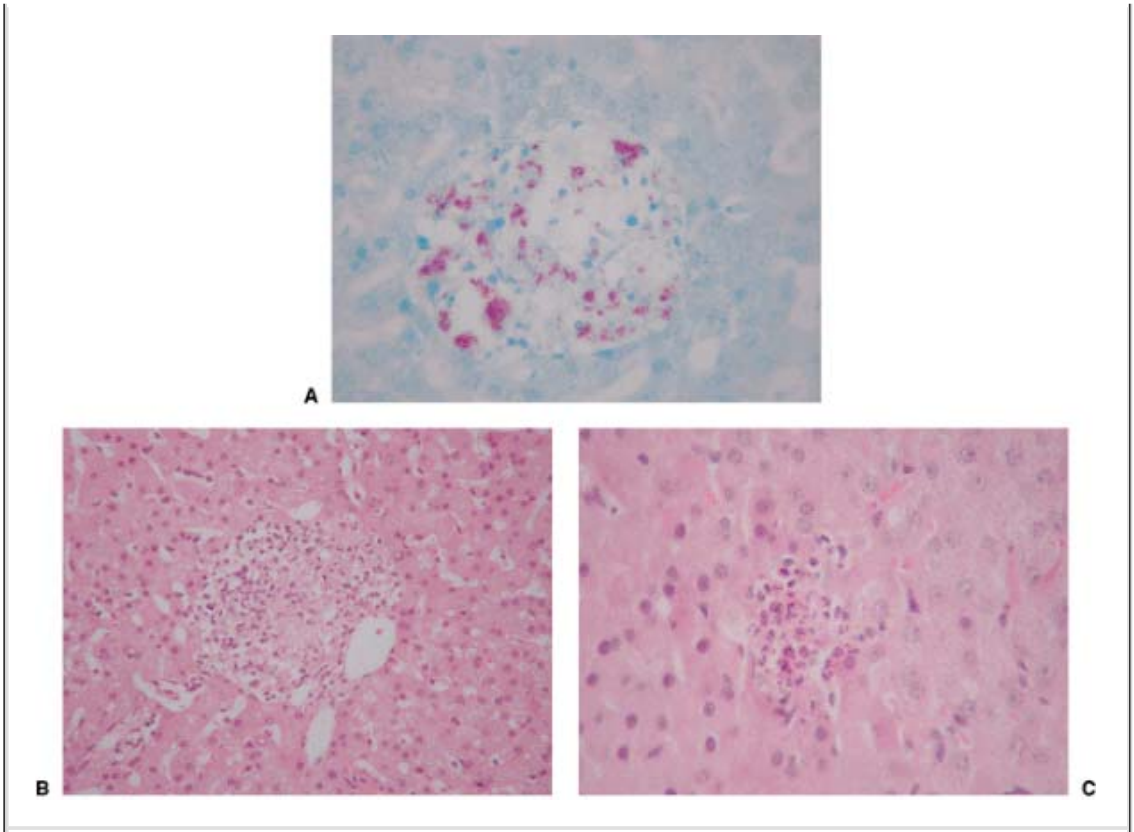
Opportunistic viral infections of the liver are often because of herpes viridae family. Although clinically significant hepatitis secondary to CMV or HSV is rare, CMV is detected frequently in autopsies of severely immunosuppressed patients with CD4 counts less than 100/mm^3 and is often a component of systemic involvement (166). Serum transaminases may be markedly elevated. Liver histology typically shows large intranuclear and cytoplasmic owl's eye inclusions with significant inflammation of portal and periportal regions and sparse necrosis. CMV infects every type of cell within the liver. CMV infection is being detected earlier now owing to pp65 antigen flow cytometry and CMV polymerase chain reaction. In addition, the development of ganciclovir (both intravenous and oral) has reduced the morbidity and mortality of CMV infection (167,168). The major toxicity of ganciclovir and valganciclovir is bone marrow suppression. Resistance can be a problem with ganciclovir that may require switching to foscarnet. The major side effect limiting the use of foscarnet is its nephrotoxicity. Hepatitis secondary to HSV occurs in patients with extensive herpetic ulcers elsewhere. Patients may develop submassive hepatic necrosis with severe transaminitis and liver failure. Pathologically, HSV hepatitis is characterized by multinucleated hepatocytes and Cowdry A intranuclear inclusion bodies that may be differentiated from those of CMV by specific immunohistochemistry. HSV hepatitis may be treated with intravenous acyclovir, ganciclovir or foscarnet. However, hepatitis secondary to either CMV or HSV responds poorly to current treatments. Varicella-zoster virus, EBV, and adenovirus are the other agents responsible for viral hepatitis in patients with HIV.

Mycobacterial Infections

Mycobacterium avium complex (MAC) is the most common opportunistic pathogen

affecting the liver. However, with the introduction of ART the incidence of disseminated MAC infection has declined, and the prognosis has been significantly improved (169,170). Infection with MAC manifests with systemic symptoms and signs, such as fever, abdominal pain, wasting, and biliary obstruction secondary to enlarged lymph nodes at the porta hepatis. It is ordinarily seen in late stage AIDS patients with CD4 count less than 50 cells/mm^3. MAC is detected in 20% to 55% of autopsies and in 10% to 30% of liver biopsies in patients with AIDS (171,172). Severe cholestasis with marked elevations in ALP is typical. However, high transaminases may be the only abnormality. Jaundice is rare. Blood cultures are the most sensitive test for diagnosis of MAC. On the other hand, liver biopsy showing diffuse, poorly formed noncaseating granulomas is necessary for definitive diagnosis of liver involvement. Abundant acid-fast bacilli may be seen on staining (Fig. 51.4), however, liver tissue culture is needed to distinguish between different *Mycobacterium* species. Liver biopsy has been reported to be more sensitive than bone marrow biopsy in diagnosing disseminated mycobacterial infection in AIDS (173). The long-term prognosis is poor with a median survival of only 6 months (174). Combination therapy with a macrolide such as clarithromycin or azithromycin, rifampin, and ethambutol is the most common regimen. Ciprofloxacin or amikacin may be added in more severe cases. Previous data suggests that 12 months of therapy may suffice for patients who are on ART with sustained CD4 counts greater than 100/mm^3 (175). Prophylaxis with azithromycin or clarithromycin is indicated in patients with CD4 counts less than 50/mm^3. Extrapulmonary *Mycobacterium tuberculosis* (MTB) infection involving the liver occurs in 5% to 10% of HIV-related tuberculosis cases and may present with tuberculous liver abscess in severely immunocompromised patients (176). However, ART and rifampicin containing antitubercular therapy have decreased the incidence, recurrence, and mortality rate of tuberculosis (177,178). Tuberculosis is usually because of the reactivation of a latent infection. Liver tuberculosis is associated with fever, abdominal pain, hepatosplenomegaly, and wasting similar to MAC infection. However, as the virulence of MTB is greater than in the other species of *Mycobacterium*, it may infect the patients who have higher CD4 counts, more than 200/mm^3 (179). Cholestasis is seen with significantly elevated ALP and mild increase in bilirubin and transaminases. The specific diagnosis is made by culture and polymerase chain reaction of blood, urine or tissue specimen including liver. Acid-fast bacilli may be seen in the liver histology, which is typically characterized by presence of caseating granulomas. As this infection often occurs in the setting of lesser immunosuppression, granulomas are better formed than those of MAC. The combination of isoniazid, rifampin, ethambutol, and pyrazinamide for 9 to 12 months is the treatment of choice for tuberculosis of the liver. Liver chemistry tests should be closely monitored

during treatment especially in elderly patients. Rarely, liver infections with other mycobacterial species such as *Mycobacterium kansasii*, *Mycobacterium xenopi*, and *Mycobacterium genavense* have also been reported.



▪ **Figure 51.4 A:** An epithelioid granuloma containing *Mycobacterium avium* (Acid-Fast Bacilli stain, ×200). **B:** A microgranuloma in a patient with mycobacterial infection (hematoxylin-eosin stain, ×200). **C:** A microabscess in the liver of a patient with AIDS and CMV infection (hematoxylin-eosin, ×200). AIDS, acquired immunodeficiency syndrome; CMV, cytomegalovirus.

Fungal Infections

Major fungal pathogens infecting the liver are *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Coccidioides immitis*, and *Candida albicans*. They are uncommon, and ordinarily seen in the setting of disseminated disease, and in patients with less than 100 CD4 cells/mm^3. They cause cholestasis, and imaging studies demonstrate focal or diffuse lesions in the liver. Liver histology often reveals poorly formed granulomas with minimal inflammatory reaction. Meningitis is the most common manifestation of cryptococcal disease in HIV-infected patients. Liver involvement occurs because of hematogenous spread. The common presenting features are fever and hepatosplenomegaly. Histoplasmosis is particularly common in midwestern United States, Central and South America, and the Caribbean including Puerto Rico. Progressive disseminated histoplasmosis is often the first sign of immunodeficiency in patients with AIDS in endemic areas (180). Constitutional symptoms along with hepatosplenomegaly and lymphadenopathy are the common features. *C. immitis* infection usually occurs in patients infected with HIV who are living in endemic areas such as the Southwestern United States. The disease typically presents with pulmonary involvement; hepatic infection is again secondary to disseminated disease. Systemic infection and liver involvement with candidiasis are quite rare unless the patients are neutropenic. The symptoms are nonspecific, such as nausea,

vomiting, abdominal pain, and hepatomegaly. *C. neoformans* and *H. capsulatum* may be rapidly detected by polysaccharide capsular antigenemia; other causes of fungal hepatitis need special staining and culture of the liver tissue for definitive diagnosis. There are also rare reports of *Aspergillus fumigatus* causing liver abscess and disseminated *Sporothrix schenckii* involving the

liver. Treatment consists mainly of amphotericin B for fungal hepatitis; however, as the relapse rate is high for most of the fungal infections in immunocompromised patients, fluconazole or itraconazole have been suggested as suppression therapy indefinitely in most cases.

Protozoal Infections

Protozoa are rare pathogens causing infections in patients with AIDS. The routine prophylaxis with trimethoprim/sulfamethoxazol (TMP-SMX) has reduced the incidence of *Pneumocystis jirovecii*, *Toxoplasma gondii*, and *Listeria monocytogenes*. In the past *P. jirovecii* (formerly *Pneumocystis carinii*) hepatitis was associated with the prophylactic use of aerosolized pentamidine for pneumocystis pneumonia (181,182). Inhalation failed to provide adequate drug levels to extrapulmonary sites and up to 39% of such patients developed extrapulmonary spread (183). A mixed pattern of elevated liver enzymes is usually seen. Abdominal CT scan may demonstrate diffuse and punctuate calcifications in the liver. Liver biopsy shows foamy nodules that are periportal or diffuse containing numerous Pneumocystis cysts that stain with Gomori's methenamine-silver. Treatment is with intravenous TMP-SMX or pentamidine. *T. gondii* also involves the liver rarely through hematogenous dissemination and may present with granulomatous disease or hepatitis. Diagnosis is made by culture or microscopic examination of Giemsa-stained specimens. TMP-SMX is the drug of choice for toxoplasmosis. Microsporidial infection of the liver is rare and is associated with a rise in bilirubin, mildly raised transaminases, and high ALP levels (184). Light microscopy reveals focal granulomatous and suppurative necrosis, mainly in the portal area, accompanied by characteristic spores. Although there is no established therapy for microsporidial hepatitis, treatment with albendazole may be efficacious for Encephalitozoon intestinalis (185). *Strongyloides stercoralis*, a helminth of the nematode family, may result in a hyperinfection syndrome in the immunocompromised patient. The liver is involved through the hematogenous spread of the larvae from the gastrointestinal tract. *Entamoeba histolytica* may invade the bowel wall and spread to the liver, forming an abscess. Reactivated *Leishmania donovani* is another rare infection of the liver.

Infections of Biliary Tract

The biliary tree including the gallbladder, is a common site of infection in HIV-infected patients with immunosuppression. It may be involved in the form of acalculous cholecystitis or cholangiopathy.

Acquired Immunodeficiency Syndrome Cholangiopathy

AIDS cholangiopathy is a form of secondary sclerosing cholangitis that occurs because of opportunistic infections in advanced stages of HIV infection, particularly in patients with CD4 counts of less than 135/mm^3 (186). Affected patients develop right-upper-quadrant pain, fever, and cholestasis. ALP is often

elevated up to 10 to 20 times above normal. Jaundice is seldom seen as biliary obstruction is usually partial (187,188). There are multiple opportunistic organisms that have been identified in the biliary tree of the patients including CMV, Cryptosporidium, Microsporidia, and less often MAC, *Isospora belli*, and *Enterocytozoon bieneusi*. However, no pathogen is isolated in up to 50% of cases (189). Although liver ultrasonography may show biliary dilatation and magnetic resonance cholangiopancreatography (MRCP) may demonstrate characteristic findings of cholangiopathy, endoscopic retrograde cholangiopancreatography (ERCP) is more sensitive and has an advantage of tissue biopsy and sphincterotomy when necessary. Cello (190) has described four patterns of abnormalities shown by ERCP: (i) stenosis of the papilla of Vater with dilated extrahepatic bile ducts, (ii) sclerosing cholangitis, (iii) combined sclerosing cholangitis and papillary stenosis, and (iv) long extrahepatic strictures with or without sclerosing cholangitis. Duodenal and papillary biopsies and biopsies from inside the biliary ducts may be sent for both culture and pathologic examinations. Endoscopic sphincterotomy may provide benefit for the symptomatic patients with papillary stenosis (188,190). Prognosis depends on the degree of underlying HIV-related immunosuppression rather than the hepatobiliary disease (191). ART has significantly improved the mortality of patients with AIDS cholangiopathy (192).

Acalculous Cholecystitis

Acalculus cholecystitis usually occurs in later stages of HIV infection at CD4 counts of less than 50/mm^3 (188). Concurrent cholangitis is commonly seen (193). Patients usually present with abdominal pain, fever, nausea, and vomiting. Jaundice is rare, but ALP and γ-glutamyl transpeptidase (GGT) are markedly elevated in most cases. In this condition, the gallbladder wall appears thickened and edematous on imaging without any gallstones. Pericholecystic fluid can be seen. Gallbladder histology often reveals an opportunistic organism. The spectrum of responsible pathogens is similar to that identified in AIDS cholangiopathy. Complications of acalculous cholecystitis include perforation and peritonitis. Cholecystectomy can be performed in most patients; in the remaining cases,

CT or ultrasonography-guided percutaneous cholecystostomy may be an option to decompress the gallbladder (194).

Hepatic Mass Lesions in Human Immunodeficiency Virus

The most common hepatic neoplastic mass lesion is Kaposi sarcoma (KS) caused by human herpesvirus 8 (HHV-8). The incidence of KS in HIV-infected patients may be 10% to 20%, more than 100,000 times that in the general population. However, its incidence in AIDS continues to decrease and the lesions may respond to ART only. Among HIV-infected individuals, KS occurs predominantly in homosexual and bisexual men. Despite the presence of hepatic KS in approximately one third of all patients with cutaneous involvement, it is seldom found on antemortem biopsy. Patients may present with abdominal pain and hepatosplenomegaly with an elevated ALP level, but most commonly it is asymptomatic. There is no specific finding on CT scan, however, the lesions are hypo-attenuated and enhance after a bolus of intravenous contrast. The tumor appears to be a vascular proliferation characterized by the presence of spindle cells, vascular channels, and a mixed cellular infiltrate on histology. B-cell lymphoma is the second most common neoplasm in patients with HIV infection

after KS. It is controversial whether the incidence of non-Hodgkin lymphoma has changed since the introduction of ART. Non-Hodgkin lymphomas in patients with AIDS are often B-cell phenotype with high grade and advanced stage, and predominantly extranodal involving most frequently the central nervous system and the gastrointestinal system (195,196). They appear to be a late manifestation of HIV disease with rates rising directly with the duration of infection. Liver is involved in approximately 10% of cases. The CD4 count is usually less than 200/mm^3. Primary hepatic lymphoma usually presents with multiple masses and involvement of other abdominal organs or lymph nodes. Persistent fever, tender hepatomegaly, and mildly abnormal liver chemistry tests combined with an elevated lactate dehydrogenase level may give a clue to the diagnosis. The lesions appear hypodense on both noncontrast and contrast-enhanced CT imaging. Diagnosis can be established by laparoscopic or CT-guided biopsy. However, as bone marrow involvement is frequent, a bone marrow aspirate or biopsy should be considered before a more invasive liver or retroperitoneal lymph node biopsy. AIDS-associated lymphomas have generally an aggressive course and respond poorly to treatment. Bacillary peliosis hepatis is a vascular lesion caused by *Bartonella henselae*, a fastidious gram-negative bacillus. It usually occurs in patients with CD4 counts less than 200/mm^3 (197). Peliosis hepatis may be found incidentally on liver biopsy or occasionally can present with abdominal pain, hepatosplenomegaly, liver failure, and portal hypertension in extensive cases. Systemic symptoms such as fever, anemia, and cutaneous lesions of bacillary angiomatosis may be observed. Laboratory analysis may reveal elevated ALP level and prothrombin time. Abdominal CT scan displays multiple, small, low-attenuated lesions scattered in the liver parenchyma. Biopsy shows cystic blood-filled spaces within the liver that are usually a few millimeters in size. They are associated with fibromyxoid stroma containing clumps of bacilli that can be detected by Warthin-Starry stain. Erythromycin is the drug of first choice for the treatment of peliosis. Other options include clarithromycin, tetracycline or doxycycline. Liver abscess secondary to mycobacterial infections and HCC that may be seen in the setting of HCV or HBV coinfection are other mass lesions observed in HIV-infected patients. The incidence of mycobacterial liver abscess seems to be decreasing because mycobacterial infection is not as common with the introduction of ART and effective antimycobacterial therapy. On the other hand, the incidence of HCC in HIV-infected patients seems to be increasing because of improved survival with ART and the rising incidence of end-stage liver disease because of HCV or HBV coinfection and alcohol abuse (198).

Liver Transplantation in Human Immunodeficiency Virus

The prognosis of infection because of HIV has improved dramatically over the last few years after the initiation of antiretroviral therapy. The outcome of liver disease is more severe in HIV-infected patients and they have a high liver related mortality (86,199,200). Until recently, the presence of AIDS was an absolute contraindication to liver transplantation and asymptomatic HIV infection was a relative contraindication (201). In recent years, liver transplantation is fast becoming the cornerstone in management of end-stage liver disease in patients with HIV infection. In the pre-ART era the outcome of liver transplantation in HIV-infected patients was poor with a high incidence of opportunistic infections resulting in higher mortality (202,203,204). However in recent years, with widespread use of ART, the outcome after liver transplantation has improved significantly. In a multicenter analysis, 24 HIV patients with end-stage liver

disease who underwent liver transplantation were compared with 5,225 HIV-negative patients from the United Network of Organ Sharing (UNOS)

database (205). In HIV-infected patients the etiology of liver disease was chronic hepatitis C in 63%, chronic hepatitis B in 29%, and acute liver failure in 13% of subjects. The cumulative survival among HIV-positive recipients was similar to that among age and race comparable HIV-negative recipients (P = 0.365). At 12, 24, and 36 months after transplant, survival was 87.1%, 72.8%, and 72.8% respectively among HIV-positive patients versus 86.6%, 81.6%, and 77.9% among HIV-negative patients. However, in the HIV/HCV-coinfected group, the survival was worse compared with the HCV-monoinfected group. In HIV-positive patients the 1-, 2-, and 3-year survival after transplant was 80%, 57%, and 57% respectively, compared with 87%, 81%, and 77% respectively, in the HIV-negative group. In this study, worse outcome was associated with posttransplant antiretroviral intolerance, a CD4 count of less than 200 cells/μL, HIV viral load greater than 400 copies/mL, and hepatitis C coinfection. In another series from King's College Hospital, London, 14 HIV-infected liver allograft recipients were evaluated (206). HCV was the etiology of liver disease in seven patients, HBV in four patients, alcohol in two patients, and acute liver failure in 1 patient. In the non-HCV group (n = 7), all patients were still alive with a survival range of 668 to 2,661 days after transplantation, none experienced HBV recurrence, and graft function was normal in all patients. However, five of seven HCV-infected patients died after transplantation at 95 to 784 days (median 161 days); most deaths were because of complications of recurrent HCV and sepsis. This study demonstrated a poor outcome in the HCV and HIV-coinfected patients. Therefore, the limited data so far suggests that the survival in the HIV-infected patients undergoing liver transplantation is comparable to their HIV-negative counterparts. However, the outcome in the HIV/HCV-coinfected patients seems to be worse in compared with the HCV-monoinfected patients.

Therefore, recent findings suggest that survival of HIV-positive liver transplant recipient does not differ from that of HIV-negative recipients and HIV should not be a contraindication to liver transplantation, provided patients meet the currently practiced inclusion and exclusion criteria for listing. In 2003, an NIH sponsored prospective multicenter study was designed to evaluate various issues in liver and kidney transplantation in people with HIV disease. One hundred and twenty-five liver transplant recipients are to be evaluated, and all patients are to be followed for 2 to 5 years. The primary endpoints are patient and graft survival. Secondary endpoints are markers of HIV disease such as opportunistic infections, HIV viral load, and CD4+ cell counts; influence of HCV, HBV, and herpes virus coinfection on graft survival and rejection; and interaction between immunosuppressive drugs and antiretroviral agents. Overall, the study aims to provide patients and clinicians with information regarding the HIV-specific risks of transplantation, to provide clinicians with information necessary to manage immunosuppressive and ART medication together, and to understand underlying basic science mechanisms that explain patient outcomes so that clinical management may be adjusted to maximize these outcomes. All HIV-infected patients with end-stage liver disease should be considered as candidates for liver transplantation provided they do not have advanced HIV disease. Those with severe immunosuppression (<100 CD4 cells/μL) should be treated with ART to control viral replication before they are evaluated for transplantation. Patients with good response to ART, but with prior AIDS-related opportunistic infections and neoplasm have higher risk of relapse while on immunosuppressive medication

after transplantation. There are some important pharmaco-kinetic drug interactions between PIs and NNRTIs and immunosuppressive agents like tacrolimus and cyclosporin. PIs can increase the levels of tacrolimus and cyclosporin, whereas NNRTIs can reduce their levels. Therefore, optimizing the dose of immunosuppressive medication to prevent toxicity secondary to drug interactions with ARV agents, use of ART to suppress HIV RNA, and maintaining CD4 counts greater than 200 to decrease risk of opportunistic infections are some ways to improve survival after liver transplantation in the HIV-infected patients. Liver transplantation in HIV-positive patients is promising, and further prospective long-term studies such as the NIH trial are needed to firmly establish its role in management of these patients.

Sherman KE, Rouster SD, Chung RT, et al. Hepatitis C virus prevalence among patients infected with Human Immunodeficiency Virus: a cross sectional analysis of the US adult AIDS Clinical Trials Group. *Clin Infect Dis* 2002;34:831–837.

In this analysis, a large sample of 1687 HIV-infected patients was studied, They demonstrated that Hepatitis C virus has emerged as an important etiologic agent of liver injury and failure in patients infected with human immunodeficiency virus (HIV), and the prevalence is related to the risk behavior. They also showed that high virus loads and genotype 1 prevalence may be important to interferon-based antiviral response rates among coinfected patients.

Sulkowski MS, Thomas DL, Chaisson RE, Hepatotoxicity associated with antiretroviral therapy in adults infected with human immunodeficiency virus and the role of hepatitis B or C virus infection. *JAMA* 2000;283:74–80.

It is well known that antiretroviral medication causes hepatotoxicity. When severe, this often results in discontinuation of treatment, putting the patient at risk for advancement HIV disease. The authors have shown that severe hepatotoxicity occurs in only 10% of patients, but the risk is increased in patients receiving ritonavir and in patients who have coinfection with hepatitis B or hepatitis C.

Torriani FJ, Rodriguez-Torres M, Rockstroh JK, et al. Peginterferon alfa 2a plus ribavirin for chronic hepatitis C virus infection in HIV infected patients. *N Engl J Med* 2004;351:438–450.

In this study a total of 868 persons who were infected with both HIV and HCV and who had not previously been treated with interferon or

ribavirin were randomly assigned to receive one of three regimens: peginterferon alfa-2a plus ribavirin, peginterferon alfa-2a plus placebo, or interferon alfa-2a plus ribavirin. The authors demonstrated that among patients infected with both HIV and HCV, the combination of peginterferon alfa-2a plus ribavirin was significantly more effective than either interferon alfa-2a plus ribavirin or peginterferon alfa-2a monotherapy.

Chung RT, Anderson J, Volberding P, et al. Peginterferon alfa -2a plus ribavirin versus interferon alfa 2a plus ribavirin for chronic hepatitis C in HIV

co-infected persons. *N Engl J Med* 2004;351:451–499.

In the AIDS Clinical Trials Group (ACTG) study viral response was better in the peginterferon and ribavirin group rather than the IFN group. Treatment with peginterferon and ribavirin was associated with a significantly higher rate of SVR than treatment with standard IFN and ribavirin. The study showed that independent factors associated with higher SVR were genotype non-1 infection, no prior intravenous drug use, and an undetectable HIV RNA at baseline.

Title: ***Schiff's Diseases of the Liver, 10th Edition***

Chapter 52
Granulomas of the Liver

James H. Lewis

Key Concepts

- Hepatic granulomas are currently found in 5% to 10% of patients in liver biopsy series, and represent a localized inflammatory response to a variety of infectious, immunologic, drug-induced, neoplastic, and nonmicrobial chemical and foreign body irritants. Both genders and all ages can be affected.
- While dozens of causes have been reported worldwide, the most common are sarcoidosis and tuberculosis (TB). More than 60 drugs have been associated with a granulomatous reaction, most often causing a hypersensitivity reaction (e.g., allopurinol, sulfonamides, phenylbutazone, phenothiazines, carbamazepine).
- Two main types of granulomas are found—lipogranulomas that form around fat droplets associated with ingestion of mineral oil, waxes, and other lipid materials, and epithelioid granulomas that are usually formed in response to a hypersensitivity reaction. A special form of epithelioid granuloma is the fibrin-ring granuloma seen with Q fever, allopurinol, and a few other causes.
- Granulomas may be found as a coincidental lesion or may serve to confirm a variety of infectious or other disorders associated with their development. They may be the only clue to the presence of certain infectious or neoplastic diseases, and occasionally are found as part of a fever of unknown origin (FUO). Approximately 10% are considered "idiopathic" with no specific etiology identified, even by utilizing modern serologic and immunohistochemical methods.
- Although biochemical tests are generally nonspecific, jaundice is unusual with most causes of granulomas, and should prompt a search for other etiologies. Certain histopathologic clues to the etiology of granulomas continue to be emphasized, such as sarcoidosis having multiple noncaseating granulomas of different ages; TB having caseating granulomas; many drugs and parasites being associated with surrounding eosinophils; and fibrin-ring granulomas suggesting Q fever among a few other causes.
- Treatment of hepatic granulomas depends on the etiology and the degree of symptomatology. Chronic cholestatic liver disease leading to biliary cirrhosis may be seen in a small percentage of patients with sarcoidosis. In general, however, granulomatous hepatic involvement by most causes is nonprogressive. Drug-induced causes often resolve after the offending agent is withdrawn.

Granulomas are focal collections of epithelioid cells, including macrophages, mononuclear and other inflammatory cells that may fuse together to form multinucleated giant cells, usually in response to a variety of infections, immunologic and neoplastic disorders, drugs, and nonmicrobial chemical irritants (1,2). They are the end result of a complex interplay of inflammatory and immunologic factors (3), depending on the nature of the infectious or antigenic stimulus. The liver is a common location for granulomas due to its prominent blood supply that exposes most drugs, infectious organisms, and other materials to its large numbers of reticuloendothelial (Kupffer) cells. When found, granulomas usually prompt a search for a specific etiology from a list that has grown to include dozens of causes, as will be discussed. Hepatic granulomas are present in approximately 5% of large modern-day liver biopsy series, with a range of 1% to 15%, varying by geographic location and disease prevalence (4,5,6,7,8,9,10,11,12,13,14,15,16,17,18) (Table 52.1). This also appears to apply to pediatric populations from around the globe (19,20,21,22,23). Granulomas may be an anticipated or incidental finding, reflecting either a primary hepatic disorder (approximately 5%), or seen as part of a systemic disease process with hepatic involvement(70%–75%), including fever of undetermined etiology (4,24,25,26,27).

Both foreign body type granulomas (nonimmunologic) and hypersensitivity-mediated granulomas can be seen in the liver (28). Granulomas are most likely to be seen when macrophages drawn to the site of acute inflammation are unable to clear antigens and inflammatory byproducts. As a result, monocytes are attracted from the blood and bone marrow and form tissue epithelioid histiocytes that fuse together to become multinucleated (Langhans-type) giant cells (29,30,31,32). Such cells lose their phagocytic function and develop secretory properties (33), such as sarcoid granulomas producing angiotensin-converting enzyme (34). The cytokine network and immunology associated with granuloma formation has been reviewed in detail by James (3).

A variety of disorders are associated with a granulomatous histological response that can involve one or more organ systems (3). Infections are the most common cause of disseminated granulomas, and previously unrecognized etiologic agents have been identified by improved diagnostic techniques (35). Nevertheless, granulomas often still present a diagnostic challenge to the clinician.

Men and women have been nearly equally represented in several large series of granulomas, although women, not unexpectedly, predominate when primary biliary cirrhosis (PBC) accounts for a significant percentage of cases (16). The ages of adult patients with hepatic granulomas generally have been in the range of forties to fifties, but

children are affected as well (19,20,21,22,23).

Pathophysiology of Granulomas

Histologically, two main types of granulomas are described—lipogranulomas and epithelioid granulomas.

Lipogranulomas are composed of loose aggregates of lymphocytes and macrophages surrounding lipid droplets, and are secondary to ingestion of mineral oil or other lipid material (36,37) (Fig. 52.1). They may also be seen in fatty livers, possibly originating from parenchymal fat being transported to portal tracts (38). In a series of 44 nonfatty liver cases reported by Dinscoy et al. (39), lipogranulomas were attached to or were in close association with the walls of hepatic venules. The lipogranulomas in their series were most likely a reaction to absorbed mineral oil or other saturated hydrocarbon foodstuffs. Lipogranulomas comprise a relatively smaller percentage of all granulomas, ranging up to 26% (16), but were described as having nearly tripled in incidence between the early 1950s and the late 1970s in one series (39). Among autopsy specimens, lipogranulomas have been found in 48% often in association with lipogranulomas in the spleen (36). They may be discovered incidentally and are generally of little, if any, clinical significance (37,40). However, reports of venous outflow obstruction (41) and a case of prolonged fever associated with lipogranulomas caused by paraffin oil have been published (42).

Epithelioid granulomas are the predominant histologic form in most series. The name is derived from

P.1427
P.1428
P.1429

their polygonal shape and abundant cytoplasm (18) (Fig. 52.2). They generally develop in response to delayed hypersensitivity reactions (3). Cytokines mediating the Th1 immune response attract $CD4^+$ and $CD8^+$ T lymphocytes and fibrocytes that form the periphery of many granulomas. Activation of the Th2 immune response occurs as a result of antigenic sensitization, leading to necrosis or caseation, depending on the nature of the antigenic stimulus (43,44,45).

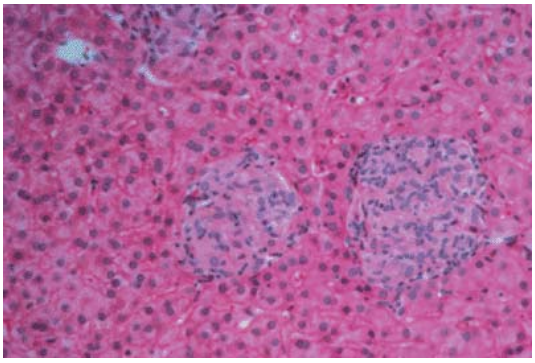
% of liver biopsies, the frequency of finding granulomas in the series of liver biopsies being reported; TB, tuberculosis; sarcoid, sarcoidosis; DILD, drug-induced liver disease; Misc., miscellaneous causes (*%of total number of granulomas in the series listed under miscellaneous); PBC, primary biliary cirrhosis; idiopathic, cause not established; —, not listed; CLD, chronic liver disease (not specified); AIH, autoimmune hepatitis; HBV, hepatitis B virus; HCV, hepatitis C virus.



▪ **Figure 52.2** Noncaseating epithelioid granuloma characterized by giant cell transformation (hematoxylin-eosin, ×300). (Courtesy of Dr. KG Ishak, Armed Forces Institute of Pathology.)

A distinctive type of epithelioid granuloma is characterized by a *fibrin ring* enclosing a vacuolar clear space of necrosis (46). These "doughnut"-shaped granulomas have traditionally been associated with Q fever (47) (Fig. 52.3A) and allopurinol toxicity (Fig. 52.3B) (48). However, this pathologic appearance is not limited to these causes, with several other infections and etiologies having been described (49,50,51,52,53) (Table 52.2).

Systemic lupus erythematosus
Staphylococcal infection
Q fever

Etiology of Granulomas

Depending on the geographic locale, the causes vary according to the diseases encountered. For example, in India, most granulomas are due to tuberculosis (TB) (13); in northern Europe, PBC tends to predominate (16); in the midwest of the United States, histoplasmosis is seen more often (5,19); schistosomiasis in the Middle East and the Tropics (17); mediterranean fever in Spain (7); brucellosis and Q fever in sheep and cattle raising regions and in slaughterhouse workers (54,55). In most series, infectious disorders are the leading causes of hepatic granulomas (56), consistent with the notion that granulomas form in response to intracellular pathogens that trigger active cell-mediated immunity, or to the persistence of nondegradable (foreign body) products (3). Table 52.1 lists several representative series of hepatic granulomas from diverse geographic areas, which attest to their spectrum of causes. The etiopathogenesis of hepatic granulomas often depends on the extent to which a specific diagnosis is sought, although no cause was identified in up to half of cases in earlier series. However, with the advanced diagnostic testing currently at

our disposal, including serologic tests and the use of polymerase chain reaction (PCR) analyses for a variety of infectious agents, the percentage of truly "idiopathic" (unexplained) granulomas has been reduced; in more recent series to about 10% (9,19). A complete listing of the causes of hepatic granulomas is given in Table 52.3.

Clinical Consequences of Hepatic Granulomas

Granulomas draw attention on the basis of the clinical setting in which they arise; either as part of an acute generalized hypersensitivity reaction or infection, during the evaluation of fever of unknown origin (FUO), or as part of the workup for abnormal liver-associated enzymes (usually alkaline phosphatase, γ-glutamyltransferase, or hyperglobulinemia). In a Mayo Clinic series (10), 74% of patients had unexplained symptoms (including fever) present for a mean of 19 months, with the remainder of granulomas being discovered on liver biopsy for abnormal results on liver function tests. While granulomas are often associated with a classic inflammatory response, significant hepatocellular dysfunction is unusual; hence the term "granulomatous hepatitis" (5,24) is less commonly applied. The term favored by most authorities is "hepatic granulomas" as used by my predecessor of this

chapter (57,58) and others (59,61). Despite the relative absence of overt hepatic dysfunction with most granulomas, several pathologically significant lesions are described in association with granulomatous involvement (Table 52.4).

Table 52.4. Clinicopathologically Significant Hepatic Lesions Seen with Granulomas

Pathologic lesion	Causative granulomas (Ref)
Veno-occlusive disease	Lipogranulomas (41)
Chronic cholestasis	Sarcoidosis (62,63),
Vanishing bile duct syndrome	Sarcoidosis, PBC (64)
Portal hypertension	Sarcoidosis, PBC, schistosomiasis (65,66)
Granulomatous hepatitis[a]	Drugs, neoplastic/immunologic disorders, infections (5,24,25,26,27)

[a]Defined as fever, weight loss, abdominal pain, myalgias, arthralgias.
PBC, primary biliary cirrhosis.

Clinical Evaluation of Hepatic Granulomas

The extent to which a specific cause of granulomas in the liver is sought often corresponds to the frequency with which certain diagnoses are found in various geographic locales. A patient's travel history, drug history, occupation, the presence of household pets, and proximity or exposure to domesticated farm or feral animals may provide useful clues as to the diagnosis (Table 52.5).

Table 52.5. Clinical and Historical Clues to the Cause of Hepatic Granulomas

Historical due	Possible cause
Exposure to sheep, cattle, etc.	Q fever, brucellosis
Cat bites or scratches	*Bartonella henselae*
Exposure to puppies	Visceral larva migrans
Slaughterhouse workers, veterinarians	Q fever, brucellosis
Miners, atomic energy plant or ceramics workers	Beryllium
Swimming, wading in streams	Schistosomiasis
Exposure to wild rodents, dogs	Rickettsioses
HIV/acquired immunodeficiency syndrome; sexually transmitted diseases,	*Mycobacterium avium*, *Mycobacterium tuberculosis*, toxoplasmosis, syphilis
Exposure to parrots and other birds	Psittacosis
Exposure to dog ticks	Boutonneuse fever (*Rickettsia conorii*)
IV drug use	Talc
BCG inoculation	BCG

Hemodialysis with silicon tubing or ball-valve prosthesis	Silicone spallation
Jejunoileal bypass for obesity	Lipogranulomas
Chrysotherapy for rheumatoid arthritis	Gold
Mineral oil ingestion	Lipogranulomas
Vineyard workers	Copper sulfate toxicity
Skin lesions	Leprosy, sarcoidosis, syphilis
Fever	TB, sarcoid, most infections, drugs causing hypersensitivity[a]
Living in disease-endemic areas	Leprosy (Mexico, China, South America); TB (worldwide, HIV-positive); histoplasmosis (eastern, midwest United States); coccidioidomycosis (southwest United States); melioidosis (South East Asia); schistosomiasis (Tropics)

[a]Excludes primary biliary cirrhosis parasites
sHIV, human immunideficiency virus; BCG, bacillus Calmette-Guérin; TB, tuberculosis.

Laboratory studies–biochemical markers associated with hepatic granulomas are nonspecific (58). Elevated levels of alkaline phosphatase or γ-glutamyltransferase may give a clue as to the presence of granulomatous disease, but by themselves are nondiagnostic, and may also signify cholestatic disorders. Clinical jaundice is unusual in TB and other infections, but may be seen in other causes, including the uncommon chronic cholestatic lesion of sarcoidosis. (62). Hyperglobulinemia may be present in TB and sarcoidosis. Other commonly employed laboratory tests that can be performed include angiotensin-converting enzyme levels for suspected sarcoidosis, antimitochondrial antibody for suspected PBC, and rapid plasmin reagin (RPR) for syphilis.

Serologic tests are available for a wide variety of infections including Q fever, mononucleosis, cytomegalovirus, Brucella, syphilis, hepatitis A, B, and C, psittacosis, among others. The reader is referred to other sources describing the most accurate diagnostic modalities for infectious causes of granulomas (35) (Table 52.6).

Additional diagnostic studies include *ova and parasite* examination of the stool to uncover schistosomiasis (the organisms), *Toxocara*, or other parasites. Uveitis

revealed on *slit lamp examination* of the eye may be a clue to the presence of sarcoidosis. A *chest x-ray* may reveal changes suggesting TB, sarcoid, Hodgkin's disease (HD), and so on.

Table 52.6. Specific Diagnostic Tests and Treatment of the Most Commonly Encountered Infectious Causes of Hepatic Granulomas

Cause	Diagnostic tests	Treatment[a]
Mycobacterium tuberculosis	Positive AFB smear, culture; PCR	Isoniazid, pyrazinamide, rifampin
Mycobacterium avium	Tissue culture, positive AFB smear	Macrolides, azalides, rifabutin
Mycobacterium leprae	Skin biopsy, positive Fite stain	Dapsone +/- clofazimine, rifampin
Q fever	Serology, PCR, culture	Doxycycline, vaccine for prevention
Brucellosis	Serology; PCR; positive blood, tissue culture	Doxycycline + rifampin or streptomycin

Syphilis	Treponemal serology, PCR	Benzathine or procaine penicillin
Schistosomiasis	Positive serology	Praziquantel
Catscratch fever	Silver stain, tissue culture, PCR	Ciprofloxacin, doxycycline, erythromycin or TMP-SMX
Histoplasmosis	Skin testing, silver stain serology	Azoles (e.g., fluconazole)
Coccidioidomycosis	Precipitin or other antibody tests, skin test, tissue culture	Azoles, amphotericin
Yersinia enterocolitica	Serology, culture	Aminoglycosides, tetracyclines, TMP-SMX or ciprofloxacin
Visceral larva migrans	Larvae in tissue, ELISA	Albendazole
Visceral leishmaniasis	Amastigotes in aspirates, promastigotes in culture, serology	Liposomal amphotericin B
Toxoplasmosis	PCR, serology, tissue isolates	Pyrimethamine + sulfadiazine or clindamycin + leukovorin
Psittacosis	Serology	Tetracycline or doxycycline

[a] Consult Mandell GL, Bennett JE, Dolin R, eds. Mandell, Douglas, and Bennett's principles and practice of infectious diseases, 6th ed. Philadelphia: Elsevier Churchill Livingstone, 2005; for specific dosages and alternates regimens used for hepatic involvement.
AFB, acid-fast bacillus; PCR, polymerase chain reaction; TMP-SMX, trimethopime-sulfamethoxazole; ELISA, enzyme-linked immunosorbent assay.

Diagnostic *bone marrow* or *lymph node biopsies* are available to help identify granulomas associated with TB, lymphoma, HD, and so on.

Radiologic evaluation may yield clues as to the cause of granulomas, although most granulomas are often too small to be seen on standard imaging. However, the *magnetic resonance imaging* appearance of granulomatous hepatitis includes nodules 0.5 to 4.5 cm in diameter; with caseating granulomas having intermediate to high signal on T2-weighted images and low signal on T1. Noncaseating granulomas were found to have an increased enhancement on arterial phase images that persisted into the late phases. (64) On *ultrasonography*, multiple echogenic lesions 3 to 5 mm in size surrounded by a hypoechoic halo have been described (65). *Diagnostic laparoscopy* is described as revealing a range of liver capsule findings, including exudative, pinpoint, granular, macular, and cord-like features. Findings of TB was most often granular while brucellosis was exudative. (66).

Histopathologic Appearance

Granulomatous reactions may take one of several forms as described by Goodman (67): simple (bland) granulomas without other associated injury; granulomatous hepatitis with hepatocellular injury, including apoptosis and parenchymal inflammation; and granulomatous cholangitis or vasculitis. The pathologic appearance and location of the granulomas may offer important clues to their cause as listed in Table 52.7. Special stains for acid-fast bacillus (AFB) and fungi, the use of polarizing microscopy looking for talc, and immunohistochemical stains for hematogenous malignancies, and so on, may be helpful. Culture of liver biopsy material has a relatively low yield in terms of *Mycobacterium tuberculosis* and other infections, but is often performed, especially in patients with FUO.

Specific Causes of Hepatic Granulomas

The most common causes of hepatic granulomas listed in Table 52.3 are described in the subsequent section.

Sarcoidosis

Sarcoidosis is a chronic multisystem granulomatous disease that is seen in all races and ages, and is the leading cause of hepatic granulomas in the United States. It preferentially affects young African Americans, who have a 10-fold higher prevalence compared to whites, and they tend to have a more severe clinical course (68). The liver is the third most common site of involvement after the lungs and lymphatics. The diagnosis requires the presence of noncaseating granulomas in at least two organs (69). The presence of

systemic symptoms (fever, weight loss, malaise) may occur without pulmonary disease. Hepatic involvement generally does not cause significant morbidity, but a small subset of patients develop progressive cholestatic disease that can lead to cirrhosis and portal hypertension (62,63). Serum alkaline phosphatase levels can become very high (>1000 IU/L), but aminotransferases and bilirubin levels are generally normal.

Table 52.7. Histopathological Clues to the Etiology of Hepatic Granulomas

Large number of granulomas: Sarcoidosis, miliary TB
Lipogranulomas: Fatty liver, mineral oil
Associated bile duct injury: PBC, sarcoidosis
Well-formed granulomas: Sarcoidosis, TB, schistosomiasis, histoplasmosis, coccidioidomycosis, chronic brucellosis, phenylbutazone
Poorly formed granulomas (granulomatous inflammation/necrosis): *Mycobacterium avium*, acute brucellosis, Q fever, many drugs
Caseation (central necrosis): TB
Uniform age of granulomas: Drug injury
Noncaseating granulomas of different ages: Sarcoidosis
Multinucleated giant cells: Sarcoidosis, TB
Inclusions:
Stellate-shaped (asteroid bodies)—sarcoidosis
Lamellar (Schaumann bodies)—sarcoidosis
Fibrin-ring granulomas (central vacuole surrounded by a ring of fibrin) often staining positive for phosphotungistic acid hematoxylin: Q fever, allopurinol, Hodgkin's disease, and other causes listed in Table 52.2
Eosinophils: Drug injury, schistosomiasis, toxocariasis, visceral larva migrans, catscratch disease, Hodgkin's disease, non-Hodgkin's lymphoma[a]
Positive AFB stain: TB, *Mycobacterium avium*
Positive silver stain: Fungi
Foamy macrophages/histiocytes: *Mycobacterium avium*
Foreign body reaction: Talc, silica, schistosome eggs, etc.
Pigment /crystals:
– Black granules—gold, titanium
– Gray-tan birefringent material in reticuloendothelial system—barium
– Coarse, pink-brown granules—thorium dioxide
– Colorless amorphous birefringent crystals—silicone
Location/distribution of granulomas:
– Lobular—drug, sarcoid, brucella
– Portal/periportal—sarcoid, TB, Q fever, drugs
– Periductal—PBC
– Perivenous—mineral oil
– Periarterial—phenytoin

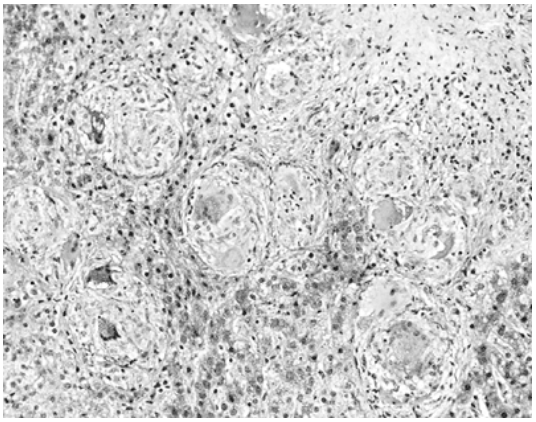
[a]Excludes TB, sarcoidosis.
TB, tuberculosis; PBC, primary biliary cirrhosis; AFB, acid-fast bacillus.

Sarcoid granulomas are compact aggregates of large epithelial cells, often with multinucleated giant cells and a rim of lymphocytes and macrophages, and others with a giant cell, surrounded by lymphocytes (Fig. 52.4). They occur diffusely throughout the liver, but are most prominent in the portal and periportal zones. Klatskin (4) estimated that there were as many as 75 million granulomas in the liver at various stages of maturation. Inclusions in giant cells (Schaumann and asteroid bodies) are characteristic, but not pathognomonic (70,71). The pathogenesis of sarcoid granulomas involves their transformation from tissue macrophages that are derived from circulating blood monocytes. According to Okabe (72), they are under the control of colony-stimulating factors and possibly vitamin D_3, which promote their proliferation. Their transformation to secretory cells, producing angiotensin-converting enzyme, was described by Gronhagen-Riska et al. (34).

Three stages of development were described by Klatskin (4); early on the granulomas are small, later on they become well-defined, ovoid in shape with associated Kupffer cell hyperplasia, and finally form fibrinoid nodules. Sarcoid granulomas tend to segment as they enlarge, forming multilobulated granulomas (18) that may persist for long periods of time. Confluent granulomas may result in extensive, irregular scarring (73). They are never caseating (in contrast to TB), not to be confused with fibrinoid necrosis that can occasionally be seen (71,73). Tissue eosinophilia is also absent (in contrast to drug-induced granulomas). Bile duct damage may be seen (although less commonly and with less severity than in PBC). Large sarcoid nodules situated in the hilum may produce biliary obstruction. Chronic cholestasis resembling PBC is a well-described but less common clinical outcome (Fig. 52.5) (62,74,75). Progression to frank biliary cirrhosis with portal hypertension (from occlusion of intrahepatic portal vein branches) requiring transplantation is relatively uncommon but the disease may recur in

allografts (76). Moreno-Merlo et al. (77) suggested that cirrhosis and focal fibrosis may be caused by ischemia secondary to primary granulomatous phlebitis of portal and hepatic veins, with portal hypertension occurring

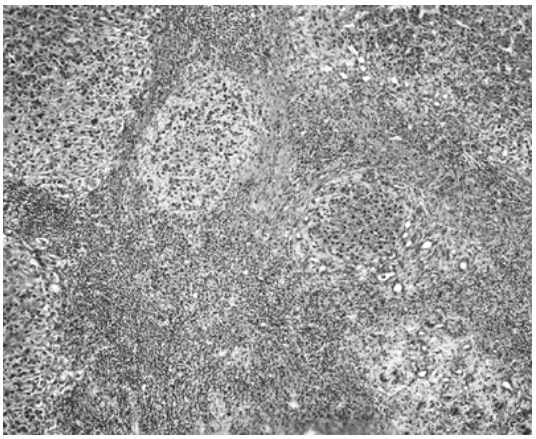
secondary to portal vein thrombosis, as cirrhosis was absent at the onset of variceal bleeding in the two patients they described.



▪ **Figure 52.4** Sarcoidosis with multiple noncaseating epithelioid granulomas having multinucleated giant cells (hematoxylin-eosin, ×150). (Courtesy of Dr. KG Ishak, Armed Forces Institute of Pathology.)

Sarcoidosis may be present in association with untreated hepatitis C (78) and can reactivate during interferon therapy (79,80); possibly through the stimulation of the Th1 immune response (81).

In a series of 100 patients with hepatic sarcoid studied by the Armed Forces Institute of Pathology (AFIP) (71), the volume of granulomas was estimated from <1% to 90%; 99% of which were noncaseating. Three biochemical patterns were found; cholestatic in 58% (nearly half of whom had bile duct lesions similar to PBC or primary sclerosing cholangitis [PSC]); necroinflammatory in 41% (with spotty necrosis and/or chronic portal inflammation), and vascular in 20% (with sinusoidal dilatation and nodular regenerative hyperplasia). Ductopenia was found in 37 of 58 individuals with chronic cholestasis. Another 12 had acute cholangitis changes without clinical evidence of ductal obstruction. Fibrosis was seen in 21 patients (periportal in 13, bridging in 2, and cirrhosis in 6).



▪ **Figure 52.5** Chronic cholestasis of sarcoidosis with micronodular biliary cirrhosis (hematoxylin-eosin, ×60). (Courtesy of Dr. KG Ishak, Armed Forces Institute of Pathology.)

The therapeutic options for sarcoidosis have been reviewed by others (68). Treatment of hepatic granulomas is usually administered only when the patient has systemic symptoms from granulomatous hepatitis or cholestatic liver disease, or other symptomatic organ involvement (69). There is no evidence that corticosteroids prevent progression of hepatic disease in asymptomatic individuals (82), although alkaline phosphatase levels may decline. Granulomas may heal without a trace (71). In a series by Gottlieb et al. (83), patients with hepatic involvement had a three-fold higher risk of relapse after a course of steroids compared to those without liver disease. Ursodiol may be beneficial in patients with the cholestatic form of the disease (84,85).

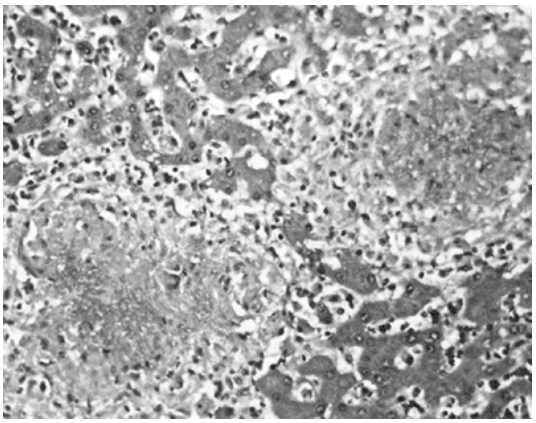
Mycobacterium Tuberculosis

Granulomas are the most common histologic feature of TB involving the liver, but a wide spectrum of nonspecific histopathologic lesions may be present (86). Granulomas are seen in approximately 20% of patients with

pulmonary TB (depending on how many sections are examined) (87) and are seen nearly universally in those with miliary TB (86). Isolated hepatic involvement is also well described (88). As many as two thirds of patients with acquired immunodeficiency syndrome (AIDS) have extrapulmonary involvement that frequently involves the liver (89) (as described in the subsequent text).

