Editors: **Schiff, Eugene R.; Sorrell, Michael F.; Maddrey, Willis C.**
Title: ***Schiff's Diseases of the Liver, 10th Edition***

Dedication

We dedicate this tenth edition of Diseases of the Liver *to Telfer B. Reynolds, who was a great teacher, mentor, clinician and contributor to the science and practice of hepatology. Furthermore, we dedicate this edition to our wives Dana, Shirley and Ann for their continuing support of our endeavors.*

Editors: **Schiff, Eugene R.; Sorrell, Michael F.; Maddrey, Willis C.**
Title: ***Schiff's Diseases of the Liver, 10th Edition***

Preface to the First Edition

In the recent words of Himsworth, the present time seems to be particularly opportune for reviewing our knowledge of liver disease. A partial list of reasons would include the advances made in the fundamental sciences as they pertain to liver structure and function; the advances in the experimental approach to liver disease; the increased knowledge in the field of viral hepatitis; the newer clinical criteria and concept of hepatic coma, with attention focused on disturbance in the metabolism of ammonia; a better understanding of the pathogenesis and the treatment of cirrhosis; a clearer concept of the metabolic defect in hemochromatosis and the apparent effectiveness of depleting iron stores in the treatment of this disorder; the implication of disturbed copper metabolism in hepatolenticular degeneration; the increasing experience with needle biopsy of the liver; and the surgical attack on portal hypertension.

This book is not intended to be encyclopedic in nature but rather the expression of present-day information pertaining to various aspects of liver disease by a group of authors particularly qualified by their experience, interest, and scientific contributions. The reader may discover certain omissions, but he usually will find these to be matters of lesser importance. He will be more than compensated by the quality of the information contained, which deals with those aspects of hepatic disease that are much more apt to concern him, including the description of the principles of treatment, both medical and surgical, by experts in the field. Furthermore, he will frequently find it unnecessary to consult other books, particularly on points dealing with basic concepts.

To various contributors the editor expresses his deep gratitude for their excellent and willing cooperation. He has considered it good fortune indeed to have been associated with them in this undertaking. He wishes to express his thanks to Cecil J. Waston, Arthur J. Patek, Jr., and to his colleague, Edward A. Gall, for their helpful suggestions.

Leon Schiff

Editors: **Schiff, Eugene R.; Sorrell, Michael F.; Maddrey, Willis C.**
Title: ***Schiff's Diseases of the Liver, 10th Edition***

Preface

The editors trust that this 10th edition of *Diseases of the Liver* provides an accurate assessment of the many states of the art in hepatology. The platform on which hepatology is based has never been sturdier. The depth of understanding of many processes that take place in the liver and the multiple factors that affect them give us hope that ever more successful ways to diagnose and treat a variety of liver disorders is in the offing.

The clinical patterns and natural history of many liver diseases are now quite well described. The complex interactions that affect the course the individual patient with a liver disorder might follow are being assessed and to an ever-increasing extent understood. The 10th edition is introduced by a presentation of an approach to the evaluation of the patient with known or suspected liver disease utilizing history, physical examination, and widely available biochemical, serologic, and imaging studies. The 10th edition ends with a series of chapters on the present status of liver replacement. In between are remarkable chronicles of progress and the posing of questions yet to be answered. The foundations of hepatology based on clinical chemistry, imaging, and the power of properly interpreted liver biopsies are well described.

Considerable attention is paid to the hepatitis viruses and the consequences of infections with each. For hepatitis C, diagnostic and assessment methods are well established. The remarkable emergence of the story of hepatitis C is well told and embroidered in several chapters. The importance of hepatitis C genotype and the level of HCV RNA on outcome and likelihood of treatment success is emphasized. The ability to treat chronic hepatitis C has improved greatly during the last decade and new antiviral and immunomodulatory approaches are likely to emerge in the near future. What is missing for hepatitis C is an effective vaccine. The complex interactions between hepatitis C and other viruses have been recognized and the apparent synergistic effect of hepatic injury from hepatitis C and alcohol on fibrosis is an area receiving great attention.

Furthermore, interest in hepatitis B has never been higher. For hepatitis B, there are effective vaccines that have proved to be life

changing in areas of the world where programs that ensure availability and utilization of vaccines have been successful. However, there are millions of patients already infected with hepatitis B and many are destined to succumb to the complications of cirrhosis or hepatocellular carcinoma unless further progress in therapeutic development occurs.

The importation of ideas from basic science and many disciplines and clinical lessons learned from other specialties are apparent throughout the book. One area of interest clearly influences another. The role of viruses and the response to the presence of the viruses in the development of hepatocellular carcinoma is a fascinating field. There has been a veritable explosion of the number of cases of hepatocellular carcinoma, especially those related to hepatitis C over the last few years.

The ability of an individual to favorably respond to an environmental insult (be it a virus or a chemical) is attracting considerable interest. In drug-induced liver disease, early (innate) responses may well determine whether a patient has a transient perturbation in the liver or develops a devastating illness.

Then there is the focus on the many roles and consequences of fat in the liver. Once considered benign, fat deposition in the liver is now viewed as a potential cause of cirrhosis and even a precursor of hepatocellular carcinoma. The stories of the interactions of fat and fibrosis have overtones of genetic influences, as well as associations with other disorders grouped as the metabolic syndrome, which are clearly of growing importance.

The ever-increasing importance of liver transplantation is recognized in this edition, with a separate section devoted to topics of importance to the clinician caring for patients before and after liver transplantation. We have fashioned a book within a book regarding liver transplantation and trust this section will provide a comprehensive resource without the necessity to refer to more specialized references sources.

There is much more to be discovered and assimilated about the liver in the near future. Ways to modulate gene expression, understand (and even regulate) the many roles of nuclear receptors, the interactions of cytokines and hepatic growth factors, and the roles of metals and minerals— all these and many more areas are discussed in the 10th edition.

The editors and the authors are pleased to present this 10th edition. Differences are being made that will be life changing for patients with liver diseases. These are the best of times for those interested in the liver.

Eugene R. Schiff

Michael F. Sorrell

Willis C. Maddrey

Title: ***Schiff's Diseases of the Liver, 10th Edition***

Chapter 1

History Taking and Physical Examination for the Patient with Liver Disease

Norton J. Greenberger

Key Concepts

- In the care of patients with jaundice, a careful history, physical examination, and review of standard laboratory tests should allow a physician to make an accurate diagnosis in 85% of the cases.
- The triad of findings of splenomegaly, ascites, and an increased number of venous collateral vessels on the anterior abdominal wall indicates a diagnosis of portal hypertension.
- The presence of two physical findings (ascites and evidence of portal-systemic encephalopathy [asterixis]) and two laboratory findings (hypoalbuminemia [<2.8 g/dL] and a prolonged prothrombin time [>3 seconds]) indicates a diagnosis of cirrhosis of the liver.
- Three physical findings (parotid enlargement, gynecomastia, and Dupuytren's contracture) indicate that a patient is almost certainly consuming excessive amounts of alcohol.
- In adult patients with a new onset of jaundice, eight disorders account for 98% of the ultimately established diagnoses. They include viral hepatitis, alcohol-induced liver disease, chronic hepatitis (all causes), drug-induced liver disease, gallstones and their complications, carcinoma of the pancreas, primary biliary cirrhosis, and primary sclerosing cholangitis. By the time patients with metastatic liver disease have jaundice, the diagnosis should be obvious because the liver has been extensively replaced by tumor.

Jaundice is a common presentation among patients with liver and biliary

tract disease. The terms *jaundice* and *icterus* are used to designate skin and eyes appearing yellow resulting from the retention and deposition of biliary pigments (biliary monoglucuronides and diglucuronides). Although bilirubin stains all tissue, jaundice is most evident in the sclerae, face, and trunk. Jaundice is most commonly caused by parenchymal liver diseases such as viral hepatitis or cirrhosis, obstruction of the extrahepatic biliary tree as in choledocholithiasis and carcinoma of the pancreas, and less commonly, disorders associated with brisk hemolysis such as sickle cell anemia. The late Franz Ingelfinger stated in 1958 that the cause of jaundice can be identified in approximately 85% of patients after a careful study of the history and the performance of a physical examination and review of standard laboratory data. The same applies today. Table 1.1 lists the general and specific questions to ask in relation to the specific causes of liver and biliary tract disease.

History Taking for the Patient with Jaundice or Abnormal Results of Liver Tests

Anorexia is a cardinal symptom of viral hepatitis and of neoplasms involving the liver, colon, biliary tree, or pancreas. Weight loss of more than 10 pounds

(4.5 kg) should always raise the question of a neoplastic disorder.

Table 1.1. Specific Questions to Ask Patients with Jaundice or Liver Disease

RELATED TO VIRAL HEPATITIS

- Blood transfusions (especially if before 1990)
- Intravenous drug use
- Sexual practices
  - Anal-receptive intercourse
  - Sex with a prostitute
  - History of sexually transmitted disease
  - Multiple sexual partners (>5/y)
  - Intercourse with individuals with hepatitis B or C
- Contact with individuals with jaundice
- Changes in taste and smell
- Needlestick exposure
- Work in renal dialysis units
- Surgeons in trauma units or operating rooms exposed to users of intravenous drugs
- Shared razors or toothbrushes
- Body piercing (ears, nose)

Tattoos
Intranasal cocaine use

SPECIAL RISK FACTORS FOR HEPATITIS A

Travel to endemic areas
Ingestion of raw shellfish (harvested from contaminated waters)
Exposure to patients in places where clusters of hepatitis may occur (e.g., institutions, restaurants, preschool nurseries)

MEDICATION RELATED

Review all prescription medications
Ask specifically about all over-the-counter drugs
Ask specifically about vitamins (especially vitamin A)
Ask specifically about any foods, herbal preparations, home remedies purchased in a health food store

ALCOHOL USE

Obtain detailed *quantitative* history of both recent and previous alcohol use from the patient *and* family members
Question whether patient has experienced withdrawal symptoms, driving-under-the-influence convictions
CAGE (cut down, annoyed, guilty, eye opener) criteria (see text)
Check for evidence of alcohol-associated illnesses (pancreatitis, peripheral neuropathy)

MISCELLANEOUS QUESTIONS

Pruritus (suggests cholestasis either intrahepatic or extrahepatic)
Evolution of jaundice (dark urine, light stools)
Recent changes in menstrual cycle (amenorrhea suggests chronic liver disease, often cirrhosis)
History of anemia, sickle cell disease, known hemoglobinopathy, artificial heart valves
Symptoms suggestive of biliary colic, chronic cholecystitis
Family history of liver or gallbladder disease
History of inflammatory bowel disease (should raise the question of primary sclerosing cholangitis and receipt, if any, of blood transfusions)
Occupational history and, specifically, exposure to hepatotoxins

Chills and fever along with headache and myalgia should raise the question of viral hepatitis, especially type A. Chills and fever along with right upper quadrant abdominal pain suggest a diagnosis of biliary tract disease, especially choledocholithiasis and ascending cholangitis.

Arthritis can be the harbinger of viral hepatitis, autoimmune chronic

hepatitis, inflammatory bowel disease with underlying liver disease, primary sclerosing cholangitis, or granulomatous disorders such as sarcoidosis.

Fleeting skin lesions are often present in patients with viral hepatitis B. Excoriations, indicating pruritus, should raise the question of either intrahepatic or extrahepatic cholestasis, particularly primary biliary cirrhosis or primary sclerosing cholangitis. With regard to abdominal pain, the standard questions to ask concern the location, character, radiation, factors precipitating or relieving pain, and whether there are other systemic symptoms that accompany the pain. Patients should be asked to compare current abdominal discomfort with other causes of abdominal pain that they have experienced in the past (e.g., gastroesophageal reflux symptoms, non–ulcer-type dyspepsia).

Questions to be asked in relation to viral hepatitis include specific questions about blood transfusions, especially whether they were received before 1990.

The date is important because before that time no serologic tests were available for the detection of infection with hepatitis C virus. Intravenous drug use is currently the most common cause of hepatitis C. It is important to ask specifically about sexual practices, especially high-risk sexual behavior. In this regard, anal-receptive intercourse is known to be a significant risk factor for hepatitis B. Sexual practices associated with an increased risk of hepatitis C include a history of sexual relations with a prostitute, history of a sexually transmitted disease, and multiple sexual partners per year. In addition, intercourse with patients known to be positive for hepatitis B and C (e.g., spouses) is known to be a risk factor for contracting these forms of hepatitis. Contact with jaundiced individuals may be a risk factor for hepatitis A and B. Changes in taste and smell occur fairly frequently in patients with hepatitis, especially viral hepatitis A. They contribute, in a large part, to the anorexia experienced by such patients. This is in part due to a decreased sense of smell (hyposmia), perception of unpleasant smells from foods that are not ordinarily perceived as unpleasant (dysosmia), a decreased sense of taste (hypogeusia), and perception of unpleasant taste (dysgeusia). Hypogeusia is often reflected by the fact that patients may spontaneously state that they have lost their taste for cigarettes.

Health care professionals are at risk of contracting hepatitis C. This can occur through needlestick exposure, by working in renal dialysis units, and in trauma units, emergency departments, or operating rooms through surgical procedures on patients harboring the hepatitis C virus in whom that diagnosis is not immediately apparent. All users of intravenous drugs should be suspected of harboring the hepatitis C virus. Special risk factors for hepatitis C include tattoos, body piercing (e.g., of the ears and nose), history of snorting cocaine, and use of

shared razors or toothbrushes.

Special risk factors for hepatitis A include travel to endemic areas such as Mexico and Latin America and the African subcontinent, ingestion of raw shellfish that may have been harvested from contaminated waters, and exposure to patients in places where clusters of hepatitis may occur. The latter has been well documented in mental institutions, restaurants, preschool nurseries, and close living quarters. Hepatitis A can be transmitted parenterally because there is brief viremia.

Medication use, including all prescription drugs and all over-the-counter drugs, should be carefully reviewed. The constellation of clinical features that include fever, arthritis or arthralgia, rash, and eosinophilia in a patient with jaundice or abnormal results of liver tests should always raise the question of medication-induced liver disease. This can be recalled by the mnemonic FARE, which stands for fever, arthritis, rash, and eosinophilia. The patient should be asked specifically about intake of vitamins, especially vitamin A, and about any foods, herbal preparations, or home remedies purchased in health food stores. Several herbal preparations have been found to be hepatotoxic.

Detailed quantitative information should be obtained from both the patient and family members about recent and previous alcohol use. For reference purposes, 1 ounce (30 mL) of bourbon whiskey contains 10 to 11 g of alcohol, as does one 12-ounce (360 mL) container of beer or 4 ounces (120 mL) of red table wine. Each one of these can be considered as 1 unit. Ingestion of more than 3 units/day everyday or more than 21 units/week is excessive, especially for women. The threshold for alcohol-induced hepatic injury appears to be 30 g/day for women and 60 g/day for men if ingested over 5 to 10 years. These numbers may have to be modified if additional risk factors for liver disease are present (e.g., hepatitis C). One also needs to determine whether the patient has experienced withdrawal symptoms. The CAGE criteria are reliable indicators of excessive alcohol use. The CAGE criteria relate to the following four questions:

1. Has the patient tried to *c*ut back on alcohol use?
2. Does the patient become *a*ngry when asked about his or her alcohol intake?
3. Does the patient feel *g*uilty about his or her alcohol use?
4. Does the patient need an *e*ye opener in the morning?

In this regard, many patients with chronic alcoholism experience morning nausea and dry heaves. The examiner should check for evidence of alcohol-associated illnesses (e.g., pancreatitis and

peripheral neuropathy).

A history of pruritus suggests cholestasis, either intrahepatic or extrahepatic. Table 1.2 shows the differential diagnosis. The patient should be specifically asked about the evolution of jaundice (i.e., the onset of dark urine and light stools), which may provide clues to the duration of illness. Recent changes in the menstrual cycle, particularly amenorrhea, if present, suggests chronic liver disease and often cirrhosis. A history of anemia, sickle cell disease, and hemoglobinopathy should also be ascertained for African-American patients. Right upper quadrant abdominal pain should prompt detailed questions about whether such pain is consistent with biliary colic or chronic cholecystitis. A history of inflammatory bowel disease should raise the question of primary sclerosing cholangitis or, if the patient has received blood transfusions in the past, hepatitis C. An occupational history should be obtained and questions about specific exposure to a known or suspected hepatotoxin should be asked of industrial workers with jaundice or liver disease.

Table 1.2. Differential Diagnosis of Jaundice

MOST COMMON CAUSES
- Viral hepatitis
- Alcoholic liver disease
- Cholecystitis, choledocholithiasis
- Carcinoma of the pancreas

COMMON CAUSES
- Drug- or toxin-induced liver disease
- Chronic hepatitis
- Sickle cell anemia
- Sepsis
- Postoperative state
- Primary biliary cirrhosis
- Primary sclerosing cholangitis

LESS COMMON CAUSES
- Hodgkin's disease, non-Hodgkin's lymphoma
- Total parenteral nutrition
- Gilbert's syndrome (unconjugated hyperbilirubinemia rarely exceeds 3.0 mg/dL and detectable jaundice is infrequent)
- Metastatic liver disease (jaundice does not develop until >85%–90% of the liver is replaced by tumor)

CAUSES AND PRESUMED SITES OF INTRAHEPATIC CHOLESTASIS
- Liver cell (hepatocellular)
  - Viral hepatitis

- Alcoholic liver disease
- Chronic active liver disease
- α_1-Antitrypsin deficiency

Hepatocanalicular
- Drugs (androgens, phenothiazines)
- Sepsis
- Postoperative state
- Total parenteral nutrition
- Hodgkin's and non-Hodgkin's lymphoma
- Amyloidosis
- Sickle cell anemia
- Toxic shock syndrome

Ductular
- Sarcoidosis
- Primary biliary cirrhosis

Bile ducts
- Intrahepatic biliary atresia
- Caroli's disease
- Cholangiocarcinoma
- Primary sclerosing cholangitis

Recurrent cholestasis
- Benign recurrent intrahepatic cholestasis
- Recurrent jaundice of pregnancy
- Dubin-Johnson syndrome

Physical Examination of the Patient with Jaundice or Abnormal Results of Liver Tests

The key elements in the physical examination of a patient with jaundice or abnormal results of liver tests are summarized in Table 1.3. Several important clues are evident on general inspection of the patient. It should be determined whether scleral icterus is present, and this should be done in natural daylight. Scleral icterus can usually be detected if the serum bilirubin level is elevated to values greater than 3.0 mg/dL. The presence of pallor suggests anemia. Wasting suggests advanced chronic liver disease or a neoplastic disorder. Needle tracks or evidence of skin popping suggest intravenous drug abuse. The presence of skin excoriation confirms that the patient has been experiencing pruritus, which can be particularly severe among patients with primary biliary cirrhosis and primary sclerosing cholangitis. The one area where such patients cannot scratch is the interscapular area, and this is usually free of evidence of excoriation. The presence of ecchymosis or petechiae raises the question of clotting problems, especially

thrombocytopenia.

Muscle tenderness and weakness are not uncommon among patients with chronic alcoholism and alcoholic myopathy. These findings are often overlooked. When associated with severe acute pancreatitis, discoloration of the abdomen is termed the *Grey Turner's sign.* This finding implies increased likelihood of death. Other less common causes of ecchymosis include rhabdomyolysis, muscle infarction, mesentery thrombosis, strangulated bowel with extensive intestinal infarction, and massive intraperitoneal bleeding.

Table 1.3. Physical Examination of the Patient with Jaundice

GENERAL INSPECTION
- Scleral icterus
- Pallor
- Wasting
- Needle tracks
- Evidence of skin excoriations
- Ecchymosis or petechiae
- Muscle tenderness and weakness
- Lymphadenopathy
- Evidence of pneumonia
- Evidence of congestive heart failure

PERIPHERAL STIGMATA OF LIVER DISEASE
- Spider angiomata
- Palmar erythema
- Gynecomastia[a]
- Dupuytren's contracture[a]
- Parotid enlargement[a]
- Testicular atrophy
- Paucity of axillary and pubic hair
- Eye signs mimicking hyperthyroidism

ABDOMINAL EXAMINATION
- Hepatomegaly
- Splenomegaly
- Ascites
- Prominent abdominal collateral veins
- Bruits and rubs
- Abdominal masses
- Palpable gallbladder

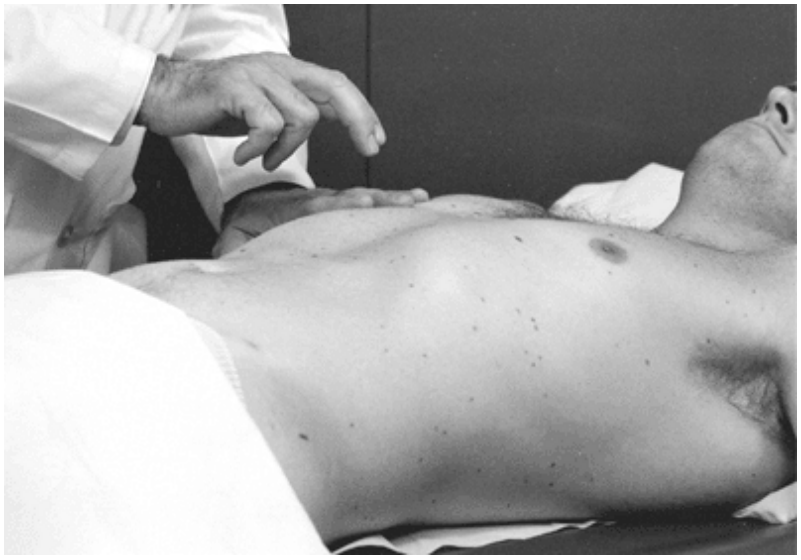
SIGNS OF "DECOMPENSATED" HEPATOCELLULAR DISEASE
- Jaundice
- Ascites

Oliguric hepatic failure
Hepatic encephalopathy
Fetor hepaticus
Asterixis
Behavioral alterations (confusion, disorientation, failure to complete simple mental tasks)

[a]This triad suggests chronic alcoholism.

The presence of lymphadenopathy, if generalized, suggests a lymphoproliferative disorder such as Hodgkin's disease or non-Hodgkin's lymphoma. Supraclavicular lymphadenopathy should raise the question of underlying malignant disease of the stomach or bronchopulmonary tract. Patients with pneumonia have jaundice in approximately 5% of cases; this is more likely to be the case among patients with pneumococcal pneumonia. Accordingly, a careful examination of the lungs is in order in the evaluation of patients with jaundice. Patients with congestive heart failure quite frequently have chronic passive congestion of the liver, which can result not only in jaundice but also in signs of portal-systemic encephalopathy.

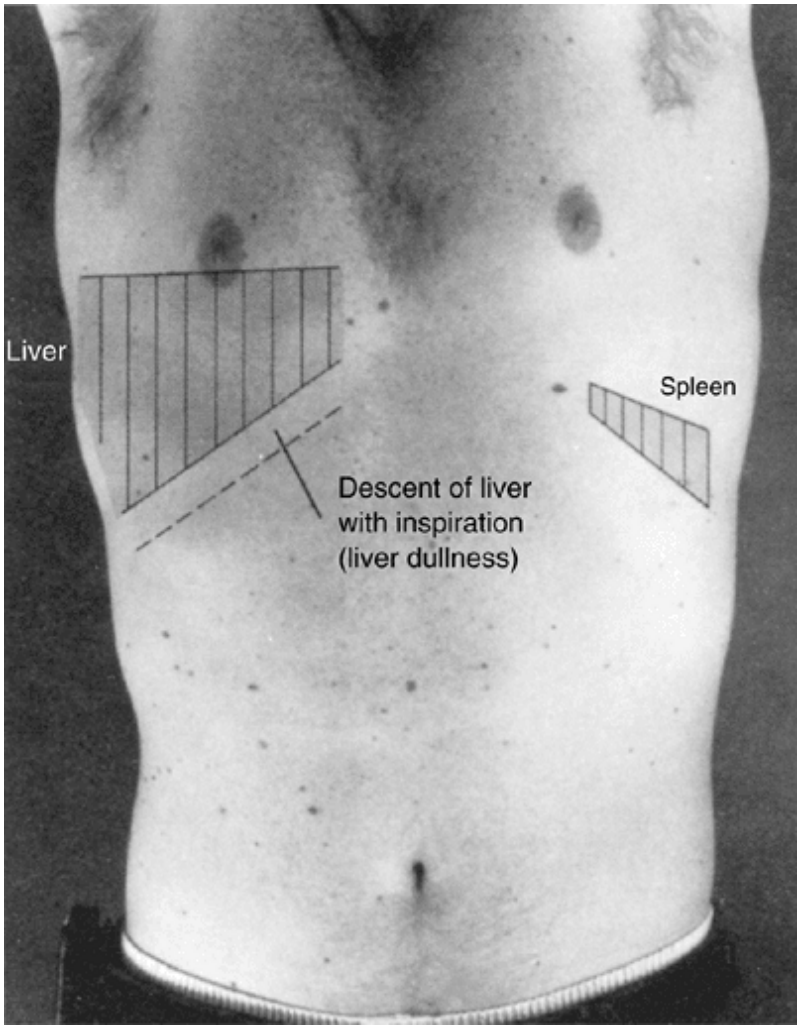
There are several peripheral stigmata of chronic parenchymal liver disease. Spider angiomata are usually found in the distribution of the superior vena cava and most commonly on the upper anterior chest, neck, face, and upper thorax. The presence of more than a dozen spider angiomata should raise the question of portal hypertension. The triad of gynecomastia, Dupuytren's contracture, and parotid enlargement should always raise the question of chronic alcoholism. Paucity of axillary and pubic hair and eye signs mimicking those of hyperthyroidism are often found among patients with advanced liver disease. Testicular atrophy, defined by a testicular diameter of less than 3 cm, is also common.



▪ **Figure 1.1** Determination of liver size by means of percussion over the lower right anterior chest and the right upper quadrant of the abdomen.

The abdominal examination is important in determining the liver size as well as the presence of an enlarged spleen. Percussion of the abdomen is important for several reasons. First, the size of solid organs such as the liver and spleen can be evaluated with percussion. One can often determine whether an increased amount of intraperitoneal fluid (ascites) is present. The upper and lower borders of liver dullness can be assessed by means of percussion along the right midclavicular line from the midchest to the midabdomen (Fig. 1.1). Liver size can be further assessed by having the patient inspire and observing the descent of the liver (Fig. 1.2). The lower border of liver dullness alerts the examiner to the site where the liver edge should be palpable. The liver span as judged by liver dullness measures 10 to 12 cm in men and 8 to 11 cm in women. A sudden decrease in liver dullness can occur in several conditions, such as viral hepatitis with the development of submassive or massive liver cell necrosis, localized dilatation of the transverse colon (as in toxic megacolon), fulminant colitis, and ileus associated with peritonitis or a perforated viscus (e.g., duodenal ulcer or diverticulitis). The spleen is normally

not palpable. Percussion over the spleen reveals an area of dullness extending from the 10th rib in the posterior midaxillary aspect to the anterior aspect of the chest (Figs. 1.2 and 1.3). When the patient inspires, the area of splenic dullness moves inferiorly and to the right.



▪ **Figure 1.2** Photograph of abdomen and chest depicts the location of the liver and the spleen as outlined by means of percussion. The liver descends 1 to 3 cm with inspiration, which is reflected by a change in liver dullness.

The detection of splenic dullness is important for the following three reasons:

1. It may indicate splenic enlargement before the spleen can be palpated.
2. It alerts the examiner to the site where the spleen may be palpated.
3. Increasing dullness of the left flank may be a valuable clue to the diagnosis of traumatic rupture of the spleen or subcapsular hematoma.

All quadrants of the abdomen must be palpated in an orderly manner. When palpating the abdomen, the hand should be warm and the palm and extended fingers of the right hand placed flat in a plane parallel to the surface of the abdomen (Fig. 1.4). The pads of the fingers are used together to perform light general palpation. Light palpation is used on the abdomen first, and as tense muscles relax, deeper palpation should be tried. Quick jabbing movements should be avoided. Any area of tenderness or any increased muscular resistance should be recognized and examined in detail.

Percussion should alert the examiner to the approximate size and lower edge of the liver. Beginning at the right iliac fossa, the right hand is moved gradually upward until the edge of the liver is appreciated (Fig. 1.4). The patient can be asked to take a deep breath slowly. The descent of the diaphragm carries the liver down, which facilitates palpation of the liver edge. The edge of the liver can be felt in most healthy individuals if the patient's abdominal wall muscles are relaxed and the patient takes a slow, deep breath. In some healthy individuals, a very low lying thin segment of the liver can be palpated in the right lower quadrant. This is termed the *Riedel lobe of the liver.* An alternative approach to feeling the edge is to gently curl the fingers of the right hand below the costal margin and ask the patient to inspire slowly (Fig. 1.5). This is termed the *Middleton method.* In this manner, the liver descent is appreciated by the fingertips. This method is important in determining minimal enlargement of the liver or a liver palpable only in the epigastrium, as can occur in advanced cirrhosis.

The examiner should determine whether the liver is soft, firm, hard, or irregular; whether the edge is rounded or sharp; whether discrete masses are present; and whether the left lobe is palpable across the midline. The presence of a palpable left lobe always denotes an abnormality, usually chronic liver disease. The size of the liver should be assessed as judged by the location of the edge below the right midclavicular line and the xiphoid. A normal liver edge is sharp, smooth, and not hard, and the left lobe is not palpable. A rounded edge suggests liver disease; a palpable left lobe suggests either chronic infiltrative or neoplastic liver disease. Modest enlargement of the liver occurs in several disorders, most notably viral hepatitis, chronic liver disease (all causes), chronic hepatitis, cirrhosis, choledocholithiasis, and extrahepatic biliary tract obstruction. Marked enlargement of the liver (edge >10 cm below the costal margin) occurs in relatively few disorders, which include (a) primary and metastatic tumors of the liver, including lymphoma, (b) alcoholic liver disease (fatty liver, alcoholic hepatitis, cirrhosis), (c) severe congestive heart failure, (d) infiltrative diseases of the liver, such as amyloidosis and myelofibrosis, and (e) chronic myelogenous leukemia. Finally, a pulsatile liver should raise the question of tricuspid regurgitation, which can occur with advanced mitral stenosis, endocarditis of the tricuspid valve, and severe

pulmonary hypertension.

Percussion of the left upper quadrant may have alerted the examiner to the presence of an enlarged spleen. Palpation of the spleen should begin in the left iliac fossa and move up to the left costal margin (Fig. 1.6). If the spleen is not felt while the patient is supine, the patient should roll onto his or her right side so the examiner can again examine the left upper quadrant (Fig. 1.7).

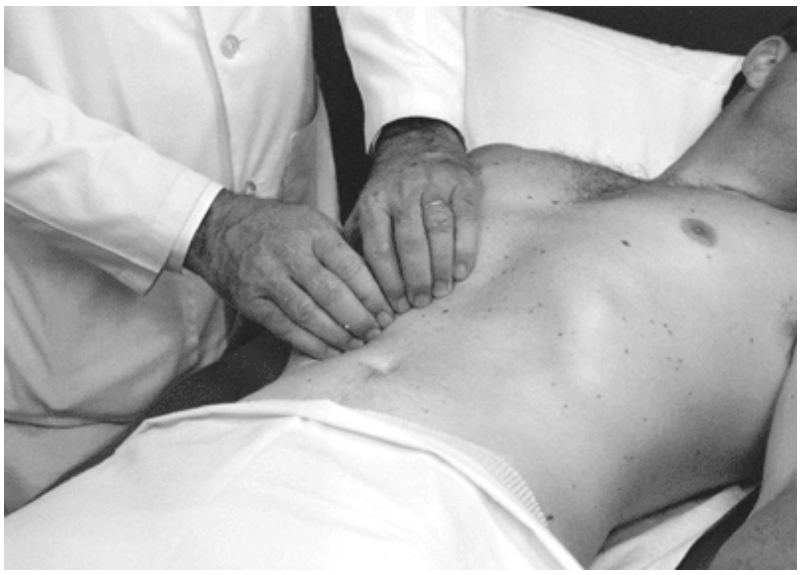
This method takes advantage of the fact that when the spleen enlarges, it becomes more easily palpable inferiorly and medially. This enlargement is better appreciated when the patient is in the right lateral decubitus position. An alternative is for the examiner to stand at the patient's right side with the patient's left hand placed under the 11th rib to elevate the thorax. The examiner then curls the fingers of either one or both hands below the costal margin and asks the patient to inspire. The splenic margin may then be felt by the fingertips.

▪ **Figure 1.3** Technique for percussion of the spleen. If splenomegaly is present, the percussion note is dull, and with inspiration, the spleen moves downward and medially and the percussion note changes accordingly.

▪ **Figure 1.4** Technique for palpation of the liver.

A common problem in evaluating left upper quadrant masses is differentiating the spleen and the left kidney. Palpation of a notch on the medial surface

suggests that the organ being palpated is the spleen. Differentiation of the left lobe of the liver from the spleen can be difficult if massive hepatomegaly is present. One can usually discern a space or open area between the two organs. Common causes of splenomegaly include the following:



▪ **Figure 1.5** Alternative technique for palpation of the liver. The best results are obtained with gentle pressure of the curled fingers on the anterior abdominal wall.

▪ **Figure 1.6** Technique for palpation of the spleen.

1. Portal hypertension caused by cirrhosis of the liver
2. Infections (viral, bacterial, fungal)
3. Leukemia, lymphoma, and Hodgkin's disease
4. Connective tissue diseases (systemic lupus erythematosus and rheumatoid arthritis)
5. Infiltrative disorders (amyloidosis and sarcoidosis)

▪ **Figure 1.7** Palpation with the patient in the right lateral decubitus position should be performed on all patients with suspected splenomegaly if the spleen is not felt with the patient in the supine position.

6. Hemolytic disorders
7. Myelofibrosis

Gallbladder

The gallbladder, when enlarged, can often be palpated in the right upper quadrant at the angle formed by the lateral border of the rectus abdominis muscle and the right costal margin. The gallbladder is palpable in approximately 25% of cases of carcinoma of the head of the pancreas (Courvoisier's law) because of painless distention of the gallbladder. The gallbladder is also palpable in approximately 30% of patients with acute cholecystitis, often because stones are impacted in the neck of the gallbladder. Often in acute cholecystitis, rather marked right upper quadrant tenderness is present, and palpation can be difficult because of intense involuntary spasms of the abdominal muscles. Percussion over the right lower anterior chest and right upper quadrant often elicits pain.

Another sign pointing to acute cholecystitis is right upper quadrant abdominal pain aggravated by inspiration (Murphy's sign). The patient is asked to inspire after the examining fingers are placed high in the

right upper quadrant; inspiration causes the gallbladder to descend and come in contact with the extended fingers, causing pain and inspiratory arrest.

Bruits

Bruits are systolic sounds usually produced by the turbulence of blood flowing through diseased or compressed blood vessels. The many causes of abdominal bruits are listed in Table 1.4. The most common causes of such bruits include calcification of the aorta, celiac axis compression, and alcoholic hepatitis. An epigastric bruit can be appreciated in 20% of healthy thin young adults, especially if auscultation is performed after a meal. Such bruits are usually caused by the compression of the celiac axis artery by muscle fibers of the crus of the diaphragm. Abdominal bruits are often important clues leading to the diagnosis of hepatocellular carcinoma, renal artery stenosis, fibromuscular hyperplasia of the renal arteries, intestinal angina, aortic aneurysm, and pancreatic cancer.

Peritoneal Friction Rub

A friction rub heard over the liver suggests the diagnosis of liver metastasis or primary hepatocellular carcinoma. Other causes of hepatic friction rub include infarction of the liver (as in sickle cell anemia and polyarteritis nodosa) and liver abscess. A transient friction rub caused by a hematoma around the puncture site is common after liver biopsy but is usually not audible 4 to 6 hours after biopsy.

Table 1.4. Causes of Abdominal Bruit

Location of bruit	Diagnostic considerations	Comment
Liver	Alcoholic hepatitis	Bruits may change day to day
	Hepatocellular carcinoma	Suspect hepatocellular carcinoma in decompensated cirrhosis with a disproportionately increased serum level of alkaline phosphatase
	Effect of surgery	

	Portosystemic shunt	
	Hepatic artery aneurysm	
	Hepatic arteriovenous fistula (trauma)	
Spleen	Splenic artery aneurysm	May see calcification in left upper quadrant on plain radiographs of the abdomen
	Splenorenal shunt	
	Splenic arteriovenous fistula	
	Calcified aorta	
Aorta	Aortic aneurysm	
	Celiac axis compression	Bruits common in thin individuals, especially after meals
	Celiac or superior mesenteric artery disease (atheroma, thrombi)	Intestinal angina characterized by the triad of (a) bruit, (b) weight loss, and (c) postprandial abdominal pain
Left upper quadrant	Pancreatic cancer (body or tail)	Bruit caused by encasement of splenic artery or vein by tumor;

		present in 25% of cases
Umbilicus	Cruveilhier-Baumgarten syndrome	Bruit caused by increased flow through umbilical veins secondary to portal hypertensions
	Renal artery stenosis (atheroma, emboli)	
	Renal artery fibromuscular hyperplasia	Bruit may be unilateral or bilateral
	Renal artery aneurysm	

Ascites

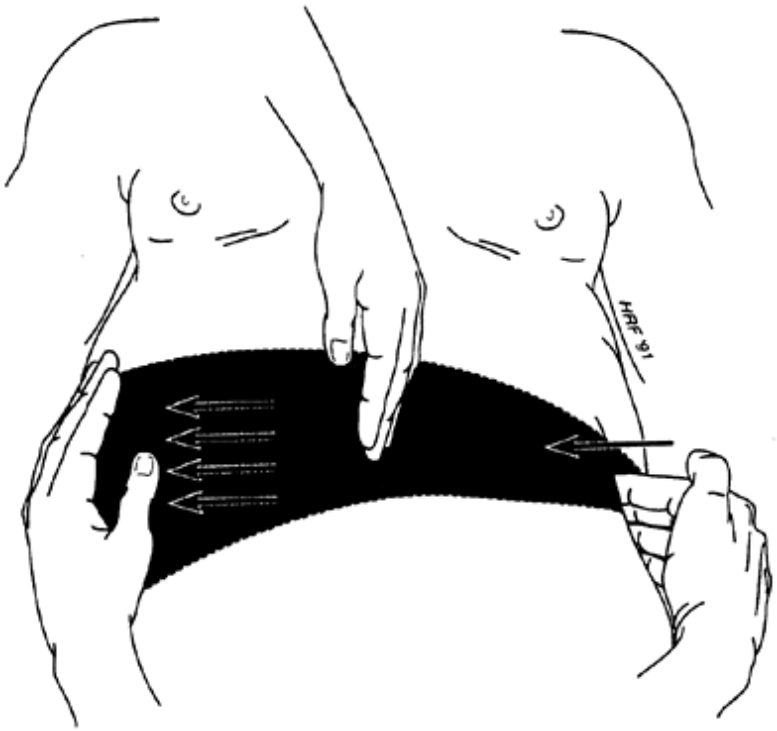
Assessment of shifting dullness is often used to determine whether ascites is present. When free fluid is present in the abdomen, such fluid gravitates to the flanks, and the intestines float upward when the patient lies on his or her back. Percussion with the patient in this position discloses tympany over the anterior abdomen and dullness over the flanks. If the patient is turned to one side, the dullness shifts, and the percussion on the side that is uppermost becomes tympanic, because that area becomes occupied by gas-filled intestine.

Another physical finding pointing to the diagnosis of ascites is the fluid wave. A fluid wave is demonstrated by tapping the left flank sharply with the right hand while the left hand is placed against the opposite flank (Fig. 1.8). Either the patient or a second examiner must place the ulnar surface of his or her hand along the midline of the abdomen. A positive test result is one in which an impulse on the opposite flank is percussed after the right flank is tapped. Neither the test for shifting dullness nor the test for a fluid wave uniformly reveals modest amounts of ascitic fluid (<1,000 mL). Indeed, both tests have a sensitivity of only approximately 60% compared with ultrasound examination. Furthermore, the test results can be spuriously positive in examinations

of obese patients.

A third sign, bulging flanks, although often present in ascites, is frequently present in obese patients as well. A fourth test of ascites is elicitation of the puddle sign. In this test, the patient lies prone for a few minutes and then moves to hands and knees. The diaphragm of the stethoscope is placed over the most dependent part of the abdomen, where puddling would be expected

to occur. The examiner then repeatedly flicks the near flank of the abdomen while moving the stethoscope toward the opposite flank. A positive test result consists of a definite change in the intensity and character of the percussion note as the stethoscope is moved.



▪ **Figure 1.8** Technique for eliciting a fluid wave. The examiner's left hand is placed on the right lateral abdomen, and the right hand taps the left flank or loin while a second examiner or the patient's hand compresses the abdomen in the midline.

The presence or absence of ascites can be confirmed most reliably with imaging procedures such as ultrasonography and computed tomography (CT). The urinary bladder is often percussed in the hypogastrium, especially if urinary retention is present.

Abdominal Masses

All nine areas of the abdomen should be palpated carefully for the presence of abdominal masses. In addition, the examiner should palpate the periumbilical area for the presence of lymph nodes. Such lymph nodes, termed Sister Mary Joseph's nodes, reflect intraperitoneal tumor and are the harbinger of peritoneal carcinomatosis.

Signs and Symptoms of Decompensated Liver Disease

Signs of decompensated liver disease in patients with cirrhosis include jaundice, ascites, portal hypertension with bleeding esophageal or gastric varices, oliguric hepatic failure, and hepatic encephalopathy. These are discussed in detail in Chapters 11, 13, and 18. A bedside diagnosis of cirrhosis of the liver can be made on the basis of two physical findings and two laboratory findings. The physical findings are ascites and asterixis, and the laboratory findings are a serum albumin level of less than 2.8 g/dL and a prolongation of the prothrombin time of more than 16 seconds.

The topic of hepatic encephalopathy is discussed in detail in Chapter 18. However, this diagnosis can be made readily at physical examination when the following findings are present:

1. Hypothermia with a temperature less than 36°C
2. Fetor hepaticus, which is a pungent odor in the breath caused by the excretion of sulfur-containing amino acid by-products such as dimethyl sulfide, methanethiol, and ethanethiol
3. Asterixis, which can be elicited by two techniques (Fig. 1.9), and abnormal cognitive functioning as evidenced by an abnormal result of a Reitan trial test or A-deletion test. The latter is performed by asking the patient to delete all the A's in one or two paragraphs of newsprint; the examiner tabulates how many A's were not deleted.

Asterixis, although characteristic of hepatic encephalopathy, is not pathognomonic of this disorder. Asterixis is also found in patients with renal failure, pulmonary insufficiency, and congestive heart failure. Patients with hepatic encephalopathy may have difficulty with seemingly simple tasks such as drawing a square, spiral, or five-cornered star or signing their names.

The diagnosis of chronic portal-systemic encephalopathy is usually established on the basis of the following five criteria:

1. Documented chronic parenchymal liver disease
2. Evidence of portasystemic shunting, occurring either naturally (varices) or following the insertion of a portacaval shunt or

transjugular intrahepatic portasystemic shunt

3. Behavioral alterations that can range from subtle abnormalities in cognitive functioning to frank unresponsive coma
4. An abnormal result of an electroencephalogram showing a decrease in mean cycle frequency
5. Improvement in mental status after measures directed at altering gastrointestinal ammonia metabolism, such as with dietary protein restriction or lactulose therapy.

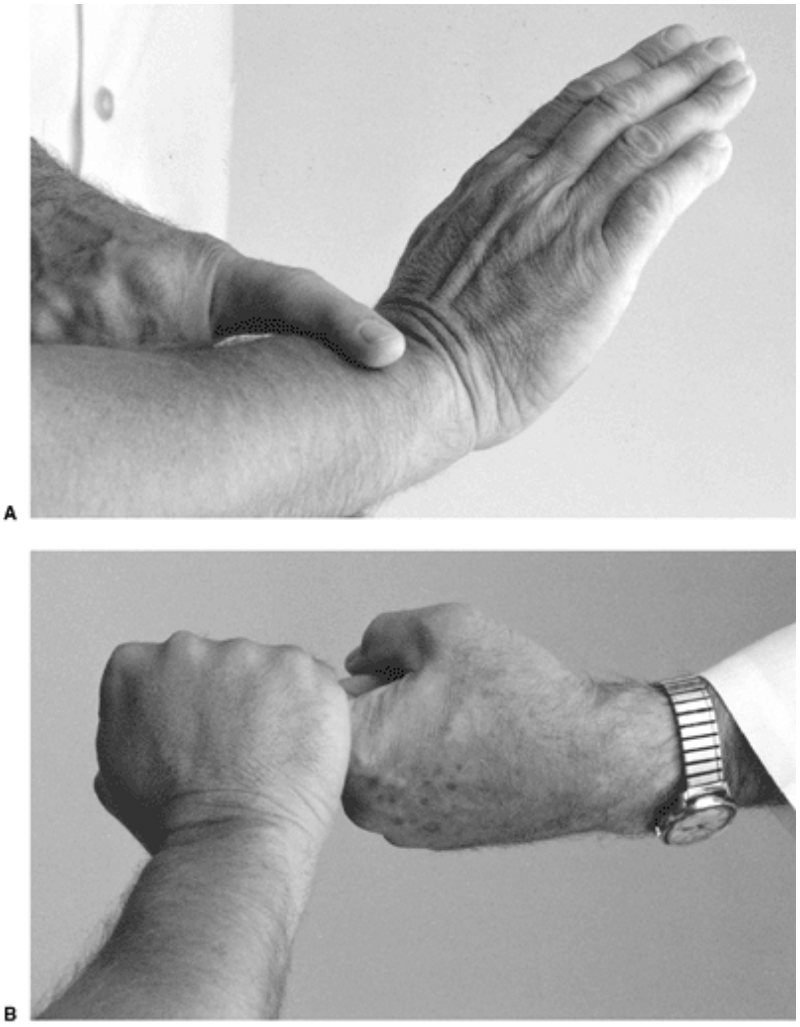
Role of Noninvasive Imaging

Role of Noninvasive Imaging of the Liver and Biliary Tree in the Evaluation of the Patient with Jaundice and/or Liver Disease

As noted earlier, in patients with jaundice, a careful history, physical examination, and review of standard laboratory tests should allow a physician to make an accurate clinical diagnosis in 85% of cases. All too often, however, an imaging procedure is done before these basic steps have been completed and such omissions may actually delay establishing the correct diagnosis. The following are offered as guidelines to be considered for ordering imaging procedures:

1. Liver imaging procedures are not indicated in a patient with acute viral hepatitis.
2. Liver imaging procedures are not necessary in a patient with a firm clinical diagnosis of nonalcoholic fatty liver disease.
3. In a patient with jaundice and obstructive-type liver test abnormalities, that is, a disproportionately elevated serum alkaline phosphatase level and serum aminotransferases less than 300 units, ultrasonography is the usual initial imaging procedure. Ultrasonography is reliable for differentiating medical, that is, intrahepatic cholestasis from extrahepatic obstructive jaundice. In a patient with a serum bilirubin greater than 10 mg/dL that has been present for more than 2 weeks, ultrasound has a

sensitivity of 95% and a specificity of 95% in differentiating intrahepatic versus extrahepatic causes of jaundice. Table 1.2 lists several causes of intrahepatic cholestasis. In some cases, the level and cause of bile duct obstruction can be identified.



▪ **Figure 1.9** Techniques for eliciting asterixis. **A:** The examiner applies his index finger over the dorsum of the patient's wrist while asking the patient to dorsiflex the wrist. Asterixis is the downward drift and abnormal recovery motion of the hand with the fingers either together or outstretched. **B:** Alternative method for eliciting asterixis in patients who may not have the requisite extensor tonus. The examiner asks the patient to clench his fingers around the examiner's fingers. Asterixis is elicited with subtle movements of the examiner's wrist. In this manner, one can both feel and see the asterixis movement.

4. If an ultrasound examination in a patient with jaundice reveals evidence of dilated intrahepatic ducts, additional imaging procedures such as CT scanning, magnetic resonance cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP), and endoscopic ultrasonography

(EUS) with biopsies are often necessary to establish the cause of obstruction. If no dilated ducts are found and the cause of jaundice is deemed to be "medical," a liver biopsy is frequently in order.

5. In patients with suspected cholelithiasis, ultrasonography is the primary diagnostic imaging procedure. In patients with suspected choledocholithiasis and especially if there is a question of ascending cholangitis, ERCP is the preferred diagnostic procedure. In addition, ERCP with papillotomy may be indicated.
6. In a patient with new onset of ascites, Doppler ultrasonography is indicated to determine the potency of the portal and hepatic venous systems.
7. In patients with obstructive jaundice due to suspected pancreatic carcinoma, EUS is superior to CT scanning with regard to detecting a pancreatic mass but comparable with regard to tumor staging and predicting either respectability or nonrespectability.
8. In patients with unexplained hepatomegaly, either ultrasound or CT scanning are appropriate initial imaging procedures.

Case Vignettes: Practical Considerations

The following are vignettes in which the salient features of a patient's illness alert the clinician to the most likely diagnosis.

1. A 35-year-old woman is referred with the diagnosis of acute viral hepatitis. Liver tests reveal a total serum bilirubin level of 3.0 mg/dL; serum aspartate aminotransferase (AST), 900 U/L; serum alanine aminotransferase (ALT), 880 U/L; serum alkaline phosphatase, 180 U/L; serum albumin, 3.6 g/dL; serum globulins, 5.8 g/dL; prothrombin time, 15 seconds (international normalized ratio [INR], 1.9).

   Key: The presence of marked hypergammaglobulinemia along with prolongation of prothrombin time suggests that this patient has *chronic* rather than acute hepatitis. The most likely diagnosis for this 35-year-old woman would be autoimmune chronic hepatitis.

2. A 30-year-old man is referred for evaluation of elevated serum aminotransaminase levels. The patient weighed 230 pounds (103.5 kg) as a high school football player, 250 pounds (112.5 kg) after graduating from college, and 300 pounds (135 kg) 5 years later. Results of all liver tests are normal except for a serum AST level of 65 U/L and a serum ALT level of 80 U/L.

   Key: If a patient has no symptoms except that the transaminase

values are elevated approximately twice the normal value, six considerations should come to mind. They include (a) excessive alcohol use, (b) obesity with body mass index (BMI) greater than 32, (c) hepatitis C, (d) excessive doses of acetaminophen (>4.0 g/day), and (e) use of statin-type cholesterol-lowering agents and (+) celiac sprue. In this patient, the most likely explanation is obesity, and he may well have nonalcoholic steatohepatitis.

3. A 30-year-old man has severe flu symptoms for 5 days. Cough, myalgia, headache, and anorexia have resulted in markedly diminished intake of food and liquid. He has been ingesting generic acetaminophen 4.0 g/day and acetaminophen plus diphenhydramine (Tylenol PM) to facilitate sleep. He was found to have a serum AST level of 5,000 U/L and an ALT level of 5,500 U/L.

   Key: Ingestion of seemingly therapeutic doses of acetaminophen by a patient who has in essence fasted for 4 or 5 days can result in drug-induced hepatotoxicity. Results of early studies indicated that concurrent ingestion of alcohol and acetaminophen was the most common cause of this presentation. However, the scenario in this case is the more common presentation now. In patients who come to medical attention with serum aminotransaminase values of approximately 5,000 U/L, the differential diagnosis is limited to viral hepatitis, effects of drugs and toxins, and ischemia with shock liver. In the United States, approximately one half of cases of fulminant hepatic failure are related to acetaminophen ingestion.

4. A 63-year-old woman with non–insulin-requiring diabetes mellitus and hypercholesterolemia has been found to have abnormal results of liver tests. Results of liver biopsy establish the diagnosis of cirrhosis, but there is no obvious cause, and the patient is considered to have cryptogenic cirrhosis.

   Key: A detailed history reveals that the patient was obese through much of her adult life, weighing in excess of 300 pounds (135 kg; BMI >32). Although she weighed only 200 pounds (90 kg) when she sought medical attention, many years of obesity coupled with diabetes and hypercholesterolemia most likely caused nonalcoholic steatohepatitis, which progressed to cirrhosis. The most common cause of cryptogenic cirrhosis is antecedent nonalcoholic steatohepatitis.

5. A 28-year-old man who has had ulcerative colitis for 10 years is found through routine screening to have a serum alkaline phosphatase level of 500 U/L. Results of all other liver tests are normal.

   Key: Persistent elevation of serum alkaline phosphatase level to

values greater than twice the normal value in patients with inflammatory bowel disease, especially those with ulcerative colitis, should raise the question of occult primary sclerosing cholangitis. This patient needs either MRCP or ERCP.

6. A 40-year-old woman is admitted to the hospital for therapy for alcohol withdrawal and impending delirium tremens. Laboratory studies reveal serum bilirubin, 2.0 mg/dL; AST, 225 U/L; serum ALT, 45 U/L; prothrombin time, 14 seconds (INR, 1.3); serum iron level 170 µg/dL; total iron-binding capacity, 200 µg/dL; iron saturation, 85%; and serum ferritin, 700 µg/dL.

   Key: The increased percentage of iron saturation and elevated serum ferritin level in this case are not indicative of a diagnosis of hemochromatosis. Serum iron levels and serum ferritin levels are frequently elevated in patients with acute liver disease and marked liver cell necrosis.

7. A 17-year-old boy is referred for evaluation of hepatosplenomegaly and thrombocytopenia. On examination, he is found to have a peculiar "wing-beating" tremor. When the patient abducts his arms and flexes his forearms, a sustained tremor develops. The patient does not have Kayser-Fleischer rings. The serum ceruloplasmin level is 30 mg/dL.

   Key: The presence of a wing-beating tremor in a young man with apparent chronic liver disease is almost pathognomonic of Wilson disease. Examination of a 24-hour urine collection for copper revealed excretion of 1,100 µg of copper. Of the three standard screening tests for Wilson disease, that is, Kayser-Fleischer rings, low serum ceruloplasmin level, and increased urinary excretion of copper, results of all three are abnormal in only one third of patients. In the remaining two thirds of patients, only one test may have a positive result. The clue in this case was the unusual tremor, which is characteristic of Wilson disease.

8. A 25-year-old Guatemalan man who does not speak English is visiting relatives in the United States. After a large meal, he develops retching and hematemesis. Esophagogastroduodenoscopy reveals esophageal varices. The patient is admitted to the hospital and found to have hepatosplenomegaly, thrombocytopenia, a normal serum albumin level, and minimal hyperbilirubinemia (serum bilirubin, 2.0 mg/dL). Through interpreters, it is learned that the patient had had his first episode of hematemesis at 10 years of age. He had several subsequent episodes managed by means of banding of varices.

   Key: The onset of variceal bleeding at 10 years of age with stigmata of chronic liver disease but with well-preserved liver

function indicates that the most likely diagnosis is congenital hepatic fibrosis.

9. A 55-year-old man is referred for evaluation of asymptomatic hepatosplenomegaly. The patient's liver spans over 20 cm with a smooth, rounded edge felt 14 cm below the costal margin with a prominent left lobe. The spleen is palpable 4 cm below the left costal margin. Serum bilirubin, alkaline phosphatase, AST, and ALT levels are normal. The serum albumin level is 3.5 g/dL and serum globulin levels, 3.0 g/dL. Prothrombin time and partial thromboplastin time are normal. Results of a complete blood cell count and routine chemical analyses are normal. Urinalysis is unremarkable except for 2+ proteinuria. Blood glucose levels are normal, and the patient is not overweight.

   Key: The finding of marked hepatomegaly with normal results of liver tests in the evaluation of a patient without symptoms should raise the question of infiltrative liver disease, such as amyloidosis. In addition to amyloidosis, relatively few disorders give rise to marked hepatomegaly. These include primary and metastatic tumors of the liver, alcoholic liver disease, severe congestive heart failure, and advanced chronic myelogenous leukemia.

10. A 49-year-old man has documented end-stage chronic liver disease due to hepatitis C and alcohol ingestion. He has had previous hospital admissions for bleeding esophageal varices and ascites. Because of lack of compliance with a salt- and fluid-restricted diet, the patient has recurrent ascites despite treatment with diuretics. He is known to have diverticular disease, having had one previous episode of diverticulitis. He is admitted to the hospital with a 2-day history of severe abdominal pain, chills, fever, and anorexia. Diagnostic paracentesis reveals the following: White blood cell count, 10,000/μL with 90% polymorphonuclear leukocytes; ascitic fluid protein, 4.0 g/dL; ascitic fluid glucose, 35 mg/dL with a simultaneous serum glucose level of 120 mg/dL and peritoneal fluid of pH 7.1.

    Key: This patient does not have spontaneous bacterial peritonitis. Rather, he has *primary* bacterial peritonitis. The triad of findings of a white blood cell count of 10,000/μL with a left shift, increased serum protein level, and low glucose level points to primary bacterial contamination of the peritoneal cavity, rather than spontaneous bacterial peritonitis, most likely from a perforated viscus. If a flat abdominal radiograph does not reveal evidence of free air, a CT scan should be obtained. If perforation is confirmed, the patient, despite the advanced liver disease, needs surgical exploration.

11. A 47-year-old man is referred for evaluation of ascites believed to be caused by chronic liver disease. There is no history of excessive

alcohol use, risk factors for hepatitis B and C, or other gastrointestinal symptoms. There is a remote history of tuberculosis 20 years earlier managed appropriately. Previous physical examinations have

been said to be unremarkable except for ascites. Repeated physical examination reveals normal vital signs except for pulsus paradoxus of 20 mm Hg. Inspiratory distention of the cervical neck veins is noticed. A third heart sound is heard to the left of the sternal border. The lungs are clear to auscultation. Abdominal examination reveals obvious ascites with a fluid wave. There is no peripheral edema. Ultrasound examination confirms the presence of ascites, reveals a liver that spans 15 cm, and a normal-sized spleen. The portal and hepatic veins are patent.

Key: The presence of pulsus paradoxus and a Kussmaul's sign (inspiratory distention of the cervical neck veins) point to a diagnosis of constrictive pericarditis manifesting as ascites and masquerading as chronic liver disease. Results of an echocardiogram confirmed the diagnosis.

12. A 47-year-old woman is referred for evaluation of hepatosplenomegaly. The patient has no risk factors for chronic liver disease. These include absence of alcohol intake, risk factors for hepatitis B and C, excessive use of vitamins or herbal teas. Urinalysis, however, reveals the presence of hematuria. CT scan shows a lesion in the right kidney consistent with renal cell carcinoma. What is the cause of the patient's hepatosplenomegaly?