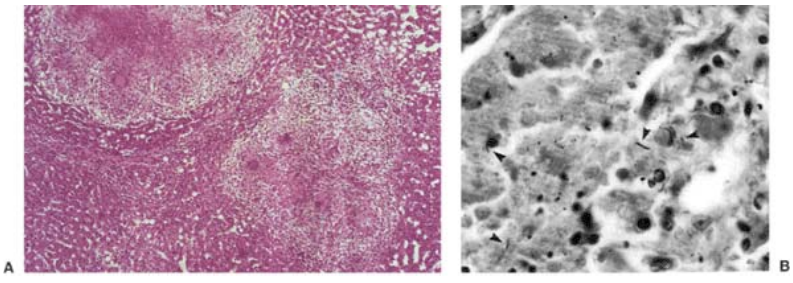
The granulomas associated with *Mycobacterium tuberculosis* are composed of mononuclear (epithelioid) cells surrounded by lymphocytes, with or without Langhans-type multinucleated giant cells (Fig. 52.6). They are generally 1 to 2 mm in size, but large tuberculomas up to 12 cm have been reported (90). Caseation (central necrosis surrounded by peripheral macrophages) is considered a hallmark finding of TB granulomas, and is present in 33% to 100% of liver biopsy specimens from various series (86). Caseation is thought to occur as a result of overwhelming acute dissemination of mycobacterial organisms, and therefore,

occurs more commonly in miliary TB. It is characteristically granular and "cheesy" in appearance; hence the term "caseous" (Fig. 52.7A). Giant cells are often present and AFB stains are positive in approximately 60% (Fig. 52.7B), in contrast to cultures often being negative (87). PCR assays have been diagnostic in most patients with TB granulomas in the liver (91,92).



▪ **Figure 52.6** Granulomas with caseation necrosis in miliary tuberculosis (hematoxylin-eosin, ×100). (Courtesy of Dr. KG Ishak, Armed Forces Institute of Pathology.)

Clinical and biochemical clues to the presence of hepatic TB are nonspecific (86). Hyperglobulinemia is often seen and serum alkaline phosphatase levels are often raised, while aminotransferase values remain normal in pulmonary disease and mildly elevated in miliary TB (93,94). Jaundice is unusual and should prompt a search for biliary obstruction or associated hepatotoxicity from anti-TB drug therapy. An uncommon form of acute miliary TB described by Essop et al. (95), and called "tuberculous hepatitis" was accompanied by fever, tender hepatomegaly, and splenomegaly, and had a very high incidence (96%) of hepatic granulomas, with caseation seen in 83%. However, tubercle bacilli were found in only 9% of cases. The demonstration of AFB has generally been low in pulmonary TB, and higher in miliary TB; but positive cultures have been rare in the literature (86,96). Following successful anti-TB treatment, complete resolution of hepatic granulomas is described as occurring within a few months (95,97).



▪ **Figure 52.7 A:** Caseous necrosis with multinucleated Langhan giant cells in granulomas associated with *Mycobacterium tuberculosis* (hematoxylin-eosin, ×100). **B:** Higher magnification demonstrated acid-fast organisms (*arrows*) in a caseating granuloma (Ziehl-Neelsen, ×1000). (Courtesy of Dr. KG Ishak, Armed Forces Institute of Pathology.)

TB affects 1% to 4% of liver allograft recipients and other solid organ transplantation patients (98). In a series of

42 postorthotopic liver transplantation patients with granulomas on liver biopsy, Ferrel et al. (99) found only 1 patient with documented TB for a prevalence of 2.4%. Granulomatous hepatitis has been attributed to isoniazid and pyrazinamide, although one wonders whether the underlying TB may have been responsible for the finding of granulomas in this setting. In general, hepatotoxicity from isoniazid and pyrazinamide takes the form of acute hepatocellular injury, including fulminant hepatic failure (86,100,101).

Rarely a mycobacterium other than *M. tuberculosis* is isolated from the liver. *M. kansasii*, *M. mucogenicum*, and other atypical mycobacterial organisms have been found (102).

Granulomatous hepatitis caused by *bacille Calmette-Guérin* (BCG) is reported in 12% to 28% of patients receiving BCG as immunotherapy for neoplastic disease (103,104), often several months after the last inoculation. A role for both Calmette-Guérin bacilli and a hypersensitivity reaction has been proposed as the mechanism. O'Brien and Hyslop (105) note that BCG organisms may remain viable for weeks to months. Hunt et al. (106) suggested that BCG preparations are antigenic, with granulomas forming as a result of a hypersensitivity response.

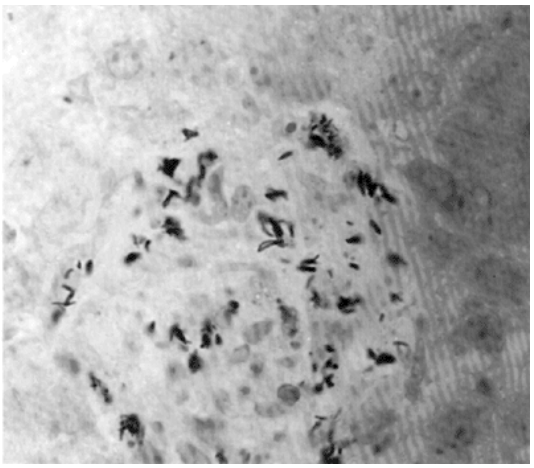
Leprosy (Mycobacterium Leprae)

Granulomas are common in lepromatous leprosy, but symptoms and signs of hepatic involvement are generally absent, apart from hyperglobulinemia (107,108). Histologically, a spectrum of epithelioid, tubercular, and foam-cell granulomas is seen (109); the first two suggesting the tuberculoid form of the disease and the latter lepromatous leprosy. Foam cells consist of Kupffer cells that are filled with *Mycobacterium leprae*. The *M. leprae* bacteria are much less common in epithelioid granulomas. Hepatic granulomas in leprosy correlated with cutaneous involvement, in the series by Chen et al. (108).

Granulomas in Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

Hepatic granulomas were seen in 37% of 501 liver biopsies in one large series (110) and in 16% to 48% of smaller series (89,111,112). A microbiological diagnosis was apparent only after liver biopsy in more than 50% of a series of patients presenting with fever and elevated alkaline phosphatase and γ-glutamyltransferase levels (113). The most common cause of granulomas appears to be due to *Mycobacterium avium* complex (MAC) that has been present in 20% to 50% of all autopsy series in fatal AIDS cases and in 10% to 70% of those undergoing liver biopsy for suspected AIDS hepatopathy (89,114,115). MAC has been reported to develop in up to 20% of patients after an AIDS-defining illness has occurred. The granulomas are generally poorly formed and are composed of foamy histiocytes with a paucity of other cells, but they contain numerous AFB (Fig. 52.8). Granulomas may be absent in a severely immunosuppressed host. In a series of liver biopsies and autopsies from 71 patients with AIDS from 1982–1986 in Paris, Astagneau et al. (116) found granulomatous hepatitis in 22 patients, half of which were associated with opportunistic infections and the rest remained unexplained. Well-formed necrotizing and non-necrotizing granulomas are described in immunocompetent patients infected with MAC (117).

M. tuberculosis has been described in 60% of AIDS patients with pulmonary disease and in 7.5% with extrapulmonary disease, often as a result of reactivated disease from a previous focus (89,118). These granulomas tend to be better formed and occur earlier in the course of human immunodeficiency virus (HIV) infection compared to *M. avium* complex. However, fewer AFB are present on immunohistochemical stains. In contrast to *M. tuberculosis*, MAC is usually the result of a primary infection, typically in the late stages of AIDS with $CD4^+$ counts $<200/mm^3$ (89). An improved response to multidrug regimens has correlated with improved survival. Alkaline phosphatase values, reflecting hepatic involvement, may normalize after successful therapy.



▪ **Figure 52.8** *Mycobacterium avium* in a poorly formed granuloma in a patient with acquired immunodeficiency syndrome. Numerous acid-fast bacillus are seen in distended histiocytes (hematoxylin-eosin, ×630). (Courtesy of Dr. KG Ishak, Armed Forces Institute of Pathology.)

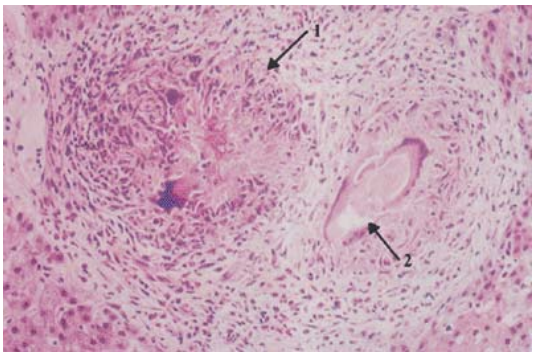
A number of parasites can cause granulomatous disease in the population with HIV. *Pneumocystis carinii* pneumonia with extrapulmonary spread is seen in more than 30% at autopsy. Toxoplasmosis, leishmaniasis, and schistosomiasis are described in this population. Fungal causes of granulomas may also be seen (58).

Other Infectious Causes of Granulomas

Schistosomiasis

Schistosomiasis (*Schistosoma mansoni, S. japonicum, S. mekongi*) is acquired by contact with fresh water infested with the parasitic larvae (cercariae) carried by their host snails. Several hundred million persons are affected worldwide, mostly in tropical regions of the Middle East, the Caribbean (Puerto Rico), Central America, Africa, and South East Asia. The life cycle of schistosomes is well described (35,119). The adult worms can survive in the host for up to 35 years, depositing hundreds to thousands of eggs daily. Most eggs find their way to the portal circulation and become trapped in several organs, notably the liver. Constant deposition of eggs results in a $CD4^+$ T-helper-cell mediated granulomatous response to egg antigens (Sm-p40 and others) (120,121,122,123,124), which can cause a chronic hepatic reaction with large granulomas in portal areas that become surrounded by fibrosis, leading to noncirrhotic

portal hypertension (125) (Fig. 52.9). Following the death of the ova, a dense portal fibrosis may be the only histologic remnant of the infection (18).



▪ **Figure 52.9** Schistosomiasis (*Schistosoma mansoni*) granuloma (*arrow 1*) next to an ovum blocking an intrahepatic portal vein branch (*arrow 2*) in a patient with portal hypertension. (hematoxylin-eosin, ×400). (Courtesy of Dr. KG Ishak, Armed Forces Institute of Pathology.)

Clinically, a serum sickness–like illness from circulating immune complexes produces fever, myalgias, arthralgias, cough, diarrhea (sometimes bloody), and eosinophilia. Eggs may be found in the stool, but an enzyme-linked immunosorbent assay (ELISA) test to detect schistosome antibodies is more reliable. Features of periportal fibrosis and portal hypertension on abdominal imaging tests may also be helpful in making the diagnosis. Friis et al. (126) described a quantitative serologic method to estimate the volume of *S. mansoni* granulomas in a murine model. They found that zinc-deficient animals had more eggs in their livers due to impaired intestinal expulsion and resorption of eggs. Jacobs et al. (127) noted that a *S. haematobium* infection modulated the *S. mansoni* egg antigen-induced granulomas and hepatic fibrosis in mice.

Q fever

This worldwide zoonosis among ruminants and birds is caused by tick-borne *Coxiella burnetti*, an obligate intracellular gram-negative bacterium forming spore-like forms that inhabits monocytes and macrophages (128,129). Acute infection in humans occurs primarily by inhalation of contaminated aerosols and dusts from domestic animals, particularly after contact with parturient females and their birth products as the placenta harbors millions of the bacteria (130). Q fever may present as a community-acquired pneumonia with high fever, cough, headache, and myalgias (131,132), or as a self-limited febrile illness without pulmonary symptoms (130). Up to 50% of patients present with acute hepatitis-like symptoms (131), several of whom have hyperbilirubinemia including jaundice (133). Hepatic involvement also presents as FUO and as an incidental finding in patients with pneumonia. Industrial outbreaks (from aerosolized spores) have been described (134), but the infection occurs most frequently among workers in sheep (55) and cattle farms (135) or in slaughterhouses (136) outside the United States. A chronic form of the disease can result in endocarditis, myocarditis, pericarditis, and chronic fatigue syndrome (137,138,139). Hepatitis generally affects younger patients, while pneumonia is seen in older individuals (54,139).

The characteristic histologic appearance is a fibrin-ring granuloma (47,140), previously referred to as a "doughnut" granulomas (141) (Fig. 52.3). They are usually seen in portal areas and accompanied by prominent lymphoid hyperplasia. Toll-like receptor 4 appears to play a role in the uptake of virulent organisms and the development of granulomas (128). In mice, the intraperitoneal route of infection led to hepatic involvement, while the intranasal route was more often associated with pneumonitis (142). Serology and PCR testing are available to confirm the diagnosis. Treatment has been successful with the use of doxycycline and steroids (54,139). A

preventative vaccine is available (136).

Syphilis

Secondary lues (*Treponema pallidum*) involves the liver in up to 50% of cases, often with tender hepatomegaly and, sometimes, overt jaundice. Elevated alkaline phosphatase levels with lesser elevations in aminotransferases is the most common biochemical finding. Spirochetes have been demonstrated by appropriate staining in up to half of affected liver specimens (143). Following successful antibiotic treatment, resolution of granulomas and other hepatic abnormalities can be expected. In tertiary syphilis, single or multiple hepatic gummas are seen, that may give rise to a lobulated appearance (hepar lobatum). Although much larger than granulomas, gummas may also resolve following treatment (35).

Yersinia enterocolitica

Diffuse granulomas of the liver and spleen are seen in the septicemic form. Twelve percent of infections have involved the liver, in some cases causing chronic hepatitis (144,145).

Bartonella henselae (catscratch fever)

Catscratch fever develops after a scratch or bite by a cat or kitten and usually results in regional lymphadenitis, although, peripheral adenopathy is not always present (146,147,148). Scattered granulomas with central necrosis may coalesce to form abscesses. This disease has been

diagnosed in a liver transplant recipient with a FUO (149).

Warthin-Starry silver staining may identify the gram-negative bacillus early in the course of infection. An antigen skin test is positive in 90% but PCR tests are now available (150).

Visceral leishmaniasis

Visceral leishmaniasis (*Leishmania donovani*, kala azar) is transmitted by the bite of the sandfly causing a papular or ulcerative skin lesion with systemic symptoms occurring after a latent period of 2 to 6 months or longer. Intermittent fever, weight loss, tender hepatosplenomegaly, and occasional jaundice are seen. Phagocytosis of the parasite by macrophages in the reticuloendothelial system (RES) allows the organism to multiply in the affected liver, spleen, bone marrow, and lymph nodes. The diagnosis is based on the finding of amastigotes in aspirates or promastigotes in culture from these tissues, as well as from serologic testing (51,151).

Visceral larva migrans

Visceral larva migrans caused by *Toxocara canis*, typically produces hepatic granulomas containing numerous eosinophils. In a series of 43 cases reviewed by Epstein et al. from the AFIP (152), 30% were younger than 20 years and 60% were asymptomatic with the disease discovered incidentally. Fever and/or abdominal pain were the most common symptoms reported in the remainder. Granulomas were multiple in 61% and central necrosis was characteristically surrounded by eosinophils and neutrophils, often with Charcot-Leyden crystals. Remnants of the parasite were detected in 23%, and immunohistochemical staining and serology confirmed the diagnosis in many others.

Brucellosis

Acquired from infected cattle (*Brucella abortus*), pigs (*B. suis*), sheep (*B. ovis*), and goats (*B. melitensis*), often from raw, unpasteurized milk and dairy products, brucellosis typically presents as an acute febrile illness with hepatic involvement.(153,154,155). Jaundice is not uncommon (155,156), as is relapsing (undulant) fever. Epithelioid granulomas are most often seen in the chronic form of the disease, with a lobular location more common that the portal tracts. Central necrosis, a polymorphic infiltrate, relatively few giant cells, and peripheral fibrosis are typically seen. The diagnosis is confirmed by serology, positive Brucella PCR (153,154), or culture of liver tissue (153). Untreated, the clinical course is usually one of spontaneous resolution within 3 to 12 months of infection, although antibiotics may shorten the illness (35,155).

Histoplasmosis

Histoplasmosis (*Histoplasma capsulatum*) is found most commonly in the midwest and central parts of the United States, especially river valleys, and usually affects young children more than adults (19). Four percent to 8.5% of patients have rare well-formed granulomas (19,157). Rarely are they caseating, resembling TB. Clinically, adrenal insufficiency may be a diagnostic clue (157).

Coccidioidomycosis

Coccidioidomycosis (*Coccidioides immitus*) is most likely to be found in the deserts of the southwest United States. Granulomas are more likely to be found in the liver compared to histoplasmosis, and eosinophilia is often present (158).

Granulomas Associated with Chronic Viral Hepatitis and its Therapy

Several reports have described granulomas in patients with *hepatitis C* infection (159,160,161,162,163), although some of these may be related to suspected or unsuspected sarcoidosis (78,164) or PBC (165). Emile et al. (160) described multiple epithelioid granulomas in 10% of cirrhotic livers without any other cause being identified. These granulomas were located within cirrhotic nodules and not in portal areas.

Interferon has been associated with granuloma formation in patients with hepatitis C virus (HCV) infection (159,160,166) although the exact pathogenesis is not always certain. Interferon-induced cutaneous sarcoid has been described in patients with hepatitis C (80), and induction (81) and reactivation (79) of systemic sarcoidosis has also occurred, possibly through the production of inflammatory cytokines mediated by interferon (167).

Granulomas are also found in a small percentage of patients with chronic hepatitis B, 1.5% among 663 patients in one series (168).

Granulomas *after liver transplantation* are reported to occur in 3% to 9% of allografts (99) and may reflect recurrence of the original disorder, such as PBC, sarcoidosis, and so on, or possibly de novo formation from interferon therapy for HCV in the post-transplantation setting. Granulomatous cholangitis may be seen in acute cellular rejection or a delayed vanishing bile duct syndrome (VBDS) (169). Infections with opportunistic agents, including TB (86) and *Toxoplasma gondii* are described. Toxoplasmosis appears within the first 3 months with fever, pneumonia, and possibly meningitis or encephalitis, usually from activation of a latent infection (170) (Table 52.8).

Table 52.8. Causes of Granulomas in the Post–Liver Transplantation Setting

Recurrence of primary disease (primary biliary cirrhosis, sarcoidosis, hepatitis C virus, hepatitis C virus)
Interferon therapy–induced
Acute cellular rejection (granulomatous cholangitis)
Chronic ductopenic rejection (vanishing bile duct syndrome)
Post-transplantation opportunistic infections (cytomegalovirus, tuberculosis, fungi, toxoplasmosis)

Granulomas in Other Chronic Cholestatic Liver Diseases

Primary biliary cirrhosis

Epithelioid granulomas are found in at least 25% of patients with PBC, usually in the early stages of the disease (171). PBC typically affects middle-aged women who may present with subclinical alkaline phosphatase elevations or with symptoms reflecting chronic cholestasis, including pruritus. The disease is associated with positive antimitochonrial antibodies (AMA) in >95% and this may serve to differentiate PBC from sarcoidosis. In addition, PBC often occurs in association with other autoimmune disorders, such as the sicca syndrome, Sjögrens syndrome, and CREST syndrome among others (171). Granulomas in the portal areas are in close proximity to injured bile ducts, and may give the appearance of being germinal centers (Figs. 52.10 and 52.11). It is thought that they form as part of the immune-mediated ductal injury, but release of bile acids and phospholipids from injured ducts may also contribute to their development (172,173). Granulomas located in the hepatic lobules are noncaseating and show less central matrix deposition than is usually seen in sarcoidosis (73). As PBC progresses, granulomas become less frequent (174). However, treatment with ursodiol therapy may also be associated with a reduction in granulomas, through its beneficial effects on the histologic features of cholestasis (175,176). The presence of granulomatous bile duct lesions can help differentiate and confirm the diagnosis of recurrent PBC from chronic rejection after liver transplantation (174).

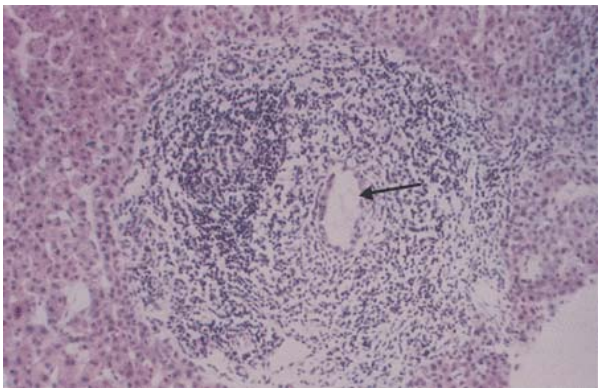
of Dr. KG Ishak, Armed Forces Institute of Pathology.)



▪ **Figure 52.11** PBC with a granuloma in an expanded portal area near a damaged bile duct (arrow) (hematoxylin-eosin, ×160). (Courtesy of Dr. KG Ishak, Armed Forces Institute of Pathology.)

Primary sclerosing cholangitis

Granulomas have also been reported in PSC (172,177). Thirteen percent of 100 patients undergoing liver transplantation for PSC had noncaseating, non-necrotizing epithelioid granulomas, some with giant cells (177). They were found in the portal areas, scars, and the hepatic parenchyma, and were present in all stages of the disease, but do not represent granulomatous cholangitis (in contrast to PBC where the granulomas are a feature of duct destruction). Ludwig et al. (177) surmise that the granulomas in PSC form in response to bile acid leakage. Perigranulomatous lymphocytic infiltrates were common.

Drug-Induced Granulomas

More than 60 drugs have been implicated (Table 52.9), although, most are isolated case reports (8,67,100,178). A few agents appear to be well-documented as causing granulomatous hepatitis, usually as part of a hypersensitivity syndrome (e.g., phenylbutazone [PBZ]) (179) (Fig. 52.12A,B), sulfonamides, allopurinol (48) (Fig. 52.3B), phenothiazines, and penicillins. Drug-induced granulomas have been reported with a frequency of up to 29% of all causes of hepatic granulomas (8); although the prevalence has usually been far lower. In the McMaster series (8), the drugs that were listed as probably or possibly related were predominantly from antihypertensive, antirheumatic, anticonvulsant, and

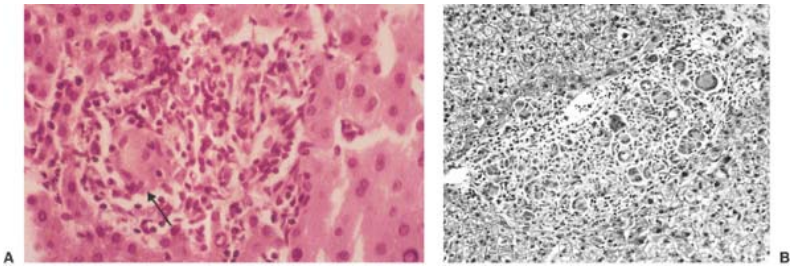
antimicrobial drug classes, and included methyldopa, hydralazine, phenytoin, isoniazid, cephalexin, penicillin, sulfonamides, and procainamide, among others. Six percent to 9.5% of granulomas in other series were due to many of the same drug classes (10,11,16) and included chlorpropamide, allopurinol, PBZ, synthetic penicillins, quinidine, carbamazepine, and phenothiazines, among others.

Table 52.9. Drugs Associated with Granulomas and Granulomatous Reactions

Allopurinol	Nitrofurantoin
Amiodarone	Norfloxacin
Amoxicillin—clavulanic acid	Oral contraceptives
Aprindine	Oxacillin
Carbamazepine	Oxyphenbutazone
Chlorpromazine	Papaverine
Chlorpropamide	Penicillin

Dapsone	Phenprocoumon
Diazepam	Phenbutazone
Dicloxacillin	Phenytoin
Diltiazem	Procainamide
Disopyramide	Procarbazine
Glyburide	Pronestyl
Glibenclamide	Pyrazinamide
Gold salts	Pyrimethamine-chloroquine
Green juice	Quinidine
Halothane	Quinine
Hydralazine	Rantidine
Interferon α	Rosiglitazone
Isoniazid	Sulfasalazine
Mebendazole	Saridon
Mesalamine	Seatone (green lipped mussel extract)
Methimazole	Sulfanilamide and other sulfa drugs
Methotrexate	Tetrabamate (Atrium)
Methyl dopa	Tetrahydroaminoacridine (tacrine)
Mineral oil	Tolbutamide
References contained in 57,58,67,100,101,178.	

The most frequent clinical presentation is an acute febrile illness, with or without a rash and peripheral eosinophilia, followed by jaundice and biochemical evidence of hepatic dysfunction (8). A latency of 1 to 16 weeks is described by McMaster et al. (8), which is consistent with the timeframe for other hypersensitivity reactions from drugs (100,101). Histologic features suggesting a drug-induced cause include the relatively uniform age of the granulomas, and the presence of eosinophils, apoptotic bodies, acute cholangitis, and/or vasculitis (67). In contrast, tissue eosinophilia is not seen in sarcoidosis or TB. The prognosis is generally good with recovery after the offending agent is withdrawn. Healing without sequellae is the rule (8,67).



▪ **Figure 52.12** Granulomas associated with acute hypersensitivity reaction to phenylbutazone. **A:** Two epithelioid granulomas similar in size and age (hematoxylin-eosin, ×100). **B:** Epithelioid granuloma containing several multinucleated giant cells (hematoxylin-eosin, ×150). Granulomas Associated with Metals and Minerals

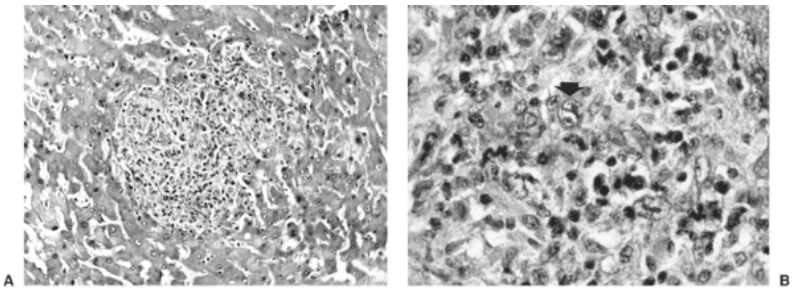
Beryllium poisoning uncommonly involves the liver, as the chronic form of the disease is primarily a pulmonary granulomatosis with dyspnea and cough (180,181). It should be suspected in occupational exposure where beryllium is employed, such as in the manufacture of ceramics and alloys, and in atomic energy workers. The granulomas seen in beryllium disease may contain Schaumann and asteroid inclusion bodies, which are the end products of actively secreting epithelioid cells (3) and may be confused with those seen in sarcoidosis (182). Tissue analysis for beryllium may be confirmatory.

Talc microcrystals are commonly seen in intravenous drug users, many of whom "cut" their heroin with talcum powder. They are found in hypertrophied portal macrophages, but generally do not develop into well-formed granulomas (183), in contrast to *silica*, which forms foreign body–type giant cells that contain the birefringent crystals (184). The presence of talc in the liver, however, may be an important clue as to the etiology of chronic hepatitis C (185).

Refractile *silicone* particles (confirmed by x-ray energy dispersive spectroscopy) were described in association with sarcoid-like granulomas, some with giant cells, in hemodialysis patients in whom embolization (spallation) of silicone was traced back to tubing traumatized in the roller pump (186,187). Abnormalities in liver-associated enzymes persisted more than 4 years later in two patients (188).

Multiple granulomas were described in long-term hemodialysis patients (189) with *aluminum* found in the cytoplasm of macrophages in the liver, spleen, and lymph nodes.



▪ **Figure 52.13** Hodgkin's disease granulomas. **A:** Focal granulomatous infiltrate (hematoxylin-eosin, ×180). **B:** Higher magnification showing a pleomorphic infiltrate with a Reed-Sternberg cell (*arrow*) (hematoxylin-eosin, ×750). (Courtesy of Dr. KG Ishak, Armed Forces Institute of Pathology.)

Granulomas Associated with Malignancy and Immunodeficiency States

HD, lymphomas, and certain hematogenous malignancies (e.g., *hairy cell leukemia* [HCL] are associated with granulomas. Granulomas are seen in approximately 10% of those with HD (190,191) (Fig. 52.13A, B), and were present in 31% of those with HCL (192). Granulomas in the liver may precede the diagnosis of HD or lymphoma (193), and may be a source of diagnostic confusion with sarcoidosis (3). Rarely have the granulomas associated with HD been caseating (194). The presence of granulomas does not appear to convey any clinical advantage as

suggested by early reports (195). Mimics of lymphomas that may be associated with hepatic granulomas include *Kikuchi lymphadenitis* among others (196).

Common variable immunodeficiency is associated with noncaseating granulomas in the liver and spleen (197). *Chronic granulomatous disease* (198) may appear in adults as well as children (199). Hypogammaglobulinemia has been associated with granulomas and asymptomatic cholestasis (200).

Miscellaneous Causes of Granulomas

Jejunoileal bypass–granulomas were among several hepatic lesions, including steatohepatitis, which were seen following jejunoileal bypass surgery for morbid obesity (201). Twenty-four percent of patients undergoing jejunoileal bypass in a series of 25 patients reported by Banner et al. developed granulomas (202). They developed within 3 months to 4 years of the

surgery and were much more common than the incidence (4%) of granulomas seen in obese patients before surgery. Their exact etiopathogenesis is unclear.

Table 52.10. Hepatic Granulomas as a Cause of Fever of Unknown Origin

Author (ref)	Year	Number of cases	Diagnoses
Terplan (205)	1971	*n* = 60	Sarcoidosis 47%; TB 25%; idiopathic 17%
Bruguera (206)	1981	*n* = 25	36% "positive" diagnosis
Israel (204)	1984	*n* = 15	Sarcoidosis 100%
Telenti (26)	1989	*n* = 20	Idiopathic 100%
Zoutman (27)	1991	*n* = 23	Idiopathic 74% (41% spontaneous regression); 26% specific diagnosis (Q fever, TB, histoplasmosis)

TB, tuberculosis.

Rheumatoid arthritis is a rare cause of granulomas (203), as are other rheumatic disorders.

Idiopathic granulomatous hepatitis and fever of unknown origin–up to 74% of hepatic granulomas in the early series were not identified with a specific diagnosis (27) (Table 52.10). Many of these patients had FUO or other systemic symptoms or hypersensitivity features, and were designated as having "granulomatous hepatitis" (25). Sarcoidosis was found in a number of such patients (204,205); and infectious agents in some of the others (205,206); although no cause remained apparent in many (26), Aderka et al. (207) found that certain clinical parameters could differentiate idiopathic granulomas from those that are secondary to lymphoma and other malignancies—namely smaller spleen size, small liver size (<4 cm below the respective costal margin), lower percentage of eosinophils (<4%), and fever lasting <4 weeks. The spectrum of hepatic candidiasis includes granulomas, especially among patients with hematological malignancies presenting with fever, and elevated alkaline phosphatase levels (208). In a series by Cunningham et al. (9), 31% of granulomas that were considered initially to be "idiopathic", were subsequently diagnosed as having a specific cause based on a more in-depth study. As a result, fewer than 10% remained without an etiology (9), on par with later series. Schlegel (60) described what he termed "factitious" granulomatous hepatitis in a health care worker who had hepatic granulomas and leukopenia attributed to quinine ingestion that was likely being taken surreptitiously.

Treatment of Hepatic Granulomas and Granulomatous Hepatitis: General Principles

Simple granulomas found incidentally are often asymptomatic but should prompt a workup for the most common causes of granulomas (Tables 52.3, 52.5, 52.9). They may not require treatment if involvement is isolated to the liver. Individuals presenting with granulomatous hepatitis, including those with FUO and other systemic symptoms, can be treated for a specific cause, if found. Those granulomas that are considered *idiopathic* may respond to an empiric course of corticosteroids (5,25,26,27). In a series of 23 cases reported by Zoutman et al. (27) presenting with FUO, 74% were considered idiopathic. In 41% of this group the granulomas resolved spontaneously, while the remaining 59% received corticosteroids or indomethacin; 18% were short-term and 41% long-term treatment (mean 33 months). All were described as having remained afebrile and healthy after a 5-year follow-up. A similarly good prognosis after long-term corticosteroid therapy of up to 10 years was described by Telenti and Hermans (26) with no progression or dissemination of an unrecognized infectious process.

In sarcoidosis, corticosteroids are usually given when there is evidence of extrahepatic sarcoidosis, as most

experts do not believe that isolated hepatic involvement requires therapy unless there is evidence of severe cholestasis (68). Methotrexate has also been utilized in this disorder (209), as has ursodiol (68), especially for the cholestatic form. Liver transplantation has been required to treat some patients with end-stage chronic cholestatic sarcoidosis (76).

Specific antibiotic therapy for various infectious causes and other treatment options directed at specific causes of hepatic granulomas are reviewed elsewhere (35) (Table 52.5). Empiric treatment for TB has been offered in some instances (209). Drug-induced causes generally resolve spontaneously once the medication has been discontinued.

In cases of symptomatic idiopathic granulomatous hepatitis (such as FUO), corticosteroids have been the mainstay of treatment (26). Longstreth and Bender (210) described the use of cyclophosphamide as a steroid-sparing maintenance agent in preventing recurrence of idiopathic hepatic granulomatosis. Methotrexate was described as being effective in seven patients presenting with fever and anorexia in a series by Knox et al. (209). Nonsteroidal anti-inflammatory

drugs (NSAIDs) were used successfully in a child with necrotizing granulomatous inflammation (211).

Summary

Hepatic granulomas are not infrequently encountered in the evaluation of a variety of infectious, chronic, cholestatic, inflammatory, hypersensitivity-mediated, and neoplastic disorders. Granulomas can be expected to be present in 5% to 10% of routine liver biopsies, and in a substantially higher percentage of patients with suspected localized or systemic granulomatous diseases. Both genders and all ages can be affected. The list of possible etiologies, including dozens of drug-related causes, has been expanding, although certain causes still predominate, namely sarcoidosis, TB, PBC, and certain drugs (especially those acting through hypersensitivity mechanisms), often relating to the geographic location of the patient. Less common causes remain a diagnostic challenge, but are being found more frequently, commensurate with the wider availability of serologic and other PCR-based test systems. Hepatic granulomas may be the only histologic clue as to the presence of several infections, such as TB and Q fever, among others. Once found, a decision regarding the extent of a further diagnostic evaluation must be made, and ultimately, what treatment, if any, is required. The cause of approximately 10% of granulomas remains undefined (idiopathic), some of which are associated with unexplained fever and other symptoms (including arthralgias and rash), that define "granulomatous hepatitis." These cases are arguably the most challenging, often having to rely on empirical treatment regimens. It is anticipated that advances in clinical and histopathologic diagnostic methodologies will help identify even the most refractory causes of hepatic granulomas in the future.

Annotated References

Collins MH, Jiang B, Croffie JM, et al. Hepatic granulomas in children. A clinicopathologic analysis of 23 cases including polymerase chain reaction for histoplasma. *Am J Surg Pathol* 1996;20:332–338.

One of the largest reviews of granulomas in a pediatric population. In comparison to adults where the most common causes are sarcoidosis, TB, drugs, neoplasms, and chronic cholestatic liver diseases, in this series, histoplasmosis accounted for 65% of granulomas with an identifiable etiology. The authors emphasize the usefulness of PCR-based testing to improve diagnostic accuracy.

Devaney K, Goodman ZD, Epstein MS, et al. Hepatic sarcoidosis. Clinicopathologic features of 100 patients. *Am J Surg Pahtol* 1993;17:1272–1280.

One of the largest series of hepatic granulomas due to sarcoidosis from the experts at the Armed Forces Institute of Pathology. They describe three main categories of hepatic sarcoidosis based on biochemical and histologic features: Cholestatic in 58% (often with bile duct injury and ductopenia similar to PBC), necroinflammatory in 41%, and those with associated vascular changes of sinusoidal dilatation or nodular regenerative hyperplasia in 20%.

Ishak KG, Zimmerman HJ. Drug-induced and toxic granulomatous hepatitis. *Baillieres Clin Gastroenterol* 1988;2:463–480.

The most comprehensive review of drugs and chemical toxins associated with hepatic granulomas from two of the leading experts in the fields of drug-induced hepatotoxicity and hepatopathology. They emphasized the role of liver biopsy in this setting. Histologic lesions that suggested a drug etiology included associated tissue eosinophilia, acute cholangitis, and the uniform age of the granulomas. Special stains and other histopathologic analyses may also play an important role in helping to confirm the diagnosis and assigning causality to a drug.

James DG. A clinicopathological classification of granulomatous disorders. *Postgrad Med J* 2000;76:457–465.

An excellent review of the pathophysiology and immunology of granuloma formation. The author describes the interplay of the invading organism, drug, chemical, or other irritants, and the cytokines and other biological mediators involved in the transformation of macrophages to epithelioid cells that comprise a majority of granulomas. An overview of many infectious, chemical, and other causes of granulomas is provided.

Lewis JH, Zimmerman HJ. Tuberculosis of the liver and biliary tract. In: Schlossberg D, ed. Tuberculosis and

nontuberculous mycobacterial infections, 4th ed. Philadelphia: WB Saunders, 1999:238–263.

A comprehensive review of tuberculous infections of the liver and the spectrum of granulomatous disease they produce. Hepatic granulomas are found most often in miliary TB and less often in pulmonary and extrapulmonary disease. Caseating necrosis is seen most commonly in association with the acute disseminating infections of miliary TB. The yield of special stains and culture remains low, but PCR-based tests of TB have improved disgnostic yields.

Raoult D, Tissot-Dupont H, Foncault C, et al. Q fever 1985–1998. Clinical and epidemiologic features of 1,383 infections. *Medicine (Baltimore)* 2000;79:109–123.

A comprehensive review of Q fever from France. This organism (Coxiella burnetti) *is responsible for a characteristic fibrin-ring type of granuloma. Acute hepatitis was the most common clinical presentation, seen in 40% of cases, often associated with Q fever pneumonitis. The authors describe a number of patient host factors that appear to dictate the clinical expressions of the disease.*

Wanless IR, Geddie WR. Mineral oil lipogranulomata in liver and spleen. A study of 465 autopsies. *Arch Pathol Lab Med* 1985;109:283–286.

Lipogranulomas are less common than epithelioid granulomas, but were found in 48% of livers examined in this large series. The authors describe the clinicohistologic features of lipogranulomas that are generally clinically silent. They appear most often in older adults, particularly men, and are associated with the ingestion of mineral oil in most instances.

Zoutman DE, Ralph ED, Frei JV. Granulomatous hepatitis and fever of unknown origin. An 11-year experience of 23 cases with three years' follow-up. *J Clin Gastroenterol* 1993;17:69–75.

One of the largest series that helps define the natural history of idiopathic granulomatous hepatitis associated with FUO. The authors were able to identify a specific diagnosis in only 26% of their patients. Among the cases without a precise etiology, 41% eventually resolved spontaneously; 18% resolved after short-term treatment with corticosteroids and anti-inflammatory drugs while the remaining 41% required long-term corticosteroid therapy to maintain clinical remission and prevention of fever over nearly 6 years of follow-up.

Chapter 53

Selection and Timing of Liver Transplantation

Richard B. Freeman Jr.

Key Concepts

- Selection of candidates for liver transplantation is not necessarily linked to the timing of liver transplantation due to the severely constrained organ donor resource. This means that individual candidates cannot always receive a transplant at the optimal time for his or her benefit.
- For most patients with chronic liver disease, selection for transplantation depends on their risk of dying from the liver disease weighed against their risk of dying from the transplantation procedure and attendant medications. Mortality risk scores have been helpful in determining when this risk of death without transplantation is greater than the risk after the procedure. Although patients with severe chronic liver disease have deteriorated health-related quality of life (HRQOL), this must be weighed carefully against the risk of death while waiting compared with the risk of death from the transplantation. There can be no quality of life for deceased candidates.
- For some liver conditions, the benefit of liver transplantation cannot be weighed against the mortality risk from intrinsic liver disease. Therefore other methods, such as estimates of disease progression, must be used for proper selection of waiting candidates. Disease progression estimates are limited by lack of good natural history data.
- Pediatric patients with liver disease face unique problems and mortality risk models utilizing variables specific for children have been developed to address these differences.
- Efficient selection of liver transplantation candidates with acute liver failure is especially challenging because of the need to rapidly assess the probable natural course of the disease so that patients not likely to recover will receive transplant priority but those more likely to recover do not receive needless transplants.
- Living donor liver transplantation improves the ability of the clinician to "time" the transplantation at the most advantageous point in disease progression for the waiting candidate. However, donor risks and informed consent must not be subjugated in an effort to maximize the timing benefit.

Inhabitants in the developed world are fortunate that, in large measure, effective treatments for most medical conditions are generally available with access to these treatments limited mostly by socioeconomic or distributive problems, rather

than scarcity of the therapeutic substrate itself. This is not the case for transplantation. Unlike any other field in medicine, the clinician's ability to apply transplantation therapy is not completely defined by the risk-benefit ratio of that therapy for the patient in question. For patients who could potentially benefit from liver transplantation, the constrained resource problem is acutely severe because alternative liver support technologies are not perfected. Therefore, the application of liver

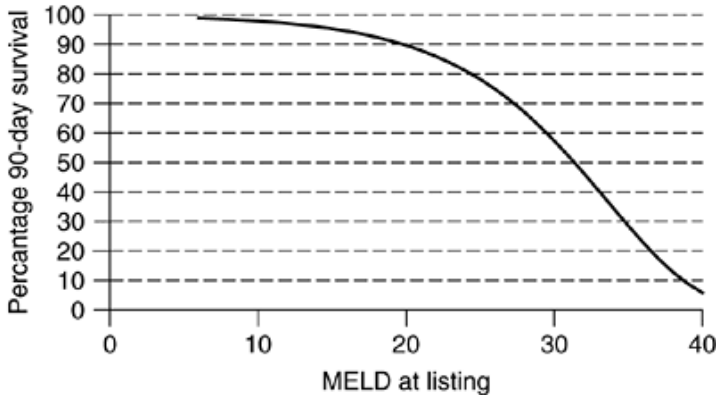
transplantation therapy, depends not only on the diagnosis of a problem for which liver transplantation is likely to provide more benefit than harm, but also on the availability of the therapeutic substrate; the liver itself. Consequently, and in contrast to most other medical conditions, determining if a patient diagnosed with progressive liver disease will receive benefit from liver transplantation is not sufficient for initiation of delivery of the treatment. This makes the optimal timing for liver transplantation a two-sided proposition: (a) Determining when a patient's disease has advanced far enough that he or she will receive more benefit than harm from the transplantation procedure and subsequent maintenance treatments, and (b) determining who, among all those who are deemed to likely receive benefit, should come first when donor constraints allow only one patient at a time to be treated. The former patient-based issue can be categorized as selection of appropriate candidates for transplantation. The second topic, timing of liver transplantation, is not entirely under the control of the treating physician or patient but much more influenced by allocation and distribution rules. Only in the case of living liver donor transplantation, can treating clinicians completely control the timing of liver transplantation for candidates they have deemed appropriate. In this chapter, the selection of patients for liver transplantation, the optimal timing of liver transplantation, absent organ donor constraints, the timing of liver transplantation in the context of living donor liver transplantation, and finally organ allocation priorities and their influence on the timing of liver transplantation are addressed.

Selection of Candidates for Liver Transplantation

Mortality Risk

Liver transplantation, like all therapies, should be offered when the risks are outweighed by the benefits. Quantitating risk and benefit however, is no easy proposition, and fraught with subjective interpretations of need for transplantation. For any candidate, comorbid conditions, such as cardiopulmonary disease (1), renal function, chronic or active acute infections, neurologic and psychiatric impairments as well as the social support system available to the patient must be assessed and considered in the overall determination of surgical risk. Caregivers and patients must weigh mortality risks, disease progression, and the impact of deterioration in quality of life for patients with liver disease who may be candidates for liver transplantation. In the past, most patients were deemed reasonable candidates for transplantation based on the development of signs or symptoms of decompensation usually related to portal hypertension (2). These original assessments of liver transplantation candidacy were subsequently incorporated into minimal listing criteria based on an anticipated 1-year survival of 90% or less if no transplantation was performed (3). This 1-year waiting list survival criterion was equated to a Child-Turcotte-Pugh (CTP) (4) score of greater than or equal to 7. However, the use of subjective variables, and differences in cholestatic versus noncholestatic liver diseases, as well as a “ceiling effect”

inherent in the CTP score for more advanced chronic liver disease, led investigators to develop mathematical models for primary biliary cirrhosis (5,6,7,8,9), and primary sclerosing cholangitis (10) to predict mortality. Subsequently, these models were compared to the CTP score and found to have similar accuracy for prediction of mortality risk (11). More recently, Malinchoc et al. defined a mathematical model to predict mortality risk in any patient with portal hypertensive complications undergoing transjugular intrahepatic portosystemic shunt (TIPS) procedure regardless of the underlying chronic liver disease (12) and without using the subjective variables employed by the CTP score (Table 53.1). This so-called Model for End-Stage Liver Disease (MELD) score has subsequently been shown to be highly predictive of 3-month mortality for a variety of cohorts of patients with chronic liver disease (13,14) and for a cohort of US patients waiting for liver transplantation (15). The MELD model has been widely accepted as a measure of chronic liver disease severity where severity of disease is defined as 3-month mortality risk and has been adapted to be incorporated into US liver allocation policy for determination of priority on the waiting list (16) (Fig. 53.1 and Table 53.1). Therefore, if one defines the need for liver transplantation in terms of risk of dying of liver disease, the MELD score provides an objective, readily available, easily applied, measure for selection of liver transplantation candidates with chronic liver disease.



▪ **Figure 53.1** Plot of Model for End-Stage Liver Disease (MELD) score at listing versus survival fraction for new listings on the liver transplantation waiting list 15 September, 2001, to 15 February, 2002.

Table 53.1. Model for End-Stage Liver Disease Score and Pediatric End-Stage Liver Disease Score

A. Malinchoc et al. (12)
$R = 0.957 \times \log_e(\text{creatinine mg/dL}) + 0.378 \times \log_e(\text{bilirubin mg/dL}) + 1.120 \times \log_e(\text{INR}) + 0.643 \times (\text{disease etiology}^a)$
B. MELD score UNOS/OPTN Policy
$R = (0.957 \times \log_e(\text{creatinine mg/dL}) + 0.378 \times \log_e(\text{total bilirubin}$

mg/dL) + 1.120 × $\log_e$(INR) + 0.643) × 10

PELD score

R = (0.463 (age[b]) – 0.687 × $\log_e$(albumin g/dL) + 0.480 × $\log_e$(total bilirubin mg/dL) + 1.857 × $\log_e$(INR) + 0.667 (growth failure[c])) × 10

MELD score as originally reported by Malinchoc et al. (12) (A), and as modified for US organ allocation (B). PELD score as reported by McDairmid et al. (17) and as is currently used for US pediatric liver allocation policy.

[a]1 for noncholestatic disease, 0 for cholestatic disease.
[b]<1 year of age + 1, ≥1 year of age = 0.
[c]>2 standard deviations below the mean for age = 1, ≤2 standard deviations below the median for age = 0.

Health-Related Quality of Life

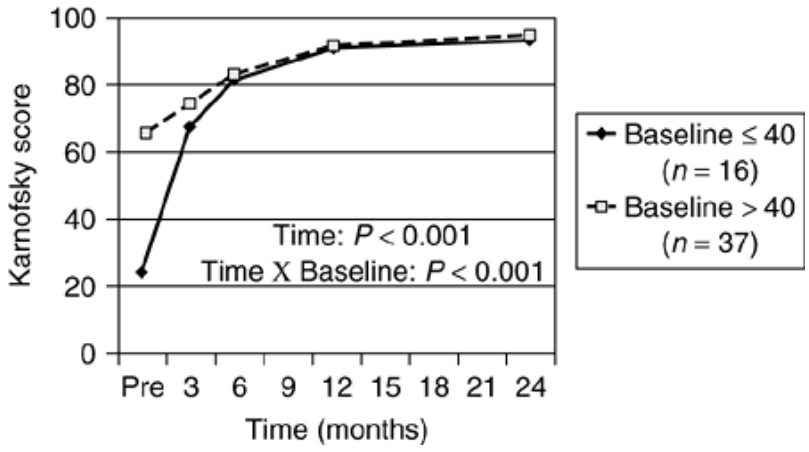
Mortality risk, however, may not be the only measure of need for liver transplantation. Numerous studies have documented that health-related quality of life (HRQOL) is poor for patients with progressive chronic liver disease (18,19,20) and that measures of mortality risk may not necessarily correlate with measures of HRQOL for these patients (21). Nonetheless, when weighing quality-of-life considerations physicians must account for mortality risk because, for patients who die, there can be no *quality* of life. Therefore, mortality risk usually takes precedence in determining the appropriate timing of liver transplantation for individual patients when the risks of death from transplantation surgery and immunosuppression are relatively low in relation to the mortality risk without transplantation although the patient's quality of life may be poor (22). For example, offering liver transplantation to patients with limitations in their HRQOL, who face a higher risk of dying because of the surgery and post-transplantation treatments than they will if they wait until their disease becomes more severe, may not be in their best interest. However, in one study of patients with end-stage liver disease, the subjects were frequently willing to accept a reduction in life expectancy in return for improved health and one half of the subjects accepted a 50% mortality risk in exchange for perfect health (23). Interestingly, almost all studies have shown significant improvements in HRQOL after transplantation (24), and the HRQOL outcome is not associated with the severity of illness before transplantation (25,26,27). Therefore, regardless of how ill patients are before the transplantation, if they survive, most can expect a reasonable HRQOL or functional status (Fig. 53.2). Therefore, there does not seem to be a justification for selecting one group of patients for liver transplantation because they are likely to achieve a better HRQOL afterwards than another group of patients. The available literature suggests that all recipients report relatively similar and significantly improved HRQOL afterwards.

Transplantation Benefit

The concept of selecting patients on the basis of estimates of transplantation benefit, as measured in number of life-years gained, has been recently addressed. Merion et al. compared the mortality risk for liver transplantation candidates remaining on the list with mortality risk for recipients of deceased donor liver transplants (DDLTs) and stratified their results by MELD score on listing. These investigators found that recipients with MELD scores less than 15 experienced a higher hazard for death than the candidates who remained on the list without transplantation at 1 year of follow-up. The authors concluded that, "liver transplants are being performed for some candidates who have a higher risk of dying from the transplantation procedure than they have from dying from their underlying liver disease" (29) (Fig. 53.3).

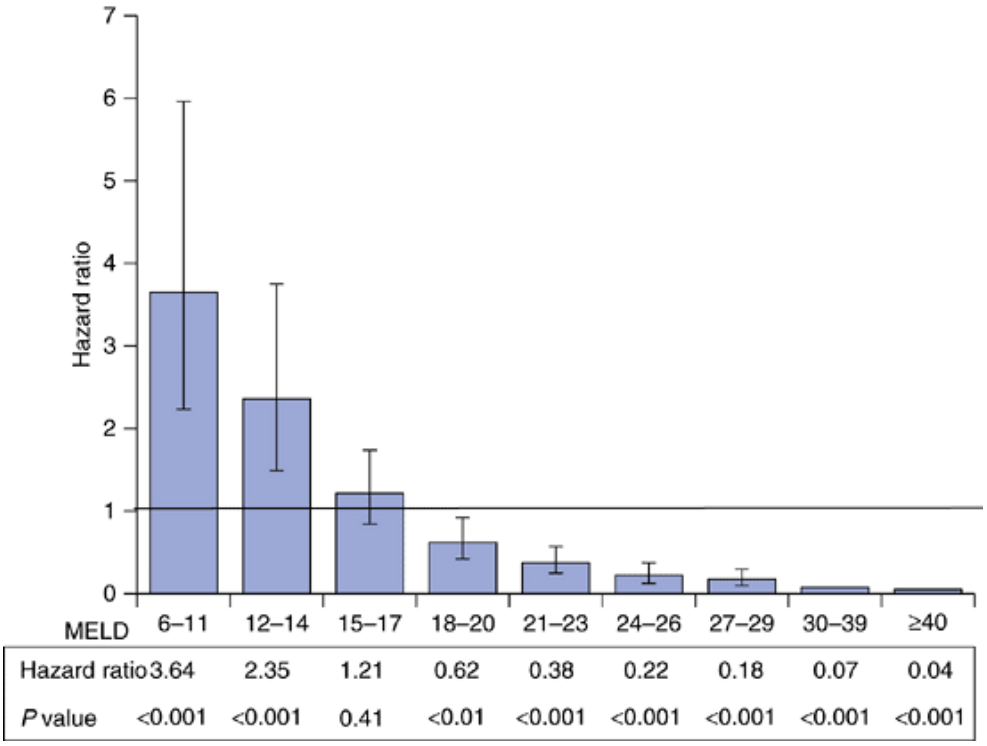
P.1456

It is interesting to note that in this study there was no MELD score beyond which a benefit in survival was obtainable. Therefore, even for candidates with very high pretransplantation mortality risks, as defined by their MELD scores, a significant benefit is achieved by liver transplantation because the success rate is still acceptable and their survival probability without transplantation is essentially zero. However, the post-transplantation survival results are based only on the candidates for whom liver transplantation was performed, and many more patients with high MELD scores than those with lower MELD scores are removed from the waiting list for reasons of death or being too sick (30). These results indicate that there is a selection process by which centers are choosing candidates with high MELD scores for whom they expect a good chance of success. From these data, the optimal timing of liver transplantation for patients with chronic liver disease can be estimated on the basis of their mortality risk, as defined by their MELD score. Most patients with nonmalignant liver disease, who have MELD scores greater than 15, will receive a benefit from liver transplantation, whereas those with lower MELD scores have a better chance of surviving for 1 year without transplantation.



▪ **Figure 53.2** Karnofsky performance scores for patients before and at various times after liver transplantation. Patients with poor baseline scores (*solid line*) had similar performance scores after transplantation compared with patients with less severe performance scores (*dotted line*) (28). (From Pinson CW, Feurer ID, Payne JL, et al. Health-related quality of life after different types of solid organ transplantation. *Ann Surg* 2000;232(4):597–

607.)