    Key: Although one would be tempted to consider metastatic liver disease to be the most likely explanation for the hepatosplenomegaly, a rare syndrome termed *Stauffer's syndrome*, is a form of nephrogenic hepatosplenomegaly. Hypernephroma, in some ill-defined way, may elaborate hepatotropic growth factors that cause enlargement of the liver and spleen. Such patients do not usually have evidence of metastatic liver disease, and with nephrectomy, the liver may actually regress in size.

13. A 57-year-old woman is referred for evaluation of ascites. She initially visited her gynecologist, who suspected that she might have ovarian carcinoma. However, a pelvic examination and pelvic and abdominal CT scans did not reveal any evidence of tumor. There is no history to explain the development of ascites except that the patient has been drinking enormous quantities of herbal tea, ingesting 18 to 24 cups/day for the last 2 years.

    Key: An ultrasound examination with determination of portal and hepatic venous flow velocity revealed findings consistent with hepatic venous occlusion. Tumors (hepatocellular carcinoma, pancreatic carcinoma, hypernephroma, and gastric carcinoma) are

infrequent causes of Budd-Chiari syndrome. The most common cause is an obvious or incipient myeloproliferative syndrome. Herbal teas may contain alkaloids that can cause both intrahepatic and extrahepatic veno-occlusive disease.

14. A 62-year-old woman has been to the hospital because of pruritus and is found to have jaundice. Except for scleral icterus, the findings of the physical examination are unremarkable. The liver span measures 12 cm at percussion. Liver tests reveal the serum bilirubin level to be 8.0 mg/dL; AST, 400 U/L; ALT, 420 U/L; serum alkaline phosphatase, 500 U/L; normal serum prothrombin time; and normal serum albumin and globulin levels. Results of serum albumin, globulin, and antinuclear antibody tests are all either negative or within normal limits. An ultrasound examination shows a normal liver, gallbladder, and pancreas.

    Key: A detailed history interview reveals that this woman took amoxicillin–clavulanic acid at a dosage of 2.0 g/day for 2 weeks, but this medication was discontinued 3 weeks earlier. Amoxicillin–clavulanic acid has been frequently reported to cause a cholestatic hepatitis. Jaundice and abnormal results of liver tests can develop 1 to 4 weeks after discontinuation of treatment. Histologic examination of the liver usually shows evidence of centrilobular (zone 3) or panlobular cholestasis, which, on rare occasions, is associated with a granulomatous hepatitis. The prognosis is excellent.

15. A 43-year-old man with a history of excessive alcohol ingestion (6 to 12 bottles of beer per day for many years) is admitted to the hospital with right upper quadrant pain, chills, fever, dark urine, and pruritus. Physical examination reveals right upper quadrant tenderness, the liver measuring 14 cm with a round, smooth, tender edge palpable 3 cm below the right costal margin. Liver tests reveal serum bilirubin, 8.0 mg/dL; AST, 220 U/L; ALT, 400 U/L; serum albumin, 3.8 g/dL; serum globulins, 3.2 g/dL; serum alkaline phosphatase, 400 U/L; mean corpuscular volume, 94 μm^3; white blood cell count, 14,000/μL with left shift; prothrombin time, 13 seconds (INR, 1.2).

    Key: In patients with alcoholic hepatitis, the AST/ALT ratio is almost invariably 2:1 or greater. In this case, although the patient has consumed excessive amounts of alcohol, the disproportionately higher ALT/AST ratio suggests a cause of jaundice other than alcoholic hepatitis. An ultrasound examination showed cholelithiasis and a dilated common bile duct. This patient, with a history of alcoholism, had biliary tract disease. A clue to the correct diagnosis was the unanticipated reversal of the AST/ALT ratio.

Chapter 2
Laboratory Tests

Daniel S. Pratt
Marshall M. Kaplan

Key Concepts

- Laboratory tests are an effective method for screening for the presence of hepatic dysfunction, directing further diagnostic evaluation of identified abnormalities, assessing the severity of disease, following the course of liver disease, and evaluating the response to treatment.
- Elevations in serum levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are nonspecific indicators of hepatocellular damage. The exception is an AST/ALT ratio greater than 2, which suggests alcoholic liver disease.
- Elevation of serum level of alkaline phosphatase in patients with hepatic dysfunction is caused by the regurgitation of alkaline phosphatase from damaged hepatocytes into the serum.
- The rate-limiting step in hepatic bilirubin production is the excretion of conjugated bilirubin into canalicular bile. This explains why patients with significant hepatocellular dysfunction have a predominantly conjugated fraction in hyperbilirubinemia.
- Significant prolongation of the prothrombin time that is unresponsive to vitamin K infusions suggests a poor prognosis in patients with fulminant liver disease.
- The roles of indocyanine green clearance, serum bile salts, aminopyrine breath test, galactose clearance, caffeine clearance, and lidocaine metabolite formation in the evaluation of patients with hepatic dysfunction are limited. These tests are neither widely used nor available.

Laboratory tests, often called *liver function tests* (LFTs), are useful in the evaluation and treatment of patients with hepatic dysfunction. First, they are a sensitive, noninvasive method of screening for the presence of liver dysfunction. This is particularly important for anicteric patients who may have unsuspected disorders, such as viral hepatitis, chronic active hepatitis, cirrhosis, or partial bile duct obstruction. Second, once the presence of hepatic dysfunction is recognized, the pattern of laboratory test abnormalities may allow clinicians to recognize the general type of liver disorder. For example, laboratory tests usually allow clinicians to differentiate hepatocellular disorders, such as viral hepatitis, from cholestatic syndromes, such as primary biliary cirrhosis and bile duct obstruction. Third, laboratory tests allow clinicians to assess the severity of liver dysfunction and occasionally allow them to predict the outcome early in the course of disease. Finally, LFTs allow the physician to follow the course of liver disease, to accurately evaluate the response to treatment, and to adjust treatment when necessary.

Although they are indispensable in the treatment of patients with liver disease, laboratory tests have certain limitations. First, they lack sensitivity. Normal results may be obtained for patients with serious liver disorders, such as cirrhosis or hepatocellular carcinoma. Second, these tests are not specific for liver dysfunction. For example, the serum albumin level may be decreased in patients with chronic inflammatory conditions, and aminotransferase levels may be elevated in patients with musculoskeletal or cardiac diseases. Finally, results of LFTs seldom lead to a specific diagnosis; rather, they suggest a general category of liver disorder. They do not help

differentiate viral hepatitis from drug-induced hepatitis or intrahepatic cholestasis from extrahepatic bile duct obstruction.

No one LFT enables the clinician to accurately assess the total functional capacity of the liver. The liver performs thousands of biochemical functions, most of which cannot be measured easily with blood tests. Laboratory tests measure only a limited number of these functions. Many tests, such as aminotransferase and alkaline phosphatase determinations, do not measure liver function at all. Rather, they show liver cell damage or interference with bile flow. To increase both the sensitivity and the specificity of laboratory tests in the detection of liver disease, it is essential to use them as a battery and to repeat them over time. When more than one of these tests provide abnormal findings, or the findings are persistently abnormal on serial determinations, the probability of liver disease is high. When all the test results are normal, the likelihood of liver disease is low.

In the evaluation of patients for liver disorders, it is helpful to group these tests into general categories. We have found the following classification most useful:

Tests of the capacity of the liver to transport organic anions and metabolize drugs: Included in this group are serum bilirubin, sulfobromophthalein sodium (bromsulphalein [BSP]), indocyanine green (ICG), serum bile acids, serum caffeine, serum lidocaine metabolites, and breath tests. Each of these tests measures the ability of the liver to clear endogenous or exogenous substances from the circulation.

Tests to detect injury to hepatocytes: These include all of the enzyme tests, of which the aminotransferases and alkaline phosphatase are the most commonly ordered and the most useful.

Tests of the biosynthetic capacity of the liver: Included in this group are serum albumin, ceruloplasmin, ferritin, α_1-antitrypsin, lipoproteins, and blood-clotting factors. These substances are synthesized in the liver for transport into the circulation.

Tests to detect fibrosis in the liver: These include serum hyaluronate, type IV collagen, procollagen III, laminin, and multiparameter tests including FibroTest.

Tests to chronic inflammation or altered immunoregulation: These include the immunoglobulins (Igs), and specific autoantibodies. These are not truly LFTs, because most of these substances are proteins made by B lymphocytes, not by hepatocytes. Some of these tests, however, are quite specific for certain liver diseases.

This chapter discusses the tests we consider most useful in evaluating liver diseases. Other tests that are of less value but are still used are discussed briefly. Whenever possible, the pathophysiologic basis of each test is reviewed together with the sensitivity and specificity of the test in assessing of the nature and severity of liver dysfunction.

Tests of Capacity of Liver to Transport Organic Anions and to Metabolize Drugs

Bilirubin

See Chapter 8.

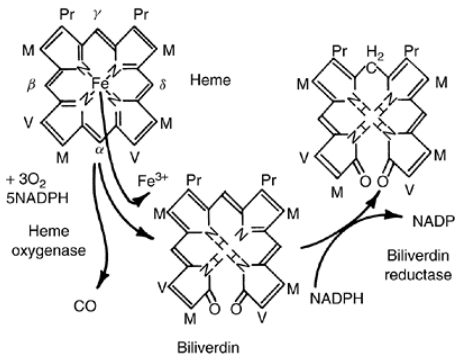
Bilirubin metabolism

Bilirubin, a tetrapyrrole pigment, is a breakdown product of ferroprotoporphyrin IX (heme), an integral part of heme-containing proteins. Approximately 70% to 80% of the 250 to 300 mg of bilirubin produced each day is derived from the breakdown of hemoglobin in senescent red blood cells (1). The remainder comes from prematurely destroyed erythroid cells in bone marrow and from the turnover of hemoproteins in tissues throughout the body (2). The liver is the main source of the latter because of its high concentration of hemoproteins with relatively high turnover rates, such as cytochrome P-450. The initial steps leading to the formation of bilirubin occur in reticuloendothelial cells, primarily in the spleen and liver. The first reaction, catalyzed by the microsomal enzyme heme oxygenase, oxidatively cleaves the α bridge of the porphyrin group, opens the heme ring, and produces equimolar amounts of biliverdin and carbon monoxide (3) (Fig. 2.1). The second reaction, catalyzed by the cytosolic enzyme biliverdin reductase, reduces the central methylene bridge of biliverdin, converting it to bilirubin (4). Bilirubin formed in the reticuloendothelial cells is lipid-soluble and almost insoluble in water. To be transported in blood, it must be solubilized. This is accomplished by reversible, noncovalent binding to albumin. Bilirubin is then transported to the liver, where it, but not the albumin, is taken up by hepatocytes in a process that involves carrier-mediated membrane transport (5) (Fig. 2.2). Although several potential transporters have been identified, none has yet been cloned. In the hepatocyte, bilirubin is coupled to glutathione-*S*-transferases (formerly called ligandins). Bilirubin is then solubilized by means of conjugation to glucuronic acid, and bilirubin monoglucuronide and diglucuronide are formed, both of which are called *direct-acting bilirubins.* The conjugation of glucuronic acid to bilirubin is catalyzed by an enzyme system in the endoplasmic reticulum of the hepatocyte that transfers glucuronic

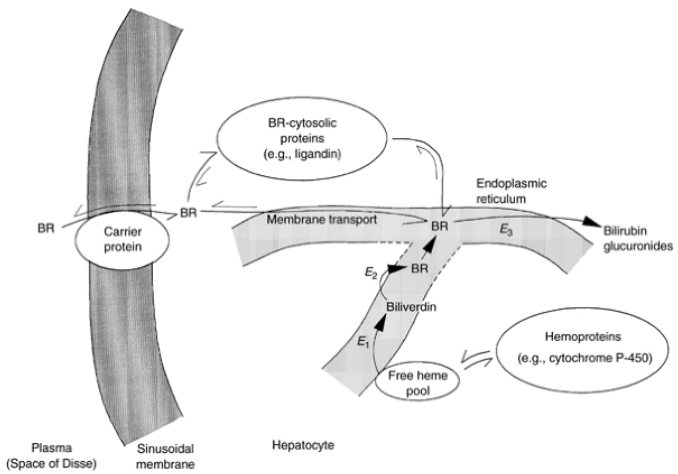
P.21

P.22

acid from uridine diphosphate (UDP)-glucuronic acid to the acyl groups of the propionic acid side chains of bilirubin (Fig. 2.3). The bilirubin conjugates are then actively transported from the hepatocyte into canalicular bile by an adenosine triphosphate–dependent transport process that is the rate-limiting step in hepatic bilirubin excretion. This process is mediated by a protein in the bile canalicular membrane called *multidrug resistance–associated protein 2.* The conjugated bilirubins drain from the bile duct into the duodenum and are carried distally through the intestine. In the distal ileum and colon, the conjugated bilirubins are hydrolyzed to unconjugated bilirubin by bacterial β glucuronidases. The unconjugated bilirubin is reduced by normal intestinal bacteria to form a group of colorless tetrapyrroles called *urobilinogens.* Approximately 80% to 90% of these products are excreted in feces, either unchanged or oxidized to orange derivatives called *urobilins.* The remaining 10% to 20% of the urobilinogens are passively absorbed, enter the portal venous blood, and are reexcreted by the liver. A small fraction, usually less than 3 mg/dL, escapes hepatic uptake, filters across the renal glomerulus, and is excreted in urine. The renal excretion of urobilinogen is complicated, partly because urobilinogen is a weak acid that passively diffuses across the renal tubule when in its undissociated form. The appearance of urobilinogen in urine depends on many factors, including urine pH and the rate of urine flow.



• **Figure 2.1** Formation of bilirubin from heme by the sequential actions of the enzymes heme oxygenase and biliverdin reductase. *M*, methyl; *V*, vinyl; *Pr*, propionic acid side chains; CO, carbon monoxide; NADPH, reduced form of nicotine adenine dinucleotide; NADP, nicotine adenine dinucleotide phosphate. (Adapted from Ostrow JD, et al. *Unit 1: Hepatic excretory function: Undergraduate teaching project*. American Gastroenterological Association, Milner-Fenwick Slides Co., with permission.)



• **Figure 2.2** Scheme of bilirubin uptake, hepatocellular transport, and metabolism. Exogenous bilirubin is taken up by the hepatocyte at the sinusoidal membrane by an unidentified carrier protein (as depicted) or by transmembrane "flip-flop." The

bilirubin is delivered to the endoplasmic reticulum by means of membrane–membrane transfer, with cytosolic binding proteins serving as a potential means to preclude the diffusion of bilirubin back to the plasma. Heme generated within the liver from endogenous hemoproteins also gives rise to bilirubin. Glucuronidation occurs primarily within the endoplasmic reticulum. *BR*, bilirubin; E_1, heme oxygenase; E_2, biliverdin reductase; E_3, bilirubin uridine diphosphate glucuronosyltransferase 1. • **Figure 2.3** Structure of bilirubin IXα and bilirubin IXα diglucuronide. In the latter, the glucuronides prevent intramolecular hydrogen bonding between the propionic acid groups and the pyrrole ring nitrogens. (From Schmid R. Bilirubin metabolism: State of the art. *Gastroenterology* 1978;74:1307, with permission.)

Measurement of serum bilirubin

The terms *direct-* and *indirect-reacting bilirubin* are based on the original van den Bergh method of measuring unconjugated bilirubin (6). This method is still used in some clinical chemistry laboratories to determine the serum bilirubin level. In this assay, bilirubin reacts with diazotized sulfanilic acid and splits into two relatively stable dipyrryl azopigments that absorb maximally at 540 nm. The direct fraction is that which reacts with diazotized sulfanilic acid in 1 minute in the absence of alcohol (6). This fraction provides an approximate determination of the amount of conjugated bilirubin in serum. The total serum bilirubin level is the amount that reacts in 30 minutes after the addition of alcohol. The indirect fraction is the difference between the total and the direct bilirubin level, and provides an estimate of the amount of unconjugated bilirubin in serum. With the van den Bergh method, the normal serum bilirubin concentration is usually less than 1 mg/dL (18 mmol/L). As much as 30%, or 0.3 mg/dL (5.1 mmol/L) of the total is direct-reacting bilirubin (6). Total serum bilirubin concentrations are between 0.2 and 0.9 mg/dL (2.0 to 15.4 mmol/L) in 95% of a healthy

population, and less than 1 mg/dL (18 mmol/L) in 99% (6). Some differences in the properties of unconjugated and conjugated bilirubin are listed in Table 2.1.

Table 2.1. Differences Between Unconjugated and Conjugated Bile Pigments

Property	Unconjugated bilirubin	Conjugated bilirubin
Van den Bergh reaction	Indirect (+ alcohol)	Direct
Water soluble	-	+
Fat soluble	+	-
Attachment to plasma albumin	+	+
Presence in icteric urine	-	+
Presence in bile	-[a]	+
Affinity for brain tissue	+	-
Association with hemolytic jaundice	++	±

Association with obstructive and hepatocellular jaundice	+	+++

[a]A small quantity of unconjugated bilirubin may be present in the common duct bile. There is a relative increase in unconjugated bilirubin in bile in conditions associated with severe unconjugated hyperbilirubinemia, such as Crigler-Najjar syndrome (7).
+, present or positive; -, absent or negative; ±, present or absent; ++, strong; +++, very strong.

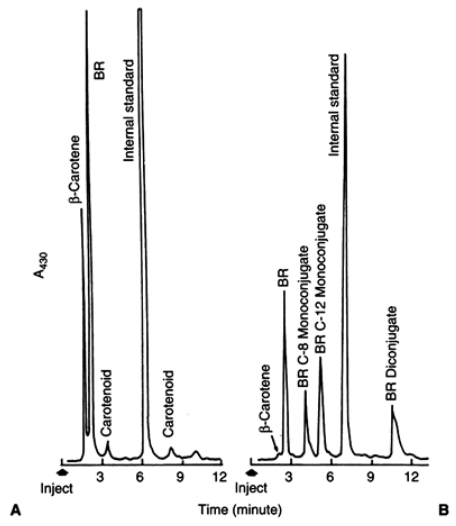
Advances in methodology have shown that the diazo method does not accurately reflect the values of the indirect- and direct-reacting fractions of bilirubin, particularly at low total serum bilirubin concentrations (8). Although these more accurate methods provided information that resolved many of the enigmas of bilirubin metabolism, they are less convenient to perform. In most clinical situations, they do not provide enough clinical advantages to replace the older, more familiar diazo methods. One more precise method involves alkaline methanolysis of bilirubin, followed by chloroform extraction of the bilirubin methyl esters, separation of these esters with high-performance liquid chromatography (HPLC), and spectrophotometric determination at 430 nm (8). Other HPLC methods do not require alkaline methanolysis, although globulins and other high-molecular-weight proteins must be precipitated from serum before chromatography. Assays based on dry reagent chemistry have also been reviewed. One method used in many clinical chemistry laboratories is based on photographic film technology, and uses Ektachem dry chemistry slides. The method can be automated and appears able to produce accurate measurements of conjugated and unconjugated bilirubin to demonstrate the presence of a bilirubin fraction called *bilirubin δ.* Bilirubin δ is conjugated bilirubin that is tightly linked to albumin through covalent bonding (9).

These new techniques considerably add to our understanding of bilirubin metabolism. First, they show that almost 100% of the serum bilirubin in healthy individuals, or those with Gilbert's syndrome, is unconjugated (Fig. 2.4), and less than 3% is monoconjugated bilirubin. Second, in patients with jaundice and hepatobiliary disease, the total serum bilirubin concentration measured with these newer, more accurate methods is lower than the values found with diazo methods (8). This suggests that diazo-positive compounds distinct from bilirubin exist in the serum of patients with hepatobiliary disease. Third, the results of these studies indicate that in patients with jaundice and hepatobiliary disease, monoglucuronides of bilirubin predominate over the diglucuronides (Fig. 2.4). Fourth, part of the direct-reacting bilirubin fraction includes conjugated bilirubin that is covalently linked to albumin (9) (Fig. 2.5). This albumin-linked bilirubin fraction represents an important fraction of total serum bilirubin in patients with cholestasis and hepatobiliary disorders (9) (Fig. 2.6). Albumin-bound bilirubin is formed in serum when hepatic excretion of bilirubin glucuronides is impaired, and the glucuronides are present in serum in increasing amounts. Because of its tight binding to albumin, the clearance rate of albumin-bound bilirubin from serum approximates the half-life of albumin—12 to 14 days—rather than the short half-life of bilirubin, approximately 4 hours. The prolonged half-life of albumin-bound bilirubin explains two previously unexplained enigmas in the care of jaundiced patients with liver disease: (a) That some patients with conjugated hyperbilirubinemia do not have bilirubinuria during the recovery phase of their disease and (b) that the elevated serum bilirubin level declines more slowly than expected in some patients who otherwise appear to be recovering satisfactorily. Late in the recovery phase of hepatobiliary disorders, all the conjugated bilirubin may be in the albumin-linked form. It is therefore not filtered by the renal glomerulus and does not appear in urine, although the serum bilirubin concentration is high. The value of conjugated bilirubin in serum decreases slowly because of the long half-life of albumin. The slow decline is unrelated to the actual hepatic status.

Diagnostic value of serum bilirubin

The bilirubin normally present in serum represents a balance between the input from production and the hepatic removal of the pigment. Hyperbilirubinemia may therefore result from (a) overproduction of bilirubin, (b) impaired uptake, conjugation, or excretion of bilirubin, or (c) regurgitation of unconjugated or conjugated bilirubin from damaged hepatocytes or

bile ducts. One may anticipate that an increase in unconjugated bilirubin in serum results from overproduction or from impairment of uptake or conjugation, whereas an increase in the conjugated moiety is caused by decreased excretion or backward leakage of the pigment.



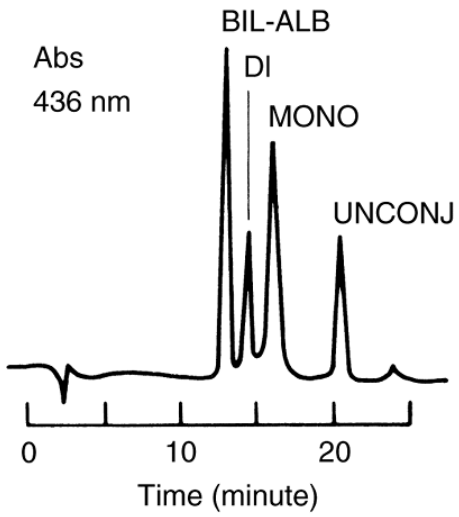
• **Figure 2.4** Chromatograms of bilirubin in the plasma of a healthy adult **(A)** and a patient with obstructive jaundice. **B:** Bilirubin glucuronides are not detected in the healthy adult. In the patient with obstructive jaundice, there is a mixture of unconjugated bilirubin, bilirubin monoglucuronides, and bilirubin diglucuronide. Bilirubin conjugates in plasma were converted to their methyl ester derivatives and then extracted and separated by means of high-pressure liquid chromatography. Xanthobiliburic acid was used

as an internal standard. *BR*, unconjugated bilirubin. (From Blanckaert N, Schmid R. Physiology and pathophysiology of bilirubin metabolism. In: Zakim D, Boyer TA, eds. *Hepatology: A Textbook of Liver Disease*, 2nd ed. Philadelphia, PA: WB Saunders, 1989:262, with permission.)

Total serum bilirubin level is not a sensitive indicator of hepatic dysfunction and may not accurately reflect the degree of liver damage. Hyperbilirubinemia may not be detected in instances of moderate to severe hepatic parenchymal damage or a partially or briefly obstructed common bile duct. This lack of sensitivity is partly explained by observations obtained in healthy persons given infusions of unconjugated bilirubin and in patients with uncomplicated hemolysis. These observations suggest that the capacity of the human liver to remove bilirubin from serum before hyperbilirubinemia occurs is at least twofold greater than the daily pigment load (250 to 300 mg [4,275 to 5,130 mmol]) normally presented to this organ. This capacity may be even higher, according to the maximal rate of excretion of bilirubin into bile—approximately 55.2 mg/kg/day (10)—and the average amount of bilirubin formed from the destruction of senescent red blood cells, 3.9 mg/kg/day. In the steady state, the serum bilirubin concentration usually reflects the intensity of jaundice and the increase in total-body bile pigment. The serum bilirubin concentration may occasionally decrease transiently with the presence in serum of substances such as salicylates, sulfonamides, or free fatty acids, which displace bilirubin from its attachment to plasma albumin and enhance the transfer of the pigment into tissues (11). Conversely, an increase in serum albumin concentration may induce a temporary shift of bilirubin from tissue sites into the circulation.

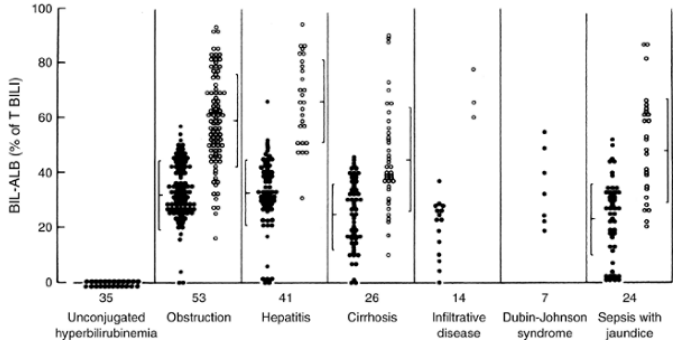
Total serum bilirubin concentration is seldom of value in specifying the cause of jaundice in individual patients because values among the various types of jaundice overlap considerably. On the average, uncomplicated hemolysis seldom causes a serum bilirubin value in excess of 5 mg/dL (85.5 mmol/L), and parenchymal liver disease or incomplete extrahepatic

obstruction due to biliary calculi gives lower serum bilirubin values than those that occur with malignant obstruction of the common bile duct.



▪ **Figure 2.5** Chromatogram of serum bilirubin from a patient with obstructive jaundice shows the presence of a bilirubin fraction bound to albumin (BIL-ALB). Serum bilirubin was separated by means of reversed-phase high-performance liquid chromatography. DI, bilirubin diglucuronide; MONO, bilirubin monoglucuronide; UNCONJ, conjugated bilirubin. (From Weiss JS, Gautam A, Lauff JJ, et al. The clinical importance of a protein-bound fraction of serum bilirubin in patients with hyperbilirubinemia. *N Engl J Med* 1983;309:147, with permission.)

Few controlled studies have critically assessed the prognostic value of magnitude and duration of hyperbilirubinemia in liver disease. In general, the higher the serum bilirubin concentration in viral hepatitis, the greater the histologic evidence of hepatocellular damage and the longer the course of disease. Nevertheless, patients may die of fulminant hepatitis with only a modest elevation in serum bilirubin level. The presence of concomitant hemolysis with overproduction of bilirubin and diminished glomerular filtration rate causing decreased excretion of the pigment may also confuse the issue by causing higher serum bilirubin values than would be expected for any degree of hepatocellular damage present. In acute alcoholic hepatitis, hyperbilirubinemia in excess of 5 mg/dL (85.5 mmol/L) is one of the findings that connotes a poor prognosis (12).



• **Figure 2.6** Albumin-bound bilirubin (BIL-ALB) as a percentage of total bilirubin (T BILI). The number of subjects is indicated for each diagnostic category. Each *solid circle* represents a serum sample from a patient with a clinically deteriorating condition and increasing total bilirubin level. Each *open circle* represents a sample from a patient with clinical improvement and decreasing total bilirubin level. The *bars* indicate means ±1 SD. Serial measurements were not obtained for subjects with unconjugated hyperbilirubinemia and Dubin-Johnson syndrome. (From Weiss JS, Gautam A, Lauff JJ, et al. The clinical importance of a protein-bound fraction of serum bilirubin in patients with hyperbilirubinemia. *N Engl J Med* 1983;309:147, with permission.)

The major value of fractionating total serum bilirubin into unconjugated and direct-reacting moieties is in the detection of states characterized by unconjugated hyperbilirubinemia (Table 2.2). Such a diagnosis appears warranted when the serum level of indirect-reacting bilirubin is in excess of 1.2 mg/dL (20.5 mmol/L) and the direct-reacting fraction constitutes less than 20% of the total serum bilirubin value. Unfortunately, when the total serum bilirubin concentration is minimally elevated, it may be difficult to differentiate the nature of the bilirubin elevation. The difficulty is caused by the inaccuracy of the diazo methods in differentiating conjugated from unconjugated bilirubin at low total serum bilirubin concentrations. This is one of the instances in which the newer, more precise methods of bilirubin determination may provide clinically useful information that is not attainable with the older diazo methods. This is particularly true in the detection of

early or mild liver injury. Total bilirubin concentration may initially be normal in some patients with cirrhosis, hepatitis, congestive heart failure, and other disorders. An increase in the direct fraction above 0.3 mg/dL (5.1 mmol/L) should alert one to the possibility of mild liver injury. If the newer, more accurate techniques are used, conjugated bilirubin concentrations greater than 0.1 mg/dL (1.7 mmol/L) should be accurate in the detection of early liver injury, because bilirubin glucuronides are normally undetectable in serum, except in hepatobiliary disorders (8).

Table 2.2. Causes of Unconjugated Hyperbilirubinemia

Cause	Mechanism
Hemolytic disorders	
Inherited:	
Spherocytosis, elliptocytosis, G-6-phosphate dehydrogenase deficiency, sickle cell anemia	Overproduction of bilirubin
Acquired:	
Microangiopathic hemolytic anemias, paroxysmal nocturnal hemoglobinuria, immune hemolysis	Overproduction of bilirubin
Ineffective erythropoiesis	
Cobalamin, folate and severe iron deficiencies, thalassemia	Overproduction of bilirubin
Drugs	
Rifampicin, probenecid	Impaired hepatic uptake
Inherited conditions	
Gilbert's syndrome	Impaired conjugation
Crigler-Najjar, types I and II	Impaired conjugation
Neonates	
Neonatal (physiologic)	Overproduction of bilirubin, impaired conjugation, increased intestinal absorption
Breast milk	Impaired conjugation and increased intestinal absorption
Other	
Hematoma	Overproduction of bilirubin

Measurement and fractionation of serum bilirubin concentration in patients with jaundice does not allow clinicians to differentiate accurately between parenchymal (hepatocellular) and cholestatic (obstructive) jaundice. The accurate HPLC methods for measuring serum bilirubin show that the levels of both unconjugated and conjugated bilirubins are increased in hepatobiliary disease. No consistent pattern of elevation of these fractions differentiates hepatocellular from cholestatic liver disease (8). Levels of both monoglucuronide and diglucuronide are elevated, the monoglucuronides predominating.

Urinary bilirubin

The presence of bilirubin in the urine indicates the presence of hepatobiliary disease. Unconjugated bilirubin is tightly bound to albumin, not filtered by the glomerulus, and not present in urine. Consequently, only conjugated bilirubin is found in urine. This occurs only when conjugated bilirubin is in the serum, that is, when there is hepatobiliary disease. The new, more precise methods for measuring serum bilirubin indicate that 100% of the serum bilirubin in healthy persons and those with Gilbert's syndrome is unconjugated bilirubin. Measurable amounts of conjugated bilirubin in serum are found only in hepatobiliary disease. Because the renal threshold for conjugated bilirubin is low and the laboratory methods used can detect bilirubin concentrations as low as 0.05 mg/dL (0.9 mmol/L) of urine, conjugated bilirubin may be found in urine when the total serum bilirubin value is normal and the patient does not have clinical jaundice. This can occur early in the course of viral hepatitis or other hepatobiliary diseases when conjugated bilirubin first appears in the serum. Conversely, the urine can become free of bilirubin long before the level of conjugated serum bilirubin falls to normal in patients recovering from hepatobiliary diseases (9). When this occurs, all the conjugate bilirubin is in the albumin-bound form and is not filtered by the glomerulus.

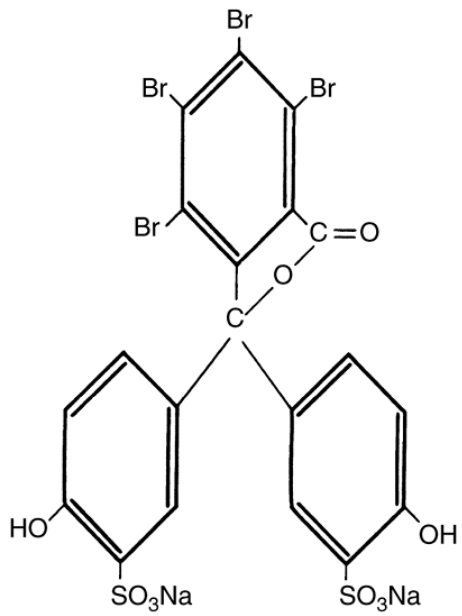
Dye Tests

Because it has long been recognized that serum bilirubin is an insensitive test of hepatic dysfunction and that at low serum levels measurement of total and direct bilirubin lacks biochemical precision, an effort was made to develop other tests of hepatic excretory capacity that were more sensitive and specific. The goal was to develop tests that could be used for more critical and specific evaluations of the excretory or detoxification capacity of the liver. Although all these tests are clearly more sensitive than the serum bilirubin test, they have limited value because of their nonspecificity; that is, the extent of the abnormality is comparable in all types of hepatobiliary disorders. These tests include dye, breath, caffeine clearance, and serum bile acid tests.

Sulfobromophthalein sodium

BSP (Fig. 2.7) was introduced in 1924 and used as a sensitive indicator of liver dysfunction until the 1970s, when its use greatly decreased. BSP is seldom used now and has been withdrawn from commercial

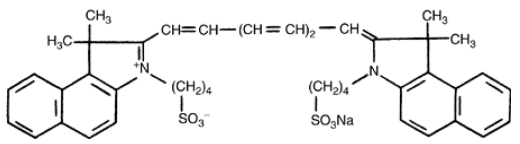
markets because of a decline in sales caused by fear of potentially fatal anaphylactic reactions after intravenous administration. The following discussion is included more for historical interest than for practical use by hepatologists and clinical investigators.



• **Figure 2.7** Structural formula for sulfobromophthalein sodium (sodium phenoltetrabromophthalein disulfonate).

BSP is soluble in water but binds rapidly to albumin and α_1-lipoprotein when it is injected intravenously. BSP or the BSP-albumin complex binds to the hepatocyte plasma membrane, and BSP is avidly taken up by the hepatocyte, where it binds to glutathione-*S*-transferases. Hepatic uptake of BSP appears saturable and there is competition for uptake with bilirubin and ICG. BSP has a first-pass clearance by the liver of 50% to 80%, and its removal from the circulation is closely related to hepatic blood flow. Much of the BSP within hepatocytes is conjugated to glutathione in a thioether linkage. The reaction is catalyzed by glutathione-*S*-transferases, the same proteins that bind BSP and bilirubin within hepatocytes. Both conjugated and free BSP are then excreted across canalicular membranes into the biliary tract. Conjugation is not required for uptake or biliary excretion of the dye.

Prolonged infusions of BSP have been used to quantify the excretory capacity of the liver by means of measurement of the hepatic uptake, storage, and maximal biliary excretion rate of BSP. Similar types of data have been generated by means of simple determination of the plasma disappearance after a standard intravenous injection of BSP. The standard test involves the intravenous injection of a fixed dose of BSP—usually 5 mg/kg—followed by sampling of blood from the contralateral arm at various times after injection. Serum is separated and alkalinized, and the BSP is read at 580 nm in a spectrophotometer. The purpose is to determine the percentage of dye remaining in plasma at a given time after injection. Normal values at 30 and 45 minutes are 10% and 5%, respectively, although these values may exclude up to 30% of healthy persons.



• **Figure 2.8** Structural formula for indocyanine green

Because the BSP retention test depends on so many factors—including hepatic blood flow, hepatic mass, functional capacity of hepatocytes, and bile flow—the test result is abnormal in all types of liver disease. As would be expected, it is also nonspecific. In addition, results are affected by fever and the concomitant use of drugs that either displace BSP from its plasma-binding proteins or inhibit its uptake or excretion by the liver. There is one clinical situation in which the BSP test is useful: The diagnosis of Dubin-Johnson syndrome and its differentiation from Rotor's syndrome. In Dubin-Johnson syndrome, an initial rapid decrease in plasma BSP concentration is followed by a secondary increase 45 to 90 minutes later (13). This reaction is caused by the regurgitation of conjugated BSP. In Rotor's syndrome, the clearance of BSP from serum is slower and no secondary increase occurs.

Indocyanine green

ICG (Fig. 2.8) is another dye used to evaluate liver function (14). ICG is nontoxic, has a higher hepatic extraction ratio than BSP (70% to 96%), and is bound to albumin and α_1-lipoprotein more avidly than BSP. Ninety-seven percent of an administered dose is excreted unchanged in bile, and the liver appears to be the only site of ICG clearance for humans. ICG and BSP appear to share sinusoidal and canalicular transport systems, but ICG has no enterohepatic circulation. ICG can be measured directly with spectrophotometry.

ICG disappearance curves can theoretically be measured without repeated blood samplings by means of dichromatic earlobe densitometry (14) or with a fingertip optical sensor (15). Results with both of these noninvasive methods appear to correlate well with those of blood sampling (15,16,17,18).

ICG is used primarily to estimate hepatic blood flow. If ICG is infused intravenously at a rate well below the capacity of the liver to clear it, a steady state is reached within 1 hour. At that time, the rate of hepatic clearance is equal to the infusion rate. Because this is known and the ICG concentration in peripheral venous blood is easily measured, hepatic blood flow can be estimated by use of the Fick equation, as follows:

$$F = \frac{R}{(ICG)a - (ICG)hv}$$

where F is the estimated hepatic blood flow; R is the hepatic removal rate of ICG, which equals the infusion rate at steady state; (ICG)a is the concentration of ICG in the hepatic artery and portal venous blood; and (ICG)hv is the concentration of ICG in hepatic venous blood.

(ICG)a is the same as the concentration of ICG in peripheral venous blood. Measurement of (ICG)hv would require catheterization of the hepatic vein and is impractical in most clinical settings. Because first-pass extraction of ICG by the liver is high (70% to 96%), the clearance rate is assumed to be 100%, and (ICG)hv is set at zero accordingly. This method can be performed at the bedside; however, the result is an underestimate of hepatic blood flow because (ICG)hv is always more than zero. This method provides a good approximation of blood flow in healthy adults (19), but not in patients with cirrhosis, because of a marked decrease in ICG extraction (20).

ICG clearance is not as sensitive an indicator of hepatic dysfunction as BSP because at doses of ICG that are safe to administer, the excretory capacity of the liver for ICG is far below maximum. To estimate the maximal ICG capacity, one would have to use four or five doses of ICG at different times and then use Michaelis-Menton–type data analysis. This is time-consuming and impractical, except in a research setting. Those who have used ICG in the evaluation of liver disease recommend single intravenous injections ranging from 0.64 to 6.4 mmol/kg and determination of a single blood level 20 minutes later. Both doses are well below the dose needed to saturate the excretory capacity of the liver for ICG, which is more than 72 mmol/kg. One group has described a new method to determine the maximal removal rate of ICG with a single submaximal dose and continuous measurement of serum ICG concentration with a fingertip optical sensor (21).

Unlike the BSP test, ICG clearance is not affected by fever (14) and is normal in patients with the Dubin-Johnson syndrome and in neonates (14). Studies have looked at the utility of ICG clearance as a predictor of poor outcome due to hepatic dysfunction in patients undergoing cardiac surgery and in patients with septic shock (22,23,24). However, because of the problems discussed earlier, ICG is seldom used in the routine evaluation of patients with liver disease.

Bile Acid Tests

Although sensitive tests to measure serum bile acid concentration (see Chapter 9) have been available for more than 20 years, physicians are still searching for a role for these tests in the evaluation of patients with suspected liver disease. Bile acids are synthesized from cholesterol in hepatocytes, conjugated to glycine or taurine, and then secreted into bile. Approximately 80% to 90% of the bile acids are stored in the gallbladder between meals; the remaining fraction is secreted continuously into the duodenum. This fraction accounts for the bile acids normally present in serum after a long fast, the concentration of which is 5 to 10 mmol/L. Cholic acid conjugates constitute less than 20% of this amount, and dihydroxy bile acids constitute the remainder.

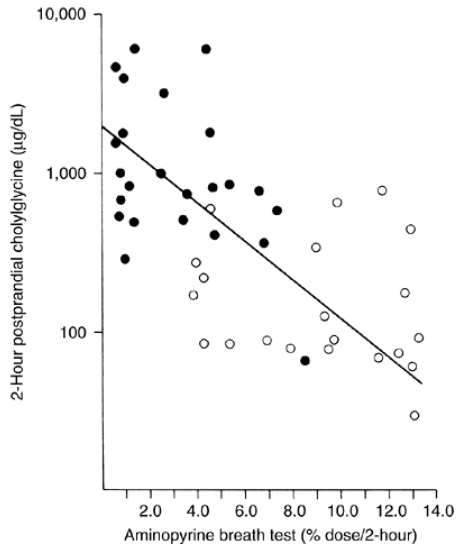
During a meal, the gallbladder contracts and discharges its pool of bile acids into the duodenum. Bile acids move rapidly down the intestinal tract, where some are absorbed throughout the intestine by means of nonionic passive diffusion. Most are actively reabsorbed by carrier-mediated transport in the terminal ileum and carried back to the liver through the portal vein. The liver efficiently extracts bile acids from portal blood; approximately 70% to 80% of dihydroxy bile acids undergo first-pass extraction, whereas 90% of trihydroxy bile acids are extracted. This difference in extraction rates is probably due to the tighter binding of dihydroxy bile acids to albumin. The fractional extraction rates of bile acids are relatively constant in healthy persons. Because a larger quantity of bile acids reach the liver after a meal and the proportion extracted is constant, a larger quantity of bile acids escapes into the circulation postprandially. This produces the normal postprandial increase in serum bile acid concentration, to a level approximately two- to fivefold greater than fasting level. In health, all the serum bile acids are from intestinal input; none comes directly from the liver. Maintenance of normal serum bile acid concentrations depends on hepatic blood flow, hepatic uptake, secretion of bile acids, and intestinal motility. A disease that affects

any of these functions should theoretically affect serum bile acid levels. This has proved to be true in practice. Serum bile acids are sensitive but nonspecific indicators of

hepatic dysfunction. They allow some quantification of functional hepatic reserve.

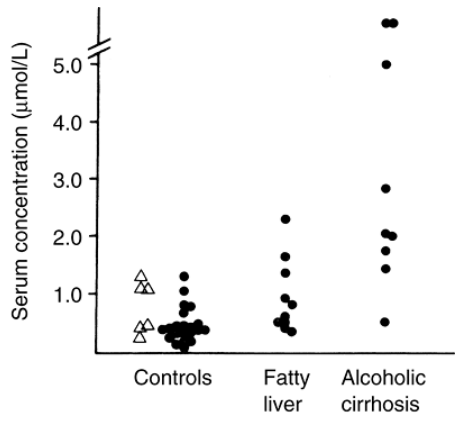
Several ways to accurately measure serum bile acid concentration are available. These include enzymatic assays, in which the bacterial enzyme 3α-hydroxysteroid dehydrogenase is coupled with either fluorometric or bioluminescence techniques; gas–liquid chromatography; radioimmunoassay; and a highly specific assay that combines gas–liquid chromatography and mass spectrometry. Only the enzyme assays and radioimmunoassays are easily adapted to the clinical chemistry laboratory. Although the radioimmunoassays can be automated, a variety of individual radioimmunoassays to detect cholic and chenodeoxycholic acids and their conjugates would have to be used to measure the total amount of bile acids in serum. This is probably not necessary if the purpose of the assay is to detect liver disease.

Serum bile acid tests may produce disproportionately elevated results in certain cholestatic liver diseases. They are useful in the management of primary biliary cirrhosis and primary sclerosing cholangitis. Serum bile acid levels may be increased 25-fold in some patients. The response to treatment with ursodeoxycholic acid can be monitored by means of measurement of the concentrations of the serum bile acids. With adequate dosing, ursodeoxycholic acid eventually constitutes nearly 60% of serum bile acids (25). Serum bile acid levels are elevated in pregnant women and particularly increased in women with pruritus of cholestasis. There appears to be no consistent advantage to the postprandial test compared with the fasting test. As might be expected, the bile acid tests are more sensitive than the serum bilirubin tests in all types of hepatobiliary disorders and correlate moderately well with results of the aminopyrine breath test (Fig. 2.9) (26). Serum bile acid levels are normal in patients with Gilbert's syndrome and Dubin-Johnson syndrome. Serum bile acid tests are as sensitive as aminotransferase measurement in the detection of acute viral hepatitis but less so than aminotransferase measurement in the detection of posttransfusion hepatitis. They are also less sensitive than aminotransferase determination as screening tests for subclinical liver disease. Serum bile acid levels are invariably abnormal in cirrhosis of any cause, and the test is equal to or more sensitive than tests such as the serum albumin measurement or prothrombin time. This finding is not unexpected and is due to the decreased functioning liver cell mass, decreased bile excretion, and portosystemic shunting usually present in chronic liver diseases, all of which affect serum bile acid levels. It has been suggested that the results of serum bile acid tests are predictive of histologic severity (26) and might replace percutaneous liver biopsy; however, investigators have found a poor correlation between serum bile acid levels and histologic severity in patients with chronic hepatitis or alcoholic liver disease (Fig. 2.10) (27,28). There is too much overlap between serum bile acid levels in patients with chronic persistent hepatitis and chronic active hepatitis with bridging necrosis or cirrhosis to obviate liver biopsy. Results of one small study suggested that total serum bile acid levels may be an indication of histologic improvement in patients with chronic hepatitis C who respond to interferon therapy (29).



▪ **Figure 2.9** Correlation between the aminopyrine breath test and the logarithm of 2-hour postprandial serum cholylglycine levels in 44 patients who underwent both tests. *Closed circles* indicate chronic active hepatitis with bridging necrosis or cirrhosis; *open circles* indicate chronic persistent hepatitis and chronic active hepatitis. Cholylglycine levels were determined by means of radioimmunoassay. (From Monroe PS, Baker AL, Schneider JF, et al. The aminopyrine breath test and serum bile acids reflect histologic severity in chronic hepatitis. *Hepatology* 1982;2:317, with permission.)

The attempt to improve the sensitivity and specificity of the serum bile acid tests with intravenous or oral tolerance tests has not proved successful. The ratio of cholic acid to chenodeoxycholic acid has also been considered a means of increasing the sensitivity and specificity of bile salt testing. Unfortunately, a marked overlap exists, both between the healthy control and various hepatic disease states. Preliminary data suggest that a drop in the cholic acid to chenodeoxycholic acid ratio may be helpful in differentiating graft rejection from other causes of hepatic dysfunction in recipients of liver transplants (30).



• **Figure 2.10** Serum bile acid levels of healthy subjects and patients with alcohol-induced fatty liver and alcoholic cirrhosis. The overlap in individual values among the three groups is evident. Serum bile acids, shown on the *ordinate*, were determined by means of combined gas–liquid chromatography and mass spectrometry with deuterium-labeled internal standards. (From Einarsson K, Angelin B, Bjorkhem I, et al. The diagnostic value of fasting individual serum bile acids in anicteric alcoholic liver disease: relation to liver morphology. *Hepatology* 1985;5:108, with permission.)

P.30

Serum bile acid tests offer the advantage of being highly specific indicators of liver dysfunction. They are less sensitive than they were originally hoped to be, however, and are nonspecific in differentiating the various types of liver disease. In this respect, these tests appear similar to the BSP and ICG clearance tests, sensitive LFTs that are rarely used. They may be useful in ruling out liver disease in patients with suspected Gilbert's syndrome and Dubin-Johnson syndrome.

Breath Tests and Other Clearance Tests

The introduction of breath tests for humans in which ^{13}C- or ^{14}C-labeled aminopyrine, phenylalanine, methacetin, phenacetin, or galactose is used represents an attempt to develop a practical test of hepatic functional reserve. The principle and method of breath tests are simple. A substance labeled with ^{13}C or ^{14}C that is given orally or parenterally is converted primarily in the liver to $^{13}CO_2$ or $^{14}CO_2$. As long as absorption is complete or reproducible, the oral route is more convenient. The labeled CO_2 exhaled in the breath is collected at various intervals in an alkaline medium that serves as a CO_2 trap. Metabolism of the labeled agent by the liver can be determined semiquantitatively through the multiplication of the specific activity of exhaled labeled CO_2 over a given time interval by a value for endogenous CO_2 output of 9 mm/kg per hour.

An ideal drug for use in a breath test of hepatic drug-metabolizing capacity would have the following characteristics:

- Metabolism of the test drug should be primarily hepatic. This important parameter is often difficult to validate in humans.
- When the drug is given orally, its absorption must be rapid and complete or at least predictable.
- The drug should have a low hepatic extraction ratio (approximately 20% to 30%) so that changes in hepatic blood flow have little influence on its clearance from blood.
- The generated labeled CO_2 should be distributed evenly throughout the body and not sequestered in an unavailable compartment.
- For ease of collection of the labeled CO_2, the drug should have a short elimination half-life.
- The drug must be safe.

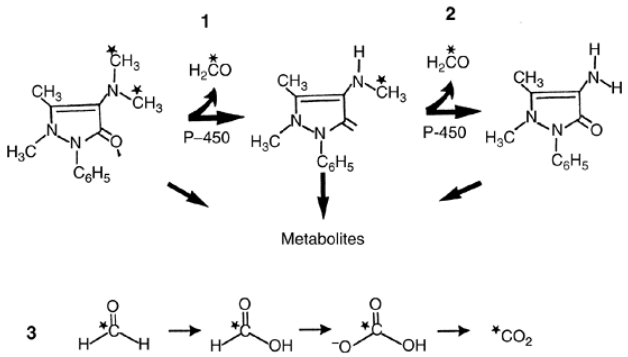
Most of these characteristics seem to have been met by the drugs in use for breath tests, although some points have not been worked out completely.

Aminopyrine breath test

There has been significant experience with the ^{13}C and ^{14}C aminopyrine breath tests. The radioactive methyl groups of aminopyrine undergo demethylation and eventual conversion through formaldehyde and formate to bicarbonate CO_2 with exhalation of labeled CO_2 in the breath (Fig. 2.11). Studies with rats have shown that the rate of appearance of $^{14}CO_2$ in the breath correlates with the mass of the hepatic mixed-function oxidase system. Studies in humans also suggest that the aminopyrine breath test is a measure of mixed-function oxidase mass because in control subjects, the rate of appearance of $^{14}CO_2$ in the breath correlates with the clearance of aminopyrine from the blood (31,32). Furthermore, the rate of appearance of $^{14}CO_2$ increases after pretreatment with phenobarbital, a known microsomal inducer, but it decreases after treatment with disulfiram, an inhibitor of the microsomal mixed-function oxidase system (31). The decreased rate of appearance of $^{14}CO_2$ in the breath also correlates well with the decreased clearance of aminopyrine from blood in patients with cirrhosis, a state in which mixed-function oxidase mass is likely to be decreased. The concept that the breath test is a measure of functioning hepatic microsomal mass is further supported by observations that low results of the aminopyrine breath test in patients with hepatocellular disease correlate well with results that reflect functional mass—the degree of prolongation of prothrombin time (33); the extent of decrease in serum albumin level (31,32); serum bile acid level (26) (Fig. 2.9); galactose elimination

P.31

capacity; and impaired BSP removal from blood. Low results of the aminopyrine breath test also correlate well with the degree of necrosis and inflammation in liver biopsy specimens from patients with alcohol-related cirrhosis (33) (Fig. 2.12). Although only 30% of the administered label is recovered in 48 hours and only 60% of the administered aminopyrine is recovered as demethylated metabolites in urine, the results of detailed analysis of the pharmacokinetics of the aminopyrine breath test support the validity of the test as a measurement of hepatic microsomal enzyme function. The clinician must be aware that factors such as diet, folate deficiency, and use of other drugs may alter the results of this test.



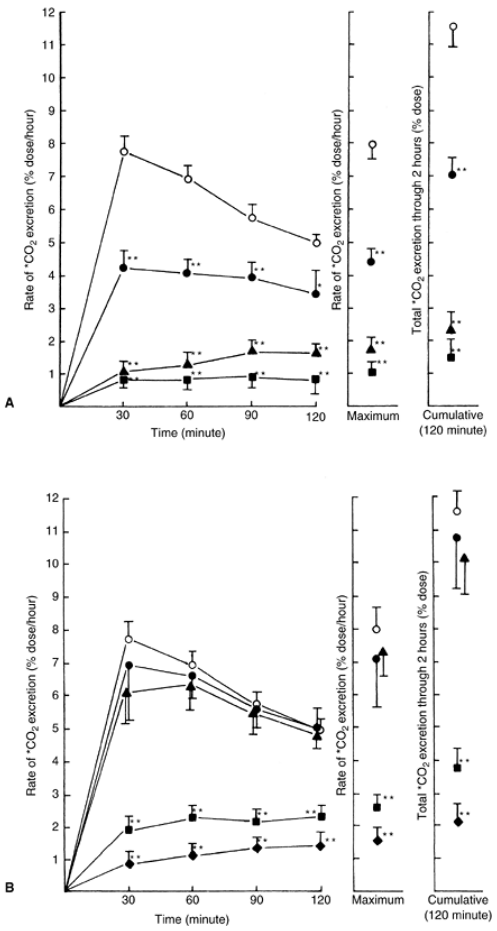
• **Figure 2.11** Metabolism of ^{14}C aminopyrine. (From Baker AI, Kotake AN, Schoeller DA, et al. Clinical utility of breath tests for the assessment of hepatic function. *Semin Liver Dis* 1983;3:318, with permission.)

The ^{14}C aminopyrine breath test is usually performed after an overnight fast. A known dose of ^{14}C aminopyrine (1 to 2 µCi) is administered orally, and breath samples are collected at 30-minute intervals for up to 4 hours. The expired CO_2 is trapped in alkali and counted. There is an excellent correlation between the percentage of administered ^{14}C expired in 2 hours (plasma clearance rate of aminopyrine) and the fractional disappearance rate of $^{14}CO_2$. Because of this, most investigators have found it satisfactory to rely on a single sample collected 2 hours after the administration of the radionuclide. Healthy persons excrete 6.6% ± 1.3% of the administered dose in the breath in 2 hours. Patients with hepatocellular injury excrete considerably less (Fig. 2.12). A single measurement at 60 minutes is more convenient for patients, yields similar data, and has been recommended (34).

The data are clear that a single breath result cannot differentiate the types of liver disease. Levels are equally depressed in patients with alcoholic cirrhosis and severe hepatitis (34). The test may have clinical value in quantifying residual functioning liver cell mass and in establishing prognosis in diseases such as alcoholic hepatitis (34). The aminopyrine breath test appears as sensitive as the measurement of aminotransferases in the detection of hepatocellular diseases and more sensitive than the measurement of serum bilirubin, prothrombin time, and albumin. The aminopyrine breath test may be more specific in the detection of histologic severity of chronic hepatitis (35), hepatitis C (36), and alcoholic liver disease (33) than are conventional liver tests (Fig. 2.12). The breath test appears to be as sensitive as a 2-hour postprandial bile acid test, and there is a moderately good correlation between the results of the two (26). The test result is abnormal more frequently in hepatocellular than in obstructive liver disease (32), and may remain normal in advanced primary and secondary biliary cirrhosis (37). The breath test has been shown to be as good, if not better, than the Child-Pugh score or model for end-stage liver disease in predicting the likelihood of death while awaiting liver transplant (38).

The degree of depression of breath test results overlaps considerably in all types of severe liver disease, including cirrhosis, hepatitis, hepatic cancer, and various histologic forms of alcohol-related disease (32) (Fig. 2.13). In one study, the results of the aminopyrine breath test were more reliable predictors of short-term survival and clinical improvement for patients with alcoholic hepatitis than were results of conventional liver tests. There have been conflicting results in studies of the utility of the aminopyrine breath test in predicting survival among patients with cirrhosis. Results of one study suggest that the aminopyrine breath test is better than the Child-Turcotte classification for predicting survival among patients with cirrhosis who are undergoing surgery. Two other studies found the aminopyrine breath test

to be no better in prediction of survival among patients with cirrhosis than were either the serum albumin or the Child-Turcotte classification test.



• **Figure 2.12** Average excretion rate of labeled CO_2 from aminopyrine in healthy subjects and in patients with alcoholic liver disease and chronic active liver disease. **A:** *Open circles* indicate healthy subjects; *closed circles*, mild alcoholic hepatitis; *triangles*, moderate alcoholic liver disease; *squares*, severe alcoholic liver disease. *Bars* indicate standard error of the mean (SEM) statistical difference from normal controls: $P < 0.05$; $P < 0.01$. **B:** *Open circles* indicate healthy subjects; *closed circles*, chronic persistent hepatitis; *triangles*, chronic active hepatitis; *squares*, chronic active hepatitis with bridging necrosis; *diamonds*, chronic active hepatitis with cirrhosis. (From Hepner GW, Vesell ES. Quantitative assessment of hepatic function by breath analysis after oral administration of (^{14}C) aminopyrine. *Ann Intern Med* 1975;83:632, with permission.)

Although breath tests have been available for more than 25 years in the United States, they are still used infrequently. There are several

reasons for this: They are less convenient to perform than are simple blood tests; they were previously performed only with the radioisotope ^{14}C, which has a long half-life and is not widely used by departments of nuclear medicine; and diagnostic tests with ^{14}C cannot be performed on children. Identical testing can be done with the stable isotope ^{13}C. In the past, the use of this agent required sophisticated and expensive mass spectrometers, which are not widely available. ^{13}C can now be measured by means of nondispersive infrared spectrometry, a simpler and less expensive method that provides results that correlate well with those of both mass spectrometry and $^{14}CO_2$ techniques (39).

Other labeled drugs that have been studied extensively include phenylalanine, methacetin, and galactose. Tests with phenylalanine and methacetin provide information comparable with that from aminopyrine tests and are not discussed further.

The galactose breath test was initially investigated as a substitute for the more laborious galactose elimination capacity (see subsequent text). Galactose metabolism occurs along a cytosolic pathway independent of the cytochrome P-450 system, unlike aminopyrine and methacetin. This independence results in a less metabolic variation due to drug interactions or genetic polymorphisms. Studies have shown that the results of the galactose breath test correlate well with galactose elimination capacity, are altered early in the course of hepatitis C infection, and correlate with the degree of liver fibrosis.