▪ **Figure 53.3** Comparison of mortality risk expressed as hazard ratio by Model for End-Stage Liver Disease (MELD) score for recipients of liver transplants compared to candidates on the liver transplantation waiting list. (From Merion RM, Schaubel DE, Dykstra DM, et al. The survival benefit of liver transplantation. *Am J Transpl* 2005;5:307–313.)

More recently, several reports have suggested that there are diagnostic groups of patients with chronic liver disease for whom MELD may not accurately reflect mortality risk. Patients with human immunodeficiency virus (HIV) and hepatitis C virus (HCV) coinfection (31), patients with intestinal failure (32), and perhaps patients with severe ascites (33) may have higher mortality risks than their MELD score defines. Future refinements in mortality risk models with concerted collection of natural history data for these patients will be required to improve the selection of patients with these conditions for transplantation. Overall, for individual patients with severe symptoms or poor HRQOL but low mortality risks, the decision of performing transplantation must be carefully weighed by the treating physicians to determine whether there is sufficient justification to accept the greater hazards of death for potential improvement in HRQOL.

Other Disease Progression Endpoints

For some patients with liver diseases treatable by transplantation, mortality or HRQOL risk may not be the correct metrics by which need can be judged. Examples of such conditions are hepatocellular cancer (HCC), metabolic liver

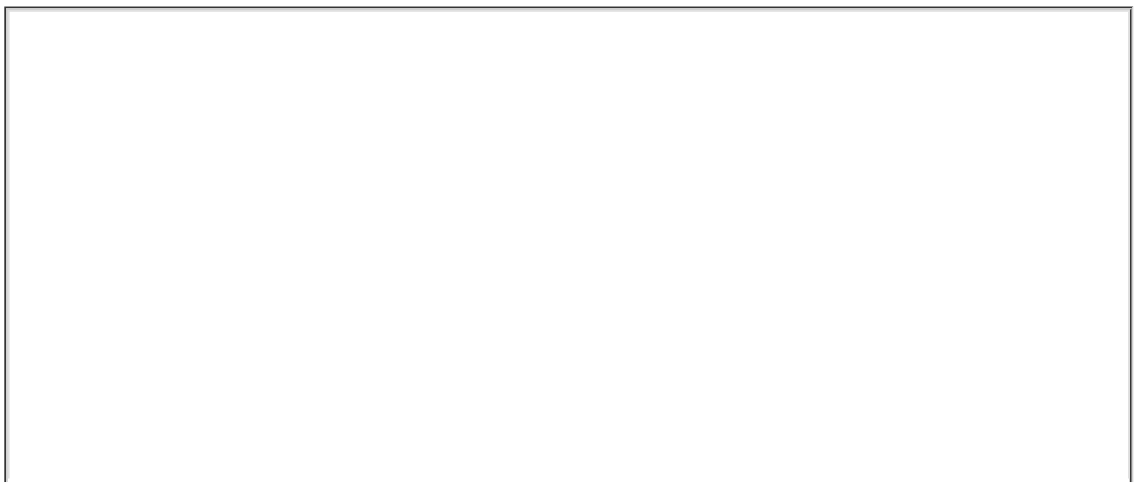
diseases, hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PPH) syndrome. Patients with these disorders usually do not have significant mortality risks from their underlying liver disease but face risks of disease progression beyond a point at which liver transplantation can be offered with a reasonable chance of success. Unfortunately, risk models for disease progression for these

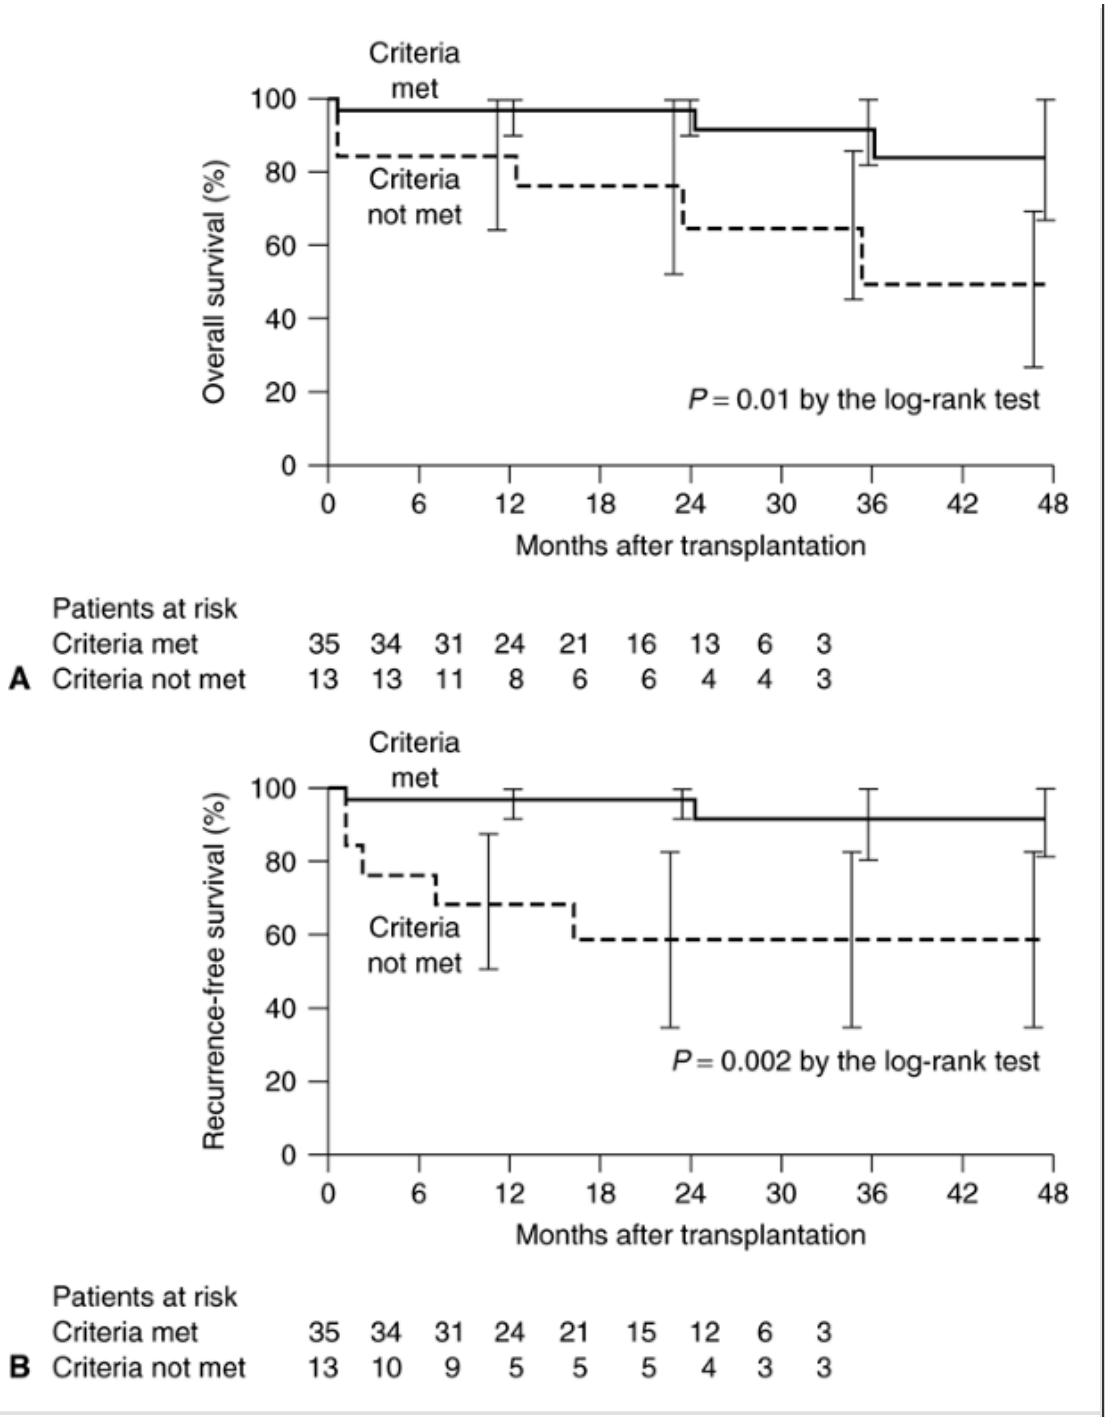
conditions have not been derived, making evidence-based selection problematic.

Hepatocellular cancer

Because HCC is increasingly recognized as a worldwide health problem (34), much more attention has been focused on its natural history and treatment. Liver transplantation was originally attempted to treat patients with extensive unresectable HCC (35). More recently excellent short- and longer-term results have been achieved with liver transplantation for patients with small HCC lesions arising in cirrhotic livers. Specifically, patients with cirrhosis and a single HCC lesion less than 5 cm in diameter or three or fewer lesions, the largest of which is less than 3 cm in diameter—the so-called Milan criteria—(36) (Fig. 53.4), have 4-year survival rates in excess of 80%, which are comparable to liver transplant recipients with nonmalignant primary liver diseases (37) and better than those undergoing surgical resection (38). These excellent results are dependent on the timing of transplantation in patients before the tumor extends to a larger size and/or disseminates. Therefore, selection of appropriate candidates with HCC for liver transplantation depends on the development of prognostic models of tumor progression. Investigators from Barcelona pointed out that the time spent waiting for a deceased donor liver was the most important determinant of HCC progression

beyond the Milan criteria (39), and it was subsequently found that application of adjuvant local treatment to HCC lesions for candidates waiting for transplantation for more than 1 year is a cost-effective strategy for maintaining these patients' candidacies within the Milan HCC criteria (40). More recent single-center studies have suggested that the probability of progression for HCC tumors that are less than 3 cm in size is approximately 10% within 1 year after listing, whereas larger tumors have an approximately 60% chance of progressing beyond the Milan criteria within a year of listing (41) (Fig. 53.5). Additional studies have been published indicating that lesions slightly beyond the Milan size criteria may have similar long-term results after transplantation (42,43,44), but these have not yet been confirmed in larger multicenter reports.



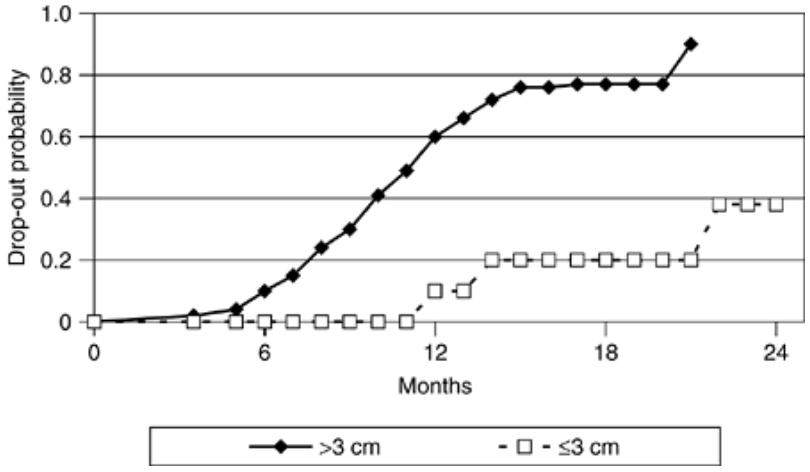


▪ **Figure 53.4** Correlation of post-transplantation pathologic confirmation of early stage hepatocellular carcinoma with overall survival **(A)** and recurrence-free survival **(B)** among 48 patients with cirrhosis. Data on the three patients who died within 1 month of transplantation were included in the calculation of recurrence-free survival. Before transplantation, all the patients were estimated to have either a single hepatocellular carcinoma 5 cm or less in diameter or no more than three tumors, each of which was 3 cm or less in diameter. After transplantation, the explanted livers were examined pathologically, and the patients whose tumors actually met the predefined criteria were compared with those whose tumors did not meet those criteria. Ninety-five percent confidence intervals (*bars*) are shown at 1-year intervals. (From Mazzafero V, Regalia E, Doci R, et al. Liver

transplantation for the treatment of small hepatocellular carcinomas in patients with cirrhosis. *N Engl J Med* 1996;334:693–699.)

For patients with HCC but minimal or no underlying liver disease, liver transplantation remains controversial. Some recent reports suggest that for patients with HCC and mild liver disease within CTP class A, long-term patient survival rates are improved with liver transplantation compared with liver resection (45). However, because of reasonable success for resection (46,47) and scarcity of organ donors, in addition to good success rates reported for salvage transplantation in patients with recurrent HCC after surgical resection (48), most authors advise surgical resection or ablation as a first-line treatment for HCC in patients with well-compensated liver disease (49,50).

Diagnostic accuracy for HCC, however, confounds the optimal timing of liver transplantation for these candidates. Many recent studies have shown that screening high-risk populations for HCC and subsequent confirmatory computed tomography (CT) or magnetic resonance imaging (MRI) can achieve sensitivity and specificity of 70% to 80% at best (51,52,53). The accuracy of imaging tests is further reduced for lesions less than 2 cm in size (52). Liver biopsy has been advocated to overcome some of these problems (54), but risks of bleeding, needle tract seeding by tumor, and sampling errors have limited its widespread use (55). Liver transplantation for patients with false-positive diagnoses of HCC who otherwise do not have severe underlying liver disease exposes these patients to increased surgical and immunosuppressive risks relative to medical management and diverts scarce organs away from those who could benefit more (See “Timing of Liver Transplantation in the Context of Liver Allocation”).



▪ **Figure 53.5** Probability of removal from the transplantation waiting list according to initial size of hepatocellular cancer tumor, comparing tumors presenting with more than 3 cm in size (*solid line*) with tumors 3 cm or less in size (*dashed line*). (From Yao FY, Bass NM, Nikolai B, et al. A follow-up analysis of the pattern and predictors of dropout from the waiting list for liver transplantation in patients with hepatocellular carcinoma: implications for the current organ allocation policy. *Liver Transpl* 2003;9:684–692.)

The available evidence suggests that patients with documented HCC within the Milan criteria who are otherwise acceptable liver transplantation candidates should be selected for the procedure. Diagnostic inaccuracy compels caregivers to confirm the diagnosis with complementary modalities (56). In the future, improved genomic or proteomic testing may be widely available and provide much more accurate diagnostic (57,58) and prognostic (44) information to optimize selection of patients for surgical resection or transplantation.

Pulmonary syndromes

Some patients with chronic liver disease develop pulmonary symptoms that impair their HRQOL and increase their risk for surgical intervention (59). These patients may or may not have severe intrinsic liver disease (60) and may not have advanced CTP or MELD scores (61). HPS defines a constellation of symptoms including dyspnea, hypoxia, reduced diffusing capacity of lungs for carbon monoxide (DLCO), and increased pulmonary arteriovenous shunting in the presence of chronic liver disease. Although there are no large-scale studies to adequately define mortality risk or even

precisely define the disease, most practitioners agree that patients with severe HPS have increased risk of death beyond that predicted by their MELD score and that they face increased operative morbidity, length of hospital stay, and transplantation procedure mortality (60,62). Results for patients selected for transplantation have been acceptable, with most patients experiencing improvement or resolution of their pulmonary condition (60,62). For these reasons, patients with signs and symptoms of HPS who do not have severe pulmonary hypertension should be considered for transplantation before their pulmonary function deteriorates to a point where anesthetic and surgical risks

become prohibitive.

Individuals with cirrhosis can also present with pulmonary hypertension or so-called PPH. In some cases these patients are asymptomatic, and their increased pulmonary resistance is discovered only at the time of invasive monitoring for the transplantation procedure. Patients with PPH have an increased mortality risk, above that expected from their underlying liver disease, and increased perioperative cardiovascular mortality has been reported for patients with elevated pulmonary artery pressures who undergo liver transplantation (62,63). Nonetheless, many of these cases can be managed effectively and outcomes for selected candidates, although sparsely reported, have been reasonable (62,64). These patients have to be carefully selected with multidisciplinary evaluation by transplantation hepatology, pulmonology, anesthesiology, and surgical specialists. Patients with elevated pulmonary artery pressures who respond to intravenous prostaglandin treatment have better results with liver transplantation than those who do not, making a trial of prostaglandin treatment a reasonable diagnostic and therapeutic choice before selection for transplantation (65,66). At this time, the available literature suggests that patients with moderate PPH or those who respond to prostaglandin treatment should be selected for liver transplantation because their outcomes are acceptable and transplantation may improve their PPH (67) afterward.

Metabolic liver diseases

Individuals with metabolic liver disease may also have legitimate indications for liver transplantation but may not have significant synthetic liver failure. Diseases such as Wilson disease, porphyria-induced liver disease, hemochromatosis, cystic fibrosis, and α_1-antitrypsin disease generally cause cirrhosis, portal hypertension, and hepatic synthetic failure. Consequently, mortality risk and existing measures of HRQOL should function well for these patients because they can be selected for transplantation using a mortality risk–based need for transplantation, defined by their intrinsic liver disease. However, patients with conditions such as familial amyloid polyneuropathy (FAP), hereditary oxalosis (HO), and inborn errors of hepatic metabolism, such as urea cycle defects, Crigler-Najjar syndrome, tyrosinemia, and other rare enzymatic diseases, may not develop hepatic fibrosis, portal hypertensive symptoms, or deterioration in hepatic synthetic function, as is normally captured by measurements of bilirubin levels, coagulation factors, or albumin synthesis, or assessment of portal hypertensive signs and symptoms. Nonetheless, particularly for metabolic defects that are intrinsic to the liver, liver transplantation has offered excellent short- and long-term results for properly selected individuals. The prime factor in selecting these patients for transplantation is whether the effects of the disease will be reversed by liver transplantation regardless of the anatomic location of the metabolic defect.

In adults, the best example of such a condition is FAP, in which the enzymatic defect usually occurs in an otherwise normal liver but causes severe systemic problems because of deposition of a mutant transthyretin (TTR) protein. Deposition of these fibrils in neurologic, cardiac, gastrointestinal, and urinary tissues results in progressive loss of function and an untreated median survival of 9 to 13 years (68). Liver transplantation restores normal TTR synthesis, with disappearance of the mutant protein from the blood of affected recipients and slowing or partial resolution of symptoms in successful cases (69,70). Therefore, the extent of secondary manifestations of FAP at the time of presentation, especially myocardial dysfunction and progressive neuropathy, limits successful

recovery after liver transplantation. Optimal selection of liver transplantation candidates with FAP requires early identification and assessment of the severity of end-organ involvement so that the candidate has sufficient cardiopulmonary reserve to survive the surgery and before these complications become so debilitating that they are irreversible. In some cases, the end-organ disease does not improve after restoring normal TTR synthesis with transplantation (68).

In children, patients with primary hyperoxaluria type 1 (PH-1), develop severe renal calculi and resultant renal failure, but the metabolic defect resides in the alanine glyoxylate aminotransferase gene that is exclusively expressed in hepatic peroxisomes. Therefore, liver transplantation cures the enzyme defect because the deficient genes are replaced by the transplantation of the normal liver, although established renal damage does not resolve after liver transplantation. Therefore, most patients with PH-1 are selected for liver transplantation after conservative measures have failed and renal disease has progressed. Consequently, many patients with PH-1 are treated with combined liver–kidney transplants (71). Preemptive liver transplantation, performed before renal complications have

progressed, has been advocated for patients with PH-1 (72), but the morbidity and mortality risks incurred by liver transplantation and immunosuppression must be considered carefully for these minimally symptomatic patients with relatively preserved renal function who may enjoy a good HRQOL and survival with conservative management for many years (73).

Other examples of diseases intrinsic to the liver are the urea cycle disorders (74,75), other hyperammonemic syndromes (76,77), maple syrup urine disease (78), and hereditary tyrosinemia type 1 (79), in which defects cause extremely elevated ammonia levels, neurologic disease, and coma, all of which can be reversed with liver transplantation if recognized early. In some cases, the neurologic consequences of these diseases progress to a point where they cannot be reversed by liver transplantation (75), making early recognition of these diseases the most critical aspect in selection of patients with these conditions for liver transplantation.

Pediatric Considerations

As alluded to in the preceding text, selecting children for liver transplantation is complicated by the fact that growth retardation, delayed development, and neurologic impairment are all deleterious sequelae of many of the liver diseases and metabolic disorders presenting in childhood. There is evidence that liver transplantation can help reverse some of the growth retardation (80,81) and developmental delays (82), but not completely (83,84,85). For these reasons, pediatricians have emphasized the need to select children for liver transplantation at a stage early enough in their disease that will provide a reasonable chance for some catch-up growth and development (83,86). There are several studies suggesting that children who receive transplantation have good HRQOL afterward (85,87), but these desirable outcomes must be weighed against the mortality risks of the surgery and immunosuppression because children who do not survive the transplantation procedure cannot possibly achieve catch-up growth, accelerate their development, or improve their HRQOL.

Mortality risk factors for children with liver disease differ from mortality risk variables in adults. The Pediatric End-Stage Liver Disease (PELD) score (Table 53.1) utilizes bilirubin level, international normalized ratio (INR), albumin level,

age, and growth failure factors to predict 3-month mortality with reasonable accuracy in patients younger than 19 years (17). Other prognostic scores such as the Wilson Disease Index employ white blood cell count and serum AST levels in addition to albumin, bilirubin, and INR values (88). Because children often present with diseases for which liver transplantation can be beneficial but without intrinsic liver synthetic failure, such as metabolic diseases discussed in the preceding text, selection of these candidates requires early diagnosis and identification of extrahepatic manifestations before they become irreversible.

Acute Liver Failure

Acute liver failure, also known as *fulminant hepatic failure* (*FHF*), remains a vexing and lethal clinical problem for pediatric and adult liver specialists. The diverse etiologies and difficulty in predicting which patients will recover spontaneously and those who will die without timely liver transplantation contribute to the complexity of selecting these patients for transplantation. Liver transplantation remains the best option for long-term recovery, but predicting who will recover without liver transplantation and who will not remains the critical issue for clinicians caring for these patients. Several prognostic scores have been developed to assist in decision making in this regard. The King's College group (89) and a French group (90) each published models for the prediction of death from acute liver failure (Table 53.2). Both these models have excellent positive predictive value for determining which patients will die from acute liver failure, but in subsequent studies both models have been shown to have relatively low negative predictive value (91,92,93). Although it may be desirable to err on the side of transplantation when the consequences of the failure to perform transplantation in a patient destined to die of liver failure are so extreme, the use of these models can result in inappropriate utilization of donor organs for patients who would otherwise recover without engraftment. More recently, in a study in which patients with acetaminophen toxicity were excluded, the MELD score was shown to have a superior positive and negative predictive value and a higher concordance for predicting which patients would die and which would recover with acute liver failure (94). These results have been further supported by a recent study of the US liver transplantation database in which the MELD score for patients with non–acetaminophen-induced acute liver failure was highly predictive of

mortality risk (95). Prognostic indicators for early mortality in patients with acetaminophen toxicity such as acetaminophen plasma half-life levels (96), coagulation factor levels (97), Gc protein levels (98), Acute Physiology and Chronic Health Evaluation (APACHE) II score (99) or phosphate levels (100), or addition of serum lactate (101) to the King's College models have been reported, but a recent meta-analysis found that these prognostic models have limited sensitivity and specificity, making them of questionable usefulness in the selection of patients with acetaminophen-induced liver failure for transplantation (102) (Table 53.3).

Table 53.2. King's College and Clichy Criteria for Liver Transplantation

King's College criteria INR >6.5 or any three of the following:

Age <10 or >40 y
Etiology: Drug toxicity or viral hepatitis
Duration of jaundice before onset of encephalopathy >7 d
INR >3.5
Bilirubin >17.5 mg/dL

Clichy criteria

Portosystemic encephalopathy
Factor V: <20% age <30 y
<30% age >30 y

INR, international normalized ratio.

Table 53.3. Results of the Meta-Analysis of the Prognostic Models for Acute Liver Failure

Criteria	No. of studies included	Positive likelihood ratio	Negative likelihood ratio
King's College[a,b]	6	12.33	0.29
pH <7.30[a]	4	7.44	0.48
PT >100 s + creatinine >300 µmol/L + encephalopathy grade ≥3	3	7.30	0.48
PT >100 s	3	2.05	0.40
Creatinine >300 µmol/L	2	1.91	0.50
APACHE II score >15	1	16.4	0.19
Increase in PT d 4	1	4.1	0.66
Factor V <10%	1	1.73	0.33
Gc-globulin <100 mg/L	1	Infinity	0.70

[a]Likelihood ratios on pooled measures of sensitivity and specificity are based on the final summary receiver operating characteristic model.
[b]King's criteria are pH <7.30 or a combination of PT >100 s + creatinine >300 μmol/L + encephalopathy grade ≥3.
PT, prothrombin time; APACHE, Acute Physiology and Chronic Health Evaluation.
From: Bailey B, Amre DK, Gaudreault P. Fulminant hepatic failure secondary to acetaminophen poisoning: a systematic review and meta-analysis of prognostic criteria determining the need for liver transplantation. *Crit Care Med* 2003;31(1):299–305.

Accurate prognostic information is essential for selection of patients with acute liver failure for transplantation. The King's, Clichy, and perhaps the MELD score may be helpful tools for patients with non–acetaminophen induced fulminant failure, but their low negative predictive value should be kept in mind. Selection of patients with acetaminophen-induced liver failure remains more problematic, and careful clinical observation for encephalopathy and trends in hepatic synthetic function remain indispensable in selection of these patients and all those with acute liver failure.

Timing of Liver Transplantation

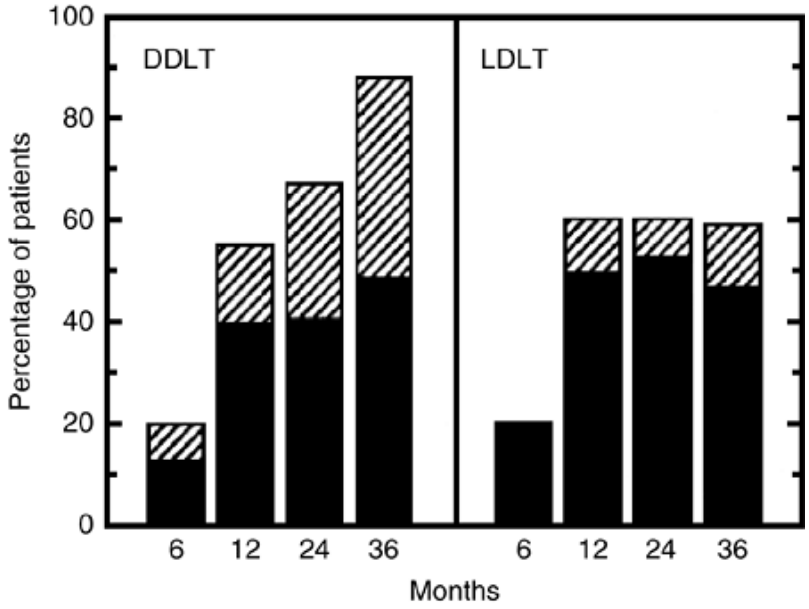
Living Donor Liver Transplantation

The advent of living donor liver transplantation in the late 1980s for children (103) and early 1990s for adults (104) introduced the possibility of electively timing liver transplantation. With this innovation, it became possible for patients with liver disease treatable with liver transplantation who are fortunate enough to have a suitable and willing donor to receive their transplant at a point where the risks of the surgery are outweighed by the risks of not performing the transplantation. This was the main justification for application of living donor liver transplantation to children (105) because pediatric deceased donor organs are even more scarce than adult organs and, as discussed previously, the timing of transplantation for children may not always be best estimated by mortality risk derived from the intrinsic liver disease. Patients selected for living donor liver transplantation have included children with most indications for liver transplantation, including acute liver failure, and adults with HCC (106,107) and other conditions that do not consistently receive enough priority on the waiting list. In general, for nonacute cases, living donor liver transplantation has been reserved for patients with less severe liver disease, and estimations of mortality risk can be helpful in selecting candidates who will derive benefit from the transplantation but who do not carry extreme post-transplantation mortality risks (108). A report from Japan used the MELD score to identify candidates who could receive the smaller left-lobe graft and still achieve an acceptable outcome (109). Controversy remains about the utility of living donor liver transplantation for patients with hepatitis C, with some reports suggesting more frequent and rapid recurrence (110,111) and others finding no difference (112,113) in recurrence rates compared with deceased donor grafts (Fig. 53.6).

Although there are limited reports of living donor liver transplantation being

performed for acute liver failure in adults (114), most clinicians would reserve the living donor procedure for patients with moderately severe chronic liver disease, in which there is sufficient time for a complete donor evaluation and informed consent without the added coercion of an acute, potentially immediate fatal liver disease in the recipient candidate. Conversely, living donor liver transplantation for pediatric candidates, in which an adult donor donates a

smaller portion of his or her liver and thereby faces a lower operative risk, seems applicable for almost all indications for liver transplantation in children.



▪ **Figure 53.6** Percentage of patients with fibrosis in their liver allograft at various intervals after deceased donor liver transplantation (DDLT) or living donor liver transplantation (LDLT). *Solid bars* represent portal fibrosis. *Hatched bars* represent bridging fibrosis. None of the patients in either group developed cirrhosis during the follow-up period. No significant difference in the percentage of patients who developed fibrosis existed between the two groups. (From Shiffman ML, Stravitz RT, Contos MJ, et al. Histologic recurrence of chronic hepatitis C virus in patients after living donor and deceased donor liver transplantation. *Liver Transpl* 2004;10:1248–1255.)

Paramount to selection of recipient candidates for living donor liver transplantation is a thorough assessment of the donor's risks for donation, estimation of the potential of success for the recipient, and fully informed consent from both donor and recipient.

Timing of Liver Transplantation in the Context of Organ Allocation

In an ideal world, all patients would receive the most effective treatment at the time when they are most likely to gain the most benefit and suffer the least harm from that intervention. However, because liver transplantation is severely limited by the availability of the therapeutic substrate, there must be some method for selection, from all those who could potentially benefit, of the few individuals who

will receive the treatment. Therefore, the timing of liver transplantation for individual patients will be determined in large part by this allocation/selection process regardless of the presence of a beneficial potential that a transplantation may pose for any of the waiting patients. Living donor transplantation introduces some flexibility for the timing of these cases, but because only approximately 5% of liver transplantation procedures in 2004 were from living donors (115), the timing of most liver transplantation procedures depends on the allocation system. Timing for these patients is not so much determined by what is most appropriate for that individual to maximize success and minimize complications and/or failures but by what is the most equitable for all users of the organ donor pool. Equitability is difficult to define, but prioritization of the measures of equitable outcomes is possible. Because deceased individuals cannot have a quality of life or growth or development, or otherwise improvement in their burden of disease, it is difficult to accept any form of liver allocation in which these nonmortality endpoints supersede the risk of death. Consequently, prioritizing an individual with a very poor quality of life or delayed growth and development before someone with a higher mortality risk is difficult to justify. However, risk of disease progression, as is conceptualized in liver allocation for patients with HCC in the United States, can also serve as an equitable prioritization tool. Therefore, timing of deceased donor liver transplantation will depend mostly on which individual from among all the waiting candidates has the highest mortality risk (or risk of disease progression) if he or she continues to wait although there may be many other individuals on the list for whom transplantation at that point of time would also be beneficial.

Chapter 54

Immunosuppression: The Global Picture

K. V. Narayanan Menon

Russell H. Wiesner

Key Concepts

- Advances in immunosuppression in recent years have led to impressive patient and graft survival rates and reduced rejection rates in liver transplantation.
- Initially immunosuppressive regimens included combination therapy with corticosteroids and azathioprine. This was followed by the introduction of antilymphocyte globulin, cyclosporine, FK506, mycophenolate mofetil, and rapamycin. A number of cytokine antibodies antagonistic to specific targets in the antigen recognition pathway, such as OKT3 and antithymocyte globulin, are also in use to help prevent rejection.
- Therapy with calcineurin inhibitors (cyclosporine or FK506) in combination with corticosteroids, azathioprine or mycophenolate mofetil is a popular regimen. Although used as induction therapy and in the treatment of rejection, use of corticosteroids has been declining especially in long-term transplant recipients. A major side effect of immunosuppression is the development of calcineurin inhibitor nephrotoxicity.
- Regular biochemical monitoring with drug levels and renal function is essential to ensure adequate immunosuppression and to prevent the development of immunosuppression-related side effects.
- The development of immunosuppressive agents that are less nephrotoxic may help decrease the incidence of renal failure in the long-term.

Outcomes after liver transplantation have shown consistent improvement in the recent years. Three and 5-year patient survival rates following deceased donor liver transplantation are 78% and 72% respectively, with graft survival slightly lower at 72% at 3 years and 64% at 5 years post-transplantation (1). These impressive patient and graft survival rates have been due to advances in surgical techniques and immunosuppression over the years. The use of combination therapy with corticosteroids and azathioprine by Thomas Starzl in the early 1960s brought about initial success in renal transplantation (2). This initial regimen was followed by the use of antilymphocyte globulin (ALG) in the late 1960s and early 1970s. The discovery and subsequent introduction of cyclosporine in 1979 represented a major breakthrough in the field of immunosuppression and resulted in continued improvements in patient and graft survival in organ transplantation. Immunosuppression in organ transplantation has been further refined by the

development and introduction of other agents such as FK 506 (tacrolimus), mycophenolate mofetil (MMF), rapamycin and a number of cytokine antibodies targeted against specific mediators in the allograft rejection pathway.

The goal of clinical immunosuppression is to provide graft acceptance with minimal side effects. However, the use of most immunosuppressive agents is associated with significant adverse effects requiring close monitoring and modification of therapy. An alternative strategy to immunosuppression in organ transplantation is to

try and induce tolerance in the recipient. Tolerance is the state of host nonresponsiveness to the transplanted organ and is induced by previous exposure to the antigen. The induction of tolerance may allow reduction in the level of immunosuppression and in some instances, may lead to its complete withdrawal. Although a few centers are involved in tolerance inducing protocols, currently there are no completely successful protocols and the induction of tolerance remains the holy grail of transplantation. In the absence of true tolerogenic protocols, immunosuppression remains the key to successful organ transplantation.

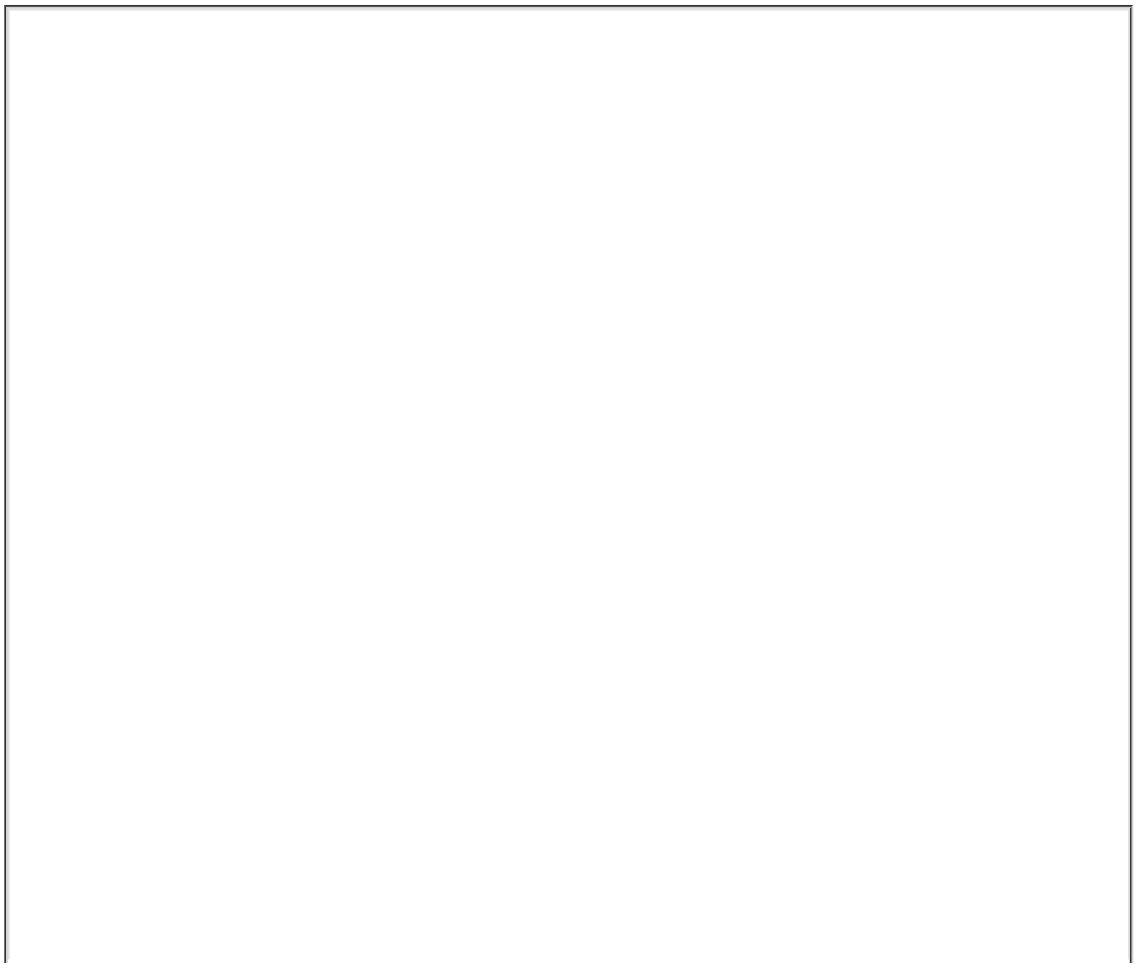
Overview of the Immune Response and General Features of Immunosuppression

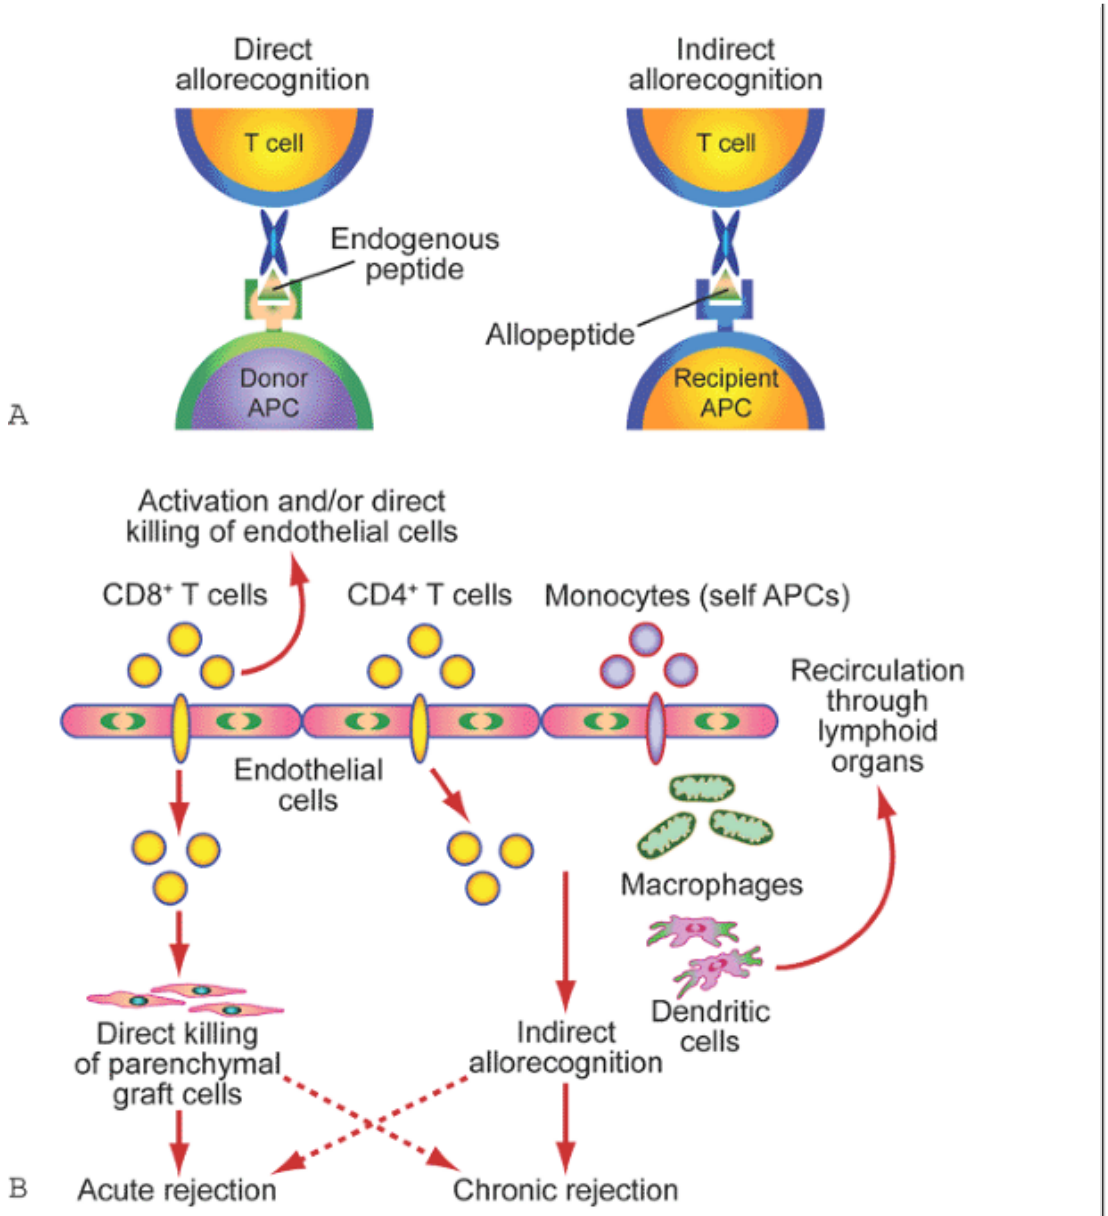
T cells respond to peptide antigens bound to the groove of class I (CD8 T cells) or class II (CD4 T cells) major histocompatibility complex (MHC). Recognition of foreign alloantigens is carried out by the recipient T lymphocytes through one of two pathways (Fig. 54.1). Donor hepatic antigen-presenting cells (APCs) express MHC molecules recognized by recipient T lymphocytes in the direct pathway. In the indirect pathway, recipient T lymphocytes react to donor alloantigen derived peptides expressed on recipient APCs. In liver transplantation, there is evidence that both these mechanisms exist (3). It is possible that the direct pathway is active during the early post-transplantation period, playing a major role in the development of acute cellular rejection. Here the APCs expressing donor antigens from the graft migrate and enter into secondary lymphoid tissue where they encounter allospecific T cells (4). These T cells, primed through the direct pathway, interact with the allograft and promote rejection. In the later stages, the indirect pathway may be important in sustaining a persistent response to the graft. This probably occurs as a result of donor antigen

derived from damaged donor liver being picked up and presented by self APCs resulting in the activation of T cells. Phagocytosis of apoptotic donor cells may be an important source of antigen for indirect presentation. However, the relative interplay and importance of the direct and indirect pathways in allograft rejection remain to be further clarified (5). Once the T-cell receptor, which is the antigen recognition unit, interacts with the MHC/peptide complexes on the surface of the presenting cell, accessory molecules including CD3 and CD4 or CD8 are brought into play. The T-cell receptor/CD3 complex interacting with the MHC molecule of the APC results in the activation of the T cell (signal 1). However, it is not known that more than one signal is needed to activate the immune system (6). Activation of the immune system by an antigen requires not only the antigen (signal 1), but also a signal from a secondary molecule (signal 2). It is also postulated that if a lymphocyte only received the signal from the antigen, it would not only fail to respond, but would also fall into a state of inactivity termed *anergy* (5). This forms the basis of the two-signal model by which full T-cell

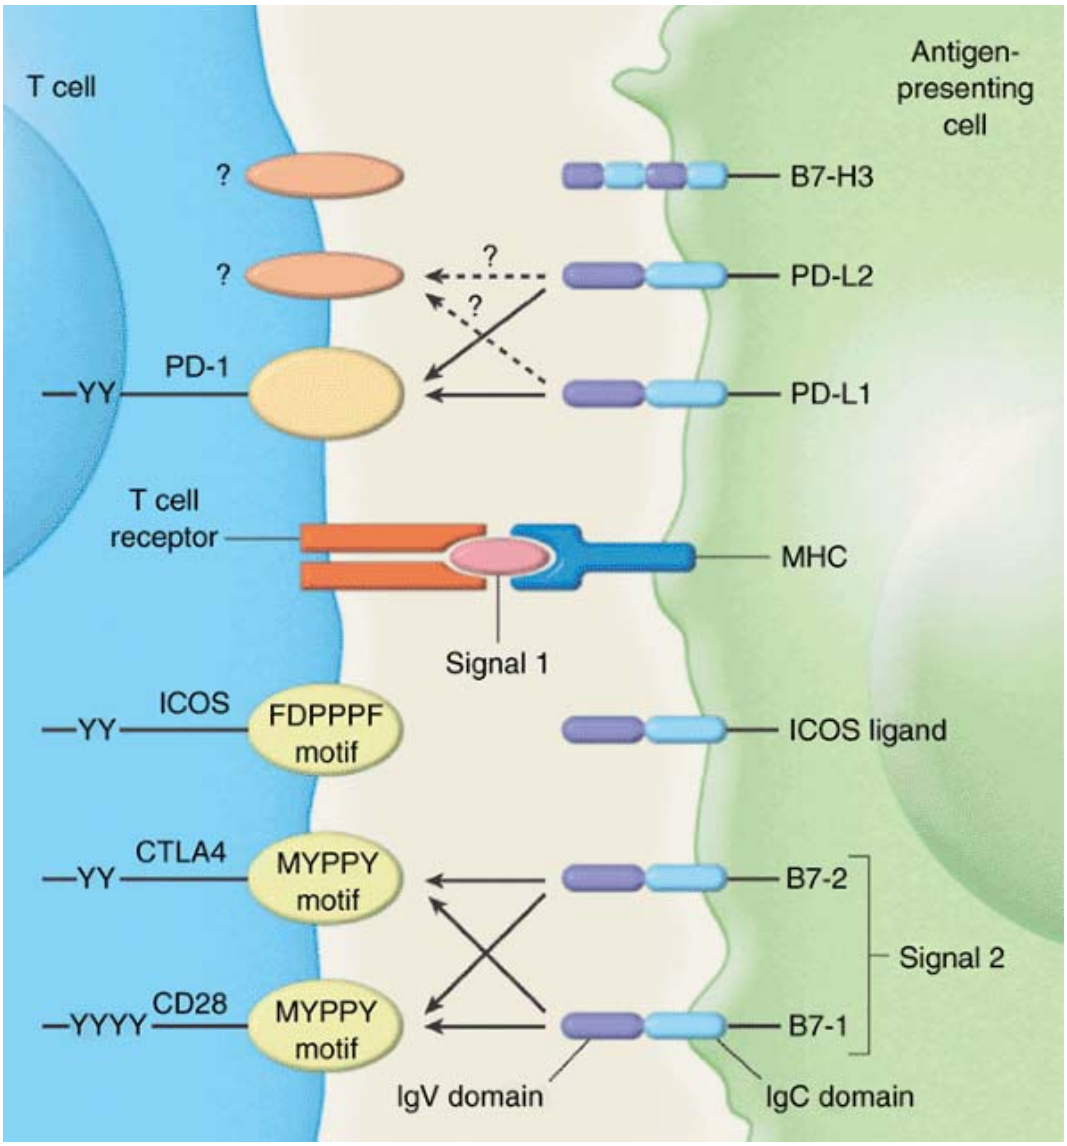
activation is dependent upon a complex array of regulatory molecules called *costimulatory* molecules (Fig. 54.2). Signal 2, a calcium-independent process, results from binding of the costimulatory molecules found on T cells with their ligands found on the APCs. Expression of costimulatory ligands on the APC is induced by factors released during tissue injury (so-called danger signals). Signal 1 and signal 2 activate an array of intracellular events mediated by calcineurin, protein C kinase, zeta associated protein-70, activation of nuclear factor of the activated T cells (NFAT), NF-κB, and activated protein (AP)-1 respectively. These factors migrate to the nucleus and bind to various gene promoters associated with T-cell activation and proliferation initiating the G0 to G1 transition in the cell cycle.

Further progression of T-cell activation results from autocrine and paracrine cytokine mediated signaling via specific cytokine receptors that include the interleukin (IL)-2 receptor family (often referred to as signal 3). An important cytokine is IL-2 that binds to the IL-2 receptor gamma chain and activates Janus kinase (JAK) 1 and 3. This triggers additional intracellular signaling pathways including signal transducers and activators of transcription (STAT) 5, Ras-Raf-MAP kinase, and mammalian target of rapamycin (mTOR)/P13-k/p7056 kinase (7). The cytokines generated by activated T cells facilitate the generation of effector cells such as antibody secreting B cells, cytotoxic T cells, and activated macrophages. Subsequently, these cells upregulate cell adhesion molecules such as CD2, LFA1, and VLA4 resulting in alteration of the migration pattern of cells. T cells also mediate cell damage by secretion of numerous factors such as tumor necrosis factor (TNF)-α, TNF-β (lymphotoxin), and fas ligand expression as well as cytotoxins such as perforin and granzymes F.





▪ **Figure 54.1** Allorecognition pathways and graft rejection. **A:** Pathways of allorecognition. In the "direct" pathway, T cells recognize intact major histocompatibility molecules on donor antigen-presenting cells (*left*). In the "indirect" pathway, T cells recognize processed alloantigen in the form of peptides presented by recipient antigen-presenting cells (*right*). **B:** Interactions among endothelial cells, T cells and recipient antigen-presenting cells in allograft rejections. The recipient monocytes are recruited by endothelial cells to the graft tissue. They are also transformed to become highly efficient antigen-presenting dendritic cells that may need to recirculate to peripheral lymphoid organs for maturation. The dendritic cells and intragraft macrophages present donor peptides via the indirect pathway to recruited $CD4^+$ T cells. $CD8^+$ T cells, on the other hand, are activated by donor endothelial cells or traverse the endothelium and kill parenchymal graft cells. APC, antigen-presenting cell. (Reprinted with permission from Briscoe DM, Sayegh MH. A rendezvous before rejection: where do T cells meet transplant antigens? *Nat Med* 2002;8:220–222.)



▪ **Figure 54.2** The two-signal hypothesis. In signal 1, the major Histocompatibility complex on the antigen-presenting cell interacts with the T cell receptor. B7-1 (CD80) and B7-2 (CD86) on the antigen-presenting cell interact with the respective ligands, CD28 and CTLA4 (CD152). CD28 and CTLA4 share common motifs (MYPPY) that are essential for binding B7-1 and B7-2. Regulatory molecules, such as programmed death 1 (PD-1) and inducible costimulator, which have different motifs, enter the regulatory cycle by affecting experienced T cells. CD28 and CTLA4 have similar structures, but opposite functions. CD28 activates T cells, whereas, CTLA4 inhibits them. PD-L1, programmed death ligand 1; PD-L2, programmed death ligand 2; MHC, major histocompatibility complex; ICOS, inducible costimulator; IgV, immunoglobulin V; IgC, immunoglobulin C. Overview of Immunosuppressive Agents

Broadly, immunosuppressive agents consist of two types: Pharmacologic and biologic. Biologic agents comprise the antilymphocyte antibodies (both the monoclonal and the polyclonal) and anticytokine receptor antibodies. Pharmacologic agents consist of corticosteroids, cytokines, suppressive agents, and cell cycle inhibitors (Table 54.1). Immunosuppressive agents act by inhibiting the pathways of foreign antigen recognition, T-cell activation, and costimulation. There are also other agents that inhibit a variety of other processes in the immune recognition pathway or lymphocyte trafficking. In addition, there are a few agents wherein the exact mechanism of action is still unknown.

Table 54.1. List of Clinically Available Immunosuppressive Agents and Target Pathways

Immunosuppressive agent	Target pathway(s)
PHARMACOLOGIC	
Corticosteroids	Selective lysis of immature cortical thymocytes Blockade of cytokine gene transcription in APC
Cyclosporine (Sandimmune, Neoral, Gengraf)	Signal 1 transduction through TCR
Tacrolimus (Prograf)	Signal 1 transduction through TCR
Rapamycin/Sirolimus and Everolimus/SDZ RAD (Rapamune and Certican)	Signal 3 transduction through IL-2 receptor
Azathioprine (Imuran)	Inhibition of purine metabolism and DNA synthesis
Mycophenolic acid (CellCept, Myfortic)	Inhibition of purine metabolism and DNA synthesis
BIOLOGIC	
Anti-CD3 pan-T cell (Orthoclone OKT3)	Causes depletion and receptor modulation in T cells Interferes with signal 1
Antithymocyte globulin (ATGAM,	Causes depletion and receptor

Thymoglobulin)	modulation in T cells Interferes with signals 1, 2, and 3 Inhibits lymphocyte trafficking
Anti-II–2 α-chain receptor (Zenapax, Simulect)	Inhibits T-cell proliferation to IL-2 (signal 3)
Anti-CD52 (Campath 1-H)	Causes depletion of thymocytes, T cells, B cells (not plasma cells), monocytes

APC, antigen-presenting cells; TCR, T cell receptor; IL, interleukin; DNA, deoxyribonucleic acid.