Because of the results of these and other studies, breath tests have been suggested as possible substitutes for liver biopsy in the evaluation of patients with chronic viral hepatitis and alcoholic hepatitis. There is little evidence, however that they will replace liver biopsy, which results in a specific diagnosis, allows assessment of the extent of liver damage, and is a measure for assessing response to therapy. Breath tests

are useful in measuring residual functional microsomal mass and may prove helpful in for establishing the prognosis and response to therapy for certain types of liver disease. However, there is little evidence that breath tests are significantly more sensitive or specific than are the currently used LFTs.

Galactose clearance

Galactose clearance has been used to measure functional hepatic mass. Galactose is given intravenously at a dose of 0.5 g/kg. Serial blood samples are collected over 60 to 90 minutes and assayed for galactose. The results are corrected for urinary galactose excretion. Patients with cirrhosis and chronic hepatitis have markedly low galactose clearance compared with healthy controls, but galactose clearance is rarely abnormal in patients with biliary obstruction. Neither the intravenous nor the oral galactose clearance test have been found better than the measurement of serum albumin in differentiating healthy individuals and patients with cirrhosis. Galactose clearance also appears to add little to standard laboratory studies in predicting the outcome for patients with fulminant hepatic failure or cirrhosis (40,41). The role of this easily performed but cumbersome test remains undefined.

Caffeine clearance

Caffeine clearance tests have been used to quantify functional hepatic capacity by means of assessment of the activity of cytochrome P-4501A2, *N*-acetyltransferase, and xanthine oxidase (42). Several variations in these tests have been described. In all studies, caffeine (200 to 366 mg) is taken orally. Early studies required that blood samples be drawn 1, 2, 3, 6, 12, 24 hours later, and plasma caffeine concentrations measured. In more recent studies, caffeine and its metabolites have been measured in 24-hour urine collections, in saliva, and in scalp hair. Results with these alternative methods are similar to those of the plasma clearance method. Overnight salivary caffeine clearance has been shown to correlate with ICG and galactose clearance and the aminopyrine breath test (43). The measurement of caffeine in scalp hair is an alternative means for collecting similar data (44). Concomitant tobacco use is a confounding factor in these tests, because it increases caffeine clearance (45). Increasing age and certain drugs may decrease clearance of caffeine and salivary pH and flow rate can produce variability with that sampling method (46). The results of caffeine clearance tests are similar to those of the ^{14}C aminopyrine test. A ^{13}C-caffeine breath test has been shown to be a valid indicator of plasma caffeine clearance, and correlates with hepatic dysfunction (47).

Lidocaine metabolite formation

Lidocaine is metabolized to its major metabolite monoethylglycinexylidide (MEGX) through sequential oxidative *N*-dealkylation within the hepatic cytochrome P-450 system (48). A dose of lidocaine (1 mg/kg) is given intravenously. Fifteen, thirty, and/or sixty minutes later, serum samples are taken to determine the MEGX concentration, which is measured most commonly by means of fluorescence polarization immunoassay. Other techniques used to measure MEGX include HPLC and gas–liquid chromatography, both of which are more specific for MEGX than is the fluorescence polarization immunoassay.

Numerous studies have been performed to assess the prognostic value of MEGX formation in patients with cirrhosis (49,50,51,52). Results of other studies suggest that a decline in MEGX concentration correlates well with histologic worsening in patients with chronic liver disease and may provide a noninvasive alternative to liver biopsy for following the course of disease (53,54,55). The MEGX test has also been shown to correlate with hepatic insufficiency and postoperative complications after liver resection in patients with cirrhosis (56). An active area of research has been the role of the MEGX test in identifying suitable donors for liver transplantation. In general, donor MEGX concentration 15 minutes after the infusion of lidocaine has been significantly higher in patients with good early graft function, than in those with poor early graft function. Unfortunately, there is significant overlap in the MEGX values between the two groups, making this test unsuitable for predicting liver function in individual cases. Additional studies will determine whether this safe and easily performed test has a role in the evaluation of hepatic synthetic function.

Tests for Detection of Injury to Hepatocytes (Serum Enzyme Tests)

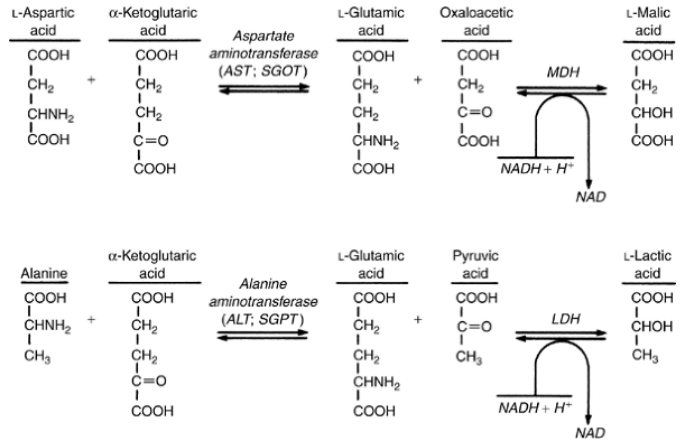
The liver contains thousands of enzymes, some of which are also present in serum in very low concentrations. These enzymes have no known function in serum and behave as other serum proteins do. They are distributed in plasma and interstitial fluid and have characteristic half-lives of disappearance, usually measured in days. Little is known about their catabolism or clearance. The elevation of activity for a given enzyme in serum is thought to primarily reflect its increased rate of entrance into serum from damaged liver cells. Serum enzyme tests can be grouped into two categories: (a) Enzymes the elevation of which in serum reflects generalized damage to hepatocytes and (b) enzymes the elevation of which in serum primarily reflects cholestasis.

Enzymes that Indicate the Presence of Hepatocellular Necrosis

Aminotransferases

The serum aminotransferases (formerly called transaminases) are sensitive indicators of liver cell injury and are most helpful in recognizing acute hepatocellular diseases, such as hepatitis. The activities of alanine aminotransferase (ALT), formerly serum glutamic-pyruvic transaminase, and aspartate aminotransferase (AST), formerly serum glutamic-oxaloacetic transaminase, in serum are the most frequently measured indicators of liver disease. These enzymes catalyze the transfer of the α-amino groups of alanine and aspartic acid, respectively, to the α-keto group of ketoglutaric acid. This results in the formation of pyruvic acid and oxaloacetic acid (Fig. 2.14). Of the numerous methods developed for measuring ALT and AST activity in serum, the most specific method couples the formation of pyruvate and oxaloacetate—the products of the aminotransferase reactions—to their enzymatic reduction to lactate and malate. The reduced form of nicotinamide-adenine dinucleotide (NADH), the cofactor in this reduction, is oxidized to nicotinamide-adenine dinucleotide (NAD). Because NADH (but not NAD) absorbs light at 340 nm, the event can be followed spectrophotometrically by means of

the loss of absorptivity at 340 nm.



• **Figure 2.14** Enzymatic assay of aspartate aminotransferase (AST) and alanine aminotransferase (ALT). SGOT, serum glutamic-oxaloacetic transaminase; SGPT, serum glutamic-pyruvic transaminase; MDH, malic dehydrogenase; LDH, lactate dehydrogenase; NADH, reduced nicotinamide-adenine dinucleotide; NAD, nicotinamide-adenine dinucleotide.

Both aminotransferases are normally present in serum in low concentration (<30 to 40 IU/L). The organ source of these enzymes in serum has never been firmly identified, although they probably originate in tissues rich in ALT and AST. AST is present in the liver, cardiac muscle, skeletal muscle, the kidneys, the brain, the pancreas, the lungs, leukocytes, and erythrocytes, in decreasing order of concentration ALT is present in highest concentration in the liver. The increase in the serum values of ALT and AST is related to damage to or the destruction of tissue rich in the aminotransferases or to changes in cell membrane permeability, which allows ALT and AST to leak into serum. The activity of these enzymes in serum at any moment reflects the relative rate at which they enter and leave the circulation. Injected aminotransferases are distributed in interstitial fluid as well as in plasma. From there, they are gradually cleared as other serum proteins are, AST being cleared more rapidly than ALT. The enzymes are presumably catabolized by cells in the reticuloendothelial system. Hepatic sinusoidal cells appear to be the main site for AST clearance. Almost no aminotransferases are present in urine, and only a very small amount is present in bile. It is therefore unlikely that biliary or urinary excretion plays a role in the clearance of ALT or AST.

ALT and AST both require pyridoxal 5′-phosphate as a cofactor, and may both be present in serum in apoenzyme as well as holoenzyme form (57). In tissues, ALT is present in the cytosol; whereas AST

occurs in two locations, the cytosol and mitochondria. The cytosolic and mitochondrial forms of AST are true isoenzymes and are immunologically distinct. They can be separated from each other with a number of techniques, including immunoprecipitation, chromatography, and electrophoresis. Approximately 80% of AST activity in human liver is contributed by the mitochondrial isoenzyme, whereas most of the circulating AST activity in healthy individuals is derived from the cytosolic isoenzyme. Neither ALT nor AST has isoenzymes that are tissue-specific. Hence, isoenzyme analysis of serum ALT or AST seldom is useful. Patients with acute myocardial infarction and chronic alcoholic liver disease may be exceptions. Large increases in mitochondrial AST occur in serum after extensive tissue necrosis. Because of this, assay of mitochondrial AST has been advocated as an accurate test for the detection of myocardial infarction. The level of mitochondrial AST is also increased in chronic but not acute alcoholic liver disease.

Aminotransferase levels are typically elevated in all liver disorders. These include all types of acute and chronic hepatitis, cirrhosis, infectious mononucleosis, acute and chronic heart failure, various infections, metastatic carcinoma, and granulomatous and alcoholic liver diseases (Fig. 2.15). Elevations up to eight times the upper limit of normal are nonspecific and may be found in any of the mentioned disorders. The highest elevations occur in disorders associated with extensive hepatocellular injury, such as drug and viral hepatitis, acute heart failure, and exposure to hepatotoxins such as carbon tetrachloride and phalloidin. Values are commonly in the low thousands, although values in the range of 10,000 to 15,000 IU/L (167 to 250 μkat/L[1]—see subsequent text) can occur in rare patients with viral hepatitis who make uneventful recoveries. Levels of aminotransferases are seldom elevated above 500 IU (8.34 μkat/L) in obstructive jaundice, viral hepatitis in patients with acquired immunodeficiency syndrome (AIDS), and cirrhosis (58) (Tables 2.3 and 2.4) and usually less than 300 IU (5.0 μkat/L) in alcoholic liver disease. One exception is acute bile duct obstruction caused by a common duct stone. AST and ALT values may reach the thousands within 24 to 48 hours of acute bile duct obstruction, and then rapidly decline to lower values. AST and ALT levels are equally elevated in most hepatobiliary disorders, with the ALT level usually being somewhat higher than the AST level. ALT appears to be a more sensitive and specific test of acute hepatocellular damage than AST and is commonly used in epidemiologic studies to document the incidence of viral hepatitis.

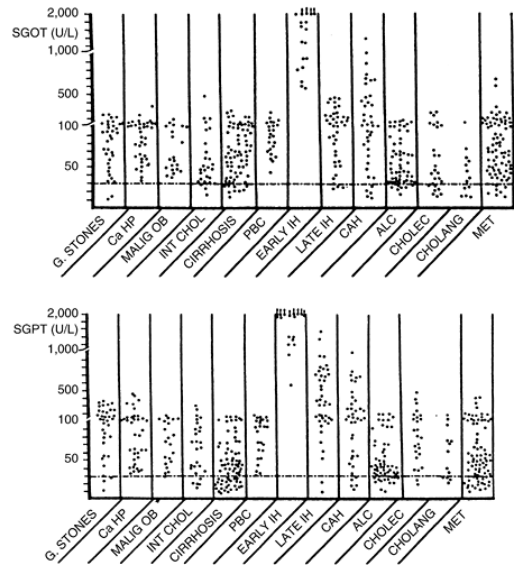
Several studies have questioned whether previously established values to define the normal ALT range are accurate, and have suggested that the upper limit of normal should be revised (59,60,61). The normal range for ALT was set in the 1950s and has changed little since then. As with most clinical laboratory tests, the normal range was defined as the mean of values from a "healthy group of individuals" ±2 SD. The healthy reference population included men and women, often medical students, blood donors, and laboratory technicians. The researchers advocating change have theorized that the "healthy reference group" possibly included patients with nonalcoholic fatty liver disease and hepatitis C, an inclusion that would have skewed the data. Researchers found that serum ALT activity was independently related to body mass index and to laboratory indicators of abnormal lipid or carbohydrate metabolism (61). They suggested lowering the upper limit of normal for men to 500 nkat/L (30 U/L) and for women to 317 nkat/L (19 U/L). Using these new values, the researchers increased sensitivity for detecting hepatitis C virus viremia from 55% to 76.3% with a drop in specificity from 97.4% to 88.5%. The benefit of this change would be marginal at best.

There is a poor correlation between the extent of liver cell necrosis and the elevation of serum aminotransferases levels. Similarly, absolute elevation of aminotransferase levels is of little value in predicting the outcome of acute hepatocellular disorders. Rapid decreases in serum aminotransferase levels are usually a sign of recovery from disease. This may be a poor prognostic sign in fulminant hepatitis, in which decreasing serum values may reflect the massive destruction and loss of viable hepatocytes.

Elevated aminotransferase activity is among the first laboratory abnormalities detected in the early phases of viral hepatitis (Fig. 2.16). In patients with jaundice due to hepatitis, the elevation of serum bilirubin level usually lags behind the increase in aminotransferase levels by approximately 1 week. Therefore, aminotransferase levels are frequently declining as bilirubin level is increasing. Aminotransferase levels typically decline steadily during recovery from viral hepatitis. Secondary increases in aminotransferase levels or

persistent elevation may indicate recrudescence of acute hepatitis or the development of chronic active hepatitis. Hepatitis C is commonly associated with fluctuations in ALT and AST levels. Many patients with persistently elevated aminotransferase levels have liver biopsy evidence of chronic hepatitis; some patients with chronic hepatitis C infection and persistently normal ALT and AST levels are found at liver biopsy to have chronic

hepatitis. The measurement of aminotransferases is one of the important means of following the clinical activity of viral hepatitis, and evaluating the response to immunosuppressive therapy for chronic hepatitis.



• **Figure 2.15** Activities of serum glutamic-oxaloacetic transaminase (SGOT; aspartate aminotransferase [AST]) and serum glutamic-pyruvic transaminase (SGPT; alanine aminotransferase [ALT]) in patients with various types of hepatobiliary disease. Upper limit of normal is shown by *dotted lines.* To convert from IU/L to µkat/L, multiply by 0.01667. G. STONES, gallstones; Ca HP, carcinoma of the head of the pancreas; MALIG OB, carcinoma of bile duct; INT CHOL, intrahepatic cholestasis; CIRRHOSIS, portal cirrhosis; PBC, primary biliary cirrhosis; EARLY IH, early infectious hepatitis; CAH, chronic active hepatitis; ALC, alcoholic hepatic disease; CHOLEC, cholecystitis; CHOLANG, cholangitis; MET, hepatic metastasis. (From Ellis G, Goldberg DM, Spooner RJ, et al. Serum enzyme tests in disease of the liver and biliary tree. *Am J Clin Pathol* 1978;70:248, with permission.)

The AST/ALT ratio is usually of little value in differentiating various hepatobiliary disorders. One important exception is the recognition of alcoholic liver disease. If the ALT is less than 300 IU (5.1 µkat/L), an AST/ALT ratio more than 2 suggests alcoholic liver disease; a ratio greater than 3 is highly suggestive of alcoholic liver disease (62) (Figs. 2.17 and 2.18). The increased ratio primarily reflects the low serum activity of ALT in patients with alcoholic liver disease (Fig. 2.19) (58). This is secondary to a deficiency of pyridoxal 5′-phosphate in patients with alcoholic liver disease (57). ALT synthesis in the liver requires pyridoxal phosphate more than does AST synthesis (57). The altered AST/ALT ratio in the serum appears to reflect the altered ratios in the liver (Fig. 2.19). The less than expected increase in serum ALT and AST values in alcoholic liver disease—usually less than 200 IU (3.3 µkat/L) and 300 IU (5.1 µkat/L), respectively—cannot be explained simply by the decreased hepatic concentrations. This becomes evident whenever a patient with alcoholic liver disease has concomitant heart failure, viral hepatitis, or drug hepatotoxicity, particularly acetaminophen. When this occurs, serum AST and ALT levels may soar to the thousands (>20 µkat/L). Despite striking elevations, the AST/ALT ratio remains increased and typical of alcoholic liver disease.

Table 2.3. Aminotransferase Values in Patients with Infectious Hepatitis and Obstructive Jaundice

Units		AST (SGOT)		ALT (SGPT)	
International (IU/L)	Infectious hepatitis SI (µkat/L)	Obstructive jaundice (Cumulative %)	Infectious hepatitis	Obstructive jaundice (Cumulative %)	
Normal		1	10	1	20
34:46[a]–200	0.57:0.77–3.33	27	81	27	60
201–400	3.35–6.67	43	98	39	93
401–600	6.68–10.00	50	99	43	97

The AST/ALT ratio has been studied as a noninvasive indicator of cirrhosis in patients with chronic hepatitis C infection (63,64,65,66). These studies have shown that an AST/ALT ratio greater than 1 indicates the presence of cirrhosis with a very high specificity (94% to 100%) but with a relatively low sensitivity (44% to 75%). The significant relation between the AST/ALT ratio and ICG clearance suggests that the increase in serum AST level that produces the increased ratio is caused by the impairment of functional hepatic blood flow in patients with cirrhosis; the result is a decrease in hepatic sinusoidal uptake of AST (65).

Researchers identified another possible contributing factor to the AST/ALT ratio seen in both alcoholics and cirrhotics (67). AST-Ig complexes were studied in 128 patients with liver disease. AST was found to bind to Ig of the IgA class, but not to either IgG or IgM. This complex was seen in 41.8% of patients with chronic hepatitis, 62.2% of patients with cirrhosis, and 66.7% of patients with alcohol-related liver disease. The high level seen in the final group likely reflected the high levels of IgA seen in patients with alcohol-related liver disease. The AST/ALT ratio was significantly higher in the patients with the AST-Ig complex, rather than those without, and this observation probably contributes to the higher AST/ALT ratio seen in patients with cirrhosis and alcoholic liver disease.

Table 2.4. Ratio of Aspartate Transferase to Alanine Transferase in Patients with High and Low Values

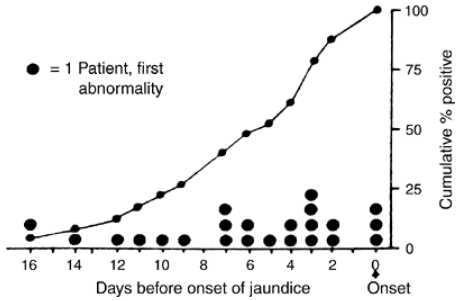
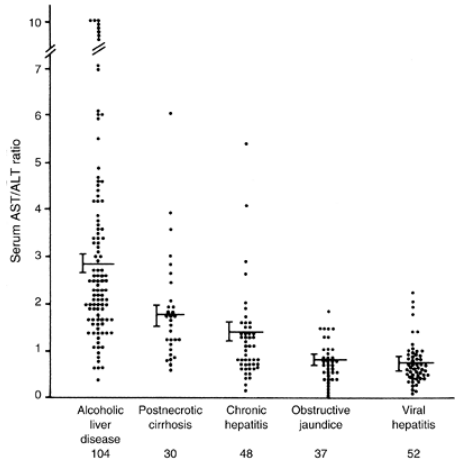
Elevated serum aminotransferase values are not specific for hepatobiliary disorders. They are also found in patients with severe cardiac and skeletal muscle damage. AST level is more often increased

in patients with myocardial infarction than ALT, and is undoubtedly of cardiac origin. Large increases in ALT in cardiac disease are probably of hepatic origin because they frequently occur among patients with large, hemodynamically significant infarcts associated with congestive heart failure and circulatory collapse. Hepatic ischemia and central hepatocellular necrosis are likely to occur in these patients.



▪ **Figure 2.16** Elevation of AST (SGOT) in the early stages of acute viral hepatitis. Relation of the first abnormality is compared with the onset of jaundice in 23 patients or volunteers closely observed during the incubation period of viral hepatitis. (From Clermont RJ, Chalmers TC. The transaminase tests in liver disease. *Medicine* 1967;46:197, with permission.)



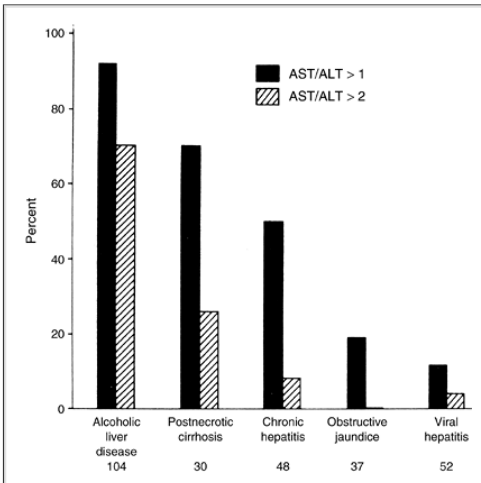
▪ **Figure 2.17** Aspartate aminotransferase (AST)/alanine aminotransferase (ALT) ratio in patients with biopsy-proven liver disease. The ratio was calculated from the serum sample that had the highest individual aminotransferase value, be it AST or ALT. (Adapted from Cohen JA, Kaplan MM. The SGOT/SGPT ratio: an indicator of alcoholic liver disease. *Dig Dis Sci* 1979;24:835, with permission.)

Increased AST and ALT values in muscle disease are probably derived from muscle. The extent of enzyme elevation in muscle disease is typically less than 300 U/L (5.1 μkat/L) but has been reported much higher (68).

P.40

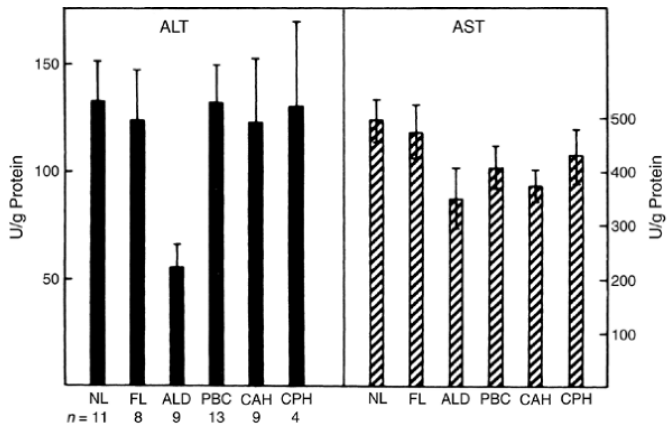
P.41

Except in instances of acute rhabdomyolysis, values rarely reach the range observed in patients with acute hepatocellular disorders. However, serum AST and, occasionally, ALT activity, can increase slightly after vigorous exercise with an AST levels of greater then 1,000 reported. In such cases the AST/ALT is initially greater than 3:1, but the ratio rapidly approaches 1:1 given the shorter half-life of AST (68). The ratio is typically close to 1:1 in patients with chronic muscle diseases or injury. This may account for the slight, usually unexplained increases in aminotransferase values observed among some runners.



▪ **Figure 2.18** Percentage of patients with aspartate aminotransferase (AST)/alanine aminotransferase (ALT) ratios greater than 1 and greater than 2. (Adapted from Cohen JA, Kaplan MM. The SGOT/SGPT ratio: an indicator of alcoholic liver disease. *Dig Dis Sci*

1979;24:835, with permission.)



• **Figure 2.19** Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activities in human liver. The activity of ALT is selectively decreased in livers of patients with alcoholic hepatitis, cirrhosis, or both. NL, normal liver; FL, fatty liver in the absence of alcoholism; ALD, alcoholic hepatitis, cirrhosis, or both; PBC, primary biliary cirrhosis; CAH, chronic active hepatitis; CPH, chronic persistent hepatitis. (Adapted from Matloff DS, Selinger MJ, Kaplan MM, et al. Hepatic transaminase activity in alcoholic liver disease. *Gastroenterology* 1980;78:1389, with permission.)

Levels of the aminotransferases can be falsely elevated or diminished under certain circumstances. Drugs such as erythromycin and para-aminosalicylic acid can yield falsely elevated aminotransferase values if older colorimetric tests are used. Conversely, low AST values can occur in patients with uremia. These low values increase after dialysis; this finding suggests that a dialyzable inhibitor of the aminotransferase reaction is present in the serum of patients with uremia.

Other Enzyme Tests of Hepatocellular Necrosis

A number of other serum enzyme tests have been promulgated as being either more specific or more sensitive in the detection of hepatocellular necrosis than is the measurement of aminotransferases. Some of these enzymes are only found in liver tissues and, theoretically, the tests should be more specific for liver disease than are the aminotransferase tests. None of them has proved more useful in practice than the aminotransferase tests, and none are more widely used. A brief description of some of these enzyme tests follows.

Glutamate dehydrogenase

Glutamate dehydrogenase, a mitochondrial enzyme, is present primarily in the liver, heart, muscle, and kidneys. In the liver, it is present in its highest concentration in the centrilobular hepatocytes. Because of this location and the fact that the level is particularly elevated after acute right-sided heart failure, serum glutamate dehydrogenase was investigated as a specific marker for liver disorders that primarily affect centrilobular hepatocytes, such as alcoholic hepatitis. An initial report that glutamate dehydrogenase may be a sensitive and a relatively specific marker for alcoholic hepatitis has not been confirmed by others. Glutamate dehydrogenase is seldom used as an LFT.

Isocitrate dehydrogenase

Isocitrate dehydrogenase (ICDH), a cytoplasmic enzyme, is present in the liver, heart, kidneys, and skeletal muscle. Its activity in serum parallels that of the aminotransferases in acute and chronic hepatitis, but it is less sensitive. Although elevations in serum ICDH are relatively specific for liver disorders, increased levels have also been reported in disseminated malignant disease without detectable hepatic involvement. Like glutamate dehydrogenase, ICDH is predominantly found in hepatocytes in the centrilobular zone. It has been advocated as a possible marker of centrilobular necrosis (69). The measurement of ICDH does not yet offer any diagnostic advantage over the measurement of aminotransferases.

Lactate dehydrogenase

Lactate dehydrogenase is a cytoplasmic enzyme present in tissues throughout the body. Five isoenzymes of lactate dehydrogenase are present in serum, and are readily separated by various electrophoretic techniques. The slowest migrating band predominates in the liver. This test is not as sensitive as aminotransferase tests in the detection of liver disease and has poor diagnostic specificity, even when isoenzyme analysis is used. The lactate dehydrogenase test is more useful as a marker of myocardial infarction and hemolysis.

Sorbitol dehydrogenase

Sorbitol dehydrogenase is a cytoplasmic enzyme predominantly present in the liver; only relatively low concentrations are found in the prostate gland and kidneys. The activity of sorbitol dehydrogenase in serum parallels that of the aminotransferases in hepatobiliary disorders. The measurement of sorbitol dehydrogenase appears to be less sensitive, however, and values may be normal in cirrhosis and other chronic liver disorders. The instability of this enzyme in serum further limits its diagnostic usefulness.

Enzymes for the Detection of Cholestasis

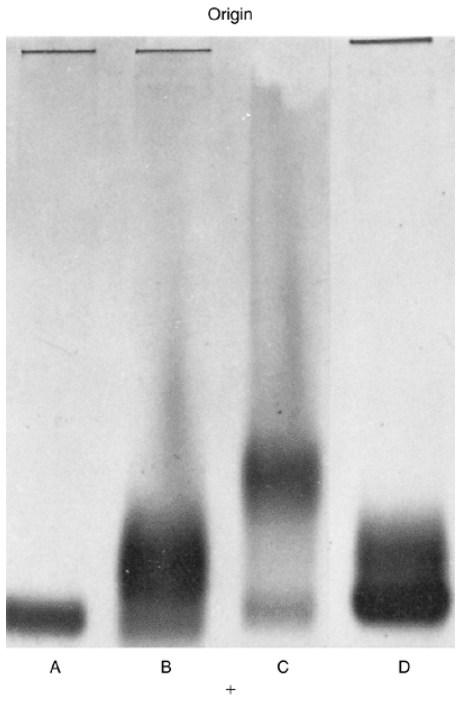
Alkaline phosphatase

Alkaline phosphatase is the name given to a group of enzymes that catalyze the hydrolysis of a large number of organic phosphate esters, optimally at an alkaline pH. Inorganic phosphate and the organic radical are generated by the reaction. The alkaline phosphatases of different tissues are true isoenzymes because they catalyze the same reaction, but differ in certain physicochemical properties (70). At least three separate genes code for the alkaline phosphatases. Most of the alkaline phosphatase isoenzymes of clinical interest are from the liver, bone, first-trimester placenta, and kidneys, and are coded by one gene. They are called *tissue-unspecific alkaline phosphatase.* They have

the same immunologic properties and amino acid sequence. Their unique physicochemical properties are conferred by the different carbohydrate and lipid side chains added by posttranslational modification. A second gene codes for third-trimester placental and intestinal alkaline phosphatase, and a third gene codes for a second intestinal alkaline phosphatase.

The precise function of alkaline phosphatase is unknown. Alkaline phosphatases are found in many locations throughout the body, including bone osteoblasts, the canalicular membranes of hepatocytes, the brush border of the mucosal cells of the small intestine, the proximal convoluted tubules of the kidney, the placenta, and white blood cells (53). In rat liver, alkaline phosphatase appears to have an active role in down-regulating the secretory activities of the intrahepatic biliary epithelium (71). In bones, the enzyme appears to be concerned with calcification, although its precise function is unknown. At other sites, it may participate in transport processes, but its actual physiologic purpose is largely unknown. Alkaline phosphatase activity is normally demonstrable in serum. There is good evidence that serum enzyme in the normal adult is primarily derived from three sources—the liver, bone, and in some instances, the intestinal tract (Fig. 2.20). The liver and bone are the major sources (70). Contribution from the intestine (approximately 10% to 20%) is of importance, primarily in individuals with blood groups O and B who secrete the ABH red blood cell antigen, and the blood level of alkaline phosphatase is enhanced after the consumption of a fatty meal (72). Studies with infused placental alkaline phosphatase have shown that the circulating enzyme appears to behave as other serum proteins do. The half-life is 7 days, and clearance from the serum is independent of the functional capacity of the liver or the patency of the bile ducts. The sites of degradation are unknown.

Some details of the more popular procedures used to measure alkaline phosphatase activity, including substrates used, end products measured, and the usual range of normal values for adults 17 to 55 years of age, are contained in Table 2.5 (70). In the most widely used procedure ρ-nitrophenylphosphate is used as a substrate and an amino alcohol, such as 2-amino-2-methyl-1-propanol, is used as a buffer. The rate of release of ρ-nitrophenol or phosphate from the substrate is measured under specified incubation conditions. The results are expressed in international units (IU/L), which is the activity of alkaline phosphatase that releases 1 mmol of chromogen or inorganic phosphate (P_i) per minute. Results obtained with these methods appear to be equally effective in the detection of a variety of clinical diseases. Use of conversion factors allows the interchange of values obtained with the different methods. These factors are based on average values, however, and correlate poorly in individual patients. This is not surprising because serum alkaline phosphatase consists of isoenzymes that differ in reactivity in various assay systems (70). A simple way of comparing the results of different methods is to express the results as multiples of the upper limit of normal. A number of analytic sources of error exist. Factors such as the concentrations of phosphate, citrate, and magnesium, and the type and concentration of the buffer may be important.



• **Figure 2.20** Alkaline phosphatase isoenzymes separated in 7.5% polyacrylamide gel slabs at pH 7.5. *A*, liver isoenzyme from a patient with obstructive jaundice; *B*, bone isoenzyme from a patient with Paget's disease of bone; *C*, liver and intestinal isoenzymes from a patient with alcoholic cirrhosis; *D*, liver and bone isoenzymes from a patient with celiac sprue and osteomalacia. (From Kaplan MM. Alkaline phosphatase. *Gastroenterology* 1972;62:452, with permission.)

In the 15- to 50-year-old age-group, mean serum alkaline phosphatase activity is somewhat higher in men than in women (Fig. 2.21). In contrast, among individuals older than 60 years, the enzyme activity of women equals or exceeds that of men, and both sexes have somewhat higher values than younger adults (73). The reasons for these differences are not known. In children, serum alkaline phosphatase activity is

considerably elevated in both sexes, correlates well with the rate of bone growth, and appears to be accounted for by the influx of enzyme from osteoid tissue. Serum alkaline phosphatase in healthy adolescent males may reach mean levels three times greater than in healthy adults, without implying the presence of hepatobiliary disease. Enzyme activity in serum may double late in normal pregnancy, primarily because of the influx of placental phosphatase.

Table 2.5. Clinical Methods of Serum Alkaline Phosphatase Determination

Method	Substrate (μmol/mL)	Temperature (°C)	Buffer pH	Unit	Normal range

Bessey-Lowry-Brock	*p*-Nitrophenylphosphate (5.4)	39	10.5 Glycine	1 µmol/L *p*-nitrophenol per 60 min	0.8–3.0

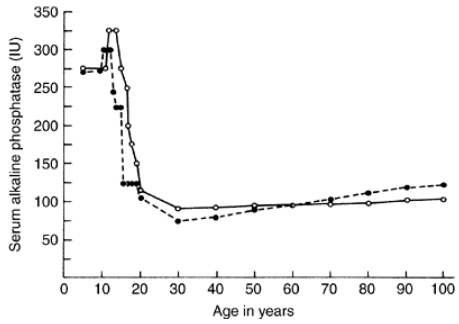
Although the elevation of serum alkaline phosphatase activity is common in various hepatobiliary diseases, similar elevations are observed in disorders of bone characterized by increased osteoblastic activity, and normally occur during growth and pregnancy. The intestinal tract may occasionally and the kidneys may rarely be the sources of an elevated serum enzyme level (70,74).



• **Figure 2.21** Normal serum alkaline phosphatase values at various ages for men (*open circles*) and women (*closed circles*). (Multiply by 0.01667 to convert to SI units, µkat/L.) (Data derived from Clarke LC, Beck EJ. Plasma "alkaline" phosphatase activity, I: normative data for growing children. *J Pediatr* 1950;36:335, and Wolf PL. Clinical significance of an increased or decreased serum alkaline phosphatase level. *Arch Pathol Lab Med* 1978;102:497.)

If an elevated serum alkaline phosphatase level is the only abnormal finding in an apparently healthy individual, or if the degree of elevation is higher than expected in the clinical setting, the identification of the source of elevated isoenzyme is helpful.

This problem can be approached in several ways. First, and most precise, is the fractionation of the alkaline phosphatase by electrophoresis (75). Alkaline phosphatases derived from the liver, bone, intestines, and placenta have differing electrophoretic mobilities. In most clinical situations, this amounts to separating the liver from bone alkaline phosphatase (76). In a study in a university hospital in which the subjects were 317 patients selected because they had elevated serum alkaline phosphatase activity, the liver isoenzyme was the source of the elevation in 253 patients, bone in 58 patients, a mixture of bone and liver in 4 patients, and the intestine in only 2 patients (76). Unfortunately, the bone and liver isoenzymes only differ slightly in electrophoretic mobility. These isoenzymes often overlap if the test is run on the electrophoretic systems used in most routine clinical laboratories. Separation on polyacrylamide gel slabs is the most reliable method and produces clear-cut separations of the liver, bone, intestinal, and placental isoenzymes (Fig. 2.20). This method is not always available, however. Electrophoresis on cellulose acetate with the addition of heat inactivation may accomplish the same purpose.

The second approach is based on the observation that alkaline phosphatases from individual tissues differ in susceptibility to inactivation by heat or 2 mol urea (70). Placental alkaline phosphatase and an isoenzyme present in certain cancers—the Regan isoenzyme—are fully heat-stable after exposure to a temperature of 56°C for 15 minutes. The enzymes derived from bone, the intestines, and the liver are partly inactivated. Accordingly, the finding of an elevated serum alkaline phosphatase level in a patient with all excess activity in a heat-stable fraction, strongly suggests that the placenta or a tumor is the source of the elevation of the enzyme level in serum. Susceptibility to inactivation by heat and urea increases, in order, for intestinal, liver, and bone alkaline phosphatases, bone being by far the most sensitive (70).

Unfortunately, in evaluations of unselected patients, both heat inactivation and 2 mol urea were not found diagnostically useful. A confounding factor in the use of heat inactivation is that slight changes in temperature—as little as 0.2°C—substantially alter the rates of inactivation (70). The presence of more than one alkaline phosphatase isoenzyme in serum, each with its own rate of heat denaturation, may also yield results that cannot be interpreted. We have not found these methods useful and do not recommend them.

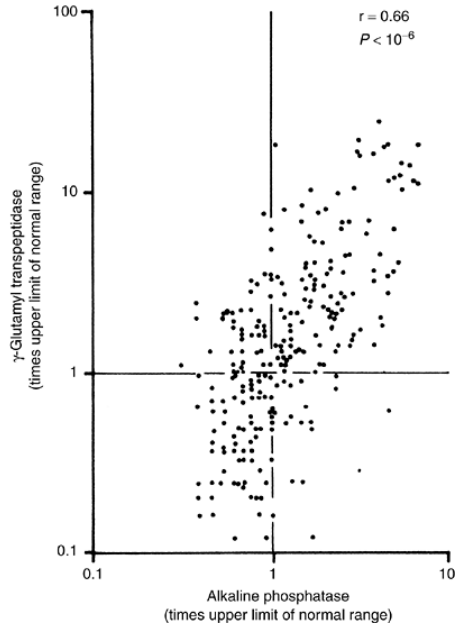
In the third and best substantiated approach, the activity of serum, leucine aminopeptidase, 5′-nucleotidase, and γ-glutamyl transpeptidase (GGT) is measured (Fig. 2.22). The levels of these enzymes, discussed later, are not elevated in bone disorders but only with liver dysfunction or, in the case of leucine aminopeptidase and possibly 5′-nucleotidase, in pregnancy. An increase of these enzymes in the serum of nonpregnant patients indicates that an elevated serum alkaline phosphatase level is caused at least in part by hepatobiliary disease. In contrast, the lack of an increased level of 5′-nucleotidase in serum in the presence of an elevated level of alkaline phosphatase does not rule out liver disease, because these enzymes do not necessarily increase in a parallel manner in early or modest hepatic injury.

In all patients who have been evaluated, elevated levels of alkaline phosphatase in serum have originated in tissues with either functionally disturbed metabolism (obstructed liver) or greatly stimulated metabolism (third-trimester placenta and bone in growing children). There is general agreement regarding the skeletal origin of the elevated serum alkaline phosphatase level in patients with bone disorders, and in growing children and the placental origin in women during the third trimester of pregnancy. Only with reference to patients with hepatobiliary disorders have there been any questions regarding the mechanism of the increased serum alkaline phosphatase level. The following two theories had been proposed: (a) The damaged liver regurgitates hepatic alkaline phosphatase back into the serum, and (b) the damaged liver, particularly if the damage is caused by obstructive jaundice, fails to excrete alkaline phosphatase made in bone, the intestines, and the liver.

This long-standing debate was resolved in favor of the former: The regurgitation of liver alkaline phosphatase into serum. The data supporting this theory are compelling. First, only hepatic alkaline phosphatase is found in the serum of patients with liver disease, particularly cholestasis (75,76). Second, the clearance rates of infused placental alkaline phosphatase are the same in patients with bile duct obstruction and in healthy individuals. Third, in experimental models of bile duct obstruction in rats, the entire increase in serum alkaline phosphatase activity is caused by the leakage of hepatic alkaline phosphatase into serum (77). The increased serum activity is paralleled by a striking increase in hepatic alkaline phosphatase activity. The increased hepatic activity cannot be accounted for by the biliary retention of alkaline phosphatase (77).

The mechanism by which hepatobiliary disease leads to an elevation of serum alkaline phosphatase has been greatly clarified. Most evidence suggests that this elevation primarily occurs because of de novo synthesis of the enzyme in the liver, and release of the phosphatase into the circulation (77,78). This process appears to be mediated by the action of bile acids,

which induce the synthesis of the enzyme and may cause it to leak into the circulation, perhaps by means of disruption of hepatic organelles and solubilization of phosphatase bound to such membranes (78). The precise manner in which the phosphatase reaches the circulation is unclear. In some patients with cholestasis, small vesicles that contain many basolateral (sinusoidal) membrane enzymes—including alkaline phosphatase—still bound to these membranes have been found in serum (79).



• **Figure 2.22** Correlation between serum γ-glutamyl transpeptidase and serum alkaline phosphatase levels in 245 healthy subjects and patients with hepatobiliary diseases. The units on the abscissa and ordinate are the logarithms of the multiples of the upper limits of normal for each test. Each point represents one patient. Although the correlation between the logarithmic values of the population (r = 0.66) is good, a considerable variation exists between the percentage of γ-glutamyl transpeptidase and alkaline phosphatase elevations in individual patients. (From Whitefield JB, Pounder RE, Neale G, et al. Serum γ-glutamyl transpeptidase activity in liver disease. *Gut* 1972;13:702, with permission.)

The principal value of serum alkaline phosphatase in the diagnosis of liver disorders is in recognition of cholestatic disorders. Approximately 75% of patients with prolonged cholestasis have alkaline phosphatase values increased fourfold or greater. Such elevations occur in both extrahepatic and intrahepatic obstruction, and the extent of the elevation does not differentiate the two. There is essentially no difference among the values found in obstructive jaundice due to cancer, common duct stone, sclerosing cholangitis, or bile duct stricture. Values are similarly increased in patients with intrahepatic cholestasis due to drug-induced hepatitis, primary biliary cirrhosis, rejection of transplanted liver, and, rarely, alcohol-induced steatonecrosis. Values are also greatly elevated in hepatobiliary disorders in patients with AIDS (e.g., primary sclerosing cholangitis due to cytomegalovirus infection and tuberculosis with hepatic involvement) (7).

Lesser increases in alkaline phosphates activity—up to three times the upper limit of normal—are nonspecific and may occur in all types of liver disorders—including viral hepatitis, chronic hepatitis, cirrhosis, infiltrative diseases of the liver—and congestive heart failure.

Isolated elevations of hepatic alkaline phosphatase or disproportionate elevation compared with results of other tests, such as the measurement of aminotransferases and serum bilirubin, may occur in partial bile

duct obstruction due to gallstones or tumor, as well as in infiltrative disease, such as sarcoidosis, hepatic abscesses, tuberculosis, and metastatic carcinoma (70). The mechanism is unknown, but probably represents local areas of bile duct obstruction with induction and leakage into serum of hepatic alkaline phosphatase from these obstructed areas. An elevated serum alkaline phosphatase level in patients with primary extrahepatic cancer does not necessarily imply metastasis to the liver or bone. Some cancers secrete their own alkaline phosphatase into serum or cause leakage of hepatic alkaline phosphatase into serum by an unknown mechanism (76).

Moderate elevations in the level of alkaline phosphatase of hepatic origin can occur in disorders that do not directly involve the liver, such as stage I or II Hodgkin's disease, myeloid metaplasia, congestive heart failure, intra-abdominal infections, and osteomyelitis (76). Certain families may also have increased levels of serum alkaline phosphatase that are genetic in origin (74). Finally, extremely low levels of alkaline phosphatase can be present in patients with fulminant Wilson disease complicated by hemolysis (80,81).

5′-Nucleotidase

5′-Nucleotidase specifically catalyzes the hydrolysis of nucleotides such as adenosine 5′-phosphate and inosine 5′-phosphate, in which the phosphate is attached to the 5 position of the pentose moiety. 5′-Nucleotidase is found in the liver, intestines, brain, heart, blood vessels, and endocrine pancreas. In the liver, the enzyme is primarily associated with canalicular and sinusoidal plasma membranes. The physiologic purpose is unknown. In most laboratories, 5′-nucleotidase activity is assayed by the use of adenosine 5′-phosphate as substrate, and measurement of either the released inorganic phosphate or the free adenosine. The presence of alkaline phosphatase in serum complicates the assay because it also hydrolyzes the 5′-nucleotide substrates. Corrections for alkaline phosphatase activity can be made in two ways: (a) Preliminary incubation of serum with appropriate concentrations of ethylenediaminetetraacetic acid, which selectively inactivates only alkaline phosphatase or (b) assay in the presence and absence of nickel (Ni^{2+}), a heavy metal that specifically inhibits 5′-nucleotidase. In most clinical laboratories, free inorganic phosphate is measured. A unit of 5′-nucleotidase activity is designated as an equivalent to the amount of enzyme that liberates 1 mg of phosphate per 100 mL of serum per hour. These units are analogous to the old Bodansky units of alkaline phosphatase activity and are expressed as such. In most series of healthy adults, the serum 5′-nucleotidase level ranges from 0.3 to 3.2 Bodansky units, and is not clearly influenced by sex or race. Values are substantially lower in children than in adults, increase gradually with adolescence, and reach a plateau after 50 years of age.

Serum values of 5′-nucleotidase are primarily elevated in hepatobiliary disease with a spectrum of abnormal values similar to that for alkaline phosphatase. The parallel behavior of these two enzymes in hepatobiliary disease probably reflects their similar subcellular location in hepatocytes (82). Both enzymes are bound to bile canalicular and sinusoidal membranes, and must be solubilized to gain access to the circulation. Bile acids may act as detergents and solubilize them. In experimental bile duct obstruction in rats, bile acid concentrations rapidly reach levels sufficient to disrupt plasma membranes and solubilize both these enzymes. The same may occur in hepatobiliary disorders in which any degree of cholestasis develops (82).

Results of most studies indicate alkaline phosphatase and 5′-nucleotidase are equally valuable in demonstrating biliary obstruction or hepatic infiltrative and space-occupying lesions. In selected patients, however, the level of one enzyme may be elevated and that of the other normal. Although the coefficient of correlation between the two enzymes is high, the values may not increase proportionately in individual patients (83).

Most data suggest that the 5′-nucleotidase and serum alkaline phosphatase are of equal value in differentiating obstructive from parenchymal liver disease. All investigators have shown some overlap in 5′-nucleotidase values in obstructive and hepatocellular jaundice. Some investigators have found this overlap to be small, and have concluded that this assay is equal to or better than the measurement of serum alkaline phosphatase for differentiating these two types of jaundice. Others have reported that the measurement of alkaline phosphatase has greater selective value (83).

Conflicting data have been reported for values of 5′-nucleotidase activity in serum during normal pregnancy. Some investigators have found an increase in enzyme activity in the third trimester, and others report no change during pregnancy. It is not clear whether these experiences are accounted for by differences in methods used to measure 5′-nucleotidase activity. The major advantage of 5′-nucleotidase over the nonspecific alkaline phosphatase measurement in serum is enhanced specificity. Most studies show that the serum level of 5′-nucleotidase does not increase in bone disease; in the few instances in which an increase was observed, it was of low magnitude (83). This is in striking contrast to results with alkaline phosphatase (83).

The greatest value of the 5′-nucleotidase assay is its specificity for hepatobiliary disease. An increased serum 5′-nucleotidase level in a nonpregnant individual

suggests that a concomitantly increased serum alkaline phosphatase level is of hepatic origin. A normal nucleotidase level in the presence of an elevated serum alkaline phosphatase level does not rule out the liver as the source of the elevated phosphatase level. The level of one enzyme may occasionally be normal and the other elevated in liver disease.

γ-Glutamyl transpeptidase

GGT catalyzes transfer of the γ-glutamyl group from γ-glutamyl peptides such as glutathione to other peptides and to L-amino acids. γ-L-Glutamyl-ρ-nitroanilide is most commonly used as a substrate in its assay with glycylglycine as the acceptor. The enzyme catalyzes the transfer of the γ-glutamyl moiety from the substrate to glycylglycine and therefore liberates the chromogen ρ-nitroaniline, which can be measured spectrophotometrically. GGT is present in cell membranes in many tissues, including the kidneys, pancreas, liver, spleen, heart, brain, and seminal vesicles. It is thought to play a role in amino acid transport across membranes as part of the γ-glutamyl cycle. Some data suggest that hydrolysis of glutathione rather than transpeptidation may be its true physiologic function. The enzyme is present in normal human serum. Serum enzyme values are usually comparable for men and women, although some investigators have found higher values in men (84). Children more than 4 years have serum values of healthy adults. Serum enzyme activity does not increase during the course of normal pregnancy. The normal range is 0 to 30 IU/L (0 to 0.5 μkat/L).

Elevated serum enzyme activity is found predominantly and in high frequency in diseases of the liver, biliary tract, and pancreas (84). Abnormal values appear in approximately the same spectrum of hepatobiliary diseases as for alkaline phosphatase, leucine aminopeptidase, and 5′-nucleotidase. Some investigators find the GGT test more sensitive than alkaline phosphatase and leucine aminopeptidase tests in the detection of liver disease (84). Others find little difference in sensitivity between GGT and alkaline phosphatase tests. A reasonably good, albeit far from perfect, correlation exists between GGT levels and those of 5′-nucleotidase and alkaline phosphatase in liver disease (Figs. 2.22 and 2.23).

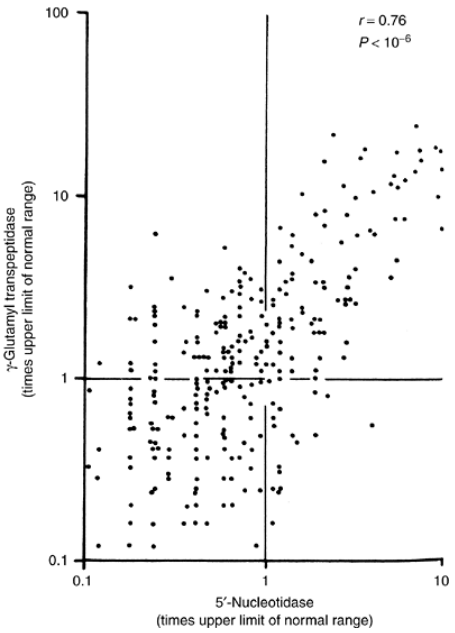
The clinical value of GGT lies in its use in conferring organ specificity to an elevated value of alkaline phosphatase, because GGT activity is not elevated in patients with bone disease. In addition, high GGT values are found in patients who take medications such as barbiturates or phenytoin (Dilantin), or ingest large quantities of alcohol (85,86), even when other serum enzyme and bilirubin values are normal. When the elevated GGT value is associated with the use of anticonvulsant drugs or alcohol abuse, no correlation between serum GGT and alkaline phosphatase values is seen. Some investigators have found that an isolated elevation in GGT level, or an elevation in GGT level out of proportion with that of other enzymes such as alkaline phosphatase or ALT is an indicator of alcohol abuse or alcoholic liver disease (Fig. 2.24). The induction of hepatic microsomal GGT by alcohol and other drugs may account for some of these observations. This is not the only explanation, however, because neither elevated serum GGT levels, nor a history of recent alcohol ingestion correlates with hepatic GGT activity in patients with biopsy-proven alcoholic liver disease (87). In addition, the alkaline phosphatase and hepatic GGT activities are similarly increased in patients with alcoholic hepatitis, yet serum GGT levels were 1,300% of normal while alkaline phosphatase serum levels were only slightly above normal (Fig. 2.24) (87). Results of in vitro studies suggest that alcohol may also cause the leakage of GGT from hepatocytes.

Normal GGT values in childhood and in pregnancy offer additional diagnostic possibilities for this test, although little has been published about clinical experience with GGT determinations in liver disease during these states. Elevation of GGT activity in serum may be depressed by female sex hormones. This was inferred from reports that GGT activity was increased less frequently and to a lesser degree in women who contracted viral hepatitis during the latter half of pregnancy or while taking oral contraceptives. In the latter study, it was also found that hyperbilirubinemia interfered with the measured activity of GGT in vitro. Both factors seem to operate in other liver disorders and undoubtedly contribute to the impaired differential diagnostic usefulness of the GGT enzyme test. Aside from its value in conferring liver specificity to an elevated alkaline phosphatase level and its possible use in identifying that a patient abuses alcohol, GGT testing offers no advantage over aminotransferase and alkaline phosphatase testing. In a prospective study with 1,040 nonselected inpatients, 139 patients (13.4%) had elevated serum GGT activity. Only 32% of these patients had hepatobiliary disease; the other 68% had other diseases that did not involve the liver (88).

Leucine aminopeptidase

Leucine aminopeptidase, a proteolytic enzyme, hydrolyzes tissue amino acids from the *N*-terminal of proteins and polypeptides. It is most active when leucine is the *N*-terminal residue; hence, its name. Leucine aminopeptidase is found in all human

tissues assayed; it has high activity in the liver, where it is primarily localized in the biliary epithelium. The function of this enzyme is not known, although it possibly involves hydrolysis of a peptide bond near an L-leucine residue, or the transfer of L-leucine from one peptide to another. The leucine aminopeptidase of normal serum, as a rule, is electrophoretically homogenous and probably originates in the liver. In hepatobiliary disease, several peaks of activity are detected, and they probably represent isoenzymes.

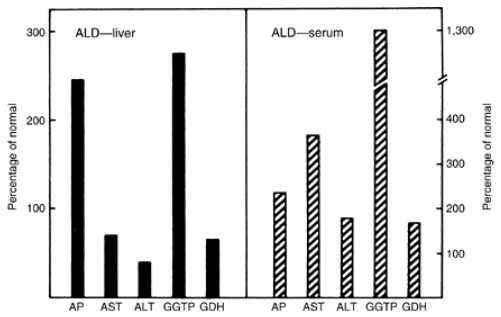


• **Figure 2.23** Correlation between serum γ-glutamyl transpeptidase and serum 5′-nucleotidase values in 245 healthy subjects and patients with hepatobiliary diseases. The units on the abscissa and ordinate are the logarithms of the multiples of the upper limits of normal for each test. Although the correlation between the logarithmic values of the population (r = 0.76) is good, there is considerable variation between the percentage of γ-glutamyl transpeptidase and 5′-nucleotidase elevations in individual patients. (From Whitefield JB, Pounder RE, Neale G, et al. Serum γ-glutamyl transpeptidase activity in liver disease. *Gut* 1972;13:702, with permission.)

The prevalent method for measuring serum leucine aminopeptidase involves α-leucyl-β-naphthylamine hydrochloride as a substrate; the liberated β-naphthylamine is assayed colorimetrically. Some evidence exists that the peptidase responsible for this reaction differs from the peptidases that hydrolyze other leucine compounds. Accordingly, in extrapolating data from one study to another, one should carefully consider the substrate used. Normal values when α-leucyl-β-naphthylamine is used usually range from 50 to 220 IU without a significant difference due to sex, age (18 to 75 years), or fed state.

Elevation in the leucine aminopeptidase level, like that of 5′-nucleotidase and to a lesser degree GGT, appears to be specific for liver disorders. The level of leucine aminopeptidase is not elevated in patients with bone disease (89), and enzyme values in children, although based on a small number of determinations, are comparable with those of adults. The only condition other than hepatobiliary disease known to result in an increase in this enzyme is pregnancy (90). The level of serum leucine aminopeptidase progressively increases during gestation and reaches a peak at term. After delivery, the enzyme level falls, decreasing approximately 35% in 4 days. Electrophoresis of serum leucine aminopeptidase from pregnant women and from individuals with liver disease shows much overlap

among the isoenzymes. This procedure is probably of no practical value in differentiating these two sources of the enzyme.



• **Figure 2.24** Enzyme values in liver tissue and serum of patients with biopsy-proven alcoholic hepatitis and cirrhosis (ALD). Values are expressed as a percentage of the values in healthy subjects. Alkaline phosphatase (AP) and γ-glutamyl transpeptidase (GGTP) activities are similarly elevated in the liver tissue of patients with ALD, but serum GGTP level is 1,300% of normal, whereas serum AP level is only 240% of normal. The data suggest that induction of hepatic GGTP by alcohol is not the sole or major cause of the serum GGTP elevation. AST, aspartate aminotransferase; ALT, alanine aminotransferase; GDH, glutamate dehydrogenase. (From Kaplan MM. Biochemical basis of serum enzyme abnormalities in alcoholic liver disease. In: Chang NC, Chao HM, eds. Early identification of alcohol abuse. *NIAAA Res Monogr* 1985;17:186, with permission.)

Serum leucine aminopeptidase testing is as sensitive as the measurement of alkaline phosphatase and 5′-nucleotidase in the detection of obstructive, infiltrative, or space-occupying lesions of the liver. Some investigators consider leucine aminopeptidase a more sensitive indicator of infiltrative diseases, rather than alkaline phosphatase in nonjaundiced patients (89). Contrary to the findings described in the original reports, pancreatic cancer without hepatobiliary disease does not cause an elevation in the level of serum leucine aminopeptidase.

Leucine aminopeptidase activity is elevated in most types of liver disease, but values are highest in biliary obstruction. Some investigators have promulgated it as a reliable test for differentiating obstructive and hepatocellular liver disease (86). Others have observed a considerable overlap in values among patient groups, and found serum alkaline phosphatase to be at least as selective. The controversy regarding the specificity of measurement of leucine aminopeptidase as a test of biliary obstruction has never been resolved. Because of the availability of other equally sensitive, convenient, and specific tests, leucine aminopeptidase is not widely used. Its possible value is its specificity only for liver disease. In this regard, 5′-nucleotidase and GGT seem to have comparable merit.

Tests of the Biosynthetic Capacity of the Liver

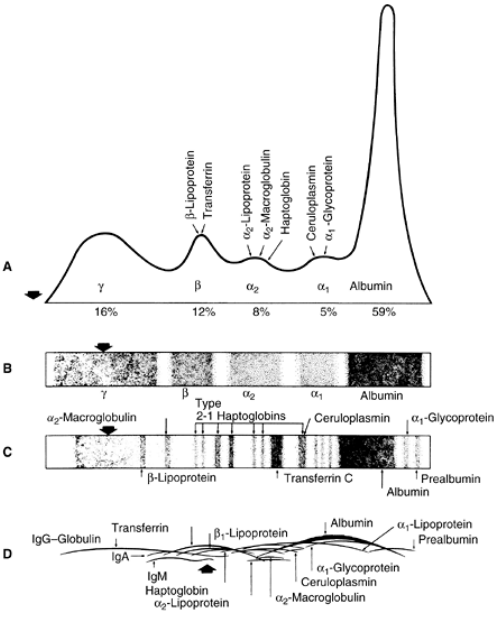
Serum Proteins

Serum contains a complex mixture of proteins that have been extensively studied with various techniques. A schematic representation of the results of some of these methods is shown in Figure 2.25. The liver is the main source of most of these serum proteins. The parenchymal cells are responsible for the synthesis of albumin, fibrinogen, and other coagulation factors, and most of the α- and β-globulins. γ-Globulins are an important exception, being synthesized by B lymphocytes (91).

In this section, we only discuss proteins used in the diagnosis of liver disease: Albumin and prothrombin, both of which are synthesized exclusively by hepatocytes, and the Igs, which are synthesized by B lymphocytes. Additional diagnostic proteins include lipoproteins, ceruloplasmin, the blue copper-containing protein, ferritin, and α_1-antitrypsin.

Total serum protein is usually determined by a variation of the biuret reaction. Its fractionation into its major constituents, albumin and globulins, is performed with automated dye-binding methods, or with paper or cellulose acetate electrophoresis. Older, salting-out techniques do not remove all the α- and

β-globulins from albumin quantitatively, and are less commonly used.



• **Figure 2.25** Schematic representation of the electrophoretic pattern of normal human serum in pH 8.6 buffer obtained with four methods. **A:** Tiselius or free boundary electrophoresis. **B:** Paper electrophoresis. **C:** Starch-gel electrophoresis. **D:** Immunoelectrophoresis. *The arrow* indicates the starting point with each method. α_2-Macroglobulin remains at the origin in starch-gel electrophoresis, but moves in the γ- to β-range with other methods. Ig, immunoglobulin. (From Putnam FW. *The proteins*, 2nd ed., Vol. 1. Orlando: Academic Press, 1975:18, with permission.)

Albumin

Albumin, which is quantitatively the most important plasma protein, is synthesized exclusively by the liver. Normal serum values range from 3.5 to 4.5 g/dL (35 to 45 g/L). The average adult has approximately 300 to 500 g of albumin distributed in body fluids, and synthesizes approximately 15 g/day (200 mg/kg day). The synthesis rate may double in conditions in which rapid albumin loss or a decrease in serum albumin concentration occurs because of dilution, such as during the rapid accumulation of ascitic fluid (92). Albumin has a long half-life, approximately 20 days. Approximately 4% is degraded each day, but little is known about the site of degradation. The serum level at any time reflects the rate of synthesis and degradation, and the volume of distribution. Albumin synthesis is regulated by changes in nutritional status, osmotic pressure, systemic inflammation, and hormone levels (92,93). The precise mechanism is not entirely known, but appears to be related to the formation of albumin messenger ribonucleic acid (mRNA) polysomes within the liver (93). Substances that stimulate albumin synthesis cause individual ribosomes to bind to the albumin mRNA to form polysomes, which synthesize albumin more efficiently (93). Amino acids such as tryptophan, phenylalanine, glutamine, and lysine function in this way and increase albumin synthesis

in vitro (93). Albumin synthesis is also stimulated by the amino acids that increase urea synthesis, that is, ornithine and arginine (94). Ornithine serves as a precursor of the polyamine spermine, a compound that promotes polysome formation (94). Corticosteroids and thyroid hormone stimulate albumin synthesis by increasing the concentration of albumin mRNA and transfer RNA in hepatocytes either by increasing its synthesis or decreasing its degradation (95). In vitro, alcohol decreases albumin synthesis by inhibiting the formation of polysomes (93), whereas inflammation decreases albumin synthesis (96) through the inhibitory effects of interleukin-1 and tumor necrosis factor (97).

Serum albumin levels tend to be normal in patients with liver disease such as acute viral hepatitis, drug-related hepatoxicity, and obstructive jaundice. Albumin levels less than 3 g/dL associated with hepatitis should raise the suspicion of chronic hepatitis. Hypoalbuminemia is more common among individuals with chronic liver disorders, such as cirrhosis, and usually reflects severe liver damage and decreased albumin synthesis. One exception is patients with ascites, in whom synthesis may be normal or even increased, but serum levels are low because of the increased volume of distribution (92). Heavy alcohol ingestion, chronic inflammation, and protein malnutrition can inhibit albumin synthesis. Hypoalbuminemia is not specific for liver disease and may occur in protein malnutrition of any cause, such as protein-losing enteropathy, chronic infection, or nephrotic syndrome. Serum albumin should not be measured when screening patients with no suspicion of liver disease. A study of patients consecutively examined in a general medical clinic, showed that in 56 of 449 patients in whom no indications for albumin measurement were present, the results were abnormal. However, in only two patients (0.4%) was the finding of any clinical significance (98).

Prothrombin Time

Clotting is the end result of a complex series of enzymatic reactions that involve at least 13 factors. The liver is the major site of synthesis of 11 blood coagulation proteins:

Factor I—fibrinogen (99)

Factor II—prothrombin (100)

Factor V—proaccelerin, labile factor (100)

Factor VII—serum prothrombin conversion accelerator, stable factor (100)

Factor IX—plasma thromboplastin component, Christmas factor (100)

Factor X—Stuart-Prower factor (99)

Factors XII and XIII—prekallikrein and high-molecular-weight kininogen

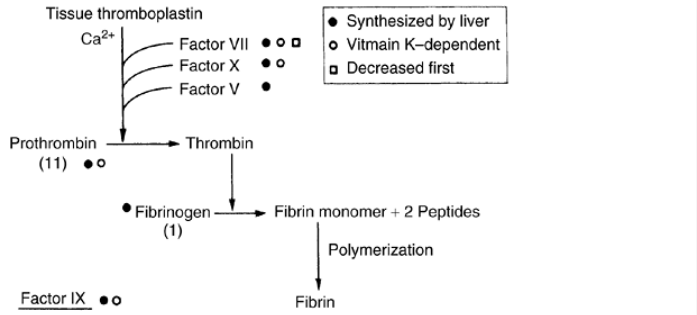
The liver is involved in clearing some of the clotting factors from serum. The levels of components of the clotting mechanism are frequently abnormal in the course of hepatic disease (101). These abnormalities can be assessed with tests in which one factor or the interplay of a number of factors is measured. The one-stage prothrombin time of Quick is one of the most useful tests available. It is used to measure the rate at which prothrombin is converted to thrombin. This occurs in the presence of a tissue extract (thromboplastin), calcium ions, and a series of activated coagulation factors (factors I, II, V, VII, and X), and is followed by the polymerization of fibrinogen to fibrin by thrombin (Fig. 2.26). The results may be expressed in seconds or as a ratio of the plasma prothrombin time to a control plasma time. A normal control is usually in the range of 9 to 11 seconds. A prolongation of 2 seconds or more is considered abnormal, and values of more than 4 seconds indicate a patient at risk of uncontrolled bleeding. The prothrombin time is prolonged if any of the involved factors are deficient, either singly, or in combination.

The international normalized ratio (INR) is often used to express the degree of anticoagulation in patients receiving warfarin sodium (Coumadin). The INR standardizes prothrombin time measurement according to the characteristics of the thromboplastin reagent used in the laboratory. The INR may not be the best expression of coagulation derangement in patients with liver failure, unless the same thromboplastin reagent is consistently used for measurement.

Hepatic synthesis of biologically active forms of factors II, VII, IX, and X requires vitamin K for the addition of carboxylic acid moieties to the g positions of glutamic acid residues in these proteins. The γ-carboxylation step is a posttranslational process that allows these proteins to bind Ca^{2+} avidly, a necessity for them to function as clotting factors (102). The absence of vitamin K, the ingestion of vitamin K antagonists, or the presence of certain hepatic disorders (hepatocellular carcinoma) inhibits vitamin K–dependent carboxylation and allows the release of des-γ-carboxy prothrombin (abnormal prothrombin) into serum (102). This can be detected with a specific radioimmunoassay (103). Healthy individuals have no abnormal prothrombin in serum. The presence of prothrombin in serum is a more sensitive indicator of vitamin K deficiency than measurement of prothrombin time, because an abnormal amount of prothrombin may be present in high concentration despite a normal prothrombin time. Prothrombin is present in high concentration in 91% of patients with biopsy-confirmed hepatocellular carcinoma (104). Plasma levels of des-γ-carboxy prothrombin do not correlate with α-fetoprotein levels in patients with established hepatocellular carcinoma,

but the two tests have a combined sensitivity of 85% (105). The des-γ-carboxy prothrombin level can return to normal with excision of or therapy for hepatocellular carcinoma, and increase again with a recurrence of the tumor (104). However, elevated des-γ-carboxy prothrombin levels were detected only in 20% of hepatocellular carcinomas less than 3 cm in diameter; therefore, the measurement of

this substance is an unsatisfactory screening test (106).



• **Figure 2.26** Factors involved in the Quick one-stage prothrombin time test.

A prolonged prothrombin time is not specific for liver disease and is seen in various congenital deficiencies of coagulation factors and in acquired conditions, including consumption of clotting factors and ingestion of drugs that affect the prothrombin complex. In these instances, the underlying cause can usually be elucidated. When the aforementioned conditions are excluded, a prolonged prothrombin time may be the consequence of either hypovitaminosis K, as is found in patients with prolonged obstructive jaundice, steatorrhea, dietary deficiency, or intake of antibiotics that alter the intestinal flora, or poor utilization of vitamin K owing to parenchymal liver disease. These two situations can usually be differentiated by means of parenteral administration of vitamin K_1. If the prothrombin time returns to normal or improves at least 30% within 24 hours of a single parenteral injection of vitamin K_1 (doses of 5 to 10 mg are usually given), it can be surmised that parenchymal function is good and that hypovitaminosis K was responsible for the original prothrombin time. In contrast, slight (if any) improvement occurs in most patients with parenchymal liver disease. Most patients with extrahepatic obstruction respond promptly to vitamin K. In patients with jaundice, the type of response to vitamin K_1 is therefore of some value in differential diagnosis. Observations of sluggish responses to vitamin K_1—prolonged values are still recorded 24 hours before normalization at 48 to 72 hours in some patients with obstructive jaundice—and of good responses among some patients with hepatocellular disease have been reported and complicate interpretation.

The prothrombin test is not a sensitive index of chronic liver disease because, even in severe cirrhosis, prothrombin levels can be normal or the prothrombin time only slightly prolonged. On the other hand, the test has high prognostic value, particularly for patients with acute hepatocellular disease. An abnormal prothrombin time with confirmed prolongation of more than 5 to 6 seconds above control is the single laboratory test that draws attention to the possibility of the development of fulminant hepatic necrosis in the course of acute viral hepatitis. Such a prolonged prothrombin time often precedes by days the manifestations of liver failure. Not all patients with abnormal prothrombin times of this extent have evidence of fulminant hepatic necrosis. Progressive shortening of the prothrombin time to normal usually precedes or accompanies other evidence of clinical improvement in the latter group. The degree of prolongation of the prothrombin time is a prognostic factor for patients with alcoholic steatonecrosis. A prothrombin time greater than 4 seconds above control value occurred six times as often in a group of patients who died (60%), than in a group who survived (10%). In patients with hepatocellular disease, an abnormal prothrombin time, particularly one prolonged more than 4 to 5 seconds that does not respond to parenteral administration of vitamin K_1, indicates extensive parenchymal damage and a poor long-term prognosis. The test is also used as an early predictor of outcome after acetaminophen overdose.

The prothrombin test is particularly important in the treatment of patients with liver disease. It allows assessment of the tendency to bleed before any contemplated surgical or diagnostic procedure,

such as closed liver biopsy, splenic puncture, or transhepatic cholangiography. When the prothrombin time is prolonged, vitamin K_1 should be administered routinely in doses of 5 to 10 mg/day parenterally up to three doses. It is difficult to identify the prothrombin time at which diagnostic procedures such as a needle biopsy of the liver are contraindicated, because the risk of bleeding has not been well correlated with the values of this test. Furthermore, vascular reactivity and coagulation factors, such as platelets, play an important contributory role. Closed needle biopsy is seldom performed in our hospital if the prothrombin time is prolonged more than 4 seconds. For patients with prothrombin times prolonged at least 4 seconds who do not respond to vitamin K_1, the mortality rate is high after surgery such as portacaval shunting. The performance of any open surgical procedure is determined by the urgency of the condition. The more pressing the need for surgery, the more prolonged is the prothrombin time accepted. It can often be corrected by infusions of fresh-frozen plasma with careful monitoring of the prothrombin time.

Tests Used to Detect Fibrosis in the Liver

There has been active research over the past decade to identify biochemical markers of liver fibrosis. The impetus for this research has been the desire to find a noninvasive alternative to liver biopsy. Liver biopsy remains the gold standard for grading and staging chronic liver disease. The single biochemical marker for fibrosis that has been studied most is hyaluronan. Others include type IV collagen, procollagen III, and laminin. Multiparameter tests have also been studied; these include the AST to platelet ratio index and the well-studied FibroTest biomarker, a multiparameter marker that includes haptoglobin, bilirubin, GGT, apolipoprotein A-I, and α_2-macroglobulin. Finally, there has been a recent report of glycomics being used to diagnose cirrhosis/advanced fibrosis.

Hyaluronan

Hyaluronan is a glucosaminoglycan synthesized in mesenchymal cells, and widely distributed in the extracellular space. It is degraded by hepatic sinusoidal cells in a specific receptor-mediated process, and has been found to be elevated in patients with cirrhosis because of sinusoidal capillarization. A fasting hyaluronan level greater than 100 mg/L had a 78% specificity and 83% sensitivity in the diagnosis of cirrhosis in one study of patients with liver disease of multiple etiologic factors (107). The sensitivity increased to 96% with a hyaluronan level greater than 300 mg/L. Hyaluronan has been shown useful for identifying advanced fibrosis in patients with alcoholic liver disease, hepatitis C, and hepatitis B (107,108,109). The serum hyaluronan level has been shown to be significantly correlated with the hepatic regeneration rate in patients undergoing hepatectomy (110), and with the development of liver failure after hepatectomy (111,112,113).

Fibrotest

The FibroTest has been studied in chronic hepatitis C, B, and alcoholic liver disease. In a study of patients with chronic hepatitis C, researchers defined "specific" and "sensitive" cutoffs for the activity index (114). The activity index is determined by a formula incorporating the five parameters listed in the preceding text. The specific cutoff had a sensitivity of 80% and specificity of 55% for identifying the presence of septal fibrosis (F2F3F4) or moderate or severe activity (A2A3) using the Metavir scoring system. The

sensitive cutoff had a sensitivity of 90% and specificity of 36%. A second group reported that the FibroTest performed poorly in predicting the presence or absence of significant liver fibrosis in patients with chronic hepatitis C (115). This biomarker produced similar results in hepatitis B (116) and alcoholic liver disease (117) as it did for hepatitis C. While the researchers who developed the FibroTest have reported low intralaboratory and intrapatient variability in FibroTest (118), a second group of researchers showed that intertechnique analytical variability of the FibroTest parameters remains a major issue (119). Specifically, depending on the assay used, there was a difference in values for apolipoprotein A-I of 12% and a 40% difference for α_2-macroglobulin.

Glycomics

Researchers applied the technique of using deoxyribonucleic acid sequencer-based total serum protein glycomics to generate profiles of serum protein *N*-glycans in patients with chronic liver disease (120). The authors chose to examine *N*-glycans because most glycoproteins found in the serum are produced by hepatocytes or plasma cells. Also, the liver is primarily responsible for the clearance of aberrantly glycosylated proteins. For these reasons it was felt that patients with chronic liver disease might have a different pattern of serum *N*-glycans, rather than control subjects. This technology yielded a biomarker that distinguished compensated cirrhosis from noncirrhotic chronic liver disease with a sensitivity of 79% and specificity of 86%. When combined with the FibroTest biomarker, the sensitivity was 75% with a sensitivity of 100%.

Tests Used to Detect Chronic Inflammation or Fibrosis in the Liver or Altered Immunoregulation

Immunoglobulins

Serum Igs are produced by stimulated B lymphocytes, and therefore, the measurement of these substances is not a direct test of liver function. Elevation of serum Ig levels in many patients with chronic liver disease is believed to indicate impaired function of reticuloendothelial cells in hepatic sinusoids or shunting of portal venous blood around the liver (91). Data indicate that antibodies directed against antigens of the normal colonic flora account for much of the increased serum Ig levels in patients with cirrhosis (91). In cirrhosis, these antigens are not taken up and degraded by hepatic reticuloendothelial cells as they normally are, but reach lymphoid tissue outside the liver where they elicit an inflammatory response.

In most cases of acute hepatitis, Ig levels are normal or minimally increased. Persistent moderate hypergammaglobulinemia suggests chronic active hepatitis, but striking increases in this Ig suggest autoimmune chronic hepatitis (121). Ig levels are also increased in most types of cirrhosis, although the values tend to be lower than in autoimmune chronic active hepatitis. Diffuse polyclonal increases in IgG and IgM are found in most types of cirrhosis and are nonspecific (121). Increases in IgM level suggest primary biliary cirrhosis, whereas increases in IgA may occur in patients with alcoholic cirrhosis. Ig levels are usually normal in obstructive jaundice. The major value of measuring Igs is to ascertain which patients might have cirrhosis or chronic hepatitis. It is also useful in monitoring the response to immunosuppressive therapy among patients with autoimmune chronic hepatitis. The presence of hypergammaglobulinemia, with or without hypoalbuminemia, is not specific for liver disease and can be found in other chronic inflammatory and malignant diseases.

Use of Liver Function Tests

We have found it useful to order the tests listed in Table 2.6 during the initial encounter with a patient with jaundice or suspected liver disease. The use of these tests, which include total and direct bilirubin, bilirubin in the urine, aminotransferases, alkaline phosphatase, albumin, globulin, and prothrombin time, as a battery increases specificity and sensitivity in the diagnosis of liver disease and makes it unlikely that any case of clinically important liver disease will not be identified.

It is helpful to divide the causes of jaundice and liver dysfunction into the broad categories shown in Table 2.6, that is, disorders of bilirubin metabolism, acute parenchymal or hepatocellular disease, cholestasis, infiltrative diseases, chronic hepatocellular diseases such as cirrhosis, and others. Because the pattern of LFT abnormalities is often similar in patients with infiltrative diseases and patients with partial bile duct obstruction, these two types of disorders are listed together.

In a patient with hemolysis or Gilbert's syndrome, the total serum bilirubin level may be elevated to as much as 5 mg/dL (85.5 mmol/L). If standard van den Bergh bilirubin fractionation is performed, more than 85% of the bilirubin is in the indirect fraction. Bilirubinuria is absent. If HPLC were used to fractionate the bilirubin, all the bilirubin would be in the indirect fraction. Results of the remaining screening LFTs, listed in Table 2.5, would be normal. Compensated hemolysis can be detected by means of measuring the reticulocyte count or the serum hemoglobin or haptoglobin. If bilirubinuria is present and more than 20% of the elevation in bilirubin level is due to the direct fraction, disorders of bilirubin metabolism, such as Dubin-Johnson syndrome and Rotor's syndrome, in which results of other LFTs are also normal must be considered. Because Dubin-Johnson syndrome and Rotor's syndrome are both benign conditions, it could be argued cogently that no further investigation is required, except to repeat these tests and verify the results. Those not satisfied with uncertainty can obtain a serum bile acid test, because the result is normal in Dubin-Johnson syndrome.

The aminotransferases are clearly the most sensitive agents for use in detecting acute hepatocellular disorders, such as viral or drug-induced hepatitis. Aminotransferase levels greater than 500 IU (8.3 μkat/L) make such a diagnosis probable. Depending on the severity of the underlying hepatocellular disorder, the bilirubin level may be normal or elevated. If the bilirubin level is elevated, bilirubinuria and increases in both the direct and the indirect bilirubin fraction should be present. Alkaline phosphatase elevations as high as three times the upper limit of normal are common for patients with acute hepatocellular disorders; however, values greater than three times normal are unusual, except in some patients with drug-induced hepatitis. Serum albumin level is usually normal, and Ig levels are normal or minimally elevated. The prothrombin time is typically normal in most patients with viral or drug-induced hepatitis. Prolongation of the prothrombin time to more than 5 seconds above the control and

failure of prothrombin time to correct within 24 to 48 hours of parenteral administration of vitamin K suggest a poor prognosis, and should alert the clinician to the possibility of massive hepatic necrosis. If the LFTs are typical of acute hepatitis, a careful medication history must be obtained along with serologic tests for hepatitis A and hepatitis B. The possibility of hepatic ischemia should also be considered.

Table 2.6. Liver Function Test Patterns in Hepatobiliary Disorders and Jaundice

Type of disorder	Bilirubin	Aminotransferases	Alkaline phosphatase	Albumin	Globulin	Prothrombin time
Hemolysis	Normal	Normal	Normal	Normal	Normal	Normal
Gilbert's syndrome	5 mg/dL >85% due to indirect					

	fraction					
	No bilirubinuria					
Acute hepatocellular necrosis (viral and drug hepatitis, hepatotoxins, acute heart failure)	Both fractions may be elevated; peak usually follows aminotransferases	Elevated, often >500 IU; ALT ≥ AST	Normal to three times normal	Normal	Normal	Usually normal; >5 s above control and not corrected with parenteral vitamin K suggests massive necrosis and poor prognosis
	Bilirubinuria					
Chronic hepatocellular disorders	Both fractions may be elevated	Elevated, but usually <300 IU	Normal to three times normal	Often decreased	Increased γ-globulin	Often prolonged; is not corrected with parenteral vitamin K
Alcoholic hepatitis	Bilirubinuria	AST/ALT >2 suggests alcoholic hepatitis or cirrhosis				
Cirrhosis						
Intrahepatic cholestasis	Both fractions may be elevated	Normal to moderate elevations; rarely >500 U	Elevated, often over four times normal	Normal, unless chronic	γ-Globulin normal	Normal; if prolonged, is corrected with parenteral vitamin K
Obstructive jaundice	Bilirubinuria				β-Globulin may be increased	
Infiltrative diseases (tumor, granuloma)	Usually normal	Normal to slightly elevated	Elevated, often over four times normal	Normal	Usually normal; γ-globulin may be increased in granulomatous disease	Normal
Partial bile duct obstruction			Fractionate, or confirm liver origin with 5′-nucleotidase, γ-glutamyl transpeptidase			

ALT, alanine aminotransferase; AST, aspartate aminotransferase.
Kaplan M. Evaluation of hepatobiliary diseases. In: Stein JH, ed. *Internal medicine*. Boston: Little, Brown, 1990:443, with permission.

LFTs are less precise in the diagnosis of chronic hepatocellular disorders, such as cirrhosis. The activity of the disease and the degree of hepatic reserve vary, and the results of LFTs vary with the activity of the disease process and the amount of hepatic reserve. LFTs may be highly insensitive in cirrhosis. Patients with end-stage postnecrotic or alcoholic cirrhosis may have shrunken livers and striking portal hypertension, and yet have LFT results that are almost normal. Breath tests, serum bile acid tests, and measurements of the undercarboxylated form of prothrombin would all be useful in such patients. On the other hand, LFT results may be strikingly abnormal in patients with chronic hepatic disorders. A serum albumin level of less than 3 g/dL, increased Ig levels, a prothrombin time 3 or more seconds above control that is not set right with parenteral vitamin K, and aminotransferase levels that are elevated but less than 300 IU make the diagnosis of cirrhosis likely. An AST/ALT ratio greater than 2 raises the possibility of alcoholic liver disease, and an AST/ALT ratio greater than 3 is highly suggestive of this possibility. Alkaline phosphatase level is seldom helpful in the diagnosis of cirrhosis.

Threefold or greater elevations should suggest the possibility of primary biliary cirrhosis in the setting of cirrhosis or portal hypertension.

There is a characteristic pattern of LFTs in cholestasis, although the routine laboratory tests listed in Table 2.6 do not differentiate intrahepatic and extrahepatic cholestasis. Alkaline phosphatase level is usually elevated out of proportion to the levels of other enzymes. Values four or more times greater than normal suggest some type of cholestasis. Depending on the severity of the underlying condition, the bilirubin level is either normal or elevated. If elevated, the direct fraction is increased and bilirubin is present. Aminotransferase levels are usually elevated, but values greater than 500 IU (8.3 μkat/L) are rare. Aminotransferase levels are usually less than 300 IU (5 μkat/L), unless the tests are performed within 24 hours of the development of acute bile duct obstruction due, for example, to the passage of a common duct stone. Albumin and globulin levels are usually normal. Increased Ig levels suggest cirrhosis in patients with cholestasis. An increased IgM fraction suggests primary biliary cirrhosis. The antimitochondrial antibody test is helpful in this situation. The result is positive in 90% to 95% of patients with primary biliary cirrhosis, and negative in patients with extrahepatic bile duct obstruction or sclerosing cholangitis. The prothrombin time is usually normal. If elevated, it is commonly due to vitamin K deficiency and should correct with parenteral administration of vitamin K.

Infiltrative liver diseases produce LFT abnormalities similar to those of partial bile duct obstruction. Often, the earliest and only abnormal value is alkaline phosphatase. If this is the case, or if the serum alkaline phosphatase level is elevated out of proportion to that of the other enzymes, it is helpful to identify the origin of the alkaline phosphatase. This can be done with electrophoretic techniques, or by means of measuring 5′-nucleotidase or GGT. The bilirubin level is often normal early in infiltrative disease, and is usually normal in partial bile duct obstruction. If the total serum bilirubin level is elevated, the direct fraction is certain to be elevated, and bilirubinuria is present. Aminotransferase levels are normal or minimally elevated in patients with infiltrative disease and partial bile duct obstruction, as are serum albumin and Ig levels and prothrombin time.

The results of these laboratory tests suggest but seldom confirm a specific diagnosis. Once this information is obtained, the results facilitate the efficient use of other diagnostic tests, such as the serologic testing for hepatitis, echography, computed tomography, percutaneous liver biopsy, and cholangiography.

With increasing experience, the breath and serum bile acid tests may be added to the list of routinely used tests in Table 2.6 or replace some of them. For example, serum bile acid tests may someday replace the direct bilirubin test as a general screening test for hepatic dysfunction. This has not yet occurred. Work continues on finding a test, or a combination of tests, that can eliminate the need for liver biopsy. Any conveniently performed inexpensive test that increases the diagnostic power of the standard LFT battery will be welcomed.

Footnote

[1]SI units (Le Système International d'Unites) are gradually replacing other units to have one common, worldwide system for reporting scientific data. The SI unit for enzymatic reactions is the katal, abbreviated kat. It replaces the international unit (IU/L) and denotes moles of substrate converted per second. For example, to convert alkaline phosphatase IU/L to SI units (μkat/L), multiply IU/L by 0.01667. The SI reference range for alkaline phosphatase is 0.5 to 2 μkat/L. This value may vary somewhat among laboratories.

Annotated References

Brensilver HL, Kaplan MM. Significance of elevated liver alkaline phosphatase in serum. *Gastroenterology* 1975;68:1556.

This paper describes the use of polyacrylamide gel electrophoresis to fractionate serum alkaline phos phatase in hundreds of patients with elevated serum alkaline phosphatase levels. The authors found that the elevation was caused by increased amounts of liver alkaline phosphatase in most patients and that patients with a variety of general medical disorders, such as congestive heart failure, Hodgkin's disease, and bacterial infection, could have a significant elevation in the level of serum alkaline phosphatase of hepatic origin.

Clermont RJ, Chalmers TC. The transaminase tests in liver disease. *Medicine* 1967;46:97.

The authors gathered all papers describing the evaluation of the AST (SGOT) test in the diagnosis of liver disease and determined the relation between the absolute value of the AST and the likelihood of a patient having obstructive liver disease, or, conversely, hepatocellular disease. The higher the AST level, the less likely for the patient to have obstructive

P.57

jaundice. Fewer than 1% of patients with obstructive jaundice have AST values greater than 700 IU.

Cohen JA, Kaplan MM. The SGOT/SGPT ratio: an indicator of alcoholic liver disease. *Dig Dis Sci* 1979;24:835.

The authors found that the SGOT/SGPT (AST/ALT) ratio is helpful in the diagnosis of alcoholic liver disease. If the ratio is greater than 2:1, alcoholic liver disease is likely. Ninety-five percent of patients with ratios greater than 3:1 have alcoholic liver disease.

Kaplan MM, Rhigetti A. Induction of rat liver alkaline phosphatase: the mechanism of the serum elevation in bile duct observation. *J Clin Invest* 1970;49:508.

This paper showed that the mechanism of the elevated serum alkaline phosphatase level in cholestasis is the induction of liver alkaline phosphatase and the leakage of liver alkaline phosphatase in serum. The authors clearly showed that the alternative theory popular at the time—that the liver clears alkaline phosphatase made in other organs from serum and excretes it into bile much as the liver excretes bilirubin—was incorrect. This paper resolved a controversy that had existed in medicine for more than 50 years.

Weiss JS, Gautam A, Lauff JJ, et al. The clinical importance of a protein bound fraction of serum bilirubin in patients with hyperbilirubinemia. *N Engl J Med* 1983;309:147.

The authors demonstrate that conjugated bilirubin in serum binds covalently to a macromolecule in serum (most likely albumin), and that the bilirubin fraction is cleared slowly from serum with a half-life similar to that of albumin. This finding demonstrated why it often takes so long for an elevated serum bilirubin level to decline in certain situations, such as when mechanical bile duct obstruction is surgically corrected.

K. Rajender Reddy

Key Concepts

- Liver biopsy is the traditional gold standard for the evaluation of chronic liver diseases. However, sampling error, particularly evident with small specimens, makes biopsy a flawed benchmark.
- Percutaneous liver biopsy is a safe procedure both with or without radiologic guidance.
- Transjugular liver biopsies may be performed in patients with coagulopathies or other contraindications to percutaneous biopsy. Samples are often smaller and more fragmented.
- Diagnostic laparoscopy with liver biopsy is a low-risk, outpatient procedure performed under conscious sedation. Direct visualization of the liver surface improves the identification of cirrhosis and facilitates the staging of metastatic and primary cancers.
- Noninvasive panels of serologic markers are being studied to accurately grade and stage chronic liver disease, particularly hepatitis C. Transient elastography is a promising new technology for assessing hepatic fibrosis.
- The role of liver biopsy has been challenged in a number of clinical scenarios, including management of viral hepatitis, nonalcoholic fatty liver disease, monitoring of methotrexate hepatotoxicity, and in the diagnosis of hepatocellular carcinoma. In select cases, clinical, laboratory, and radiologic imaging data may obviate the need for a biopsy.

Introduction

Liver biopsy was first performed in 1883 by Paul Ehrlich (1). The procedure was lengthy and impractical until Menghini reported a quick "one-second" aspiration technique in the late 1950s (2). Transjugular hepatic vein catheterization in 1967 introduced a new biopsy technique with less risk for bleeding (3). Other technologic advances have expanded technical options for the performance of a liver biopsy. At present, large numbers of liver biopsies are performed safely each year, although life-threatening complications ensue occasionally. A variety of needles can be used during a percutaneous, transjugular, or laparoscopic approach. Both hepatologists and radiologists commonly perform biopsies either "blindly" or under radiologic guidance. Choice of technique depends on the

available expertise and the clinical situation. Percutaneous biopsy, with or without radiologic guidance, is most commonly performed and has a long track record of safety. The transjugular approach is often used when there are contraindications to percutaneous biopsy, such as a bleeding diathesis, obesity, or ascites. Laparoscopic liver biopsy is a more invasive procedure that is useful for the evaluation of various intra-abdominal malignancies and ascites of unknown cause. Fine-needle aspiration of focal liver lesions can be performed under radiologic guidance.

Liver biopsy has traditionally been the gold standard for the evaluation of chronic liver diseases. Recently, noninvasive markers of fibrosis and inflammation have been introduced, particularly for the evaluation of hepatitis C. As experience with these new techniques

grows, biopsy may be avoided in some clinical situations. Furthermore, with the advent of specific serologic testing, the need for liver biopsy has been challenged in some clinical scenarios. In hepatitis B and C, biopsy is useful, but not mandatory in making the decision to initiate treatment. Nonalcoholic fatty liver disease (NAFLD) can be diagnosed on the basis of clinical and imaging features, and biopsy generally does not influence management decisions. The role of periodic liver biopsy to assess for hepatotoxicity in patients taking methotrexate remains controversial. Finally, the role of liver biopsy in hepatocellular carcinoma (HCC) has become contentious because characteristic features on radiologic imaging, complemented by an elevated α-fetoprotein can now accurately diagnose these lesions.

Percutaneous Liver Biopsy

Before a percutaneous liver biopsy is performed, the patient must be prepared properly. A complete physical examination and history, review of medications, and measurement of clotting parameters are essential. Criteria for the safe performance of an outpatient biopsy and contraindications to a percutaneous approach are listed in Tables 3.1 and 3.2 (4). Explaining the procedure and possible minor and major complications and obtaining written consent from the patient are mandatory (5). It is preferred that prothrombin time, partial thromboplastin time, and platelet count be measured within 4 weeks of biopsy. Salicylates and nonsteroidal anti-inflammatory drugs are discontinued for 1 week before and 1 week after biopsy. A light breakfast 2 to 3 hours before the procedure can facilitate gallbladder emptying and may reduce the risk of gallbladder puncture. Alternatively, an overnight fast can be advised, particularly when conscious sedation is used, to reduce the risk of aspiration in case of vomiting. Venous access is established, preferably in the left arm, so that the patient can lie comfortably in the right lateral decubitus position after the biopsy. Patients are frequently anxious, and intravenous fentanyl and midazolam can alleviate apprehension, facilitate the procedure, provide some postprocedure relief of pain, and achieve some degree of amnesia. Most patients do well with approximately 50 μg of fentanyl and 2 mg of midazolam without impairment of their ability to cooperate with the biopsy. Older patients may require less sedation.

Table 3.1. Criteria for Outpatient Liver Biopsy

Patient must be able to return to the hospital in which the procedure was performed within 30 min of adverse symptoms
Patient must have a reliable individual staying with him or her during the first night after biopsy to provide care and transportation, if necessary
Patient should have no complications or associated serious medical problems that increase the risk of the biopsy
Facility in which the biopsy is performed should have an approved laboratory and blood banking unit, easy access to an inpatient bed, and personnel to monitor patient for at least 6 h after the biopsy
Patient should be hospitalized after the biopsy if any serious or persistent complications develop

Table 3.2. Contraindications to Percutaneous Liver Biopsy

ABSOLUTE
Uncooperative patient
Bleeding tendency
  Prothrombin time ≥4 s over control, international normalized ratio ≥1.5
  Platelet count <60,000/mm^3
Unavailability of blood transfusion support
Serious consideration of echinococcal disease
Presumed hemangioma or other vascular tumors
RELATIVE
Ascites
Infection in right pleural cavity
Infection below right diaphragm

The patient lies supine with the right hand placed under the head. The point of maximum liver dullness is percussed over the right hemithorax between the anterior and midaxillary lines and is usually found between the sixth and ninth intercostal spaces. In certain situations, it may be higher (e.g., obesity) or lower (e.g., emphysema). Dullness should be present in both inspiration and expiration, as some patients may inadvertently take a deep breath during the procedure and thereby risk a pneumothorax. One percent lidocaine (Xylocaine) is injected over the upper border of a rib, avoiding the intercostal nerve and vessels that run along the lower border. A small incision is made, and a suction needle containing saline solution is advanced through the subcutaneous tissue and peritoneum; during this process, two "pops" may be felt. A small amount of saline solution is flushed into the peritoneal cavity to expel any tissue that may have inadvertently entered the needle. After expiration, the patient holds his or her breath, and suction is applied to obtain a biopsy. A similar approach is used with cutting needles, either the manual Tru-Cut needle or the spring-loaded automatic needles.

Needles used to perform percutaneous liver biopsy are broadly categorized as suction needles (Menghini, Klatskin, and Jamshidi needles) and cutting needles

(Vim Silverman and Tru-Cut needles and the more recent spring-loaded needles with triggering mechanisms) (6). Different needles acquire various lengths

and diameters of hepatic tissue. Specimen diameters range from 1.0 to 2.0 mm. The automated devices generally acquire smaller samples. The cutting needles, except for those with a spring-loaded and triggering mechanism, generally remain in the liver for a longer time during the biopsy. A greater risk of bleeding after biopsy has been noted with larger-diameter needles, although not consistently (7,8). If cirrhosis is clinically suspected, a cutting needle is preferred to a suction needle because fibrotic tissue tends to be fragmented by the latter (9,10).

Most physicians perform an imaging study before biopsy to identify "silent" mass lesions and to define positions of the liver, gallbladder, and other organs. However, the routine use of ultrasonography to guide a percutaneous biopsy remains controversial. Currently in the United States, one half to three fourths of surveyed gastroenterologists who perform liver biopsy report the routine use of ultrasonographic guidance (11,12,13). In a prospective, randomized study of 836 patients, Lindor et al. (14) showed that ultrasonography with biopsy was less often associated with pain, compared to biopsies performed without radiologic imaging (37% vs. 50%). Furthermore, the postbiopsy hospitalization rate was lower if biopsy was performed with ultrasonography (0.5% vs. 2.2%); the most common reason for admission was pain (14). However, use of ultrasonography reduced neither the percentage of patients with pain requiring narcotics nor the rate of major complications (bleeding or hypotension) (14). Moreover, a large British survey failed to demonstrate differences in major complications or pain between biopsies performed with and without ultrasonographic guidance (15,16).

In contrast, a retrospective study using historical controls suggested that major complications may be reduced by the use of ultrasonographic guidance (17). In one study, ultrasonography changed the site of percutaneous liver biopsy determined by the percussion technique in as many as 15% of patients (18). If the site had not been moved, what complications may have resulted is not known. A follow-up study showed that ultrasonography may not be of any greater utility in selected patients, such as those with difficult percussion, obesity, or chest wall deformity. Ultrasonography was just as likely to mandate movement of the biopsy site in patients with these features compared to unselected patients (19). Cost-effectiveness studies have failed to resolve the controversy regarding the routine use of imaging to guide biopsy (20,21). A decision analysis suggested that the use of ultrasonography to prevent major complications was cost-effective, although the authors' definition of cost-effectiveness is not a standard one (cost-effective defined as incremental cost to avoid a major complication <$10,000) (20). Because of the established safety of the percussion technique and lack of convincing evidence of improved safety, tissue sample, or cost-effectiveness, routine ultrasonography to guide percutaneous biopsy should not be considered the standard of care (22,23) (Table 3.3).

Table 3.3. Ultrasonographic Guidance of Percutaneous Liver Biopsy

Advantages	Disadvantages
May decrease likelihood of	Has not been shown to decrease the

postbiopsy pain	frequency of major complications
May change biopsy site, as determined by percussion	Long track record of safety for performance without ultrasonographic guidance
May be cost-effective (controversial)	Adds expense to the procedure
	Inconvenient to perform

Because a liver biopsy samples at most 1/50,000th of the entire liver, it may not be representative. It is increasingly recognized that longer biopsy samples performed with larger bore needles are needed to accurately stage and grade the extent of liver injury. Traditionally, studies have accepted liver biopsies as adequate if samples were a minimum of 15-mm length, had 4 to 6 portal tracts, or were considered "acceptable" by a pathologist (samples as small as 10 mm have been used in some studies) (24). More recent data suggest that these minimum criteria are inadequate. Patients with Hepatitis C and biopsies of minimal length 1.5 cm showed significant variability in grade and stage between two simultaneous biopsies (at least 33% had a 1 point or more difference in stage) (25,26). In contrast, a study with mean specimen length of over 2.5 cm showed minimal variability between two samples taken from the same patient with hepatitis C (27). A recent study used digitized images of whole sections of hepatitis C–infected livers to allow for "virtual biopsies" of variable lengths. A 2.5-cm biopsy length was adequate to reliably stage fibrosis (28). Moreover, use of larger bore needles (>18 gauge) has also been shown to improve diagnostic accuracy (29). A study using large bore samples (1.4 mm) of at least 2 cm length reliably produced at least 11 to 15 complete portal tracts and allowed for accurate pathologic evaluation of chronic hepatitis B and C (30). In contrast, a recent study showed that even large biopsy samples may not be reliable for evaluation of NAFLD. Two biopsies with large bore (16 gauge) cutting needles of average length 2 cm were obtained in patients with NAFLD. There was surprising variability between the two biopsies with 41% discordance rate for one or more stages. These results could only partially be explained by intraobserver variability (31). We can therefore conclude that larger bore biopsies of longer length are desirable to reliably grade and stage chronic

liver disease (Table 3.4). However, liver biopsy must be regarded as a flawed gold standard for the evaluation of chronic liver diseases because of significant problems with sampling variability.

Table 3.4. Characteristics of an Optimal Biopsy

≥2–2.5 cm long

≥1 mm diameter (use at least 18-gauge needle) ≥11–15 complete portal tracts

Complications of Percutaneous Liver Biopsy

Although the liver is a highly vascular organ, major complications associated with this procedure are fortunately rare (Table 3.5). The most dreaded complication is hemorrhage. Sixty percent of complications are recognized within 2 hours after the procedure, and 96% within 24 hours (5,7). Fatal complications typically occur within 6 hours. A hospitalization rate of 1.4% to 3.2% for the management of complications following a liver biopsy has been reported, with pain or hypotension being the predominant cause (32,33).

Approximately one third of patients experience right upper quadrant or right shoulder pain (16), although one study reported a rate of up to 83% (34). The pain is usually mild, dull, and responsive to analgesics. Pain medications are required in approximately one third of patients after biopsy, approximately one half of whom are given narcotics (35). While pain typically resolves within a few hours of biopsy, one group found that it may persist up to 24 hours after biopsy (34). On-going severe abdominal pain should alert the physician to the possibility of bleeding or peritonitis. Predictors of pain include a history of intravenous drug abuse and preprocedural anxiety (34,35). Prebiopsy anxiolysis with a benzodiazepine like midazolam might be expected to prevent or lessen postbiopsy pain, although this has not been formally studied.

Table 3.5. Complications of Percutaneous Liver Biopsy

Pain (0.056%–83%)
  Pleuritic
  Peritoneal
  Diaphragmatic
Hemorrhage
  Intraperitoneal (0.03%–0.7%)
  Intrahepatic[a] and/or subcapsular (0.59%–23%)

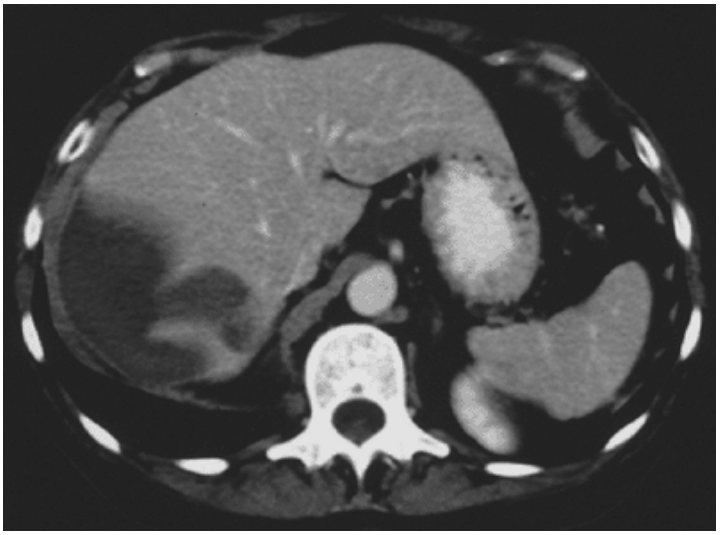
[a]Symptomatic and asymptomatic.
[b]Asymptomatic.
From references (4,7,16,33,34,39–41,52).

Hemorrhage after liver biopsy can manifest as a free intraperitoneal bleed, intrahepatic or subcapsular hematoma, or hemobilia. Risk factors for hemorrhage after liver biopsy include presence of malignancy, performance of multiple passes, advanced age, mycobacterial infection, requirement for prebiopsy platelet transfusion, acute liver failure, cirrhosis, heparin administration on the day of biopsy, treatment with corticosteroids, and use of nonsteroidal anti-inflammatory agents (7,8,36). Significant intraperitoneal hemorrhage is the most serious complication and often becomes apparent within the first 2 to 3 hours after the procedure (7,8,33). Free intraperitoneal hemorrhage may be related to a laceration sustained during deep inspiration or to a penetrating injury of a large vessel. In a study of 68,276 liver biopsies, hemoperitoneum occurred in 0.32% of patients (7). Patients may experience abdominal pain, tachycardia, and hypotension, and ultrasonography or computed tomography (CT) scan may confirm the clinical suspicion. Volume resuscitation must be undertaken immediately. If hemodynamic instability persists despite aggressive resuscitation over a couple of hours, then angiography with embolization of the bleeding site is the preferred approach (37,38). In some cases, surgical exploration is required.

Intrahepatic or subcapsular hematomas are noted in up to 23% of cases when ultrasonography is performed after a liver biopsy (39,40,41). These are usually asymptomatic, and the frequency is similar in both laparoscopically guided and "blind" liver biopsies (41). The duration of bed rest after a liver biopsy does not influence the likelihood of hematoma formation (39). Large hematomas may cause pain, liver enlargement, tachycardia, hypotension, and a delayed drop in the hematocrit (Fig. 3.1). Conservative treatment generally suffices, and angiography is rarely required.

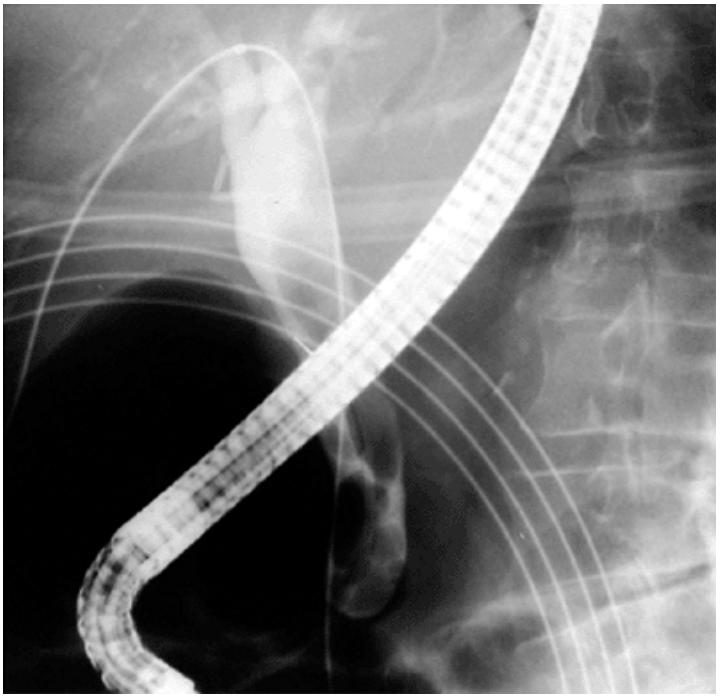
Hemobilia is an infrequent complication of liver biopsy, presenting with the classic triad of gastrointestinal bleeding, biliary colic, and jaundice (42). Piccinino et al. (7) reported four cases out of 68,276 biopsies (7). Bleeding is usually arterial in origin, but can be venous. Its severity ranges from life-threatening hemorrhage to occult bleeding with chronic anemia. In contrast to intraperitoneal hemorrhage, hemobilia is

generally delayed, with mean onset of 5 days after biopsy (42,43).



▪ **Figure 3.1** Computed tomography scan demonstrating an intrahepatic and subcapsular irregular, hypodense collection in the liver, consistent with bleeding after a percutaneous liver biopsy.

Endoscopy may reveal blood flowing from the ampulla of Vater. Endoscopic retrograde cholangiopancreatography (ERCP) demonstrates linear, irregular densities in the biliary tree and gallbladder that do not have the configuration of gallstones (Fig. 3.2), and endoscopic sphincterotomy may facilitate the removal of these clots. However, angiography is the preferred modality for diagnosis and embolization therapy.



▪ **Figure 3.2** Endoscopic retrograde cholangiopancreatographic finding of irregular filling defects in the common bile duct, representing blood clots after hemobilia complicating a percutaneous liver biopsy. (Radiograph courtesy of Gregory Ginsberg, MD)

Transient bacteremia has been reported in 5.8% to 13.5% of patients (44,45) after liver biopsy. This is usually of no clinical significance, although sepsis can sometimes occur in patients with biliary obstruction (46,47,48). No recommendations are currently available regarding prophylactic antibiotics for those with risk factors for endocarditis. Other complications of liver biopsy include asymptomatic intrahepatic arteriovenous fistula, biliary ascites, bile pleuritis, and biliary peritonitis (49,50,51,52). The most common cause of bile peritonitis is puncture of the gallbladder, which becomes apparent immediately and is characterized by severe pain and vasovagal hypotension. Bile peritonitis is also more likely if biliary obstruction is present. Pain may be followed by fever, abdominal pain, leukocytosis, and ileus. Ultrasonography or CT scan may identify an intra-abdominal collection of bile, and ERCP or biliary scintigraphy may demonstrate a bile leak. Surgery is indicated when clinical deterioration occurs despite the administration of intravenous antibiotics, fluid, and pain control. Pneumothorax and hemothorax after liver biopsy often spontaneously resolve, and placement of a chest tube is seldom required. Inadvertent perforation of other abdominal organs is generally not of clinical significance (7).

Transjugular Liver Biopsy

During transjugular biopsy, liver tissue is obtained from within the vascular system to minimize the risk of bleeding. The right internal jugular vein is punctured percutaneously, a catheter is passed under fluoroscopy into the right hepatic vein, and a liver specimen is obtained with a special needle. Electrocardiographic monitoring is performed to detect arrythmias associated with the passage of the wire through the heart. Infrequently, it may be necessary to perform the biopsy from the left internal jugular vein after attempts to enter from the right side have failed. A femoral vein approach has also been described (53,54).

Adequate tissue can be obtained in 80% to 100% of cases (55,56,57,58,59,60,61). In a single large experience involving 1,000 transjugular liver biopsies, the success rate was as high as 99.3%, with one or two attempts required in 57.7% of cases (56). Multiple passes are usually required to obtain adequate samples, and typical length of the tissue ranges from 0.3 to 2.0 cm. Biopsies obtained by the transjugular approach tend to be smaller, more fragmented, and include fewer complete portal tracts, as compared to tissue acquired by the percutaneous route (57,59). Aspiration needles and manual and automated Tru-Cut–type needles with spring-loaded devices are available (55,62,63,64). Cutting needles provide larger transjugular biopsy samples than those obtained with aspiration devices (63,64).

Table 3.6. Situations in which Transjugular Biopsy is Preferred over a Percutaneous Approach

Coagulopathy (international normalized ratio >1.5)
Thrombocytopenia (platelets <60,000/μL)
Ascites
Obesity
Fulminant liver failure
Vascular hepatic tumor
Peliosis hepatis

The procedure is indicated for patients with significant coagulopathy, moderate to severe ascites, or fulminant hepatic failure (Table 3.6). Other indications include a previously failed percutaneous liver biopsy, massive obesity, and suspected vascular tumor or peliosis hepatis. A transjugular biopsy is advisable if concomitant measurement of the hepatic venous pressure gradient or placement of transjugular intrahepatic portosystemic shunt is planned.

Major complications after transjugular liver biopsy include major hemorrhage with hepatic capsule perforation and bacterial cholangitis after fistula formation between the biliary tree and the portal or hepatic vein. These complications occur at a rate of 1.3% to 2.7% with mortality of less than 0.3% (57,60,62). Minor complications may include pain, bleeding from the neck puncture site, neck hematoma, cardiac arrhythmia, and pneumothorax.

Liver Biopsy in Special Patient Populations

Patients with clotting parameter abnormalities or thrombocytopenia require special consideration before planning a liver biopsy. Transjugular liver biopsy is generally preferred for patients with a platelet count of less than 60,000/μL or prothrombin time prolonged by 4 seconds or more (international normalized ratio [INR] >1.5). A study has observed that patients with mild thrombocytopenia (50,000 to 99,000/μL) or prothrombin times prolonged by less than 4.2 seconds do not have increased risk of bleeding after percutaneous liver biopsy (65). Such patients may not benefit from prebiopsy platelet transfusion or fresh frozen plasma administration. The use of prophylactic fresh frozen plasma for a prothrombin time of 4.0 seconds or more (INR ≥1.5) with rechecking of the prothrombin time after infusion has been recommended and widely adopted. However, data supporting this practice are not available (66). In a recent retrospective study among patients with severe thrombocytopenia and hematologic malignancy, transjugular liver biopsy was safely performed after platelet transfusion to a median posttransfusion platelet count of 30,000/μL. The authors propose 30,000/μL as a threshold for platelet transfusion before performing the transjugular liver biopsy (67). Until better safety data are available, we recommend the transjugular approach with prophylactic platelet transfusion for patients with platelet count less than 60,000 μL. For patients with either thrombocytopenia or increased prothrombin time, the use of fibrin glue may prevent bleeding. In this patient population, percutaneous biopsy followed by injection of fibrin glue to seal the tract has been performed with good safety

(68,69). We do not recommend the routine use of bleeding time to assess the risk of bleeding after liver biopsy. Bleeding time measurement is controversial and is unlikely to provide much value (70,71).

Patients with chronic renal failure may have deficient platelet functioning despite a normal platelet count. Dialysis performed the day before the procedure or the use of deamino-8-D-arginine vasopressin (DDAVP) just before the procedure has been advocated, but should not be regarded as mandatory. A recent study of patients with chronic renal failure did show a significantly lower rate of major hemorrhage after transjugular liver biopsy, as compared to percutaneous puncture (72).

Patients taking an oral anticoagulant should discontinue the drug at least 72 hours before liver biopsy, provided discontinuation is not contraindicated. Heparin may be started approximately 24 hours after the biopsy. Immediate restarting of oral anticoagulation after biopsy is not preferred because delayed bleeding has been reported in patients taking oral anticoagulants (73,74). It is preferred that oral anticoagulation be restarted 48 to 72 hours after biopsy.

Aledort et al. (75) reported a rate of significant bleeding as high as 12.5% among hemophiliacs who underwent liver biopsy before 1981 (75). This high bleeding rate prompted serious concerns regarding biopsy in this population, but other studies have not reproduced those results. Reports of percutaneous liver biopsies performed in hemophiliacs during short hospitalizations with clotting factor replacement have shown no significant bleeding (76,77,78,79,80,81). Case series of transjugular liver biopsies performed in hemophiliacs after clotting factor infusions have also demonstrated excellent safety (82,83,84,85).

Laparoscopy

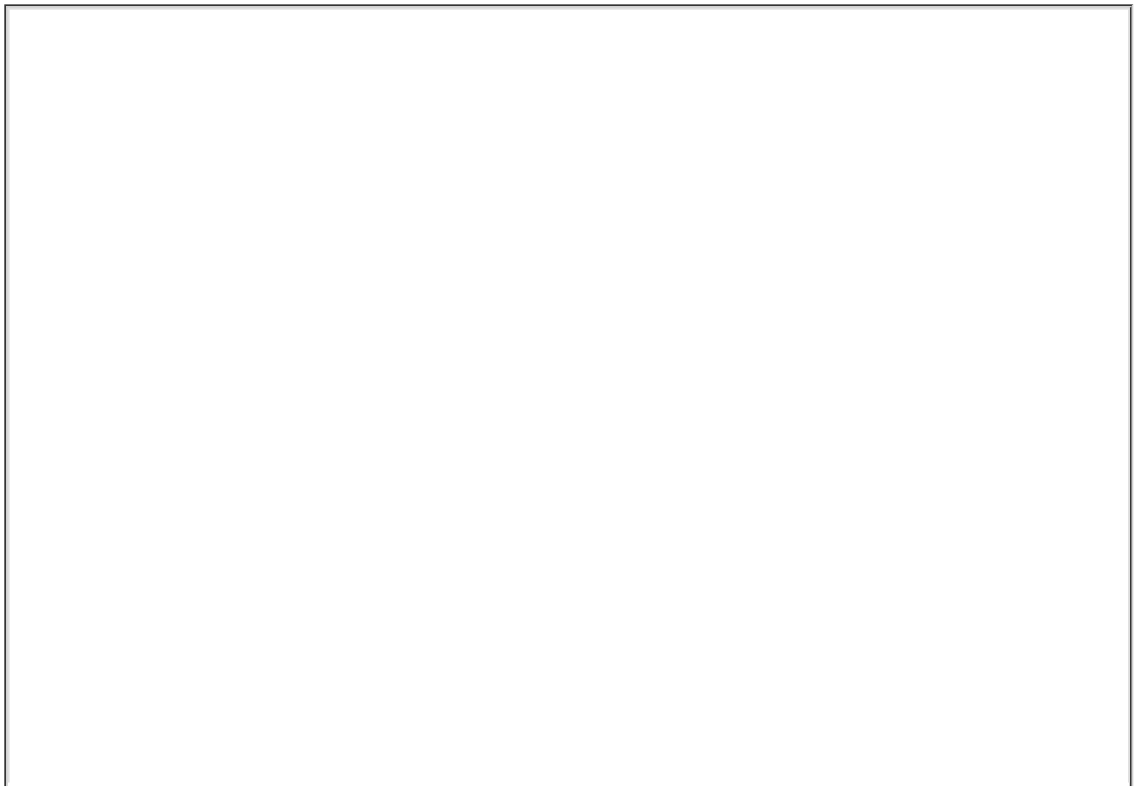
Use of laparoscopy to evaluate liver disease is well established in Continental Europe, but is much less frequently performed in North America than in other parts of the world. During laparoscopy, direct inspection of the liver surface is performed and tissue is acquired. The procedure can be performed under conscious

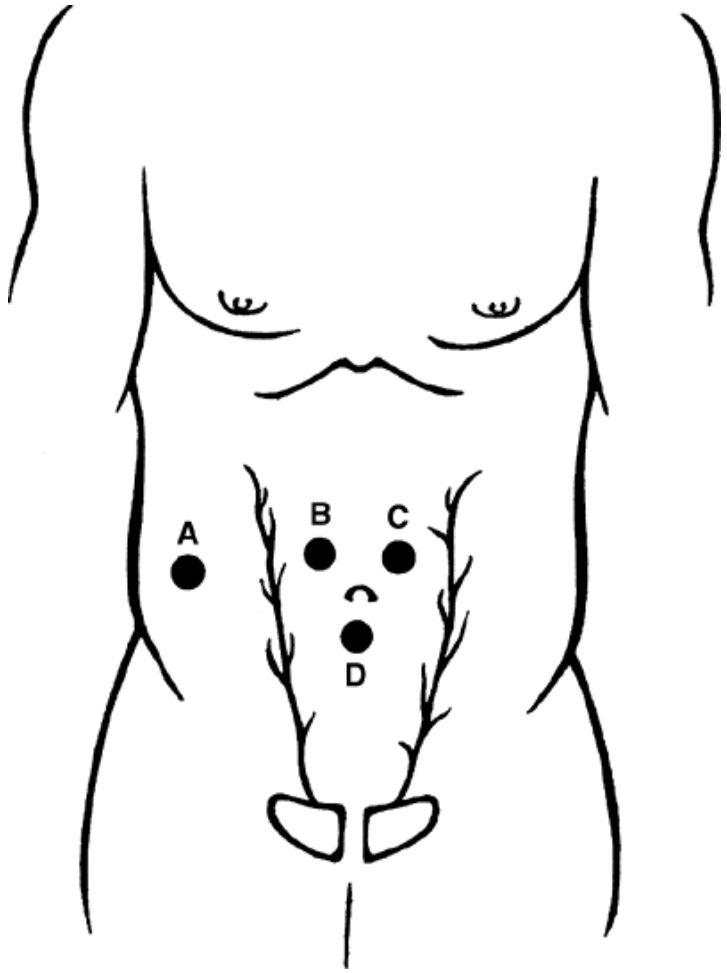
sedation in the outpatient setting. Recent introduction of mini-laparoscopy and laparoscopic ultrasonography has made the procedure potentially safer and more attractive.