Corticosteroids were one of the earliest immunosuppressants used in the field of organ transplantation. Corticosteroids, in combination with the antimetabolite azathioprine, the earliest widely used immunosuppressive drug in transplantation, made renal transplantation a realistic option in the 1960s. Starzl et al. (2) and Murray et al. (8) showed independently that combining corticosteroids with azathioprine enabled prolonged survival of human renal allografts. Corticosteroids continue to play a major role in immunosuppression in liver transplantation. A recent report by the Scientific Registry of Transplant Recipients (SRTR) from an analysis from the United Network of Organ Sharing (UNOS) database revealed that corticosteroids were used in more than 90% of liver transplant recipients at the time of discharge (1). The use of azathioprine, however, has declined and only 4% of patients discharged from the hospital following liver transplantation were on this drug (1). Following the success of combination therapy with azathioprine and prednisone, the field of immunosuppression advanced in the late 1960s and early 1970s with the introduction of ALG and monoclonal anti–T-cell antibodies such as OKT3. However, immunosuppression finally came of age in the late 1970s with the description by Borel JF et al. of the striking effects of cyclosporine on the immune system, and the demonstration by Calne et al.

of the impressive advantage of using cyclosporine A in patients undergoing renal transplantation (9,10). Subsequently in 1989, FK506 (tacrolimus) was used in transplantation for multiple indications including treatment of persistent rejection with continued decrease in the incidence of rejection (Fig. 54.3) (11). Currently the field of immunosuppression is expanding with a number of agents with differing modes of action being studied for use in liver transplantation. Rapamycin which inhibits signal transduction, a different mechanism of action from tacrolimus which basically inhibits lymphokine synthesis, is currently being used in select patients in liver transplantation. MMF, a drug that blocks purine synthesis and salvage pathways is also being increasingly used in liver transplantation with approximately 50% of patients being on it at the time of discharge (1). Antibodies directed against T lymphocytes such as antithymocyte globulin or against specific cytokines such as the IL-2 receptor antibodies are also being increasingly used. A variety of investigational agents such as FK778,

WH1 P154 and FTY720 are also being tested (Table 54.2).

Table 54.2. Investigational Immunosuppressive Agents in Clinical Testing and Target Pathways

Immunosuppressive agent	Target pathways
FK778	Interferes with pyrimidine metabolism and DNA synthesis
WHI P 154	Signal 3 transduction through JAK3/STAT5
LEA29Y	Signal 2—also known as CTLA4-Ig and inhibits B7/CD28 interaction
FTY720	Inhibits naïve T cell homing to the high venule endothelial cell on secondary lymphoid tissue

DNA, deoxyribonucleic acid; JAK, janus kinase; STAT, signal transducers and activators of transcription.

Corticosteroids

Corticosteroids were one of the earliest agents used for immunosuppression, first developed in the late 1940s and introduced into immunosuppressive regimens in the late 1950s (12). They have been applied in a variety of ways in liver transplantation. These include: (i) As induction immunosuppression by way of bolus corticosteroid therapy at the time of organ implantation, (ii) as maintenance therapy to prevent rejection, and (iii) in the treatment of established acute cellular rejection. Although their chronic, long-term use is somewhat disputed in recent years, they continue to be widely used both in induction therapy and during short-term maintenance therapy in liver transplantation. Corticosteroids have multiple effects and their exact mechanism of action is unknown. The most common agents used in liver transplantation include prednisone, prednisolone, and methylprednisolone. These steroid agents possess a predominantly anti-inflammatory immunosuppressive potency with relatively low mineralocorticoid potency. Prednisone is rapidly absorbed from the gastrointestinal tract; however, it needs to be metabolized to prednisolone for biologic activity. Following absorption, corticosteroids are primarily metabolized into inactive compounds by the liver and excreted in the urine. They exert their effects through their actions on a wide variety of white cells (including lymphocytes, granulocytes, macrophages, and monocytes) and endothelial cells. Glucocorticoids circulate either in the free form or in association with cortisol-binding globulin in the blood. The free form of the steroid readily diffuses through the plasma membrane of lymphocytes and binds with high affinity to intracellular glucocorticoid receptors. This ligand receptor complex, following activation, modulates transcription both positively and negatively, in the nucleus of specific genes

and coding factors critical in the generation and maintenance of the immune and the inflammatory responses. In addition to modulating transcription, glucocorticoids can also influence later cellular events including RNA translation, protein synthesis, and secretion (13). Leukocytes, by their mechanism of localization and activation, generate numerous products that play a key role in cellular rejection, and corticosteroids therefore, modulate this function. On lymphocytes the major mechanism of action of corticosteroids seems to be a negative regulation of cytokine gene expression. Regulation of cytokine gene production occurs through the inhibitory action of glucocorticoid on gene transcription through inhibition of AP-1 and nuclear factor NF-κB. Glucocorticoids also affect other cells such as macrophages, neutrophils, eosinophils, basophils, mast cells, and endothelial cells. Glucocorticoids antagonize macrophage differentiation and inhibit many of their functions that promote inflammation. Glucocorticoids inhibit neutrophil adhesion to endothelial cells, thereby decreasing their extravasation to the site of inflammation. This process may partly explain the neutrophilia that is seen with glucocorticoid therapy. However, neutrophil functions are only minimally influenced by glucocorticoids. In addition to their action on neutrophils and macrophages, glucocorticoids also decrease circulating eosinophil and basophil counts, inhibit IgE-dependent release of histamine and leukotriene from basophils and inhibit degranulation of mast cells. Additionally, glucocorticoids downregulate endothelial cell function including expression of class II MHC antigen, expression of adhesion molecule (ELAM-1) and the intracellular cell adhesion molecule (ICAM)-1), formation of IL-1 and arachidonic acid metabolites, thereby inhibiting the expression of cyclo-oxygenase type II.

Corticosteroids are administered at various stages of liver transplantion. High-

dose methylprednisolone is usually given intravenously around the time the liver is implanted, and continued for several days postoperatively. Induction doses range from 300 to 1,000 mg intravenously. Initially thought to be essential, trials have now demonstrated that corticosteroid-free regimens do not necessarily lead to increased rejection (14,15,16,17). These trials have however, used other induction agents such as antithymocyte globulin or IL-2 receptor antibodies. For maintenance therapy, steroids are rapidly tapered from the time of surgery to a daily maintenance dose of 5 to 10 mg per day. Subsequently, many centers now taper and stop prednisone after 3 to 6 months. Prednisone cessation does not seem to adversely affect the graft in most instances and may be beneficial in ameliorating some of the side effects of long-term prednisone use such as osteoporosis, diabetes, weight gain, hypertension, cataracts, hyperuricemia, and cosmetic problems. However, in patients who have undergone transplantation for autoimmune liver disease and in patients with conditions such as ulcerative colitis continuing prednisone therapy, albeit at a low-dose, may be prudent. Corticosteroids have also been used in the treatment of acute cellular rejection. In this context, intravenous methylprednisolone is given at a dose of 1,000 mg on alternate days for a total of 3 doses. The high-dose intravenous regimen for the treatment of rejection is usually stopped after this intensive protocol (18).

Table 54.3. Side Effects of Corticosteroids

Impaired wound healing
Hypertension
Weight gain
Hyperglycemia
Hyperlipidemia
Osteoporosis
Fluid retention
Hirsutism
Acne
Myopathy
Cataracts
Infection

Corticosteroid therapy is not without its side effects. Short-term corticosteroid use such as IV boluses to treat acute cellular rejection may cause transient hyperglycemia. Infections can also be unmasked or exacerbated by short-term high-dose corticosteroids. In patients with hepatitis C, the use of bolus high-dose intravenous corticosteroid therapy to treat acute cellular rejection has also been associated with a more severe and earlier recurrence of hepatitis C (19). Long-term corticosteroid therapy is associated with a number of side effects some of which may be reversed by steroid withdrawal (Table 54.3). Cosmetic side effects such as acne and hirsutism may adversely affect compliance especially in the younger population undergoing transplantation.

Azathioprine

Azathioprine was one of the earliest agents to be used in combination with corticosteroids in the long-term management of the transplant recipient, and has brought about a major improvement in graft survival. Azathioprine is absorbed

readily from the gastrointestinal tract, and peak plasma concentrations are achieved 1 to 3 hours after oral administration (20,21). Azathioprine is rapidly cleared from the circulation but approximately 30% is bound to serum proteins. Azathioprine is a derivative of mercaptopurine, which is rapidly metabolized to 6-mercaptopurine and subsequently to other active and inactive metabolites. The metabolites

are excreted through the urine with little intact drug excreted. The half-life of azathioprine is approximately 3 hours with normal kidney function and up to 50 hours in patients with anuria. The active metabolite acts as a purine analog, which is incorporated into cellular DNA and inhibits purine nucleotide synthesis and metabolism. The resultant alteration in RNA synthesis and function prevents mitosis and proliferation. Azathioprine acts early during the proliferative phase of cell cycle thereby inhibiting primary cell-mediated and humoral responses (22).

Azathioprine was first used in combination with corticosteroids for renal transplantation, and was found to be highly efficacious. It is currently used in combination with a calcineurin inhibitor and corticosteroids. Daily doses between 1 and 2 mg/kg are generally used in combination therapy. More lately, azathioprine has been replaced by MMF in a large number of transplant recipients as reported by the SRTR from their analysis of the UNOS database. Use of azathioprine at the time of discharge from the hospital was noted in only 4% of patients compared with 48% of patients on MMF.

Although used for a number of years, azathioprine has well-documented side effects. These include myelosuppression, reversible hepatotoxicity, alopecia, and gastrointestinal side effects such as nausea and dyspepsia, and acute pancreatitis. Other short-term side effects include the development of fever, skin rash, arthralgias, myalgias, and an acute hypersensitivity reaction. During long-term therapy an increased incidence of malignancies of the skin such as squamous cell carcinoma, and non-Hodgkin's lymphoma have been reported. Xanthine oxidase, a major enzyme in the catabolism of azathioprine metabolites is blocked by allopurinol and hence, when used concurrently with allopurinol the dose of azathioprine must be decreased to 25% to 33% of the original dose. Other drugs that interact with azathioprine and worsen its bone marrow suppression include methotrexate and angiotensin converting enzyme inhibitors.

Cyclosporine

Cyclosporine is a highly aliphatic cyclic undecapeptide. It was originally isolated from the soil fungus *cylindrocarpon lucidum* (9). Since its discovery, cyclosporine has remained the cornerstone of immunosuppression, not only for liver transplantation, but also for kidney, heart, and other organ transplantations. Cyclosporine came into widespread clinical use in the early 1980s in renal transplantation and was responsible for significantly improving early graft survival with some centers reporting almost doubling of their graft survival rate (10,23). In liver transplantation, Starzl et al. reported the first use of cyclosporine and prednisone in 1981 with 83% of their patients alive after 8 to 14½ months (23).

Cyclosporine enters cells and lymphocytes through diffusion and at high concentrations by active transport through the low-density lipoprotein (LDL) cholesterol receptor. In the cell, cyclosporine binds to a number of carrier proteins including cyclophilin, which are important for protein folding. The cyclosporine/cyclophilin complex binds to calcium activated calcineurin, a serene

threonine phosphatase important in the lymphocyte activation cascade, preventing the dephosphorylation of the transcription factor, NFAT. This prevents NFAT from engaging to specific DNA- binding sites in the promotor region of several T-cell growth factors and cytokines such as IL-2, interferon-γ, TNF-α, and costimulatory molecules such as CD40. This lack of engagement downregulates the expression of these various cytokines essential for the rejection process (24,25). Therefore, cyclosporine enables the activated cells to potentially return to their quiescent state inhibiting early antigen recognition, reducing clonal expansion, and inhibiting the synthesis of multiple cytokines necessary for rejection. Cyclosporine is not cytotoxic and does not inhibit the myeloid or the erythroid cell lines.

An earlier formulation of cyclosporine (Sandimmune) was notable for variable absorption and bioavailability. However, with the recent introduction of a microemulsion nonaqueous form (Neoral), absorption and bioavailability have become more predictable (26). Cyclosporine is absorbed primarily in the proximal jejunum, and achieves peak blood levels in 2 to 4 hours (26). It is widely distributed with highest concentrations found in adipose, kidney, adrenal, pancreatic, and liver tissues. Cyclosporine is metabolized primarily through the liver, occurring through the P450 system and excreted predominantly through the bile (22). Therefore, with liver failure, the propensity to develop toxic cyclosporine concentrations should be recognized. Cyclosporine has an average half-life of approximately 27 hours (range 10 to 40 hours). Various drugs that stimulate or inhibit the hepatic P450 enzyme system may increase or decrease dose levels and can result in underimmunosuppression or toxicity. These agents include the calcium channel blockers, antifungal agents, macrolide antibiotics, prokinetic agents such as cisapride and metoclopramide, and a variety of miscellaneous agents such as amiodarone, cimetidine, omeprazole, and protease inhibitors. Dosing of cyclosporine is generally regulated by examining a 12-hour trough level, as this is convenient to patients. However, it has been shown that trough concentrations do not accurately reflect the area under the curve for cyclosporine exposure in individual patients. More recently, the peak cyclosporine level at 2 hours after

oral administration is thought to be a better measure of the area under the curve, and may be more useful in controlling toxicity and enhancing efficacy. Target trough and peak levels vary with respect to time after liver transplantation. Within the immediate post-transplant period, 12-hour trough levels between 250 and 300 ng/mL are desirable. With time, however, 12-hour trough levels between 100 and 125 ng/mL may be sufficient to prevent rejection and minimize toxicities. Cyclosporine is commonly used in conjunction with prednisone and either azathioprine or MMF soon after transplantation. With time, the other agents may be withdrawn leaving cyclosporine as the sole immunosuppressant.

The main side effects of cyclosporine include nephrotoxicity and hypertension (27,28). With long-term follow-up of liver transplant patients, it is becoming apparent that 15% to 20% of the patients on calcineurin inhibitors will end up with chronic renal insufficiency requiring dialysis and/or renal transplantation (29,30). The nephrotoxicity of cyclosporine is thought to result from its vasoconstrictor effects on renal blood vessels. Although early toxicity resulting in renal dysfunction may be reversible, the late stages of cyclosporine nephrotoxicity resulting in advanced tubular interstitial fibrosis and scarring may be irreversible. Other significant side effects from cyclosporine include neurologic

sequelae, which occur in 10% to 20% of the patients (20). These include paresthesias, tremors, hallucinations, confusions, and migraine-like headaches. Other rare side effects may include seizures, especially in patients receiving intravenous cyclosporine. Cyclosporine may also cause hirsutism and gingival hyperplasia that causes significant cosmetic problems in the younger patient undergoing transplant (28). Other less commonly reported side effects include nausea, vomiting, thrombocytopenia, allergic reactions, tinnitus, myalgias, and arthralgias.

Tacrolimus

Tacrolimus (FK506) is a metabolite of a fungus *streptomyces tsukubaensis* and was isolated in 1986 (31). Its mechanism of action is identical to that of cyclosporine. When it enters the cell, it binds with an immunophilin referred to as FK-binding protein 12. This complex then inhibits calcineurin, preventing the dephosphorylation of the transcription factor NFAT and inhibiting the transcription of cytokines necessary for rejection (22). Tacrolimus is considered to be 10 to 100 times more powerful than cyclosporine. Its first successful use was reported by Starzl et al. in 1989 as rescue therapy for liver grafts failing conventional therapy (11). Subsequently, tacrolimus was evaluated for routine use in liver transplantation. A multicenter trial, that compared the efficacy and safety of tacrolimus with cyclosporine showed that tacrolimus was associated with significantly fewer episodes of corticosteroid resistant or refractory rejection, although graft survival and patient survival were not significantly different (32). Similar results were also seen in the European Multicenter Study; additional findings included a lower incidence of chronic rejection and infection. However, the use of tacrolimus in the US Multicenter Study was associated with a higher incidence of adverse events requiring withdrawal from the study, primarily nephrotoxicity and neurotoxicity. Tacrolimus has been proved to be safe and efficacious in long-term immunosuppression after liver transplantation with fairly low incidences of rejection and malignancies (33,34). Tacrolimus is absorbed in the duodenum and jejunum and, unlike cyclosporine, does not require the presence of bile (22). The recommended initial dose is 0.1 mg/kg/ per day every 12 hours. Initial levels after liver transplantation are maintained between 10 and 15 ng/mL. With time, 12-hour trough levels may be lowered to between 5 and 10 ng/mL to reduce side effects. Although initially used in combination with other immunosuppressive agents, most commonly corticosteroids and azathioprine or MMF, tacrolimus monotherapy in the later stages of liver transplantation is more widely practiced.

The side effects of tacrolimus are similar to those of cyclosporine (35). The most significant effects include nephrotoxicity and neurotoxicity. The neurotoxic side effects of tacrolimus include headaches, insomnia, tremors, dysarthria, seizures, and coma (36). It may be necessary to switch over from tacrolimus to cyclosporine therapy to obviate some of these side effects. The incidence of hypertension may be lower with tacrolimus. Tacrolimus also seems to be a more diabetogenic medication when compared with cyclosporine with up to 10% of the patients developing de novo diabetes mellitus (37). The other side effects include hyperlipidemia, nausea, diarrhea, abdominal pain, and pruritus.

Mycophenolate Mofetil

MMF is a prodrug that is rapidly hydrolyzed to its active metabolite, mycophenolic acid. It is a selective and noncompetitive inhibitor of inosine monophosphate

dehydrogenase, which is an important enzyme in the de novo pathway of guanine nucleotide synthesis (22,38). This results in the inhibition of DNA synthesis in T and B lymphocytes thereby inhibiting cell proliferation and function. Other cell types can use salvage pathways and are not affected; therefore, the effects of MMF are largely seen on the immune cells with few effects on the nonimmune system. Although long known to be an

immunosuppressive, it is only recently that its use has increased in liver transplantation.

MMF is metabolized to mycophenolic acid glucuronide which is excreted in bile and has an enterohepatic circulation. It is excreted in the urine in humans and to a lesser extent in the bile. There may be larger variations in pharmacokinetics in liver transplant recipients related to fluctuations in serum albumin, unlike that seen in renal transplant recipients (39).

Clinically, MMF is used mainly as a replacement to azathioprine in liver transplantation. It has similar side effects as azathioprine, but it is less myelotoxic and has fewer hepatotoxic side effects. It is usually used in combination with a calcineurin inhibitor and steroids. The use of MMF in conjunction with corticosteroids and tacrolimus has been shown to be superior in preventing rejection and improving renal function than the combination of tacrolimus and corticosteroids alone. Patients discharged home on immunosuppression that included MMF appear to have better long-term patient and graft survival (40). It is possible that the use of MMF may enable a lower dose of a calcineurin inhibitor to be used or withdrawn, in an attempt to preserve renal function (41,42,43). Therefore, MMF may be particularly useful in patients who may be at a higher risk of rejection such as younger patients undergoing liver tranplantation for fulminant liver failure and patients with autoimmune liver disease. MMF as monotherapy after calcineurin inhibitor withdrawal has been associated with a high incidence of acute cellular rejection and steroid-resistant acute cellular rejection (44,45). Therefore, the use of MMF alone may not be sufficient to prevent rejection after liver transplantation. The usual dose is 1,000 mg given orally twice daily. Dose-reductions are made depending on toxicity. An enteric-coated preparation (Myfortic) is available that allows delayed release of the active drug in the small intestine rather than the stomach. This may help alleviate some of the gastrointestinal side effects of MMF.

The significant side effects of MMF include gastrointestinal symptoms, mainly diarrhea, abdominal discomfort, anorexia, and bone marrow suppression including neutropenia. The incidence of side effects is high and dose dependent. Variations in pharmacokinetic from changes in serum albumin levels may increase the incidence of side effects if drug levels are high. Side effects may require dose-reduction and withdrawal in 25% to 57% of patients (46). Occasionally patients with gastrointestinal side effects may respond to increasing the frequency of dosage to three or four times daily. Gastrointestinal side effects may be reduced by acid reduction with a proton pump inhibitor. Bone marrow suppression usually responds to dose-reduction, but in some instances may require drug discontinuation.

Rapamycin

Rapamycin or sirolimus is a new macrolide antibiotic immunosuppressive agent. Rapamycin is structurally similar to tacrolimus. It is named after its isolation from the fungus, S*treptomyces hygroscopicus*, found in soil samples from Rapa

Nui or Easter Island brought back in 1968. However, its immunosuppressive properties were not reported until 1988. Like the calcineurin inhibitors, cyclosporine and tacrolimus, rapamycin acts by binding to an immunophilin FKB12. However, this does not affect calcineurin activity, but instead, the complex binds to and inhibits a protein called the *mTOR*. Inhibition of mTOR results in selective inhibition of synthesis of new ribosomal proteins which are essential for progression of the cells from the G1 to the S phase (47). In addition, rapamycin has also been associated with diminished fibroblastic activity by its actions on the 70 kDa S6 kinase in the fibroblast (48).

In liver transplantation, rapamycin is primarily used as an immunosuppressive agent for its renal sparing effect. In addition, it has some unique properties such as antiproliferative and antineoplastic effects, and hence may be useful in patients who undergo liver transplantation for hepatocellular carcinoma and cholangiocarcinoma. The usual regimen is to provide a loading dose, 5 mg PO, and continue with maintenance doses of 2 to 3 mg perday. It is usually used in the later post-transplant period and levels are maintained between 5 and 10 ng/mL.

Rapamycin has a number of side effects, which currently restricts its usage in liver transplantation. (49,50,51,52). In early trials in liver transplantation, rapamycin was combined with FK506 in the immediate post-transplant period in an attempt to reduce the incidence of renal dysfunction. However, when used with FK506, rapamycin was associated with a higher incidence of adverse events which included thrombotic events such as hepatic artery thrombosis, infection, and death (53,54,55). Hence, most centers use rapamycin in the later post-transplant period, usually after a period of 3 to 6 months. The adverse effects of rapamycin include thrombocytopenia, leukopenia, anemia requiring blood transfusions, arthralgias, hyperlipidemia, pneumonitis, and diarrhea (56). There have also been reports of wound complications in the immediate post-transplant period (57). This effect is presumably a result of its antilymphoproliferative effects on fibroblasts, thereby delaying wound healing. Oral ulcers were seen with the liquid preparation; however, this does not seem to be a problem with the pill preparation. In addition to the those mentioned in the preceding text, there have been reports of an increased risk of nephrotoxicity when combining rapamycin with high doses of calcineurin inhibitors (58).

An analog of rapamycin, RAD (Everolimus) is currently undergoing clinical trials in liver transplantation. It differs from rapamycin only in its bioavailability.

Antibody Therapies

Antibody therapies in liver transplantation may consist of either the polyclonal antibodies or monoclonal antibodies. Polyclonal antibodies include antithymocyte globulin and ALG. Polyclonal preparations may be obtained by immunizing either the horse or rabbit with different immunogens, whereas monoclonal antibodies are produced in response to a single antigen (59). The advent of hybridoma technology to fuse two cell lines, one capable of specific antibody production and the other capable of permanent cell growth, was a key breakthrough in monoclonal antibody production (60).

Polyclonal Antibodies

Polyclonal antibodies include antithymocyte globulin and ALG, which are prepared

by immunizing animals such as the horse or rabbit with immunogens from different sources. These immunogens may include lymphocytes, thymocytes, blast cells, or T cell lines. Antithymocyte globulin is produced by using human thymocytes as immunogens, whereas, ALG is produced by using human lymphocytes. Polyclonal agents have been in use since the early 1960s. The initial agents, termed *antilymphocyte serum* (ALS) consisted of unfractionated serum obtained from animals after immunization with human lymphocytes. Subsequently, this preparation was purified and the immunoglobulin was concentrated, as it was known that the immunosuppressive properties of the serum were contained in the immunoglobulin fraction. Various preparations of polyclonal antibodies are available throughout the world. In the United States, the commonly used preparations are antithymocyte globulins derived either from the horse (Atgam) or the rabbit (Thymoglobulin). The polyclonal antibodies exert their action through various mechanisms, which include complement mediated cell lysis, increased uptake of T cells by the reticuloendothelial system, and also by modulation of surface receptors of lymphocytes and blocking their function. The administration of polyclonal antibodies results in profound lymphopenia. Currently, they are not commonly used in liver transplantation. There have been reports of their successful use in corticosteroid-free protocols with comparable rates of rejection (14,15,16,17). In addition, they may have a role in the treatment of steroid-resistant acute cellular rejection.

In addition to profound leukopenia, administration of antibody therapy is associated with the cytokine release phenomena characterized by fevers, chills, hypotension, which may require admission to the intensive care unit (60,61,62,63). Other less common side effects include nausea, diarrhea, arthralgias, thrombocytopenia, dyspnea, and seizures. Concerns about an increase in the infectious complications and increase in the incidence of post-transplant lymphoproliferative disorders are also present with the use of these therapies.

Monoclonal Antibodies

Monoclonal antibodies are produced in relation to a specific antigen. These include the mouse monoclonal antibody muromonab (OKT3), which is specific to the CD3 receptor. Other antibodies include the IL-2 receptor antibodies that include daclizumab and basiliximab. In addition, other monoclonal antibodies such as Campath 18 (alemtuzumab) are also being investigated.

OKT3 has been the most extensively used monoclonal antibody in liver transplantation. It was originally used in 1987 for prophylaxis against acute cellular rejection (64,65). OKT3 is directed against the CD3-antigen complex found on T cells. Binding of OKT3 to this complex results in deactivation of the CD3-antigen complex and subsequent internalization of the T cell receptor, thereby preventing subsequent antigen rejection (66). Administration of OKT3 results in rapid depletion and extravasation of most T cells from the blood stream and peripheral lymphoid organs such as lymph nodes and spleen. This depletion is secondary to both cell death and margination of the T lymphocytes onto vascular endothelial walls and redistribution to nonlymphoid organs such as the lungs. OKT3 is currently used for the treatment of steroid-resistant cellular rejection in liver transplantation (61,62). It is associated with a high incidence of adverse events related to the cytokine release phenomena, and premedication with steroids and/or antihistamines is generally advised (63) (Table 54.4). This syndrome usually occurs within an hour of drug administration during the first 2

to 3 doses of OKT3. Additionally, during OKT3 administration, prophylaxis against infections such as cytomegalovirus (CMV), pneumocystis and fungi are also advised. The use of OKT3 may also be associated with early and severe recurrences of hepatitis C after liver transplantation (67), and hence, must be used with caution in this cohort of patients. The total lymphocyte counts and CD3 counts are usually monitored during therapy and dose adjustments may be needed to ensure adequate suppression of the CD3 count.

Table 54.4. Side Effects of OKT3

Fever
Hypotension
Chills
Headache
Rash
Nausea
Vomiting
Chest pain
Diarrhea
Pulmonary edema

Two IL-2 receptor antibodies, daclizumab and basiliximab, are currently being studied in liver transplantation. The exact mechanism of action is still incompletely understood, but likely results from their binding to the IL-2 receptor on the surface of activated, but not resting, T cells. They are fairly well tolerated and have a low incidence of side effects (58,68,69). They may be used for induction immunosuppression especially in patients with renal failure to provide a window of opportunity for the kidneys to recover before commencing calcineurin inhibitors. They have also been used for induction immunosuppression in corticosteroid-free protocols (70,71,72,73).

Alemtuzamab or Campath is a humanized recombinant anti-CD52 monoclonal antibody. Campath produced profound depletion of circulating lymphocytes for about several months with slow lymphocyte recovery (74,75). Experimentally it has been used in the treatment of multiple sclerosis with thrombocytopenia and Graves' disease observed as side effects. Campath has been used in liver transplantation in tolerance inducing protocols (76). Severe recurrence of hepatitis C has been noted. Currently, the use of Campath in liver transplantation is considered experimental and its use is confined to research protocols.

Newer Immunosuppressive Agents

The prevention of nephrotoxicity from calcineurin inhibitors remains a difficult challenge. The development of newer immunosuppressive agents that are less nephrotoxic may help prevent the development of renal dysfunction in the long-term. There are various agents currently being developed as immunosuppressive agents in liver transplantation. These include FK778, a synthetic analog of leflunomide which interferes with pyrimidine metabolism and DNA synthesis, FKY720 derived from *Isiria sinclaivii*, which alters cellular homing patterns of

lymphocytes, JAK inhibitors that inhibit activation of immune cells, and agents such as CTLA4 IG and betacelept that cause costimulation blockade (77,78,79,80,81,82,83). These agents are all considered investigational and are currently undergoing clinical trials.

Goals of Immunosuppression

The goals of immunosuppression are to control alloreactivity to eliminate acute rejection, but not adversely influence the development of recurrent hepatitis C, minimize side effects, preserve renal function, and reduce costs. In the absence of satisfactory markers of overall immunosuppression, tolerance and rejection/alloreactivity, and poor correlation between rejection and the degree of liver enzyme elevations or immunosuppression levels, immunosuppression in transplantation still remains an art. The key is to tailor immunosuppression to the individual patient. In patients with renal insufficiency at the time of liver transplantation, calcineurin inhibitors are withheld and an IL-2 receptor blocker may be used as an induction agent. Calcineurin inhibitors are introduced once renal function has recovered. In the event of non-recovery of renal function, the addition of rapamycin may be considered. Switching to rapamycin may also be considered in patients who develop renal dysfunction while on calcineurin inhibitors. An alternative to this regimen would be to consider adding MMF and lowering the dose of the calcineurin inhibitor. Patients with complications from long-term corticosteroid use may benefit from being weaned off from corticosteroids in a controlled fashion while carefully monitoring for rejection. Caution must be exercised before embarking on this protocol in patients who have undergone liver transplantation for autoimmune liver disease such as autoimmune hepatitis, primary sclerosing cholangitis or primary biliary cirrhosis, and in younger patients to prevent recurrent disease or rejection.

Conclusion

Calcineurin inhibitors in conjunction with steroids and MMF continue to play a major role in immunosuppression following liver transplantation. Efforts are currently underway to develop newer immunosuppressants with less nephrotoxic effects, which will help reduce the incidence of long-term renal complications in these patients. In future, the development of these newer agents with less nephrotoxicity, and advances in inducing tolerance in the recipient will enable prolonged survival in patients undergoing liver transplantation.

Chapter 55

The First 6 Months Following Liver Transplantation

Tram T. Tran

Paul Martin

Key Concepts

- Clinical assessment immediately postoperatively in the liver transplant recipient focuses on hemodynamic stability and multiorgan function, including neurologic assessment and renal function, which reflect graft function. Early profound graft dysfunction suggests primary nonfunction or hepatic artery thrombosis (HAT), which necessitate prompt retransplantation
- Care in the early weeks of post-transplantation care involves monitoring graft function for acute cellular rejection (ACR), prophylaxis against opportunistic infections such as cytomegalovirus (CMV), and management of immunosuppression and its side effects.
- Immunosuppression initially involves of calcineurin inhibitors (CNIs) (tacrolimus or cyclosporine) and corticosteroids, transitioning to maintenance regimens that reduce or eliminate corticosteroids. Adjunct agents such as mycophenolate mofetil or sirolimus are added in some cases, particularly if there is renal insufficiency
- Significant side effects of immunosuppression including diabetes, hypertension, and hyperlipidemia need to be anticipated. Recommendations for routine health maintenance issues must be reinforced.
- ACR becomes less of a concern as patients progress further from the time of transplant but differentiation of rejection from recurrent disease can become a challenge during the initial 6 months. Chronic ductopenic rejection may evolve following ACR. Other important causes of late graft dysfunction include late recognition of HAT.

Intensive Care Unit Management

Following liver transplantation (LT), the focus of medical care immediately shifts from managing the manifestations of decompensated liver disease to monitoring liver graft function, anticipating complications such as rejection, maintaining effective immunosuppression while minimizing its side effects, and caring for a patient recovering from complex major abdominal surgery.

On return from the operating room to the intensive care unit (ICU), close clinical and hemodynamic monitoring is essential. Careful attention is paid to the patient's level of consciousness, urinary output, and hemodynamic status. Although less frequently used than previously in donor-recipient bile duct anastamosis, a T-tube allows easy assessment of bile output with pale scanty bile implying poor graft function.

Assessment of the graft function in the initial 24 to 48 hours after transplantation may be somewhat difficult, as elevated serum aminotransferases and other biochemical evidence of graft injury due to a variety of factors including graft ischemia and reperfusion injury are the norm. Serum aminotransferases may be markedly elevated initially but should rapidly decline if graft function is satisfactory along with normalization of prothrombin time in the first several days post-LT. Simple clinical observations including alert mental

status, adequate urine output, and hemodynamic stability are also reflective of good graft function. There are two major causes of profound graft dysfunction in the immediate postoperative period, which require prompt recognition: Primary graft nonfunction and hepatic artery thrombosis (HAT). Importantly, hyperacute rejection due to preformed antibodies is extremely rare post-LT. Primary graft nonfunction (PNF) occurs in 7% to 10% of allografts and is manifested by persistent coagulopathy, encephalopathy, poor bile production, and elevated serum aminotransferases in the immediate postoperative period. Risk factors for PNF include a reduced-size graft, donor graft steatosis greater than 20%, older donor age, retransplantation, renal insufficiency, and prolonged cold ischemia times (1). Recognition of PNF is an indication for prompt retransplantation.

HAT complicates 7% of adult LTs (range 4% to 25%), and 10% to 40% of pediatric cases (2). Risk factors include technical and anatomic difficulties, including small size of donor hepatic artery and complex hepatic artery anastomosis. Clinical signs of HAT resemble PNF, also reflecting profound graft dysfunction, if HAT occurs in the first several days following LT. Color Doppler ultrasonography is performed to confirm blood flow in the hepatic artery. The sensitivity of ultrasonography is reported to be approximately 90% in detection of acute HAT but angiography may be needed for definitive diagnosis. Late complications of unrecognized HAT, reflect ischemia of the biliary tree and include biliary strictures and bilomas. In common with PNF, HAT in the early postoperative period is an indication for prompt retransplantation although occasionally surgical thrombectomy may be successful.

Infectious precautions, including oral antibiotic prophylaxis for gut decontamination and intravenous antibiotics, are taken before the transplantation and in the operating room. Intravenous antibiotic prophylaxis should be continued for at least 24 hours after transplantation, and should cover a broad spectrum of organisms, specifically gram-positive skin flora and enteric gram-negative organisms. Opportunistic infections are not a major concern in the first few weeks following LT if graft function is good. Infections are typical of any patient recovering from major abdominal surgery, notably wound and pulmonary infections. Along with assessment of allograft function, routine ICU care including ventilatory management with weaning and pulmonary toilet as indicated. Other important issues at the bedside include monitoring of output from the Jackson-Pratt abdominal drains placed at the time of surgery to exclude a bile leak or intra-abdominal bleeding before their eventual removal, incentive spirometry once extubated, gradual advancement of oral intake as tolerated, and pain management. Once stable, transfer to a ward where the staff is experienced in the care of LT recipients is important for continuity of patient care.

Therapeutic immunosuppression is divided into induction (initial immunosuppression) and maintenance immunosuppressive phases, with additional immunosuppression for treatment of acute cellular and chronic ductopenic rejection. A number of immunosuppressive agents are currently employed (3). Newer immunosuppressive agents have often undergone evaluation initially in renal transplant recipients, reflecting the greater need for effective antirejection regimens in other areas of solid organ transplantation. Although rejection cannot be discounted in LT, the more formidable threat to ultimate graft viability is recurrent disease. An uncomplicated episode of acute cellular rejection (ACR) conveys a survival advantage in many LT recipients reflecting a relatively well-preserved immune system in contrast to renal transplant recipients in whom it results in diminished graft survival (4). The primary goal of immunosuppression is to prevent graft rejection and loss; a secondary goal is to avoid the adverse consequences of antirejection therapy. Immunosuppression is initiated intraoperatively with a steroid bolus. Although regimens vary by center, steroids are continued at a high dose for the first several days following LT while the mainstay of modern immunosuppression, a calcineurin inhibitor CNI, is introduced within the first postoperative day. Increasingly mycophenolate mofetil is added to the regimen as an adjunct immunosuppressive agent (which can allow for calcineurin sparing) in the setting of preexisting renal insufficiency or acute oliguric renal failure. Rejection is generally not a concern for the first week to 10 days post-LT.

Floor Care

Clinical care following transfer of patient to the floor is aimed at continued close monitoring of graft function, along with titration of immunosuppression into therapeutic range, wound care, early ambulation or physical therapy as tolerated, and patient and caregiver education.

Graft function in the days subsequent to discharge from ICU should continue to improve with resolution of coagulopathy and biochemical dysfunction (Table 55.1). Some clues to a likelihood of continued early allograft dysfunction that may portend a poor worsened long-term patient and graft survival include recipient prothrombin time or bilirubin that stays persistently elevated, donor age greater than 50 years, cold ischemia time greater than 15 hours, and donor preprocurement acidosis (5). Rejection also becomes an increasing concern in this phase of post-LT period. Any significant elevation in liver enzymes should prompt a diagnostic

liver biopsy. Biopsy-proven acute rejection occurs in up to 75% of LT recipients, typically within the first year.(6). Balancing adequate immunosuppression with the side effects of the CNIs, especially renal toxicity, is important (Table 55.2). ACR occurs in up to 70% of liver transplant recipients in the first year, of these 68% had both biochemical and histologic abnormalities consistent with ACR, while 32% had only histologic findings on protocol biopsies, without biochemical abnormalities. The latter is of unclear significance (7). ACR becomes most frequent after the first week. Most patients are clinically asymptomatic despite early mild acute rejection; however, hepatomegaly and tenderness to palpation of the allograft can be seen in late or severe acute rejection. Elevations in total bilirubin, transaminase (aspartate transaminase [AST] and alanine transaminase [ALT]), γ-glutamyl transpeptidase (GGT), and/or alkaline phosphatase levels, after initial normalization post-LT, suggest, but are not specific for, ACR which requires confirmation by liver biopsy as histopathology remains the gold standard for its diagnosis. Rejection is suggested by the presence of portal inflammation, bile duct damage, and venous subendothelial infiltration by inflammatory cells (Table 55.3). In many cases, the presence of eosinophils can also be a helpful indication of acute rejection (8). However, cellular rejection can be difficult to distinguish from recurrent disease, especially recurrent hepatitis C infection, although the latter does not usually occur for at least several weeks post-LT. Importantly, treatment of apparent ACR with steroid boluses is a predictor of more severe recurrent hepatitis in recipients with hepatitis C virus (HCV) infection, so the distinction is not merely of academic interest (9). ACR is typically treated with increased immunosuppression, initially with a corticosteroid bolus and/or an increase in the dosage of maintenance immunosuppressant medication (such as tacrolimus) especially if blood trough levels are found to be subtherapeutic. Antilymphocyte therapy such as antithymocyte immunoglobulin or the monoclonal antibody OKT3 may be used in the setting of steroid refractory rejection.

Table 55.1. Graft Function and Dysfunction in the Liver Transplant Recipient

	First week	Second and third week	Third to twelfth week	Third to sixth month
Physiologic	Aminotransferase normalize INR diminishes to normal Discharge from intensive care unit	Continued improvement in hepatic and renal function Discharge from hospital	Normal liver chemistries	Normal liver function
Pathologic	Hyperacute rejection PNF HAT	Acute cellular rejection Impaired graft function	Acute cellular rejection Cytomegalovirus Recurrent HCV Delayed HAT	Recurrent HCV Biliary stricturing due to HAT Recurrent primary sclerosing

				cholangitis

INR, international normalized ratio; PNF, primary graft nonfunction; HAT, hepatic artery thrombosis; HCV, hepatitis C virus.

Table 55.2. Common Side Effects of Immunosuppression

Tacrolimus	Cyclosporine	Prednisone
Nephrotoxicity	Nephrotoxicity	Osteoporosis
Tremor	Tremor	Osteonecrosis
Hypertension	Hypertension	Diabetes
Headache	Headache	Hyperlipidemia
Gastrointestinal symptoms	Hirsutism	Hirsutism
Alopecia	Gingival hyperplasia	Hypertension
Diabetes		Cushingoid habitus

Cytomegalovirus (CMV) is a major cause of morbidity and mortality in the first 14 weeks after transplantation before effective routine prophylaxis against and was implicated in other adverse outcomes such as chronic rejection (CR) (10,11) Particularly at risk of primary CMV infection are seronegative recipients of allografts from seropositive donors. Other risk factors include retransplantation and the use of antilymphocyte antibodies. CMV infection may manifest as asymptomatic viremia or overt disease with multiorgan involvement of skin, gastrointestinal tract, and graft dysfunction. Intravenous ganciclovir (6 mg/kg/day) given for 100 days postoperatively reduced the risk of CMV infection to 5% to 10% (12). Recent studies comparing oral ganciclovir (after a 14 day intravenous induction) to intravenous ganciclovir until day 100 after transplant showed no statistical difference in 1 year CMV infection rates, obviating the need for long-term intravenous access (13). Clinical disease is generally treated with intravenous ganciclovir. Although resistant strains of CMV occur, clinical disease typically reflects inadequate prophylaxis rather than CMV resistance.

Pneumocystis carinii (*PCP*) infection occurs in 6% to 20% of patients undergoing solid organ transplantation in the absence of prophylaxis. Trimethoprim-sulfamethoxazole (TMP/SMX) is effective in preventing

PCP and is generally given for 6 to 12 months after transplantation at the time of highest immunosuppression and greatest risk. Intolerance to TMP/SMX may then require second line

agents including aerosolized pentamidine or atovaquone.

Table 55.3. Rejection Activity Index and Grading of Acute Liver Allograft Rejection

(A) Rejection Activity Index (RAI)
Criteria that can be used to score liver allograft biopsies with acute rejection, as defined by the World Gastroenterology Consensus Document

Category	Criteria	Score
Portal inflammation	Mostly lymphocytic inflammation involving, but not noticeably expanding, a minority of the triads	1
	Expansion of most or all of the triads, by a mixed infiltrate containing lymphocytes with occasional blasts, neutrophils, and eosinophils	2
	Marked expansion of most or all of the triads by a mixed infiltrate containing numerous blasts and eosinophils with inflammatory spillover into the periportal parenchyma	3
Bile duct inflammation damage	A minority of the ducts are cuffed and infiltrated by inflammatory cells and show only mild reactive changes such as increased nuclear:cytoplasmic ratio of the epithelial cells	1
	Most or all of the ducts infiltrated by inflammatory cells; more than an occasional duct shows degenerative changes such as nuclear pleomorphism, disordered polarity, and cytoplasmic vacuolization of the epithelium	2
	As above for 2, with most or all of the ducts showing degenerative changes or focal lumenal disruption	3
Venous endothelial inflammation	Subendothelial lymphocytic infiltration involving some, but not most of the portal and/or hepatic venules	1
	Subendothelial infiltration involving most or all of the portal and/or hepatic venules	2
	As above for 2, with moderate or severe perivenular inflammation that extends into the perivenular parenchyma and is associated with perivenular hepatocyte necrosis	3
Total RAI Score = _/9		

From (7a) *Hepatology*. Banff schema for grading liver allograft rejection: an international consensus document. 1997;25(3):658–663.

(B) Grading of acute liver allograft rejection
Global assessment of rejection grade made on a review of the biopsy and after the diagnosis of rejection has been established

Global assessment[a]	Criteria
Indeterminate	Portal inflammatory infiltrate that fails to meet the criteria for the diagnosis of acute rejection (see reference in subsequent text)
Mild	Rejection infiltrate in a minority of the triads, that is generally mild, and confined within the portal spaces
Moderate	Rejection infiltrate, expanding most or all of the triads
Severe	As in preceding text for moderate, with spillover into periportal areas and moderate to severe perivenular inflammation that extends into the hepatic parenchyma and is associated with perivenular hepatocyte necrosis

[a]Verbal description of mild, moderate or severe acute rejection could also be labeled as Grade I, II and III, respectively.
From (7a) *Hepatology*. Banff schema for grading liver allograft rejection: an international consensus document. 1997;25(3):658–663

Neurologic dysfunction can present during this phase of hospitalization as acute delirium, seizures, hallucinations, and tremor. The differential diagnosis includes metabolic causes (uremia, electrolyte imbalance), infection, residual encephalopathy, and medication side effects. Steroids and CNIs have known neurologic side effects, and switching from tacrolimus to cyclosporine or adding an adjunct medication such as mycophenolate mofetil to reduce the CNI dose may be of benefit. Any localizing symptoms should be assessed with prompt imaging to rule out focal hemorrhage or infarct. Central pontine myelinosis (CPM) is a neurologic finding associated with variable symptoms that can include coma, dysarthria, dysphagia, ophthalmoplegia, quadriparesis, tremor, locked-in syndrome, and ataxia among others. Development of CPM can be associated with rapid sodium shifts in the perioperative period, which lead to intramyelinic edema and subsequently demyelination in the pons. CPM has been reported in 5% to 12% of orthotopic liver transplantation (OLT) autopsy series, however, is more rarely seen in clinical practice. Prevention includes minimizing serum sodium fluctuations and avoiding excessively high levels of CNIs.

Mild to moderate ascites after transplantation is common but usually resolves over days to weeks. Conservative management with continued moderate salt restriction and the judicious use of diuretics as tolerated by renal function usually leads to fairly rapid resolution of the ascites. If large volume ascites persists, investigation should be initiated toward hepatic vein

and atrial pressure measurements to detect pressure gradients. Rodes et al. found that factors contributing to large volume ascites post-OLT included inferior vena cava preservation with piggyback technique, suggesting difficulty in graft blood outflow (14).

Other medical issues during the course of hospitalization include the management of systemic hypertension and diabetes. Hypertension is the most common cardiovascular complication following liver transplantation occurring in up to 50% to 80% of recipients. The relative risk of ischemic cardiac events was 3.07 in allograft recipients compared to an age-matched population without transplantation (15). Mechanisms for hypertension include altered vascular

reactivity and vasoconstriction related to CNIs, impaired glomerular filtration rate (GFR) and sodium excretion, and the effects of steroids. Treatment of hypertension should counteract sodium and water retention due to CNIs. A thiazide diuretic may be effective if used judiciously to volume depletion. Vasoconstriction due to CNI use is also a factor in systemic hypertension, so vasodilatation with a calcium channel blocker is appropriate first-line therapy. Diltiazem and verapamil increase the CNI levels and have more limited use than nifedipine. Angiotensin-converting enzyme (ACE) inhibitors, due to aggravation of renal dysfunction and hyperkalemia, are generally not recommended in the early post-transplantation course but may be useful in transplant recipients with diabetes, in the long term. Poorly responsive hypertension may require addition of a β-blocker or a centrally active agent such as clonidine.

Impaired glucose tolerance and diabetes are common in patients with cirrhosis due to peripheral insulin resistance, which predisposes them to post-transplantation diabetes (PTDM). HCV infection also enhances the risk of PTDM. The diabetogenic effect of immunosuppressives, mainly tacrolimus and cyclosporine as well as that of corticosteroids, are important factors. Treatment of diabetes in OLT recipients is based on the same principles as in the nontransplant patient. Treatment with a regular insulin sliding scale while hospitalized to assess insulin needs, then discharge on oral medications and/or insulin is usual. Insulin requirements should lessen as reduction in corticosteroids and other immunosuppressive medications occurs. Diet, lifestyle modification, obesity reduction, and the continued use of insulin or oral hypoglycemic agents may be indicated; with glyburide being an initial choice if an oral agent is felt to be sufficient. Metformin is best avoided because of concern about lactic acidosis in the presence of renal dysfunction that is common in this population.

Patient and caregiver education is the final key to a successful hospitalization for OLT. A thorough discussion with a member of the transplantation team on medication indications, side effects, and interactions is important in the assurance of patient compliance. Patients should be made aware of “warning signs” for which an immediate call to the transplantation center is warranted. Emphasis is placed on good general medical care, use of sunscreen because of an increased risk of cutaneous malignancies, and age appropriate health screening.

Early Clinic Visits

Frequency of outpatient clinic visits vary, but usually are weekly in the first 1 to 2 months, biweekly thereafter, and monthly for up to 1 year. Goals of the clinic visit include assessment of the patient's overall health and well being, activities of daily living, medication compliance, and biochemical and immunosuppression monitoring. In the first weeks following transplantation, a continued low threshold for suspicion of rejection needs to be maintained, and liver biopsy has to be obtained for any significant elevation on serum aminotransferases. Elevations in bilirubin and/or alkaline phosphatase or features of obstruction on liver biopsy suggesting an obstructive clinical picture should prompt a cholangiogram. The cholangiogram may be performed through the T-tube, if present, or increasingly by magnetic resonance cholangiopancreatography (MRCP) if a Roux-en-Y anastomosis was performed. Endoscopic retrograde pancreatography (ERCP) may also be performed by experienced biliary endoscopists but risks of perforation or pancreatitis must be considered. Biliary imaging can distinguish between an anastomotic stricture versus the more worrisome intrahepatic biliary stricturing, which may reflect hepatic arterial occlusion leading to biliary ischemia or use of a suboptimal graft with, for instance, protracted cold ischemia.

Anastomotic strictures are usually amenable to biliary stenting whereas intrahepatic stricturing may require retransplantation because of its frequent association with HAT or other graft dysfunctions and lack of success with stenting. Nonanastomotic strictures in addition to ischemia can reflect other problems such as prolonged cold ischemia time, ABO incompatibility, and more recently the use of organs procured for transplantation from non–heart beating donors.

CMV infection should still be suspected if diarrhea or pneumonitis occur with fever and graft dysfunction, especially if prophylaxis has been discontinued. The diagnosis of CMV infection is confirmed by culture of tissue or blood with rapid tissue culture techniques using indirect immunofluorescence. Treatment is with high-dose ganciclovir.

Immunosuppression levels continue to be monitored with fasting levels drawn of specific CNIs, such as cyclosporine or tacrolimus. Serum drug levels may vary based on diet and concomitant medication usage

and need to be adjusted accordingly. Duration of steroid taper varies by transplantation center, but most recipients are weaned to low or no steroids by 6 months post-OLT.

Hyperlipidemia, with a mixed profile of elevated cholesterol and triglyceride levels, is noted in up to 30% of OLT recipients. Elevated lipid levels may be associated with allograft vasculopathy. The etiology of hyperlipidemia is multifactorial including obesity, preexisting disease, and medication induced. Cyclosporine causes inhibition of bile acid synthesis, and sirolimus and corticosteroids have been shown to cause dyslipidemia. Treatment of obesity and diabetes as well as dietary and lifestyle modifications are first-line measures. If serum lipid levels do not fall, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors can be safely prescribed. Myositis, rhabdomyolysis, and hepatotoxicity are uncommon side effects. The choice of agent is dependent on cost, degree, and type of hyperlipidemia. Nicotinic acid, bile acid binders, and fibric acid derivatives are generally avoided because of their potential hepatotoxicity or interference with other medications. Importantly, many OLT recipients succumb to nonhepatic causes as time from transplantation increases, reflecting factors such as an increased risk of cardiovascular disease, neoplasia, and other factors such as calcineurin-induced renal failure (16). Meticulous attention to systemic hypertension and other risk factors for adverse outcomes therefore assume major significance in the care of the OLT recipient.

Late Clinic Visits

After the first several weeks of close follow-up by the transplantation team, good communication with the primary care physician should lead to a smooth transition to long-term care.

CR, although uncommon, usually occurs after the first 6 months. Patients with CR can be relatively asymptomatic but typically present with laboratory parameters of cholestasis, such as a rise in alkaline phosphatase, GGT, and/or total bilirubin levels. On biopsy, loss of small bile ducts and obliterative angiopathy are classic histologic features. Several risk factors contribute to CR. Almost all affected patients have had at least one episode of acute rejection. Other contributing factors are inadequate immunosuppression in the early postoperative phase, CMV infection, primary biliary cirrhosis (PBC), primary sclerosing cholangitis (PSC), or a history of autoimmune hepatitis (17). CR redevelops in as many as 90% of patients who undergo retransplantation for this reason (18). A number of reports have implicated interferon therapy for recurrent HCV infection in CR, as is discussed elsewhere in this book (see Chapter 58). Steroid boluses and antilymphocytic treatment, although efficacious in the treatment of acute rejection, have little effect in CR. Tacrolimus has proven to be the most effective treatment of CR, especially if the diagnosis of CR was made within 3 months of transplantation (19).

Other important causes of late graft dysfunction include recurrence of the original liver disease as exemplified by HCV (see Chapter 58); however, nonviral diseases including cholestatic and autoimmune hepatitis can also recur. In PBC, biopsy features typical of the disease in the native liver are observed whereas in PSC, biliary stricturing reminiscent of disease in the absence of OLT can also occur. Although recurrence of the cholestatic liver diseases occur less frequently than HCV, and previously hepatitis B virus (HBV), at least some grafts are lost and with long-term follow-up about one fourth of patients who underwent transplantation for cholestatic disease experience clinically overt recurrence. Possible factors implicated in disease recurrence include tacrolimus-based immunosuppression in PBC and absence of colectomy in PSC. No definitive strategy to prevent or ameliorate recurrent disease has emerged. In contrast, recurrent autoimmune hepatitis with reappearance of autoantibodies is generally steroid responsive. A de novo form of autoimmune hepatitis, especially in the pediatric population, may be more difficult to control. Recurrent and de novo nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH) are also recognized.