Technique

Although laparoscopy is commonly performed under general anesthesia, the safety and efficacy of outpatient diagnostic laparoscopy using conscious sedation has been demonstrated (86,87,88). In some centers, diagnostic laparoscopy is performed in the endoscopy suite. With the patient in a supine position, the abdomen is scrubbed with povidone-iodine (Betadine) and covered with sterile drapes. Application of 2-L oxygen by nasal cannula and monitoring with electrocardiography and pulse oximetry are recommended (89,90). The Veress needle and trocar are usually placed in the left paramedian area; however, a right paramedian or subumbilical approach can be used in patients with an enlarged left hepatic lobe, splenomegaly, or previous splenectomy (Fig. 3.3). A local anesthetic (1% lidocaine) is injected intradermally 2 cm above and to the left of the umbilicus (Fig. 3.4A). Then, a 16-gauge needle is inserted through the center of the wheal to the parietal peritoneum, which usually provokes some

pain. Approximately 15 to 20 mL of 1% lidocaine is applied to the subcutaneous tissue and fascia within a 2-cm radius. It is important that sufficient local anesthesia be applied. A small incision is made in the center of the wheal, and the patient is asked to distend the abdominal wall without arching the back. The Veress needle is then inserted into the abdominal cavity, and two distinct "pops" are heard (91). Aspiration with a 10-mL syringe may avoid air embolism or inadvertent entry into the intestines, both of which are rare complications (92,93). Whereas carbon dioxide used for insufflation during therapeutic laparoscopy is a peritoneal irritant and provokes pain, the nitrous oxide commonly used for diagnostic laparoscopy is better tolerated (89,90). Insufflation to an abdominal cavity pressure of 20 mm Hg is accomplished by delivering 3 to 6 L of nitrous oxide through the Veress needle (Fig. 3.4B). A 20-mL syringe, half filled with saline solution, is then inserted and rotated within the abdominal cavity. Gas bubbles within the syringe indicate an unobstructed area for trocar placement. The patient is then instructed to distend the abdomen, and the trocar is inserted into the peritoneal cavity. Two distinct "pops" confirm placement. An oblique-view laparoscope is then inserted into the abdominal cavity under direct vision. The area perpendicular to the scope is inspected for insertion-related damage. With the patient in Trendelenburg's position, the bladder and other pelvic structures can be visualized. Placement of the patient in reverse Trendelenburg's position allows thorough inspection of the right and left upper quadrants (94). A second trocar is inserted into the right midclavicular line to allow, via another laparoscope, the inspection of the superior aspect of the right lobe and the delivery of accessory equipment, such as the biopsy needle and palpating probe. Liver specimens are obtained with a biopsy gun or, less commonly, a Tru-Cut needle. To avoid large blood vessels, a tangential approach to the liver left of the falciform ligament is recommended (Fig. 3.4C,D,&E). More recently, mini-laparoscopy has been described with use of a 1.9-mm end-viewing instrument (95,96,97). A randomized study between mini- and conventional laparoscopy demonstrated similar success with both procedures, and shorter procedure time with mini-laparoscopy (97).

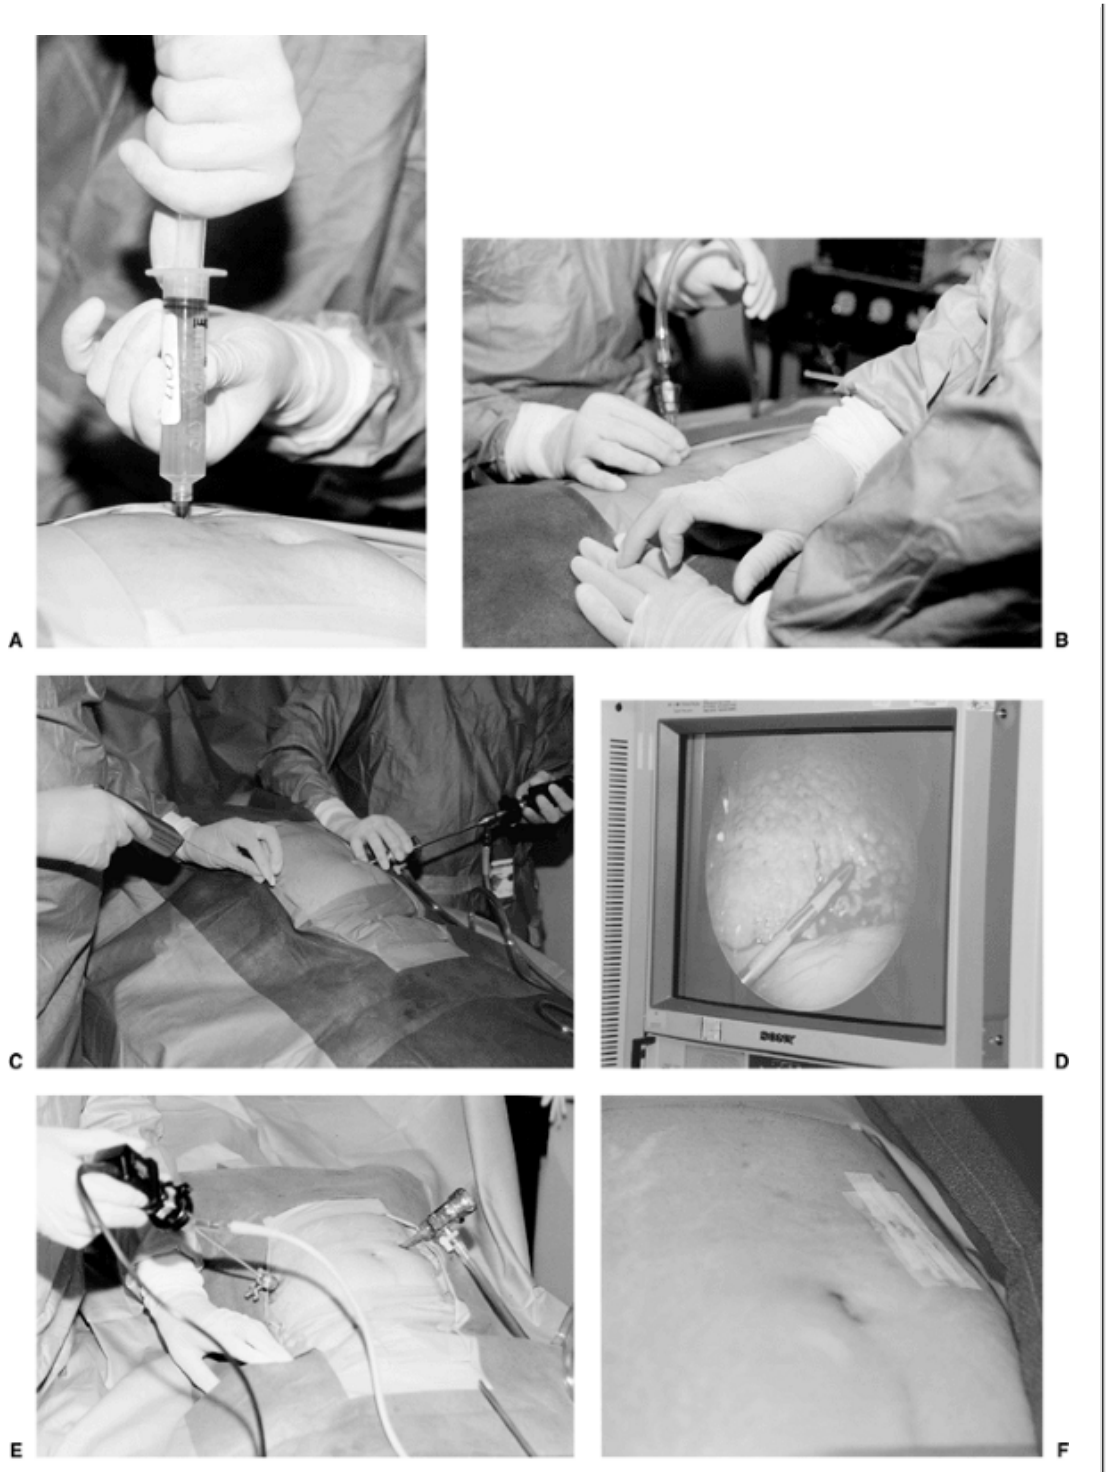




▪ **Figure 3.3** Veress needle and trocar entry sites. *A*, Secondary trocar site for the visualization of the superior aspects of right lobe and placement of accessory equipment. *B*, Alternate site in patients with splenomegaly or previous left upper quadrant surgery. *C*, Preferable site with excellent view of left lobe. *D*, Subumbilical alternate site, least vascular.

After the examination is completed, the trocar and biopsy sites can be closed with Steri-Strips or by sutures if larger incision is made to accommodate larger trocars and laparoscopes (Fig. 3.4F). Patients are observed for approximately 18 to 24 hours postprocedure and discharged to resume regular activity in 3 to 4 days. Right shoulder pain for 6 to 8 hours after the procedure is common. In a survey of 215 patients with gastrointestinal malignancies who underwent outpatient

staging laparoscopy under conscious sedation, only 7% required narcotics 2 to 5 hours after the procedure (87).



▪ **Figure 3.4 A:** Laparoscopic site with injection of local anesthetic to the left of the umbilicus. **B:** Nitrous oxide placed through Veress needle with assistant verifying the loss of hepatic dullness. **C:** Laparoscopic guidance of biopsy gun. **D:** Palpation probe on biopsy site after procedure to ensure hemostasis. **E:** Three-millimeter mini-laparoscope visualizing the original laparoscopic trocar site for signs of bleeding. **F:** Completion of procedure; laparoscopic site closed with Steri-Strips.

Patients should avoid nonsteroidal anti-inflammatory drugs and salicylate

compounds for 1 week before and after the procedure. Recommendations for patients with clotting factor and platelet count abnormalities are similar to those of percutaneous liver biopsy. In patients with end-stage renal disease, laparoscopy can be performed safely the day after dialysis with careful observation of the biopsy site before the procedure is terminated (98). Recently, the use of recombinant factor VIIa before laparoscopic liver biopsy has been reported (99). Moreover, mini-laparoscopy appeared safe in a small study of 61 patients with a platelet count less than 50,000/μL and/or INR greater than 1.5 (100). Most patients required the application of argon plasma coagulation directly to the liver to stop postbiopsy bleeding; there were no reports of delayed bleeding (100).

Indications for Laparoscopy

Laparoscopy allows direct visualization of the liver and can be performed for a variety of indications (Table 3.7). Although reporting of laparoscopic findings has not been rigorously standardized, chronic liver disease causes a spectrum of changes in the gross appearance of the liver (Fig. 3.5). In patients with mild disease, the surface of the liver tends to appear smooth. With more advanced disease, granularity or early nodularity may be seen. Cirrhosis is associated with diffuse nodularity and features of portal hypertension. Liver biopsy specimens tend to understage the degree of fibrosis assessed by laparoscopic inspection. Liver biopsy, while specific for cirrhosis, may be up to 30% less sensitive for demonstrating cirrhosis as compared to laparoscopy (95,96,97,101,102). Furthermore, specific laparoscopic features, including the presence of irregular regenerative nodules, a high degree of nodular regeneration, and an atrophic right lobe, may predict the development of HCC in patients with hepatitis C cirrhosis (103).

Table 3.7. Indications for Diagnostic Laparoscopy

Chronic liver disease
Hepatocellular carcinoma
Benign hepatic tumors
Staging of gastrointestinal malignancy
Metastatic liver disease
Ascites of unclear cause
Peritoneal infection
Lymphoma
Fever of unknown origin
Evaluation of abdominal mass
Chronic abdominal pain
Hepatosplenomegaly of unclear cause
Liver disease in renal failure
Assessment for liver transplantation
Subfulminant hepatic failure

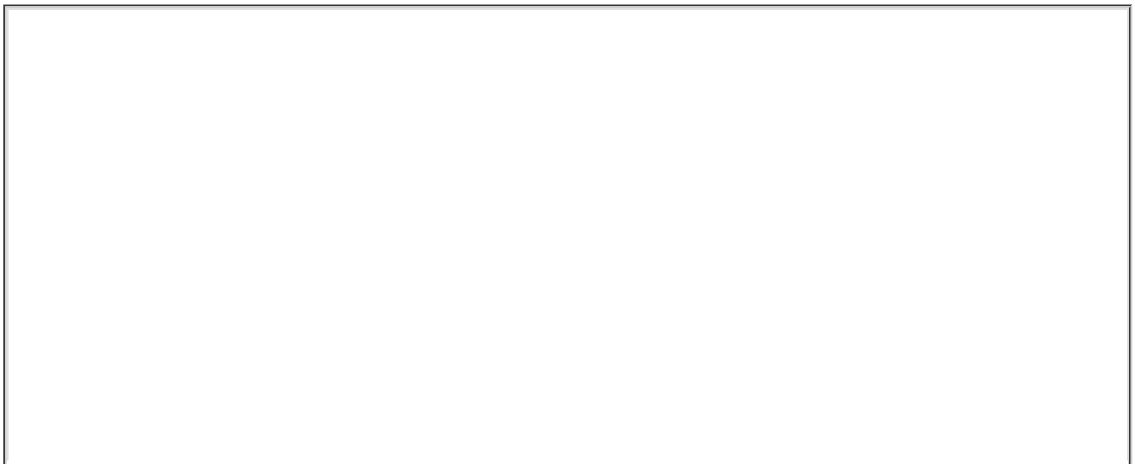
Diagnostic laparoscopy can help in evaluating ascites of unknown cause. During laparoscopy, tuberculous peritonitis commonly appears as miliary lesions in the parietal peritoneum and occasionally in the liver. Thick adhesions of the bowel to the parietal peritoneum may be seen (104). In one series, tuberculous peritonitis

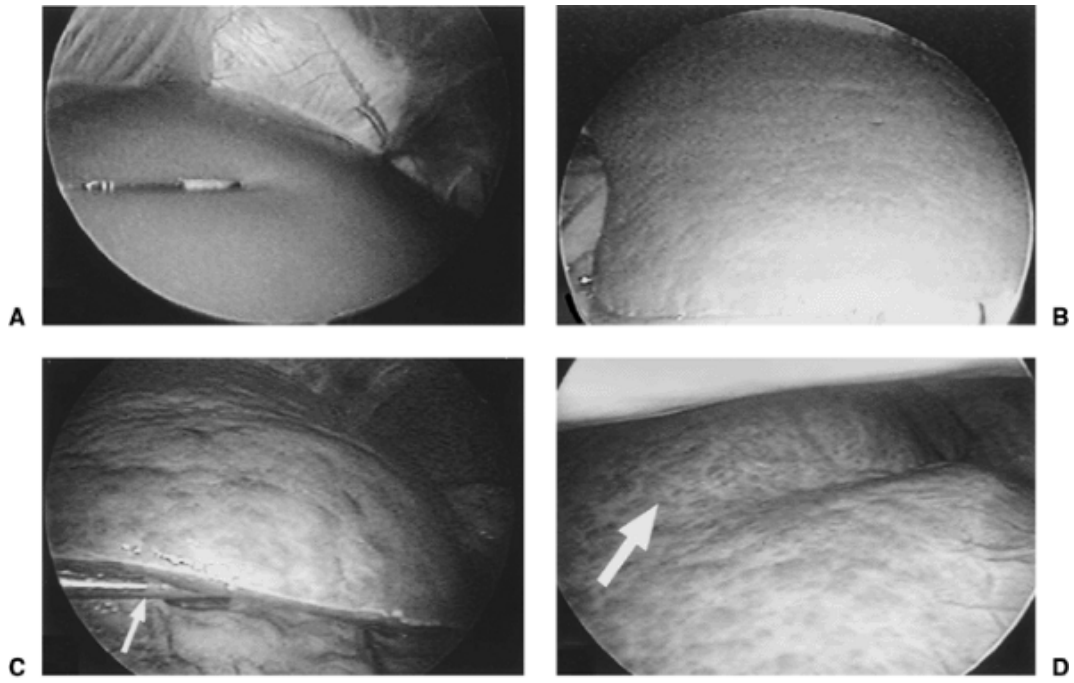
was associated with ascites in only 60% of cases (105). Chu et al. (106) performed 129 laparoscopies for ascites of unclear cause (106). They reported peritoneal carcinomatosis in 61%, tuberculous peritonitis in 20%, a nondiagnostic procedure or miscellaneous causes in 14%, and cirrhosis in 5% of cases. Laparoscopy may also identify lymphoma in patients with human immunodeficiency virus (HIV) and ascites (107).

Laparoscopy is used both diagnostically and therapeutically in the management of HCC. The liver surface may demonstrate changes suggestive of HCC, such as hypervascular nodules and hyperemic, pigmented lesions (108). The risk of sampling HCC is controversial, but most cases of biopsy-proven seeding of the needle track have been reported after percutaneous biopsy (109, 110). Laparoscopy can also be used in patients with suspected HCC to assess the extent of the primary lesion and to examine other areas for synchronous tumors (111). In addition, it may be helpful to perform laparoscopy in patients with rising levels of α-fetoprotein and unrevealing imaging studies. Furthermore, laparoscopy with ultrasonography is superior in the diagnosis of HCC compared to laparoscopy alone (112). Local therapy with ethanol injection, microwave coagulation, or radiofrequency ablation has been applied laparoscopically or percutaneously; nevertheless, recurrence of HCC at the port site has been described after local therapy (113, 114).

Laparoscopy is effective for staging a variety of cancers. In a study of pancreatic cancer, laparoscopy identified metastases undetected by CT scan in 31% of patients (115) (Fig. 3.6). Other studies have validated the usefulness of laparoscopy to help identify pancreatic cancer patients who could benefit the most from surgical resection (115,116,117,118,119). In a decision analysis model comparing multiple strategies for the staging and treatment of pancreatic cancer in which CT scan was performed first, endoscopic ultrasonography followed by laparoscopy was shown to minimize costs and unnecessary surgical explorations (120). Laparoscopic staging is also valuable in identifying surgical candidates for the management of cancers of the esophagus, stomach, ampulla, and bile ducts (121). Finally, laparoscopy is a valuable aid in staging lymphoproliferative diseases and requires the conversion to an open procedure in less than 5% of cases (122,123,124). In one

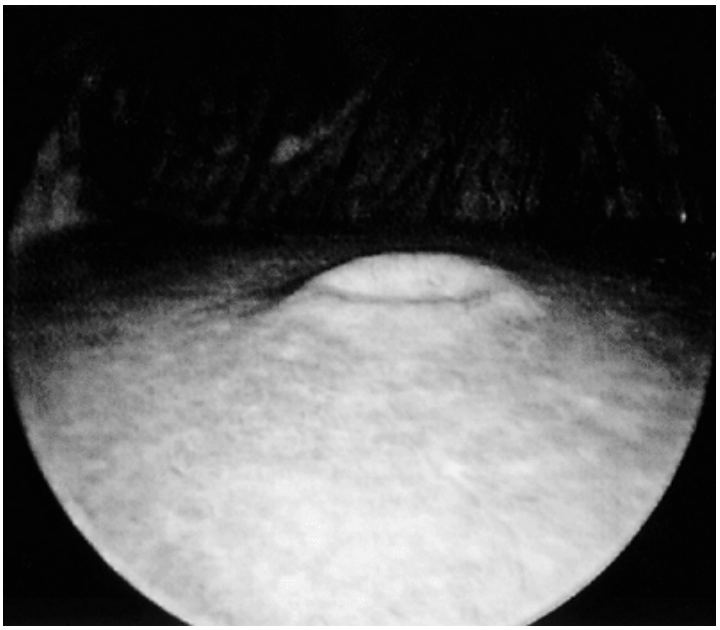
study, laparoscopy was more sensitive than CT scan for the detection of lymphomatous invasion of the liver. White spots or nodules visualized during laparoscopy were 100% specific for lymphoma (125). As imaging technologies continue to evolve, the added value to performing staging laparoscopy must be assessed on an on-going basis.





▪ **Figure 3.5** Progression of hepatitis C in four different stages. **A:** Smooth appearance of liver, stage I histology. **B:** Finely granular appearance of liver, stage II. **C:** Uneven surface with early nodularity (early cirrhosis). **D:** Nodular liver with large regenerating nodule in the superior aspect of the right lobe.

Introduction of laparoscopic ultrasonography has further improved the accuracy of staging gastrointestinal malignancy (126). During laparoscopic ultrasonography, the liver parenchyma is swept with a linear array probe placed in contact with the liver surface. The operator can also obtain tissue samples and perform radiofrequency ablation. General anesthesia is commonly used. The value of laparoscopic ultrasonography has been demonstrated in a number of settings. In a prospective study, laparoscopic ultrasonography prevented unnecessary laparotomy in 65% of patients referred for the resection of HCC (127). Moreover, laparoscopic ultrasonography changed surgical decision making in 36% of patients referred for the staging of pancreatic carcinoma; 5% of those patients had appeared unresectable by conventional imaging (128). Laparoscopic ultrasound may also play a role in staging tumors of the proximal bile duct and gallbladder (129).



▪ **Figure 3.6** Staging laparoscopy in a patient with pancreatic carcinoma; 8-mm lesion with crater seen in the left lobe.

Complications of Laparoscopy

In a large series of 1,794 diagnostic laparoscopies, major complications occurred in only 8 patients (0.44%), minor complications were observed in 31 patients (1.73%), and one death occurred (93) (Table 3.8). Minor complications, such as vasovagal reactions, subcutaneous emphysema, pneumoperitoneum, and abdominal pain, can be controlled during the procedure (93,130,131,132,133). Bleeding from the biopsy site is controlled with the application of lateral pressure, use of a heater or bicap probe, or the topical application of thrombin. Delayed bleeding or hemobilia is seen primarily in patients with portal hypertension. Bowel perforation can be a risk in patients with a history of multiple surgeries, bacterial peritonitis, or tuberculous

peritonitis (93,106). If the trocar site is found to be bleeding, a second trocar can be inserted to visualize the bleeding source. Avitene plugs placed within the trocar track are generally effective in stopping bleeding.

Table 3.8. Complications of Diagnostic Laparoscopy in 1,794 Patients at the University of Miami (93)

Complication	No. (%)
MAJOR	
Abdominal viscus perforation	3 (0.16)

Bleeding from liver biopsy site	2 (0.11)
Hemobilia	2 (0.05)
Spleen laceration	1 (0.05)
Total	8 (0.37)
MINOR	
Ascitic fluid leakage	9 (0.50)
Abdominal wall hematoma	6 (0.33)
Fever	6 (0.33)
Vasovagal reaction	5 (0.27)
Prolonged abdominal pain	4 (0.22)
Seizures	1 (0.05)
Total	31 (1.70)

Noninvasive Surrogates for Biopsy

Although liver biopsy is generally considered the gold standard for the evaluation of liver disease, sampling errors may limit its accuracy. In contrast, noninvasive markers may potentially represent a more global assessment of liver injury. Furthermore, noninvasive methods may be safer, more attractive to patients, and cheaper than biopsy. Three main types of surrogates for biopsy have been investigated: Indirect markers (aspartate aminotransferase [AST] to alanine aminotransferase [ALT] ratio, aspartate aminotransferase to platelet ratio index [APRI], FibroTest, and ActiTest), direct markers of extracellular matrix turnover (hyaluronic acid and YKL-40), and ultrasonographic evaluation of liver stiffness (FibroScan) (Table 3.9). Most studies have focused on the evaluation of the extent of fibrosis and degree of inflammation in hepatitis C. Noninvasive identification of significant fibrosis (often defined as portal fibrosis with some septae) allows stratifying patients with hepatitis C most in need of therapy.

Table 3.9. Noninvasive Surrogates for Biopsy

Test	Description	Comments
INDIRECT MARKERS		
AST/ALT ratio	Simple index derived from widely available blood tests	Ratio >1 has limited accuracy in predicting cirrhosis in viral hepatitis and NAFLD
APRI	Ratio of AST/upper limit normal to platelet count × 100	Good prediction of significant fibrosis in hepatitis C (APRI <0.5 and >1.5 predict absence and presence, respectively) Good prediction of cirrhosis in hepatitis C (APRI <1.0 and >2.0 predict absence and presence, respectively)
FibroTest	Commercially available panel of α_2-macroglobulin, haptoglobin, apolipoprotein A1, GGT, bilirubin	Good prediction of significant fibrosis and cirrhosis in hepatitis C and B
ActiTest	Commercially available panel which consists of all elements of FibroTest and includes ALT	Reliable prediction of moderate activity in hepatitis C and B
DIRECT MARKERS		
Hyaluronic acid	Marker for extracellular matrix turnover	Very sensitive for cirrhosis in viral hepatitis and alcoholic liver disease. Low value rules out cirrhosis
YKL-40	Marker for extracellular matrix turnover	Some utility to predict fibrosis
OTHER		

FibroScan	Transient elastography Probe induces vibration and ultrasonographically measures transmission through liver to estimate stiffness (fibrosis)	Excellent test for fibrosis and cirrhosis in hepatitis C. Has not been evaluated in populations with significant obesity

AST, aspartate aminotransferase; ALT, alanine aminotransferase; APRI, aspartate aminotransferase to platelet ratio index; NAFLD, nonalcoholic fatty liver disease; GGT, γ-glutamyl transferase.

Receiver operator characteristics (ROC) curve analysis is an important method to compare the test characteristics of noninvasive markers. ROC curves plot the sensitivity and specificity achieved for different test thresholds. Excellent diagnostic tests are those that achieve good sensitivities and specificities over a wide range of possible test "cutoff" values. Area under the receiver operator characteristics curve (AUROC) greater than 0.9 is excellent and that between 0.8 and 0.9 indicates a good test. Noninvasive markers cannot be expected to achieve perfect test characteristics because these panels are compared to liver biopsy,

a modality that does not perfectly assess global liver injury. When only large biopsies are used as the gold standard, noninvasive markers have demonstrated better test characteristics (134,135).

Simple, widely available, noninvasive tests have some value in predicting cirrhosis. Ultrasonography is widely used in the evaluation of liver diseases. It is moderately specific for identifying cirrhosis, but not sensitive (136). An increased AST/ALT ratio greater than 1 helps identify cirrhosis in viral hepatitis and NAFLD, particularly if the increased ratio is associated with a platelet count of less than 130,000/μL (137,138,139). Furthermore, APRI has demonstrated excellent ability to predict cirrhosis (AUROC 0.89 to 0.94) and good ability to predict significant fibrosis (AUROC 0.80 to 0.88) in patients with hepatitis C (140). A recent study in patients with hepatitis C confirmed good test characteristics for APRI, but observed that the AST/ALT ratio was a poor test (AUROC = 0.57 for significant fibrosis and AUROC = 0.73 to 0.75 for cirrhosis) (141).

The MULTIVIRC group studied 339 patients using a panel of five nonroutine serum markers (α_2-macroglobulin, haptoglobin, apolipoprotein A-I, γ-glutamyl transferase, and total bilirubin) in patients with hepatitis C. This panel of markers, now known as *FibroTest*, demonstrated an AUROC between 0.83 and 0.85 for the prediction of significant fibrosis. Fifty percent of patients could be accurately stratified using the test and could thereby avoid a liver biopsy (142). Subsequent studies have validated these findings in other people with hepatitis C (134,143,144,145). A somewhat less robust prediction has been demonstrated in chronic hepatitis B (146). Moderate or severe activity in hepatitis C can be predicted accurately by the ActiTest, which uses the same set of markers as FibroTest and also includes ALT (134). In hepatitis B, reliable prediction of moderate or severe activity was achieved with the ActiTest (AUROC = 0.82), which was similar to the prediction simply by AST or ALT tests (AUROC = 0.82,

0.81, respectively) (146). Forns et al. (147) developed another panel of markers (age, platelet count, γ-glutyl peptidase, and cholesterol) with good ability to predict significant fibrosis in hepatitis C (147).

Direct markers of extracellular matrix formation and removal have demonstrated less clinical utility to date. Hyaluronic acid is very sensitive (97%) for cirrhosis in viral hepatitis and alcoholic liver disease, and a low level can be used to rule out cirrhosis (148,149). Different test thresholds must be used for different etiologies of liver disease (148). YKL-40 is a glycoprotein involved in tissue remodeling and has also shown some utility as a predictor of fibrosis (149). Recently, a combination of hyaluronic acid, tissue inhibitor of metalloprotease-1, and α_2-macroglobulin was successfully used to identify significant fibrosis in hepatitis C (AUROC = 0.83) (150).

Transient elastography (FibroScan) is a promising new technique to evaluate fibrosis. A probe applied to the abdomen transmits a low-frequency vibration. The vibration induces an elastic shear wave, which is propagated faster in stiffer (more fibrotic) liver tissue. Ultrasonographic interrogation of the wave allows measuring the shear wave velocity. Tissue elasticity can then be determined. FibroScan has demonstrated good prediction of significant fibrosis and excellent prediction of cirrhosis (135,151). A potential concern with the technique is that it has so far been studied only among French patients with relatively low body mass indices. How successful FibroScan will be in higher body mass index (BMI) populations, such as in the United States, is not yet known.

A recent study compared noninvasive assessment of fibrosis in patients with hepatitis C using APRI, FibroTest, and FibroScan (145). All three tests achieved similar AUROC for the evaluation of significant fibrosis and cirrhosis. The authors suggest that the use of FibroTest and FibroScan together achieves the most accurate assessment of fibrosis. However, it is not obvious that the diagnostic combination is much better than performing one test alone. Cost-effectiveness studies are needed to help clarify the role of these new technologies.

Indications for Liver Biopsy

Liver biopsy is often an important component of the evaluation of chronic liver disease. With advances made in serologic and imaging tests, its use in some situations has been challenged. We describe in the subsequent text some disease states in which the routine use of liver biopsy has been questioned (Table 3.10).

Hepatitis C

Chronic hepatitis C infection globally affects approximately 170 million individuals. Candidates for treatment need to be carefully selected because hepatitis C therapy is associated with significant side effects, considerable expense, and less-than-ideal response rates, particularly in genotype 1 patients. Furthermore, most infections are asymptomatic and not progressive (152).

Liver biopsy aids in identifying treatment candidates because it is currently the best predictor of progressive disease. On the basis of retrospective data, most patients with moderate inflammation develop cirrhosis within 20 years and nearly all patients with severe inflammation or bridging fibrosis develop cirrhosis within 10 years. Patients with mild inflammation and/or minimal fibrosis have a low risk of progression to cirrhosis (153). Hepatic steatosis is also emerging as a major risk factor for fibrosis progression in hepatitis C (154,155).

As experience with FibroTest, FibroScan, APRI, and other noninvasive markers grows, fewer biopsies will likely need to be performed to evaluate the urgency of initiating hepatitis C treatment.

Table 3.10. Utility of Biopsy in Specific Clinical Situations

Issue	Pros of biopsy	Cons of biopsy
HEPATITIS C		
Prognosis	Extent of fibrosis and inflammation are best predictors of disease progression	Noninvasive markers may accurately stage and grade disease
Decision to treat	Genotype 1: Identify those most in need of therapy (therapy longer in duration and less likely to succeed)	Genotypes 2 and 3: Patients motivated for therapy may forgo biopsy (therapy shorter in duration and more likely to succeed)
Treatment-related side effects	Severity of liver disease helps in deciding whether to endure or stop therapy	Commitment to therapy should be independent of disease severity
Previously treated	Lower success with retreatment Identify those most in need of therapy (advanced fibrosis)	Motivated patients who are genotype 2 or 3, were previously treated with interferon monotherapy, had significant dose reductions, or were on-treatment responders have relatively good prospects for response to retreatment
HEPATITIS B		
Decision to treat	Consider biopsy if minimal elevation or fluctuating ALT; consider treatment if at least moderate inflammation	Hepatitis B serologies, hepatitis B virus DNA, and ALT generally determine decision to treat

Identify cirrhosis	Prompts screening for varices and HCC	HCC surveillance recommended whether cirrhosis is present or not
ABNORMAL HEPATIC BIOCHEMICAL TESTS AND NAFLD		
Elevated ALT	Confirm diagnosis	Cause accurately identified clinically in >90% cases without biopsy
Diagnosis of NAFLD	Patients may not have classic NAFLD risk factors	Accurate diagnosis of NAFLD generally possible without biopsy
Identify severity of NAFLD	Only biopsy can distinguish simple steatosis from steatohepatitis	Noninvasive markers may be developed to distinguish the two
Treatment of NAFLD	Presence of steatohepatitis or fibrosis may motivate some to undertake risk factor modification	There is no proven therapy for NAFLD Absence of steatohepatitis or fibrosis may remove motivation for some to undertake risk factor modification

ALT, alanine aminotransferase; HCC, hepatocellular carcinoma; NAFLD, nonalcoholic fatty liver disease.

Liver biopsy may also reveal unsuspected cirrhosis, which would prompt initiation of a surveillance strategy for HCC and esophageal varices. Presence of advanced fibrosis is also negatively associated with the probability of response to hepatitis C therapy. In a study of pegylated interferon-α 2b with ribavirin, the absence of bridging fibrosis or cirrhosis was significantly associated with a sustained virologic response (57% vs. 44%) (156).

Clinical information may help refine prognosis but cannot substitute for the valuable data obtained from biopsy. Risk factors for accelerated fibrosis progression include age at infection greater than 40 years, daily alcohol consumption, male gender, ALT, increased BMI, immunosuppression, and coinfection with hepatitis B or HIV (157,158,159,160,161,162,163,164). Twenty-five percent to 40% of patients with chronic hepatitis C have persistently normal ALT levels (165,166). This group tends to exhibit less fibrosis and inflammation than patients with hepatitis C and elevated ALTs (167). Moreover, in one study of 102 patients, the median progression of fibrosis was twice as fast in an elevated ALT group compared to a persistently normal ALT group (168). Despite these

reassuring findings, patients with persistently normal ALTs may have significant inflammation (19% with moderate inflammation) (169) and even cirrhosis (6%) (170).

Although the information obtained from liver biopsy is useful, it is not mandatory to perform biopsy before treating hepatitis C. Patients with genotype 2 or 3 may undergo therapy regardless of findings on liver biopsy because therapy is likely to succeed (80%) and its duration is short (24 weeks). Biopsy is more useful for genotype 1 patients. Because therapy is long in duration (48 weeks) and less likely to succeed (<50%), only patients at risk for progressive liver disease may opt for therapy. Once treatment is started, knowing the extent of fibrosis, inflammation, and steatosis may help patients and providers decide whether to continue therapy in the face of significant side effects. Furthermore, patients undergoing treatment with pegylated interferon and ribavirin can expect a low chance of sustained virologic response if they failed prior interferon monotherapy (28%) or prior interferon and

ribavirin therapy (12%) (171). Therefore, patients with mild disease should not generally attempt retreatment. Recent studies have shown that in the absence of therapy, few patients progress by more than one stage of fibrosis over 3 to 5 years (158,159,160). Therefore, repeating liver biopsy after 3 to 5 years is reasonable to reassess the need for treatment on an on-going basis. In select cases, biopsy may be avoided before initiating retreatment. Motivated patients who are genotype 2 or 3, and were prior on-treatment responders, had significant dose reductions, or were previously treated with only interferon monotherapy have relatively good chances for response to retreatment.

Although histologic improvement may be demonstrated after successful hepatitis C treatment, a posttreatment biopsy is generally not useful. In nonresponders, the role that liver biopsy should play in identifying candidates for maintenance therapy is still unclear. In one study of virologic nonresponders who had achieved a histologic response after 6 months of therapy, patients were randomized to 2 years of maintenance interferon or placebo. Treatment led to a decrease in fibrosis (172) We await data from the on-going Hepatitis C Antiviral Long-Term Treatment Against Cirrhosis trial of maintenance pegylated interferon for patients with advanced fibrosis (171).

Hepatitis B

Liver biopsy is frequently performed in hepatitis B, but clinical and serologic information are more often used to determine its management. Biopsy can identify unsuspected cirrhosis, which would prompt a surveillance strategy for esophageal varices. Screening for HCC should be considered in all hepatitis B surface antigen–positive patients, even in the absence of cirrhosis. Risks for HCC include acquisition of virus in an endemic area, male gender, family history of HCC, cirrhosis, and coinfection with hepatitis C or D (173,174). Risk factors for progressive liver disease include older age, persistence of serum hepatitis B viral DNA, occurrence of acute serologic exacerbations, elevated ALT, and presence of severe inflammation on liver biopsy (175,176,177). A recent study showed that both ActiTest and ALT correlate well with histologic inflammation (146).

Ideal candidates for treatment of chronic hepatitis B have significant hepatitis B viremia ($\geq 10^5$ copies/mL if hepatitis B e-antigen positive and $\geq 10^4$ copies/mL if hepatitis B e-antigen negative). To expect successful therapy, serum transaminases are ideally elevated at least two times above the upper limit of

normal (178,179,180,181,182). Histologic findings generally do not affect the decision of whether to initiate treatment, although there are some important exceptions. Patients with cirrhosis and hepatitis B virus viremia should undergo treatment (173,174). Furthermore, it may be reasonable to perform liver biopsy in patients with fluctuating or minimal elevation in transaminases (<2 times the upper limit of normal). A small percentage of these patients will have severe inflammation and, if treated, have an acceptable chance of response (183). Liver biopsies performed on patients with viremia and with normal ALTs (immune-tolerant phase) show no or mild liver disease (184). Such patients do not require treatment until ALT is consistently elevated, and biopsy is not recommended (174). Generally, treatment length is determined by serologic endpoints and not by changes demonstrated on histology from repeated biopsy.

Nonalcoholic Fatty Liver Disease and Abnormal Hepatic Biochemical Tests

Hepatologists are commonly asked to evaluate patients with chronically elevated hepatic biochemical tests. Determining the etiology requires a careful history, physical examination, review of medications and alcohol use, serologic studies, and imaging. Generally, an etiology can be identified without liver biopsy. In most of the remaining cases, the diagnosis is NAFLD. For example, in one series of 1,124 patients presenting for evaluation of chronically elevated hepatic biochemical tests, only 81 patients (8%) had an undetermined etiology after complete clinical evaluation. On liver biopsy, 73 patients had NAFLD, and 8 biopsies were normal (185). Sorbi et al. (186) reported on 36 patients with persistently elevated hepatic biochemical tests and an unrevealing noninvasive investigation. Prebiopsy diagnosis was NAFLD in 67%. Biopsy led to a change in diagnosis in only 14%, 80% of whom had normal liver biopsies (186). In contrast, one study observed that biopsy directly affected management in 18% of patients with persistently abnormal hepatic biochemical tests (187).

Liver biopsy is considered the gold standard for the diagnosis of NAFLD. However, clinical suspicion with supportive radiologic imaging and absence of serologic findings are adequate to diagnose NAFLD in most patients without incurring the expense, inconvenience, and risk of liver biopsy. Metabolic syndrome (obesity, dyslipidemia, and/or diabetes mellitus) is present in most patients with NAFLD, although some investigators have found significant numbers of patients without these characteristic risk factors (188,189). Radiologic imaging can complement clinical suspicion for diagnosing NAFLD. Ultrasound, CT scan, and magnetic resonance imaging (MRI) are highly accurate for identifying at least moderate steatosis; however, imaging cannot distinguish steatohepatitis or fibrosis from simple steatosis (190,191).

Histologic findings of steatonecrosis and fibrosis identify a subset of patients with a worse prognosis (192,193). Cirrhosis is present in 10% to 20% of patients and moderate to severe fibrosis, in up to 40% (189,194,195). Clinical features are helpful, but not definitive, for prognosis. Risk factors for worse disease include age over 45, obesity, diabetes mellitus, hypertriglyceridemia, hypertension, and increased ALT (139,194,196). Recent reports have highlighted the observation that the entire histologic spectrum of nonalcoholic steatohepatitis (NASH) can exist among patients with normal ALT (197,198).

The major benefit of performing liver biopsy is to distinguish patients with steatosis from those with steatohepatitis. Certainly this distinction is critical to

studies of investigational agents for the treatment of NASH. Apart from studies, current therapy for NASH focuses on addressing obesity, diabetes mellitus, dyslipidemia, and hypertension. No specific therapy can yet be recommended for NAFLD. Performing a biopsy may motivate some patients to pursue treatment of metabolic syndrome more aggressively. On the other hand, if a biopsy shows only mild changes from NAFLD, some patients with metabolic syndrome may derive a sense of false security that they need not make major changes in diet and exercise. We generally do not perform biopsy to evaluate NAFLD.

Methotrexate-Induced Hepatotoxicity

Methotrexate is a potentially hepatotoxic drug used to treat psoriasis, rheumatoid arthritis, and other diseases. Evidence-based recommendations for monitoring liver toxicity differ between the dermatology and rheumatology literature. Early studies reported that up to 26% of patients with psoriasis treated with long-term methotrexate developed cirrhosis (199). Dermatology guidelines recommend pretherapy liver biopsy in high-risk patients, followed by serial biopsy after every cumulative exposure of 1 to 1.5 g of drug. Demonstration of moderate fibrosis would preclude further therapy (200). A more recent series using modern fibrosis-scoring methods reported a much lower risk of methotrexate injury, and the authors raise questions about the necessity for such intensive monitoring (201).

Reports of significant fibrosis and cirrhosis are relatively rare among patients with rheumatoid arthritis taking methotrexate. Lower incidence of hepatotoxicity may be due to more rigorous exclusion of chronic liver disease in the rheumatology literature or to a disease-specific risk associated with methotrexate hepatic injury. Because persistent AST elevations have been associated with liver injury (202), rheumatology guidelines recommend biopsy only if most ASTs during the course of a year are elevated. An elevated AST prompts reduction in methotrexate dose, and treatment is discontinued if a biopsy demonstrates moderate fibrosis. Pretreatment biopsy is performed if chronic liver disease is suspected (203). Long-term safety has been demonstrated in patients with rheumatoid arthritis adhering to this monitoring schedule (204). Our approach to potential methotrexate-induced hepatotoxicity in patients with both rheumatoid arthritis and psoriasis is to perform a pretreatment liver biopsy in selected patients who have risk factors for chronic liver disease and for those with persistent elevations of aminotransferases during therapy.

Hepatocellular Carcinoma

HCC must be suspected in a patient with cirrhosis and a focal liver lesion. Sensitivity of fine-needle biopsy for the detection of HCC is between 86% and 90% and depends on nodule location and size (more often diagnostic for lesions >3 cm) (205,206,207). Noninvasive methods of diagnosing HCC include tumor markers and radiologic studies. Although α-fetoprotein may not be elevated in up to 40% of HCC, a significant elevation can help make the diagnosis. In one study, an α-fetoprotein greater than 200 ng/mL had 99% specificity for HCC (208). CT scan and MRI have demonstrated excellent accuracy for diagnosing HCC (209). Recent European guidelines suggest that HCC can be diagnosed without biopsy if a characteristic mass greater than 2 cm in a cirrhotic liver is evident in two imaging modalities. Elevated α-fetoprotein (>400 ng/mL) may help confirm the diagnosis (210).

Biopsy of HCC carries a significant risk of needle-track seeding (1.6% to 5%)

(109,205,206). A recent report of a polyethylene shield device may reduce that risk, but is as yet unproven (211). If a diagnosis of HCC can be confidently made on the basis of imaging with or without the help of α-protein, we do not perform fine-needle liver biopsy to confirm the diagnosis. At our institution, biopsy of HCC is generally reserved for patients in whom no definitive surgical intervention is planned and can be obtained at the time of nonsurgical treatment (radiofrequency ablation, alcohol ablation, or chemoembolization).

Conclusion

Liver biopsy is a time-honored and safe method to evaluate chronic liver diseases. Growing evidence suggests that biopsies may not be representative of disease processes affecting the entire liver, especially when small samples are obtained. Biopsy is generally performed percutaneously with or without radiologic guidance. Transjugular biopsies may be performed on

patients with ascites, obesity, or a bleeding diathesis. Laparoscopy, more commonly used in Continental Europe, is a safe outpatient procedure useful for accurately determining the presence of cirrhosis and for staging various gastrointestinal cancers.

Recently, panels of markers that can serve as surrogates to biopsy in identifying the extent of fibrosis and inflammation have been introduced. As experience grows with these tests, it is possible that performance of biopsy may decline in some clinical situations, such as identifying candidates for hepatitis C therapy. Routine use of biopsy has been questioned in a number of clinical scenarios. In hepatitis C, biopsy may help stratify which patients are at risk for progressive disease and therefore most in need of therapy. Genotype 2 or 3 patients have a high response rate and a shortened treatment course and may therefore opt for therapy without biopsy. In hepatitis B, biopsy generally does not affect treatment decisions except in the subset of patients with minimally elevated or fluctuating transaminase levels. Distinction of NASH from bland steatosis can only be accomplished by biopsy. In the absence of any specific therapy for patients with either NASH or NAFLD, biopsy results currently do not affect management decisions. In monitoring methotrexate toxicity, the need for periodic liver biopsy has been questioned, and most patients can avoid biopsy if transaminases remain relatively normal. Finally, radiologic imaging can now accurately diagnose HCC without risking possible needle-track seeding from biopsy.

Chapter 4

Imaging

Furqaan Ahmed
Deirdre Coll
Ira M. Jacobson

Key Concepts

- Recent technologic advances have led to considerable improvements in liver imaging.
- Ultrasonography is a quick, widely available, and inexpensive modality for hepatic imaging and is often the initial imaging test ordered.
- Multidetector computed tomography (CT) scan and magnetic resonance imaging (MRI) allows three-dimensional imaging of the hepatic parenchyma and vasculature.
- Evaluation of hepatic malignancies is facilitated by 2-fluoro-deoxy-D-glucose (FDG) positron emission tomography.
- Ultrasonography, noncontrast CT scan, and magnetic resonance imaging (MRI) are able to demonstrate the presence of hepatic steatosis; however, none of these imaging modalities is able to distinguish between steatosis and steatohepatitis.
- Ultrasonography with Doppler imaging is a useful first tool for the diagnosis of hepatic venous thrombosis; MRI allows superior visualization of the inferior vena cava and hepatic veins, as well as liver parenchyma.
- Ultrasound guidance is commonly used for percutaneous liver biopsies in patients with diffuse liver disease. Although studies have suggested that this practice may result in fewer complications, more data are needed before this can be established as a uniform standard.

Noninvasive Imaging of the Liver

Recent technological advances have allowed considerable improvement in imaging of the liver. This introductory section provides a short description of the imaging modalities, with brief guidelines on which test to use and when. An in depth explanation of the physics is beyond the scope of this text. The aim is that the referring physician will understand the advantages and limitations of the imaging modalities available. It is hoped that this will facilitate the choice of the most appropriate diagnostic tool for better and more cost-effective patient care. The second portion of the chapter will address selected clinical problems in which critical use of radiologic modalities plays a role in evaluation and management.

Ultrasound

This test should serve as a baseline for nearly all patients who initially present with symptoms suggestive of liver or gallbladder disease. It is fast, cost-effective, noninvasive, widely available, and involves no radiation.

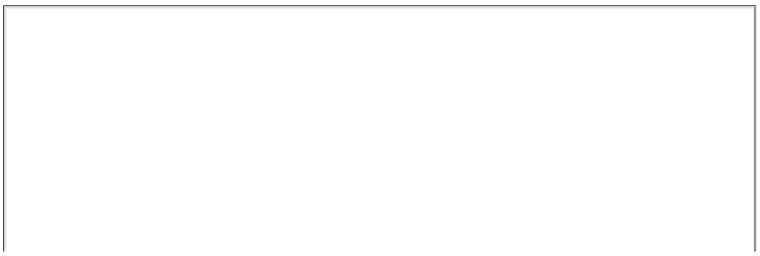
The basic principle of ultrasound is the transmission of sound waves into the liver from a transducer. These waves reflect at interfaces between tissues with differing acoustic impedance. For example, at the soft tissue–air interface almost total reflection occurs, which explains the use of ultrasound gel to allow the sound waves to pass into the body. As the ultrasound wave passes through the liver, the sound wave is affected by changes in tissue type and is refracted and reflected. The transducer is able to detect the reflected sound waves and uses the time delay from transmission to

calculate depth within the body. The ultrasound image displays the amplitude of reflection as a function of position, with the "whiteness" of the image directly proportional to the amplitude of reflection. The liver is best evaluated with a 2 to 5 MHz ultrasound transducer. In larger patients, the lower frequency permits greater tissue penetration. The higher frequency transducers offer improved spatial resolution but less penetration. Therefore, imaging of superficial structures should be preferentially performed with a higher frequency transducer.

The appearance of a lesion within the liver is explained by its relative reflectivity compared with the surrounding liver parenchyma. When the sound wave passes through a structure without any reflection, no echoes are generated and the structure appears black or anechoic, such as a hepatic cyst (Fig. 4.1). When nearly all of the sound wave is reflected, the structure appears white or hyperechoic such that the lesion appears brighter than the liver. This is well demonstrated with a cavernous hemangioma whose classic appearance is that of a homogenously hyperechoic structure (Fig. 4.2). This is secondary to its complex internal structure whose network of vascular structures almost completely reflects the ultrasound beam. When some of the sound waves pass through, and some are reflected, the lesion will be gray or hypoechoic. This means that the lesion is less bright than the liver. An example is colorectal metastases (Fig. 4.3).

Tissue harmonic imaging is an alternative method of producing an image. When an ultrasound wave insonates tissues in the body, this produces secondary sound waves at integral multiples of the fundamental transmitted frequencies. Harmonic imaging utilizes these frequencies (generally only the second harmonic or twice the transmitted frequency) to produce an image. These images generally have improved axial resolution due to shorter wavelength, and better lateral resolution due to improved focusing with higher frequencies. They also have fewer artifacts, as the smaller amplitude of the harmonic waves decreases the detection of echoes from multiple scattering events; they also have less reverberation and side lobe artifacts, and increased contrast resolution as compared to standard sonography. This is particularly useful for obese and technically difficult patients. It also provides for a more accurate characterization of cystic lesions. The disadvantages of this technique are that the harmonic echoes are weaker, which can cause a noisier image. They also have less penetration than images obtained with conventional sonography. This technique is

available on most of the latest ultrasound machines (1,2,3).



• **Figure 4.1** Simple hepatic cyst (*arrow*). Note the posterior acoustic enhancement.

• **Figure 4.2** Hemangioma. Transverse ultrasound image through the left lobe of the liver shows a hyperechoic (*arrow*) 2 cm hemangioma.

• **Figure 4.3** Hepatic metastasis. Saggital view through the left lobe of the liver shows four metastatic lesions (*arrows*) in a patient with metastatic colon cancer.

In conventional sonography, the liver is isonated at a single constant angle. In real-time compound sonography, the image is obtained by combining slices from multiple different angles. As the object is now imaged from multiple spatial orientation and the image is formed from the summation of the individual frames, this results in reduced image artifacts, better delineation of surface noise, and better image contrast to produce a better sonographic image. Limitations include blurring from motion, as the image takes longer to acquire. There is also less posterior acoustic shadowing, which is often a useful artifact when trying to characterize a lesion (4). It is possible to combine compound and harmonic imaging modalities; one study has suggested that this technique will produce images superior to either technique alone (5).

Ultrasound specific intravenous contrast agents are intravenous "microbubble" contrast agents that consist of an encapsulating shell material (albumin, phospholipid or polymer) surrounding air or flourocarbon gas. These particles are relatively stable in the bloodstream and highly reflective when isonated by ultrasound at typical frequencies used in medical imaging. In fact, there is linear reflection (at the same frequency as that transmitted by the transducer) and a non linear component of reflection that is useful for harmonic imaging (see the subsequent text). In general, the degree of increased echogenicity in a liver lesion will depend on the relative perfusion of the lesion compared to the liver (thus yielding information similar to a contrast-enhanced computed tomography (CT) scan or magnetic resonance imaging (MRI). These agents have not been approved by the U.S. Food and Drug Administration (FDA) for use in the United States, but they have been used in Europe for the past few years. Contrast-enhanced scans are thought to provide more information than color Doppler alone. Tissue harmonic imaging can detect nonlinear vibrations of microbubble contrast agents and is a fertile area for future research (6).

Given the relatively low sensitivity of ultrasound for the detection of liver lesions in patients with parenchymal liver disease, contrast agents offer the potential of bringing ultrasound to a comparable level with CT scan and MRI. A recent study utilizing contrast agents for

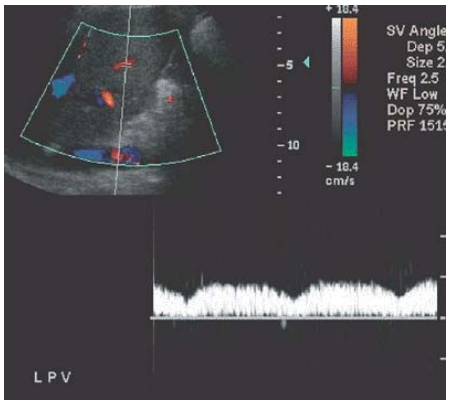
the detection of small hepatocellular carcinoma (HCC) reported sensitivity and specificity rates of 94% and 93%, respectively (7). In contrast, conventional ultrasonography has been reported to have a sensitivity of 74% to 88% for the detection of cirrhosis when liver biopsy and/or gross observation at laparoscopy were used as standards of reference (8,9,10).

The reported sensitivity of conventional ultrasonography for the detection of metastatic lesions in the liver is relatively poor (53% to 77%) and is inferior to that of contrast-enhanced CT scan and MRI. Lesions are missed at ultrasound either because they are too small, with the sensitivity for lesions smaller than 1 cm being as low as 20%, or because the lesions are isoechoic with the background tissue and therefore very difficult to perceive. This also explains why it is difficult to detect lesions in cirrhotic and fatty liver. The parenchymal changes in these livers increase the reflectivity and they appear "brighter" on ultrasound and will therefore "hide" lesions, which are of the same echogenicity (11,12,13,14).

Color, spectral, and power Doppler imaging provide a noninvasive method of measuring flow in the hepatic blood vessels, and assessing vascularity within a lesion. Spectral Doppler provides a tracing of the Doppler wave from which we can calculate various indices, including peak systolic velocity and resistive indices (Fig. 4.4).

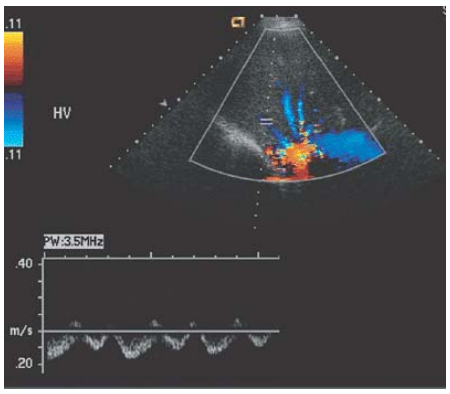
In conjunction with the color Doppler, it enables the operator to determine the direction of blood flow. Power Doppler imaging displays the integrated power of the color signal to depict the presence of blood flow. The color Doppler display reflects the mean Doppler frequency shift. Power Doppler is therefore a more sensitive method of demonstrating flow, but does not give any quantitative information about the velocity or the direction of blood flow (15,16). Nearly all ultrasound machines now have, as standard, color and spectral Doppler imaging. It is routine to document the presence or absence of flow, and the direction of flow in the hepatic veins and portal veins (Figs. 4.5 and 4.6). Interrogation of the hepatic artery is not routinely done except when specifically requested, or in a posttransplant patient.

• **Figure 4.4** Hepatic artery. Spectral Doppler tracing of the right hepatic artery. Peak systolic velocity and minimum diastolic velocity values are used to calculate the resistive index.



• **Figure 4.5** Portal vein. Spectral Doppler tracing of the left portal vein shows a normal hepatopedal (above the baseline) flow into the liver. It is normally of low velocity with an undulating spectrum.

There are no absolute contraindications to ultrasonography. Relative contraindications include morbid obesity, in which it is often difficult for the sound waves to penetrate the patient to produce a diagnostic image. Patients with respiratory compromise may not be able to suspend respiration. As discussed in the preceding text, the ultrasound of the liver is limited if the patient has parenchymal disease such as steatosis or cirrhosis. In these patients this limitation should be documented on the radiology report, and if there is persistent suspicion the physician should be aware that a CT scan or an MRI must be performed for further evaluation.



• **Figure 4.6** Spectral doppler tracing of the right hepatic vein as it drains into the inferior vena cava. The normal triphasic spectral tracing reflects the pulsatility of the right atrium.

Patients will need to fast for 6 hours to reduce the amount of bowel gas so that the gallbladder and the biliary system can be assessed at the same time. The test, in general, will take approximately 30 minutes, and the patient will be asked to hold their breath repeatedly so the technologist can take images during suspended respiration.

Computed Tomography

Just as the introduction of CT scan impacted the detection of liver lesions, recent advances in CT scan have revolutionized the characterization of these lesions. Spiral and helical CT scan are terms that are used interchangeably. Helical CT scan is now performed almost universally, enabling the acquisition of thinner slices with improved spatial resolution more rapidly than conventional CT scan. The difference between helical and conventional CT scan is that spiral scanners are able to continuously rotate the x-ray CT scan tube, while the patient is moved through the scan plane. Therefore, instead of producing single slices, spiral scanners are able to acquire data over a volume of the patient (such as the craniocaudal extent of the liver), while the x-ray CT scan tube is continuously rotated.

Early helical scanners were able to rotate 360 degrees in roughly 1 second (1,000 ms gantry rotation) and used a single detector (single-slice CT scan) with a thickness of approximately 1 cm (1 cm spatial resolution). This single axial image was formed by the rotation of a single detector, coordinated with incremental CT scan table advancement and a pencil like CT scan source. The first generation CT scanners took 25 minutes to produce five views of the head. This progressed to a linear row of detectors with a fan beam, to a partial circle of detectors, and finally to the present, in which the patient is moved through the scanner and a helix of raw projection data is generated. Instead of a single row of detectors there are multiple rows of detectors. This is how the term multislice CT scan, originated. Multislice scanners are so named because they have more than one detector (between 2 and 64), and can therefore produce more than one slice per rotation. Currently, slices are as thin as 0.4 mm and can be acquired using gantry rotation times as low as 0.33 seconds (165 ms temporal resolution).

Most facilities now have helical CT scan available to them. At the time of writing, many facilities have 64 row scanners and there are plans to have up to 125 rows, followed eventually by volumetric scanning. These scanners allow images to be produced more quickly: For example, with a 16-row scanner we can scan the patient from head to toe in less than a minute. Therefore, we can scan through the

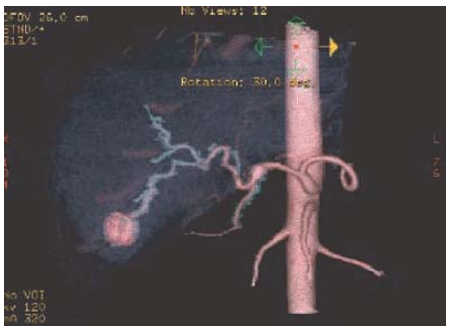
entire liver in less than 10 seconds, which allows scanning in multiple phases of enhancement, and also lessens the problems of respiratory artifact. These scanners can take thinner slices through the liver—with 0.625 mm slices; this allows almost isometric imaging (voxels of identical dimensions in all three planes) and exquisite three-dimensional (3D) images. These advantages also permit more advanced image processing, such as digital subtraction and CT scan perfusion (17,18).

Nearly all facilities now have helical scanners and can scan through the liver in multiple phases. 3D and CT angiography can be routinely performed. While 3D is not needed routinely for the assessment of a liver lesion, 3D imaging and CT angiography are very helpful in identifying the location of the lesion for the surgeon and for vascular mapping, and should be considered for patients who are candidates for surgery. (Figs. 4.7 and 4.8). CT angiography is now routinely used for the preoperative work up of living related donors for partial hepatectomy. This also allows liver volume estimation before surgery (Fig. 4.9).

In summary, the development of multidetector CT scan has greatly advanced the image quality of hepatic imaging. CT scan offers the highest spatial and temporal resolution, allowing advanced applications and very high quality 3D imaging of both the parenchyma and hepatic vasculature. CT scan should be considered as the first option in older patients for whom radiation is not a concern. In particular, elderly patients who will have difficulty holding their breath will usually do better with CT scan than with MRI.

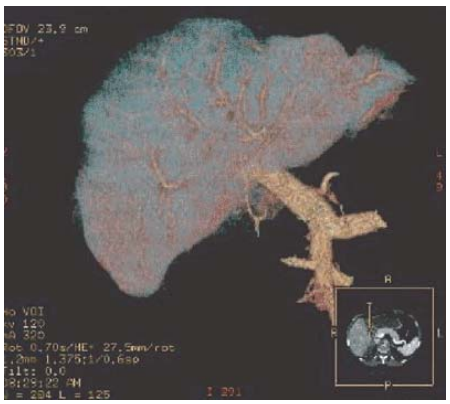
For a dedicated examination of the liver, patients need to fast for 6 hours. This has a twofold advantage; the gallbladder is distended which allows a better evaluation, and the patient has an empty stomach, which will reduce the risk of any vomiting post injection of intravenous contrast. There is usually no need to drink oral contrast for a dedicated hepatic CT scan, unless there is some reason to evaluate the bowel also. For an examination targeted to the biliary system, many centers are now advocating that the patient drinks a liter of water prior to the scan. This distends the bowel and helps to trace the course of the common bile duct

as it passes into the duodenum. For most examinations of the liver, patients will get an intravenous cannula inserted in their arm. The actual scanning time is approximately 5 minutes, but the patient should expect to be within the radiology department for about an hour. Most patients are observed for approximately 20 minutes for postcontrast reactions. If they have a history of allergy, they will need to be premedicated or an MRI scan considered.



• **Figure 4.7** 3D volume rendering of a liver with a small hepatocellular carcinoma in the right lobe (*arrow*). The computed tomography angiogram provides exquisite detail of the segmental branch of the right hepatic artery, which is supplying the tumor. This provides the surgeon with a clear road map to enable accurate preoperative planning.

• **Figure 4.8** 3D volume rendering of the same patient (fig. 4.7) now showing the relationship of the portal venous system to the tumor in the right hepatic lobe.



• **Figure 4.9** 3D volume rendering of the liver. The contour of the liver is traced on individual axial slices and then summed to give an accurate estimation of liver volume.

Relative contraindications include pregnancy, allergy to iodinated dye, renal failure, and patients with end stage cirrhosis who are at risk for hepatorenal syndrome.

Radiation

There has been much concern about radiation dose with CT imaging. If all medical x-ray imaging modalities are analyzed, CT scan accounts for 40% to 67% of the radiation dose, but only 5% of the number of tests ordered. The number of CT scan examinations being performed is increasing every year (19). Most of this concern is focused on the pediatric and younger populations, which are most sensitive to radiation. However, both the radiologist and the ordering physician should be aware of the radiation dose.

The unit for assessing the risk of cancer from a CT scan is the "effective dose" which is measured in millisieverts (mSv; 1 mSv = 1 mGy in the case of x-rays.) Effective dose allows comparison of the risk estimates associated with partial or whole-body radiation exposures. It

also incorporates the different radiation sensitivities of the various organs in the body. The actual effective dose from a CT scan can vary by a factor of 10 or more depending on the type of CT scanner, the protocol (how many phases, kVP, mAs etc.) and patient weight. Table 4.1 shows a list of radiology tests and their associated doses taken from a report of the European Commission (20). The reduction of the dose in general requires lowering mAs and kVp and increasing pitch. Therefore, there is always a trade-off between the image quality and the dose. Most radiology departments have dose reduction policies in place, particularly for the pediatric population (21).

Nephrotoxicity

The field of contrast usage has progressed from high osmolar contrast agents (osmolality five times higher than that of serum) to low osmolar contrast agents twice the osmolality of serum, and finally to iso-osmolar (290 mOsm/L) agents, which are almost isotonic with blood. They have been reported to have less nephrotoxic effects than the other contrast agents (22). Other approaches to reducing contrast induce nephropathy (CIN) have been the use of *N*-acetylcysteine. This has the advantage of being inexpensive, safe, and is widely used. Although, not all studies have shown a definite benefit, the use of *N*-acetylcysteine has become routine in many centers for patients with renal insufficiency. (23,24).

Computed tomography perfusion

The basis of CT scan perfusion is that it detects the difference between regional and global alteration in blood flow. It was initially developed in the brain to try to quantify blood flow for patients with a cerebrovascular accident. The ability to distinguish between arterial and portal venous phase on a global and regional basis imaging provide the basis for CT scan perfusion of the liver.

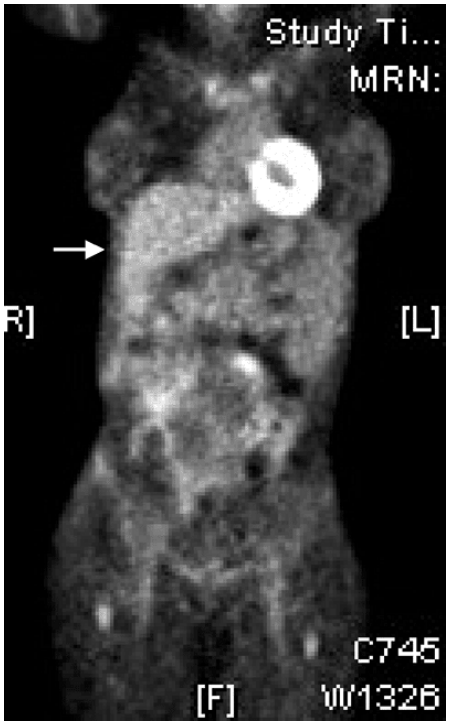
In order to perform this technique, the purchase of a separate software package is required. Perfusion measurement is the blood volume divided by time divided by tissue volume. For example, there is a relative increase in arterial versus portal venous flow in cirrhosis, offering potential for the early noninvasive detection of cirrhosis, but this remains to be proven. A similar rationale exists to offer the hope of earlier detection of HCC and metastatic disease. Dose considerations means that this technique is not yet feasible for these options (25). The technique of CT scan perfusion remains investigational, and is not available on a routine basis.

Positron Emission Tomography and Computed Tomography–Positron Emission Tomography

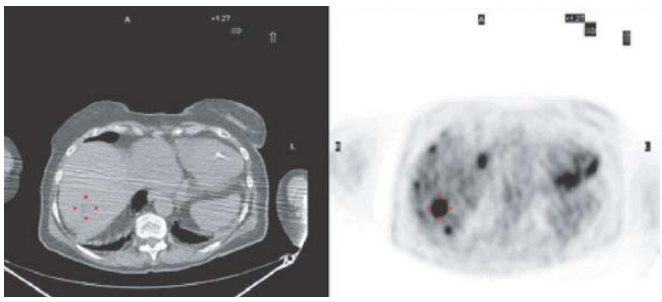
Positron emission tomography (PET) is a functional imaging modality. It utilizes positron emitters such as fluorine-18, oxygen-15, nitrogen-13 and carbon-11. However, all of the above except fluorine have very short half-lives, which means that an on site cyclotron would be required. Therefore, this discussion will be limited to the use of fluorine-18 which is widely available as 2-fluoro-deoxy-D-glucose (FDG). FDG has a half-life of 110 minutes and has high uptake in most cancers.

FDG-PET is based on the principle that there is increased glucose metabolism seen in malignant tissue relative to that of the surrounding normal tissue, and that this increase in metabolism is seen as a more intense uptake on FDG-PET images (Fig. 4.10). FDG competes with glucose for transport into a cell. Inside the cell, like glucose, FDG is phosphorylated by hexokinase into FDG-6-phosphate. In normal liver cells, there is a high concentration of glucose-6-phosphatase, which causes dephosphorylation and allows it to exit from the cells. Therefore, in the healthy patient there is rapid clearance of FDG from the liver. In malignant cells the up regulation of hexokinase causes increased glucose utilization (26).

These cells often have decreased glucose-6-phosphatase, and the FDG remains trapped within the cell (27,28,29). Increased FDG uptake is, however, nonspecific and may occur in any condition associated with increased tissue metabolism. This accounts for the uptake seen in acute or chronic inflammatory or infectious processes (30).



• **Figure 4.10** Normal positron emission tomography scan of the body demonstrating the normal uptake in the liver (*arrow*).



• **Figure 4.11** Positron emission tomography–computed tomography scan of a patient with multiple colorectal metastases. The dominant lesion in the right lobe of the liver is marked on both images (*arrows*).

PET–CT scan combines the cross-sectional anatomic information from CT scan with the functional information acquired by PET. They are both acquired during a single examination and fused. The ability to fuse information from both studies allows the accurate localization of increased FDG activity to specific anatomic locations. This is often difficult with PET alone (31).

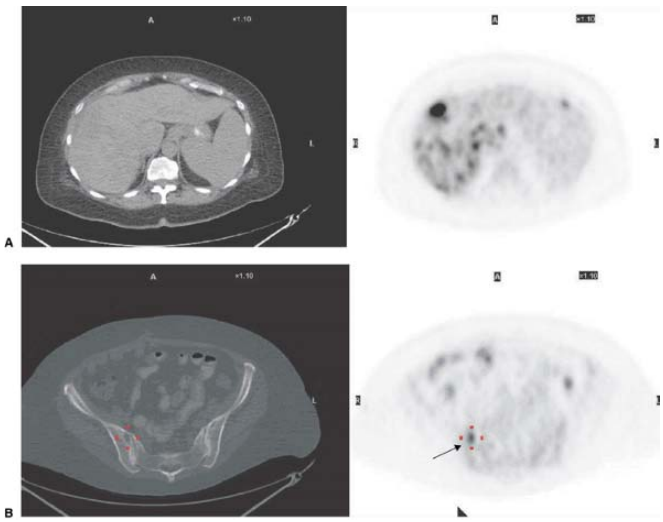
Hepatic metastatic disease

Studies utilizing PET have shown encouraging results when evaluating patients for metastatic liver disease. In studies of patients with a known solitary hepatic metastasis identified on conventional imaging, PET can detect other lesions. This is of particular importance in this patient population, as it may radically change patient management (32,33,34).

In a meta-analysis of the literature on colorectal liver metastases from January 1990 to December 2003, sensitivity estimates on a per-patient basis for helical CT scan, 1.5-T MRI, and FDG-PET were 64.7%, 75.8%, and 94.6%, respectively. On a per-lesion basis, sensitivity estimates for helical CT scan, 1.0-T MRI, 1.5-T MRI, and FDG-PET were 63.8%, 66.1%, 64.4%, and 75.9%, respectively. Therefore, FDG-PET had significantly higher sensitivity on a per-patient basis, compared with that of the other modalities, but not on a per-lesion basis (35). A meta-analysis looking at noninvasive imaging methods for the detection of hepatic metastases from colorectal, gastric, and esophageal cancers found that at equivalent specificity, FDG-PET is the most sensitive noninvasive imaging modality for the diagnosis of hepatic metastases from colorectal, gastric, and esophageal cancers (Fig. 4.11) (36).

False-negative FDG-PET can occur secondary to physiologic movements of the liver, infectious/inflammatory foci, underestimation of uptake, and recent completion of chemotherapy or radiotherapy. PET has demonstrated a high sensitivity for detection of disease when the lesions are larger than 1cm. As it does not reliably detect tumors less than 1 cm, it is suggested that PET-CT scan offers the patient the benefit of both imaging modalities (37,38). Most of the work on hepatic metastases has focused on patients with colorectal carcinoma.

One of the major advantages of PET is also the ability to survey the whole body for metastatic disease. Studies suggest that when PET is added to CT scan in preoperative planning for patients with hepatic metastases, additional sites of extrahepatic disease are identified in 11% to 23% of patients. This has had significant clinical impact in the management of these patients (39,40).



• **Figure 4.12 A:** Positron emission tomography–computed tomography (PET–CT) scan of a multifocal highly aggressive hepatocellular carcinoma. The PET scan shows the extent of the disease. **B:** In the same patient, images through the sacrum show a metastatic bone lesion in the right ileum. The PET–CT scan can help to detect unsuspected metastatic disease.

Hepatocellular carcinoma

HCC has a low uptake of FDG. Consequently, the detection rate of PET scans for HCC is approximately 50% (41,42). The uptake of FDG appears to correlate with the degree of differentiation of the HCC (Figs. 4.12A,B). Poorly differentiated tumors have greater uptake of FDG than well-differentiated tumors. This is thought to be due to the fact that in well-differentiated HCC, there is a high intracellular concentration of glucose-6-phosphatase so that well-differentiated HCC and normal hepatocytes metabolize glucose-6-phosphate and FDG at the same rate (43). Also, glucose transporters do not seem to be overexpressed in HCC as often as in other malignancies (44).

11-C acetate is a newer PET tracer with a half-life of 20 minutes. Therefore, an on site cyclotron would be required to utilize this tracer. In contrast to FDG, it

is taken up in well-differentiated HCCs, but it cannot detect poorly differentiated HCCs (45). Recent studies have suggested that the delayed imaging of the liver at 2 to 3 hours may offer improved results for the detection of HCC. This is thought to be due to a gradual increase in uptake in FDG by the tumor, and decreased uptake by the hepatocytes.

In summary, FDG should not be used for the routine detection of HCC. FDG uptake depends on the histological grading of the tumor and is highest in the poorly differentiated tumors, whereas 11-C acetate uptake is better for the well-differentiated tumors. Delayed scans post injection may offer a better sensitivity.

Cholangiocarcinoma

The largest study (31 patients) looking at the use of PET for the detection of cholangiocarcinoma showed a sensitivity of 61% and a specificity of 80%. It showed a better sensitivity for nodular than infiltrating lesions. Care must be exercised in patients with biliary stents as they can cause a false-positive reading. Acute inflammation in patients with sclerosing cholangitis can also cause a false-positive reading. The authors suggest that PET is accurate in predicting the presence of nodular cholangiocarcinoma (mass >1 cm) but is not helpful for the infiltrating type (46). Other studies have shown decreased sensitivity for the detection of mucinous tumors (47,48). Hilar and extrahepatic cholangiocarcinoma are less intense on FDG-PET than peripheral cholangiocarcinoma (49,50). The use of standardized uptake values for evaluating the uptake of FDG shows promising results in trying to distinguish between extra hepatic bile ducts malignant and benign strictures (51).

In summary, it appears that if cholangiocarcinoma has sufficient tumor volume, it will take up FDG-PET. It is not sensitive for mucin containing tumors and will have false-positive results for those patients with inflammatory conditions such as sclerosing cholangitis.

Radiation dose

One study has reported the effective dose per PET–CT scans examination at or about 25 mSv. Please see Table 4.1 for comparison to other examinations (52,53,54).

Patient information

Although each center will have its own specific procedures, the following are general guidelines. The PET scan and the CT scan will be performed during a single visit. Patients should fast for at least 4 to 6 hours prior to their scan. They will receive an intravenous injection of 18FDG, following which there is usually a wait of about an hour for the FDG to distribute throughout the body. The patient is then taken to the scanner. The CT portion of the scan is usually completed first. This will take only approximately 5 minutes. Depending on the part of the body being imaged, patients may receive another injection at this stage of radiographic contrast. Intravenous radiographic contrast is not used routinely at present. On the same imaging table, the PET portion of the scan is then performed. This may take up to 45 minutes.

Table 4.1. Typical Effective Doses of Ionizing Radiation from Common Imaging Procedures (20)

Class	Typical effective dose (mSv)	Examples
0	0	US, MRI
I	<1	Chest x-ray
II	1–5	IVU, lumbar spine x-ray, CT head and neck
III	5–10	CT chest and abdomen, cardiac nuclear medicine studies
IV	>10	PET studies

US, ultrasonography; MRI, magnetic resonance imaging; IVU, intravenous urogram; CT, computed tomography; PET, positron emission tomography.

If the blood sugar is elevated over 200 mg/dL, the scan will be postponed. All diabetic patients must have their blood sugar levels regulated. Insulin should not be injected near the time of the scan, as it will cause increased uptake in the local skeletal musculature. It is recommended that FDG-PET be performed in the morning after an overnight fast. The patient should not exercise for 24 hours prior to the scan. The patient's bladder should be emptied prior to the scan. The patient should be asked about recent surgery, active inflammation, or infection.

Magnetic Resonance Imaging

State of the art MRI of the liver is now routinely performed with a torso phased array coil. This is a surface coil placed on the patient which provides a better image by allowing a greater signal-to-noise ratio. Stronger magnets and improved software now allow imaging of the entire liver in one breathhold. Multiple sequences are performed in a routine liver MRI. These sequences should include T1, T2, in-and out-of-phase images, and pre– and post–dynamic contrast images. The pre- and post contrast sequence can be performed either with standard 2 dimensional axial sequences, or a 3D volume acquisition.

The advantages of MRI are the lack of radiation and the use of non-nephrotoxic contrast material. It offers higher contrast resolution but decreased spatial resolution when compared to CT scan. Nearly all liver

examinations require administration of contrast. However for an MRCP, no contrast is given. Therefore, if the sole goal of the test is to evaluate the bile ducts for calculus disease, contrast is not required. However, if a simultaneous evalution of the pancreas or liver parenchyma is desired, or if there is any concern about malignancy, the study will require dynamic administration of intravenous contrast.

MRI is the test of choice for the noninvasive quantification of liver iron. The presence of iron causes a decrease in the MRI signal intensity causing the liver to appear dark. This is caused by a decrease in the T2 relaxation rate of protons. Other limitations are that the amount of fibrosis and inflammation in the liver can affect liver iron measurements (55).

Contrast agents

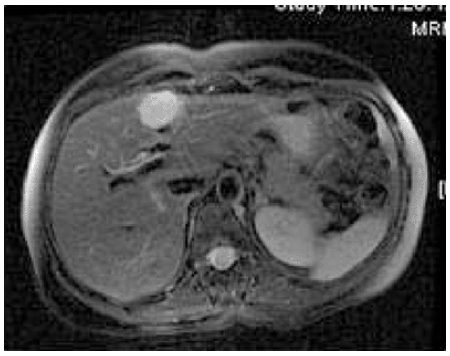
The vast majority of liver MRI is performed with gadolinium chelate contrast agents, which have characteristics similar to the contrast agents used for CT scan examinations. Newer contrast agents are liver targeted. The three different types of contrast agents are nonspecific gadolinium chelates, reticuloendothelial system specific agents, and hepatocellular-specific agents.

Nonspecific gadolinium chelates are the contrast agents routinely used in liver MRI examination. They are nonspecific extracellular

gadolinium chelates. It is a paramagnetic substance, which causes increased signal in tissue on the post injection T1-weighted images. The agent initially distributes in the intravascular compartment, and then diffuses into the extracellular space. This enables the characterization of the tumor vascularity. It is safe, relatively low cost, and has good patient tolerance.

Iron oxide particles are taken up into the reticuloendothelial system (RES). In the liver, they are taken up by the Kupffer cells. Reticuloendothelial system specific agents (superparamagentic iron oxide particles) are administered as a slow infusion over 30 minutes. The most common side effects are hypotension and lumbar pain. Most focal liver lesions lack Kupffer cells. The normal liver will appear dark on T2-weighted images due to the normal uptake of the particles—thereby increasing sensitivity for the detection of focal liver lesions (Fig. 4.13). The lesions cannot be characterized as benign or malignant (56). Newer agents with ultra small iron oxide particles also offer dynamic imaging as they are taken up more quickly into the Kupffer cells. They offer the possibility of characterization of lesions, as lesions containing Kupffer cells will take up the contrast agent (57).

Hepatocellular-specific agents, including newer agents such as mangafodipir trisodium, are administered by slow infusion, accumulate in hepatocytes, and are excreted by the biliary system. This causes an enhancement of the liver parenchyma, but not of masses of nonhepatocytic origin. This may lead to greater detection of lesions. This has been shown to be most useful when assessing patients with liver metastases to determine if they are viable surgical candidates. It does not, however, help to characterize the lesion as benign or malignant. As HCCs contain hepatocytes; these agents are not useful for the detection of HCC. It has also been postulated for use to evaluate the biliary system, such as for the detection of biliary leaks (58,59,60,61).



• **Figure 4.13** T2-weighted axial image through the liver shows a left lobe hemangioma in a patient who has received ferridex. Note the low signal intensity of the liver.

Combinations of perfusion and hepatocellular agents combine the properties of a conventional extracellular contrast agent with those of a liver specific contrast agent: Examples of these agents are gadobenate dimeglumine (Multihance Bracco Diagnostics, Princeton, New Jersey) and gadoxetic acid disodium (Eovist Schering, Berlin, Germany). They are initially distributed in the vascular interstitial compartment like the normal extracellular gadolinium chelate contrast agents, and then a percentage is taken up into the hepatocytes in a delayed fashion. Therefore, they can offer both dynamic characterization and the opportunity for increased liver lesion detection (62,63,64).

Summary

Characterization of liver lesions with standard extracellular contrast agents remains the standard of care in the United States. In Europe, however, the use of liver specific contrast agents now offer the possibility of a one-stop test to evaluate focal liver lesions.

A dedicated liver MRI examination will require at least 30 minutes in the magnet. This involves multiple breath holds. It is a much longer examination than a CT scan of the liver. This is often stressful for elderly patients or patients with a large amount of ascites

who are unable to successfully suspend respiration for 20 to 30 seconds in a repetitive fashion for this time period. In these patients a CT examination should be considered. However for the younger patient where radiation is a concern, or where there are renal problems, MRI is the test of choice. Nearly all patients will require an intravenous injection. This is approximately 20 mL, plus a saline flush of a gadolinium based contrast material. The bore of the magnet is relatively small but most patients, unless claustrophobic, tolerate the examination. The presence of a pacemaker or ferromagnetic materials in a patient is a contraindication to performing an MRI.

Selected Clinical Problems

Nonalcoholic Fatty Liver Disease

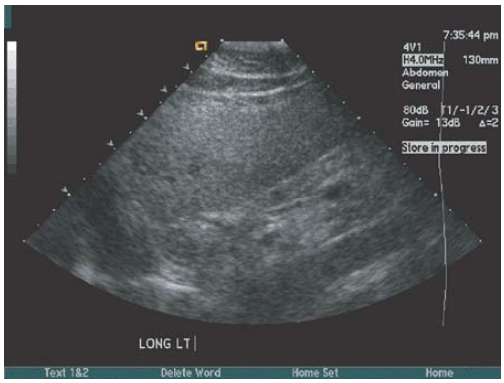
Exceeding by a wide margin the prevalence of any other liver disease, nonalcoholic fatty liver disease (NAFLD) occurs in about 20% of people in the United States. In recent years, increasing evidence has accumulated supporting the potential for NAFLD to cause progressive hepatic fibrosis with all its attendant complications (65), including HCC. A distinction has been made between steatosis alone, which appears to have a relatively benign prognosis and is the more prevalent of the two variants of NAFLD and nonalcoholic steatohepatitis (NASH), which is the variant that carries greater potential for progressive fibrosis (66,67). Thus, distinguishing between steatosis and steatohepatitis is a key component of the evaluation of patients with NAFLD.

One of the leading dilemmas faced by clinicians in evaluating patients with suspected NAFLD is the role of liver biopsy. A consensus that liver biopsy is required for all patients with this disorder would lead to a marked increase in the number of biopsies and would possibly be unrealistic in terms of the available resources. Imaging has the potential to play a critical role in the management of such patients. Among the leading questions are the following: (i) What is the sensitivity and specificity of imaging in the diagnosis of NAFLD in patients with elevated liver enzymes who have no evidence of other liver diseases? (ii) Can imaging be used to distinguish steatosis from steatohepatitis? (iii) To the extent that imaging has a role, which imaging modality is most useful? (iv) Can imaging be used to follow patient response to therapeutic interventions? These questions will be considered in the discussion that follows.

Detection of fatty liver by imaging

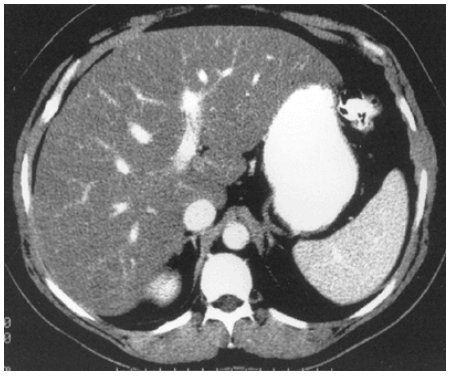
On ultrasound, fatty liver can be recognized by several characteristics, including increased parenchymal echogenicity, or a bright echo pattern which accentuates a normally inconspicuous difference between the liver and the renal cortex or the spleen (Fig. 4.14) (68); increased attenuation of the ultrasound beam, causing posterior darkness and loss of definition of the diaphragm; and loss of intrahepatic architectural detail producing loss of definition of the portal veins (68). The loss of portal vein definition occurs because the fat normally surrounding the portal veins, which usually offsets the veins from the parenchyma, now has the same echogenicity as the liver. The increased echogenicity caused by fibrosis has led to the term “fibrofatty pattern” (69). The nonspecificity of this pattern in distinguishing fibrosis from fat is one of the limiting features in the use of ultrasound for fatty liver disease. Furthermore, increased hepatic echogenicity is not specific for hepatic steatosis and may be seen in other diffuse liver diseases. Attempts to grade the severity of steatosis using

ultrasound criteria are limited by the generally broad categories described, and by the operator dependency of the technique and differences due to ultrasound settings used (69,70).



• **Figure 4.14** Fatty liver. Ultrasound image shows an echogenic, attenuating liver.

The accuracy of CT scan in detecting fatty liver is greatest with noncontrast studies. Contrast-enhanced CT scan is less accurate for the diagnosis of hepatic fat deposition because of the varying densities of the liver and spleen on these images, and the interference of the contrast with fat detection (71). In contrast to sound waves, fatty liver results in the *decreased* attenuation of x-rays, resulting in a darker appearance than normal and, in a reversal of the usual pattern, a liver which is darker than spleen. Fatty liver is diagnosed on CT scan if the liver attenuation is less than 40 Hounsfield units or a relative attenuation of 10 Hounsfield units less than the spleen (Fig. 4.15). The spleen is used as the reference organ as it does not accumulate fat (72,73).



• **Figure 4.15** Fatty liver. Computed tomographic scan shows diffuse low attenuation to the liver consistent with fatty infiltration.

Other diffuse liver diseases, including acute hepatitis, may also cause decreased hepatic attenuation. There is a relationship between the degree of hepatic steatosis and CT scan density but, as for sonography, a reliable distinction of steatosis from steatohepatitis cannot be made with CT scan, nor can the degree of fibrosis be reliably assessed (68,74,75). Although the radiation exposure with CT scan places practical limits on the widespread use of serial assessments for hepatic steatosis with this technique, some studies have used serial CT scan for assessing the response of hepatic steatosis to therapy (76).

MRI quantifies the fat content of the liver by chemical shift imaging, which takes advantage of the difference in resonant frequencies between protons in a fat and water environment. A recent study has described the successful quantitation of hepatic fat morphology and the severity of steatosis with MRI (77). Chemical shift imaging is not confounded by the presence of hepatic fibrosis (77). The liver is imaged on a T1-weighted gradient dual echo sequence using both "in-phase" and "out-of-phase" images. In steatosis there is a decrease in the MR signal intensity on the "out-of-phase" images. Comparison is performed with the spleen, which does not usually accumulate fat. However, the spleen can accumulate iron, which will cause the signal intensity to decrease. In this situation, the skeletal muscle or the kidney may provide a more accurate comparison for the assessment of changes in hepatic signal intensity.

Magnetic resonance spectroscopy (MRS) allows the quantitation of hepatic fat that can be used for serial estimations without the radiation exposure of CT scan. Studies in patients with both alcoholic and nonalcoholic fatty liver disease have reported accurate measurements of hepatic fat deposition with this technique (78,79).

Performance characteristics of imaging modalities

In a recent analysis of the literature, the sensitivity of ultrasound for recognizing fat in the liver ranged from 60% to 89%, and the specificity was 84% to 95%. The positive predictive value for an ultrasound suggesting fatty liver was 96%, while an ultrasound not demonstrating fatty liver was associated with a 19% chance of fatty liver being present (68). The ultrasound criteria for the determination of fatty liver has varied in these published studies with some requiring only increased hepatic echogenicity (without comparison with the echogenicity of other organs) for diagnosis. More strict criteria for the ultrasound diagnosis of steatosis and more severe degrees of steatosis result in improved performance characteristics (70,80). A study of 187 morbidly obese patients compared ultrasonography with liver histopathology from liver biopsies done at the time of bariatric surgery. In this patient population, the sensitivity, specificity, and positive predictive value for ultrasound in detecting hepatic steatosis was 49%, 75%, and 95%, respectively (81).

On CT scan there is a good inverse correlation between the degree of steatosis and CT scan density scores (68). In a series of 25 consecutive patients with biopsy-proven steatosis undergoing sonography, CT scan and MRI, the presence of greater than 33% fat on liver biopsy was optimal for detecting steatosis on radiological imaging (82). Ultrasound and CT scan were 100% and 93% sensitive in detecting greater than 33% fat, with positive predictive values of 62% and 76% respectively. The degree of intraobserver and interobserver

agreement was best for MRI, but none of the modalities were able to distinguish steatosis from steatohepatitis, leading to the authors' conclusion that liver biopsy remains the "gold standard."

In a direct comparison of MRI with ultrasound, MRI was more sensitive than ultrasound in detecting relatively small degrees of steatosis, and correlated better with microscopic fat content. MRI correlated better with macrovesicular steatosis than mixed macrovesicular and microvesicular steatosis. Unlike ultrasound, with which several patients with severe fibrosis were misinterpreted to have severe steatosis despite low levels of hepatic fat content on biopsy, MRI was not influenced by the presence of fibrosis (77).

A combination of proton ^{1}H MRS and total body MRI was studied in 11 subjects with biopsy-proven hepatic steatosis and in 23 healthy volunteers (83). Intrahepatocellular lipid signals were detectable in all subjects but were significantly greater in hepatic steatosis than in healthy volunteers, and were greater in overweight than in lean subjects. In addition to the relationship between hepatic fat content and total

body fat as a percentage of body weight, the strongest correlation was between central obesity and hepatic fat content. The authors proposed that a combination of their technique with ^{31}P MRS, which reflects cell membrane turnover and fibrosis, might in the future help resolve the current limitations of noninvasive imaging modalities in distinguishing steatosis from steatohepatitis with fibrosis (83).

Role of imaging in practice

Hepatic imaging has a limited but useful role in the evaluation of patients with unexplained liver enzyme abnormalities. If the history and serologic tests are negative for evidence of alcohol, hepatotoxic drugs, toxins or viral, genetic, and autoimmune liver diseases, an ultrasound revealing an echogenic liver or other characteristics of fatty liver disease strongly implies NAFLD or NASH—particularly if there is no clinical, physical, or laboratory evidence of advanced fibrosis, which may confound the interpretation of ultrasound for steatosis. At that point, the decision as to how to proceed depends upon the therapeutic options perceived to be available. If the liver enzyme abnormalities are mild and without evidence of hepatic functional compromise, the patient appears well, and there are noninvasive avenues available for intervention (e.g., overweight status, modest alcohol consumption, or hyperlipidemia) it is reasonable to address these issues for a period of time and observe the effect on the liver tests. If there are worrisome clinical or laboratory features, or if noninvasive approaches have been exhausted, a liver biopsy to distinguish steatosis from steatohepatitis is appropriate.

Since all imaging modalities are limited by the inability to distinguish steatosis from steatohepatitis, the threshold for proceeding to biopsy will vary among clinicians and their therapeutic approach to patients with fatty liver disease, especially steatohepatitis. For example, the frequency of liver biopsy to assess for NASH is likely to depend substantially upon the evolving evidence that specific treatments for steatohepatitis, for example, insulin-sensitizing drugs, are effective, and whether in the next several years such agents will continue to be investigational, or are officially approved for such use. With the increased understanding of the pathophysiology of fatty liver disease, it is highly likely that additional new treatments will be developed, leading to a greater reliance upon liver biopsy when there are clinical and/or radiologic findings suggesting hepatic steatosis. On the other hand, it is hoped that there will be progress in combining imaging with serum markers, such as fibrosis assays, that will help make the distinction between steatosis and steatohepatitis, a trend that would further entrench imaging in a central role in the evaluation of these patients.

If a patient with unexplained liver test abnormalities has no evidence of steatosis on ultrasound, there is still a potential role for liver biopsy, since the positive predictive value of steatosis on sonography is greater than the negative predictive value. However, negative imaging in the setting of unexplained liver disease increases the suspicion for other liver diseases, and may therefore provide an additional impetus for liver biopsy. With further research and experience MRI, possibly in association with MRS as suggested in the preceding text, may play an increasing role given its capacity to detect smaller amounts of hepatic fat than ultrasound.

Impact of fatty liver on accuracy of hepatic imaging

It is now widely accepted that patients with cirrhosis from a variety of causes, including hepatitis B, hepatitis C, hemochromatosis, alcoholic liver disease, nonalcoholic fatty liver disease, α_1-antitrypsin deficiency, primary biliary cirrhosis, and others, should undergo noninvasive hepatic imaging periodically to screen for evidence of early HCC. Although data from prospective controlled trials are limited, there is near unanimity among hepatologists and surgeons that early detection does favorably impact upon prognosis. Indeed, the presence of HCC increases the Model for End-Stage Liver Disease (MELD) score substantially, propelling the patient forward on the transplant waiting list.

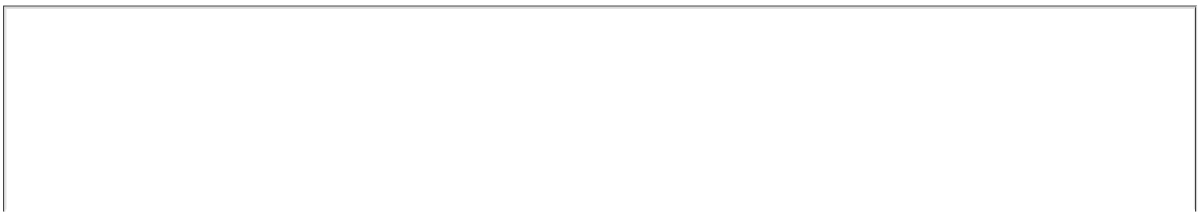
From a cost-effective viewpoint, ultrasound is generally used as the most common hepatic imaging modality for HCC screening, and is combined with periodic determination of serum α-fetoprotein level. However, as is discussed in a separate section, ultrasound is not as sensitive as MRI with gadolinium or CT scan with intravenous contrast, raising the question of when one of the other modalities should be used. The situation in which ultrasound suffers the greatest decrement in relative sensitivity is in patients with fatty liver or in obese patients. Accordingly, some clinicians resort to MRI or CT scan for HCC screening in such patients. It is a matter of clinical judgement how frequently one of the alternative techniques should be obtained relative to ultrasound. When cost is not an issue, an argument can be made for exclusive reliance upon CT scan and/or MRI, bypassing ultrasound completely, particularly when the radiologist explicitly points out in an ultrasound report that sonographic visualization of the liver was limited. Another approach, when the ultrasound images are satisfactory but suboptimal, is to alternate CT scan or MRI with sonography such that one or the other is done every 6 months on a rotating basis. At present, however, periodic ultrasound remains an accepted standard. When the other imaging modalities are incorporated into a surveillance program, an

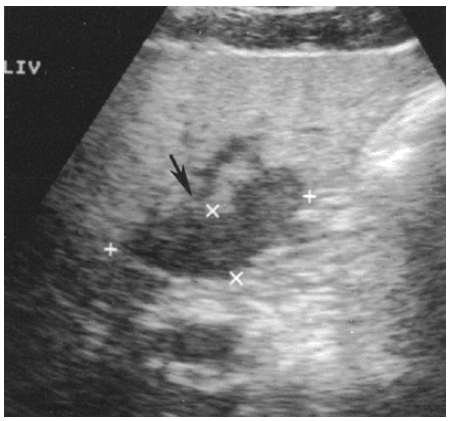
MRI has the advantage over CT of avoiding repeating doses of ionizing radiation over what may prove to be a long period of time.

Focal fat sparing and focal fat infiltration

Although hepatic fat deposition often occurs fairly uniformly throughout the liver, focal fat deposition or focal sparing of an otherwise fatty liver are not uncommon, and result from aberrant blood supply. These conditions may cause diagnostic confusion by raising the possibility of a focal neoplastic lesion. Focal fat sparing is thought to occur because of gastric venous or other aberrant blood flow into the affected area, instead of blood flow from the portal system, with its lipid-rich blood supply. Common areas affected by focal fat sparing include the medial segment of the left lobe of the liver, adjacent to the gallbladder fossa, and the porta hepatis. These areas appear hypoechoic on ultrasound and hyperdense on CT scan in comparison with the rest of the fat infiltrated liver (Fig. 4.16).

Focal fatty infiltration occurs as a result of excess triglyceride deposition. These areas appear hyperechoic on ultrasound and hypodense on CT scan (Fig. 4.17). Common locations for focal hepatic steatosis include liver tissue adjacent to the falciform ligament, gallbladder or liver capsule, and the medial segment of the left lobe of the liver. In some instances, an area of increased fat deposition in an underlying fatty liver may also give the appearance of a focal lesion. Focal fat deposition is sometimes multifocal, mimicking metastatic disease. Chemical shift MRI using T1-weighted gradient echo sequences is useful in this situation (84).





• **Figure 4.16** Focal fatty sparing. Ultrasound image shows hypoechoic apparent mass (*arrow*) in a patient with hyperechoic fatty liver. Subsequent magnetic resonance imaging confirmed the presence of focal sparing from fatty liver.

• **Figure 4.17** Focal fatty liver. Ultrasound scan shows a focal echogenic mass (*arrow*) confirmed with magnetic resonance imaging to represent focal fatty liver.

Areas with either focal fatty sparing or deposition occur in typical locations, have sharply demarcated boundaries, angular margins, and do not exhibit a mass effect or vascular involvement, allowing differentiation from neoplastic and other lesions.

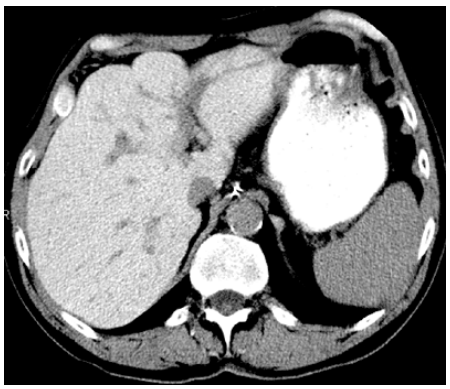
Imaging for Hepatic Iron Overload

Determination of hepatic iron status is important for the diagnosis of iron overload, to help decision making on whether treatment is needed, and to help determine response to therapy. The gold standard for hepatic iron determination is a liver biopsy, which can quantify the amount of iron in the liver. However, this test has limitations, including its invasive nature with the risk of significant complications. Variability in measured hepatic iron from small liver biopsy tissue samples, and in patients with cirrhosis, may also limit the usefulness of information gathered from this test. Therefore, noninvasive methods to assess hepatic iron are needed. CT scan has been investigated, but the most promising imaging techniques are MRI and magnetic susceptibility measurements.

Computed tomography

On CT scan, hepatic iron deposition results in an increase in liver density, usually measuring between 70 and 130 Hounsfield units (85). This appearance of the liver is a consequence of increased x-ray density due to greater density of iron compared with normal liver tissue (Fig. 4.18). However, a normal attenuation does not exclude hepatic iron overload. CT scan will

generally not demonstrate an attenuation difference until there is five times more than the normal iron contrast.



• **Figure 4.18** Hemochromatosis. Nonenhanced computed tomography demonstrates diffuse hyperattenuation of the liver parenchyma secondary to increased iron stores within the liver.

Guyader et al. compared 46 patients with hemochromatosis with 32 patients with chronic liver disease, and 22 controls using hepatic iron quantification as the reference method. Despite a high specificity (96%), the measurement of hepatic density on CT scan had a low sensitivity (63%) (86). In this study, CT scan did not detect iron overload in 14 of 18 patients with low and moderate hepatic iron overload (liver iron concentration <150 μmol/g dry liver weight). Steatosis also affected liver attenuation in this study. Others have also shown that steatosis and hepatic fibrosis affect the sensitivity of iron detection by CT scan (87,88). Moreover, an increase in hepatic density on CT scan is a nonspecific finding and is also seen in other conditions, including gold or thorotrast deposition (89,90), type IV glycogen storage disease (91), Wilson disease (92), and with certain medications including amiodarone (93).

Magnetic resonance imaging

MRI has been shown to be a more sensitive test for the detection of hepatic iron overload than CT scan (86,94,95). MRI takes advantage of the paramagnetic effect of iron to indirectly assess iron accumulation. The paramagnetic effect of iron has a T2-shortening effect, which causes a decrease in signal intensity on T1- or T2-weighted images. As a result, the liver appears darker than the spleen and other parenchymal organs on T2-weighted images (Fig. 4.19).

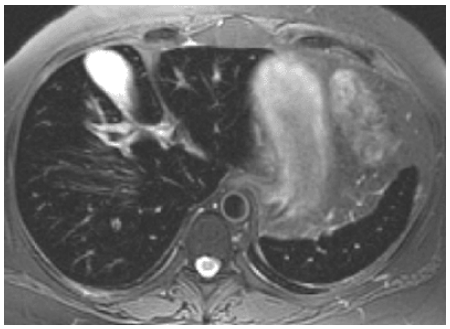
In efforts to optimize the accuracy of the assessment of hepatic iron, investigators have studied MRI performance specifications including the use of T2-weighted images, MRI magnet strength, the standard with which to compare hepatic signal intensity, and gradient recalled echo (GRE) versus spin-echo (SE) sequences. Higher strength magnets (1.5 T) provide more accurate hepatic iron assessments, particularly for lower levels of iron overload (94,96,97,98). Standard MRI utilizes SE sequences which are sensitive but not specific for distinguishing mild from severe iron deposition (99). GRE sequences are more sensitive to the inhomogenities induced by the paramagnetic effects of iron (100), and therefore provide more accurate estimations, particularly for low levels of hepatic iron.

• **Figure 4.19** Hemochromatosis. T2-weighted magnetic resonance image demonstrating decreased signal intensity of the liver in comparison to the spleen secondary to increased tissue iron content.

Hepatic signal intensity is compared with other tissue standards to calculate signal intensity ratios used to make hepatic iron determinations. The normal liver signal intensity lies between that of the higher signal spleen and the lower signal muscle. When there is iron overload, the liver signal intensity becomes as low or lower than that of muscle. Conflicting results have reported optimal signal intensity ratios comparing the liver with paraspinous muscle (95,101,102), fat (100), the spleen (86), and background noise (97). Studies with 1.5-T MRI using liver to muscle signal intensity ratios have reported sensitivity and specificity rates of 89% to 100% and 74% to 80%, respectively, for hepatic iron detection (103,104).

MRI has been reported to be capable of differentiating hepatic parenchymal iron overload seen with primary or hereditary hemochromatosis from reticuloendothelial iron overload seen with secondary hemochromatosis (105). Parenchymal iron deposition results in low signal intensity on T2-weighted SE or GRE images. In patients with hemochromatosis with pancreatic and hepatic parenchymal iron deposition, there was a decrease in signal intensity in the

pancreas, compared with the skeletal muscle standard. In contrast, patients with secondary, reticuloendothelial system iron overload, there is a tendency toward decreased splenic, but not hepatic or pancreatic, signal intensity (Fig. 4.20). Rocchi et al. found that genetic hemochromatosis was associated with a dark appearing liver on T2 MRI images, while in patients with secondary or transfusional iron overload, the spleen and bone marrow also appear black, reflecting iron deposition in these organs as well (94). In patients with advanced iron overload, however, it is usually difficult to determine whether the etiology is primary or secondary iron overload.



• **Figure 4.20** Posttransfusion hemosiderosis. T2-weighted fast spin-echo magnetic resonance image demonstrates diffusely decreased

signal intensity of the liver and spleen secondary to increased iron content of tissue.

Olynyk et al. reported the use of MRI to assess the degree of fibrosis in patients with hemochromatosis (106). They initially evaluated the use of hepatic iron concentration (HIC) to predict the presence of low grade versus high grade fibrosis, and reported a sensitivity of 100% and a specificity of 67%. Using the product of the HIC and the patient's age, which allowed an estimation of the duration of hepatic iron exposure, resulted in higher specificity (86%) rates. Further studies are necessary to confirm this method.

MRI has several advantages over liver biopsy, including the noninvasive nature of the test, which is especially important in patients with bleeding disorders or decompensated liver disease. In these patients a liver biopsy may be contraindicated, while MRI has the ability to evaluate other organs that may be affected by iron deposition, include the pancreas and the heart (107), as well as capacity to perform serial evaluations and to simultaneously screen for HCC.

MRI can be used as a screening test to exclude iron overload in patients with low or moderate suspicion. Performance of an MRI is difficult in patients with claustrophobia, and the test is limited by the inability to provide information on hepatic histology, including the degree of hepatic fibrosis.

Quantification of iron and assessment of response to therapy

In addition to the detection of iron overload in the liver, the estimation of the degree of iron accumulation has practical implications. Quantification of hepatic iron content provides information about the degree of iron accumulation and can be used to follow response to therapy with either phlebotomy or chelating agents. Serial liver biopsies are not practical because of safety concerns and the risk of complications, but serial MRI images can be helpful.

A number of studies have reported accurate noninvasive quantification of hepatic iron using MRI (97,108). The logarithm of signal intensity and the transverse relaxation rate of images acquired using both gradient echo and SE techniques have a linear correlation with liver biopsies (97). There are limitations of hepatic iron quantification, including a lack of standardization between MRI machines and variations according to specific MRI technique. The presence of hepatic fibrosis and steatosis may affect the accuracy of MRI assessments of hepatic iron. While some investigators have reported that the presence of cirrhosis or steatosis do not significantly affect iron quanitification by MRI (100,103), others have come to different conclusions (109). The test may also be less accurate at extremes of hepatic iron deposition. Gandon et al. reported accurate hepatic iron estimations in the range of 80 to 300 μmol/g. Quantification of iron levels greater than 300 μmol/g was not possible because of very low liver signal intensities (100).

Serial MRI may also be useful in assessing the response to therapy for iron overload. A number of investigators have shown an increase in hepatic signal intensity in response to both phlebotomy (110) and chelation therapy (94,111). Jensen studied 11 nonthalassemic patients with transfusional iron overload who underwent chelation therapy with desferrioxamine (112). Hepatic iron quantification (39 to 626 μmol iron/g) was done using MRI 1.5 T, SE images, and signal intensity ratios between liver tissue and skeletal muscle. MRI hepatic iron quantification appeared to be a more accurate estimation of response to chelation therapy than monitoring serum ferritin levels.

Magnetic susceptibility measurement

A recently described technique is superconducting quantum interference device (SQUID) biomagnetic liver suseptometry testing which takes advantages of the paramagnetic properties of ferritin and hemosiderin, the major storage forms of iron, to

determine tissue iron concentrations. The magnetic susceptibility is determined by the strength and direction of the magnetic response of a tissue when a constant magnetic field is applied. Normal human tissue evokes a very weak magnetic response that is opposite to the applied field. Hepatic tissue with iron overload produces a response in the same direction as the applied magnetic field, and the strength of the response is proportional to the iron concentration in the tissue (113). Hepatic iron estimations by this method have been shown to closely correlate with tissue iron estimations by liver biopsy (114). A number of studies have used SQUID to assess the response to chelation therapy with deferiprone and desferoxamine in patients with β-thalassemia (115,116). The widespread use of SQUID is limited by the cost and limited availability of the equipment for the test. Only a few susceptometers were in clinical use, as of 2005.

Other noninvasive tools for assessing hepatic iron content have been described. One technique that utilizes a modification of MRI, measuring tissue proton transverse relaxation rates, and allowing liver iron concentration measurements (117). Advantages of this technique are avoidance of motion induced artifact in hepatic iron assessment with T2-weighted images (118).

Magnetic resonance imaging for iron overload: conclusion

Although liver biopsy remains the "gold standard" for the diagnosis of hepatic iron overload and the assessment of hepatic fibrosis, there are several clinical scenarios in which MRI can be useful, including the following: (i) Patients without the genotype for hereditary hemochromatosis (HHC) in whom there is nevertheless a suggestion on laboratory testing of possible excessive iron stores, making it desirable to exclude iron overload. For example, patients with chronic hepatitis C or fatty liver disease often have elevated ferritin levels, but may have mild or no secondary iron overload and therefore, do not require iron depletion therapy; (ii) patients with the genotype for HHC, that is, homozygosity for the C282Y gene but are unlikely to have advanced fibrosis, such as patients under 40 years of age with ferritin less than 1,000 ng/mL; (iii) patients with the genotype for HHC and cirrhosis in whom liver biopsy is risky because of coagulopathy, and in whom an MRI can confirm the presence of iron overload.

Hepatic Venous Thrombosis

Hepatic venous thrombosis (HVT) is characterized by hepatic venous outflow obstruction at the level of the inferior vena cava (IVC), hepatic veins, and/or the small centrilobular venules (veno-occlusive disease [VOD]). HVT occurs as a consequence of a variety of congenital and acquired hypercoagulable states including myeloproliferative disorders, paroxysmal nocturnal hemoglobinuria, antiphospholipid syndrome, use of oral contraceptives, and deficiencies of protein C, protein S, and antithrombin III. Other associated conditions include inferior vena caval membranous webs (seen more commonly in Asia), inflammatory bowel disease, and trauma; it is estimated that up to 60% of cases are idiopathic. The condition may have fulminant, acute, subacute, or chronic presentations and should be suspected in patients presenting with ascites, abdominal pain, and hepatomegaly.

The diagnosis of VOD is difficult based on radiological imaging alone, and often requires a liver biopsy. This discussion will focus on the diagnosis of thrombosis of the IVC and hepatic veins. Imaging may demonstrate the obstruction of hepatic venous or IVC blood flow. Furthermore, changes in the liver parenchyma occurring as a consequence of HVT may also be seen. Other findings include caudate lobe hypertrophy (which has independent venous drainage), ascites, and splenomegaly.

Ultrasonography

Ultrasonography with color Doppler imaging is an excellent first-line imaging technique for the diagnosis of hepatic vein thrombosis. Characteristic findings of hepatic vein thrombosis on ultrasound include absence, reversal, or turbulence of flow in a large hepatic vein; large intrahepatic or subcapsular collateral vessels; a "spider-web" appearance near the hepatic vein ostia without a normal appearing hepatic vein in the vicinity; and an absent or flat hepatic vein waveform (119,120). The presence of collateral vessels is more sensitive than alterations in hepatic venous flow, which may be seen in association with cirrhosis from other causes as well. Membranous webs may appear as an echogenic obstruction on ultrasound (121).

Doppler ultrasonography provides useful information on the flow direction and pattern through the hepatic veins and IVC. With HVT, blood flow may be noted to be absent, slowed, reversed, turbulent, or without pulsatility. Intrahepatic or subcapsular collateral vessels with hepatofugal flow (away from the liver), is a sensitive finding for HVT. The sensitivity of Doppler ultrasonography has been reported to be greater than 85% (120,122).

Changes in the liver parenchyma occurring as a consequence of venous outflow obstruction may be seen, although these findings are less specific. These changes include hypoechoic areas representing hemorrhagic infarcts in patients with acute forms of the disease, and increased echogenicity in patients with

chronic HVT who have developed cirrhosis. The caudate lobe may appear enlarged; however, this may also be seen in patients with cirrhosis from other causes. The reported accuracy of ultrasound imaging for the diagnosis of HVT is 70% (119). Ultrasound is inexpensive and widely available, but is operator dependent and its usefulness is limited in obese patients.

Computed tomography

CT scan is helpful for the evaluation of parenchymal abnormalities, caudate lobe enlargement, and the presence of collateral vessels (119). The peripheral atrophic liver parenchyma may demonstrate more enhancement than normal or hypertrophied liver. On dual-phase CT scan, the central liver initially appears hyperdense and then in the washout phase, appears hypodense in comparison with the peripheral liver tissue, which gradually accumulates contrast via subcapsular collaterals (Figs. 4.21 and 4.22). This appearance has been described as a "flip flop" pattern. The presence of portal hypertension may cause delayed enhancement of hepatic veins. As a result, unopacified hepatic veins may be confused with HVT (123). This results in a decreased accuracy of CT scan for the diagnosis of HVT which has been reported to be as low as 50% in some studies (119).

Magnetic resonance imaging

Advantages of MRI include superior visualization of the IVC and hepatic veins, as well as the liver parenchyma. Furthermore, MRI may allow differentiation between the acute and chronic forms of the disease. Differences in signal intensity between the peripheral and central areas of the liver and differences in enhancement patterns have been described in patients with acute versus chronic HVT. In acute HVT, peripheral hepatic signal intensity in T1- and T2-weighted images is lower and higher, respectively, than the central liver (124,125). In contrast, the differences in signal intensity are less pronounced in patients with chronic HVT. Similarly, gadolinium-enhanced images demonstrate diminished peripheral enhancement in acute HVT but minimal differences in enhancement in patients with chronic HVT. The caudate lobe may be spared the effects of the disease in the early stages of the process due to its independent venous drainage, and may therefore have a normal or increased enhancement. Patients with acute on chronic and subacute presentations have MRI findings in between the extremes just described. In chronic HVT, nodular regenerative hyperplasia may develop, appearing as large nodules with increased signal intensity on T1-weighted images. Other findings in chronic HVT include intrahepatic collateral vessels which appear as "comma-shaped" structures (126) and a "spider-web" appearance of collateral vessels (124). Accuracy rates of 80% have been reported for detection of HVT by MRI. (119)

• **Figure 4.21** Acute Budd-Chiari syndrome. Portal venous phase contrast-enhanced computed tomographic scan shows peripheral low attenuation of the liver parenchyma, sparing of the caudate lobe (in which attenuation is normal), ascites, and thrombosed hepatic veins (*arrows*).

• **Figure 4.22** Chronic Budd-Chiari syndrome with nodular regenerative hyperplasia. Portal venous phase contrast-enhanced computed tomographic scan shows multiple hyperattenuating nodules (*arrows*). Note the caval stent for treatment of prior inferior vena cava occlusion and thrombosed right hepatic vein (*arrowhead*).

Venography

Hepatic venography, performed by inferior vena caval opacification and retrograde hepatic vein cannulation via access through the femoral vein, allows the direct assessment of hepatic vein and IVC patency. Characteristic patterns on retrograde hepatic venography in patients

with HVT include a "spider-web" pattern when the catheter tip is wedged in an occluded vein, a network of collateral veins starting at the catheter tip and

ending near the entry of the hepatic vein into the IVC in patients with a partially occluded vein, and a patent hepatic vein proximal to a stricture (127,128). Venography allows the measurement of the gradient between the portal vein and the IVC to determine the feasibility of portacaval shunting. There is a greater risk of complications with hepatic venography compared to other imaging modalities given its more invasive nature.

Summary

Ultrasonography with Doppler imaging should be the first test when Budd-Chiari syndrome is suspected. An MRI should be considered next. Although CT scan allows better visualization of the hepatic parenchyma and detection of collateral vessels, its use is limited by inaccuracy when hepatic veins are not visualized, and should be considered in patients who cannot undergo MRI. Venography, now used uncommonly, should be reserved for patients in whom the diagnosis cannot be confirmed by other radiologic imaging modalities, for patients in whom transjugular intrahepatic portosystemic shunt (TIPS) placement is planned, or for patients in whom the venous anatomy needs to be defined prior to surgery.