Osteopenia is common in patients with cirrhosis and typically is due to osteoporosis rather than osteomalacia, although the latter can occur in severely cholestatic patients. Factors implicated, apart from calcium and vitamin D deficiency include low muscle mass, immobility, long-term corticosteroid use, poor nutrition, and alcohol abuse. After transplantation, rapid bone loss occurs in the first 3 to 6 months, but ultimate recovery of bone mass can continue for up to 7 years after OLT. For patients awaiting OLT, serum calcium, phosphorus, thyroid

function studies, and parathyroid hormone should be evaluated along with bone densitometry studies. In addition to calcium and vitamin D, calcitonin or bisphosphonates may be considered if bone density indicates osteoporosis or if long-term corticosteroids are used. Once weekly oral dosing with alendronate or risedronate is well tolerated and convenient.

Skin cancer, lymphoma, and oropharyngeal cancer are more common in OLT recipients. Cigarette smoking is obviously prohibited. The patient should see a dermatologist on a regular basis. Patients with transplantation for PSC who have inflammatory bowel disease remain at high risk for colonic dysplasia and colon cancer, and require regular colonoscopy even in clinically quiescent disease.

Beyond 6 months, post-OLT recipients should be vaccinated for influenza, pneumococcus, and tetanus.

Live vaccines like measles, mumps, and rubella, and live oral polio vaccine should not be given.

Chapter 56
The Long-Term Care of Transplanted Patient

Timothy M. Mccashland

Key Concepts

- Common medical problems in the long-term liver transplant recipient include obesity, osteoporosis, cardiovascular disease (CVD), and diabetes mellitus, all of which may result in increased morbidity and mortality.
- Technical related problems of biliary complications may be corrected by endoscopic therapy. However, living-related biliary complications are common both in the donor and the recipient and require a multidisciplinary team approach.
- Common causes of deaths in survivors for more than 1 year include development of de novo malignancy, cardiovascular causes, renal failure, and recurrent disease. Diligent surveillance for these diseases may lead to early detection and lower morbidity.
- Renal impairment is common in long-term survivors. Development of end-stage renal disease is reported in up to 18%, with markedly decreased survival in these patients.
- Recurrent hepatitis C leading to impaired allograft function is common. Treatment with combination therapy of pegylated interferon and ribavirin results in 20% to 35% clearance of the virus, but often requires growth factors and meticulous follow-up.

The traditional model of care in most transplantation centers is for the transplantation surgeon to manage the immediate postoperative care, with gradual incorporation of transplantation hepatologists and primary care physicians (1,2). With increasing success in liver transplantation, the need to manage these patients beyond the initial 6-month period often requires multiple providers and a larger commitment to prevent medical complications. Distinct differences exist among transplantation centers as to who becomes the primary physician in charge of long-term management (3). The transplantation hepatologist can provide expertise to encompass the overall care of common medical conditions, gastrointestinal- and transplantation-related problems. In a survey of transplantation centers, 40% of programs regarded the transplantation hepatologist as the primary care provider. An equal 40% had the primary care physician (family medicine/internist) as the principal provider of long-term management (3). Therefore, the management of long-term care seems to become the responsibility of internist/family physicians and transplantation hepatologists. Interestingly, transplantation surgeons and referring gastroenterologists were not expected to provide much input. Transplantation centers do not want primary care physicians managing immunosuppression, acute allograft rejection, recurrent disease, and biliary complications.

Several comprehensive reviews of medical complications and management of liver transplant recipients have been published previously (4,5,6,7,8). In 2006, the American Board of Internal Medicine will initiate a subspecialty board certification in transplantation hepatology of which 25% of the test will be related to the management of long-term care (9). This chapter will address management of long-term care of the liver transplant recipient divided into topics of quality of life (QOL), causes of death in long-term survivors, medical

problems (obesity, gout, vaccines, bone disease, cardiovascular problems, diabetes

mellitus), inflammatory bowel disease (IBD), pregnancy, and transplantation-related diseases (biliary complications, de novo neoplasia, renal dysfunction).

Quality of Life

The immediate goal of liver transplantation is to improve survival of the recipient. However, the secondary goal is to improve the QOL and return the patient to a productive life. Numerous studies have been published on this topic (10,11). Diverse results are likely due to different assessment tools and methods. Early studies with follow-up of less than 2 years noted liver recipients achieve very satisfactory levels of health-related quality of life (HRQOL). However, the HRQOL levels were below that of the general population (10). A meta-analysis confirmed these early findings (11). A prospective multicenter study assessing pretransplantation and post-transplantation HRQOL using the 36-item short-form health survey (SF-36) and EuroQol (EQ-5D) instruments with follow-up of 2 years showed a significant improvement in all dimensions of the SF-36 and role-emotion dimensions of the EQ-5D scores (12). Longer survival after transplantation, younger age, and patients from larger transplantation centers were independent predictive variables of higher QOL scores. Panter et al. studied patients up to 5 years after transplantation and found that the number of comorbid conditions and participation in physical activity were significant independent contributors to improved HRQOL (13). A recent French study compared QOL in survivors beyond 10 years after liver, kidney, and heart transplantation with the general population (14). The National Institute of Diabetes and Digestive and Kidney Disease transplantation QOL questionnaire was used to assess 315 patients (liver 126). Perceived physical health, personal function, and social and role functions were similar in the transplantation patients, but lower than the general public. Perceived psychological health was better than the general public in liver and heart transplant recipients but lower in kidney recipients. The QOL beyond 10 years in liver transplant recipients is similar to the general public according to this study. Moore et al. in a large, single-center study, found that functional performance and HRQOL were not affected by donor, recipient, or technical characteristics (15). Chronic immunosuppression, while it may contribute to some complications after transplantation, had little impact on HRQOL in one study (16). Jennings et al. noted no difference in QOL between Laennec's cirrhosis and non-Laennec's patients with follow-up to 5 years (17). However, another study at a mean follow-up of 4 years found impaired lower global QOL, physical functioning in hepatitis C patients with recurrent disease (18).

Psychological improvement after liver transplantation has also been shown to begin immediately after surgery. More recent long-term studies tend to show that depression-coping skills, anxiety, and social environments are more relevant in liver transplant recipient's QOL than other somatic factors (19,20,21). Not surprisingly, elevated levels of anxiety and neuroticism before transplantation were associated with worse psychological health after transplantation (22). A concerning and interesting investigation by Lewis et al. using multiple tests in cognitive function in 36 patients 10 years after transplantation showed that the patients scored significantly lower than healthy controls across a wide range of cognitive functions (23). Unfortunately, the reason for this lower function is unknown and needs further study. Blanch et al. using the psychosocial-adjustment-to-illness scale found that women had poorer adjustment to orthotopic liver transplantation (OLT) than men; the proportion of women with poor adjustment was higher (31.5% vs. 16.7%) (21). Women showed a greater dysfunction in health care orientation, sexual relations, and extended family relationships and psychological distress. Therefore, women may need more psychological intervention after transplantation than men. Therefore, psychological factors are important contributors to QOL issues in the long-term management of liver transplant recipients.

Causes of Death in Long-Term Survivors

According to the United Network of Organ Sharing (UNOS) database, the overall 1-, 3- and 5-year survival rates for liver transplant recipients are 82.5%, 73.5%, and 67.5% respectively (24). The well-known causes of death during the first year after transplantation include graft dysfunction, technical problems, and infections (25). There have been several studies looking at the cause of death in patients who have survived at least 1 year. These studies have generally defined the patient with survival greater than 1 year as a long-term

survivor (26,27). A few studies have looked at mortality after 3 or 5 years (28,29,30,31). The common evolving theme is that mortality occurring more than 1 year after liver transplantation in adults includes malignancy (recurrent and de novo), recurrence disease (especially hepatitis C virus [HCV] infection), cardiovascular events, chronic rejection, and less frequently infections and chronic renal failure (CRF). Table 56.1 illustrates the common causes of death in patients having survival greater than 1 year.

Table 56.1. Long-Term Causes of Death Post–Liver T

Recommendations

- *Recognition, prevention and surveillance for common causes of late mortality are imperative to improve the survival of this patient population*.

Medical Care

Obesity

Obesity is a major health problem in the United States In the NHANES III study, 22.5% of the general public had a body mass index (BMI) of greater than 30 kg/m^2. Weight gain is also common after liver transplantation. In a large cohort study, 21.6% of nonobese patients become obese in the first 2 years following transplantation (32). The most recent study noted that by 1 and 3 years post-transplantation, 24% and 31% of patients had a BMI greater than 30 kg/m^2 (33). Predictive factors included age greater than 50 years and pretransplantation BMI greater than 30. Another study reports development of obesity after transplantation in up to 60% of patients (34). Appetite stimulation caused by corticosteroids, change to a less restrictive diet, lack of exercise, and higher cumulative doses of prednisone lead to increased weight. An early study from Virginia, reported that severely obese patients had greater transfusion requirements, higher wound infections, and higher rate of death due to multiorgan failure (35). Nair et al. in a single-center study from Johns Hopkins University, evaluated 121 patients to compare outcomes in moderate and severely obese recipients versus nonobese recipients. Postoperative complications of respiratory failure (23% vs. 3%) and systemic vascular complications (14% vs. 2%) were much higher in the severely obese group (36). The length of hospitalization and total hospital costs were higher in severely obese patients compared to nonobese patients. The same investigators, using the UNOS database, assessed the morbidity and mortality in obese patients after liver transplantation (37). Primary graft nonfunction and immediate, 1-year, and 2-year mortality were significantly higher in the morbidly obese group. Five-year mortality was higher in the severely obese (28%) and morbidly obese patients (27%) mainly due to infections and cardiovascular events. This study has led many centers to institute weight-restriction guidelines for liver transplantation. Interestingly, no studies exist on the success of weight loss after transplantation, either by diet or by obesity surgery. The National Heart, Lung and Blood Institute and National Institute of Diabetes and Digestive and Kidney Diseases guidelines for obesity recommend a target of 10% of baseline weight at a weight loss rate of 1 to 2 lb/week (38).

Recommendations

- *Yearly evaluation for weight gain*.
- *If obesity develops, target weight loss of 1 to 2 lb/week. This requires multiple clinical visits and the supervision of a nutritionist*.

Gout

Hyperuricemia is a common disorder associated with liver transplantation (39,40). Calcineurin inhibitor immunosuppressant medications impair the excretion of uric acid (41). Neal et al. in a study of 134 consecutive liver transplant recipients, found that 47% of patients had hyperuricemia (39). The levels correlated with renal dysfunction. Interestingly, only 6% developed gout located in the wrist, knees, ankle, or elbow at a mean of 25 months after transplantation. All those treated with allopurinol had resolution of their symptoms. In another study, hyperuricemia was present in 85% of patients, with only 3% developing gout (40). Therefore, with the incidence of gout being quite low, treatment of isolated hyperuremia with allopurinol is not likely needed. The management of gout in these patients is potentially complicated by interactions of immunosuppressants and renal insufficiency. The combined use of azathioprine and allopurinol may lead to myelosuppression. Extreme care should be used with this combination.

Recommendations

- *Allopurinol 100 mg/day, for patients with a history of gout and hyperuricemia*.
- *Acute gout may be treated with colchicine, 0.6 mg every 2 hours up to 5 doses*.
- *If symptoms persist, a trial of prednisone tapered over 1 week may be helpful*.

Vaccines

Immunosuppressed liver transplant recipients are at risk for infections, even many years after transplantation. Influenza poses a yearly risk. Previously published studies reported influenza vaccination response in adult liver transplant recipients to be from 50% to 95% seroconversion (42,43,44). These authors recommended a second dose to increase response rates. Soesman et al. found an increase of 20% in response rate with this strategy (44). Duchini et al. studied 20 post-transplant recipients at baseline and 6 weeks after vaccination (45). Side effects were well tolerated, but all had significantly lower titers than healthy individuals.

In 1996, the Advisory Committee on Immunization Practices recommended all patients with chronic liver disease be vaccinated for hepatitis A virus (HAV).

Unfortunately, some patients are not vaccinated pretransplantation and may require the vaccine after transplantation. In a liver or renal transplant recipient study, Stark et al. found a seroconversion rate of 97% for HAV vaccination, but unfortunately found a rapid decline in antibody titers (46). Furthermore, only 39% of cyclosporine-treated patients had protective antibody titers versus 79% of tacrolimus-treated patients. A Mayo Clinic study of 39 patients evaluated HAV seroconversion rates at 1 and 7 months after the first dose utilizing two standard doses given at 6 months apart (47). Seroconversion rates were dramatically lower in the OLT patients compared to patients with chronic liver disease and healthy controls: 1 month (8% vs. 83% vs. 93%) and 6 months (21% vs. 97% vs. 98%). The few responders were much longer away from transplantation (average 75 months) than nonresponders, which may be related to higher immunosuppression at time of vaccination.

Prevention of hepatitis B after liver transplantation is becoming less difficult with the use of hepatitis B immunoglobulin (HBIG) and nucleoside analog medications. Several investigators have tried hepatitis B vaccination as another alternative (48,49,50). Sanchez-Fueyo et al. in a pilot trial of recombinant hepatitis B virus (HBV) vaccine in liver transplant recipients reported anti-HBs titers greater than 10 IU/L in 14 of 17 patients. However, as described in an editorial, the patients were atypical in being many months removed from transplantation (48). The Berlin group evaluated antibody response to hepatitis B surface antigen in 10

patients 2 years after transplantation (50). In contrast to other studies, patients were continued on HBIG during the study. They additionally received 20 µg of recombinant HBV antigen with a novel adjuvant (monophosphoryl lipid A) at weeks 0, 2, 4, 16, and 18. Five of ten patients developed antibody titers greater than 500 IU/L.

We have previously reported on pneumococcal vaccination before transplantation but to our best knowledge no study has been performed on pneumococcal vaccine response in patient after transplantation (51).

Recommendations

- *Yearly influenza vaccination of liver transplant recipients*.
- *All personnel associated with care of liver transplant recipients should receive the annual influenza vaccination*.
- *Vaccinate before liver transplantation if possible for HAV*.
- *If unvaccinated for HAV before transplantation, consider vaccination, however, response rate will be better after 1 year removed from transplantation*.
- *Discontinuation of passive immunoprophylaxis of HBIG with HBV vaccination has not become common practice. Large multicenter trials need to be performed to address this issue*.

Bone Disease

Osteoporosis is characterized by reduced bone mass and altered architecture increasing the risk of fracture typically in the spine, hip, or wrist areas (52). Many patients may have severe osteoporosis due to their chronic liver disease, especially cholestatic liver diseases. Early studies report immediate bone loss after transplantation with the nadir of bone mineral density (BMD) being around 6 months after transplantation with gradual recovery (53,54,55). Feller et al. noted in 28 patients that spine BMD had returned to pretransplantation levels by a mean of 85 months (56). However, another study did not show any improvement in the BMD of the proximal femur 36 months after transplantation (57). Guichelaar et al. reported gradual improvement of osteoporosis with follow-up to 7 years post-transplantation (58). Hamburg et al. reported that lumbar bone density increased in the second year after transplantation, stabilizing thereafter with follow-up to 15 years (59).

Fractures are common in the high-risk group, most commonly in the hip, pelvis, spine, ribs, and wrist with frequently reported risks ranging from 5% to 35% (60,61). Haagsma et al. in a prospective study of 36 adult patients reported development of vertebral fractures in 38% of patients within 6 months of transplantation (62). A more recent prospective study by Hardinger et al. from St. Louis followed up 153 patients over 10 years (63). The prevalence of symptomatic fractures was 15% at a mean of 2.2 years post-transplantation. The only factor associated with risk of fracture was being female. Age, time from transplantation, race, menopause, renal insufficiency, family history of osteoporosis, BMD, and T score did not predict either osteoporosis or fractures after liver transplantation. Others have found older age (64), vertebral fracture before transplantation (61), cholestatic liver disease (60), and smoking (61) to be risks for fractures.

Immunosuppressive medications are also proposed to contribute to osteoporosis. Glucocorticoids increase bone resorption by inhibition of osteoblast activity even at low doses of less than 7.5 mg per day (65). Cyclosporine has been shown to increase osteoporosis risk in renal transplant recipients (66). A histomorphometric analysis of 33 patients after liver transplantation by the Mayo Clinic suggested that patients with tacrolimus therapy have earlier recovery of bone formation and trabecular structure by 4 months compared to cyclosporine-treated patients (67). The role of secondary hyperparathyroidism remains controversial in this patient population with small increases in parathyroid levels within a few months of transplantation (68).

Vitamin D deficiency is not rare in patients with chronic liver disease and Feller et al. demonstrated a rapid rise in 25-hydroxyvitamin D levels after transplantation (56).

Treatment of osteoporosis after liver transplantation has usually been reported in small uncontrolled series. Velero et al. noted increased BMD in 40 patients treated with calcitonin (69). Whereas, Hay et al. found subcutaneous calcitonin of 100 IU/day ineffective in preventing fractures in a subset of patients undergoing transplantation for primary biliary cirrhosis (PBC) or primary sclerosing cholangitis (PSC) (70). Neuhaus et al. found improvement in BMD with daily doses of calcitriol, calcium, and sodium flouride (71). Two studies report on the use of IV pamidronate but showed little efficacy in preventing fractures (72,73). Interestingly, no data for oral bisphosphonates has been reported.

Two comprehensive reviews by Crippin and Compston provide excellent guidelines on management of osteoporosis in liver transplant recipients (74,75).

Recommendations

- *Pretransplantation evaluation with dual energy x-ray absorptiometry (DEXA) bone scan, serum tests of calcium, phosphorous, parathyroid hormone level, testosterone (men), estradiol (women), and a 25-hydroxyvitamin D levels*.
- *Treatment of all patients with 1,500 mg of calcium/day and correction of any deficiencies*.
- *If severe osteoporosis is noted by a T score greater than 2 SD below normal, then consider starting oral bisphosphonates*.
- *Those under treatment for osteoporosis should have yearly DEXA, measurement of calcium, phosphorous, and thyroid function*.

Cardiovascular Complications

Established risk factors for development of cardiovascular disease (CVD) in liver transplant recipients include hypertension, hyperlipidemia, hyperhomocysteinemia, diabetes, renal insufficiency, obesity, family history of CVD, advanced age, African American race, male gender, tobacco abuse, and immunosuppressive medications (76,77,78,79,80,81) (Table 56.2). Remarkably, the extent of morbidity and mortality related to CVD remains controversial (79). In an early study from the United Kingdom, 110 consecutive patients were studied, the relative risk for cardiovascular deaths was two and half times greater as compared to age-matched population without transplantation using the Framingham risk score (77).In contrast, a Spanish study, found that the prevalence of hypertension, diabetes, hypercholesterolemia, and hypertriglyceridemia was lower at 5 years after transplantation compared to 1 and 3 years after transplantation and no different from the general Spanish population (80). Neal et al. in a comprehensive study of cardiovascular complications from the United Kingdom looked at the prevalence of risk factors for coronary heart disease and the effect on the predicted 10-year risk of developing coronary heart disease and incidence of cardiovascular events (82). One hundred and eighty-one patients were studied with most of them treated with cyclosporine. The 10-year predicted risk of CVD increased to 11.5% compared to 6.9% before transplantation and matched the control population of 7% at 10 years. Compared to matched controls, the incidence ratios of myocardial infraction and stroke were 0.55 and 1.45. Therefore, by 10 years the mortality associated with CVD was similar to that of the general population.

Hyperlipidemia is common after liver transplantation (Table 56.2). Mixed hyperlipidemia (types 2a, 2b, and 4) with high cholesterol and triglyceride levels is the common pattern after transplantation. The etiology of hyperlipidemia is multifactoral (79). Steroids increase secretion of very low-density lipoprotein (LDL) and conversion of LDL. Cyclosporine inhibits 26-hydroxylase reducing the transport of cholesterol into bile, and binds to LDL receptor increasing the levels of LDL cholesterol (83). Tacrolimus in several studies has been noted to cause a lower incidence of dyslipidemia than cyclosporine (84,85). A study by investigators in Philadelphia, in converting patients from cyclosporine to tacrolimus monotherapy found that mean cholesterol levels decreased from 251 to 202 mg/dL and

triglycerides decreased from 300 to 207 mg/dL (86). Several studies have evaluated dyslipidemia with sirolimus therapy in liver transplantation (87,88,89). In 57 patients treated with a combination of cyclosporine or tacrolimus with sirolimus Trotter et al. found hypercholesterolemia and hypertriglyceridemia were more common in the combination of cyclosporine and sirolimus than tacrolimus (hypercholesterol, 30% vs. 6%, hypertriglycerides, 18% vs. 3%) (87). Whereas in a more recent study of patients receiving sirolimus and tacrolimus for a mean of 57 months after transplantation compared to a group of tacrolimus monotherapy or in combination with mycophenolate mofetil, hypercholesterolemia and hypertriglyceridemia were similar (hypercholesterol, 15% vs. 9%, hypertriglycerides, 10% vs. 9%) (88). The proposed mechanism of sirolimus-induced hyperlipidemia is thought to be related to elevated apoCIII levels which inhibit lipoprotein lipase activity (90). Surprisingly, little data exists on use of statins for hyperlipidemia in liver transplant recipients. In a small study of 16 patients, cerivastatin and pravastatin decreased cholesterol by 21% and 15%, and LDL by 27% and 17% (91). Our center uses atorvastriatin because it is more potent and treats both cholesterol and triglycerides.

Hypertension early after transplantation is almost universal, likely due to high vascular volume and high

levels of calcineurin inhibitors, which reduce endothelial release of vasodilating factors (nitric oxide and prostacyclin) and increase the release of vasoconstrictor factors (endothelin and thromboxane) (92). Neal et al. found an increase in plasma endothelin levels and increases in arterial stiffness associated with hypertension (93). Earlier hypertension studies within the first year noted hypertension ranging from 17% to 82% (76,77,78). In a large European study at 6 months after transplantation, 26% of cyclosporine-treated patients and 17% of tacrolimus-treated patients had hypertension (94). More recent studies using a standard definition of hypertension reading greater than 140/85, reported that incidence at 3 months was 82% in cyclosporine patients and 32% in tacrolimus patients, and at 6 months 50% of patients were hypertensive (93). In studies with longer follow-up from 3 to 5 years after transplantation, overall incidence was around 50%. Detailed analysis in the Rabkin et al. study noted that 58% required a single antihypertensive agent, 29% required two agents, and 10% needed three agents (95). Galioto et al. found that nifedipine was effective in only 22% of patients, whereas 33% of carvedilol treated patients after liver transplantation responded (96). In a large study, Neal et al. reported that 46% of patients responded to amlodipine, with a decrease in systolic blood pressure from 154 mm Hg to 130 mm Hg (97). Patients unresponsive or intolerant to amlodipine were randomized to bioprolol or lisinopril. Lisinopril was successful in 84% of patients, reducing the systolic blood pressure from 154 mm Hg to 130 mm Hg.

Table 56.2. Cardiovascular Risk

Cambridge 2004			67 fk		

Csa, cyclosporine; fk, tacrolimus.

Recommendations

- *Monitor fasting lipid profiles at 6 months and 1 year post-transplantation, then annually*.
- *Attempt to attain total cholesterol levels less than 200 mg/dL, LDL levels less than 130 mg/dL, and normal triglycerides levels after transplantation*.
- *First-line treatment should be dietary modification in accordance with the American Heart Diet*.
- *If unsuccessful, 3-hydroxy-3methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) are to be used*.
- *Early treatment of hypertension incorporates the use of diuretics, clonidine, or calcium channel blockers*.
- *Diltiazem and verapamil can alter cyclosporine or tacrolimus levels, therefore are rarely used*.
- *Angiotensin-converting enzyme inhibitors especially in patients with diabetes are a good choice for treatment of hypertension*.

Diabetes

The prevalence of diabetes in candidates for liver transplantation has ranged from 4% to 13% in previous studies (98,99). In a prospective study of 115 liver transplantation candidates, a group from Spain describes 25% of patients having impaired glucose tolerance and 53% as having diabetes by oral glucose tolerance test (100). Therefore, many patients are at risk of worsening diabetes after transplantation. Immunosuppressive medications are diabetogenic. Corticosteroids induce insulin resistance. Calcineurin inhibitors decrease insulin synthesis and secretion and induce insulin resistance (101). Cyclosporine and tacrolimus appear to have the same diabetic risk, although some have noted a higher risk

with tacrolimus (102,103,104). Other immunosuppression medications including azathioprine, myophenolate mofetil, and sirolimus do not induce diabetes.

Several risk factors for development of new-onset diabetes after transplantation have been recently characterized. A family history of diabetes among first degree relatives and those of Hispanic or African American ethnicity indicate a greater risk (105,106). Age above 40 years, obesity, and many episodes of steroid resistant rejections are also thought to be risks (106,107,108,109). In a large Canadian study, new-onset diabetes was associated only with transplantation for hepatitis C (odds ratio [OR] 4.12) (110). In the multicenter NIDDK-Liver Transplant Database, hepatitis C was also found to be predictive of transient diabetes, but not persistent diabetes after liver transplantation (109). In a small French study, alcoholic cirrhosis and male gender were independent predictors of new-onset diabetes (107).

The incidence (4% to 38%) of new-onset diabetes after liver transplantation has been variously reported because of terms of definition, duration of follow-up, and changing criteria of diabetes. John and Thuluvath from Johns Hopkins University found that 10.5% of post–transplantation patients developed new-onset diabetes, of whom 18 were insulin dependent and 28 were treated by oral hypoglycemic medications (111). In another large single-center study, 37.7% of patients developed new-onset diabetes, 28% had transient diabetes and 9% had persistent diabetes (98). Using the UNOS database, Yoo et al. that found 7.6% were patients with type 1 diabetes and another 7.6% were patients with type 2 diabetes at 1 year after transplantation (112).

Morbidity has been reported as similar among nondiabetic and diabetic patients (113). However, Khalili et al. reported that the overall infectious episodes in the presence of diabetes were fivefold higher (109). Higher morbidity in diabetic patients versus nondiabetic patients of cardiac episodes (48% vs. 24%), major infections (41% vs. 25%), minor infections (28% vs. 5%), neurologic (22% vs. 9%), and neuropsychiatric (22% vs. 6%) episodes were seen in the Baltimore study (111). Two studies found that survival was not worse in diabetic patients (100,114). In contrast, the UNOS

database study reported that 5-year patient survival was lower in patients with type I (insulin dependent diabetes) compared to those without diabetes (63% vs. 75%) (112). Patients with diet-controlled diabetes had a minimally decreased 5-year survival compared to nondiabetic patients. Furthermore, patients with type 1 diabetes or coronary artery disease were 40% more likely to die within 5 years of transplantation compared to those without these risk factors. A German study had similar poor 5-year survival in patients with type 1 diabetes (104).

Consensus guidelines on new-onset diabetes after transplantation have been developed on the basis of definitions from the American Diabetes Association, World Health Organization, and American College of Endocrinology (115).

Recommendations

- *Management of patients who develop new-onset diabetes is similar to recommendations of patients with type 2 diabetes*.
- *Those with a Hemoglobin A1C level greater than 6.5% should be started on treatment*.
- *Initial treatment is lifestyle modifications (exercise, weight loss) and education (dietary and natural history)*.
- *If glycemic control is unsuccessful with dietary modification, consideration of oral diabetic agents may be considered*.
- *Insulin should be used if blood glucose levels do not fall below 120 mg/dL before meals or lesser than 160 mg/dL after meals*.
- *Liberal use of endocrinology consultation is recommended for patients with difficult to control diabetes*.

Inflammatory Bowel Disease

Conflicting results have been published on the prevalence and severity of IBD after liver transplantation (116,117,118). Differences may be attributed to variation in immunosuppression and/or maintenance IBD medications, duration of IBD, and length of follow-up. Papatheoddoridis et al. reported an aggressive natural history in those not treated with steroids after transplantation (119). Conversely, others have noted mild symptoms and few flares of disease (116,117). Haagsma et al. in a single-center study, reported that 36% of patients with pre-OLT IBD experienced exacerbations at a median of 1 year after transplantation (120). Additionally, 11% of patients developed de novo IBD, with risks of 4% (3 years), 11% (5 years), and 14% (10 years) after transplantation. Interestingly, none of the patients was continued on IBD medications such as aminosalicylates. Most transplantation centers now continue specific IBD medications along with immunosuppressants. A unique feature of this study was that the IBD-free survival was increased in patients not receiving tacrolimus immunosuppression and in those receiving azathioprine. From a different perspective, Dvorchick from Pittsburgh analyzed 303 patients to look at the risk of colectomy after transplantation (121). Twenty-two patients (7%) had colectomy due to refractory disease in follow-up to 12 years post-transplantation. Surprisingly, only OLT was the significant risk factor for colectomy (HR 3.1).

Patients with PSC and IBD may have an increased risk of developing colorectal cancer after liver transplantation (122,123). Prior studies have shown the cumulative risk to be between 9% and 14%. Vera et al. from Birmingham, England studied 82 patients with PSC and IBD to identify risk factors for colorectal cancer (124). Colorectal cancer developed in 9.6% of these patients with a mean interval of 46 months (21 to 68 months) between liver transplantation and cancer onset. The cumulative risk of developing colorectal cancer was 14% and 17% after 5 and 10 years after transplantation. Multivariate analysis identified three variables significantly related to colorectal cancer–dysplasia post-transplantation, duration of colitis more than 10 years, and pancolitis. When all three variables were present the risk of colorectal cancer was 100% by 5 years post-transplantation.

Recommendations

- *Maintenance use of IBD medications after transplantation (i.e., aminosalicylates)*.
- *Yearly colonoscopy with surveillance biopsies in patients who underwent transplantation for PSC*.
- *If dysplasia is found, colectomy is warranted*.

Pregnancy

Recovery of normal menstrual function occurs rapidly (within 1 to 2 months of transplantation) in women (125). Unintended pregnancy can occur, therefore contraception should be a topic discussed immediately after transplantation. The most frequent contraceptive practices noted in a questionnaire were barrier methods and tubal ligation (126). In addition, 70% of sexually active patients indicated satisfaction with their relationship, and 75% had weekly intercourse.

Pregnancy outcomes after liver transplantation have been reported from single centers to national transplantation registries (127,128,129). All reports demonstrate favorable maternal and neonatal outcomes, with low incidence of congenital malformations. The two most recent reports support the results of prior studies (128,129). The mean birth weights were lower than normal

(approximately 50%), at a mean gestational age of 36 weeks with around 50% delivered by cesarean section. The Mount Sinai study noted higher pregnancy complications of diabetes mellitus (37%), anemia (33%), elevated creatinine greater than 1.3 mg/dL (25%), preeclampsia (21%), and hypertension (21%). Elevated liver enzymes, graft loss (2%), and rejection were uncommon in the Pittsburgh study, but the Mount Sinai report describes that 10% of patients had spontaneous first-trimester abortions and 26% had terminations of

pregnancy due to elevated liver function that was thought related to graft rejection. This was more common in patients in whom the etiologies of liver disease were autoimmune hepatitis (4/8) and PBC (2/3).

Table 56.3. Pregnancy Categories for Transplantation Medications

Category B (no evidence of risk)
Prednisone
Category C (risks cannot be ruled out)
Cyclosporine
Tacrolimus
Mycophenolate mofetil
Rapamycin
Lamivudine
Ganciclovir
Interferon
Category D (evidence of risk)
Azathioprine
Category X (contraindicated)
Ribavirin

Common transplantation medications carry pregnancy categories of B to X. (Table 56.3)

Recommendations

- *Counsel regarding contraceptive practice immediately after transplantation*.
- *The National Transplantation Pregnancy Registry advises female liver transplant recipients to wait for more than 1 year to become pregnant*.
- *Pregnancy management should include an obstetrician skilled in high-risk pregnancy and the multidiscipline transplantation team*.

Transplantation-Related Complications

Biliary Complications

After OLT, biliary complications occur in 7% to 50% as described in earlier studies (130,131,132,133,134,135). Previously, biliary complications usually required surgical revision; however, endoscopic or interventional radiologic treatment is now the standard of care. Two recognized categories of biliary complications are strictures (anastomotic and nonanastomotic) and leaks (T-tube or anastomotic). In addition, stricture or leaks can be classified as early (<30 days) or late and may be associated with hepatic artery thrombosis. Leaks may be associated with T-tube migration or after T-tube is removed or poor healing of the duct to duct anastomosis. The aim of therapy of leaks is to divert the bile away from the leak site by decompressing the biliary tree and to allow healing of the leak site. Living-related transplantation has been reported to have biliary complications twice as frequently as OLT due to its challenging technical reconstruction of either a Roux-en-Y hepaticojejunostomy or duct to duct anastomosis (136,137,138,139,140). Furthermore, Halme et al. demonstrated that biliary complications were higher among recipients with cytomegalovirus antigenemia, compared with recipients without (75% vs. 49%) (141). Diagnosis of the biliary complication may be obtained by endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic cholangiogram (PTC) or more recently magnetic resonance cholangiopancreatography (MRCP). The Barcelona group verified in a group of 63 patients that MRCP had the correct diagnosis of biliary complication in 91% of patients with a sensitivity of 95% and positive predictive value of 97% (142). However, with a high incidence of abnormal findings many physicians proceed directly to

ERCP or PTC due to the ability to perform therapeutic procedures.

Tables 56.4, 56.5, and 56.6 illustrate the most recent published data on biliary strictures, leaks, and living-related biliary complications. As documented in Table 56.4 overall stricture rates of 4% to 13% are reported, more commonly anastomotic and treated with dilatation and stents. A study from the expert endoscopists of Indiana reported that 24.5% of patients had a biliary complication after OLT, from 1988 to 1999 (143). Strictures and stones were commonly found, which required multiple ERCPs (approximately 3) to successfully treat the complication, with the highest reported outcome of 100% success. In contrast, the Edinburgh group had to convert to a Roux-en-Y hepaticojejunostomy in 60% of patients, most commonly in those with late complications (144). Leaks were equally common (4 to 11%), with anastomotic or T-tube leaks variably noted (Table 56.5). Biliary stents were almost universally used with successful outcomes of more than 85%. However, Wolfsen et al. in a study of only 9 patients demonstrated that sphincterotomy alone was associated with good outcomes in 78% of the patients (145).

Living-related transplantation continues to regularly note biliary complications of 35% to 56% in recipients (Table 56.6). Treatment is more difficult and usually requires a multidiscipline approach. Gondolesk et al. from Mount Sinai provide the most in-depth study to date (139). Forty percent of the recipients had biliary complications equally distributed between leaks and

P.1500

P.1501

P.1502

strictures regardless of the type of biliary reconstruction. Biliary leaks occurred early (mean 12 days) and were from the anastomosis 62% or cut edge 38%. Strictures were diagnosed much later (mean 277 days) with 36% requiring surgical correction. Patient survival was lower in those who had a biliary complication compared to those who didn't (76% vs. 89%) at 2 years after transplantation.

PTC, percutaneous transhepatic cholangiogram; ERC, endoscopic retrograde cholangiogram.

Recommendations

- *Diagnosis of the biliary complication may be obtained by ERCP, PTC, or MRCP.*
- *Biliary strictures are treated with dilatation and placement of progressively larger stents with longer duration (>6 months).*
- *Biliary leaks are treated with biliary stents (usually < 6 weeks duration).*
- *Living-related biliary complications require a multidiscipline team approach.*

De Novo Malignancy

As noted in the prior section of late deaths, development of de novo malignancies in liver transplant recipients has emerged as a severe long-term complication. Incidence rates are reported from 3% to 15% with specific cancer rates 3 to 5 times higher than the general population from large registry data (146,147,148,149,150,151,152). Table 56.7 summarizes the published reports from 2000 to 2005 on de novo malignancy; all are single-center experiences. Earlier studies showed liver transplant recipients have a high rate of lymphoma. These are commonly EBV-driven lymphoma, predominately of B cell origin.

Risk factors for de novo malignancy after liver transplantation include smoking, alcohol use, IBD, and older age. The Pittsburgh experience reported higher risks of oropharyngeal and lung cancers in patients who underwent transplantation for alcoholic cirrhosis (153). The Kings College group showed greater risk of all types of de novo malignancies in patients who underwent transplantation for alcoholic liver disease compared to other etiologies (154). The Cincinnati Transplant Tumor Registry suggests that the incidence of common tumors (such as colon, breast, lung, and prostate) is similar to the general public, but tends to occur earlier (155). A recent study by Oruc et al. of Pittsburgh confirmed that de novo breast cancer incidence was similar to that of age-matched general population (156). The role of immunosuppression influence on de novo malignancy remains uncertain. No difference in de novo tumor development was noted in cyclosporine versus tacrolimus-based immunosuppression in many studies (148,154,157); however, one Pittsburgh study

suggested that the risk was lower with tacrolimus (158). Comparison between individuals administered muromonab CD-3 (OKT3) and those not administered also showed no differences in development of tumors (159). The risk of de novo cancers with newer immunosuppressant medications such as mycophenolate or rapamycin remains unknown.

In a large single-center study, Sanchez et al. noted that basal cell skin cancer developed earlier, 19 months after transplantation (159); whereas lymphoma, breast cancer, lung cancer, and non–basal cell skin cancer developed later (27 to 47 months). The cancers with the longest time from transplantation were head and neck and colon cancers (61 and 50 months).

Several studies have shown marked decreased survival in noncutaneous neoplasia (148,154,157,159). The Pittsburgh group revealed poor 1 year survival in patients who developed oropharyngeal cancer (34%) or lung cancer (37%) (158). Herrero et al. in a recent

P.1503

P.1504

study, reported that 15 of 27 patients died of malignancy at a median of 5 months after diagnosis (157). The Baylor group noted the greatest mortality rates in lung cancer (73%) and lymphoma (69%) (159). An alarming study reported that only 40% of patients had dermatologic or oral examination, or mammograms within 2 years of transplantation (160). Eleven percent had a gynecological examination in follow-up and only 50% had either sigmoidoscopy or colonoscopy.

Unk, unknown.

Recommendations

- *Cessation of smoking and alcohol use*.
- *Utilize screening protocols similar to those used in the general population*.
- *Annual examination for skin cancer and use of sunscreen lotion of SP 50 or greater, when exposed to sunlight*.
- *Mammograms and gynecological evaluations should be done biannually for women*.
- *Yearly measurement of prostate-specific antigen in men older than 50 years is recommended*.
- *Patients who undergo transplantation for alcoholic cirrhosis may benefit from annual examination of mouth and throat, combined with chest x-ray*.
- *Patients with IBD must have annual colonoscopy with surveillance biopsies for dysplasia. Colonoscopy every 5 years for liver transplant recipients without IBD is recommended*.

Renal Dysfunction

Development of renal dysfunction is becoming a major problem after liver transplantation in patients with greater long-term survival. Calcineurin inhibitor medications (cyclosporine and tacrolimus) remain the cornerstone of immunosuppression in liver transplantation, however, not without some risk of renal dysfunction. A decrease in glomerular filtration rate of 30% to 50% within 6 months of transplantation is commonly seen (161). Renal biopsies in those with CRF associated the calcineurin inhibitors demonstrate interstitial fibrosis, tubular atrophy, arteriolar hyalinosis, and sclerosis and collapse of the glomeruli (162).

The incidence of CRF and end-stage renal disease (ESRD) after liver transplantation has been widely described, likely due to difference in definition, method of measurement, and duration of follow-up (163,164,165,166,167,168). Earlier studies from England in a large cohort group found that by 10 years after transplantation, the cumulative incidence of CRF (serum creatinine [Cr] >250 μM) was 8% and ESRD was 4.2% (169). The Pittsburgh group at 5 years post-transplantation reported an incidence of CRF (Cr >2 mg/dL) of 28% (170). The most frequently sited study by Gonwa et al. from Dallas studied 834 patients with follow-up to 13 years after liver transplantation with a definition of CRF as a Cr of greater than 2.5 mg/dL (171). The incidence of ESRD gradually rose from 1.6% at year 1 to 3% at year 5 and 9.5% at year 13. The total incidence of severe renal dysfunction (CRF + ESRD) at year 13 was 18.1%. A significant difference in development of CRF and ESRD was seen in patients with pretransplantation hepatorenal syndrome compared to those without (by year 13, HRS group: CRF 8%, ESRD 11% vs. non-HRS group: CRF 4%, ESRD 4%). Postoperative 1-year Cr, 3-month Cr and 4-week Cr were predictive of CRF and ESRD. Additionally, a profound difference in survival (27% vs. 71%) was noted by year 6 after transplantation in

patients who developed ESRD receiving hemodialysis compared to those receiving a kidney transplant. The Mayo Clinic has additionally described an incidence of renal dysfunction of 10% at 10 years after transplantation as measured by glomerular filtration rate (GFR) by iothalamate clearance of lesser than 40 mL/minute/body surface area (165). If a patient had a GFR of less than 40 at 1 year, by year 3, 65% still had renal dysfunction. ESRD (dialysis or kidney transplant) developed at a mean time of 7.5 years from transplantation. Similar results from the Baltimore groups of a serum Cr greater than 1.2 mg/dL at any time before transplantation or a baseline GFR less than 70 mL/minute/1.73 m^2 or a GFR of less than 30 mL/minute/1.73 m^2 at 3 months were predictive of renal failure (166). Velidedeoglu et al. from Philadelphia analyzing 181 patients found that pretransplantation diabetes (OR 5.7) and early postoperative acute renal failure (Cr >2 mg/dL, OR 10.2) were predictive of CRF (164). The most comprehensive study of this topic was reported recently by Ojo et al. using the Scientific Registry of Transplant Recipients database from January 1990 to December 2000 analyzing patients who received either a heart, lung, heart–lung, liver or intestine transplant (172). With a median follow-up of 36 months, CRF developed in 16.5% of patients, of which 29% required dialysis or renal transplantation. Risk factors associated with CRF included advanced age, female sex, pretransplantation hepatitis C infection, hypertension, diabetes mellitus and postoperative acute renal failure. Those that developed CRF had a fivefold greater risk of death compared to those without CRF. Concentrating on the liver transplantation recipients, by year 5 after transplantation 18% developed CRF, a higher rate than all other types of transplants except intestinal transplantation. This study concludes that an enormous financial burden of treatment of ESRD in this population is likely in the future, if not already here.

What can be done to reduce this risk of CRF in liver transplant recipients? First, can immunosuppression be altered? Several studies have tried substitution of calcineurin inhibitors with mycophenolate moretil (173,174,175,176,177)

or rapamycin (178,179,180) with mixed results and complications (Table 56.8). Poorer results are noted when exchange is long after transplantation. Furthermore, the largest change in GFR is in the first 6 months, leading many to consider delayed use of calcineurin inhibitors.

CNI, calcineurin inhibitors; MMF, mycophenolate mofetil; Cr, serum creatinine; csa, cyclosporin tacrolimus; GFR, glomerular filtration rate; rapa, rapamycin; CrCl, creatinine clearance; ESRD, renal disease.

Recommendations

- *Those with known variables of high risk of development of CRF should be considered for nontraditional immunosuppression and careful monitoring*
- *Consider calcineurin inhibitor free immunosuppression regimen for patients with*

development of renal insufficiency

- *If progressive renal dysfunction is seen, evaluation by ultrasound and consultation by nephrology is warranted*
- *Kidney transplantation offers such a significant survival difference compared to chronic dialysis, therefore patients should be counseled regarding these differences*

In summary, with longer survival of patients after transplantation more frequent complications related to medical, immunosuppression and surgical treatment of these patients is observed. However, the QOL appears to improve in the long-term survivor. Common complications of development of de novo malignancy, CVD or diabetes require annual evaluations and surveillance to prevent or lower the risk of morbidity or mortality. Renal dysfunction appears to be increasing with often dire consequences. Lastly, recurrent hepatitis C is becoming the most pressing and overwhelming problem with a low chance of eradication with treatment after transplantation.

Chapter 57
The Surgical Options of Liver Transplantation

Jean F. Botha
Debra L. Sudan

Key Concepts

- Liver transplantation has become the victim of its own success; recipient need far exceeds donor supply.
- Donation after cardiac death (DCD) is becoming an accepted alternative technique to increase the size of the donor pool.
- Split-liver transplantation provides transplants for two recipients from one cadaveric organ. This is either performed as an extended right lobe graft for an adult recipient and a left lateral segment graft for a pediatric recipient or alternatively as right and left lobe grafts for two adult recipients.
- Living donor liver transplantation (LDLT) for adult recipients has also become an established means of increasing the number of organs available for transplantation. In the United States of America, centers have been slow to adopt this technique primarily over concerns for donor safety.
- There are unique issues to right lobe living donor transplantation with respect to graft size, venous outflow and biliary complications that make this a particularly challenging operation.

Liver transplantation is the only effective treatment available for patients with severe complications of end-stage liver disease. Unfortunately, the successful application of the treatment has led to increasing referrals that far exceed the cadaveric donor supply. Over the last decade the number of people on the liver transplant waiting list has increased dramatically with 17,913 registrants based on UNOS Scientific Registry Data as of August 2005 (http://www.unos.org). Unfortunately, the number of cadaveric donor livers available for transplantation has increased marginally from 1994 (3,591) to 2004 (5,845). The disparity between the number of potential recipients and the number of available cadaveric donors has led to an inevitable increase in the number of deaths on the waiting list. In 1995, there were 847deaths in patients waiting for liver transplantation compared to more than 1,800 per year in each year since 1999. In this chapter, we will review the standard techniques followed for cadaveric whole liver transplantation as well as the currently used alternatives to increase the number of transplantable livers including split-liver transplantation and living donor liver transplantation (LDLT).

Cadaveric Donor Hepatectomy

Most cadaveric donors are multiorgan donors where the liver is removed along with other abdominal organs such as the kidneys, pancreas and possibly the intestine. The techniques for removal have been somewhat standardized so that the blood supply to each organ is protected. The selection of donors is beyond the scope of this chapter, but generally includes demonstration of normal or adequate graft function by laboratory and/or histologic assessment and an evaluation for the potential transmission of infectious diseases or malignancy. Organs are then allocated according to the UNOS system. For liver allocation, the patient's Model for End-Stage Liver Disease (MELD) or Pediatric End-Stage Liver Disease

(PELD) scores are analyzed by

the UNOS computer and the patient with the highest score is offered the organ.

In most cases (>90% in the United States) organ procurement is from the cadaveric donor in whom brain death has been confirmed and documented according to requirements of the individual state's laws. The donor dissection is performed during normal perfusion of the organs and before the heart has stopped. This allows for careful dissection of the vasculature of each abdominal organ while pulses are palpable. Normally, the aorta and inferior vena cava are completely dissected from the overlying peritoneum, lymph nodes and soft tissues, in order to identify the renal vein and superior mesenteric artery (SMA). The distal aorta is ligated and a very large bore catheter is inserted into the aorta in a retrograde fashion. Next the supraceliac aorta is isolated just below the diaphragm. An additional catheter is sometimes placed (if size permits) into the inferior mesenteric vein for direct portal venous flush. Further dissection of the hepatic hilum is performed to carefully divide the common bile duct, and isolate the hepatic artery and portal vein. The gastroduodenal artery is usually ligated at this point, which assists in tracing the common hepatic artery proximal to the level of the splenic artery. Next the inferior vena cava is isolated above and below the liver. When the dissection is complete, the cold preservation solution (either University of Wisconsin or histidine-tryptophan-ketoglutarate [HTK] solution) is flushed through the distal aortic catheter. A clamp is placed at the level of the diaphragm to stop the flow of solution from entering the thoracic organs while perfusing all of the abdominal organs. Finally, the vena cava is divided just above the diaphragm to allow blood and the preservation solution to exit the organs. Some surgeons place slush on the abdominal organs during the flushing in order to assist rapid cooling of the organs. The liver (often en bloc with the pancreas and/or intestine) is removed first by dividing the vena cava above and below the liver, and the aorta above the celiac axis and below the SMA. Usually in a slush filled basin with preservation solution, these organs are separated by dividing the portal vein, splenic artery and aorta between the celiac axis and SMA, taking care to identify any replaced right hepatic arteries that might arise from the SMA. This can be somewhat difficult when excessive soft tissue is present in the donor, which obscures these planes.

Donor after Cardiac Death

Although the earliest cases of human transplantation were performed with organs procured from donors whose hearts had stopped prior to organ procurement, this practice was largely abandoned after the acceptance of brain death criteria. However, in recent years with the increased need for cadaveric organ donors, attempts to increase the number of available organs has led to the increased use of donors who do not meet brain death criteria. Specific protocols have been established to ensure that the patient is pronounced dead (i.e., lack of cardiorespiratory activity for a specified period of time) by physicians who are not involved with the procurement of the donor organs in order to protect the public from potential abuses. There is an increased risk fof ischemic injury to these organs and only young donors are usually accepted. For the liver allograft, there is an increased risk for both primary nonfunction, which is rare, and for biliary stricture formation, which is more common. In 1998 donor after cardiac death (DCD) donors accounted for 0.7% of the deceased liver donors in the United States. In 2003 this figure has increased to 2.8% and is expected to continue to increase over the next few years (http://www.unos.org)

From a technical perspective, in cases where the procurement occurs after the donor's heart beat has stopped, that is, from a DCD donor, skin incision and isolation of vasculature is done rapidly in order to quickly flush with preservation solution (either University of Wisconsin or HTK solution) and rapidly cool the organs. The dissection in DCD donors is then done after cooling the organs and when no blood is flowing through the grafts. Although DCD donors may experience a higher degree of warm ischemia, which can lead to graft injury, the technical aspects of the procedure do not differ other than the speed and order as described in the preceding text.

Liver Transplantation—Recipient Procedure

The removal of the native liver at the time of liver transplantation is usually the most challenging part of the procedure and arguably one of the most difficult operations performed by surgeons. The development of portal hypertension and vascularized adhesions places the recipient at high risk for rapid and excessive blood loss. A successful transplantion team not only requires a gifted surgeon, but also requires an experienced team of anesthetists to manage the blood loss and electrolyte shifts intraoperatively. The recipient hepatectomy is achieved by ligating and dividing the native bile duct, the proper hepatic artery or it's individual branches, clamping and dividing the portal vein high in the hilum and dividing the inferior vena cava above and below the liver. Figure 57.1 shows the abdominal cavity after the native hepatectomy.

The whole liver allograft is then taken out of the cold preservation solution. The anastomosis of the donor suprahepatic inferior vena cava is made end to end to the native inferior vena cava at the level of the

native hepatic veins. The infrahepatic vena caval anastomosis is likewise performed end-to-end above the native renal veins in the recipient. The portal venous anastomosis is then performed end-to- end and often the graft is revascularized at this point to minimize the length of warm ischemia. Next the hepatic artery is reconstructed to the native hepatic artery, the gallbladder is then removed and the bile duct is anastomosed to the native bile duct, often over a T-tube. Figure 57.2 shows these attachments in the recipient. There are technical variants to this standard approach such as the piggy-back technique, the use of interposition grafts or the use of the inferior vena cava for portal venous inflow in cases of portal vein thrombosis that are beyond the scope of this chapter.

Alternatives to Standard Cadaveric Liver Transplantation—Historical Perspective

In response to the increasing risk of death for patients awaiting liver transplantation, alternatives to whole organ cadaveric grafts (such as the use of DCD donors described in the preceding text) have been sought. The most commonly used clinical alternative to whole cadaveric liver transplantation has been partial liver transplantation, which includes reduced-size, split-liver and living related transplantations.

Reduced-Size Liver Transplantation

The technique of reduced-size liver transplantation (RSLT) is presented primarily for historic purposes. Although this technique increased the number of livers available for transplantation in children, it had the undesired effect of reducing the pool of cadaveric organs available for adult recipients, who represented more than 90% of the patients on the waiting list. It has therefore been all but abandoned for the alternative of split-liver transplantation described in the subsequent text. RSLT implies the use of a portion of the donor liver and was the first form of partial liver transplantation introduced. The technique of reduction of the liver allows livers from larger donors to be used in smaller recipients, who traditionally had higher rates of mortality on the waiting list (1). It was introduced clinically in 1981 and Bismuth first reported the successful transplantation of a reduced-size liver graft in 1984 (2). The technique was primarily used for the smallest children awaiting transplantation and at one time accounted for as many as 75% of transplants performed on children weighing less than 10 kg (3). The main goal of RSLT was to decrease pretransplant mortality and this was achieved. With this experience it became apparent that these reduced-size livers functioned well and not good as full-sized organs with comparable rates of postoperative complications. The successful application of RSLT directed efforts to divide the liver in such a way that not only the pediatric recipient could receive a transplant, but that the larger right side of the liver could be transplanted into another recipient, often a larger child or adult. This technique came to be known as *split-liver transplantation*.