Hepatic Cysts

Liver cysts are often found incidentally when abdominal imaging is done for other indications. Liver cysts may either be single or multiple and varied in size, and their prevalence tends to increase with age. Solitary hepatic cysts have been reported to occur in 3% to 18% of patients (129,130,131). Differences in the reported prevalence of hepatic cysts may be attributed to the population screened and the method used. Solitary cysts may be infectious, neoplastic, or traumatic in nature, or may be the result of congenital malformations. Most cysts are asymptomatic and do not require therapy. However, large cysts may cause abdominal symptoms including right upper quadrant pain, abdominal distension, bloating, and anorexia. Such large, symptomatic cysts may require drainage either by percutaneous or surgical techniques. Rarely, bleeding may occur into cysts or they may become infected.

Most hepatic cysts are benign. Neoplastic cysts include biliary cystadenomas and cystadenocarcinomas. Multiple liver cysts may be seen in patients with polycystic liver disease. With age, these cysts increase in number and size and may be associated with complications including hemorrhage, infection, rupture, biliary obstruction, portal hypertension, and malignancy (132).

Characterization of the cysts by a variety of imaging modalities allows the important differentiation between benign and neoplastic cysts.

Ultrasonography

Ultrasonography allows differentiation between cystic and solid lesions. Simple cysts in the liver appear anechoic, with a smooth round contour, and have a thin wall (Fig. 4.23). Echinococcal cysts have septations and may demonstrate cyst wall calcifications; the presence of daughter cysts on an ultrasound helps in the diagnosis of these lesions. Other cyst features that can be assessed by ultrasound include the presence or absence of septations and debris within the cyst (Fig. 4.24). Biliary cystadenomas have septae and are multilocular. Septae or nodularity within the cyst are suggestive of malignancy. Hemorrhage into a cyst may make the discrimination between simple and malignant cysts difficult.

Computed tomography

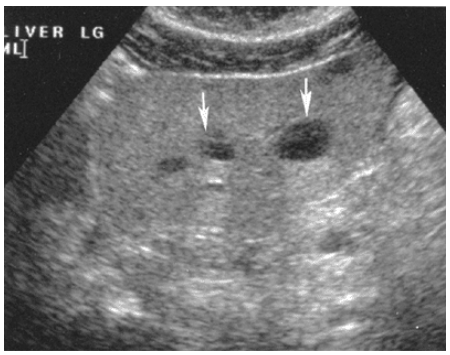
For the evaluation of hepatic cysts, CT scan should be done with and without intravenous contrast. On CT scan, hepatic cysts do not enhance after the administration of IV contrast and demonstrate water attenuation (0 to 10 Hounsfield units). Furthermore, cyst walls are usually imperceptible. CT scan is useful in providing data about the relationship between a cyst and its surrounding liver parenchyma and vascular and biliary structures.

Septae or papillary projections within a cyst are features suggestive of neoplasia. After the administration of intravenous contrast, the cyst walls, septae, and soft tissue components of biliary cystadenomas enhance.

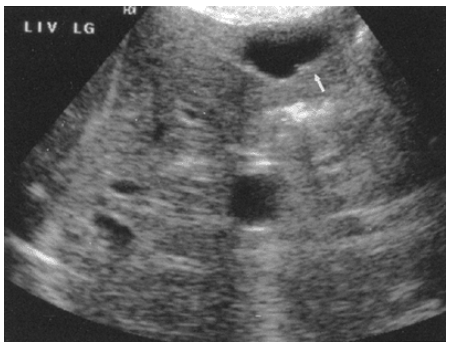
Magnetic resonance imaging

On MRI, simple hepatic cysts demonstrate the same signal intensity as water, that of a high signal intensity

on T2-weighted images and low signal intensity on T1-weighted images. They do not enhance after the administration of gadolinium (Fig. 4.25). The presence of enhancing components post gadolinium indicates a complex cyst, which may be of an infectious, inflammatory, or malignant etiology.



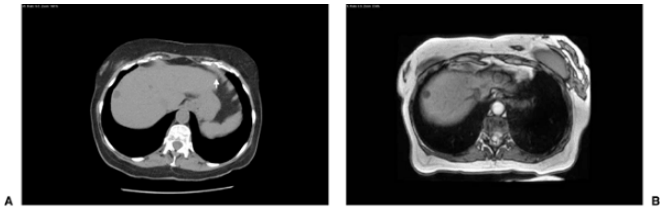
• **Figure 4.23** Liver cysts. Longitudinal ultrasound image shows two simple hepatic cysts (*arrows*) with posterior acoustic enhancement.



• **Figure 4.24** Complex hepatic cyst. Longitudinal ultrasound image shows anterior hepatic cyst with wall irregularity (*arrow*) that suggests complex hepatic cyst.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is discussed in detail in Chapter 23. The issues involving imaging in clinical practice are as follows: (i) Does MRCP suffice in the diagnosis of PSC, rendering endoscopic retrograde cholangiopancreatography (ERCP) unnecessary in certain clinical situations, and (ii) what is the role, if any, of periodic imaging, potentially combined with tumor marker surveillance, in the early detection of cholangiocarcinoma (CCA) given the substantial lifetime risk of 6% to 20% of this complication in patients with PSC (133,134).



• **Figure 4.25** Liver cysts. **A:** Computed tomographic image demonstrates a 1.4 ×1.3 cm hepatic cyst (*arrow*) in the anterior segment of the right lobe. The lesion is nonenhancing and demonstrates water attenuation. **B:** Magnetic resonance image demonstrates the same cyst (*arrow*).

Studies have shown the sensitivity and specificity of MRCP in the diagnosis of PSC to be excellent, approaching the corresponding values for ERCP. An advantage of MRCP is that it allows the visualization of all ducts, including those proximal to severe stenoses, which may not be seen on ERCP. In a study in which two radiologists independently conducted a blinded random review of MRCP in 102 patients, of whom 34 had PSC, interobserver agreement was excellent and the higher scoring radiologist detected PSC with a sensitivity of 88%, specificity 97%, positive predictive value 94%, and negative predictive value 94% (135). Consistent with these results, many clinicians including the authors have had the experience of seeing occasional patients whose MRCP studies have been read as negative in whom ERCP has revealed characteristic features of the diagnosis. This may be particularly expected in patients with early intrahepatic disease alone. Indeed, two caveats also apply to ERCP. First, the diagnosis can be missed if inadequate filling pressures are used to study the intrahepatic biliary tree, and second, some patients with early PSC may not have any findings even on a technically well done ERCP. In such patients, liver biopsy may reveal characteristic changes such as "pericholangitis" and periductal fibrosis prior to the development of large ductal changes. Thus, even ERCP does not have 100% negative predictive value for this disease.

A more common scenario is the finding of characteristic changes of PSC on MRCP studies (Fig. 4.26), at which time the clinician must decide whether to still obtain an ERCP with its attendant risks. Potential arguments in favor of this approach are that ERCP has long been the "conventional" means of ascertaining the diagnosis, that ERCP will establish the baseline biliary anatomy with the highest degree of accuracy for the purposes of future comparison, and that ERCP

will afford the opportunity for cytologic brushings in the event that dominant strictures are encountered. Since MRCP can be overwhelmingly suggestive of the diagnosis, however, the first of these arguments is not compelling. Moreover, since MRCP can delineate the anatomy well, one can argue that a high quality baseline MRCP can serve as an adequate basis for future comparison. Finally, there are no guidelines indicating that baseline brush cytologies should be obtained when PSC is first diagnosed in the absence of suspicious clinical changes, for example, worsening cholestasis, recurrent jaundice or cholangitis, or the absence of a dominant stricture. Therefore, in a stable patient with features of PSC but without recent change in clinical or biochemical status, a diagnostic MRCP is sufficient to establish the diagnosis of PSC firmly, and the patient can then be followed.

• **Figure 4.26** Primary sclerosing cholangitis. Magnetic resonance cholangiopancreatography image shows multifocal dilatation (*thin arrow*) and narrowing (*thick arrow*) of the bile ducts.

An effective screening regimen to detect cholangiocarcinoma at a treatable stage is a coveted goal in patients with PSC. At the present time, there is no such regimen of proven efficacy, and clinicians vary in their practices from no screening to schedules of periodic determination of tumor markers and/or imaging, albeit in the absence of evidence that detection will result in altered outcomes. The use of the tumor markers CA-19-9 and carcinoembryonic antigen (CEA) was supported by a study of 74 patients with PSC, of whom 15 had tumors, 22 had severe PSC necessitating transplantation with nonmalignant explants, and 37 had stable PSC. An index using the formula CA-19-9 + (CEA × 40) with a cutoff of 400 gave an accuracy of 86% in the diagnosis of cholangiocarcinoma, with 10 of the 15 cases of cancer having an increased value compared with none of a group of 22 cases with no tumor. Six of eleven patients with occult tumors had abnormal values (136). In another multicenter, case-control study, 26 patients with PSC and CCA diagnosed over a 7-year period at eight academic centers were compared with 87 patients with PSC but no CCA. Serum CA-19-9 was significantly higher in patients with CCA than in those without (mean 177 U/mL vs. 61 U/mL). A serum CA-19-9 greater than 100 U/mL had 75% sensitivity and 80% specificity in identifying patients with PSC and CCA (137).

On the other hand, a clinical benefit could not be demonstrated in a prospective study of 75 patients with PSC without clinical signs of CCA investigated every 6 months for 3 years with liver tests and four tumor markers—CEA, CA-19-9, CA 50, and CA 242. The patients were then followed clinically for another 5 years. The authors found the tumor markers to be of limited value for the detection of CCA in patients with PSC because of low specificity (138). A previous study examining explants in patients coming to liver transplantation similarly found that CA-19-9 levels were not predictive of CCA (139).

There are no prospective studies with long-term outcomes combining tumor markers with imaging studies. Of the conventional imaging studies, the one that might in theory be most suited to screening is MRI, because the liver parenchyma can be visualized with T1-weighted images, while the biliary tract can be outlined with T2-weighted images. Thus, MRI-based screening can potentially detect peripheral cholangiocarcinomas as well as masses arising from the main biliary tree, or at least document changes such as the development of dominant strictures in the biliary tract, which might require further investigation. Again, however, there are no studies indicating that imaging surveillance affects outcomes.

There has been considerable interest in PET scanning for the detection and staging of CCA, whether in PSC or otherwise. PET scanning relies upon the fact that malignant tumors have high glucose metabolic rates and accumulate (18F)-fluorodeoxyglucose (FDG), a positron-emitting tracer. In one of the first studies demonstrating promise for PET, six of six patients with known PSC and CCA had "hot spots," while nine patients with PSC and no evidence of CCA and five controls had no such spots (140). A subsequent study that suggested that PET was highly sensitive and specific in a group of 26 patients with CCA, 8 with benign biliary tract disease, and 20 controls, reinforced the implications of this study. The only significant limitation of PET in this study was greater sensitivity for distant metastases than regional lymph node metastases (141).

More recent studies have raised concerns about the sensitivity and/or specificity of PET scanning in the diagnosis of CCA. In a study of 36 patients evaluated for suspected CCA, of whom 31 ultimately proved to have the disease, sensitivity was 85% for the nodular morphology but only 18% for the infiltrating morphology. One patient with PSC and acute cholangitis had a false-positive result, while 7

of 12 patients had FDG uptake along the tract of a biliary stent (142). In another study of ten patients with PSC being evaluated for liver transplantation, eight of whom were transplanted and in whom the explants were therefore available for study, there were two false-positive and one false-negative PET scans (143). In another series of 15 patients with suspected hilar tumors, PET was true-positive in 10, false-positive in 2, and false-negative in 3 (144).

The literature on PET scanning does not directly address the issue of surveillance in patients with PSC. Most of the literature addresses the issue of sensitivity and specificity in patients with clinical features leading to the suspicion of CCA, or patients with actual CCA proven by other means in whom correlations with PET were evaluated. In these latter populations PET scanning, although promising, has insufficient accuracy to be used as a stand-alone study, particularly in surveillance, especially with the demonstrated potential for false-positive examinations. Accordingly, as for MRI there are no guidelines calling for the routine use of PET scanning in the screening or surveillance of patients with PSC for CCA. The role of PET scanning requires further study in this population.

Choledocholithiasis

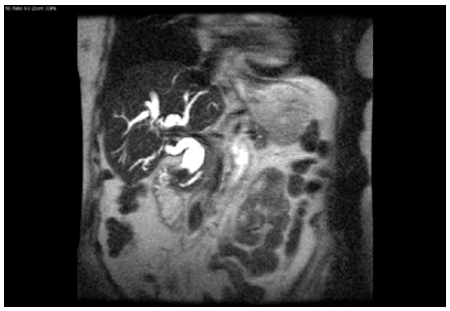
Prior to the widespread availability of MRCP and EUS, noninvasive imaging of the biliary tract centered on sonography and CT scanning. When biliary tract pathology was suspected, direct cholangiography with ERCP or percutaneous transhepatic cholangiography (PTC), with their attendant risks, was required. In the context of suspected choledocholithiasis, the frequent need to proceed to ERCP for its potential therapeutic applications was particularly problematic in the absence of a high level of confidence that the procedure would reveal the underlying pathology in question. Thus, patients were commonly exposed to the risk of ERCP, most notably acute pancreatitis, when in retrospect the procedure would not have been necessary if highly accurate noninvasive imaging were available. As a result, a large body of literature emerged addressing the issue of the proper role for ERCP in suspected, but unproven, choledocholithiasis (145,146).

CT scan can detect a substantial proportion of CBD stones, but magnetic resonance cholangiopancreatography and endoscopic ultrasound have dramatically improved upon the ability to make the diagnosis of biliary tract stones without resorting to invasive techniques (Figs. 4.27, 4.28 and 4.29). For common bile duct stones, MRCP has an overall sensitivity of 85% to 100%, with positive and negative predictive values as high as 95% (147,148,149,150,151,152). The chief limitation is in patients with small stones. False negative studies can occur if MRCP slice thickness is greater than 3 to 4 mm, or from motion artifact obscuring small stones if the patients are unable to hold their breath. Pneumobilia and blood clots may mimic small stones. Surgical clips, a tortuous common bile duct, and extraductal compression from the right hepatic or gastroduodenal artery can also cause diagnostic confusion.

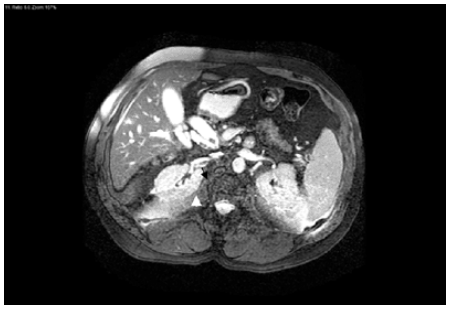
• **Figure 4.27** Choledocholithiasis. Computed tomographic image demonstrating a 5 mm stone in the distal common bile duct (*arrow*).

In addition, MRCP may not always be available within the time frame necessary for it to impact upon therapeutic decision-making, particularly since patients with bile duct stones frequently present with clinical features that require prompt resolution, such as cholangitis or severe pain. Despite these limitations, MRCP has proven to be extremely useful in patients with low or intermediate levels of probability of harboring bile duct stones, and ERCP can often be avoided as a result of negative MRCP examinations in such patients. In such situations, when the gallbladder is intact, the surgeon may proceed to cholecystectomy with a high

level of assurance that preoperative ERCP is unnecessary and that postoperative complications related to unsuspected bile duct stones are unlikely to occur. In such instances, the decision to perform intraoperative cholangiography must be individualized.



• **Figure 4.28** Choledocholithiasis. Magnetic resonance cholangiopancreatography coronal image demonstrating a 1.4 cm stone (*arrow*) in the common bile duct with proximal intrahepatic and extrahepatic biliary dilatation.

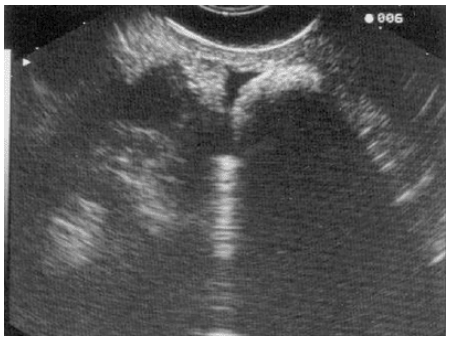


• **Figure 4.29** Choledocholithiasis. Magnetic resonance cholangiopancreatography image showing multiple stones in the common bile duct (*black arrow*) and cyst duct (*white arrow*) with intrahepatic and extrahepatic biliary ductal dilatation.

In contrast, when there is a high level of probability of choledolithiasis, such as rising cholestatic liver chemistries with a dilated bile duct, or active cholangitis, the clinician's judgement may still be that ERCP in the absence of noninvasively demonstrable bile duct stones is desirable. If a patient has presented with recurrent fever and shaking chills over the course of a few days, and has hyperbilirubinemia with a significantly elevated alanine aminotransferase (ALT) and alkaline phosphatase, even a nondilated duct on ultrasound and a negative MRCP may still be associated with the finding of small stones and/or dense sludge emerging from the bile duct after a sphincterotomy. A decision to perform sphincterotomy empirically in such situations must be individualized and based on the level of suspicion for intraductal pathology.

Endoscopic ultrasound has a level of sensitivity and specificity for common bile duct stones equaling or often exceeding that of MRCP, and easily rivaling published figures for ERCP in comparative studies (153,154,155,156) (Fig. 4.30). In one study, for example, EUS had a sensitivity of 98%, a specificity of 99%, a positive predictive value of 99%, a negative predictive value of 98%, and an accuracy of 97% (154). Its major limitation relative to ERCP is that, despite being unassociated with the significant element of risk of ERCP, particularly with regard to pancreatitis, it is still an invasive procedure requiring intravenous sedation. Moreover, the ability to offer it promptly may be limited in many centers, and the expertise to offer it concurrent with ERCP by the same endoscopist within one facility does not exist at many centers. When such expertise does exist, EUS offers a potentially powerful approach, especially in the setting of acute illness such as gallstone pancreatitis, because the diagnosis can be obtained with minimal risk and therapy offered, if appropriate, in one endoscopic session (157). Recently, intraductal ultrasound, which can also be done concurrent with ERCP, has been shown to be capable of increasing

the yield over cholangiography alone, and can also distinguish air bubbles introduced during cholangiography from true stones (150,158).



• **Figure 4.30** Choledocholithiasis. A endoscopic ultrasound image demonstrating a stone in the common bile duct with distal acoustic shadowing (*arrow*).

Ultrasound Guidance for Liver Biopsy

Liver biopsy is an essential part of the diagnostic evaluation of many parenchymal liver diseases. The determination of the degree of inflammation and fibrosis in patients with chronic hepatitis C is probably the most common indication for this procedure, but other diseases for which the procedure is frequently performed include hepatitis B, fatty liver disease, autoimmune hepatitis, cholestatic liver diseases, and the investigation of elevated liver tests. Most liver biopsies are done percutaneously via a lateral intercostal approach, although an anterior subcostal percutaneous approach to the left lobe of the liver has also been described (159).

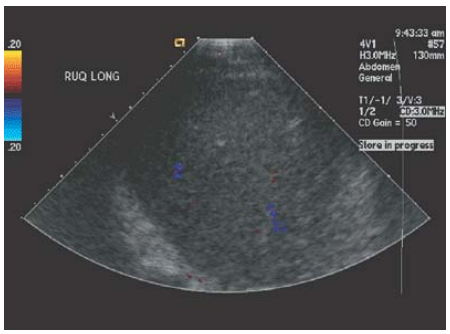
Complications associated with percutaneous liver biopsy can be divided into minor and major events. Minor complications include pain at the biopsy site or right shoulder, transient hypotension, and skin hematomas. Major complications, usually related to the inadvertent puncture of organs in close proximity to the liver, include bleeding with hemoperitoneum or hemobilia, bile peritonitis from perforation of the gallbladder, puncture of the lung resulting in hemothorax, pneumothorax or pleural effusion, and puncture

of the colon, pancreas or right kidney. Punctures of other organs do not invariably result in significant clinical problems, however. Based on a published series of thousands of liver biopsies, complication rates ranging from 0.3% to 3.2% (160,161,162) and mortality rates of 0.01% to 0.12% (161,163) have been reported.

In an effort to improve patient safety and to decrease the rate of complications, prebiopsy ultrasonography to delineate a patient's anatomy and choose the optimal site for the biopsy is widely performed. The role of routine ultrasound guidance in the performance of biopsy of a focal hepatic lesion is well established (164) but remains controversial for diffuse liver diseases with proponents both for (165,166,167,168,169,170) and against (171,172) its use. Although there are limited data supporting an improved outcome with this practice, some practitioners have incorporated ultrasound guidance so firmly into their method of performing liver biopsies that they feel that it would be unethical to do a randomized controlled trial comparing the impact of ultrasound-guided versus blind liver biopsy (169).

Bedside ultrasonography prior to percutaneous liver biopsy is used either after or in place of localization of the biopsy site by percussion. Less commonly, real-time ultrasonography is done with visualization of the liver biopsy needle throughout the procedure. Ultrasound allows the identification and avoidance of perihepatic structures including the gallbladder, right kidney, colon, and the right lung (Figs. 4.31 and 4.32). Ultrasonography also allows evaluation of large blood vessels. Riley et al. conducted a prospective study of 165 consecutive outpatient liver biopsies where the site for the biopsy was first identified using percussion, following which ultrasonography was done to evaluate the adequacy of the marked site. Ultrasonography resulted in either an alteration of the site of biopsy or aborting the procedure in 25 (15.1%) of the patients. The reasons for the change in management included the identification of lung, gallbladder, large blood vessels, colon, a greater than 4 cm rim of ascites, or a focal liver lesion in the "field" of biopsy. No complications occurred in this study (173).

• **Figure 4.31** Ultrasound image demonstrating the gallbladder and kidney in the liver biopsy field (*arrows*).



• **Figure 4.32** Ultrasound demonstrating a good window for percutaneous liver biopsy.

Image guidance may be especially useful in obese patients, those with chronic obstructive pulmonary airway disease or ascites, and in patients in whom there was failure of localization by percussion. Some centers also perform a postprocedure ultrasound with Doppler for the early identification of potential complications, especially bleeding. When this occurs, blood may be seen extending from the intrahepatic vessel to the capsule or a subcapsular hematoma. The disadvantages of ultrasonography include the extra time and cost added to the procedure. Furthermore, many gastroenterologists are not trained in ultrasonography requiring the presence of an ultrasonographer or technician for the procedure.

Studies have surveyed the practices of hepatologists in the United States, England, and France (167,168,174,175). A survey of practitioners in the Washington DC metropolitan area (168) revealed that 64% of gastroenterologists utilized image guidance for liver biopsies. All of these physicians used a radiologist to perform the ultrasound. A second survey of practices of 128 American Association for the Study of Liver Disease members revealed that although 76% of respondents were taught the blind technique of liver biopsy during fellowship training, 76% were currently using ultrasound guidance (175). Most gastroenterologists (97%) did not routinely perform a postbiopsy ultrasound. A survey of liver biopsy practices in the United Kingdom (174) found that 34% of biopsies were done with image guidance although some of the biopsies included in this study were done by radiologists for focal liver lesions. Two deaths were reported in this

series of 1,500 biopsies (intraperitoneal hemorrhage, bile peritonitis from gallbladder perforation); both occurred in patients who underwent blind biopsies. A prospective review of 2,084 liver biopsies in France reported that ultrasound guidance was used by 56% of gastroenterologists (167). In this study, complications with puncture of other viscera occurred only with blind biopsies. The American Gastroenterology Association published a "Statement on outpatient percutaneous liver biopsy" prepared by its Patient Care Committee (176). They noted that the procedure appears to be safer when performed with ultrasound guidance, but did not include ultrasound guidance in their recommendations.

There are limited data comparing ultrasound-guided with blind liver biopsies. Most of the data are retrospective in nature or have other methodological weaknesses that limit their generalizability. Caturelli et al. performed a retrospective review of 753 consecutive percutaneous liver biopsies done with ultrasound guidance (170). A retrospective control group of 702 patients who had undergone blind liver biopsies was used for comparison. A significantly higher major complication rate was noted in the historical cohort compared to the patients undergoing image-guided biopsy (2.1% vs. 0.53%, $P = 0.007$). Also, prebiopsy ultrasound increased the diagnostic yield of the procedure. Colombo et al. randomized 1,192 patients with diffuse liver disease to undergo a liver biopsy with either a Tru-Cut or a Menghini needle (169). All the patients underwent a prebiopsy ultrasonography. A low rate of multiple passes and failed procedures in this study was attributed to the routine use of image guidance. A prospective study compared patients undergoing blind liver biopsies using a Tru-Cut needle with ultrasound-guided biopsies using Automated-Needles (165). Patients undergoing guided biopsies had significantly less pain and morbidity after the procedure, than those undergoing a blind procedure. However, it is difficult to attribute this difference to the ultrasound guidance alone, given that the type of needle used was different in the two groups. Papini et al. compared the standard blind Menghini liver biopsy technique with an ultrasound-guided anterior subcostal approach to the left lobe of the liver (159). Patients undergoing the ultrasound-guided technique had fewer complications and better sample sizes. The benefits of ultrasound guidance suggested by this study are limited by the fact that the anterior subcostal approach is not commonly performed, the biopsies were done primarily by radiologists, and the biopsy technique differed in the two groups.

The single randomized controlled trial comparing blind versus guided liver biopsies was conducted by Lindor et al. who compared the use of Tru-Cut versus automatic-needle biopsy with or without the use of ultrasonography (177). Eight hundred thirty-six patients were enrolled in this study, most of whom had chronic viral hepatitis. The use of ultrasonography was found to result in significantly lower rates of hospitalization (2.2% vs. 0.5%, $P = 0.04$), and significantly less pain requiring treatment (50% vs. 37%, $P = 0.03$). Eleven patients required hospitalization for pain (seven patients) or hypotension (four patients); nine patients underwent a blind liver biopsy, and two of these had ultrasound guidance. However, there was no significant difference in the frequency of bleeding and hypotension between the two groups. Furthermore, investigators were aware of whether patients underwent ultrasonography or not, and there were no formal objectives for determining the occurrence of pain or hypotension after the procedure, raising the possibility of bias in this study. One major complication occurred in a patient who sustained a gallbladder perforation; this patient underwent a blind biopsy.

A number of studies have suggested that ultrasound guidance may result in less abdominal pain after the procedure. Proposed mechanisms for this include avoidance of the pleura and large blood vessels and bile ducts; puncture of these structures may cause pleural irritation, subcapsular bleeding, or irritation of the diaphragm by bile or blood. **A**lso, ultrasound guidance may allow the gastroenterologist to feel more comfortable with the site chosen for the biopsy, leading to less probing of the intercostals spaces and liver capsule with the biopsy needle.

Two studies have assessed the cost-effectiveness of ultrasound guidance for percutaneous liver biopsy (178,179). In a decision analysis model, ultrasonography was found to be cost-effective if the additional charge for the ultrasound was low (<$102) (178). Another study, based on the assumption that ultrasonography reduces the incidence of complications from percutaneous liver biopsy by 60%, found that ultrasound-guided liver biopsy is cost-effective.

Conclusion

There has been a strong trend toward the use of ultrasound guidance as an adjunct to the performance of percutaneous liver biopsy in patients with nonfocal liver disease. To an important extent, in the United States this has been driven by a shift in many gastroenterology practices toward the performance of the procedure by radiologists. Among hepatologists and gastroenterologists who perform the procedure, an increasing number also use ultrasound guidance for the reasons outlined in this section. Several published reports suggest that there may be less postprocedure pain and other complications when ultrasound guidance is used. However, the cumulative published experience is not sufficiently conclusive to establish a uniform standard.

The Hepatic "Incidentaloma"

The expanding use of cross-sectional imaging techniques has led to the increased detection of hepatic lesions in asymptomatic patients. This section aims to provide an over all guide of what to do with these patients and their appropriate workup. The general starting point here is that the lesion is seen on a routine ultrasound in an asymptomatic patient and the patient is then referred for further evaluation.

Clinical history and examination

The first step involves a routine clinical history and examination. The age, sex of patient, history of oral contraceptive use, occupational history, personal and family medical history should all be recorded. The clinical examination aims to identify any stigmata of liver disease or other systemic diseases. If either of the above point to an underlying disease, then evaluation will change to focus on that. The following discussion only applies to the asymptomatic patient. This discussion will use the ultrasound report as a triage point from which to guide us to the next appropriate imaging test.

The ultrasound report should indicate whether this lesion is solid or cystic. It should also indicate if this is a simple or complex cystic mass.

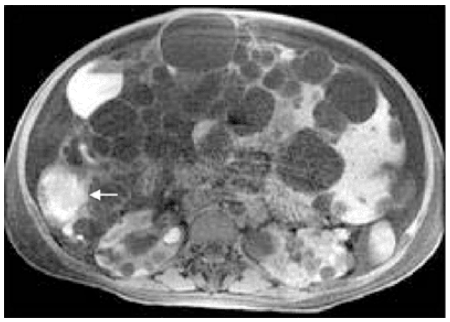
Simple cyst

If this is a solitary simple cyst then there is no need to do anything else except to reassure the patient. Criteria defining a simple cyst are discussed in the section devoted to hepatic cysts. Liver cysts occur in 2.5% of the general population. If there are multiple cysts, the next thing to consider is the age of the patient. 7% of patients over 80 years will have hepatic cysts (131). In a young patient, however, it is more unusual to have multiple cysts (Fig. 4.33). Underlying syndromes such as polycystic kidney disease or von Hippel-Lindau must be excluded.

Complicated cyst

A complicated cyst can be seen with hemorrhage, infection and malignancy. A history of foreign travel or fever points toward infection, including echinococcus. Simple hemorrhage will not show any enhancement post contrast on either CT scan or MRI. An MRI can be particularly helpful in assessing complex cystic cases as it can help to age the hemorrhage, and assess for enhancement also with the use of subtraction techniques.

The presence of solid enhancing lesions and nodular or thickened septations raises the questions of malignancy. The most common etiology would be that of metastatic disease from a cystadenocarcinoma usually from the ovary, bowel, or pancreas (Fig. 4.34). Other considerations are a bile duct adenoma or adenocarcinoma. In these cases, percutaneous biopsy of the liver lesions is recommended with ultrasound guidance.

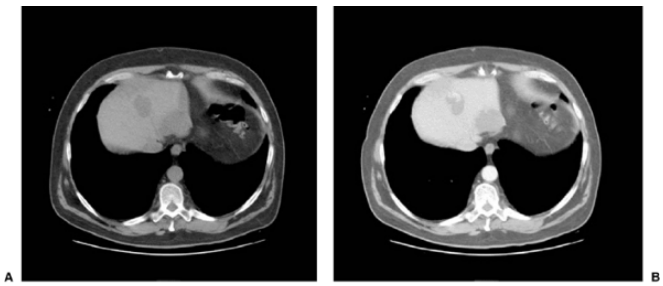


• **Figure 4.33** Axial T1-weighted image shows most of the parenchyma of the liver is replaced with cysts of varying size. The high signal in some of the cysts is secondary to either blood or protein (*arrows*).

Solid lesion

The initial guiding point here will be the description of the echogenicity of the lesion from the ultrasound report. This should determine your next imaging test. The age and sex of the patient should be considered, as the most common benign lesion in the liver is a hemangioma. We shall use this as a starting point.

• **Figure 4.34** Cystic hepatic metastatic lesion. Transverse ultrasound image shows multiple complex cysts in a patient with a history of ovarian carcinoma. The biopsy findings indicated the presence of cystic metastatic disease.



• **Figure 4.35** Hemangioma. Noncontrast **(A)** computed tomographic image showing a nonspecific hypodense lesion measuring 3.5 × 3.0 cm in size (*arrow*). Arterial **(B)** enhanced computed tomographic image demonstrates peripheral nodular enhancement characteristic for a hemangioma (*arrow*).

P.109

Hyperechoic lesion—hemangioma

In young women the most common etiology of an asymptomatic lesion would be a hemangioma. If the description is that of a homogenous hyperechoic lesion which is less than 3 cm with well-defined margins and posterior acoustic enhancement, this suggests a hemangioma (180). In the absence of any other risk factors, it has been advocated that the patient should be managed conservatively with simple follow-up in 6 months and no further follow up if the lesion is stable (181).

If further evaluation is deemed appropriate, then the most useful test to confirm this is a dedicated liver MRI. An MRI is recommended over CT scan because of the absence of radiation in this generally younger female population. Also, the sensitivity and specificity of MRI for hemangiomas has been reported as high as 90% to 98%. The classic imaging finding is that of early peripheral nodular enhancement with delayed (182) (Fig. 4.35). When contrast CT scan is used, delayed scans should be performed at 5 minutes.

Giant or atypical hemangiomas can cause problems in diagnosis as they often contain central areas of fibrosis. Giant hemangiomas are usually defined as those larger than 10 cm (183). In these cases, Tc 99m pertechnetate–labeled red blood cell scintigraphy can play a very useful role. With this method, there is decreased activity on early or perfusion images and increased activity on delayed or blood pool images. The specificity of red blood cell scintigraphy in the detection of hemangioma approaches 100% with very few false-positive results reported (184,185) (Fig. 4.36).

Limitations of this technique are that the sensitivity in the detection of hemangioma varies considerably from (65% to 90%). Larger lesions, which are 2 cm or larger can usually be seen with planar imaging. However, as lesion size decreases below 1.5 cm, they are difficult to detect. Lesions which are deep within the liver or adjacent to large vascular structures are less often identified even with single photon emission CT scan (186,187). Therefore, radionuclide scintigraphy is a valuable tool when the diagnosis cannot be achieved with other imaging modalities (188).

Percutaneous biopsy, including fine-needle aspiration biopsy, has been described as both safe and effective. It does however carry the risk of hemorrhage (189,190).

Isoechoic lesion—focal nodular hyperplasia

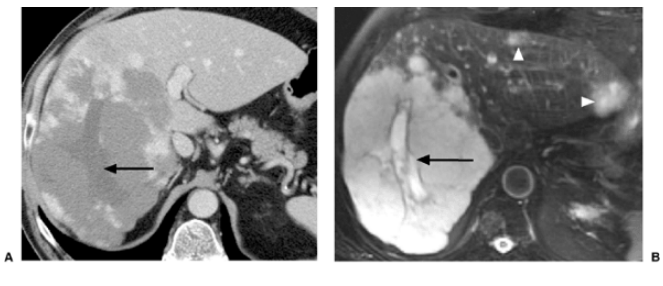
This is the second most common benign liver lesion. It is also more common in younger women aged 30 to 50. It is most often a solitary mass with a central scar (191). Although use of the oral contraceptive pill has not been shown to cause this lesion, it is thought that estrogens may influence its growth and development (192).

This diagnosis should be considered, if on ultrasound lesion's echogenicity is similar to that of the adjacent liver parencyhma. This has led to its description as the "stealth lesion." It can be very subtle and difficult to define. This differs from a hemangioma which is generally hyperechoic and easy to distinguish (193). The central scar may be seen as a central hypoechoic linear or stellate area (194).

Therefore, if a lesion is described as "isoechoic" or difficult to define, this should raise the diagnosis of focal nodular hyperplasia (FNH). The correct diagnosis of FNH is critical, as other hypervascular liver lesions such as hepatic adenoma, HCC, and hypervascular

P.110

metastases will require treatment. In particular, fibrolamellar carcinoma must be distinguished from FNH, because both are seen in young adults without prior history of cirrhosis, and because both have a central area of scar as a hallmark at imaging.



• **Figure 4.36** Giant hemangioma. **A:** Portal venous phase contrast-enhanced computed tomographic image shows typical peripheral nodular enhancement. Note the lack of enhancement, however, of the central scar (*arrow*). **B:** T2-weighted fast spin-echo magnetic resonance image shows heterogeneous high signal intensity and central scar (*arrow*). Additional smaller hemangiomas (*arrowheads*) are present in the left lobe.

It is suggested that the next test ordered should be an MRI. This will confirm the presence of a mass and also evaluate for other masses, which may have been missed at ultrasound. A preference is expressed by the authors for MRI due to the lack of radiation and the avoidance of iodine based contrast issues in this generally younger population. However, if MRI is not available, CT scan is an excellent alternative. Studies have indicated that MRI has 70% sensitivity and 98% specificity for the diagnosis of FNH (195). Other studies have indicated a

greater degree of difficulty with the diagnosis (196,197). Standard MRI criteria for a typical FNH have been described (198,199).

A classic FNH can generally be diagnosed with confidence on CT scan or MRI. Similar to a hemangioma, its appearance on imaging has been described as classic (80%) and non classic (20%). Generally, on T1-weighted images FNH is iso- or hypointense, on T2-weighted images it is slightly hyper- or isointense, and has a hyperintense central scar on T2-weighted images. It shows intense homogeneous enhancement in the early phase, and enhancement of the central scar in the later sequences (Fig. 4.37).

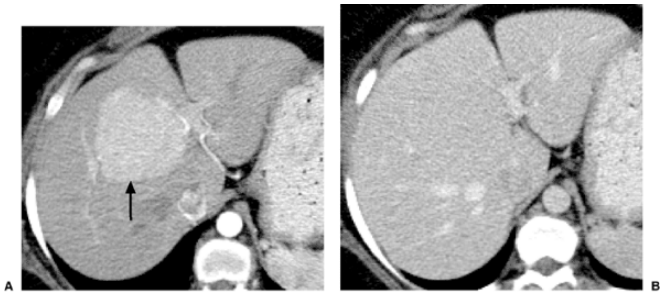
If this diagnosis is made on imaging characteristics alone, it is recommended that a single follow-up examination be performed in 6 to 12 months to document stability (200).

Twenty percent of lesions will remain indeterminate. If FNH is suspected but there are some atypical features, it is suggested that a sulfur colloid scan be performed. FNH is composed of hepatocytes, Kupffer cells, and bile ducts. The reticuloendothelial system component in the liver is the Kupffer cells, which will uptake sulfur colloid. The uptake of Tc 99m–labeled sulfur colloid in substantial quantities at scintigraphy, is highly specific for FNH (201).

Importantly, Kupffer cells are not significantly present in fibrolamellar carcinomas, so they appear on Tc 99m–labeled sulfur colloid images as photopenic defects (197,202,203). Isolated reports have shown that HCC and adenomas can show reticuloendothelial uptake on sulfur colloid scans, but usually to a lesser degree than FNH. However, the majority of adenomas are cold due to an absence of or markedly decreased Kupffer cells (204,205). Hepatobiliary scintigraphy (performed with Tc 99m dimethyl iminodiacetic acid [HIDA] or an analog) can also be useful in diagnosing FNH, as this lesion contains abnormal bile ducts and will appear as a hot spot due to the delayed clearance of the radio isotope.

Hepatocyte selective intravenous agents that are used for liver MRI are distributed in the extracellular space with renal excretion and are taken up by hepatocytes and excreted by the biliary system have shown some promising results. In these cases, the normal information from the post-contrast dynamic scans is available, then a delayed scan is performed. As FNH contains some malformed bile ducts, there is delayed excretion of the contrast agent and typical FNHs have

an iso- or hyperintense appearance relative to the surrounding normal liver, while hepatic adenomas have a hypointense appearance (206,207).



• **Figure 4.37** Focal nodular hyperplasia. Arterial **(A)** and portal venous phase **(B)** contrast-enhanced computed tomographic images demonstrate typical hyperintense, nearly homogeneous arterial phase enhancement (*arrow*) and nearly isoattenuating portal venous enhancement.

Heterogenous or nonspecific appearance—adenoma

Hepatic adenomas are rare benign tumors, and are usually the next consideration in a young female patient. These lesions are less common than FNH. Although the precise pathogenic mechanism of hepatic adenomas is still unknown, they are linked to the use of oral contraceptives, androgen steroid therapy, type I glycogen storage disease, and galactosemia. They are a solitary lesion in 70% to 80% of cases (208).

The sonographic appearance of an adenoma is nonspecific. It can be hyperechoic, hypoechoic, isoechoic, or heterogenous. However, they can be seen as a hyperechoic mass due to the high lipid content of the hepatocytes, or as a result of hemorrhage (209).

In this setting, where the ultrasound is nonspecific, an MRI or CT scan would be a suitable next choice. In most cases, an MRI will be able to exclude a typical hemangioma or FNH. In contrast to an FNH, an adenoma typically shows no central scar and subcapsular feeding arteries. An adenoma is also suggested by areas of fat or hemorrhage (Fig. 4.38). They may be complex in appearance due to repeated hemorrhage (210,211,212,213).

An adenoma is a true neoplasm, which is composed of normal or atypical hepatocytes, and generally lacking Kupffer cells and bile ducts. As noted in the preceding text, Kupffer cells are occasionally present but usually in lower numbers than in the normal liver parenchyma. Bile ducts and portal tracts are absent. Therefore, radionuclide scintigraphy is rarely helpful in the diagnosis of a hepatocellular adenoma (214).

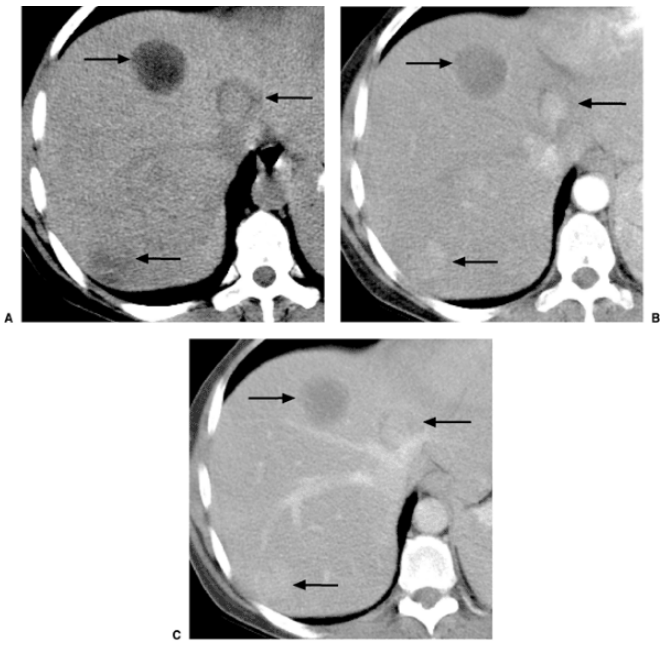
Following the guidelines outlined above, it is usually possible to distinguish an adenoma from an FNH. The other differential to consider is hypervascular metastases. The most common primary in this age group will be from a breast or thyroid primary. Metastases will usually be multiple and will be hypoattenuating or hypointense relative to the normal liver, and areas of fat and hemorrhage are rare in hypervascular metastases. When doubt remains with atypical features present, MRI with hepatocellular-specific contrast agents or nuclear medicine studies can be considered. Ultimately, in indeterminate cases the patient should be referred for an ultrasound-guided biopsy.

Screening for Hepatocellular Carcinoma

HCC is the sixth most common cancer and the third most common cause of cancer-related death worldwide, with approximately 626,000 new cases diagnosed in 2002 (215). In the United States, the incidence of HCC has been increasing with a doubling of the age-adjusted incidence between 1985 and 1998 (215a). The presence of underlying liver disease is a significant risk factor for the development of HCC. The risk is particularly high in cirrhotics, in whom the yearly incidence rate of HCC is 3% (216). Screening for HCC in this at-risk group of patients is widely practiced, and has been endorsed by two consensus conferences on the subject (217,218).

However, many basic questions about the ideal frequency and modality for HCC screening have yet

to be answered, since only one randomized trial has been done to evaluate the impact of the diagnosis of HCC, within versus outside of a screening program, on survival. Furthermore, HCC screening is affected by the patient population that is being screened including the patient race, the underlying liver disease, and the degree of existing liver injury.



• **Figure 4.38** Glycogen storage disease type 1 and multiple hepatocellular adenomas. **A:** Nonenhanced computed tomographic image demonstrates several lesions (*arrows*) containing varying amounts of fatty tissue with lower attenuation than that of the surrounding liver. **B:** Arterial phase contrast-enhanced computed tomography image shows enhancement of the posterior and medial segment adenomas (*arrows*), which are nearly isoattenuating on a portal venous phase image **(C)**.

α-Fetoprotein

Serum α-fetoprotein (AFP) has been reported as a tumor marker for HCC since 1963, but is not specific for HCC, with elevated levels seen in other conditions including chronic liver disease (especially viral hepatitis), and nonhepatic malignancies including pancreatic, gastric and biliary tumors, and germ cell tumors. In patients with HCC, AFP levels may range from normal to greater than 100,000 μg/L, and lack a linear correlation with tumor size or stage. Although AFP levels greater than 400 are highly associated with HCC, not all HCC secrete AFP and elevated levels may be seen in the absence of HCC. Performance characteristics depend on the AFP cutoff used; as the threshold for a "significant" AFP level is increased, the sensitivity of the test decreases and the specificity increases. The trend of serial AFP measurements in a particular patient over

time is perhaps equally, if not more, significant than absolute AFP level in many cases (219).

A number of cross-sectional and retrospective studies have evaluated the performance characteristics of AFP for the detection of HCC (Table 4.2). The sensitivity and specificity, respectively, have been reported for AFP levels of greater than 20 ng/mL (55% to 65%, 80% to 91%), greater than 100 ng/mL (31% to 41%, 97% to 99%), and greater than 200 ng/mL (22% to32%, 99% to 100%).

Performance characteristics of the test determined during prospective HCC screening studies are similar (Table 4.3). The largest studies screened HBsAg positive patients with AFP measurements every 6 months, and reported sensitivity rates of 55% to 64% and specificity rates of 87% to 91% (225,226).

Smaller studies have screened patients with cirrhosis on a 6-monthly basis. AFP cutoffs of 20 ng/mL resulted in sensitivity rates of 39% to 63%, and specificity rates of 76% to 94% (227,228,229,230). A higher AFP cutoff of 100 units resulted in lower sensitivity rates (13% to 41%) and higher specificity rates (93% to 97%) (227,228,230). One study reported performance characteristics of an AFP threshold of 200 with the highest specificity rate of 100% (228).

Other serum markers for HCC including des-γ-carboxy prothrombin (DCP), urinary TGFβ 1, and soluble interleukin-2 receptor have also been proposed and tested for HCC screening, but are not widely used in clinical practice (232,233,234).

Ultrasound

Ultrasound is the most widely used and studied radiologic examination for HCC screening. On ultrasonography, HCC appears as round or oval lesions with sharp, regular borders. There is no specific appearance of HCC on ultrasound and small lesions, in particular, may vary in appearance. Small lesions are often hypoechoic, but may be hyperechoic if there is fat in the lesion. HCC may be indistinguishable from regenerative nodules and, in certain instances, from hemangiomas. The addition of a Doppler examination allows the evaluation of the vascularity of the lesion; unlike regenerative nodules, HCC tends to exhibit neovascularity (a fine network of blood vessels around and extending into the lesion), although this is often difficult to visualize. The presence of a psuedocapsule is very suggestive of HCC but is not often seen.

The use of ultrasonography has been studied for the detection of HCC in studies comparing preoperative ultrasound examinations with a pathologic examination of explanted livers from patients undergoing either liver transplantation or partial hepatectomy. In patients with cirrhosis, sensitivity of ultrasound has varied widely from 30% to 89% (Table 4.4). Greater specificity has been reported in these studies (71% to 100%).

Prospective studies have evaluated ultrasonography every 3 to 12 months for HCC screening and reported higher sensitivity rates (59% to 100%) (Table 4.5) than those reported with AFP screening (13% to 64%). The greatest drawback of ultrasonography for HCC screening is that the test is strongly operator dependent. The test is also affected by the population screened and is not as accurate in patients with cirrhosis, in those who are obese or have significant steatosis, and in differentiating regenerative nodules from HCC.

AFP and Ultrasound

Few studies have compared the effectiveness of this combined screening protocol with either AFP or ultrasound alone. The combination of AFP and ultrasound was compared to AFP alone in a study screening patients with chronic hepatitis B (225). Unfortunately, the sample size of this study was not adequate to compare the two screening protocols. In a mathematical model, it was predicted that AFP and ultrasound

combinations increased the sensitivity of screening by 5% to 10% compared with ultrasound alone (249). In a retrospective analysis of 106 patients who underwent ultrasonography and AFP measurements prior to liver transplantation, the combination of ultrasound and AFP (79%) demonstrated a higher sensitivity than either ultrasound (58%) or AFP (≥20, 58%; ≥50, 47%) alone (220). Another study in patients with chronic viral hepatitis, reported that the use of AFP (>10 ng/mL) and ultrasonography resulted in higher sensitivity (100%) than either ultrasound (87%) or AFP (75%) alone (250).

In the single prospective randomized controlled trial of HCC screening 18,816 patients with chronic hepatitis B in Shanghai, China were randomized to undergo screening with both AFP and ultrasound on a 6-monthly basis, or no screening at all (251). Over an approximately 5-year period, patients were offered screening five to ten times; 58% of screening opportunities were accepted. In the screening group, the number of HCC lesions identified and resected was 86 and 40 (47%) versus 67 and 5 (8%) in the control group. In patients with HCC, the 5-year survival rate was 46% in the screening group versus zero in the control group. In this study, bi annual screening reduced HCC mortality by 37%.

Computed tomography (CT)

The classical appearance of a HCC on a dynamic CT scan of the liver is that of early arterial phase enhancement, followed by rapid washout on a later phase. A pseudocapsule if present generally shows delayed enhancement. Small well-differentiated lesions may be

P.114
P.115
P.116
P.117
P.118

more difficult to detect because of a tendency to have similar attenuation than the surrounding liver tissue. This may be partially overcome by triple-phase CT scan where images are taken in the arterial, portal venous, and the delayed or equilibrium phases. In this type of imaging, the portal venous and delayed phase sequences are useful in identifying small, well-differentiated lesions (Fig. 4.39).

Table 4.2. Performance Characteristics of α-Fetoprotein for Hepatocellular Carcinoma Screening

Study	Number of patients	Population	Study design	Screening frequency	Mean follow-up (range)	HCC	AFP cutoff	Sensitivity (%)	Specificity (%)

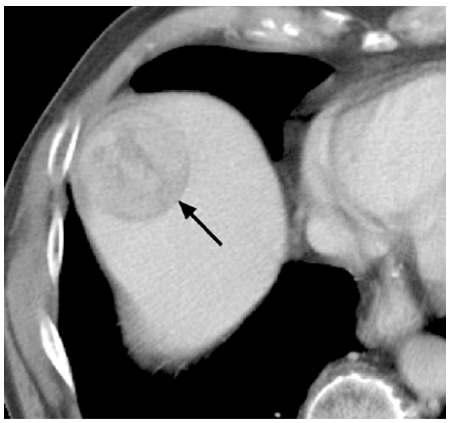
Chalasani (228)	285	Cirrhotics	Prospective	6 m	15 m (6–42 m)	27	59	93

HCC, hepetocellular carcinoma; HCV, hepatitis C virus; ALT, alanine aminotransferase; AST, aspartate aminotransferase; AFP, (α)-fetoprotein.

Proper timing of these sequences is crucial for the accurate characterization of the lesions, particularly for hypervascular lesions. HCC lesions typically demonstrate a hypervascular appearance with enhancement in the arterial phase, and rapid washout in the portal venous and delayed phases. Dysplastic nodules and regenerative nodules do not display this enhancement and usually appear similar or less attenuated than normal liver tissue. However, when the HCC is small, other benign lesions such as small hemangiomas, dysplastic nodules, and arterial to portal shunts can show homogenous arterial phase enhancement and mimick small HCC (252).

CT scan is often used to further evaluate lesions seen on ultrasonography. In studies comparing preoperative CT scan with the pathology of explanted livers (not screening studies), the sensitivity of CT scan has ranged from 47% to 89% with specificity ranging from 69% to 100%. The performance characteristics may have been influenced by the average tumor size in these studies.

Some studies have investigated the use of CT scanning for HCC screening. Although CT scan is useful for screening small groups of patients at high-risk for HCC, and for further evaluation of lesions seen on ultrasonography, it is an impractical modality for mass screening, particularly in less developed countries where it is cost-prohibitive. Also, repeated CT scans, every 6 to 12 months as part of a screening protocol, results in significant radiation exposure.



• **Figure 4.39** Hemochromatosis and hepatocellular carcinoma. Portal venous phase contrast-enhanced computed tomography demonstrates tumor (*arrow*) within the dome of the liver.

Chalasani et al. retrospectively reviewed 285 patients with cirrhosis who underwent initial screening for HCC with AFP, ultrasound, and CT scan testing followed by semiannual AFP and ultrasound imaging in patients who were considered eligible for liver transplantation. In this study, CT scan had a higher sensitivity (88%) than both AFP greater than 20 ng/mL (62%) and ultrasound (59%). However, other studies have not shown a benefit in tumor detection with the CT scan. In a study of patients undergoing triple-phase CT scanning, while awaiting liver transplantation, only 59% of HCC lesions were identified prior to transplant (241). In a retrospective analysis of 106 patients who underwent liver transplantation, the addition of CT scan to AFP and ultrasound did not increase the sensitivity of tumor detection (220).

Magnetic resonance imaging

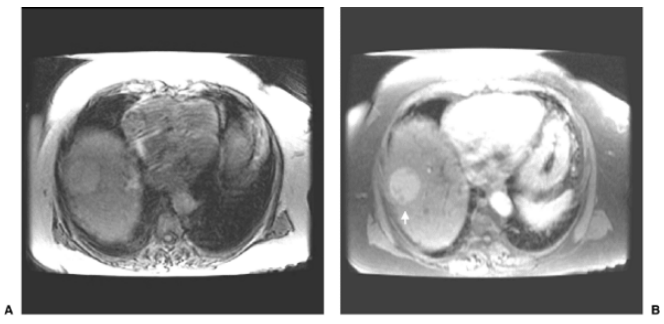
The appearance of HCC on MRI varies according to the characteristics of the lesion. Well-differentiated tumors generally appear hyperintense on T1-weighted images and isointense on T2-weighted images. Gadolinium-enhanced dynamic MRI allows the visualization of the liver in arterial, portal venous, and delayed phases (Fig. 4.40). Typical HCC appearance of arterial phase enhancement and portal venous phase washout allows the differentiation of these lesions from the less vascular regenerative and dysplastic nodules. MRI, however, like CT scan, does not perform well in the detection of small lesions.

In studies comparing preoperative MRI studies with the pathology of liver explants, the reported sensitivity and specificity rates have ranged from 50% to 100% and 57% to 95%, respectively. These results are similar to what has been reported for CT scan. MRIs are helpful in evaluating lesions that may represent HCC and has the advantage of not having the radiation exposure of CT imaging, but are considered too expensive for mass screening purposes.

Screening frequency

Screening for HCC with imaging is recommended at 6- to 12-month intervals (253). There have been no prospective comparisons of different screening schedules. The 6-month interval has evolved from studies that suggest the doubling time for HCC is approximately 3 months. In a study by Sheu et al. the growth rates of 31 asymptomatic HCC detected by ultrasound as part of a prospective screening program

were followed (254). The mean doubling time was 117 days (range 29 to 198 days, geometric mean 110 days). The only randomized trial of screening versus no screening showing a benefit of screening used 6-month intervals (251), a commonly applied approach in the United States. However, a randomized trial of 6- versus 12-month intervals showed no survival benefit for 6 months (255). These data are limited and do not support the widespread use of a longer screening interval.



• **Figure 4.40** Hepatocellular carcinoma. A 4 cm lesion in hepatic segment VIII seen before **(A)** and after **(B)** administration of gadolinium contrast on T1- weighted magnetic resonance images.

Outcome studies

Randomized, controlled studies comparing survival in patients undergoing HCC screening with controls who are not screened, are limited. Studies have looked at surrogates for survival including tumor size, tumor stage, and resectability in patients who have undergone screening. Several studies have demonstrated that HCC screening programs result in the detection of tumors that are smaller, and at an earlier stage making them more amenable to curative surgery (255,256,257,258). An improvement in patient survival based on screening has yet to be conclusively demonstrated, but has been suggested in retrospective studies (224,255,259). Furthermore, all these studies may be subject to lead-time bias.

Three large published screening trials will be discussed here. Two US-based studies screened HBsAg-positive patients. In the study by

Sherman et al. 1,069 hepatitis B carriers underwent AFP or AFP with ultrasonography every 6 months (225). Over a 5-year period, 14 hepatocellular carcinomas were identified. In seven of these patients, curative resection was not possible at the time of tumor detection because of tumor stage, and one additional patient refused surgery. Six patients underwent surgery with a curative intent; HCC recurred in one patient at 4 months. HCC had not recurred in the remaining five patients at follow-up periods ranging from 6 to 38 months, which is not a long enough duration to exclude tumor recurrence. A study screening 1,487 Alaskan natives with chronic hepatitis B were screened with AFP measurements every 6 months for a 16-year period (260). Patients with an elevated AFP underwent ultrasound examinations. HCC was detected in 32 patients; tumors less than 6 cm were found in 23 patients, of whom 22 underwent resection. The 5- and 10-year survival rates for patients diagnosed with HCC during this trial were 42% and 30%. A historical control group was selected of HBsAg positive patients diagnosed with HCC prior to the study; none of those 12 patients survived beyond 2 years after HCC diagnosis. Finally in a study of 1,125 patients with chronic viral hepatitis who underwent AFP and ultrasound examinations every 3 months, HCC was diagnosed in 67 patients (250). Median survival in the 24 patients who underwent tumor resection was 26 months, compared to 6 months in the 43 patients with unresectable tumors.

Unresolved questions regarding hepatocellular carcinoma screening

Large, prospective, randomized controlled trials are needed to definitively establish the optimal HCC screening modality and frequency that would result in a survival benefit. Such studies would be challenging to conduct, given the large number of patients required and the ethical dilemmas related to conducting such a study.

Chapter 5

Interventional Radiology Procedures for Diagnosis and Treatment of Hepatobiliary Disease

Bart L. Dolmatch

Douglas M. Coldwell

Key Concepts

- Advances in noninvasive imaging and endoscopy continue to modify the indications for interventional procedures, some of which, such as transabdominal splenoportography, have been altogether abandoned. Other procedures such as hepatic arteriography and transhepatic percutaneous cholangiography are infrequently required for diagnosis.
- Catheter-based assessment of the portal and hepatic venous systems remains important for a number of conditions. There are several safe ways of studying the portal venous system.
- Angioplasty and stenting have become important adjuncts for treating arterial, venous, and biliary obstructions.
- Liver biopsy can be performed transabdominally with a high degree of safety and excellent diagnostic yield. Transjugular biopsy is reserved for patients with diffuse liver disease and contraindication to transabdominal biopsy.
- Tumor ablative therapies include transcatheter and percutaneous methods. There are recent data to support the use of transarterial chemoembolization of hepatic malignancies when curative resection is not considered.
- Percutaneous drainage has become a cornerstone in treatment of liver abscesses.