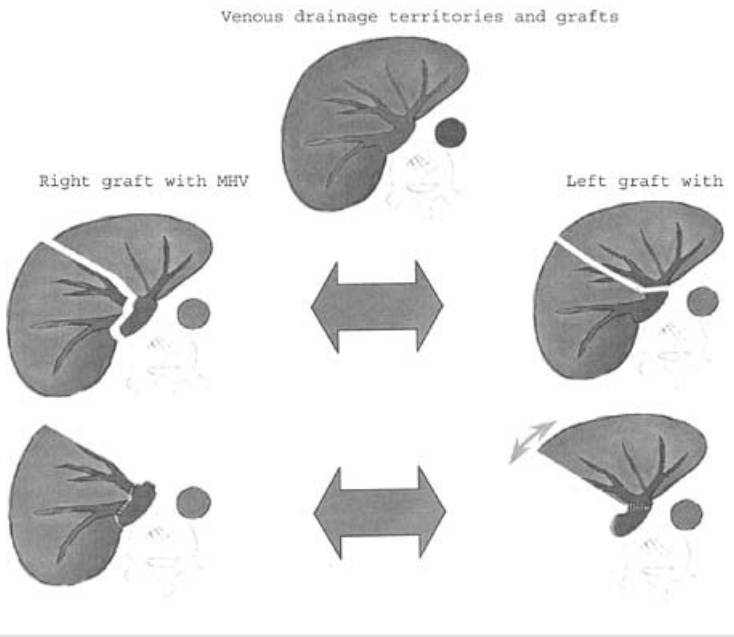
Split-Liver Transplantation

Split-liver transplantation is an attractive concept that provides transplants for two recipients from a single cadaveric liver. Typically, the left lateral segment is

transplanted in a child and the right lobe in an adult (or larger child). The first reported split-liver transplantation was performed by Pichlmayr et al. in 1988 who transplanted the right lobe into an adult with primary biliary cirrhosis, and the left lateral segment into a child with biliary atresia (4). Subsequently, Bismuth et al. reported using the technique to transplant in two patients with fulminant hepatic failure (2). These results were discouraging due to technical complications and poor recipient selection. However, perseverance by a few centers has proved that standard application of split-liver transplantation can increase the number of available liver grafts from cadaveric donors as much as 26% to 28% (5,6). Generally, only optimal cadaveric donors are considered candidates for splitting because of the potential for increased preservation injury, especially if the splitting occurs ex vivo. Estimates based on usual donor characteristics in the United States reveal that between 15% and 25% of cadaveric donors may be suitable for splitting (7).

Ex vivo technique

The technique of ex vivo split begins with a standard whole organ procurement and its packaging in preservation solution. After the graft is transported to the recipient transplantion center, the graft is divided on the back table. The hilar structures (hepatic artery, portal vein and bile duct) are dissected and divided between the two hemi-livers. Cholangiography and/or arteriography to delineate anatomy are performed as needed (5,8). There are varying opinions as to how the vessels should be divided. The key to successful splitting of the liver is to share vascular and biliary structures between the two grafts without compromising either side and preferably providing each graft with a single first-order arterial and biliary structure. Some centers routinely retain the full length of the hepatic artery and portal vein with the left hemi-liver and other centers routinely retain the full length of the vessels with the right hemi-liver. Most centers retain the vena cava with the right lobe graft. Because the left biliary anatomy is more consistent, the left bile duct, which is generally a single duct, is usually divided above the hepatic bifurcation, and the common hepatic duct is retained with the right lobe graft. The parenchymal transection is performed either with the mosquito fracture technique or by sharp dissection. The line of transection extends from the confluence of the left and middle hepatic veins (MHVs) to the right side of the falciform ligament and umbilical fissure down to the hilar plate (Figure 57.3) (9,10). In most centers, Couinaud segments I and IV are resected and discarded, to avoid acute necrosis or less common gradual atrophy (9,11).

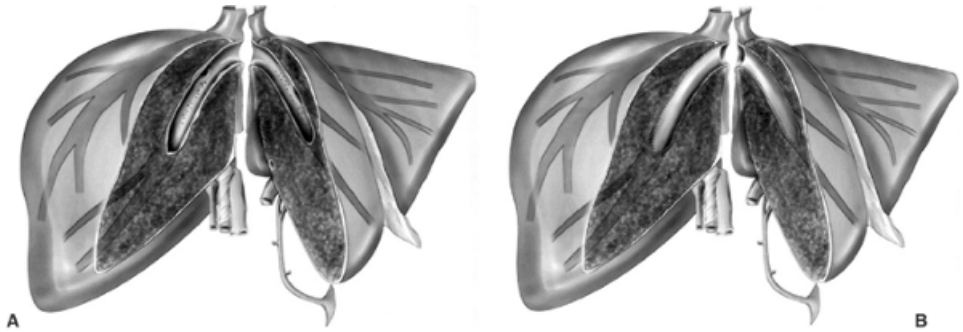


▪ **Figure 57.3** Lines of transection for the different split-liver allografts.

Recently, full-left full-right splitting for two adult recipients has been reported by Colledan et al. This technique leaves a right lobe graft comprising Couinaud segments V—VIII, and a left lobe graft consisting of segments I–IV. The vena cava and MHV are retained with the left lobe graft (12). Early experience suggested that using this technique put the right lobe graft at risk for congestion of the anterior sector (segments V–VIII) and that the recipients of the left lobe grafts may develop inferior outcomes due to small-for-size syndrome. Solutions to these problems include preserving the MHV with the right lobe graft or reconstructing the segment V and VIII veins. Preserving the MHV is a less attractive option as this further reduces the size of an already small left lobe graft. A recent report by Broering et al. describes a novel technique of splitting the MHV between the left and right lobe grafts and using a split iliac vein conduit as a patch venoplasty (Figures 57.4A and 57.4B). This technique in conjunction with their previous description of splitting the vena cava between both grafts creates a common venous outflow for the whole left or right lobe graft. This technique can be performed only by ex situ splitting, but appears to provide improved outcome compared to prior reports of splitting cadaveric livers for two adult recipients (13).

In situ technique

The in situ split technique is essentially the same as the living liver donor technique further discussed in the subsequent text. Rogiers et al. reported the first case of split-liver transplantation with the in situ technique in 1995 and a series of 14 split grafts in 1996 (14,15). A left lateral segmentectomy was completed in the heart beating cadaveric donor and flushed on the back table with preservation solution. This was followed by standard multiorgan procurement of the remainder of the intra-abdominal organs with in situ flushing of University of Wisconsin solution as described in the preceding text. Hepatic segments I and IV could therefore be evaluated in the donor prior to the flushing to assess perfusion after ligation of the left sided vessels, and excised only if the appearance suggested that they were compromised (14). Busuttil et al. in his series likewise performed the hepatic transection without vascular interruption, however he flushed both the hepatic segments in situ prior to removal from the cadaveric donor (7).

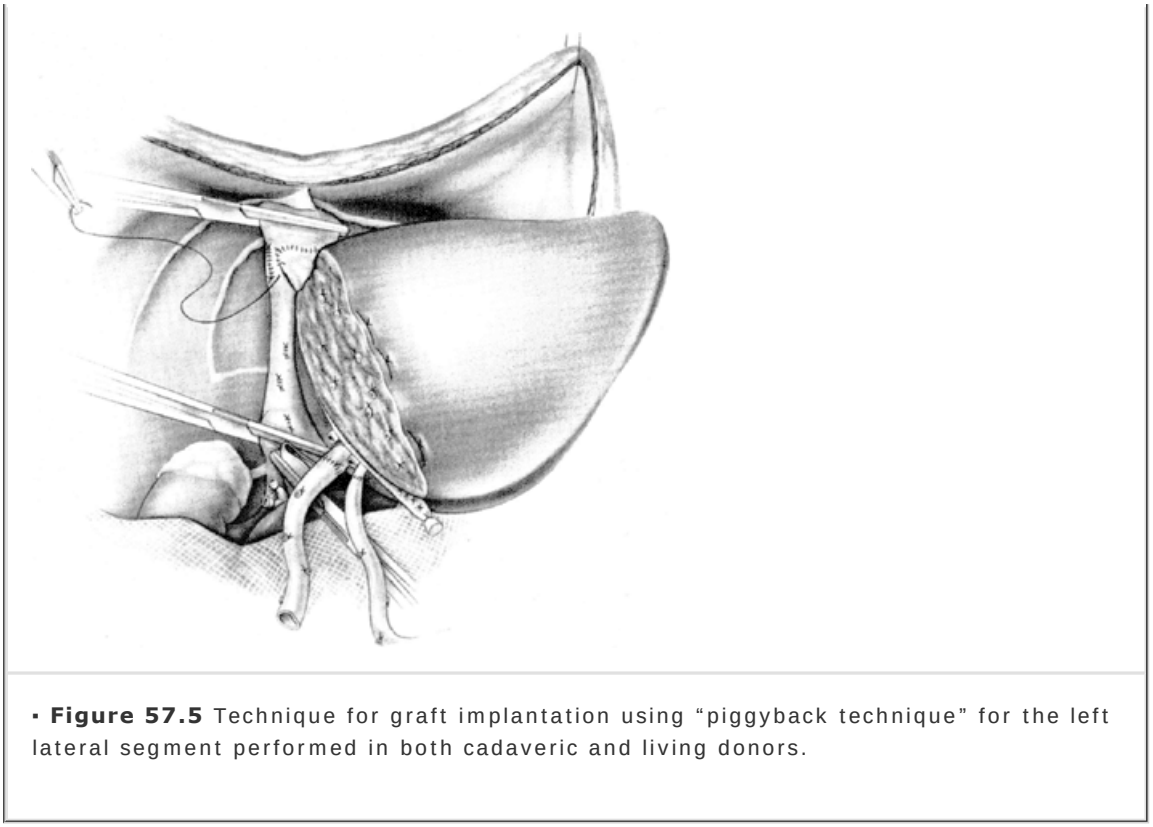


▪ **Figure 57.4** Proposed method for division of the middle hepatic vein for split-liver graft for two adults.

The implantation of the split allograft is independent of the method of procurement (ex vivo or in situ). Generally, the right split graft retains the donor retrohepatic inferior vena cava and is therefore transplanted in the standard orthotopic technique described for whole organ grafts. The left split graft is generally implanted in the so-called piggyback technique to the confluence of the native middle and left hepatic veins (see Figure 57.5). Extension grafts of donor iliac vessels may be used with either the left or right split graft for the hepatic artery or portal vein as needed. Bile drainage is frequently performed by formation of a hepaticojejunostomy, however choledochostomy has also been reported (14).

Results

Until recently, the patient and graft survival rates for recipients of split-liver grafts (50%–67% and 43%–50%, respectively) were lower than the rates for whole organ grafts (6,16,17). The decrease in patient and graft survival was most pronounced for the recipients of the right lobe. The diminished survival was probably a result of poor recipient selection combined with prolonged cold ischemia, and warming of the graft during the ex vivo preparation (7). By restricting split-liver transplantation to elective situations, the results have improved and are now comparable to whole organ grafts even for the right lobe graft (5,18). Reports of in situ splitting have revealed that this technique can be used even in urgent recipients without compromising patient and graft survival (7).



▪ **Figure 57.5** Technique for graft implantation using “piggyback technique” for the left lateral segment performed in both cadaveric and living donors.

Complications of split graft transplantation

Transplantation with a split graft was initially associated with increased bleeding. In the early series as many as one-third of ex vivo split-liver graft recipients required reoperation or transfusion for early postoperative bleeding (6). In contrast, after in situ split-liver grafting, bleeding occurred in less than 3% of recipients (7,14). Ex vivo splitting is also associated with a higher risk of biliary complications (22%–27%) compared to whole organ (4%)or in situ split grafts (0%–3%) (5,6,7,14,18). Rates of arterial thrombosis and primary graft nonfunction in recent series are similar regardless of graft source (7,9,14).

Split-liver grafts more efficiently use cadaveric donors than RSLT because the total number of livers available for transplantation is doubled. Furthermore, with split-liver grafts the redistribution of adult cadaveric livers to pediatric recipients created with reduced-size grafts is avoided (19). Despite the recent publication of splitting for two adult recipients, split-liver transplantation is currently used primarily to provide a left lateral segment graft for a pediatric recipient with an adult recipient receiving the extended right lobe graft. Unfortunately, the most attractive potential application of the technique (i.e., splitting a liver for two adult recipients) has not been generally achieved. There are a variety of reasons for this failure to apply split-liver transplantation for two adults in the United States. One of the most important considerations, however is that the full left lobe of the liver provides inadequate functional hepatic mass for most adult recipients in the United States because of the relative obesity of the population. The acceptable range of hepatic mass required to achieve successful hepatic function after liver transplantation is further discussed in subsequent text. As clinical experience with liver resections and partial liver grafts from cadaveric donors increased, it appeared feasible to safely use living donors for partial liver transplantation.

Living Donor Liver Transplantation

The introduction of live donors for liver transplantation (LDLT) was delayed compared to kidney transplantation. Although LDLT has been practised since the 1960s, and according to UNOS in 2004 accounted for 41% of all kidney transplants performed, LDLT was first introduced in 1989 for pediatric recipients (http://www.unos.org) (20,21). The right lobe

LDLT for adult recipients was introduced much later in 1998 (22). The main impediments to broader application of LDLT to larger recipients were twofold. First, surgeons were concerned with donor safety associated with larger hepatic resections and secondly, they were concerned about providing adequate hepatic mass for the recipient. Owing to the resection of up to 75% of the hepatic parenchyma during a right lobe resection, the risks for complications in the donor are much higher than in left lateral segment liver resection or removal of a kidney. The focus of this section will be a review of world experience with LDLT for adult recipients.

Graft size considerations

Two methods for determining whether a graft will have adequate functional hepatic mass have been developed. The first method involves the calculation of the graft to recipient weight ratio (GRWR) which compares the mass of the graft to the overall body mass of the recipient (23). The second method involves the calculation of the liver volume as a percentage of the standard liver volume (SLV) (% SLV) using a mathematical formula based on measurements of the liver at autopsy (24). Table 57.1 shows examples of both of these calculations. A recent review shows that there is a nearly perfect (i.e., linear) correlation between these two estimates of liver volume, and both the methods can therefore be used interchangeably (23).

Early experience with living donor transplantation in adult recipients

The earliest experience with transplantation of adults using living donors merely extended the pediatric experience using either the left lateral segment or full-left lobe grafts (with or without the MHV) (26,27,28). The size of partial left liver grafts, however, in most cases

corresponds to only 20% to 35% of the recipient's expected SLV (Table 57.1). Although successful graft function has occurred with grafts as small as 0.6% GRWR (25% SLV) (29), others have reported increased risk for postoperative morbidity and mortality with the use of grafts less than 1.0% GRWR (50% SLV) (23,24,30). Grafts less than 0.8% to 1.0% GRWR or “small-for-size grafts” generally demonstrate poor graft function marked by pronounced cholestasis and prolonged coagulopathy (30). The use of left lobe grafts in adult recipients is therefore limited to recipients with body weight in the range of 45 to 55 kg. In the United States, one would expect this weight restriction to represent only a minority of individuals on the waiting list. Indeed, at the University of Nebraska Medical Center this represents only 11% of the adult waiting list. The right lobe of the liver on the other hand represents approximately 60% of the hepatic parenchyma and for most adults in the United States would provide at least 1% GRWR. The Kyoto group performed the first right lobe liver transplant in a child in 1994; however because of concerns about donor safety right lobe living donor liver transplants were not offered to adult recipients until 1997 and 1998 (22,31,32). Since 1998 right lobe liver grafts from living donors have become the standard graft for adult recipients (32,33,34).

Table 57.1. Methods of Evaluating Adequacy of Partial Liver Graft for a Recipient

GRAFT-TO-RECIPIENT WEIGHT RATIO
Example. Recipient body weight = 70 kg
Graft weight = 700 g
GRWR = 700 g ÷ 70 kg = 0.01 (or 1%)

Optimal GRWR = 1%–3%
CALCULATION OF STANDARD LIVER VOLUME [a](SLV) (24)
Japanese formula for SLV (mL) = 706.2 × (body surface area [m^2]) + 2.4
Example. In a 5 ft. 8 in. 75 kg recipient BSA is approximately 1.88 m^2
SLV = 1.33 L (or approximately 1330 g using above formula)
If donor right lobe estimate on computed tomography scan measures 700 g, then 700/1330 = 53% SLV
Optimal % SLV = >50%
SLV, standard liver volume; BSA, body surface area. [a]Since North European and American whites generally larger than Japanese individuals, revised formula in the subsequent text may be more accurate in these populations (25). Heinemann formula (25) for SLV (ml) in whites = 1072.8 × (body surface area [m2])—345.7[a]

Donor Selection

There are two key issues in donor selection. First, living liver donation should be voluntary without coercion and without financial incentives. Secondly, the potential donor should have minor and well-controlled or no medical conditions in order to avoid increased risk from the donor operation. Most living donors have been immediate family members and rarely close friends (34,35). Caution must be exercised in the evaluation process however, because family members may intentionally or unintentionally place pressure on relatives of appropriate age and blood type to donate. The evaluation process includes an interview with the potential donor in the absence of other family members and is ideally performed by a physician who is not a member of the transplant team. The potential donor is informed of the option for the transplant team to provide a “medical excuse” at any time if he/she chooses not to donate. Minors are generally excluded from living donation. Some have raised concerns over the issue of informed consent with the small experience that currently exists (36). The American Society of Transplant Surgeons (ASTS) position paper presented at the May 2000 meeting concurs that insufficient information currently exists “to accurately assign risk for the donor” and this should be acknowledged to the potential donor during the evaluation. The evaluation process of the potential donor includes determination of blood type and confirmation that this is compatible with the recipient's blood type. Other commonly performed laboratory tests include liver and kidney function tests and viral serologies. Most donors in published series are between 24 and 61 years old. Age is not an absolute contraindication to living donation, however older individuals have a higher likelihood of silent cardiac or cerebrovascular disease that may increase the perioperative risk and the liver may have a decreased potential for regeneration in the older donor. Computed tomography (CT) angiography or magnetic resonance (MR) angiography with three-dimensional reconstruction are the current imaging modalities used to delineate hepatic vascular and biliary anatomy and to determine the potential graft and whole liver volume. Magnetic resonance cholangiopancreatography (MRCP) is usually performed when MR angiography is done but intraoperative cholangiography is

usually performed in addition to further delineate biliary anatomy.

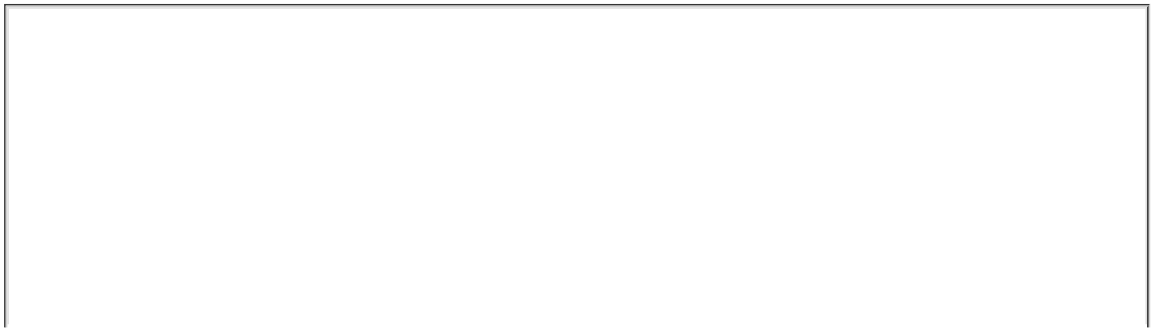
Donor Safety

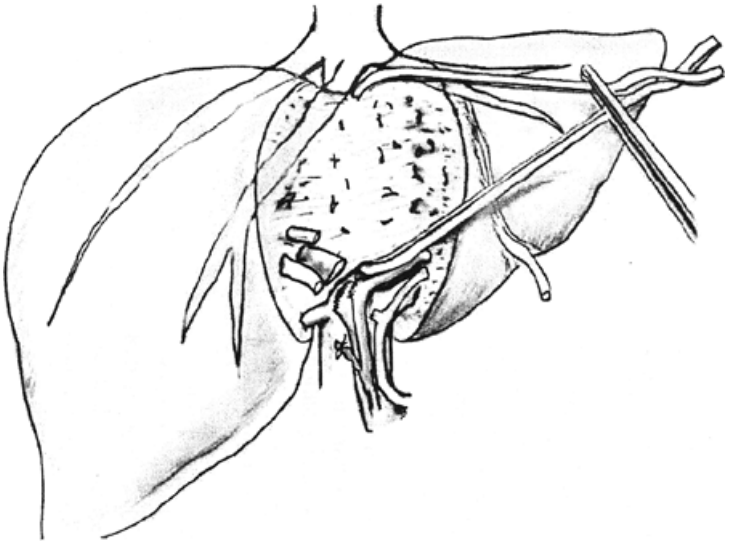
Since the highly publicized donor death in New York, donor safety has become the overriding concern with respect to LDLT. A recent survey by Brown et al. of 449 living donors in the United States documented the actual risk of death to be 0.2% (37). To date however there have been three reported deaths in the United States of America, four in Europe and one each in Japan, India, Egypt and South America (37,38). Interestingly, many of the largest centers in the United States have been the slowest to adopt this technique primarily due to concerns over donor safety. The National Institutes of Health (NIH), the ASTS and the US Department of Health and Human Services have organized a multicenter study to gather and follow sufficient numbers of patients undergoing right lobe LDLT in the United States of America, which will hopefully guide future application of this valuable technique.

Technique for Procurement of the Living Donor Right Lobe Graft

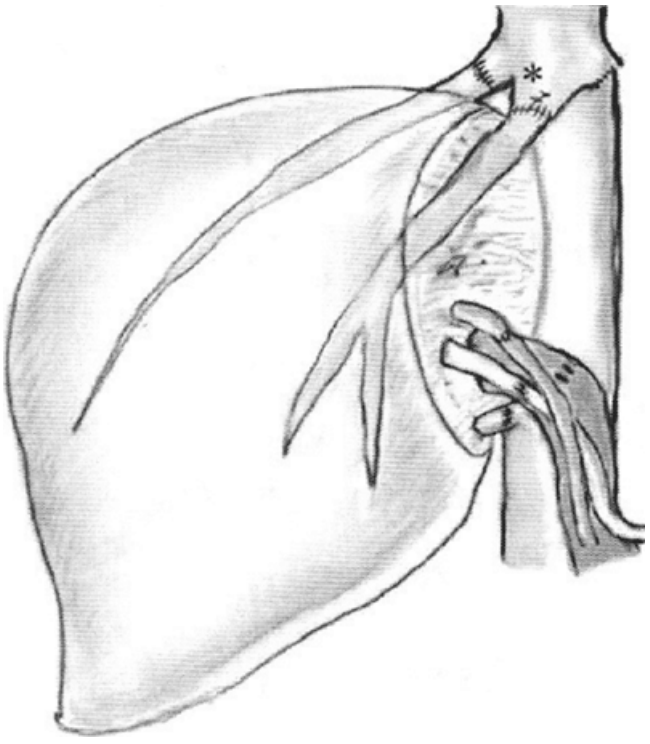
The right liver graft consists of segments V-VIII with or without inclusion of the MHV. There is much debate over the provision of adequate drainage of the anterior sector of the graft and inclusion of the MHV. The donor liver procurement of the right lobe graft begins with a bilateral subcostal incision and division of the hepatic ligaments to the right hepatic lobe. The ligamentous attachments of the left lobe remain intact to prevent torsion of the remnant liver after right lobectomy. The liver is then mobilized off the retrohepatic vena cava carefully ligating small accessory hepatic veins. Marcos et al. recommends preservation of any accessory hepatic vein greater than 5 mm in diameter for reimplantation (33). Intraoperative ultrasound is then used to identify the intrahepatic course of the right and MHVs to determine the optimal line of transection. Hilar dissection is performed to identify the branches to the right lobe from the hepatic artery and portal vein. Minimal if any dissection is performed of the right hepatic duct(s) and left hilar structures. Cholecystectomy and cholangiography are then performed to assess biliary anatomy. The right hepatic vein (RHV) is also isolated prior to parenchymal transection if possible and controlled with a vessel loop. At the University of Nebraska Medical Center the Cavitron ultrasound surgical aspirator (CUSA) ultrasonic dissection is used to transect the hepatic parenchyma. Although this is a somewhat tedious process, it allows identification and ligation of large portal and hepatic venous branches that cross the plane of transection thereby minimizing blood loss. No inflow or outflow vascular occlusion is performed during the process of hepatic parenchymal transection in order to minimize ischemic injury to either portion of the liver. Figure 57.6 shows the right lobe graft after parenchymal transection and division of the hepatic artery, portal vein, right hepatic duct and RHV. Figure 57.7 demonstrates the method of implantation of this

right hepatic lobe graft. This differs from the technique of reduced-size or split-liver right lobe grafts because of the absence of the donor inferior vena cava. In the recipient of the living donor right lobe graft the native inferior vena cava is preserved and the donor RHV is anastomosed directly to the recipient RHV orifice in the so-called “piggy back technique”. Extension vascular grafts are rarely required with the right lobe graft. Biliary drainage is most commonly performed by Roux-en-Y hepaticojejunostomy although duct-to duct anastomosis has also been reported (22).





▪ **Figure 57.6** Technique of living donor right lobe graft including the middle hepatic vein and demonstrating division of the right portal vein, hepatic artery and right lobe bile duct.



▪ **Figure 57.7** Implantation of the right lobe graft.

Ongoing Controversies

The two main controversies with regard to right lobe LDLT that warrant further discussion are the venous drainage of the anterior sector of the right lobe graft and the preferred

mode of biliary reconstruction.

Hepatic Venous Drainage

Although graft size is now well documented enough to be a critical factor in the success of partial liver grafts, the importance of good venous drainage in order to prevent congestion particularly of the anterior sector of the graft and the development of small-for-size syndrome (prolonged cholestasis, coagulopathy and ascites) has been more recently recognized (39). Different approaches have been adopted to prevent congestion from occurring, ranging from reconstruction of segment V and VIII veins to routine inclusion of the MHV with the graft (40). Although Lo et al. routinely include the MHV, the overriding concern with this practice is that the remnant native liver may be decreased excessively in size or have poor venous drainage leading to greater risks for complications in the donor.

Lee et al. reported on five right lobe living donor transplants without drainage of segment V and VIII veins or inclusion of the MHV. They found congestion followed by ascites, cholestasis and sepsis in two of the five, with one of the patients dying twenty days after transplant (41). Subsequently the same authors reported reconstruction of the segment V and VIII veins using interposition vein grafts of either iliac vein or saphenous vein and now recommend this in all cases (42). The Tokyo group proposed a selective approach to drainage of the segment V and VIII veins based on the results of two intraoperative tests during the donor operation (43). (1. After MHV clamping, Doppler flow in the portal vein is assessed. Reversal of flow indicated the need for drainage of the anterior sector veins. 2. After clamping the MHV and the right hepatic artery, if the anterior segment became dusky, drainage was required.) Cryopreserved or autologous vein grafts were used to provide this drainage as needed. Of thirty right lobe living donor transplants performed, 18 required reconstruction based on these tests (42).

The Hong Kong group as noted in the preceding text recommends routine inclusion of the MHV with the right lobe graft in order to avoid congestion of the graft (40,44). They have reported a 96% graft survival at 2 years using this technique. De Villa et al. proposed a selective approach to inclusion of the MHVs only when the right lobe graft volume estimate is <50% SLV (measured by CT scan), the right lobe is drained by a small RHV or large segment V and VIII veins are present (45). Although donor risk is the main concern with this technique, Cattral examined operative risk to the donor in 56 right lobe donors at his center. The outcomes were similar comparing 28 patients where the MHV was included in the graft and 28 patients in whom the MHV was retained in the donor (46). Others have reported prolonged prothrombin times in donors where the MHV was included in the graft; these usually recovered by the end of the first week (47). For now, the issue of anterior sector drainage continues to be controversial with considerable variation in practice from center to center as to whether the MHV is included in the graft or the segment V and VIII veins are reconstructed in the recipient.

Biliary Reconstruction

As mentioned in the preceding text, hepatico-jejunostomy was the standard biliary reconstruction technique for left lateral segment living donor transplants and most early series of right lobe grafts. Wachs et al. confirmed the feasibility of duct-to-duct biliary anastomosis and cite advantages such as minimization of bowel contamination, preservation of bilioenteric and bowel continuity, early return of bowel function, and elimination of the risk of internal herniation (22,48,49,50). Gondolesi et al. showed that there was no difference in the incidence of biliary complications between the two techniques (51). Liu et al. likewise demonstrated a similar incidence in biliary complications; however mortality appeared to be lower in the group with duct-to-duct reconstruction (0% vs. 11%) (48). Duct-to-duct biliary reconstruction appears to be gaining in popularity but it remains controversial as to whether there is any benefit over hepatico-jejunostomy.

Recipient Results

Recently published results of right lobe LDLT in adults are summarized in Table 57.2. The overall experience

with adult LDLT is still relatively small, but clearly patient and graft survival rates are better with right lobe grafts than left. Right lobe grafts appear to have comparable survival rates compared to whole cadaveric liver grafts as currently applied. A recent report from the NIH sponsored Adult-to-Adult Living donor Liver transplant (A2ALL)consortium, showed 1 year Kaplan Meier patient and graft survival was 89% and 81%, respectively in a cohort of 385 adult LDLT (52). Most series of living donor right lobe grafts report recipients of living donor grafts with lower MELD scores than cadaveric graft recipients. In the survey of Brown et al. 79% of LDLT recipients were not hospitalized at the time of transplantation and MELD scores were more frequently in the 11 to 20 range (41%) as compared to only 3.9% in the 21 to 30 range (37). The reason for limiting adult-to-adult LDLT to more elective patients is that recipients will have the maximum chance for survival. This was also the approach early in the experience of living donor transplantation for pediatric recipients. The severely ill recipient may not tolerate a smaller volume of hepatic mass than is provided with a whole organ cadaveric graft.

Table 57.2. Recent Results of Living Donor Right Lobe Liver T

Author	Center	Year	No. of recipient	Type of graft	Graft weight	Blood loss Donor (donor)	Pat Surv	Gr Surv	R cor

Donor Complications after Liver Donation/Resection

While the mortality rate for living donors is less than 1%, morbidity is not uncommon. In the survey published by Brown et al. 14.5% of donors suffered one or more complications including biliary leak, the most common complication occurring in 6%, need for transfusion (5%), reoperation (4.5%), and major post operative infection (1%) (37). Following right hepatectomy the remnant native liver may demonstrate mild dysfunction including elevations of the transaminases, total bilirubin, and mild coagulopathy (34). The Kyoto group reported a mean peak total bilirubin of 3.2 mg/dL after right lobectomy that returned to normal within the first week (34). Others have reported coagulopathy with a mean peak prothrombin time of 18.7 seconds in the first 7 days after extended right lobectomy in living donors (29). Other surgical complications reported after right hepatic lobectomy include incisional hernia, biliary stricture, sepsis, pancreatitis and sepsis, and neuropraxia (22,33,34). In addition, pulmonary embolus has been reported after left lobe and left lateral segment living donation and clearly any patient undergoing right lobectomy would also be considered at risk for this complication (27,53).

Recipient Morbidity after Living Donor Right Lobe Transplantation

Biliary and vascular complications are the major morbidities associated with right lobe LDLT. The A2ALL study reported hepatic artery thrombosis (HAT) in 6% of recipients and portal vein thrombosis in 3% (52).A major vascular complication generally leads to loss of the graft. Biliary complications, including both leaks and strictures, occur in 15% to 60%, which is more frequent than after whole organ cadaveric liver transplantation (33,34). The A2ALL study reported bile leaks occurring in 32% and strictures in 17% of recipients (52). Other complications in recipients are similar to whole liver transplantation and include reoperation (25%), infections (41%), ascites (14%), hernia (6%), abscess (9%), bleeding (7%) and

pleural effusion (20%) (52).

Overview

Reduced-size liver grafts were an important step in the development of partial liver grafts. In large part, however, RSLT has been abandoned for techniques that increase the overall number of transplants that can be performed. Split-liver transplantation and adult LDLT using right lobe grafts are technically demanding procedures. Currently, only a few centers have gained significant experience with either technique. These methods of liver graft procurement differ from standard liver resection by the preservation of blood flow during hepatic parenchymal transection. Clearly when either split-liver transplantation or adult-to-adult living donor transplantation are performed by surgeons experienced with these techniques they can be performed safely with excellent graft function and limited donor morbidity or mortality. The introduction of these techniques has increased the number of available liver allografts for recipients; nonetheless there remains a large gap between the number of patients listed and the number of available donor livers. Perhaps in the future xenografts may fill this void.

Chapter 58

Recurrent Disease Following Liver Transplantation

Hugo R. Rosen

James R. Burton Jr.

Key Concepts

- Recurrent liver disease can occur for virtually all indications of liver transplantation.
- Hepatitis C virus (HCV) recurrence defined by histologic injury is almost universal and a significant proportion (20% to 30%) develops allograft cirrhosis by the fifth year post-transplant.
- HCV-related allograft cirrhosis is associated with a high rate of decompensation and mortality.
- The natural history of hepatitis B virus recurrence has been dramatically modified and outcome substantially improved by use of human immune globulin and nucleoside analogs.
- Recurrent autoimmune liver diseases (primary biliary cirrhosis, primary sclerosing cholangitis, and autoimmune hepatitis) appear to have excellent intermediate patient and graft survival rates.
- The diagnosis of recurrent autoimmune liver diseases requires careful exclusion of alternative diagnoses (e.g., rejection, biliary obstruction) that can mimic the recurrent disease.
- Although recurrent alcohol use after transplantation for alcoholic liver disease is common, direct or indirect negative effects of recurrent alcohol use on the allograft is rarely seen.
- Recurrent Budd-Chiari syndrome can occur days to years after transplantation.

Liver transplantation is a well-established standard of care for many patients with end-stage chronic liver disease and acute liver failure. Despite excellent long-term survival, disease recurrence after liver transplantation is a relatively common problem. The clinical significance of this recurrence varies widely depending on the primary indication for liver transplantation. This chapter will primarily focus on disease recurrence after liver transplantation for viral hepatitis and autoimmune liver diseases with emphasis on natural history, risk factors for recurrence, diagnosis and management (Table 58.1). Significant attention will be paid to recurrent hepatitis C virus (HCV) infection, because currently HCV is the leading indication for transplantation and unlike other indications for liver transplantation, it is not a question of whether recurrence will happen, but how it will affect outcome and how best to manage or prevent recurrent viral hepatitis. Discussion on hepatitis B virus (HBV) will focus on the historical evolution of treatment with hepatitis B immune globulin, and more recently, the use of nucleoside analogs in preventing and managing disease recurrence. Clinically significant recurrent autoimmune liver diseases appear to be relatively rare; furthermore, study of this problem is limited by variable study design, small patient numbers, different immunosuppressive regimens, lack of long-term follow-up and established criteria and markers for diagnosing disease recurrence. Brief discussion will include recurrent alcoholic liver disease (ALD), a major contributor to the

development of end-stage liver disease in the United States, as well as to Budd-Chiari Syndrome (BCS). Recurrent hepatocellular carcinoma and cholangiocarcinoma are discussed in Chapters 44 and 45, respectively. In addition, the important issue of retransplantation for recurrent disease is discussed in detail in Chapter 59.

Table 58.1. Recurrent Diseases

Category	Incidence of recurrence	Diagnosis	Biopsy findings	Cholangiogram findings	
VIRAL HEPATITIS					
Hepatitis C	Viremia universal; 60%–80% acute hepatitis at 4–6 mo, chronic hepatitis 80%–100% at 1–4 y	HCV RNA by PCR	Periportal inflammation, lobular hepatitis	Normal	A r H ir h tl a h
Hepatitis B	Historically, without HBIG, 50%–85%; risk <10% with HBIG and lamivudine	HBsAg (often HBeAg-positive with high HBV DNA levels)	Periportal inflammation, lobular hepatitis	Normal	A r H ir h tl a h
AUTOIMMUNE COMPONENT					
Primary biliary cirrhosis	15%–25%	Biopsy and exclude alternative diagnoses	Florid duct lesion (granulomatous cholangitis) or destructive lymphocytic cholangitis within a dense portal infiltrate	Normal	A r G o ir
Primary sclerosing cholangitis	20%	Biopsy and/or cholangiography, exclude alternative diagnoses	Fibro-obliterative lesions and/or firbrous cholangitis with/without ductopenia, biliary fibrosis	Nonanastomotic extra/intrabiliary stricturing, beading and irregularity >90 d and diverticulum-like outpouchings	D r a s h tl n s

			or biliary cirrhosis		d i C p is
Autoimmune hepatitis	20%–30%	Biopsy, positive autoantibodies, and exclude alternative diagnoses	Periportal hepatitis, lobular inflammation	Normal	A r h (h tl b o

Recurrent Viral Hepatitis

Hepatitis C Virus

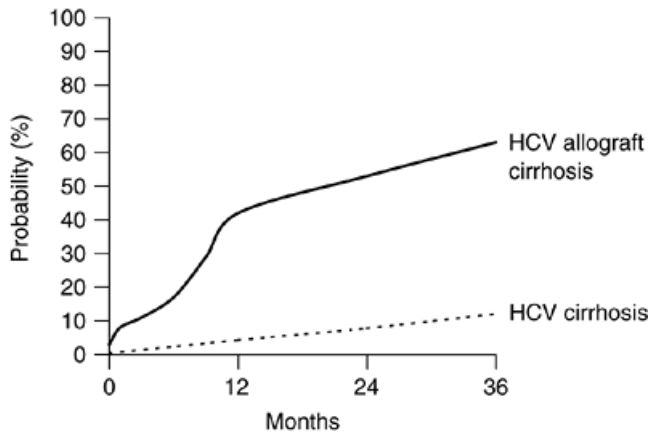
HCV-related end-stage liver disease is the most common indication for liver transplantation in the Western world. Recurrence of HCV infection after liver transplantation is nearly universal based on the presence of HCV ribonucleic acid (RNA) in the serum. During the anhepatic period HCV RNA levels typically decline to low and sometimes even undetectable levels (1,2). Four to 8 days after transplantation, viral levels often increase to levels 20-fold greater than in the pretransplant period (3), typically peaking between 1 and 3 months post-transplantation.

Evidence of histologic damage may occur in the non–HCV-infected recipient because of several causes including recurrent disease, however, abnormal liver biopsies are significantly higher in HCV-infected recipient than among controls (70% vs. 15% at 1 year post-transplantation; $P < 0.0001$) (4). Acute hepatitis occurs in 60% to 80% at a median of 4 to 6 months after transplantation and chronic hepatitis in 80% to 100% by 1 to 4 years (5,6,7). Acute recurrent HCV infection often causes increasing serum aminotransferases. Typically, liver biopsy is performed at this time to exclude acute cellular rejection (ACR), although uniform practice in this respect between transplant centers does not exist. Empiric treatment of ACR is not recommended as both ACR and recurrent HCV can improve with steroid boluses and steroid boluses have been shown to promote fibrosis progression in recurrent HCV (8,9). ACR often occurs within the changes of recurrent HCV; therefore often the distinction is not between recurrent HCV infection and ACR, but rather between ACR with or without underlying features of recurrent HCV infection. Table 58.2 outlines the histologic features of recurrent HCV and ACR (10,11). Following this acute HCV recurrence, chronic recurrent HCV develops, demonstrated by chronic hepatitis with variable degrees of mixed portal, periportal, and lobular inflammation with or without viable degrees of portal and/or periportal fibrosis. The severity of recurrent HCV should be defined by grade (necroinflammation) and stage (fibrosis).

Table 58.2. Histologic Features of Recurrent Hepatitis C Virus Versus Acute

Cellular Rejection

	Recurrent hepatitis C virus (HCV)	Acute cellular rejection
Time post–liver transplantation	Anytime; usually within the first year	Usually in first 2 mo
Portal Inflammation	Most cases; mononuclear infiltrate	Always; mixed infiltrate
Aggregates	Usually	Occasionally
Follicles	50% of cases	Very rarely
Eosinophils	Inconspicuous	Almost always
Steatosis	Often	Never
Acidophilic bodies	Common	Uncommon
Duct damage	Approximately 50% of cases	Very common
Other	Bridging necrosis or fibrosis	Endotheliitis and central venulitis
Atypical features	Cholestasis, ballooning degeneration without significant inflammation, marked ductular proliferation mimicking obstruction, granuloma	Prominent periportal and lobular necroinflammatory activity without subendothelial venular inflammation



▪ **Figure 58.1** Probability of developing decompensated cirrhosis (ascites, encephalopathy, or variceal hemorrhage) from the time of diagnosis of hepatitis C virus (HCV) cirrhosis (pretransplant) and HCV allograft cirrhosis (post-transplant). ▪ **Figure 58.2** Survival rates for compensated and decompensated hepatitis C virus (HCV) cirrhosis and HCV allograft cirrhosis. (Adapted with permission from Berenguer M, Prieto M, Rayon JM, et al. Natural history of clinically compensated HCV-related graft cirrhosis following liver transplantation. *Hepatology* 2000;32:852–858; and Fattovich G, Giustina G, Degos F, et al. Morbidity and mortality in compensated cirrhosis type C: a retrospective follow-up study of 384 patients. *Gastroenterology* 1997;112:463–472.)

The natural history of chronic HCV is highly variable and poorly understood. For some, the natural history is accelerated compared with the nontransplant setting; 20% to 40% of patients transplanted for HCV develop allograft cirrhosis after only 5 years as compared to 3% to 20% after 20 years in the nontransplant setting (12,13,14,15). Once cirrhosis develops in the transplant setting, two-thirds will develop decompensation within 3 years (Fig. 58.1) (15,16). The development of decompensation is associated with a very poor outcome with

approximately only 10% surviving 3 years (Fig. 58.2) (15,16). Although nearly all patients develop some evidence of histologic recurrence, approximately a third will develop only minimal fibrosis after 5 years of follow-up (17). Although many studies have shown that short-term patient and graft survival is similar for patients undergoing liver transplantation for HCV compared to other indications, these studies were likely underpowered to detect small differences. Analysis of the United Network for Organ Sharing (UNOS) database revealed significantly diminished survival at 5 years after primary liver transplantation in HCV-positive patients (65.6% vs. 56.7% for HCV-negative transplant recipients; $P < 0.05$) (18).

The presence of rapidly progressive cholestatic HCV is observed in approximately 5% of patients transplanted for HCV, typically developing 1 to 3 months post–liver transplant and resulting in graft failure in 3 to 6 months (19). Characteristics of this syndrome have been outlined by a recent consensus conference (19). Patients typically have very high serum HCV RNA levels with serum bilirubin levels greater than 6g/dL and alkaline phosphatase

levels greater than five times the upper limit of normal. Patients should not have a history of hepatic artery thrombosis, nor any surgical biliary complications (i.e., normal cholangiogram). Liver biopsy often reveals ballooning of hepatocytes predominantly in the perivenular zone (not necrosis or fallout), paucity of inflammation, and variable degrees of cholangiolar proliferation without bile duct loss. The pathogenesis of this syndrome remains undefined, but preferential Th2 cytokine production by intrahepatic lymphocytes has been implicated (20,21). Optimum treatment remains uncertain, but is focused on reducing very high HCV RNA levels by reducing immunosuppression and indefinite use of interferon (22).

A number of factors have been identified that impact both severity of HCV recurrence as well as patient and graft survival. Table 58.3 outlines these viral, recipient, donor and post-transplant factors. The effect of HCV on living donor liver transplantation (LDLT) is controversial. Some studies have suggested earlier and more severe recurrent HCV, including cholestatic HCV, following LDLT compared to deceased donor controls (33,34,35), whereas others have suggested no difference in recurrence or patient or graft survival (36,37). Each

study has limitations, including small numbers, being from a single center, lack of protocol liver biopsies, and short-term follow-up. Results of the National Institutes of Health (NIH) sponsored multicenter Living Donor Liver Transplant Cohort Study will help clarify these issues. Another controversial issue in terms of HCV recurrence is the suggestion that the rate of fibrosis progression in recent years appears to be accelerating (38). There are many potential factors that could account for this finding including development of new immunosuppressive agents, reduction in overall immunosuppression, more frequent use of interferon therapy prior to liver transplantation, thereby selecting for more virulent HCV strains and use of older and marginal donors in patients with chronic HCV infection.

Table 58.3. Factors Associated with Severe Recurrence and Patient and Graft Survival After Liver Transplantation for Hepatitis C Virus

Viral	Recipient	Donor
Pre-LT viral load (23,24)	Age >60 y (25)	Age >50 y (26,27)
Early post-LT viral load (28)	Lack of $CD4^+$ response (29)	Warm ischemia time (30)
Pre-LT lack of IFN response (?)	Non-white (24,25)	Steatosis (?)
Post-LT	Female gender (18)	Cold ischemia time (?)
Treatment of rejection with steroids (8,9)	CMV infection (27,31)	HLA-matching (?)
Treatment of rejection with anti-lymphocyte preps (24,32)	Diabetes (25)	LDLT (?)
Rapid steroid taper (26)	Previous HCV Treatment (?)	HCV-positive (?)

LT, liver transplantation; ?, data either conflicting or unknown; CMV,

Cytomegalovirus; HLA, human leukocyte antigen; LDLT, living donor liver transplantation; HCV, hepatitis C virus.

The optimum immunosuppressive regimen for HCV-infected liver recipients remains to be defined. The use of high-dose maintenance steroids for prevention of ACR has been associated with decreased patient and graft survival compared to non–HCV-infected transplant patients (24). One consistent finding in the literature is the lack of significant differences in outcome in recipients treated with tacrolimus versus cyclosporine-based immunosuppression. The impact of mycophenolate mofetil on HCV recurrence is unclear and the effect of sirolimus has not been thoroughly studied.

Given the accelerated natural history of HCV recurrence, several approaches have been proposed to prevent or slow the progression to HCV-related graft failure. Current treatment strategies fall into three general categories: (i) Pretransplant antiviral therapy, (ii) preemptive therapy (prophylaxis) started in the early post-transplant period before the development of clinically apparent acute hepatitis, and (iii) post-transplant therapy at the time of diagnosis of acute hepatitis or for established and/or severe chronic hepatitis. With viral clearance post-transplant, both long-term absence of HCV RNA in the liver and marked histologic improvement (inflammatory scores much more so than fibrosis scores) have been described (39). Unfortunately, most published studies investigating the role of treating recurrent disease with interferon with or without ribavirin (no longer the standard of care) have been small, single center, uncontrolled trials with significant variability in patient selection and type and timing of antiviral therapy administered, and study endpoints evaluated (i.e., histologic response, end of treatment response [ETR], sustained virological response [SVR]). Rates of SVR are far less than those achieved in immunocompetent HCV-infected patients. Potential reasons for this difference include higher HCV RNA levels post–liver transplant, a high frequency of genotype 1 patients and the clinical status of liver transplant patients, especially in the early post-transplant period, leading to poor tolerability and need for frequent dose reductions. Approximately only 60% of transplant recipients are eligible for preemptive therapy with interferon and ribavirin and the need for dose reductions during therapy are frequent, occurring in 28% to 50% of treated patients (40,41). The major reason for dose reductions is cytopenia, seen both at baseline in many transplant patients and as a direct result of therapy. Use of growth factors to prevent this problem is not uncommon. Another problem in the transplant patient is renal insufficiency, limiting the use of ribavirin on account of its associated risk of hemolytic anemia. The risk of rejection with interferon therapy is controversial. Some studies have not noted an increased risk of rejection with interferon treatment (41,42,43,44), whereas others have described an increased risk (45,46). The exact prevalence and severity is therefore debatable. Whether rejection is more common with pegylated interferon remains to be proven.

Pretransplant antiviral therapy for HCV is discussed elsewhere. In terms of HCV-infected patients on the transplant waitlist, these patients are often deemed too ill to consider therapy. However, 93% of infected patients on the waitlist have Model for End-Stage Liver Diseases (MELD) scores of 18 or less (19,47). The arguments to consider therapy in cirrhotics pretransplantation is that clearance or suppression may eliminate risk of developing recurrent HCV and suppression of HCV viral load pretransplant might reduce disease severity post-transplant (48). Successfully treating patients on the waitlist with a

low, accelerating dosage regimen has been described (49). Of 124 patients with advanced HCV disease (mean MELD = 11.0 ± 3.7; Child-Pugh class B and C was 36% and 19%, respectively), 22% achieved a SVR (13%—genotype 1, 50%—nongenotype 1). Of the 47 patients in this cohort that underwent liver transplantation, 15 had undetectable HCV RNA prior to transplant and 12 remained HCV RNA negative at least 6 months post-transplant. Current consensus recommendations are to strongly consider treatment in patients with MELD scores less than 19 (Child-Turcotte-Pugh [CTP] <8) and in selected cases between MELD scores of 19 to 25 (CTP 8 to 11), especially in those with genotypes 2 and 3 (19).

The rationale for preemptive antiviral therapy is based on evidence from the nontransplant setting that low viral levels predict greater rates of SVR and high rates of clearance in treatment of acute hepatitis soon after an exposure (50). Preemptive therapy is strongly considered in patients undergoing retransplantation for rapidly progressive HCV disease and HCV-negative patients receiving a HCV-positive donor although data supporting these practices are limited. With the preemptive approach, antiviral therapy is typically started within 1 to 4 weeks of transplantation when viral levels are low and prior to histologic hepatitis. However, it is also during this time that patients are often more ill, at greatest risk for infection and rejection, and

more susceptible to the side effects of treatment. Data supporting this approach are scarce. Two randomized trials have evaluated the role of interferon in this setting (Table 58.4). In one study, histologic disease recurrence at 1 year was lower in the interferon-treated group than in the no-treatment group (8 of 30 vs. 22 of 41; $P = 0.01$) (42). In another study, the incidence of histologic recurrence did not differ, however, development of acute HCV hepatitis was delayed in the treatment group compared to the untreated group (408 days vs. 193 days; $P = 0.05$) (43). In a small uncontrolled trial of preemptive interferon and ribavirin started 3 weeks post–liver transplantation for 1 year, SVR was achieved in 33% (20% genotype 1, 100% genotype 2) (53). Investigation on the use of pegylated interferons in this setting did not show significant virological or histologic benefits (41). Poor tolerability and need for dose reductions in all these studies was high. Further well-designed randomized, controlled studies are needed to determine who is most likely to benefit from this treatment approach and whether the histologic improvements and reduction in HCV recurrence is beneficial in the long run. A recent consensus panel concluded that preemptive therapy remains to be defined and should only be used in unusual circumstances (19). Clearly, we need to identify early predictors of severe recurrence and develop a targeted approach that treats only a subset of patients.

Alternatively, many transplant centers follow protocols to initiate treatment when clinically significant evidence of recurrent HCV develops. Table 58.4 reviews the three randomized controlled treatment trials. With careful monitoring for graft fibrosis through use of protocol liver biopsies, antiviral treatment can be initiated at either the diagnosis of acute hepatitis C in the graft or at first sign of significant graft damage (e.g., stage 2 fibrosis). This latter approach balances the risk/benefit of treatment; avoiding the expense and toxic side effects of treatment with an overall SVR of approximately 20% (54) considering not all patients will develop severe recurrence. Delaying therapy theoretically allows most patients time to be in better physical shape and to be maintained on lower doses of immunosuppressants (less bone marrow suppression), thereby allowing full antiviral therapy. However, adverse events requiring dose modifications or cessation of therapy have been reported to occur in as many as two thirds of treated patients (55). Among the therapeutic approaches, combination therapy with pegylated interferon and ribavirin will probably yield the greatest potential for benefit in patients treated for established disease, assuming patients can tolerate therapy. Controlled data is currently lacking, but SVRs of 45% have been reported in a pilot study (56). Again, responders are often those with nongenotype 1 and patients who are able to complete therapy. Although, combination therapy may not achieve a SVR in most patients, the question remains whether fibrosis progression can be slowed with continued therapy, as suggested for nontransplant HCV. A small study using paired liver biopsies concluded that interferon therapy does not consistently improve allograft histology months to years after achieving viral clearance and does not improve liver histology at all in nonresponders (57). These results are consistent with our own experience, and we feel that unless virologic clearance is achieved, the natural history of HCV is not modified with antiviral therapy after

transplantation.

Unlike the effectiveness of hepatitis B immune globulin (HBIG) in preventing HBV recurrence after liver transplantation, treatment with hepatitis C immunoglobulin (HCIG) has not yet been shown to be effective in preventing graft reinfection. Its benefit was suggested by a study that showed the risk of HCV recurrence lower in HBV and HCV coinfected patients receiving HBIG prior to introduction of HCV screening (pre-1990) compared to after introduction of HCV screening (post-1990) (58). However, a randomized controlled trial for prevention of HCV recurrence found no benefit (59). Current data are inconclusive as to whether HCIG is effective in preventing HCV infection. Further study in this area is ongoing to determine if combination therapy to lower circulating HCV RNA levels might enhance the efficacy of HCIG.

For patients who either fail or do not tolerate antiviral therapy, the only option for those developing allograft failure from recurrent HCV is liver retransplantation (see Chapter 59), which has been associated with a number of complex issues. The current MELD allocation system favors medical urgency over a post-transplant outcome, without regard to whether a patient has already received an allograft. Maximizing utility (transplanting organs to those who will make the best use of them) in respect to retransplantation for recurrent HCV allograft failure may require placing more weight on post-transplant outcome, through the use of a more restrictive policy on retransplantation (60,61). While limiting access, a more selective approach will undoubtedly result in improved outcomes and better use of a scarce resource.

Hepatitis B Virus

HBV is a leading cause of morbidity and mortality worldwide, both from development of end-stage liver disease and as a risk factor for hepatocellular carcinoma. Currently HBV accounts for approximately 5% of all liver transplants performed in the United States, for both chronic and fulminant liver disease. Historically, liver transplantation for HBV had been associated with poor outcome due to HBV recurrence and graft

loss, leading to lack of support by some third-party payers. In the past 15 years there have been significant advances in the prevention and treatment of recurrent HBV after liver transplantation. Survival rates today for patients transplanted for HBV-related liver disease are now comparable and even exceeding other indications for liver transplantation (62).

Table 58.4. Randomized Controlled Trials Evaluating Efficacy of Antiviral Therapy for He Liver Transplantation

	Reference	No. of Patients (Tx/No Tx)	Treatment regimen	ETR (%)	SVR (%)	Histologic Response	Disc vs.
PREEMPTIVE TRIALS	Sheiner et al. 1998 (42)	35/46	IFN, 3 MU TIW × 12 mo	n/a[a]	n/a[a]	IFN group less likely to develop hepatitis, effect greatest with viral levels	26
	Singh et al. 1998 (43)	12/12	IFN, 3 MU TIW × 6 mo	n/a	0 vs. 0	No difference in hepatitis or	42(?

						outcome; time to diagnosis of hepatitis longer in IFN group	
	Reddy et al. 2002 (51)	21/11	IFN, 1.5 to 3 MU TIW + ribavirin 400—1,000 mg/d × 48 wk	n/a	16 vs. 0	No difference	31 (or decr

[a]Only HCV Ab(+) necessary to enter study. HCV RNA not known on all patients.
[b]All patients tolerated 1.5 MU daily.
ETR, end of treatment response; SVR, sustained virologic response; IFN, interferon; ?, informat
IFN, pegylated interferon.

For consistency in this chapter, the term *recurrent HBV* refers to HBsAg positivity post-

transplant in patients transplanted for HBV-related liver disease complications (cirrhosis, hepatocellular carcinoma, and fulminant failure). This definition implies de novo HBV infection in the allograft. This should be differentiated from *reactivation* of HBV, which refers to HBsAg positivity in patients transplanted for *non*-HBV related liver disease who receive a hepatitis B core antibody positive (anti-HBc (+)) donor liver.

The use of HBIG with or without use of a nucleoside analog (e.g., lamivudine and adefovir) has greatly improved the long-term graft survival following liver transplantation for HBV diagnoses. Prior to the use of HBIG, recurrence of HBV infection after transplantation was very high (>80% in patients alive for more than 2 months after liver transplantation was a major factor in 73% of all post–liver transplantation deaths beyond the first 60 days) (63). Once recurrence was established it often followed an aggressive course, progressing from severe chronic hepatitis to cirrhosis and graft failure within 1 to 2 years of reinfection and a 2-year mortality of 50% compared with 20% among patients transplanted for other liver diseases (64). A quarter of patients would develop an aggressive fibrosing cholestatic variant leading to rapid graft failure (64,65). Because of these poor outcomes with transplantation for HBV, many programs considered HBV infection (especially with viral replication) a relative contraindication to transplantation in the early 1990s.

A landmark multicenter European study of 334 liver transplant recipients with HBV helped identify three key determinants of HBV recurrence after liver transplantation: (i) Presence of HBV replication, (ii) type of HBV-related liver disease, and (iii) presence of passive immune prophylaxis using HBIG (66). Three-year actuarial risk of HBsAg recurrence among patients with HBV-related cirrhosis was 83% in patients seropositive for HBV deoxyribonucleic acid (DNA) at the time of transplant, 66% among those seronegative for HBV DNA and seropositive for HBeAg and 58% in those seronegative for both HBV DNA and HBeAg ($P < 0.05$). Three-year actuarial risk of recurrence was significantly higher among patients undergoing liver transplantation for HBV-related cirrhosis (67%) than among those undergoing transplantation for hepatitis delta virus–related cirrhosis (32%) or fulminant HBV (17%) ($P < 0.001$). Risk of recurrence was significantly reduced with long-term use of HBIG (>6 months) as compared to no immunoprophylaxis and short-term use (<6 months) ($P <0.001$). Multiple smaller studies have confirmed the European experience and have showed that the median rate of recurrent HBV infection in patients receiving long-term HBIG therapy was approximately 20% (range 5% to 50%) (67). Tables 58.5 and 58.6 summarize risk factors for HBV recurrence. As suggested by previous studies, Asians and non-Asians do not appear to have differences in rates of HBV recurrence (76).

Table 58.5. Risk Factors for Hepatitis B Virus Recurrence After Liver Transplantation

HBV DNA >100,000 copies/mL at time of LT (68)
Inadequate anti-HBs titers in patients with high viral load (69)
Development of immune escape mutants[a] (70, 71)
Lamivudine resistance pre-LT (72,73)
HBV precore mutants? (74,75)

HBV, hepatitis B virus; DNA, deoxyribonucleic acid; LT, liver transplantation; anti-HBs, hepatitis B surface antibody.
[a]Most common glycine to arginine substitution at codon 145 of the HBV S protein reducing binding to anti-HBs.

The mechanisms whereby HBIG protects the allograft against HBV recurrence are poorly understood. It has been hypothesized that HBIG protects naïve hepatocytes against HBV released from extrahepatic sites through blocking of a putative HBV receptor (77); alternatively, it may neutralize circulating virus through immune precipitation and immune complex formation (78). Use of HBIG does not lead to HBV eradication as HBV DNA by

polymerase chain reaction (PCR) can be detected in the liver, serum, and peripheral mononuclear cells of HBsAg-negative transplant recipients on HBIG (79,80).

In the United States, most centers use a fixed dose regimen (Fig. 58.3). Unlike the regimen used by many European centers that maintains a trough hepatitis B surface antibody (anti-HBs) titer at 100 IU/L, the fixed dosing regimen results in a wide range of

anti-HBs titers with many trough titers greater than 500 IU/L (80). A high degree of interpatient variability in HBIG requirements is evident after transplantation. The anti-HBs levels outlined in Figure 58.3 (70) have been reported to reduce the recurrence rates of HBV infection to less than 20% (80). Patients who are HBeAg-positive pretransplant require more HBIG to achieve these targets, especially in the first week post-transplant. Unfortunately, the use of IV infusions of HBIG are very expensive (first year charges of >$100,000 and subsequent yearly charges of >$50,000) (81). Although previously associated with many potential side effects (immune-mediated reactions, anaphylaxis, mercury toxicity, and transmission of blood-borne infections), the new formulation of HBIG (NABI-HB; NABI, Rockville, MD) has largely eliminated safety and tolerability concerns. Although licensed for intramuscular use, if administered in large amounts, it can be used intravenously. Several centers use intramuscular HBIG rather than intravenous HBIG either from the beginning or transitioning to it months to years after transplant (82,83,84,85). The benefit of the intramuscular route is that the doses to achieve adequate titers are smaller; 4% to 15% of the 10,000 IU/month high-dose intravenous regimens (82,85). This dose reduction equates to significant cost savings; $52,600 per recurrence prevented compared to $371,000 per recurrence prevented for intramuscular HBIG plus lamivudine and intravenous plus lamivudine, respectively (85). A few differences between intramuscular and intravenous dosing include: (i) Intramuscular injection has a depot effect, so maximal intravenous levels are reached 3 to 5 days post-injection, (ii) 55% to 60% of the antibody diffuses into extravascular compartment, and (iii) the half-life of immunoglobulin G (IgG) given intramuscularly is 25 days, therefore monthly intervals can expect to maintain certain trough levels of anti-HBs (67). Alternative regimens to reduce HBIG requirements (and cost) have included lamivudine monotherapy, low-dose HBIG and lamivudine, and short-term HBIG plus long-term lamivudine, all at varying effectiveness.

Table 58.6. Rates of Hepatitis B Virus Recurrence Using Hepatitis B Immune Globulin in Terms of Initial Diagnosis for Liver Transplantation

Initial liver disease	Recurrence (%)
Acute hepatitis B	0–10
HBV-HDV coinfection cirrhosis	10–20
HBV cirrhosis without HBV replication	20–35
HBV cirrhosis with HBV replication	30–80

HBV, hepatitis B virus; HDV, hepatitis D virus.

▪ **Figure 58.3** Generalized summary of prophylaxis regimen to prevent hepatitis B virus (HBV) recurrence after liver transplantation. [a]Fixed dose regimen. [b]Alternatively some centers use IM hepatitis B immune globulin (HBIG) or stop IV HBIG after 6 to 24 months.

The development of nucleoside analogs has changed the current standard of care for preventing HBV recurrence. Lamivudine and adefovir are both safe and effective in liver transplant recipients. Both agents have been used alone and in combination with HBIG as prophylactic therapy (Fig. 58.3) and for patients who develop HBV recurrence after liver transplantation (86). The benefit of lamivudine is its low cost and excellent tolerability in cirrhotics and liver transplant recipients. The main disadvantage of lamivudine is resistance (20% after 1 year, 50% after 3 years) (87). Both wild-type and lamivudine-resistant HBV are sensitive to adefovir. Addition of adefovir to lamivudine can reduce HBV recurrence in patients transplanted with lamivudine resistance (86,88). Resistance to adefovir has been described, although the incidence of this resistance is low (3% in the first 2 years of therapy) (86). Entecavir was approved for treating chronic HBV infection in early 2005. Although clinical

studies in decompensated cirrhotics and liver transplant recipients have not been published, its safety profile and efficacy suggest it will be another antiviral agent to be used pre– and post–liver transplant. The incidence of entecavir resistance is low (1% after 1 year of treatment) and only in patients with preexisting lamivudine resistance (89). Tenofovir, approved for human immunodeficiency virus (HIV), has activity against wild-type and lamivudine-resistant HBV and appears to be safe and efficacious for use in decompensated cirrhosis and liver transplant recipients.

Given the associated increased risk of HBV recurrence with demonstrated viral replication pretransplant, it has become standard of care to start patients on nucleoside analogs prior

to transplantation and to continue their use post-transplant with the use of HBIG (combination therapy). Although use of antiviral therapy pretransplant has been shown to stabilize and improve liver function (in some cases obviating the need for transplantation all together), clinical improvement is slow and may not be helpful in very advanced disease (90,91,92). The optimum timing of initiating lamivudine pretransplant is unclear. Clinical effect can take 3 to 6 months, arguing for early initiation; however, risk for resistance increases with duration of therapy, negating the initial benefit and increasing risk of recurrent HBV after liver transplantation. The development of new nucleoside analogs effective against the YMDD mutation provides additional alternatives (93). The efficacy of lamivudine monotherapy to prevent recurrent HBV infection post-transplant is determined by the HBV DNA status of the patient at the time lamivudine is started. In the North American multicenter trial, 1- and 3-year post-transplant recurrence rates were 40% and 60%, respectively among patients who were HBV DNA positive before initiation of lamivudine therapy compared to 18% and approximately 20%, respectively, among patients who were HBV DNA negative before initiation of lamivudine therapy (94). Whether all patients in this later group of "nonreplicators" were truly HBV DNA undetectable is not known as a relatively insensitive assay (detection limit approximately 10^7 copies/mL) was used. In contrast, a Hong Kong study on lamivudine monotherapy reported only one of 26 patients (3.8%) developing reappearance of HBV DNA in serum after transplantation (58% were either HBV DNA or HBeAg-positive at time of transplant) (95). Some centers have shown good results with sequential prophylaxis with HBIG followed by lamivudine in patients who are HBeAg-negative and/or HBV DNA negative. In one study (96), 24 patients who received at least 6 months of HBIG were randomized to either HBIG (n = 12) or lamivudine (n = 12) for 1 year. Recurrent HBV occurred in 1 of 12 patients on HBIG therapy and 2 of 12 on lamivudine. Another study of 30 patients who were HBeAg-negative prior to transplant were considered for lamivudine substitution after 2 years of HBIG (97). Of the 16 patients who participated in the study, none developed evidence of HBV recurrence after a median follow-up of 13 months. Similar findings were seen in a prospective randomized trial comparing lamivudine monotherapy after 1 month of HBIG (n = 14) and lamivudine with long-term HBIG (n = 15) (98). After 18 months of follow-up all patients survived without HBV recurrence (all patients were HBV DNA negative at the time of transplant with or without use of lamivudine). Further studies are needed to define the subset of patients in whom HBIG can be discontinued and what the risk of lamivudine resistance and virologic breakthrough is with longer follow-up.

The combination of HBIG (either intravenously or intramuscularly) with a nucleoside analog appears to be more effective than either agent alone with rates of HBV recurrence ranging from 0% to 18% in patient populations with prevalence of HBeAg/HBV DNA positivity ranging from 34% to 90% (74,82,83,84,99,100,101). As a general rule, the studies showing the greater rates of recurrence (11% (101) and 18% (74)) used lower maintenance doses of HBIG and all patients who developed recurrence had lamivudine resistance prior to liver transplantation. Excluding these studies suggests that use of HBIG with lamivudine (or another nucleoside analog) offers the lowest rate of recurrence (<10%). The use of adefovir (95) (or entecavir) to treat lamivudine resistance pretransplant and post-transplant will likely enhance our current armamentarium to manage HBV in the transplant setting.

The effectiveness of passive immunoprophylaxis with use of HBIG at preventing HBV recurrence has led some to examine the role of active immunoprophylaxis (HBV vaccination) at preventing HBV recurrence post-transplant. There have been several reports on this issue, but their results have been conflicting. In two consecutive reports from Barcelona (102,103), 14 of 22 patients transplanted for HBV-related liver disease, who were receiving HBIG prophylaxis alone or in combination with lamivudine developed anti-HBs titers greater than 10 IU/mL after being immunized with one to two courses of double-dose recombinant HBV vaccine. Similarly, another Spanish group (104,105) reported of 9 of 12 patients developing anti-HBs titers greater than 10 IU/mL after HBV vaccination. In these studies, HBIG or HBIG with lamivudine was stopped and no HBV recurrence occurred over a mean postvaccination follow-up of 40 months. Another group reports similar success with 16 of 20 patients acquiring anti-HBs after vaccination allowing discontinuation of HBIG (106). Contrary to these successful reports, an Italian group describing their experience with HBV vaccination consisting of three, double doses of vaccine found that only 3 of 17 patients

developed postvaccination titers greater than 10 IU/mL (107). Possible reasons for these discrepant

results include the lack of patients with acute liver failure in the latter study, different vaccination scheduling, and the variable use of lamivudine. Nonetheless, it appears that successful vaccination followed by withdrawal of HBIG is possible, and further studies with larger number of patients and different forms of vaccine are needed to investigate these issues further.

Recurrence of HBV after transplant is defined by presence of HBsAg. Once recurrence develops, continued use of HBIG is not necessary as its role is purely a prophylactic one. The course of recurrent HBV has been modified by the availability of effective antiviral therapy. In a study of lamivudine in recurrent HBV infection, 60% had undetectable levels of HBV DNA after 52 weeks of therapy; however, 31% developed breakthrough infection secondary to lamivudine resistance (108). There are no current practice guidelines for treatment of recurrent HBV in transplant recipients, but given the need to avoid resistance in this population, the use of combination therapy is encouraged. If recurrence develops with use of HBIG alone, a nucleoside analog (lamivudine and/or adefovir) should be started. If recurrence develops in the setting of lamivudine use (i.e., presumed YMDD mutation), adefovir or entecavir should be added to lamivudine until viral suppression is achieved. Most investigators recommend a minimum of 3 months overlap (109). There is no data on the use of interferon in those nonresponsive or intolerant to nucleoside analogs.

Recurrent Autoimmune Liver Diseases

A number of diseases treated with liver transplantation are believed to be the result of immune dysregulation. Theoretically, disease recurrence of the autoimmune disease in the transplanted liver is prevented by the use of immunosuppressive therapy to prevent allograft rejection. For some, recurrence of the primary autoimmune disease can occur sometimes leading to allograft failure. This section will discuss the following recurrent diseases: Primary biliary cirrhosis (PBC), primary sclerosing cholangitis (PSC), and autoimmune hepatitis (AIH).

Primary Biliary Cirrhosis

PBC is an immune-mediated disease leading to destruction and eventual loss of small intralobular bile ducts. This damage eventually leads to cholestasis and eventual cirrhosis and liver failure. Liver transplantation is a well-established treatment for PBC-induced end-stage liver disease with excellent long-term survival after liver transplant. Recurrent PBC after liver transplantation was first described in 1982 (110). Despite initial debate, it is now well accepted that PBC can recur after transplantation (111,112,113,114). Determination of recurrence rates has been difficult because most studies have not included protocol liver biopsies and disease recurrence is not always associated with cholestatic liver enzyme abnormalities. Moreover, the presence of cholestatic liver enzyme abnormalities may represent an alternative diagnosis after transplant (drug effect, infection or chronic rejection). Recurrence rates from the largest published series of 400 patients from Birmingham, England found histologic evidence of recurrence in 17% of patients at mean follow-up of 36 months (112), consistent with other series (115,116).

The gold standard for diagnosing recurrent PBC is liver biopsy. The key definitive diagnostic criterion is demonstration of a florid duct lesion (granulomatous cholangitis) or destructive lymphocytic cholangitis within a dense portal infiltrate (115). Sampling variations, particularly with early or mild recurrence may limit the identification of these findings. Less specific findings may be all that is identified, including mononuclear inflammatory infiltrate, formation of lymphoid aggregates, epithelioid granulomas, and bile duct loss. Recurrent PBC is considered definite if three of the four portal tract lesions are present in a patient transplanted for PBC with persistently positive antimitochondrial antibody (AMA) (113). It should be ensured that other diagnoses such as acute and chronic rejection, graft versus host disease (GVHD), biliary obstruction, viral hepatitis (Cytomegalovirus [CMV] and HCV), fungal infections and drug effects (sulfonamides, azathioprine, oral contraceptives, and penicillin-based antibiotics) are excluded. Although the AMA is the serologic hallmark of the

disease in the pretransplant setting, these antibodies can persist post-transplant, although there is typically a small and transient fall from pretransplant levels (117). Their presence does not correlate with clinical or histologic disease.

Risk factors for recurrence include younger donors, older recipients and prolonged warm ischemic time (112). The use of tacrolimus has also been implicated as a risk factor for PBC in one series (118), whereas azathioprine may have a protective effect (116). Whether this represents an adverse effect of tacrolimus or a benefit of azathioprine is not clear. Although graft failure from recurrent disease has been described (112,119), recurrence is not typically associated with graft loss. Although ursodeoxycholic acid (UDCA) is the mainstay of treatment of PBC pretransplant, its role in treatment of recurrent PBC has not been defined.

Primary Sclerosing Cholangitis

PSC is a chronic progressive disorder characterized by diffuse inflammation and fibrosis of medium and large intra- and extrahepatic bile ducts. This bile duct injury

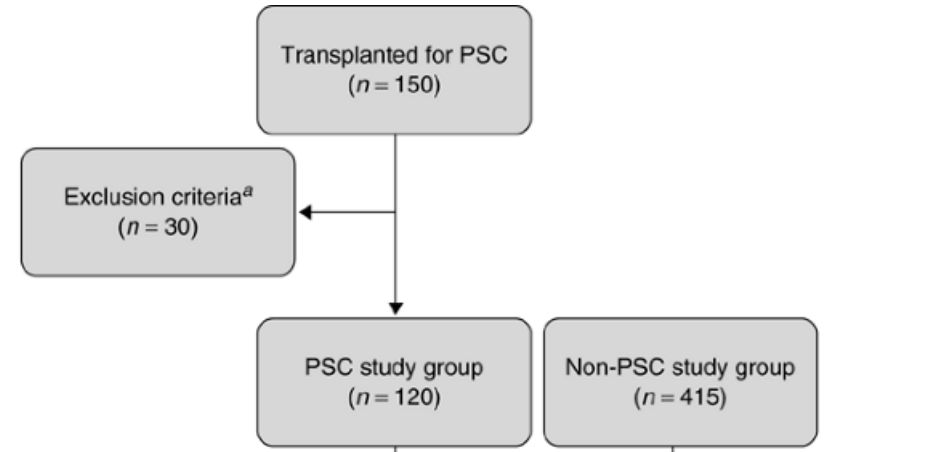
is most likely immunologic-mediated leading eventually to biliary obstruction and end-stage liver disease. Liver transplantation is the treatment of choice for patients with end-stage liver disease with 5-year survival rates as high as 85% (120,121). Diagnosis of PSC is made by demonstrating the characteristic biliary strictures on cholangiogram (diffuse, multifocal strictures and focal dilatation of the bile ducts, leading to a beaded appearance). A liver biopsy can confirm the diagnosis, but is rarely diagnostic due to a high incidence of sample variability. Liver biopsy findings include fibrous cholangitis (concentric rings of fibrous tissue with edema and inflammatory cells), bile duct obstruction, bile duct proliferation, and biliary cirrhosis).

The diagnosis of recurrent PSC is based largely on cholangiographic findings in combination with biochemical and histologic features of PSC. A large number of alternative diagnoses may lead to similar findings, and therefore, these diagnoses should be considered and excluded (Table 58.1).

Most patients with PSC undergo roux-en-Y loop anastomosis with removal of the recipient bile duct given the risk for cholangiocarcinoma in the native duct. These anastomoses are prone to biliary reflux and biliary infections, which can contribute to biliary stricturing. Studies comparing patients transplanted for PSC with those receiving an allograft with a roux-en-Y anastomosis have noted a greater frequency of nonanastomotic biliary strictures (122) and histologic features of biliary obstruction (123) in the PSC patients, supporting recurrence of PSC after liver transplantation.

Recurrence rates of PSC ranged from 8.6% to 20% with no associated reduction in patient or graft survival (120,124,125). The largest study of 120 patients transplanted for PSC compared outcome to 415 controls without PSC using strict cholangiographic and/or hepatic histologic criteria in which other causes of biliary strictures were excluded (Table 58.1 and Fig. 58.4) (125). In this Mayo Clinic study, of those with nonanastamotic lesions consistent with recurrent PSC, 59% had liver biopsies considered either marginal or not suspicious for PSC. Histologic evidence of recurrent PSC was noted in 11 (9.2%), 8 with fibrous cholangitis, and 3 with classic fibro-obliterative lesions at a mean of 1,380 days (range 420 to 3,240 days). In two patients without cholangiographic evidence of recurrence, both had advanced biliary-type fibrosis with ductopenia, which was otherwise unexplained and felt to be compatible with PSC. No specific risk factors for recurrence were identified. Patients fulfilling the criteria of recurrent PSC had significantly elevated serum alkaline phosphatase levels compared to the nonrecurrent group. In those with levels greater than 250 U/L after 1 year, recurrence should be suspected and cholangiogram and/or liver biopsy considered to

confirm diagnosis of recurrent PSC. No differences in patient or graft survival at 5 years in patients with recurrent PSC were noted, although patients with PSC recurrence may develop allograft failure (126,127,128).



Incidence of nonanastamotic strictures >90 days	18.3%	1.2%	$P < 0.001$
Histologic recurrence only	1.6%	n/a	
Days for nonanastamotic strictures to occur	360 ± 164 days	64 ± 89 days	$P < 0.001$
Graft survival at 5 years	79%	82%	P = NS
Patient survival at 5 years	86%	91%	P = NS

▪ **Figure 58.4** Summary of recurrent primary sclerosing cholangitis (PSC) after liver transplantation. [a]Excluded ductopenic rejection, anastomotic stricture alone, hepatic artery thrombosis, nonanastomatic strictures less than 90 days, ABO incompatibility, Cytomegalovirus (CMV) infection, prolonged ischemia. (Adapted from Sreekumar R, Gonzalez-Koch A, Moar-Kendler Y, et al. Early identification of recipients with progressive histologic recurrence of hepatitis C after liver transplantation. *Hepatology* 2000;32:1125–1130.)

There are no medical or surgical therapies to prevent or modify the rate of PSC recurrence. Whether differences to primary immunosuppression (cyclosporine vs. tacrolimus) regimens may modify or delay recurrence is not clear. A trend toward lower rates of recurrent PSC in early withdrawal of corticosteroids has been suggested (129). Whether corticosteroids avoidance only delays recurrence is not known. Use of OKT3 has been associated with higher risk of PSC recurrence (29% vs. 10%; odds ratio [OR] 3.7 [1.0 to 14.6]; P <0.05) (129). The use of high-dose UDCA (20 to 30 mg/kg) may have clinical benefits in the pretransplant setting (130), however, the potential benefits in patients transplanted for PSC is unknown.

Autoimmune Hepatitis

AIH represents a progressive, inflammatory disorder of the liver that may present as an acute hepatitis and liver failure. Patients with the diagnosis of AIH account for approximately 1.8% to 4% of liver transplant recipients (131,132). Compared to the general liver transplant population, these patients are more often young and female. Five-year patient survival after transplantation ranges from 82% to 92% (131,132). There does not appear to be a difference between patient and graft survival in patients with and without recurrent disease (131,132,133). Neuberger et al. reported the first case of post-transplant recurrence of AIH in 1984 when a 26-year old woman developed histologic and serologic evidence of AIH when corticosteroids were discontinued (134). The exact frequency of recurrence is unknown, and in early studies, was further confounded by lack of testing for HCV. Published reports have ranged from 2% to 42% (131,132,133,135,136,137,138) with 20% to 30% noted in most studies. A multicenter study of 72 cases of recurrent AIH

reported a median time to diagnosis of recurrence from 15 to 72 months (137). The recurrence rate appears to increase over time, possibly due to reduction in immunosuppression over time (8% at 1 year increasing to 67% at 5 years) (131).

Making the diagnosis of recurrent AIH is difficult given the lack of a single specific diagnostic marker. The diagnosis relies on a confident diagnosis of AIH as the primary indication for liver transplantation. Diagnostic criteria (139) for AIH have been established (see Chapter 31), and the diagnosis of recurrent AIH often involves using these same criteria. However, post-transplant, the use of immunosuppressive medications may influence the presence of biochemical and autoantibody markers. Recurrence can be indolent and only picked up by either routine laboratory testing or liver biopsy. Indeed, histologic abnormalities consistent with AIH on protocol liver biopsies have been detected when patients have no evidence of biochemical hepatitis (140,141). Although autoantibodies are often present, they are generally present at lower titers than they were pretransplant, possibly due to impaired autoantibody formation in the setting of immunosuppression. It is important to recognize that autoantibodies have also been seen de novo after liver transplant in the setting of rejection (142). Because diagnostic markers for recurrent AIH are lacking, the presence of characteristic histologic findings are important for making the diagnosis. While most often patients are clinically asymptomatic when recurrent AIH is diagnosed, the diagnosis is typically made when patients undergo liver biopsy in the setting of elevated liver enzymes to rule out rejection. For recurrent AIH, the biopsy should not reveal histologic features versus tacrolimus (endotheliitis or ductulitis), but rather a mononuclear infiltrate of lymphocytes and plasma cells extending from portal tract and into lobular parenchyma. With these findings it is important to exclude viral hepatitis (CMV, HBV, and HCV) and to consider exposure to hepatotoxic drugs. Histologic findings of recurrent AIH may be less well developed than AIH in the pretransplant setting because of immunosuppressive therapy. Differentiating recurrent AIH from rejection on biopsy, namely chronic rejection can be difficult, especially because chronic rejection may be a complication of recurrent AIH (143). There are also reports of late recurrence having been diagnosed by protocol liver biopsy in patients with normal liver enzymes (140). The diagnosis of recurrent AIH may depend more on exclusion of alternative diagnoses rather than identifying classical features of AIH.

Risk factors associated with the development of recurrent AIH include human leukocyte antigen (HLA) DR3-positive recipients (131,132,144), type 1 disease type (145), and suboptimal immunosuppression (131,134,136). Pretransplant necroinflammatory activity in patients with AIH, may also predict post-transplant disease recurrence (135). Prognosis in children may be worse than in adults (146).

Although there have been reports of successful steroid withdrawal in patients transplanted for AIH (147), numerous studies have described an association between recurrence of AIH with reduction in immunosuppression (134,136,148), suggesting that patients with AIH may require higher doses of immunosuppressive medication and prompting recommendations to wean steroids with caution. Further supporting the use of higher immunosuppressive dosing is the higher frequencies of ACR, steroid refractory rejection and chronic rejection in patients with AIH compared to patients with ALD (149) and genetic liver diseases (133). Whether cyclosporine versus

tacrolimus-based immunosuppressive regimens offer advantages is unknown. Lower incidences of ACR have been described in patients receiving a tacrolimus-based immunosuppressive regimen as compared to those receiving cyclosporine (149). Immunosuppressive management in AIH after liver transplantation requires further study.

Table 58.7. Predictors of Alcohol Relapse After Liver Transplantation

Abstinence <6 mo (150,151)	Absence of a life insurance policy[a](152)

Family history of alcoholism (153,154)	Prior alcohol rehabilitation (153)
History of drug abuse (152)	Daily alcohol consumption (155)
[a]Reflects stability of relationships and employment.	

Despite being more likely to have ACR during the early post-transplant period and reports of poor response to treatment (136), patients transplanted for AIH do not appear to have a significant difference in graft or patient survival (131,132,135,136), with exception of pediatric patients who have been reported to have rapid rates of recurrence frequently requiring retransplantation (146). Treatment of recurrence most often involves adjustments in immunosuppression. Recurrence of AIH does not appear to affect graft or patient survival (132), although longer follow-up is needed.

Recurrent Alcoholic Liver Disease

Alcohol is a major contributing factor in the development of end-stage liver disease with ALD representing the second most common indication for liver transplantation in the United States. Although ALD can be cured with transplantation, the disease of alcoholism remains and needs to be treated as such. Given the shortage of donor organs, alcohol use after transplant (recidivism) is a major concern to transplant centers. Many centers require that patients abstain from alcohol for at least 6 months before being listed for liver transplantation. This cutoff comes from studies suggesting abstinence of less than 6 months is a predictive factor for recidivism (150,151). Table 58.7 lists the factors predicting relapse of alcohol after liver transplantation.

Determining the incidence of alcohol use after liver transplantation is difficult given the highly variable means of detection (patient/family interviews, blood/urine testing, histologic findings) and different interpretations of recidivism (a single isolated drink to daily heavy use). A recent review of 30 published studies on alcohol use following liver transplantation for ALD using a definition of "any alcohol use" estimated a rate of approximately 20% (range 7% to 95%) at follow-up of 21 to 83 months following transplantation (156). This most likely is an under-representation.

Concerns that patients transplanted with ALD who resume moderate to heavy drinking will damage their transplanted livers either by developing recurrent ALD or by development of acute/chronic rejection because of noncompliance has not been supported by the literature (157,158,159,160,161), although a recent study has suggested that 10-year survival rates in patients with recidivism to be significantly lower than those without recidivism (45.1% vs. 85.5%, respectively; $P < 0.01$) (162). The high mortality rate in this study was explained by more frequent cancer and cardiovascular events. Although recidivism does not appear to directly lead to recurrent ALD, heavy alcohol use after transplantation can contribute significantly to other health problems. Patients transplanted for ALD are at a much greater risk of developing head and neck malignancies, especially if there is a history of heavy tobacco use. In addition, alcohol use in patients infected with HCV has potential to result in rapid recurrence of HCV in the allograft (163).

Recurrent Budd-Chiari Syndrome

Hepatic venous outflow obstruction at any level from the small hepatic veins to the junction of the inferior vena cava (IVC) and the right atrium is termed BCS (see Chapter 40). Most cases in western countries are the result of hypercoagulable states either related to an

underlying myloproliferative disease (MPD) or inherited thrombogenic diseases. Management is both medical (anticoagulation, diuretics, treating underlying hematologic disorder) and radiological/surgical (transjugular intrahepatic portosystemic shunt [TIPS] and liver transplantation). For patients undergoing transplantation, there is a risk of recurrence. The incidence of BCS after liver transplantation ranges from 0% to 27%, with a mean incidence of 8.5% (164,165,166,167,168,169). Often recurrence is associated with subtherapeutic anticoagulation. Recurrence typically develops months to years after transplantation, however, a recent report describes two cases of early recurrence (hours to days) despite initiation of anticoagulation within 24 hours of transplantation (169). Anticoagulation is not required for patients transplanted for protein C, protein S and antithrombin III deficiencies, as transplantation cures the underlying thrombogenic disorder. All other patients transplanted for BCS require long-term anticoagulation. A safe and effective alternative to anticoagulation in patients with underlying MPD is use of hydroxyurea and aspirin (168).

Summary

In summary, virtually all liver diseases that necessitate liver transplant can recur. Although recurrent disease has the potential to have the greatest impact on long-term outcomes after transplantation, the pace, frequency and severity of recurrence vary significantly according to the underlying disease. Precise predictors of who is likely to develop recurrence that threatens graft function remain largely undefined. For many with graft failure, retransplantation is the only option, and a number of groups have defined the parameters associated with outcome following retransplantation (see Chapter 59).

Chapter 59
The Role of Retransplantation

Kim M. Olthoff
James F. Markmann

Key Concepts

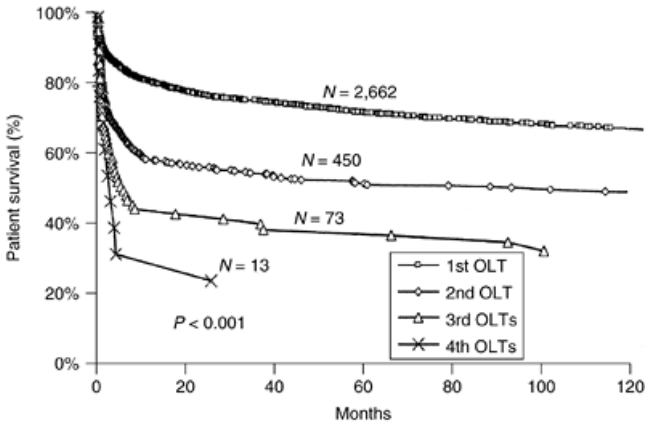
- Retransplantation after primary orthotopic liver transplantation (OLT) accounts for approximately 8% to 10% of all liver transplants in the United States.
- Overall graft and patient survival is lower following retransplantation compared with results after one transplant. The best outcome is achieved if retransplantation is undertaken immediately in the first week or at a much later stage after transplantation.
- Care should be taken in the decision to retransplant for recurrent disease, and should not be done in the setting of a severely decompensated patient who has poor functional status, high Model for End-Stage Liver Disease (MELD) scores, is advanced in age, on ventilator dependence, or on dialysis.
- Transplantation for recurrent hepatitis C remains controversial, however the presence of hepatitis C virus (HCV) in and of itself should not be a contraindication to retransplantation.
- Models to predict the outcome after retransplantation, which take into account patient status, disease severity, and donor graft characteristics should be further developed and validated.
- Although retransplantation offers outcomes that are inferior to primary transplantation, it should still be offered as potential life-saving therapy in cases of acute graft dysfunction, or in well-selected cases of recurrent disease and chronic graft failure.

The great success of liver transplantation since the 1980s has led to a rapid increase in the number of patients on the waiting list, with an unmatched increase in the number of cadaveric or living donors available. This gap continues to widen with the most recent published statistics showing over 17,000 on the waitlist in 2003, with only 5,364 transplants performed (1). Because of this disparity, the process of prioritizing individual patients for organ allocation is a constant source of debate, and critical in the discussion of appropriate allocation of livers to patients with a failed first graft. Despite increasing improvements in medical decision making, surgical technique, intensive care, and immunosuppression, a certain percentage of patients still experience acute or chronic graft failure and therefore require retransplantation—accounting for approximately 8% to 10% of all transplants performed in the United States per year. In 2003, 478 recipients (8.9%) had a prior liver transplant. During this same period, 1,819 patients died while still awaiting a first liver (the Scientific Registry of Transplant Recipients [SRTR] 2004 Annual Report). In addition, the outcome after retransplantation is not as successful as with primary transplantation in general, with long-term survival decreasing with each successive transplant (Fig. 59.1) (2).

Liver retransplantation not only poses a clinical and technical challenge, but also brings to bear serious financial and ethical issues because of increased costs and a finite number of available donors. Hospital charges are significantly higher and the length of stay is longer

for patients receiving a second transplant and

there is an obligatory net loss from the donor organ pool for patients who may have a greater chance of survival (3,4). In this chapter we will address the reasons for retransplantation, technical considerations, factors that contribute to the outcome after retransplantation, and also briefly explore the ethics of retransplantation.



▪ **Figure 59.1** Survival estimates of recipients undergoing multiple liver transplantations. Recipient survival after primary orthotopic liver transplantation (OLT) was compared with survival after transplantation with second, third, or fourth OLTs in a single-center series from the University of California at Los Angeles (UCLA) spanning two decades (2). (Reprinted from Busuttil RW, Farmer DG, Yersiz H, et al. Analysis of long-term outcomes of 3,200 liver transplantations over two decades: a single-center experience. *Ann Surg* 2005; 241(6):905–916.From Lippincott Williams & Wilkins.)

Rate of Retransplantation and Indications

The overall reported rate of retransplantation in the past 10 years in individual centers seems to vary between 7% and 17% (2,4,5,6,7,8,9,10,11,12,13). These rates have not remained constant over the years. The University of Pittsburgh studied the rates and causes of retransplantation in three eras—early eighties, late eighties, and nineties. The overall rate of retransplantation declined significantly over time: From 33% in the early eighties to 13% in the nineties (10), likely the result of improved clinical judgment, immunosuppression, advanced technical skills, and better antiviral medications. The overall rate of retransplantation in the United States, in a cohort of patients who underwent transplantation, in 2001 and 2002 was 9.4% of all patients receiving a deceased donor liver transplant (the US Organ Procurement and Transplantation Network [OPTN] and SRTR 2004 Annual Report).

Just as the overall rate of retransplantation has changed over time, so have the indications for transplantation. There has been a marked decrease in the rate of retransplantation for acute and chronic rejection. According to a series of 114 retransplants performed in Germany, the major causes of retransplantation during the early 1980s were acute and chronic rejection, with an incidence of 27% in each (14). However, in a more recent series, UCLA identified primary nonfunction (PNF) as the primary cause, accounting for over 25% of all retransplantation cases (15). According to data from a retrospective study of retransplantation at Pittsburgh over a 19-year period, the rate of retransplantation for rejection declined from 13.2% to 1%, and the rate of retransplantation for hepatic artery thrombosis (HAT) declined from 8.1% to 3.8%, with the rate for PNF increasing from 4.6% to 6.0% (10).

Retransplantation is also a significant event after pediatric liver transplantation, usually for different indications than adults, often for technical reasons. The incidence of

retransplantation in children is higher than in adults, with a range of 15% to 29% (16,17,18). The use of split and reduced size grafts, the small size of donors and recipients, and noncompliance in the teen years, are predisposing factors for an increased retransplantation rate in this population. The willingness of transplant surgeons and hepatologists to give more than one graft to children, or even more than two grafts, is greater, and fortunately, outcome is significantly better in the pediatric population as well.

The indications for retransplantation for adults and children can essentially be divided into two groups—those patients needing emergent retransplantation in the early days and weeks following transplant due to graft failure secondary to graft dysfunction or technical complications, and those requiring late retransplantation due to chronic rejection, recurrence

of disease, or late technical complications from vascular or biliary issues.

Indications for Early Retransplantation

Primary Graft Dysfunction

Early graft dysfunction is a term that is used to describe a spectrum of clinical conditions in which the transplanted allograft fails to provide adequate metabolic and/or synthetic function. These patients present with various degrees of hemodynamic and metabolic instability, and the potential for the development of multiorgan system failure. The severity of global hepatic dysfunction may be assessed by biochemical and metabolic markers including elevated transaminases, persistence of metabolic acidosis, elevated international normalized ratio (INR), and rising bilirubin. A diagnosis of PNF is a diagnosis of exclusion made if a graft shows complete lack of initial function and its dysfunction cannot be attributed to technical or other recipient causes, and is the most common cause of retransplantation in the initial days after OLT. A more stringent definition is used for the allocation of a second organ, where PNF is defined as graft dysfunction within the first week post-transplant leading to the death of the patient or retransplantation. Requirements include aspartate aminotransferase (AST) of value 5,000 or more, and either INR of value 2.5 or more, pH less than 7.3, or lactate value 4.0 or more. This allows for rapid relisting of patients at a Status 1 designation that places the patient at the top of the allocation list. Other grafts may present with a less dramatic picture, demonstrating prolonged cholestasis, evidence of ischemic/harvest injury on biopsy, and slow or inadequate restoration of function. Termed *early allograft dysfunction* (EAD) or delayed nonfunction (DNF) these grafts may require retransplantation if they fail to recover, although they often do not meet Status 1 criteria. These patients often have prolonged intensive care unit (ICU) stays with an increased risk of serious infectious complications (19,20).

The use of “marginal,” or extended criteria donor (ECD) grafts, that is, from higher risk donors based on demographic, clinical, laboratory, or histologic data, may increase the risk for early graft dysfunction. Although the definition of ECD is not clearly defined, grafts that may have an increased risk of graft dysfunction usually include livers from older donors, death-after-cardiac-death (DCD) donors, steatotic livers, split liver grafts, and those with prolonged cold ischemic times. Each of these factors has been associated with decreased graft survival, thereby leading to an increased potential need for retransplantation. There has been a steady increase in the use of ECD organs as the gap grows between recipients and the number of livers available. For example, there were 519 donor liver grafts over 65 (9.1% of all liver grafts) in 2003, compared to only 164 older grafts (4% of all grafts) in 1994, whereas the number of DCD donors increased by 43% between 2002 and 2003 (21). An increased rate of PNF has been associated with an increase in the utilization of donor organs from donors above 50 years of age from 1.5% in the early eighties to 22.5% in the nineties (10). From an ethical perspective, it is precisely the availability of retransplantation at a high status that allows for the use of these donors by providing a safety net if the ECD liver does not function properly. Previously, these grafts were used in patients in desperate situations and were associated with dismal graft and patient survival. As experience has been gained and results analyzed, it is now generally accepted that these grafts should be used in less critically ill recipients in order to obtain acceptable outcomes, as more stable patients may be able to better tolerate a period of relative graft dysfunction, or the need for

a retransplant procedure (22). Although this matching of donor to recipient is ideal, it is often not possible with our current allocation system that does not factor in graft quality.

Hepatic Artery Thrombosis

Acute HAT, despite a decreasing incidence (approximately 5%), is still a devastating problem that often requires retransplantation and is associated with markedly increased morbidity and mortality. In a review of 15 European liver transplant centers, the incidence of HAT was less than 5% but mortality rate was as high as 55% and the retransplantation rate was approximately 80% (23). The use of fibrinolysis, surgical thrombectomy, and immediate revascularization may avoid the necessity of retransplantation in some instances, but most patients still need a second graft. Previously patients with HAT were given Status 1 if diagnosed in the first week. However, recent data has shown that patients with HAT have a significantly lower risk of death while awaiting retransplantation than those requiring transplantation for other Status 1 designations (fulminant failure or PNF) (24), therefore, HAT can only be given Status 1A in adults if associated with a fulminant type of hepatic failure in the first 7 days (up to 14 days in children). Beyond 7 days, increased Model for End-Stage Liver Disease (MELD) exception points up to 40 may be requested.

Indications for Late Retransplantation

Chronic Rejection

Current modalities in immunosuppression have essentially eliminated the need for retransplantation for acute

rejection, and the incidence of retransplantation for chronic rejection has declined significantly. However, it still remains a significant cause in the late retransplant group. In a recent large series from Gainesville, Florida, 27% of late retransplants in both children and adults were for chronic rejection (25), and the Kyoto group reported a 35% rate of chronic rejection in a series of living donor liver transplants as a cause for primary graft loss requiring retransplantation (26).

Primary Biliary Cirrhosis

Although there was initially some controversy, recurrence of primary biliary cirrhosis (PBC) has been reported and is estimated at about 10% to 20%, occurring on an average 3 to 6 years after transplantation. Progression of recurrent PBC is often slow and may not necessitate retransplantation (27). In a series from the University of California, San Francisco (UCSF), recurrence of PBC was seen in eight patients with three graft failures that resulted in one death, one relisting for transplant, and one successful retransplant (28).

Primary Sclerosing Cholangitis

Histologic evidence of recurrence of primary sclerosing cholangitis (PSC) has been documented with rates ranging from 14% to 41% post-OLT (29). Injury to the bile ducts due to anastomotic, ischemic, and infection-related strictures may present similarly to PSC, therefore these causes of bile duct damage must first be ruled out. In a study of the United Network of Organ Sharing (UNOS) database of 2,154 patients with PSC, 315 (14.6%) required retransplantation (30). It was postulated that the reasons behind this were not just disease recurrence, but also a high rate of biliary complications and chronic rejection.

Autoimmune Hepatitis

Liver transplantation for autoimmune hepatitis (AIH) is highly successful; however, there is a high risk of rejection and severe recurrent AIH. Recurrence rates range from 16% to 46%. Treatment with steroids and increased immunosuppression may control disease progression, but a significant number of patients may require retransplantation (31).

Nonalcoholic Steatohepatitis

Small case series have demonstrated recurrent nonalcoholic steatohepatitis (NASH) in 10%

to 47% of patients post-OLT (32,33). Diabetes mellitus, hyperlipidemia, and obesity, often associated with NASH, are common after transplantation and progression from fatty liver to cirrhosis post-OLT has been documented in serial biopsies, with cumulative steroid use being a potential risk factor (33). There is very little, if any, data on retransplantation for recurrent NASH, but as the percentage of patients that are transplanted for this disease increases in the United States, it may become a very significant concern.

Alcoholic Liver Disease

Alcoholic liver disease is the second most common cause of liver failure leading to OLT. Multiple studies have looked at recidivism rates that may be as high as 30% to 40%, but the recurrence of alcohol-induced cirrhosis and liver failure is rare (34). Earlier arguments that suggested that alcohol recidivism would lead to poor adherence to immunosuppressive regimens and premature graft loss, have also been proven false (35). Obviously, resumption of alcohol use would be a contraindication for re-OLT and careful assessment of the psychosocial situation is necessary before approval in this patient group.

Hepatitis B Virus

Historically, recurrent hepatitis B virus (HBV) after OLT resulted in rapidly progressive hepatic deterioration and extremely high mortality rates (36). Prophylaxis with hepatitis B immunoglobulin (HBIg) and oral nucleoside therapy has greatly decreased the recurrence rate and made survival following OLT for Hepatitis B comparable to that of other causes of liver disease (37). However, occasional recurrence evolves (approximately 5%), mainly due to acquired HBV mutations (38), but retransplantation for recurrent disease is now rare.

Hepatitis C Virus

Cirrhosis from hepatitis C virus (HCV) is now the most common indication for liver transplantation in the United States (39,40). After liver transplantation, HCV can be detected in the serum of nearly all patients who had HCV before transplant, although the degree of histologic recurrence is highly variable (41). Hepatitis C viral RNA levels may increase up to ten times of pre-OLT levels at 4 weeks after transplantation and hepatic fibrosis may have an accelerated course (42,43,44,45). Unlike HBV, no therapy has been conclusively shown to alter HCV recurrence or disease progression, although some progress has been made in antiviral therapy (46,47). The natural history of post-transplant HCV infection is quite indolent but approximately 20% may have continuing graft damage progressing to cirrhosis in 5 to 10 years, and this percentage may be increasing (48,49).

Results of Retransplantation

Comparison to Primary Transplantation

Early studies in liver transplantation showed significantly worse patient and graft survival after retransplantation when compared to primary transplants. Along with the improvement in the results of primary grafting, a comparable trend is noted with the outcome of retransplantation. However, when all patients are included, the results with retransplantation still fall short of primary grafting (2,50,51). Recent data from the SRTR show that patients who underwent transplantation between 2001 and 2002 who had prior transplants have lower survival than those receiving an initial transplant (OPTN/SRTR 2004 Annual Report—Table 59.1).

Timing of Retransplantation

Several analyses have shown that timing plays an important role in the outcome of retransplantation (5,50,52,53). The series from UCLA demonstrated that the survival of patients who underwent transplantation within 1 week is nearly equivalent to that seen in patients who underwent retransplantation at a much later date. It was the patients who underwent retransplantation in the period between 8 and 30 days who had a significantly worse outcome, emphasizing the need for early recognition of patients who require early

retransplantation.

There is a clear differential outcome between those requiring early urgent retransplantation and those who require an “elective” second graft. In some cases, the patients who underwent retransplantation many months after the primary transplant exhibit survival curves similar to those receiving a single transplant. For urgent retransplantation, which likely coincides with the first 30 days after surgery and is likely due to primary graft dysfunction, hospital charges are higher, the length of stay longer, and survival worse (4). Although easier from a technical point of view, the mortality is likely high because of the poor clinical condition of the recipient (9).

Outcomes of Retransplantation in Hepatitis C Virus Patients

This remains a controversial subject with a great difference of opinion between centers. Early reports suggested that retransplant in HCV patients had a significantly worse outcome compared with other diseases with the presence of HCV being an independent risk factor for increased mortality (44,54,55,56,57). The presence of early fibrosing cholestatic hepatitis was considered a contraindication for retransplantation by many centers. Looking carefully at some of the earlier reports, it is found that many of the postoperative deaths were in the first 90 days, perhaps reflecting not just death from severe recurrent HCV, but also the poor perioperative condition of the patient with recurrent HCV undergoing retransplantation. Some centers have supported retransplantation for recurrent HCV if retransplantation was performed early in the course of recurrent disease (54). Others have reported that it is the physical condition of the HCV-infected patient at the time of retransplantation that is most predictive of outcome (58). A recent report from the SRTR database assessed the relative effect of HCV diagnosis on mortality after retransplantation demonstrating that retransplant recipients with HCV had a 30% higher covariate-adjusted mortality risk than those without HCV (59) (Fig. 59.2). Of concern was the fact that the increased risk associated with mortality was concentrated in younger patients (age 18 to 39) and in patients transplanted in more recent years (2000 to 2002), perhaps reflecting a willingness of transplant centers to perform retransplantation in younger patients who may be more severely ill. This study, however, did not compare outcomes between recipients with HCV and other specific disorders, and inherent differences between cohorts may have less importance than the degree of illness at the time of re-OLT (60).

Although retransplantation for HCV-positive patients accounts for approximately 40% of all retransplants in the US, and is predicted to increase in number, most second transplants are performed for causes other than recurrent disease. In some reports there appears to be little difference in the survival rate for HCV patients undergoing re-OLT when compared with other causes of re-OLT, if all other variables are kept equal (61,62), and therefore retransplantation should be considered a potential option for the treatment of recurrent disease. However, these patients require a more careful decision-making process when compared to non-HCV patients, and re-OLT is best performed before severe decompensation (51,63). This can be a difficult task in the current system of liver allocation that provides grafts to the “sickest first.”

Cause of Death Following Retransplantation

The development of sepsis and multiorgan failure accounts for most of the deaths in the patients undergoing retransplantation, and the largest proportion of deaths occur in the first few weeks after transplant. The

incidence of death secondary to sepsis is twice as high in patients undergoing retransplantation compared with those receiving just one graft with a 50% incidence of fungal infection (55,64). In a recent series from UCSF, 28% of patients who underwent retransplantation experienced serious infections in the first month, and 17.5% died within the first 6 months from multiorgan dysfunction associated with sepsis or poor graft function (65). Roayaie et al. reported that approximately two thirds of deaths after retransplant for HCV recurrence were associated with infection (57). The high incidence of graft loss due to

sepsis in these patients may reflect the immunosuppressed status of the patients prior to retransplantation, as well as their deteriorated functional status. In light of these findings, it may be prudent to reduce immunosuppression perioperatively, and initiate more effective antimicrobial prophylaxis for patients undergoing retransplantation. Less frequent causes of death following retransplantation include technical problems such as intraoperative mortality, arterial and portal vein thrombosis, and postoperative complications such as cardiac events, neurologic complications, recurrent disease, and persistent liver failure.

Table 59.1. Unadjusted Graft Survival, Deceased Donor Liver Transplants, Primary Ver Survival at 3 Months, 1 Year, 3 Years, and 5 Years

		3 months			1 year			3 years

Predictors of Mortality After Retransplantation

In an attempt to maximize the use of valuable organs, there have been many efforts to determine which factors are associated with the outcome in order to develop a model that might accurately predict survival in patients undergoing liver retransplantation. It has become increasingly apparent that it is not just the quality of the donor, but the status of the recipient that contributes most to the outcome after retransplantation. A multivariate analysis performed at UCLA determined that donor cold ischemia time over 12 hours, preoperative mechanical ventilator requirement, preoperative serum creatinine greater than 1.6, and serum total bilirubin over 13 were all independent risk factors predictive of a patient's poor outcome (53,64). Rosen and Martin identified bilirubin and creatinine as predictive of poor outcome in HCV patients (56). The University of Pittsburgh identified older donor age, gender, and choice of immunosuppression as predictive of poor outcome (52). In a series from Mount Sinai Medical Center, recipient age over 50, a preoperative creatinine greater than 2, and the use of intraoperative blood products, significantly impacted the survival of those patients requiring retransplantation over 6 months after the primary transplant (55).

Models to Predict Survival After Retransplantation

The critical shortage of donor organs and the resultant prolonged patient waiting periods before transplantation have prompted many to define a mathematic model that adequately predicts survival after retransplantation. Rosen et al. assigned a mortality risk score based on preoperative variables in patients undergoing retransplantation, which included recipient age, creatinine, bilirubin, non-PNF diagnosis, and UNOS

status (66). Individual patients were then stratified into low-, medium-, and high-risk groups, in an attempt to predict survival, finding recipient age, creatinine and bilirubin levels, and timing of transplant between 15 and 60 days as being predictive of outcome. These findings were validated in a multicenter international study (67). Another model put forth by Markmann et al. from the UCLA database, similarly employed a scoring system utilizing five noninvasive and readily available clinical parameters, including recipient age, creatinine, bilirubin, cold ischemia time, and ventilatory status (64). Patients having four out of a possible five points had a 1-year survival of only 27%. This classification system adequately discriminated high-risk and low-survival patients in three databases to which it was applied (UCLA, Baylor University Medical Center, and the UNOS registry). More recently, a universal model for predicting survival was proposed by Ghobrial et al. for both primary transplants and retransplants hoping to provide guidance for tailoring specific organ needs to specific recipients on the basis of the severity of disease and expected outcomes, which incorporated MELD score, recipient age, and timing of transplantation (63). Interestingly, none of these models found the diagnosis of HCV as a poor prognostic indicator in multivariate analysis. Applications of models such as these can theoretically result in better decision making, improved survival, and an increased efficacy in organ utilization.

Meld Score and Retransplantation

In primary transplantation, MELD score has not correlated with post-transplant outcome except at the very highest of MELD scores (68). However, in the population who undergo retransplantation, MELD score may have a more significant impact, although there is some disagreement here as well (69). MELD scores correlated with survival outcome in patients who underwent retransplantation at the University of Nebraska (70). In the multicenter

study by Rosen, the MELD score was predictive of survival in patients undergoing retransplantation after 15 days (67). In a recent paper by Yao et al. there was a trend for a correlation between CTP and MELD scores with 1-year post-OLT mortality, with CTP value of 10 and more and MELD scores of 25 and more having worse outcome at 1 and 5 years (65). These studies demonstrate that using MELD scores for liver allocation in this patient population may have distinct disadvantages, because patients undergoing retransplantation would need to be quite ill before reaching the top of the allocation list, thereby losing their "window of opportunity" to have a good outcome after retransplantation. Retransplantation at a lower MELD score would contribute to better outcomes. Other models have been proposed to determine which MELD score is associated with the greatest utility for retransplantation in patients with HCV and those without HCV, with the optimal outcome for retransplantation appearing to be achieved at MELD scores less than 28, with the maximal utility achieved at a MELD score of 21 for patients with HCV, and a MELD score of 24 for patients without HCV (57,71).

Living Donor Liver Transplantation and Retransplantation

With the increasing use of right lobe grafts for adult liver transplants, transplant surgeons and hepatologists will be faced with technical decisions regarding the use of living donors for retransplants, and ethical issues whether retransplantation should be performed in living donor recipients transplanted outside UNOS criteria, such as for large hepatocellular carcinomas. In a recent series of living donor liver transplants from the A2ALL consortium, 37 of 385 (9.6%) recipients of adult to adult living donor liver transplants required retransplantation, mostly for technical reasons (72). These technical issues markedly decreased as experience improved, and it may be that there will be less retransplantation in this group as technical complications decrease.

Summary

Along with the improvements in the results of primary grafting, a comparable trend is noted with the outcome of retransplantation. However, the national 1-year survival after retransplantation is currently approximately 65%, significantly less than primary OLT (2004 Annual Report SRTR). Certain clinical criteria have been found to affect the outcome of retransplantation. The most important factors appear to be the preoperative status of the recipient as indicated by ventilator dependence, renal failure, physical condition, age, and MELD score. The time interval to retransplantation, donor cold ischemia time, and donor quality also contribute to the overall outcome. The overall impact of retransplantation on the survival of all patients awaiting liver transplantation and the cost-effectiveness of this procedure are issues of current debates. What also remains controversial and unanswered is whether retransplantation for recurrent HCV has prohibitively poorer outcomes, as some analyses have identified the patient medical status as most predictive in this population, and it may be that improved judgment may also ensure better outcomes in this patient population (60,73).

Despite continued improvements, the generally inferior outcome has prompted many to question the

appropriateness of hepatic retransplantation on both economic and ethical grounds. On the other hand, an outright prohibition of hepatic retransplantation raises its own ethical questions of patient abandonment. In addition, limiting retransplantation would impede current efforts to expand the organ pool by utilization of marginal donors. The safety net of retransplantation is needed if an aggressive donor organ acceptance strategy is to be adopted by all transplant centers. Retransplantation is an essential treatment for patients undergoing liver transplant, who experience liver failure after their primary transplant. However, it must be applied with some discretion and careful decision making so that futility is avoided and maximal utility is achieved. Relying on MELD score alone to allocate organs seems insufficient in this patient population and needs to be studied. Futile transplants and retransplantation in subgroups of patients with little chance of successful outcome should be avoided. It is for this reason that mathematic models are being developed and tested in order to identify the subset of patients who will have acceptable outcomes and to identify factors that influence survival. These models and analyses should

provide valuable information on which sound clinical judgment for the selection of candidates most suitable and appropriate for retransplantation can be based.

Chapter 60

Hepatobiliary Complications of Hematopoietic Cell Transplantation

Josh Levitsky

Michael F. Sorrell

Key Concepts

- The most accurate prognostic indicator for the development of severe liver dysfunction is an early rise in liver function tests after hematopoietic cell transplantation (HCT).
- The most common causes of acute liver disease after HCT are acute graft versus host disease (GVHD), drug toxicity, and viral infection.
- Liver biopsy is often not necessary in classic presentations of GVHD and sinusoidal obstruction syndrome (SOS); however, the absence of full diagnostic criteria or the presence of other potential etiologies may indicate the need for histologic confirmation.
- Hepatitis B virus (HBV), hepatitis C virus (HCV), iron overload, and chronic GVHD are among the most common etiologies for chronic liver disease after HCT.
- The risk of HBV flare after HCT is highly dependent on the presence of detectable donor or recipient HBV deoxyribonucleic acid (DNA).
- The degree of hepatic iron overload present after HCT correlates well with the future development of hepatic fibrosis.
- Hepatic herpesvirus and fungal infections after HCT, although uncommon, can be life threatening and warrant immediate diagnosis and treatment.

Over the last few decades, hematopoietic cell (bone marrow or stem cell) transplantation (HCT) has evolved from an experimental procedure into a lifesaving, potentially curative therapy for patients with a wide variety of hematologic and oncologic diseases. It is now a recognized treatment option for refractory leukemia, lymphoma, thalassemia, aplastic anemia, sickle cell anemia, breast cancer, and immunodeficiency syndromes. Advances in preparative regimens, GVHD prophylaxis, and anti-infective prophylaxis and treatment have brought significant improvements in long-term disease-free survival after HCT.

Acute and chronic hepatobiliary complications remain the "Achilles' heel" of HCT and, despite advances in HCT, are responsible for significant morbidity and mortality after transplantation. Pretransplantation evaluation of donors and recipients and close monitoring after HCT reduces the development of severe hepatic complications. This chapter focuses on the specific common and

uncommon etiologies, diagnosis, and management of these complications.

Prevalence

The prevalence of chronic liver disease in HCT recipients varies in the literature, depending on sample size, length of follow-up, and method of diagnosis. Abnormal liver biochemistry test results in the first 12 months are common, particularly in recipients of allogeneic transplants (1). In this period, the most common causes of abnormal liver function in recipients of allogeneic transplants are GVHD, drug hepatotoxicity, and viral hepatitis. In autologous transplantations, disease recurrence and sepsis are predominant. Liver disease

may be responsible for up to 30% of deaths in HCT recipients (2). Recipients who have unrelated donors or donors with abnormal liver function have an increased risk of developing significant liver disease (2).

Chronic liver disease, often due to viral hepatitis, is seen in a high percentage of HCT recipients who survive long term (3). The largest study (>3,700 recipients) of long-term survivors showed a slow progression to cirrhosis (4). The cumulative incidences of cirrhosis 10 and 20 years after HCT were 0.6% and 3.8%, respectively. In comparison to matched controls without cirrhosis, only hepatitis C was found to be more prevalent in recipients.

Donor Evaluation

Once a suitable donor is selected, the evaluation should consist of liver function tests and serologic testing for infectious agents that are potentially transmissible to the immunosuppressed recipient (Table 60.1). Most notably, testing for previous exposure to hepatitis B virus (HBV), hepatitis C virus (HCV), and cytomegalovirus (CMV) provides an important estimate of the risk of transmission and the need for closer monitoring or prophylaxis. These etiologies are discussed in further detail in subsequent sections.

Recipient Diagnosis and Evaluation

The differential diagnosis of liver disease in this population depends on the specific period after HCT (Fig. 60.1). Liver function tests and clinical signs of liver disease (e.g., right upper quadrant pain, jaundice, ascites, weight gain) should be monitored frequently in the course of post-HCT care. Any suggestion of liver disease should be evaluated immediately as early diagnosis and treatment results in improved prognosis for most etiologies. The initial approach should be to evaluate for infection, review the recent drug history, and screen for viral hepatitis. Imaging tests may be helpful in all stages after HCT, particularly when sinusoidal obstruction syndrome (SOS), complications from gallstones, or the development of cirrhosis are suspected.

Table 60.1. Evaluation of Donor and Recipient in Hematopoietic Cell Transplantation

Donor	Recipient
Liver function tests	Liver function tests

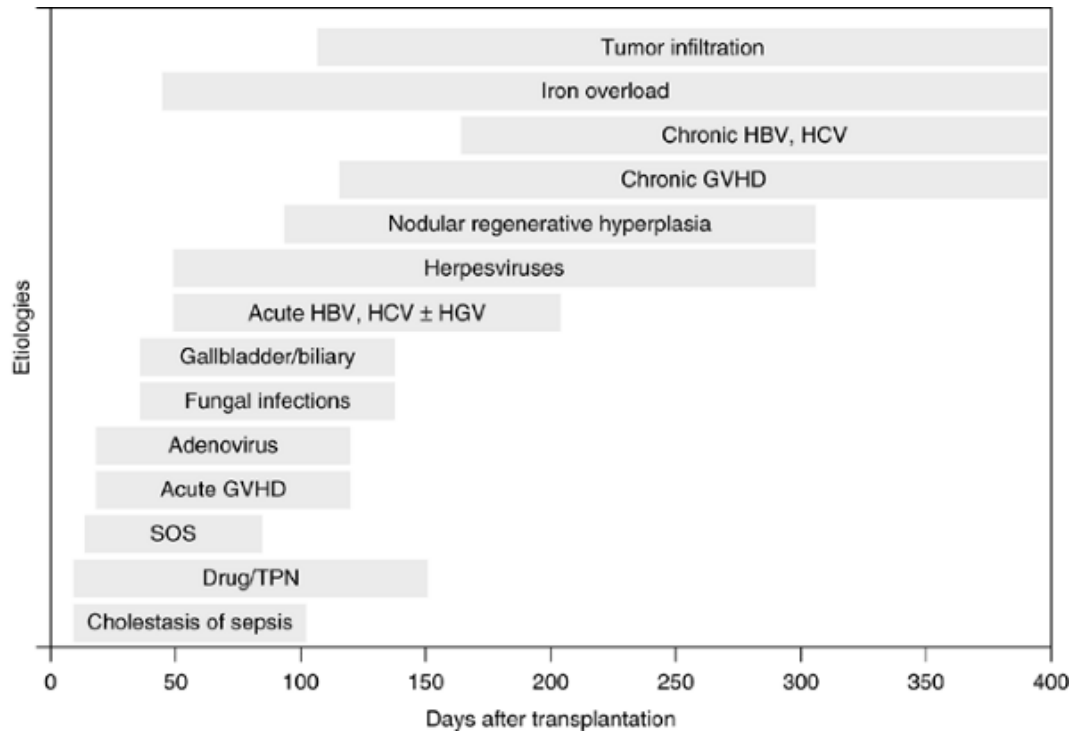
Hepatitis B virus	Hepatitis B virus
Surface antibody and antigen	Surface antibody and antigen
Core IgG	Core IgG
DNA	DNA
Hepatitis C antibody	Hepatitis C antibody
Cytomegalovirus IgG	Cytomegalovirus IgG
	Varicella zoster virus IgG
	Epstein-Barr virus IgG
	Iron studies
	Iron, TIBC, ferritin
	Hepatobiliary ultrasonography with vascular Doppler
IgG, immunoglobulin G; DNA, deoxyribonucleic acid; TIBC, total iron binding capacity.	

The use and safety of liver biopsy to evaluate abnormal liver function after HCT are debated. Clinical criteria for diagnosing specific etiologies, such as SOS and GVHD, may obviate the need for liver biopsy. However, a significant percentage of diagnoses and management decisions may be altered because of liver biopsy findings, particularly when risk factors for hepatitis B and C reactivation are present (5,6,7,8). Coagulopathy and thrombocytopenia can limit the ability to perform a safe liver biopsy. Percutaneous biopsy can be performed in patients with low bleeding risks (platelets >75,000 and international normalized ratio [INR] <1.5). Ultrasound-guided biopsy with a small cutting needle has been associated with a lower rate of complications in these patients (9). Transjugular biopsy with hepatic venous pressure gradient (HVPG) measurements may be safer and help identify patients with SOS in uncertain cases (5,7). A HVPG greater than 10 mm Hg highly correlates with the histologic diagnosis of SOS. In patients with platelet counts less than 50,000, laparoscopic liver biopsy may be indicated to control any potential bleeding complications (6).

Prognostic Indicators

An early rise in liver function test results after HCT may foreshadow a more severe clinical picture and worse prognosis. Within 200 days post-HCT, a bilirubin increase from 1 to 3 mg/dL is associated with a greater than sixfold increase in mortality (10,11).

Biopsy findings may be predictive of severe liver disease, often in direct relation to the number of characteristic findings and degree of necrosis on histopathology (12). Other factors associated with worse prognosis include advanced age, having an unrelated donor, and an abnormal alanine aminotransferase (ALT) level before HCT (13,14).



▪ **Figure 60.1** Causes of liver disease after hematopoietic cell transplantation. HBV, hepatitis B virus; HCV, hepatitis C virus; GVHD, graft versus host disease; HGV, hepatitis G virus; SOS, sinusoidal obstruction syndrome; TPN, total parenteral nutrition.

Common Complications

Graft Versus Host Disease

Acute graft versus host disease

Acute GVHD typically occurs between 15 and 100 days of HCT in up to 70% of allogeneic HCT recipients. T cells from the allogeneic graft recognize major and minor histocompatibility antigens on biliary cells, leading to lymphocytic intrahepatic biliary destruction. Rarely, an acute GVHD-like syndrome with identical histologic features can be seen in recipients of autologous transplants,

potentially caused by autologous T cells that react to self–major histocompatibility complex (MHC) class II antigens (15). Risk factors for the development of acute GVHD include age greater than 50, busulfan conditioning, and HCT recipients having unrelated or human leukocyte antigen (HLA)-mismatched donors (16,17,18,19). Organ involvement is typically less than that of chronic GVHD and is usually limited to the skin, gastrointestinal tract, and liver. Liver involvement often occurs after other organ involvement and is characterized by a cholestatic pattern of liver function tests.

Liver biopsy may not be necessary in a patient with skin or gastrointestinal GVHD who develops cholestatic parameters. However, if skin and gastrointestinal GVHD are not present or other etiologies, such as SOS, drug hepatotoxicity, or viral infection, are suspected, liver biopsy may be indicated. One study reported that suspected cases are classified as acute GVHD in only 43% of biopsies and that acute GVHD is picked up on biopsy in 17% of unsuspected cases; therefore, liver biopsy confirmation is almost always justifiable (7). Histologic findings of acute GVHD include lymphocytic involvement of intralobular bile ducts, bile duct epithelial cell dropout, and often a lack of significant inflammation because of early post-HCT immunosuppression. High levels of interleukin-6 and soluble interleukin-2 receptors are often seen early in patients who develop acute GVHD but may also be seen in SOS and sepsis (20,21). These tests have not been utilized clinically because of their expense and lack of specificity.

Prophylactic agents have had varied success in preventing acute GVHD after HCT. Immunosuppression with tacrolimus or cyclosporine and/or methotrexate is associated with a relatively lower incidence (19%

to 55%) of acute GVHD than those without prophylaxis, although toxicity from these agents may contribute significantly to morbidity (22,23,24,25,26,27). These studies have generally involved small numbers, are not placebo controlled, and have failed to show significant improvements in overall survival. Larger studies with cyclosporine prophylaxis have shown less acute GVHD, particularly when used in combination with methotrexate and corticosteroids (26,27). Ursodeoxycholic acid (12 mg/kg per day) given up to 90 days post-HCT significantly lowers the incidence of severe acute GVHD and is associated with an improved 1-year survival over placebo (28). Intravenous immunoglobulin is not effective in preventing GVHD over placebo (29).

Initial treatment of acute GVHD is usually with corticosteroids or cyclosporine. Both are more effective than antithymocyte globulin infusions and lead to resolution in approximately 40% of cases (26,30). Skin and gastrointestinal manifestations of GVHD respond better to corticosteroids than hepatic involvement (30). For steroid-refractory acute GVHD, options including mycophenolate mofetil, interleukin-2 receptor inhibitors (daclizumab), anti-CD54 antibodies (alemtuzumab), and rapamycin have shown some success in small studies (31,32,33,34). In severe, refractory cases, orthotopic liver transplantation (OLT) appears to be an acceptable treatment option for GVHD if other treatments fail. Data from reported cases and review of the national database of OLT for severe hepatic GVHD were examined recently (35). Post-OLT 1- and 5-year actuarial survivals were surprisingly high at 72.4% and 62.9%, respectively.

Chronic graft versus host disease

Chronic GVHD develops in 30% to 70% of patients after allogeneic HCT and is

more common in HCT recipients from unrelated donors (1,3,19). Other significant risk factors include age, busulfan conditioning, acute GVHD, varicella zoster virus (VZV) infection, and granulocyte colony-stimulating factor infusions (13,18,36,37). The distinction between acute and chronic GVHD is made on clinical and histologic grounds. Organ involvement tends to be more extensive than that in acute GVHD and, in addition to skin and gastrointestinal tract, may include exocrine glands, genitourinary tract, and lungs. MHC class II antigens are detected on the intrahepatic bile duct epithelium in patients with chronic GVHD and are involved in the signaling pathways leading to eventual destruction of these bile ducts (38). Portal involvement with lymphocytes and bile duct dropout, periportal fibrosis, piecemeal necrosis, and cholestasis are the predominant histologic features.

Liver test result abnormalities are typically cholestatic and slowly progressive in nature. Rises in alkaline phosphatase and 5′ nucleotidase levels are more specific for the diagnosis of chronic GVHD in comparison to elevation in bilirubin and aminotransferase levels (39). Patients with chronic GVHD can have a clinical and histologic presentation similar to that in patients with primary biliary cirrhosis (PBC) (40,41,42). Antimitochondrial antibodies may be seen in both, although autoantibodies are more likely to be false-positives in chronic GVHD. Biliary epithelial staining with pyruvate dehydrogenase complex-E2 specific monoclonal antibodies is present in the liver tissue of patients with PBC but not in those with chronic GVHD (41).

Acute hepatitis with aminotransferase levels greater than 1,000 U/L can be the first presenting sign of chronic GVHD, particularly in patients with recent reduction or cessation of immunosuppressant therapy (43,44,45,46). On liver biopsy, lobular hepatitis with hepatocyte necrosis and acidophil bodies are seen in comparison to the characteristic cholestatic features of chronic GVHD (44). Rapid reinstitution of immunosuppressive therapy results in outcomes and resolution similar to those in typical presentations of chronic GVHD. Ursodeoxycholic acid may be beneficial in these cases (45).

Prophylaxis for acute GVHD often leads to reduced rates of chronic GVHD. Tacrolimus and cyclosporine prophylaxis may reduce the incidence of chronic GVHD to 25% to 50% (24,27). Although most studies have not shown a survival benefit with prophylaxis, tacrolimus plus methotrexate has been associated with a 2-year disease-free survival of 50% in one study (23). Ursodeoxycholic acid does not reduce the incidence of chronic GVHD, but 1-year survival is improved mainly because of reduction in acute GVHD (28).

Initial treatment of chronic GVHD involves corticosteroids plus other immunomodulators. Refractory cases are seen in less than 30%. Salvage treatments result in response rates of 19% to 77% (31,32,47,48,49,50,51). Mycophenolate mofetil has the highest efficacy in refractory cases but may be associated with gastrointestinal side effects and opportunistic infections (31,47). Tacrolimus improves and normalizes liver test results in 60% and 33%, respectively (51). Lower response rates have been seen in cases treated with daclizumab (32). Ursodeoxycholic acid improves liver test results in the short term, but long-term treatment has not been evaluated (50). The success of OLT for refractory chronic GVHD was previously based on small case reports and series (52,53,54). When data from published studies and the national transplant database were combined, the 5-year survival after OLT for chronic GVHD was excellent at 62.9% (35). The rate of retransplantation was low and no patient developed recurrent GVHD. Therefore, OLT for either acute or chronic GVHD

appears to be a feasible option for severe, refractory cases.

Sinusoidal Obstruction Syndrome

SOS typically occurs within 30 days of HCT. Early studies showed a high incidence (54%) of mild to moderately severe SOS after HCT (55). Later reports with larger numbers showed that SOS occurred in a low percentage (4.7% to 5.3%) of recipients and that it was associated with a poor prognosis and death if clinically severe (56,57,58,59). Overall less than 20% die from SOS, whereas over 60% die from the severe form of the disease (59). Multiorgan failure, including fulminant hepatic failure, is associated with a near 100% fatality rate (56,57).

Risk factors for SOS in HCT are shown in Table 60.2. High-dose cytoreductive treatment is strongly associated with the development of SOS (55,59). Busulfan, cyclophosphamide and its metabolites, and combination treatment are the main offenders implicated (60). The risk of SOS is increased almost threefold with busulfan conditioning (57). Some have suggested monitoring the pharmacokinetics of busulfan by plotting area-under-curve (AUC) graphs because high AUC levels are associated with the development of SOS and subsequent mortality after HCT (61,62,63). The liposomal form of busulfan appears to have a lower incidence of SOS (64). Abnormal liver test results before HCT and HCV may also increase the risk of SOS (55,59,65,66,67). Other major pretransplantation risk factors include advanced disease status, high Karnofsky score, prior treatment with gemtuzumab ozogamicin, and allogeneic transplantation (11,59,68,69,70,71). Recently, $CD34^+$ selection in recipients of stem cell transplants was shown to lower the incidence of SOS (68,72).

Early histologic findings include central vein subendothelial thickening, sinusoidal dilatation, red blood cell extravasation outside the sinusoids, and pericentral hepatocyte necrosis. Local activation of the coagulation cascade and collagen deposition in the perivenular and subendothelial region results in reduction in blood flow from the sinusoids to the central veins (73). In addition, activated stellate cells, identified by immunohistochemical staining for α-smooth muscle actin antibodies, play an important role in the development of luminal narrowing and sinusoidal fibrosis (74,75). With ongoing obstruction and necrosis, the fibrosis can extend from these obliterated central veins. Terminal hepatic venule occlusion is not seen in all cases; therefore, the term *SOS*, rather than the old terminology veno-occlusive disease (VOD), more accurately reflects the pathophysiology (12). The number and degree of perivenular changes is associated with the clinical severity of SOS (12,76). These changes include hepatocyte necrosis, occluded venules, eccentric thickening of the venular subendothelium, phlebosclerosis, and perivenular fibrosis.

Table 60.2. Risk Factors for Sinusoidal Obstruction Syndrome in Hematopoietic Cell Transplantation

Definite	Suspected
High-dose conditioning	Glutathione-*S*-transferase M1 polymorphism

Busulfan	Immunoglobulin infusions
Cyclophosphamide	Unrelated or allogeneic transplant
Thiotepa	Norethisterone
Hepatitis C virus	Prior abdominal irradiation
Advanced disease status and Karnofsky score	
Abnormal liver enzymes	
Gemtuzumab ozogamicin	
T cell–depleted transplant	
Low protein C activity	

Activation of the coagulation cascade due to endothelial cell injury may precede the development of SOS. Levels of endogenous anticoagulants, protein C, and antithrombin III may be significantly reduced soon after HCT in patients who later develop moderate to severe SOS compared to those with mild or no SOS (77,78,79). Low levels of protein C are seen before and after cytoreductive therapy in those who develop SOS (80,81). Plasminogen activator inhibitor-1 (PAI-1) level is significantly elevated in SOS compared to other causes of liver disease after HCT (82,83,84). In addition, a significant decrease in PAI-1 levels with treatment of SOS is a good predictor of response (85). Others have shown that PAI-1 levels are not specific for SOS and are also elevated in sepsis, capillary leak syndrome, and GVHD (86). Procollagen type III level is also elevated in SOS and may be an early predictor for the development of SOS (87,88,89). Other factors seen with activation of the coagulation cascade and endothelial cell injury include d-dimer, tissue plasminogen activator (TPA), fibrinogen, vascular endothelial growth factor (VEGF), and hyaluronic acid (78,90,91,92). Although not typically used in clinical practice, knowledge of the levels, particularly of protein C, before and after HCT may indicate the need for reduced myeloablative therapy and closer monitoring for SOS.

Rapid diagnosis and intervention are critical in the management of SOS. Early intervention was associated with complete response in 76% and 50% of all and

severe cases of SOS, respectively (93). An increase in bilirubin level for 2 consecutive days within 20 days of HCT is significantly associated with the development of SOS (11). In clinical practice, the diagnosis of SOS is often made

on clinical grounds in the absence of alternative etiologies (55,66). Patients present with hepatomegaly, hyperbilirubinemia (>2 mg/dL), and weight gain (>5%) due to ascites formation. The diagnosis is secure in patients who meet these clinical criteria, although those with less than or equal to two criteria are less likely to have SOS and may need liver biopsy for confirmation (94). HVPG greater than 10 mm Hg correlates highly with the histologic diagnosis of SOS and may be useful when the biopsy or clinical scenario is inconclusive (3,7).

Noninvasive tests, such as Doppler ultrasonography and magnetic resonance imaging (MRI), may assist in making the diagnosis. Ultrasonographic findings, such as splenomegaly, ascites, low flow in the paraumbilical vein, and an elevated hepatic artery resistive index, correlate with the clinical and histologic diagnosis of SOS (95,96,97). Low portal vein velocity or portal vein thrombosis appear to be somewhat less reliable (79,98,99). Hepatic vein narrowing and gallbladder wall thickening may be seen on MRI in patients with SOS (100).

Before HCT, prophylactic strategies to prevent SOS are often employed. The most promising agents are ursodeoxycholic acid, heparin, and defibrotide (101). A pilot study and two of three randomized trials showed a significant reduction in the incidence of SOS with the use of ursodeoxycholic acid compared to placebo (28,102,103,104). Heparin, either unfractionated or low molecular weight, or in combination with defibrotide, is also effective in preventing SOS compared to placebo, with a low rate of bleeding complications (105,106,107,108,109,110).

Once SOS has developed, immediate attempts at treatment are required. Response rates depend on early diagnosis and severity of disease. An initial report on the compassionate use of defibrotide for severe SOS showed a response in 8 of 19 patients (111). Subsequent larger studies showed overall and severe disease response rates to be 55% to 76% and 36% to 50%, respectively (85,93,112). Defibrotide is preferred over other thrombolytic agents, such as recombinant TPA, that have a significantly higher rate of bleeding complications (113,114,115,116,117). Other less well-reported treatment strategies include antithrombin III, charcoal hemofiltration, *N*-acetylcysteine, and prostaglandin E_1 (118,119,120,121). For refractory cases, transjugular intrahepatic portosystemic shunt (TIPS) has been shown to reduce HVPG and improve abdominal pain and ascites but does not generally result in improved survival (122,123,124,125). In select cases, liver transplantation may be performed with a potential for long-term survival, although the data are sparse (53,126,127,128).

Hepatitis B Virus

Donor evaluation

HBV can be transmitted from donor to recipient and cause acute hepatitis soon after HCT. De novo HBV has been reported to occur in 3.2% of recipients (2). The risk of hepatitis relates to the presence of donor hepatitis B surface antigen (HBsAg) and replicating HBV deoxyribonucleic acid (DNA). (129) Hepatitis B carriers (HBsAg with little or no HBV DNA) less commonly transfer HBV to recipients, causing acute hepatitis (2,130). In recipients who convert from surface antibody positivity to negativity after HCT (reversed seroconversion), acute hepatitis does not occur if the donor is surface antigen negative but may occur if the donor is surface antibody negative (131,132).

Adoptive transfer of surface antibody from donor to recipient may result in loss of surface antigen and acquisition of surface antibody by the recipient

(131,133,134). In addition, donors who are vaccinated before donation may also transfer surface antibody to recipients (134,135). This may be particularly important in preventing acute flares of HBV after HCT and in long-term protection. Core antibody can also be transferred from donor to recipient and result in loss of surface antigen (136).

Risk of reactivation and acute flare

The most significant factor for developing severe HBV infection after HCT is the replicative status of the virus immediately before HCT, either in the donor or in the recipient. Recipients with surface antigen and undetectable HBV DNA have a significantly lower risk of reactivation than those with detectable DNA (130,137).

Precore or core promoter mutations in the viral genome predispose these patients to more severe reactivation and decompensation after HCT (130). The presence of recipient core antibody also poses a risk, particularly in the setting of detectable DNA and chronic GVHD (138,139). Finally, even patients with surface antibody who have presumed immunity can develop acute hepatitis after HCT, potentially related to low surface antibody titers and the presence of viral DNA in either blood or tissues (140,141). Fulminant hepatic failure can occur if the diagnosis is made late and therapy is not instituted in time (141,142).

Treatment

Acute reactivations of HBV, typically in the setting of immunosuppression tapering or withdrawal, are becoming less common with advances in the treatment and prophylaxis of HBV before and after HCT. Lamivudine is typically the first agent selected for HBV flares after HCT, unless the patient has a known lamivudine-resistant strain. In these patients, no data exist about

treatment with interferon and other agents associated with a low risk of viral resistance (e.g., adefovir, tenofovir, and entecavir). This being said, these agents are often used in patients with lamivudine-resistant HBV for lack of an alternative. Famciclovir, when added to lamivudine, may potentiate the antiviral effect (143). In addition, HBV replication has been shown to be suppressed by ganciclovir, which is given for CMV infection, although use of this drug primarily for HBV is not recommended (144). The length of treatment in all cases is also unknown. Those with reactivation during immunosuppression withdrawal should be treated until immunosuppressive agents are tapered or discontinued and for an undefined period thereafter.

Prevention

If possible, patients with chronic HBV should be treated before HCT with the goal of undetectable virus at the time of HCT. In this setting, treatment should be continued in patients long after engraftment and immunosuppression withdrawal. Patients who cannot wait until viral clearance with treatment should be given antiviral prophylaxis as soon as possible, at least 1 week before HCT. Recipients with surface antigen who are given lamivudine prophylaxis have a significantly higher 1-year survival (94% vs. 54%) and lower incidence of hepatitis flares (5% vs. 45%) and acute liver failure (0% vs. 15%) compared to those given no prophylaxis (145,146,147). A small study showed that famciclovir prophylaxis was associated with less reactivation and death than no prophylaxis (148). Another strategy involves vaccinating donors immediately before and/or after HCT. Seroconversion rates are surprisingly acceptable even in the period of

intense immunosuppression (149). This may prevent HBV flares once seroconversion takes place.

Hepatitis C Virus

The prevalence of HCV in HCT recipients is highly variable in the literature depending on patient number, year of publication, and indications for HCT. The largest study involving 63 transplantation centers reported that 5% of HCT patients were HCV antibody positive, although other studies have shown much higher percentages (31% to 51%), particularly in patients with thalassemia (150,151,152). Seventeen percent to 24% of patients are HCV ribonucleic acid (RNA) positive before HCT (67,151,153). HCV has been shown to be the etiologic factor in up to 50% of chronic liver disease after HCT (3). Most HCT recipients acquire HCV from previous blood transfusions, although donor-to-recipient transfer may occur in the setting of high donor HCV RNA levels (154). Transmission of HCV is currently low because of newer-generation HCV antibody testing and treatment of donors (87,155).

Risk of acute flare

Unlike HBV, patients rarely develop acute hepatitis or fulminant hepatic failure with withdrawal of immunosuppression after HCT (67,156,157,158). Although a common cause of chronic liver disease, HCV alone is not a predictor of the development of liver failure in patients undergoing HCT (159). However, HCV-positive recipients with abnormal liver enzyme levels before HCT have an increased risk of SOS-related liver failure and death (67,160). Therefore, patients with HCV should be monitored carefully for the development of SOS after HCT.

Treatment

Data about HCV treatment after HCT are sparse. One study involved 11 patients, 24 to 65 months post-HCT, who were treated with interferon for 6 to 12 months (161). Ten of 11 completed the protocol; 40% had a sustained virologic response and 50% had improved liver histology. Another smaller study of four HCT patients showed a 50% end-of-treatment response rate at 12 months with ribavirin monotherapy (162).

Long-term prognosis

Progressive fibrosis and clinical deterioration from HCV has been reported in multiple studies in HCT recipients (153,163,164,165). The median time to the development of cirrhosis is significantly shorter in HCT recipients—18 years compared to 40 years in non-HCT controls (166). Other studies have shown that HCV does not lead to higher morbidity and mortality long term after HCT (67,167). What might differentiate those with mild liver disease from those with progressive fibrosis is the hepatic iron load, particularly in patients undergoing transplantation for thalassemia. Patients with HCV and heavy iron deposition have a significantly higher incidence of hepatic fibrosis than those without iron deposition (168). Other potential risk factors for progression are HCV genotype and the presence of extrahepatic manifestations of HCV (166,169).

Iron Overload

Iron overload may be responsible for a significant percentage of chronic liver disease in patients after HCT (3,170). Hepatic iron content increases shortly after

HCT and is associated with an elevated ferritin level (171,172). However, progressive fibrosis due to hepatic iron deposition in HCT recipients is most commonly seen in patients with a pre-HCT history of iron overload from multiple blood transfusions (thalassemia) (173). Studies have also shown that the presence of severe iron overload significantly impacts survival and transplantation-related mortality (174,175). Those

who have hepatomegaly and fibrosis before HCT will invariably develop progressive iron overload and fibrosis years after HCT (173). This degree of progression correlates well with the hepatic iron content and the presence of HCV (168).

The diagnosis of iron overload is often made by an elevated ferritin and transferrin saturation. Liver biopsy may not be necessary in the right clinical context, although hepatic iron stores often reflect total body iron stores accurately and may give prognostic information (176). Iron overload suggestion on MRI examination is common after HCT and may correlate with the number of previous blood transfusions (177).

Initial detection of significant iron overload may identify those patients at highest risk for adverse post-HCT outcomes. In small studies, early iron reduction with phelobotomy or iron chelation therapy has been shown to be safe and effective in maintaining low ferritin levels immediately after HCT (178,179,180). Iron reduction is, however, better tolerated after HCT when adequate return of red cell production by the bone marrow occurs. Studies have shown significant improvements in ferritin level, transferrin saturation, liver enzyme levels, hepatic iron concentration, and fibrosis scores in patients with undergoing phlebotomy years after HCT (5,176,181).

Common Causes of Cholestasis

Sepsis

Sepsis of any cause, particularly in the setting of neutropenia or high levels of immunosuppression, may lead to biochemical liver abnormalities and cholestasis (182). The pathophysiologic features of cholestasis of sepsis are similar in the general and transplantation populations. Canalicular cholestasis is the most common histologic finding, typically with dilated periportal ductules and occasionally inspissated bile in cholangioles. Other nonspecific findings include steatosis and pericentral ischemic necrosis, potentially related to poor perfusion from sepsis (183). In severe septic shock, jaundice may be marked. Laboratory studies have shown that cytokine release in the circulation related to bacterial lipopolysaccharides downregulates bile acid transport and bile secretion (184). Ductal obstruction resulting in jaundice can be easily differentiated from cholestasis of sepsis by ultrasonography and histologic features of nonsuppurative cholestatic injury (185). Resolution of sepsis invariably results in normalization of bilirubin and cholestasis.

Total parenteral nutrition

Determining that total parenteral nutrition (TPN) is the primary cause of cholestasis after HCT is challenging. Multiple other factors are often present, such as sepsis, drugs, viral infections, and GVHD. Cholestasis related to TPN is much more common and severe in infants compared to older children and adults. Typically in adults, increases in levels of serum transaminases, alkaline

phosphatase, and γ-glutamyl transpeptidase (GGT) are seen within 3 weeks of TPN initiation and return to normal in over 75% of patients (186,187). The most common histologic abnormalities include intrahepatic cholestasis, portal/periportal fibrosis, and periportal macrovesicular steatosis (188). This fibrosis may persist but does not generally progress after TPN discontinuation. Progression to cirrhosis and the development of clinically significant liver disease is uncommon in adults receiving long-term TPN. The initial management of TPN cholestasis involves reduction of dextrose content in TPN with conversion to more lipid-based calories and cycling infusions to allow "TPN-free" periods to improve biliary flow. Progressive cholestasis, despite these measures, should warrant discontinuation of TPN if possible.

Drugs

Numerous medications given after HCT can lead to intrahepatic cholestasis and liver test abnormalities. Hepatotoxic agents cause either dose-dependent intrinsic liver injury or dose-independent idiosyncratic toxicity, often related to an immunologic or metabolic reaction. Many chemotherapeutic agents and corticosteroids can cause steatosis, SOS, cholestasis, and/or hepatocellular injury. Prophylactic or therapeutic anti-infective agents such as sulfonamides, macrolides, cephalosporins, penicillins, and azole antifungals can lead to significant cholestasis, vanishing bile duct syndrome, or phospholipidosis. High doses of nonsteroidal anti-inflammatory drugs (NSAIDs), such as sulindac, diclofenac, and indomethacin, may cause cholestasis and/or hepatocellular injury. Lastly, agents used for GVHD, for example, cyclosporine and less commonly tacrolimus, can lead to cholestasis in the setting of high serum and tissue levels of these agents (189). Histologic changes consist of bile duct epithelium hypertrophy with cytoplasmic vacuoles and foamy deposition within the hepatic sinusoids. In rat models, cyclosporine decreases bile flow and bile salt secretion (190).

Uncommon Complications

Herpesvirus Infections

Although herpesvirus infections are well described in HCT recipients, the literature, specifically on hepatic involvement, is sparse. Whether this represents a lack of reporting or a true low incidence is unknown. Advances in antiviral prophylaxis and early recognition

and treatment are major factors lowering the risk of viral dissemination.

Herpes simplex virus 1 and 2

Fulminant hepatitis due to herpes simplex virus (HSV) early after HCT has been reported, although incidence data specific for herpes hepatitis in this population are not available (191). Risk factors for reactivation include pretransplantation conditioning, HSV seropositivity, and a history of leukemia (192). Herpes hepatitis typically causes massive coagulative necrosis with purple nuclear inclusions surrounding the regions of necrosis. Skin lesions are not always present, making the diagnosis more difficult. HSV DNA detected in peripheral leukocytes is more specific for disseminated infection (e.g., esophagitis, hepatitis) and may have predictive value when its level is rapidly rising (193,194).

Immediate treatment with intravenous acyclovir is warranted. Prophylactic strategies after HCT, including use of acyclovir and its derivatives, have been shown to lower the incidence of HSV infections in general. However, the effect of prophylaxis on viral dissemination, including hepatitis, has not been reported probably because of the low incidence of this complication (195,196,197). Acyclovir- and foscarnet-resistant HSV strains have been increasing with use of prophylaxis, although they have not been associated with a higher risk of dissemination (195,198,199).

Varicella zoster virus

The incidence of VZV infections has been declining, likely because of antiviral prophylaxis and less intense immunosuppression (200,201,202). Although the overall incidence of disseminated VZV after transplantation has been reported to be approximately 5%, those who develop skin lesions (chicken pox) have a greater chance (11% to 33%) of subsequently developing organ involvement. (200,203,204). Infections typically occur within the first year of transplantation and often occur in the setting of GVHD, pretransplantation VZV seropositivity, and recent discontinuation of antiviral prophylaxis (37,200,201,203,204,205). Similar to HSV, VZV dissemination without skin involvement can occur in the presence of high VZV DNA levels (206,207). Clinically, patients with VZV hepatitis may present with severe abdominal pain and significant liver enzyme level elevation (208). Fulminant hepatic failure from varicella hepatitis, although uncommon, has been reported after HCT (209). Hepatic lesions are similar to HSV hepatitis, with necrosis and a paucity of significant inflammation. Electron microscopy, immunocytochemistry, and polymerase chain reaction (PCR) analysis may help differentiate VZV from other herpesviruses (183).

Morbidity after VZV infections is high. However, with prompt antiviral treatment, death from dissemination is rare (200,203,204,205). Acyclovir is the drug of choice for treatment (210). For prophylaxis, acyclovir reduces VZV reactivation significantly, although VZV can occur soon after prophylaxis is stopped. Longer-term prophylaxis may be considered in patients at high risk for VZV (i.e., previous zoster, GVHD) (201). Varicella vaccination given before and after HCT has been shown to significantly reduce zoster infections and the potential for viral dissemination (211,212).

Epstein-Barr virus

Infection with Epstein-Barr virus (EBV) after HCT rarely involves the liver alone. Proliferation of EBV in the setting of high immunosuppression, antilymphocyte therapy, and T-cell depletion results in B-cell proliferation and the potential for post-transplantation lymphoproliferative disorder (PTLD) (213,214,215,216). Critical to controlling EBV proliferation is the presence of $CD8^+$-specific T cells (217,218). Clinical signs, such as fever, lymphadenopathy, splenomegaly, weight loss, abnormal aminotransferase levels, and bone marrow suppression, are common. Histopathology shows a diffuse lymphocytic infiltrate in the sinusoids and occasionally focal apoptotic cells (219). Rapid increases in serum EBV DNA levels greater than 10^4 is highly associated with the development of PTLD after HCT, suggesting the need for monitoring viral load (220,221,222,223). In addition, rapid reduction in DNA levels with treatment predicts a successful response (224).

Studies have shown that preemptive treatment with an anti-CD20 antibody, rituximab, when EBV DNA levels greater than 10^3 or $CD8^+$ responses to EBV are

detected, may prevent the subsequent development of PTLD (218,225,226). Infusion of EBV-specific cytotoxic T cells at the time of HCT or at peak EBV viral load may reduce viremia and the risk of PTLD (227,228). Polyclonal EBV infections typically respond to reduction in immunosuppression, while various treatments for PTLD have had varied success, including rituximab, standard lymphoma chemotherapy, ganciclovir, and α-interferon (229,230).

Cytomegalovirus

Little data exist on the incidence of CMV hepatitis after HCT. A higher rate of CMV infection is seen in recipients of CD34-selected peripheral blood stem cell transplants, alemtuzumab infusions, and transfusions without leukocyte depletion or CMV screening (231,232,233,234,235). Patients may present with a variety of signs and symptoms, including fever, cytopenia, colitis, pneumonitis, and abnormal transaminases. The pathognomonic findings are an enlarged hepatocyte, bile duct epithelium or endothelial cell containing

cytoplasmic basophilic granules, and an intranuclear inclusion surrounded by a clear halo (“owl's eye”). Blood CMV DNA testing is more sensitive than culture or antigen testing and may predict the development of CMV end-organ disease.

Antiviral prophylaxis after HCT, including acyclovir, valacyclovir, ganciclovir, and valganciclovir, are all highly successful in reducing the incidence of CMV infection (236,237,238,239,240). Intravenous ganciclovir is the treatment of choice for known infections, with foscarnet given for known ganciclovir-resistant strains. Another approach (preemptive) is to closely monitor for CMV infection by culture, antigen, or DNA and only treat once CMV is detected (241,242,243). Compared to culture, monitoring CMV DNA frequently after HCT and treating once DNA is detected has been found to reduce the subsequent development of symptomatic CMV disease and related mortality (244,245,246). Isolation and donor transfer of T cells with specific activity against CMV target antigens may reconstitute cellular immunity against CMV and may represent a novel approach for future treatment (247,248).

Human herpesvirus-6

Infection with human herpesvirus-6 (HHV-6) in transplant recipients may result in a lobular, nonspecific hepatitis (183,249). This virus can be transmitted from donor to recipient, resulting in an early post-transplantation hepatitis (250). The detection of HHV6 early after HCT may be associated with delayed engraftment (251). A high percentage of HCT recipients have HHV6 viremia, but symptoms and disease specifically related to HHV6 are uncommon (252). Bone marrow suppression and gastrointestinal involvement are the most common presenting signs. Cidofovir and foscarnet appear to have the highest antiviral activity against HHV6 (253).

Adenovirus

Adenovirus infection after HCT is rare but may lead to acute hepatic failure in the setting of induction chemotherapy, high levels of immunosuppression, and GVHD (254,255,256,257,258). Overall, adenovirus infection is seen in up to 5% of recipients and presents in a manner similar to that of CMV, with pneumonia, gastroenteritis, hepatitis, and less commonly encephalitis and hemorrhagic cystitis (257,258). Fulminant hepatic necrosis with intranuclear inclusions is seen. Differentiating adenovirus from HSV hepatitis can be difficult and is aided

by electron microscopy and immunohistochemical staining (256). Treatment with antiviral agents, such as cidofovir and ribavirin, has had limited success (255,259).

Hepatitis G Virus

Hepatitis G virus (HGV) is a transfusion-transmitted flavivirus often seen in HCT recipients with HCV. A significant percentage (15% to 48%) of transplant recipients have detectable HGV RNA levels before and after HCT (153,260,261,262,263). The only real consequence of HGV infection may be delayed transplant engraftment (264). Although higher transaminase levels may be seen in HCT recipients with HGV, clinically significant hepatitis or chronic liver disease is not thought to be caused by HGV alone (261,263,265). The hepatic complications of HGV infection may only be a result of HCV coinfection (153,260). No specific treatment is recommended in HGV-infected HCT recipients. While treatment with interferon for HCV may clear HGV in immunocompetent patients, it is not known whether this occurs in immunocompromised HCT recipients (266,267). It is also not know whether HCV is more difficult to treat in HCT patients with HGV.

Fungal Infections

In the early days of HCT, up to 9% of cases were found on autopsy to have fungal involvement of the liver (268). Currently, this entity, particularly hepatosplenic candidiasis, is uncommon after HCT and more commonly seen in patients before HCT. Risk factors for fungal liver involvement after HCT include superficial infections, deep fungal infections, and severe liver dysfunction from SOS or GVHD (268). The most common fungal infections involving the liver are candidiasis, aspergillosis, and zygomycosis, but other mycoses, such as cryptococcosis, histoplasmosis, blastomycosis, and coccidiomycosis, can be seen depending on the regional prevalence. Hepatosplenic candidiasis can present with multiple portal and periportal abscesses and granulomas, with yeast and hyphae present in the sinusoids (183). Before HCT, patients can be treated aggressively with amphotericin to eradicate candidiasis and still successfully undergo HCT (269,270). Aspergilli (*Aspergillus fumigates* and *Aspergillus flavus*) can cause hemorrhagic hepatic necrosis and local infarction because of blood vessel invasion (183). Zygomycosis is an infection caused by a group of fungal organisms, such as *Rhizopus*, *Mucor*, and *Absidia*, which can proliferate in the setting of immunosuppression and transplantation. Similar to aspergillosis, widespread vascular invasion from zygomycosis causes ischemic necrosis and multiple, necrotic hepatic nodules.

Assessing the size, morphology, and special staining on histology typically confirms the diagnosis of fungus in the liver. Culture of liver tissue and blood, although often of low yield, is the most specific test. Others have proposed using panfungal PCR assays to allow for a rapid early diagnosis (271). Imaging tests such as ultrasonography and computed tomography (CT)

scan, particularly for hepatosplenic candidiasis, may provide additional evidence for invasive hepatic infections, although the sensitivity is quite low (268,272). Fungal abscesses can only be seen on imaging tests after neutropenia resolves post-transplantation. The treatment of invasive hepatic infections depends on the organism and includes the use of amphotericin B, azole antifungals, and echinocandins. Post-HCT prophylaxis with itraconazole, fluconazole, or low-dose

amphotericin can significantly reduce the incidence, morbidity, and mortality associated with invasive fungal infections (273,274,275).

Biliary Complications

Gallbladder disorders

While gallbladder sludge and cholelithiasis are commonly seen in HCT recipients, complications such as cholecystitis, gallstone ileus, and choledocholithiasis are uncommon (98,276). Gallbladder sludge after HCT contains nonspecific residue, calcium-binding protein, and calcium bilirubinate crystals (277). The formation of sludge occurs early after HCT and often progresses to stone formation, unrelated to the conditioning regimen or gallbladder contractility (278). Cholecystitis can occur after HCT in a small percentage of patients with gallstones and is treated with either cholecystectomy or nonsurgical measures (e.g., antibiotics, percutaneous drainage) in poor surgical candidates (279,280). Acalculous cholecystitis is even less common and may be associated with prolonged fasting, SOS, transfusions, and the use of TPN (280,281). If possible, the best chance for survival is cholecystectomy as acalculous cholecystitis is associated with gallbladder wall necrosis and perforation.

Biliary obstruction

New hepatobiliary abnormalities are common in the first few months after HCT and are often multifactorial (98). Diagnosing biliary obstruction as a cause of jaundice may be difficult when other disorders are present and bile ducts are not particularly dilated on imaging. The incidence of biliary obstruction after HCT was reported to be 0.1% in one large study involving two major transplantation centers (282). Of the small number of cases reported, the etiologies were biliary sludge, choledocholithiasis, duodenal hematoma, stricture, recurrent malignancy, and EBV-associated PTLD (282). Chronic GVHD and peribiliary chloroma may also cause biliary obstruction (283,284). An experimental model of GVHD in mice has shown that the early nonsuppurative lymphocytic cholangitis may evolve into ductal fibrosis of intra- and extrahepatic bile ducts, similar to that seen in primary sclerosing cholangitis (285).

Tumor Infiltration

Recurrent and secondary malignancies can involve the liver after HCT. Leukemia and lymphoma may infiltrate the liver, leading to hepatomegaly and high levels of alkaline phosphatase (286,287,288). Solid cancers occur almost twice as frequently in HCT recipients than the healthy population (289). Hepatocellular carcinoma may occur at a higher rate after HCT in patients with HBV, HCV, or cirrhosis of any cause (289). Bile duct adenocarcinoma leading to obstructive jaundice after HCT has also been reported (290). Biopsy is important in differentiating malignancy from infections and regenerative nodules (291).

Nodular Regenerative Hyperplasia

Nodular regenerative hyperplasia is characterized by idiopathic, non-neoplastic nodule formation in the absence of hepatic cirrhosis. Most nodules are less than 1.0 cm in size and distort the hepatic architecture enough to cause portal hypertension. The diagnosis after HCT is often confused with that of SOS and can sometimes only be determined on laparotomy or autopsy (292,293). Ascites is the most common portal hypertensive complication. The etiology is unknown and

is not thought to be related to age, the underlying disease, or cytoreductive regimens (292). The treatment is directed at the symptoms related to portal hypertension. Nodular regenerative hyperplasia may resolve spontaneously months after HCT and typically does not contribute to significant morbidity or mortality (292).

living donor 1451 1453 1454 1461–1462
indication for 1274
patients selected for 1461
use of 602
long-term management of 1450–1451
mortality risk 1454
ongoing controversies 1519
orthotopic 350 1070 1077
outcome of 492
overview of 1521
pediatric considerations 1460
posttransplantation, survival results 1456
preanhepatic stage of 358
during pregnancy 1297
prevention of hepatitis B after 1494
psychological improvement after 1490
recipient procedure 1512–1513
recipient results of 1519–1521
recurrent disease 1451–1452
reduced-size 1513
retransplantation 1451–1452
right lobe 1520
risk factors 492
selection and timing of 1449 1453–1462

selection criteria for 615–619
split 1511 1513–1516
ex vivo techniques for 1514–1515
in situ techniques for 1515
results of 1515
steroids 1471
surgical options 1451
surgical options of 1511–1521
thrombosis rates in randomized trials using antifibrinolytic agents in 359
timing of 1461–1462
treatment of osteoporosis after 1495
waiting list, probability of removal from 1458
Liver transplantation surgery, hemodynamic changes 321
Liver transplantation therapy, application of 1454
Liver tuberculosis 1414
Liver tumors 928
benign 1296
Liver X receptor (LXR), major ligands of 643
Liver–kidney microsomal-1 (anti-LKM-1) antibody 1328
Living donor liver transplantation (LDLT) 1462 1511 1516 1529
Living donor right lobe graft, technique for procurement of 1518–1519
Living donor right lobe transplantation, morbidity after 1521
Living donor transplantation 1037
in adult recipients 1516–1517

LKM *See* Anti–liver/kidney microsomal (LKM)

Weight-reduction surgery 1146
Weil disease 1385
Wernicke's encephalopathy 1285
Wernicke-Korsakoff encephalopathy 590
White blood cells (WBC) chemoattraction 403
WHO *See* World Health Organization (WHO)
WHV *See* Woodchuck hepatitis virus (WHV)
WHVP *See* Wedged hepatic venous pressure (WHVP)
Wilson disease 97 138 266 294 294 322 330 569 607 618 867 1023–1038 1141 1188 1254 1296
  clinical manifestations of 1034–1035
  clinical presentations of 1034
  copper metabolism and pathophysiology of 1026
  diagnosis of 1023 1031–1033
  diagnostic tests in 1032
  end stage 295
  fulminant 46

hepatic failure in 1023
presentations of 602
gene, isolation and identification of 1025
genetics of 1024–1025 1024
hepatic pathology of 1027–1029
history of 1023–1024
homozygotes 1024
light microscopic findings in liver 1028
molecular genetic studies of 1033
molecular testing 1031
neuropathology of 1029
pathologic changes of 1029–1031
pathology of 1027–1031
pathophysiology of 1025–1027
pharmacologic treatments for 1035
pharmacotherapy for 1037
recognition of 1024
structural features of 1025
symptoms of 1034
tissue damage in 294
treatment of 1035–1038
albumin dialysis 622

ultrastructural studies of 1033–1034
Wilson index 1460
Wilsonian fulminant hepatitis 1034
Wing-beating tremor 18
Wolman's disease 250 290 1314–1315
Woodchuck hepatitis virus (WHV) 765
World Health Organization (WHO) 749