Ongoing advances in noninvasive imaging have rendered many diagnostic interventional methods of the last decade obsolete. Computed tomography (CT), magnetic resonance imaging (MRI), ultrasound, and radionuclide imaging often provide sufficient diagnostic information for medical management and surgical planning. Endoscopic techniques have mostly replaced percutaneous transhepatic cholangiography (PTHC) and percutaneous biliary intervention. Diagnostic angiography and PTHC are now reserved for those cases in which less invasive diagnostic evaluation proves inconclusive.

What remains under the heading of interventional radiology procedures, therefore, includes an aray of diagnostic procedures that are used when noninvasive imaging is just not adequate, alongside a growing number of interventional therapies for treating both benign and malignant conditions. Many percutaneous therapeutic interventional procedures have been developed to ablate hepatic malignancies, including transarterial chemoembolization (TACE), various percutaneous probe-directed ablative therapies, and most recently, selective internal radiation therapy (SIRT) performed by

transarterial delivery of radioactive particles. Although many of these ablative procedures are considered safer than open surgeries, validation of the results in well-controlled comparative studies has been lacking, except for TACE in which recent randomized trials confirm the usefulness of this technique.

This chapter addresses a broad spectrum of percutaneous diagnostic and therapeutic procedures, attempting to temper unfounded enthusiasm while noting those areas where invasive techniques offer safe and effective medical care for patients with hepatobiliary disease.

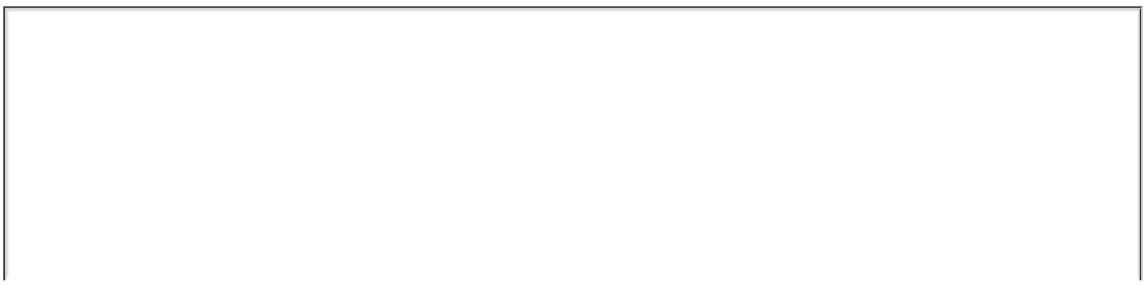
Angiography

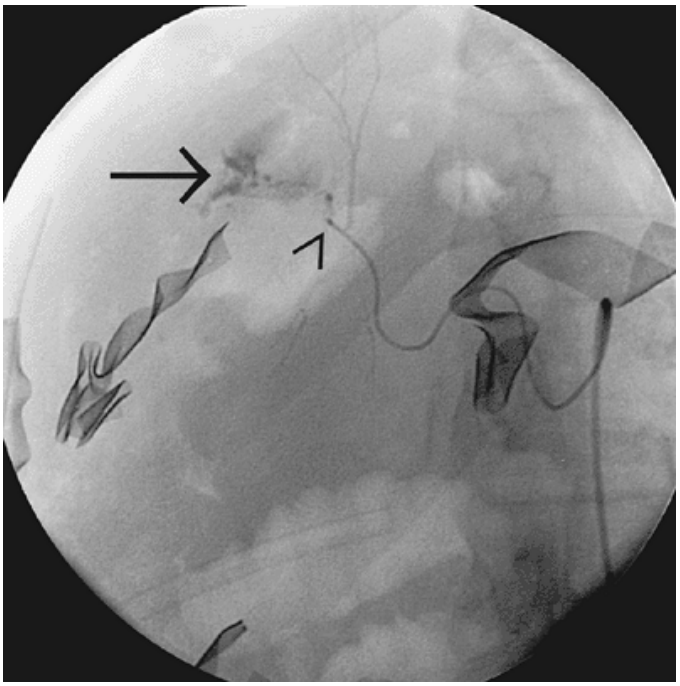
These days the term *angiography* requires some clarification. Once only the domain of percutaneous catheterization, angiography (visualization of arteries and veins) can now be done by a number of imaging methods without the need for direct vascular puncture. Several methods do not even require the administration of any type of contrast agent. Examples include color-flow sonography and magnetic resonance angiography (MRA) using imaging techniques based on the physical properties of flowing blood to distinguish blood vessels from static tissues. Not only can these two techniques image blood vessels without using contrast agents and percutaneous puncture but they can also avoid ionizing radiation and virtually all the risks that accompany catheter-based angiography. With the addition of intravenous contrast administration, both CT scan and MRA are capable of rendering arteriograms and venograms that often rival conventional angiograms obtained with catheterization techniques. Furthermore, noninvasive angiography with sonography, CT scan, and MRA techniques are far less expensive than catheter-based angiography. These noninvasive methods also demonstrate anatomy beyond the blood vessels and can show changes in the soft tissues and bones that may not be seen with conventional angiography.

If these noninvasive methods produce angiograms that are consistently comparable to conventional angiograms in spatial and contrast resolution there will be no reason to insert a catheter for vascular diagnosis ever again. Noninvasive angiograms obtained with ultrasound, CT scan, and MRA, however, are not always adequate for arriving at a diagnosis or may not be sufficient to guide further therapy. Therefore, catheter-based angiography is still required in a number of clinical situations.

Hepatic Arteriography

The principles and practice of catheter-based hepatic arteriography have improved during the last decade. Catheter size, measured by outer diameter of the catheter, has been reduced to 4 to 5 Fr (1 Fr = 0.33 mm). This translates to a smaller arterial puncture at the groin and a theoretic reduction in puncture site complications. Introduction of the Glide Wire (Boston Scientific, Natick, MA) in clinical practice has facilitated visceral catheterization as well. Our ability to reach distant branch vessels has been further enhanced by the introduction of "microcatheters" that are inserted through a standard 5-Fr angiographic catheter and directed toward the target artery with "microwires." It is now routinely possible to enter vessels in the liver that are fourth- and fifth-order branches, typically 0.5 to 1.0 mm in diameter, regardless of the degree of vascular tortuosity (Fig. 5.1).





▪ **Figure 5.1** Digital angiogram of a superselective hepatic artery catheterization. Contrast extravasation (*arrow*) is seen at the site of the traumatic liver laceration. The microcatheter tip (*arrowhead*) has been placed in a fourth-order right hepatic arterial branch.

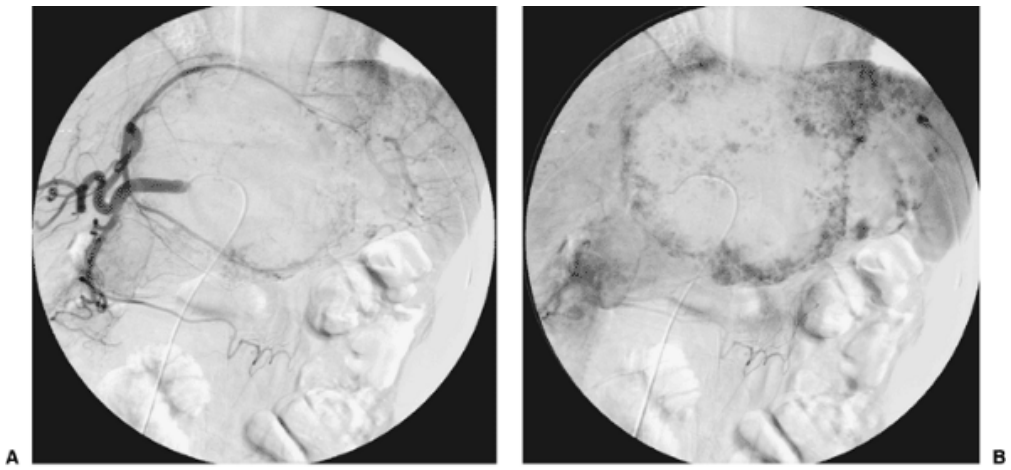
Fluoroscopic and digital angiography equipment have also improved. State-of-the-art systems have been available for most of the last decade and afford up to four times the resolution of earlier digital imaging systems. Additional developments permit the angiographer to freeze an angiographic image on top of a live fluoro image, thereby providing a "roadmap" on which difficult catheterizations can be performed.

A number of other advances make hepatic arteriography safer than ever. These include the use of low osmolar contrast agents that reduce the discomfort and idiosyncratic reactions caused by iodinated contrast injection; the widespread use of hemodynamic monitoring, permitting the safe use of conscious sedation; and a variety of recently introduced puncture closure devices. These puncture closure devices use absorbable sutures, bovine collagen, thrombin, or a combination of these agents. They have been approved for use in patients who are anticoagulated and may provide a margin of safety when arterial catheterization is performed in a patient with known coagulopathy (i.e., prolonged prothrombin time and thrombocytopenia), a condition often seen in patients with liver disease.

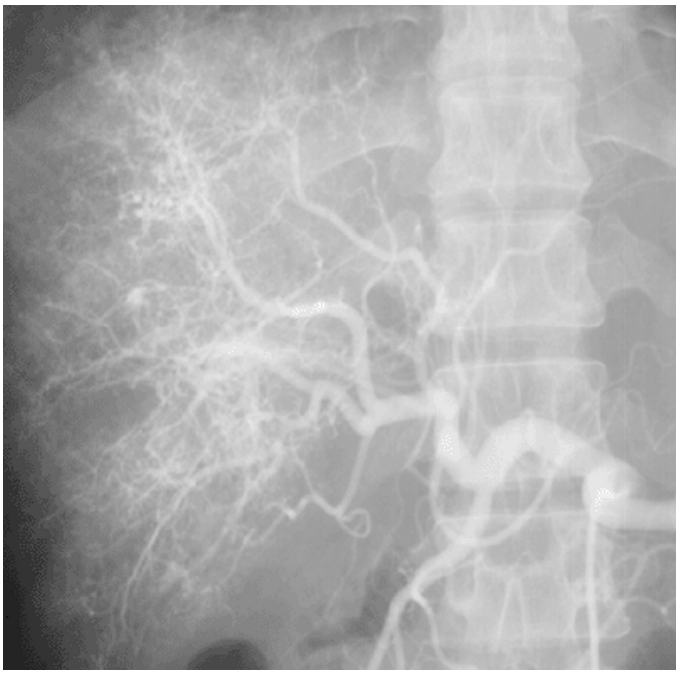
Although hepatic arteriography is safer and more diagnostic than ever before, the indications for arteriography of the liver have declined as noninvasive imaging methods have improved. For example, it is rarely necessary to demonstrate the arteriographic "starry night" early phase and vascular lakes appearance on delayed

images that are characteristic of a cavernous hemangioma in the liver (Fig. 5.2A,B) because MRI, CT, ultrasound, and radionuclear imaging can make the diagnosis in most cases. The same is true for most hepatocellular carcinomas (Fig. 5.3) and metastases (Fig. 5.4A,B) in which noninvasive imaging may be followed by percutaneous biopsy if indicated, avoiding the need for arteriography. Catheterization of the mesenteric arteries for CT arterial portography is now of dubious value because noninvasive

imaging methods such as multiphase CT scanning show similar sensitivity for detecting small (<1 cm diameter) liver lesions without arterial catheterization (1,2,3). The reality is that hepatic angiography is only occasionally used as a diagnostic test. More often, angiography is used to guide percutaneous procedures such as embolization, angioplasty, and stenting or to create a vascular map for the surgeon who contemplates shunt surgery or liver transplantation when noninvasive imaging is not sufficient.



▪ **Figure 5.2** Early-phase and late-phase arteriogram of a cavernous hemangioma of the liver. **A:** Displacement of both branches of the left hepatic artery by this extremely large cavernous hemangioma. This type of vascular displacement is not typical of hemangiomas until they become massive. Early filling of the hemangioma is noted by a faint "starry night" appearance at the end of the small arterial branches. **B:** Characteristic contrast lakes are seen at the periphery of the cavernous hemangioma as the vascular spaces within the hemangioma fill during angiography.



▪ **Figure 5.3** Hepatocellular carcinomas. There is diffuse neovascularity, seen as a cobweb pattern, throughout the right lobe of the liver in this patient with multifocal hepatocellular carcinomas.

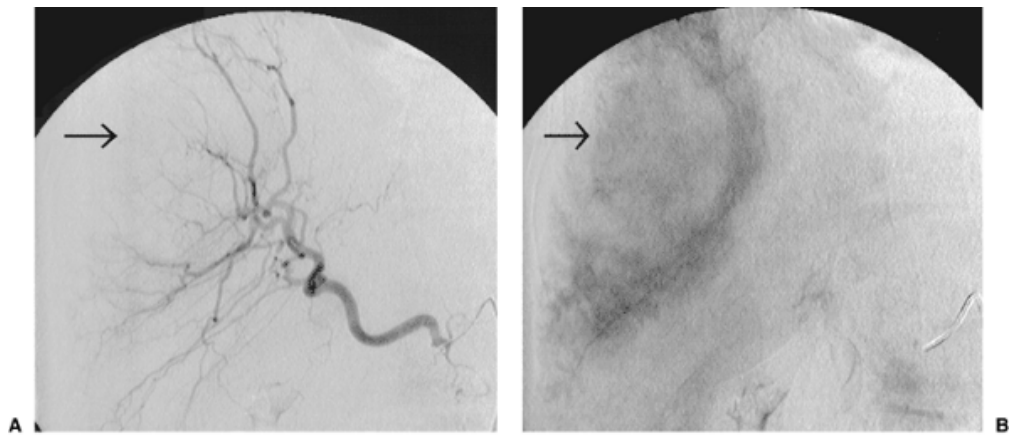
Portal and Hepatic Venography

Although arteriography is on the decline, venography of the portal venous system and hepatic veins remains an important procedure for diagnosis and guidance of therapy.

Portal venography

Venographic imaging of the portal vein is often required in the preoperative assessment of portal hypertension before shunt surgery and, occasionally, before liver transplantation. It is also an important component of the transjugular intrahepatic portosystemic shunt (TIPS) procedure and used on occasion during the assessment of Budd-Chiari syndrome (BCS). There are four angiographic methods that can be used to image the portal vein and its tributaries which are as follows:

1. Arteriographic portography
2. Transvenous portography



▪ **Figure 5.4** Early-phase and late-phase hepatic arteriogram of metastatic disease to the liver. **A:** There is splaying of the right hepatic arterial branches by a large colorectal metastasis (*arrow*). **B:** Late arterial phase angiogram shows the hypovascular defect produced by the metastasis (*arrow*) with some hypervascularity in the adjacent liver that may represent compression of normal liver tissue by the metastasis.

3. Transabdominal–transhepatic portography
4. Transabdominal–transsplenic portography

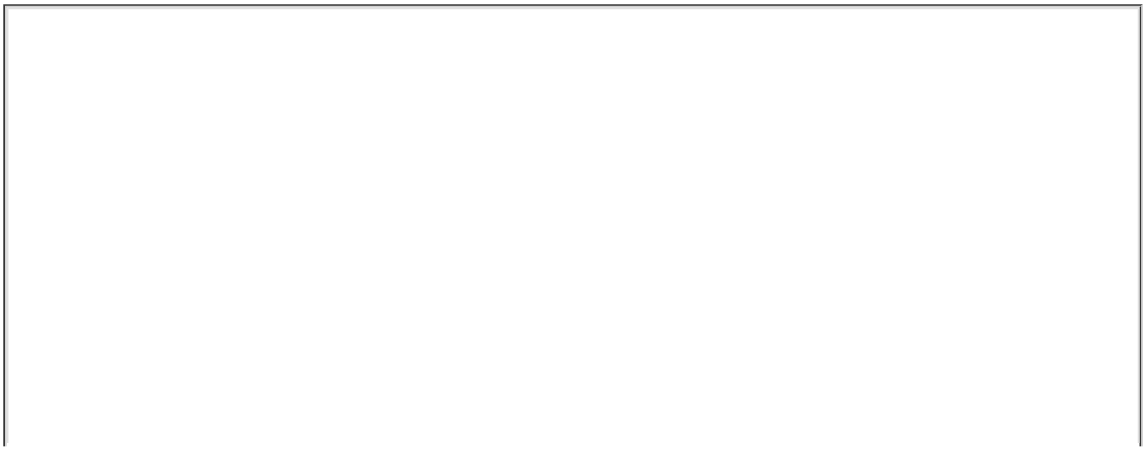
Arteriographic portography implies arterial catheterization with selective contrast injection into the splenic artery, superior mesenteric artery, or inferior mesenteric artery. After contrast passes through the visceral capillaries, it enters the portal

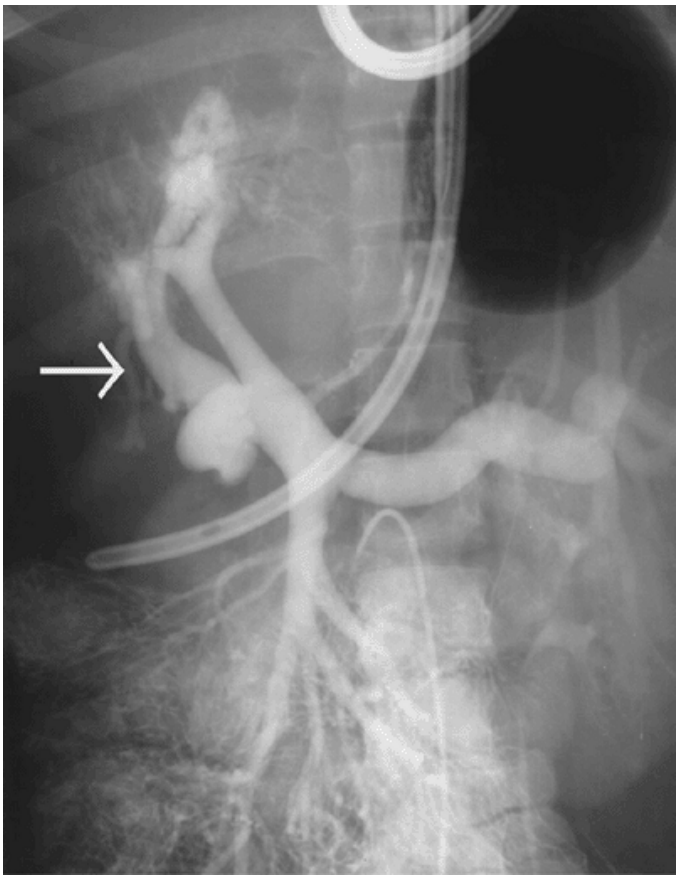
venous tributaries and then the portal vein itself. "Late" filming after arterial injection of contrast will therefore demonstrate the entire portal venous system in most patients. This method is the best way of assessing dynamic flow patterns in the portal venous system because it images all portal venous branches, collaterals, and varices as they fill with contrast. This is important when assessing flow dynamics of variceal filling before surgery. For example, dynamic portal venous flow patterns often guide the surgeon during portocaval shunting, distal splenorenal shunting, and devascularizing procedures of gastroesophageal varices by delineating the relative importance of flow into the left gastric vein (coronary vein), splenic vein, and umbilical vein (recanalized paraumbilical venous collateral system) (Fig. 5.5).

Limitations of arteriographic portography include dilution of contrast by nonopacified blood before reaching the portal system, which often limits visualization. This is a particular problem when contrast is injected into the splenic artery of patients with hypersplenism; in such cases contrast does not pass swiftly through the enlarged spleen into the portal venous system. Portal vein filling may be delayed for more than 20 or 25 seconds in patients with portal hypertension, and it is frequently not possible for a patient to hold his breath for this duration during the imaging sequence. When a patient breathes during digital subtraction angiography, the motion of the liver and bowel may obscure faint portal venous filling. Finally, in some patients with high portal venous pressure, hepatofugal flow may prevent portal vein opacification altogether.

Transvenous portography is performed by systemic venous puncture, advancing a catheter through the hepatic vein until it becomes wedged in one of the small hepatic vein branches. Iodinated liquid contrast or carbon dioxide (CO_2) gas is then injected into the catheter, which passes back from the small hepatic vein into the hepatic sinusoids and finally retrograde into the portal vein (4). CO_2 gas is now preferred over iodinated liquid contrast agents because it affords more reliable and complete filling of the portal vein. When attempting transvenous CO_2 portography, digital subtraction angiographic equipment is needed because CO_2 gas is difficult to distinguish from adjacent soft tissues without the subtraction technique (Fig. 5.6). Although widely adopted for portal vein visualization during transhepatic portosystemic shunt formation for the treatment of portal hypertension, this method is limited by several factors that are typically not known before attempting the procedure. First, the degree of sinusoidal destruction due to cirrhosis or inflammation may impede an adequate volume of CO_2 gas from crossing through the sinusoids and entering the portal system for adequate visualization of the portal vein. Also, in some patients it is difficult to wedge the catheter with sufficient force to prevent the reflux of CO_2 into the hepatic vein that has been

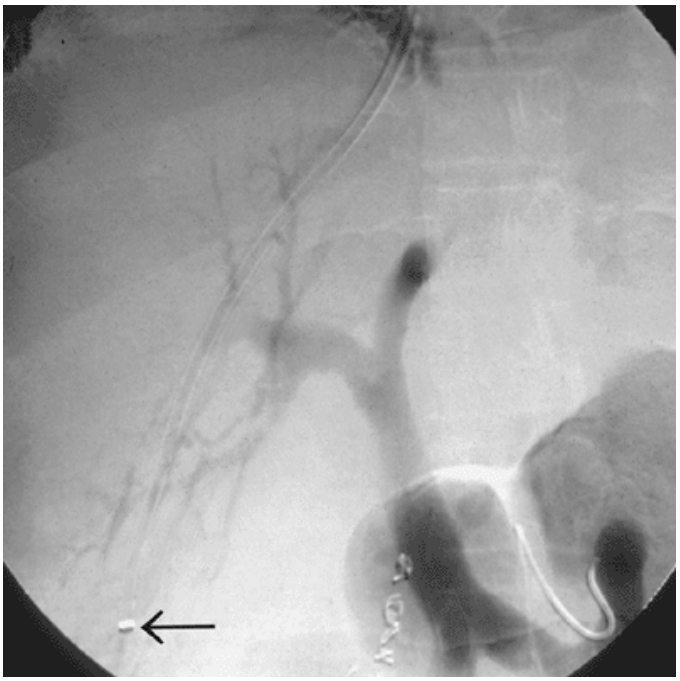
catheterized. Finally, this technique only rarely depicts the portal system proximal to the main portal vein because CO_2 flash fills the main portal vein and its intrahepatic branches for 1 to 2 seconds before the portal circulation forces it back into the sinusoids.





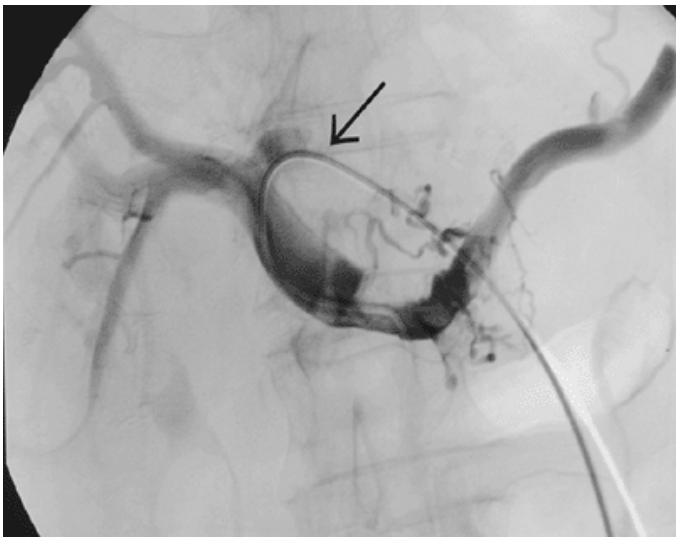
▪ **Figure 5.5** Schistosomiasis with sinusoidal portal hypertension. This is the late phase (portal venous phase) of a superior mesenteric artery angiogram, in which expected filling of the superior mesenteric vein, occurs and the relatively small main portal vein, as well as some hepatofugal filling of the splenic vein. Note the recanalized paraumbilical vein (*arrow*) that arises from the left portal vein and travels in the falciform ligament toward the umbilicus.

There have been several case reports of fatality after transvenous portography when forceful injection of liquid contrast agents or CO_2 gas has ruptured the liver capsule rather than having passed through the sinusoids (5,6). Breach of the liver capsule can be immediately recognized on the venographic images obtained during the attempted transvenous portogram. Transcatheter embolization of the tear should be performed immediately using gelfoam pledgets and/or occlusive coils in an attempt to halt bleeding into the peritoneal cavity. Even when these measures are taken, it is possible that a capsular tear will result in excessive intraperitoneal hemorrhage. Therefore, to avoid capsular tear, transvenous portography should be attempted after making all reasonable efforts to wedge the catheter in an hepatic vein branch located within the central substance of the liver far from the liver capsule. This can be facilitated by reviewing the CT, MRI, or ultrasound studies that have invariably been done before performing transvenous portography, noting whether there is excessive atrophy of the right lobe of the liver, which would preclude safe injection into the right or middle hepatic veins (MHVs).



▪ **Figure 5.6** Wedged transvenous carbon dioxide (CO_2) portogram. A vascular sheath is introduced through the right internal jugular vein, with its tip (*arrow*) wedged in a small venous tributary to the right hepatic vein. CO_2 is passed through the sinusoids and refluxed into the portal venous system, with excellent visualization of the right, left, and main portal veins on the digital subtraction angiogram.

Transabdominal–transhepatic portography was first described in 1974 by Lunderquist and Vang (7). Although it is infrequently used in contemporary practice, we have found this to be a safe and relatively easy way of entering and imaging the portal venous system. The technique requires ultrasound guidance for transabdominal (transhepatic) puncture into the left or right portal vein. The left portal vein is preferred because it is closer to the skin than the right portal vein and compression can be applied over the hepatic puncture site in most patients when the catheter is removed. Once the puncture needle enters the right or left intrahepatic portal vein, a guide wire is introduced and the needle is replaced with a small (5 Fr) hemostatic sheath. An angiographic catheter can be placed into the portal system through this sheath and used to image the entire portal venous system. Pressure measurements can also be obtained directly. Another advantage is that selective contrast injections can be made into the portal vein branches, and sequential imaging can then demonstrate the flow dynamics with a much better depiction of the portal vein anatomy than transarterial portography.



▪ **Figure 5.7** Transabdominal-transhepatic portal venogram. The catheter is placed into the left portal vein branch with sonographic guidance (*arrow*), and it passes retrograde into the main portal vein. The tip of this catheter is at the confluence of the splenic vein and main portal vein. Partially occlusive thrombus, adjacent to the catheter tip, was treated using thrombolytic therapy.

We have used this method when approach the portal system while providing transcatheter therapies such as thrombolysis of portal vein clot (Fig. 5.7) or embolic occlusion of a vascular shunt that involves the portal venous system. In fact when Lunderquist and Vang first described this technique, it was used to provide access for transcatheter embolization of the coronary vein.

Transabdominal–transsplenic portography is only of historical interest. This procedure has a complication list that includes significant hemorrhage (500 to 2,000 mL) in up to 2% of patients (8), with the need for splenectomy in some of these patients. Additionally, there is an increased incidence of splenic artery branch pseudoaneurysms because of laceration caused by the needle tip (9). Given the development of the three other methods for portal venous imaging, as well as the use of transhepatic portal vein catheterization for obtaining pressure measurements (and hepatic vein catheterization with free/wedge hepatic vein pressure measurements, as described in the following text), there is no longer a clinical need for this procedure.

Portal pressure measurements

As noted in preceding text, direct entry into the portal venous system is possible by a transabdominal–transhepatic approach using ultrasound-directed puncture into an intrahepatic portal vein branch. Although we have found that this approach to be technically straightforward and safe, it is possible to obtain information about portal venous pressure quite simply (if indirectly) by catheterization of one of the hepatic veins. The portal venous pressure is calculated by measuring the wedged hepatic vein pressure and the "free" hepatic vein pressure (pressure in the hepatic vein without wedging the catheter tip). Subtraction of the free hepatic vein pressure from the wedged pressure yields an indirect calculation of the portal vein pressure, called the *corrected sinusoidal pressure* (*CSP*). The CSP is normal (<5 mm Hg) when there is no portal hypertension and when there is portal hypertension due to presinusoidal portal venous occlusion (such as main portal vein thrombosis). The CSP is elevated in

sinusoidal and postsinusoidal causes of portal hypertension, with values between 6 and 10 mm seen in mild portal hypertension and between 11 and 15 mm Hg in moderate portal hypertension (10).

Other methods to measure portal venous pressure include direct entry into the portal vein by a transjugular intrahepatic puncture (the first step in creating a TIPS shunt). This is technically more challenging than the transabdominal–transhepatic approach and is usually reserved for portal vein pressure measurements only during the TIPS procedure. Finally, portal venous pressures were obtained for many years by transsplenic puncture and measurement of the splenic pulp pressure, but as noted in the preceding text, there is no longer any reason to perform this procedure because other methods are safer.

Hepatic venography

Hepatic venography remains an important procedure for the evaluation of BCS and for the assessment of certain diffuse hepatic processes such as veno-occlusive disease. It is also necessary during transjugular liver biopsy and TIPS, and for the occasional evaluation of vascular malformations of the liver.

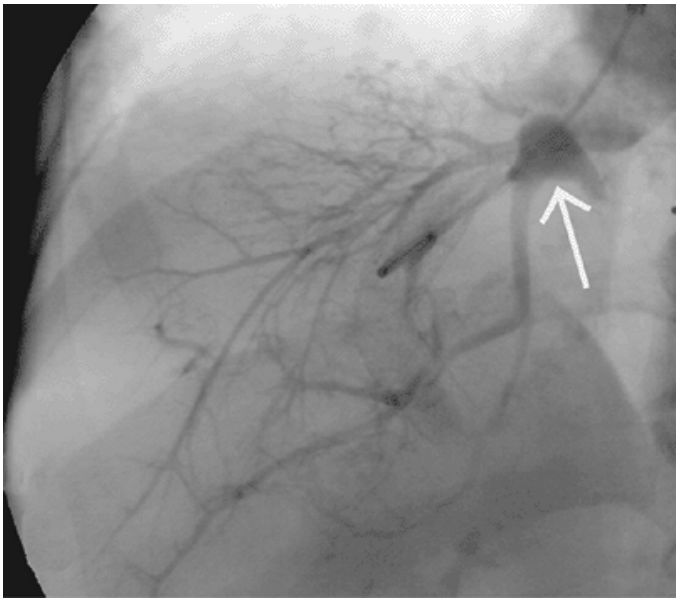
This procedure is typically performed by puncturing the internal jugular vein because the hepatic veins are most easily catheterized by gaining entry into the inferior vena cava (IVC) from above. Nevertheless, some interventionalists prefer entry by a femoral vein puncture. In case of BCS, it may be necessary to perform hepatic venous catheterization using both the jugular and femoral approaches because IVC stenosis or occlusion due to a web or compressive effect on the IVC caused by hepatic hypertrophy may confound the interventionalist who attempts this procedure only using the jugular vein approach. As noted in the preceding section, the usefulness of hepatic venography may be augmented by wedged and free hepatic vein pressure measurements if portal hypertension is suspected.

Venous anatomy of the liver can be studied by selective catheterization of each of the three hepatic veins. The right hepatic vein enters directly into the IVC (Fig. 5.8), whereas the MHV and left hepatic vein (LHV) form a common trunk just before entering the IVC (Fig. 5.9). Other hepatic veins include small caudate veins that typically enter directly into the IVC below

the level of the dominant hepatic venous drainage, as well as the inferior right hepatic vein (IRHV) that enters the IVC at the level of the caudate lobe (Fig. 5.10).

▪ **Figure 5.8** Right hepatic venogram. The catheter is introduced from the right internal jugular vein.

As mentioned in the preceding text, venographic findings in BCS include thrombosis or webs of the hepatic veins and stenosis of the IVC due to a web (Fig. 5.11A,B) or hypertrophy of the left lobe of the liver. Contrast, on being injected into diseased hepatic veins central to the occluding clot or webs, will often fill a rich network of intrahepatic venous collaterals that bridge the hepatic veins (Fig. 5.12A,B) and may collateralize to the portal and systemic venous systems.



▪ **Figure 5.9** Middle and left hepatic veins of the same patient as in Figure 5.8. The *arrow* indicates the confluence of these two venous branches. There is excellent filling of the middle hepatic vein branches and limited filling of the left hepatic vein branches.

▪ **Figure 5.10** Catheterization of the inferior right hepatic vein (IRHV) in a patient with an inferior vena caval web (see Fig. 5.11 for additional venograms of this patient).

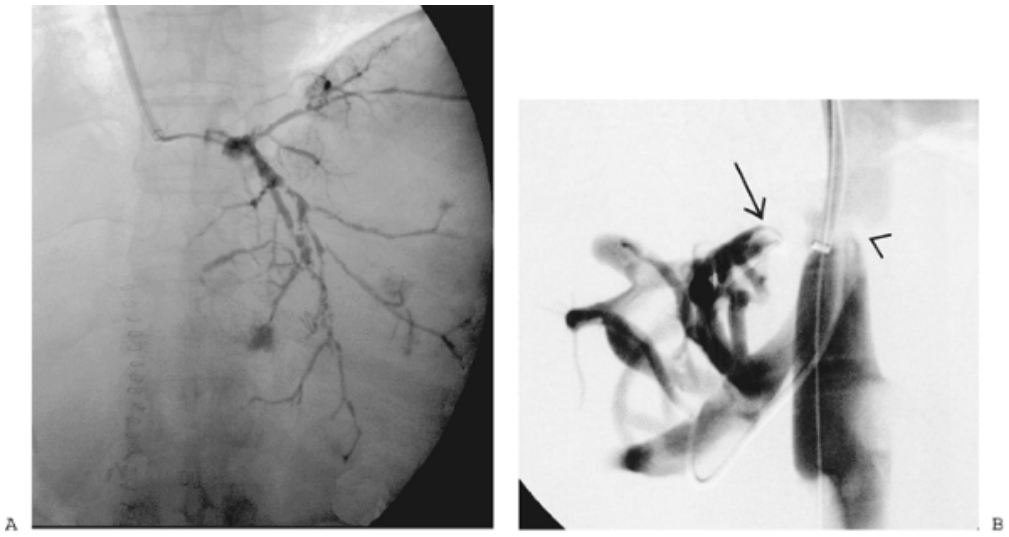
Percutaneous Transhepatic Cholangiography

Developed through the 1960s and 1970s, the current technique for PTHC was revolutionized by the Japanese, with the introduction of a long, thin, flexible needle named the *Chiba needle* in honor of the city in which it was invented (11,12,13). PTHC, although relatively safe, carries the risk of cholangitis, sepsis, and hemorrhage. It is therefore of little surprise that noninvasive tests and endoscopy have replaced PTHC in the diagnosis of most types of biliary disease.

Contemporary assessment of biliary disease usually begins with ultrasound to assess biliary dilatation/obstruction. Endoscopy can often reveal the etiology and location of the biliary obstruction and the endoscopist can often insert a catheter for biliary drainage. Subsequent imaging evaluation may include CT scanning (to look for stones, a pancreatic head mass, masses in the porta hepatis, or intrahepatic disease), scintigraphy (to assess biliary excretion), and magnetic resonance cholangiopancreatography (MRCP) (to evaluate the biliary anatomy).

The most frequent indications for PTHC include suspected biliary obstruction at or above the common hepatic duct, failure of endoscopic cannulation of the ampulla of Vater due to prior surgery or other anatomic factors, prior Roux-en-Y anastomosis, nondiagnostic MRCP, or when percutaneous access into the biliary

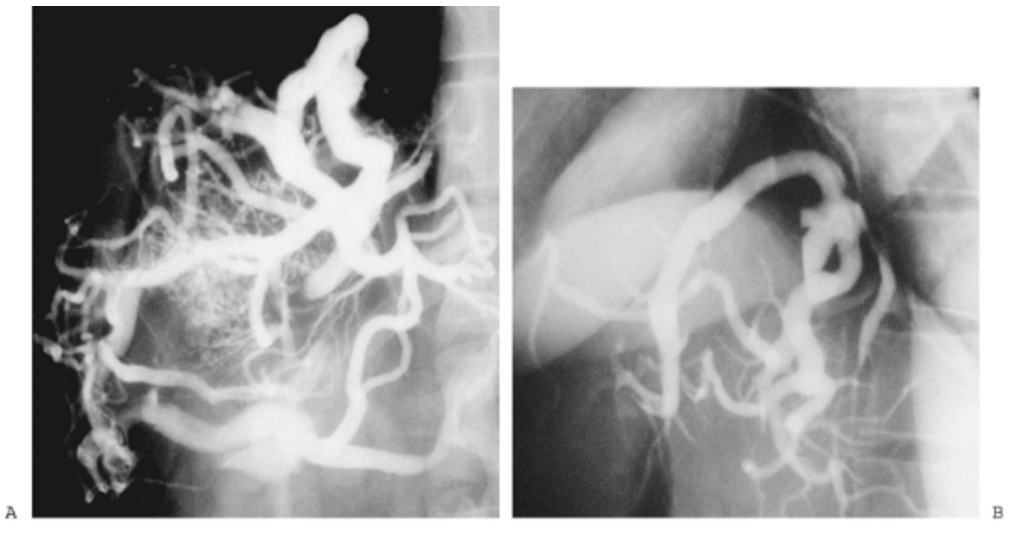
tree is needed for drainage, biopsy, stone manipulation, or other interventions.



▪ **Figure 5.11** Left hepatic venogram and inferior vena cavagram in a patient with Budd-Chiari syndrome. **A:** Multiple branches of the left hepatic vein undergo thrombosis and recanalization, giving a "scrawny" appearance to the veins that fill with contrast. **B:** A web in the inferior vena cava is noted (*arrowhead*), and the occluded right hepatic vein (*arrow*) fills through inferior right hepatic vein collaterals.

Patient preparation is essential for safe performance of PTHC. We always administer prophylactic antibiotics before performing PTHC and typically provide antimicrobial coverage for gram-positive cocci and gram-negative rods using ampicillin with tobramycin, gentamicin, or a second-generation cephalosporin. Additionally, all reasonable efforts should be made to correct any abnormal coagulation parameters before performing PTHC, including normalization of the prothrombin time and transfusion of platelets during the

procedure if necessary. Although ascites is a relative contraindication to PTHC, there are ways to avoid the complications of peritonitis and intraabdominal hemorrhage, such as drainage of the ascitic fluid, before PTHC.



▪ **Figure 5.12** Budd-Chiari syndrome—anteroposterior (AP) and lateral venograms. **A:** AP hepatic venogram shows the chaotic appearance of an engorged hepatic venous system. **B:** Lateral hepatic venogram shows that there is no identifiable outflow from the hepatic veins into the inferior vena cava.

PTHC may be approached from either the right or the left side of the liver. We prefer a left-side approach regardless of whether there is biliary dilatation. Access into the left intrahepatic bile duct avoids transpleural puncture, reduces respiratory motion of the liver during the procedure, and permits extrinsic compression of the puncture site if necessary. Furthermore, injection of contrast into the left biliary tree usually yields complete filling of the bile ducts in both hepatic lobes because iodinated contrast is denser than bile and flows down into the dependent right biliary system as the patient lies supine. When there is distal obstruction of the extrahepatic bile duct, the left bile duct is typically more dilated than the right and, therefore, more easily punctured. Radiation dose is always of concern when working from a left hepatic lobe puncture because there is a tendency to cross one's hands in front of the x-ray beam. But since entry into the biliary tree is facilitated from the left side using ultrasound guidance, we believe that the total radiation exposure of the operator's hands to the x-ray beam, as well as exposure from scattered radiation emanating from the patient, will be less than that sustained from a right-side puncture under fluoroscopy alone.

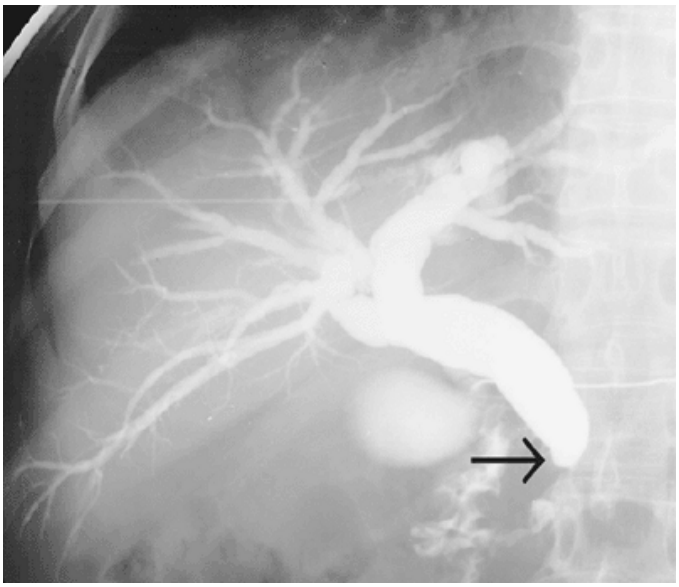
Ultrasound is used in virtually every PTHC that we perform because it guides puncture into the bile duct, often reducing the interventionalist's efforts to only one needle pass. Even when intrahepatic bile ducts are not dilated, ultrasound is used to identify the left portal vein that serves as a reliable marker for the portal triad (and therefore the left biliary ductal system). An acceptable site of entry into the biliary tree is especially important when biliary drainage is considered. The site of entry should not be too peripheral because the biliary radicals are small and close to the liver capsule where leakage of bile can cause peritonitis. Likewise, the puncture should not be too central because injury to the hepatic artery is more likely. Usually a second-, third-, or fourth-order biliary radical is preferred. But with a nondilated system, virtually any bile duct will suffice for diagnostic PTHC because there is no guarantee that additional needle passes will have any success in finding an optimal duct for opacification.

Excessive filling of the biliary tree with contrast may lead to sepsis and death if bile is colonized or infected. This may occur even when prophylactic antibiotics are given because the bacteria that are already in the bile cause sepsis by releasing endotoxin into the bloodstream. Whereas overfilling is dangerous, underfilling may render the study nondiagnostic. This is a dilemma for the interventionalist, who relies on his experience and judgment during PTHC. Once the system is filled with adequate contrast, imaging should be performed in multiple projections. Obstructions should be evaluated accurately to determine whether they represent stones, strictures, or tumors. The ease with which contrast flows past a stricture is particularly important when assessing a surgical anastomosis because there is typically some narrowing after surgical reanastomosis of the bile duct to the bowel that may not represent a functional obstruction. Manometry has been used to determine the significance of benign biliary strictures, as described in the following text. For malignant strictures, determination of the location of the obstruction is crucial because it may render a malignant obstruction amenable to surgical bypass (and even potential cure) or may convince the surgeon that curative surgery is fruitless and that nonoperative palliative measures are warranted.

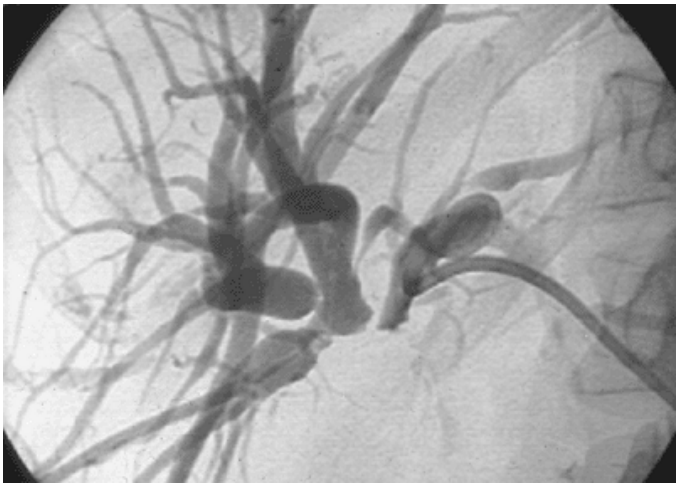
There have been many papers that describe the findings of stones, amorphous sludge, cholangitis, cholangiocarcinoma, benign strictures, and sclerosing cholangitis. Despite the degree of certainty with which some authors distinguish these conditions, it is

often not possible to distinguish sclerosing cholangitis from cholangiocarcinoma, or stones from sludge. Nevertheless, stones are typically identified as round or oval luminal filling defects that do not change in shape or size. Air bubbles that may have been introduced inadvertently during the procedure are usually round, mobile filling defects that can often be aspirated back through the needle. Obstruction of the distal common bile duct with an abrupt taper usually represents pancreatic carcinoma (Fig. 5.13). Obstruction of the

middle or high extrahepatic duct represents cholangiocarcinoma or extrinsic metastases (Fig. 5.14). When the intrahepatic ducts are occluded, the differential diagnosis includes cholangiocarcinoma, sclerosing cholangitis, and malignancy or lymphadenopathy at the porta hepatis (Fig. 5.15A,B).

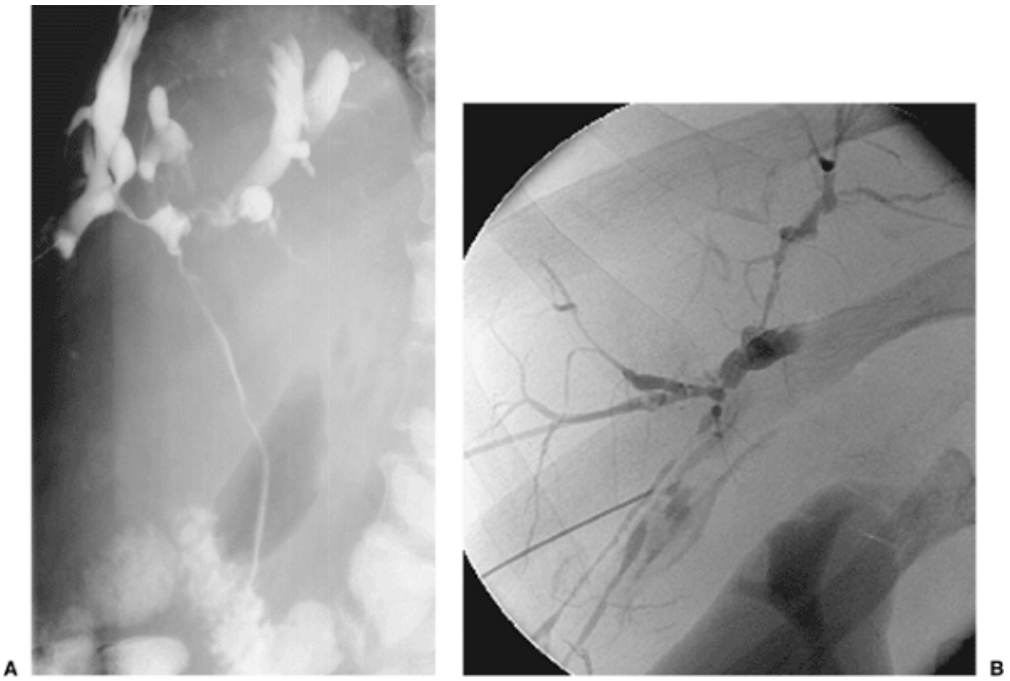


▪ **Figure 5.13** Percutaneous transhepatic cholangiogram in a patient with pancreatic carcinoma and jaundice. There is dilatation of the extrahepatic biliary system with abrupt tapering at the head of the pancreas (*arrow*) and mild intrahepatic ductal dilatation (left greater than right).



▪ **Figure 5.14** Percutaneous transhepatic cholangiogram and biliary drainage from both the right and left lobes of the liver. There is an obstructing mass (metastatic gastric carcinoma) to the porta hepatis, with obstruction of all bile ducts at this level.

When an obstruction is seen involving the extrahepatic bile ducts or the lobar bile ducts at the porta hepatis, the puncture needle is exchanged over a guide wire and an external drainage catheter is placed. An 8- or 10-Fr drainage catheter works adequately for external biliary drainage in most cases unless the bile is purulent or excessively thick, in which case a 12-Fr drainage catheter may be used. External drainage typically concludes the procedure for the day. Additional procedures that may require successful passage across the biliary obstruction, such as external–internal catheter drainage (Fig. 5.16), or internal stent placement, are best done after bile has been drained for 1 or 2 days and the risk of biliary sepsis has passed. Furthermore, external drainage for this period allows the biliary tree to decompress and return to a more normal caliber. This also reduces the time the interventionalist must spend attempting to pass the obstruction and helps limit catheter manipulations and both the patient's and the physician's radiation exposure.



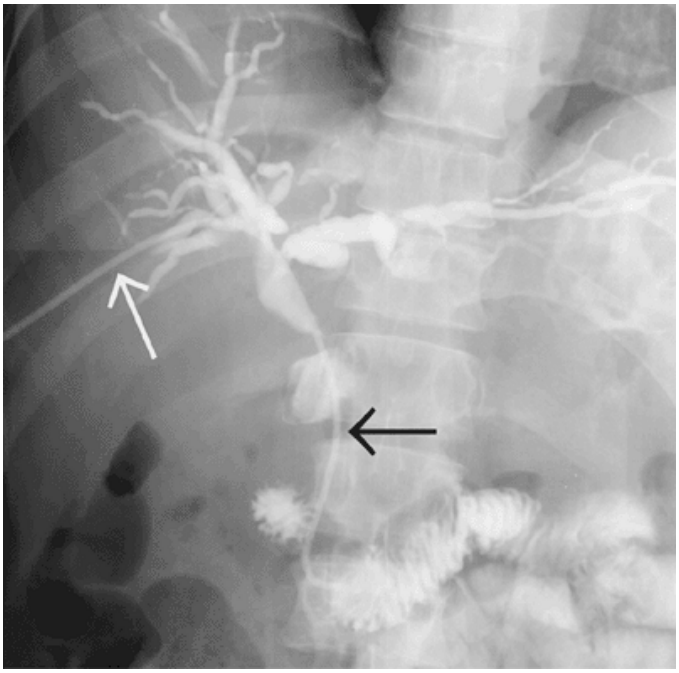
▪ **Figure 5.15** Examples of intrahepatic biliary strictures seen on percutaneous transhepatic cholangiogram. **A:** Cholangiocarcinoma involving the right and left intrahepatic bile ducts just above their confluence, with dilatation of the biliary tree in the periphery. **B:** Sclerosing cholangitis with strictured and irregular intrahepatic biliary radicals seen in many areas.

Liver Biopsy

Two methods are used to biopsy the liver—transabdominal biopsy and transvenous biopsy. The transabdominal approach is preferred in most situations because it can be

used to sample diffuse and focal liver disease and is generally quite safe and effective.

Transvenous liver biopsy is usually reserved for patients who have diffuse liver disease and comorbid conditions that make transabdominal biopsy unsafe.



▪ **Figure 5.16** Percutaneous transhepatic biliary drainage in a patient with an obstruction at the middle of the common bile duct. Both the *arrows* point to the 8-Fr drainage catheter that passes into the liver, through the right biliary system, down the common bile duct, and terminates in the duodenum. This type of catheter can be used for external drainage or capped for internal drainage.

Transabdominal Liver Biopsy

Transabdominal liver biopsy requires a needle to be passed through the skin, across the peritoneum, through the liver capsule, and into the substance of the liver. It can be performed "blind" without any imaging when there is diffuse liver disease, but the addition of ultrasound guidance ensures the safety and effectiveness of the procedure with minimal additional cost. When focal lesions of the liver are biopsied, imaging is essential. If the lesion cannot be visualized with ultrasound, the procedure may need to be performed with CT guidance. Lesions as small as 0.5 to 1.0 cm can be biopsied with this guidance (14,15,16).

The biopsy may be performed using small gauge needles (21 or 22 ga) to aspirate a sample for cytology. The presence of a qualified cytopathologist at the time of biopsy will help ascertain that adequate diagnostic material has been collected. Alternatively, a variety of cutting needles with spring-loaded handles may be used to obtain a core of the liver for histology, which can be transferred to fixative (such as 10% buffered formalin) and analyzed with various staining techniques. This is particularly important for the biopsy of certain lesions, such as lymphoma and cholangiocarcinoma, in which adequate sampling and sample preparation are crucial in arriving at a diagnosis. When these types of malignancies are suspected, special staining techniques can be used to improve the diagnostic accuracy. Overall, the accuracy of achieving the final diagnosis for image-guided biopsy ranges from 90% to 100% for core biopsies and 60% to 84%

for fine-needle aspirates (17,18).

The risks of transabdominal liver biopsy include intraperitoneal bleeding, hematobilia, pneumothorax (for right-lobe biopsies when the needle is passed through the base of the lung), and arteriovenous (AV) fistula formation. Bleeding can be avoided by taking a number of steps before and during the biopsy procedure. Correction of any coagulation abnormalities is essential. When ascites is present there is an increased likelihood of intraperitoneal hemorrhage, so postbiopsy embolization of the transhepatic tract and/or preprocedure drainage of ascites should be considered. All efforts should be made to ensure that the patient avoids deep respirations during the passage of the biopsy needle because this will help avoid liver laceration. If possible, the patient should be counseled to breathe shallowly if the biopsy requires more than 20 seconds or breath holding if the biopsy can be performed in less than 20 seconds. Postprocedure monitoring will reveal signs of bleeding, such as tachycardia, hypotension, and prolonged pain. We typically check the hematocrit 4 to 6 hours after liver biopsy and compare the results to the prebiopsy hematocrit. A drop of more than 2% to 3% should prompt further evaluation.

In a series of 853 ultrasound- and CT-guided liver biopsies, the rate of significant complications was 0.3% (19). The overall mortality rate for transabdominal biopsy is in the range 0.004% to 0.031% (20,21).

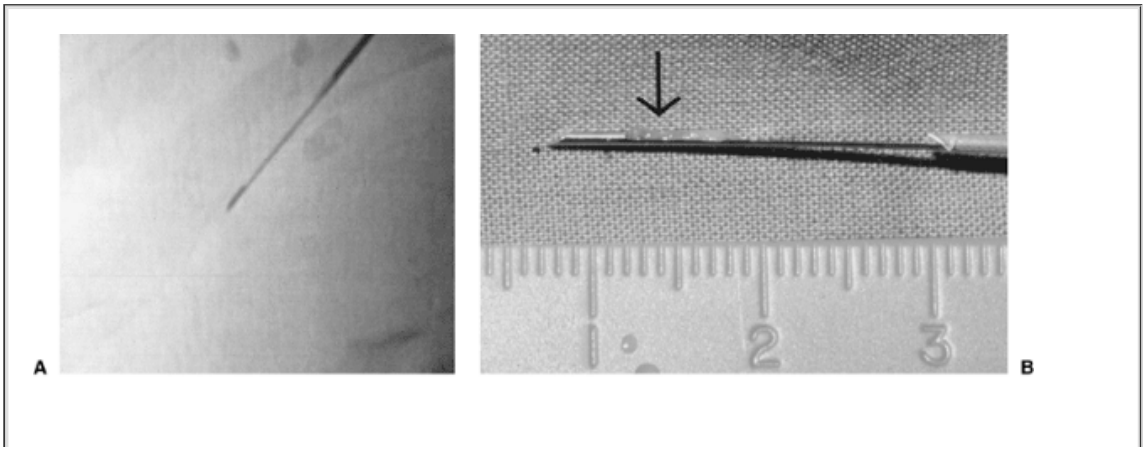
Transjugular Liver Biopsy

For patients who need liver biopsy and have comorbid conditions, such as coagulopathy (thrombocytopenia or elevated prothrombin time), ascites, or morbid obesity, or who are undergoing hepatic venography, transvenous liver biopsy is a reasonable alternative to the transabdominal approach. Over the last few years a variety of new biopsy needles have been developed that offer advantages over the original beveled 15-ga Colapinto needle.

Transjugular liver biopsy (TJLBx) was originally described in 1973 by Joseph Rosch (22), however, it was not until the 1980s that this technique was used commonly. This technique assumes that passage of the biopsy needle may induce bleeding, but because the bleeding will occur into the hepatic vein (the site where the biopsy needle enters the liver), blood will enter the vascular system without clinical consequence. The theoretic advantage of this approach has been confirmed in thousands of TJLBxs.

TJLBx needles can rarely be directed with accuracy into focal hepatic lesions because the needles are

relatively cumbersome and few hepatic lesions can be seen under fluoroscopy. Therefore, TJLBx is reserved for patients with diffuse liver disease, including cirrhosis, BCS, veno-occlusive disease, and infiltrative and metabolic processes of the liver such as storage diseases, hemochromatosis, and Wilson disease. On occasion, TJLBx can be used to perform biopsy on a large centrally located tumor within the liver.



▪ **Figure 5.17** Transjugular liver biopsy (TJLBx). **A:** TJLBx needle placement immediately before obtaining a core biopsy. **B:** Partial core within the cutting chamber of the needle (*arrow*).

TJLBx is typically started with an internal jugular vein puncture, either right sided or left sided. If necessary, the external jugular vein can be accessed. A catheter is negotiated through the superior vena cava, right atrium, and IVC, under fluoroscopic guidance. Then, one of the hepatic veins is entered, confirming the location of the catheter by hepatic venography. The catheter is exchanged over a guide wire for the biopsy system, and a puncture is made from the hepatic vein into the hepatic parenchyma (Fig. 5.17A). The needle is withdrawn and the specimen is inspected (Fig. 5.17B) and then transferred from the biopsy needle to the fixative for ultimately delivering to the laboratory.

A recent advance, the Quick-Core biopsy needle (Cook Inc., Bloomington, IN), has improved the yield from TJLBx. This device is a spring-loaded cutting needle that gives reliable core biopsy samples for histology while maintaining the safety of the biopsy procedure (23,24).

Although the incidence of TJLBx-related complications in this high-risk group is low, there are nevertheless some procedures in which the biopsy needle inadvertently traverses the liver capsule. The rate of intraperitoneal hemorrhage has been reported as 0.35% in TJLBxs from Colapinto's series of 2,271 cases (25). Yet, with careful patient selection, preprocedure review of imaging studies, attention to procedural detail, and postprocedure patient monitoring, TJLBx has become a safe method for obtaining liver tissue from patients who are considered to be at risk for transabdominal liver biopsy.

Angioplasty and Stenting

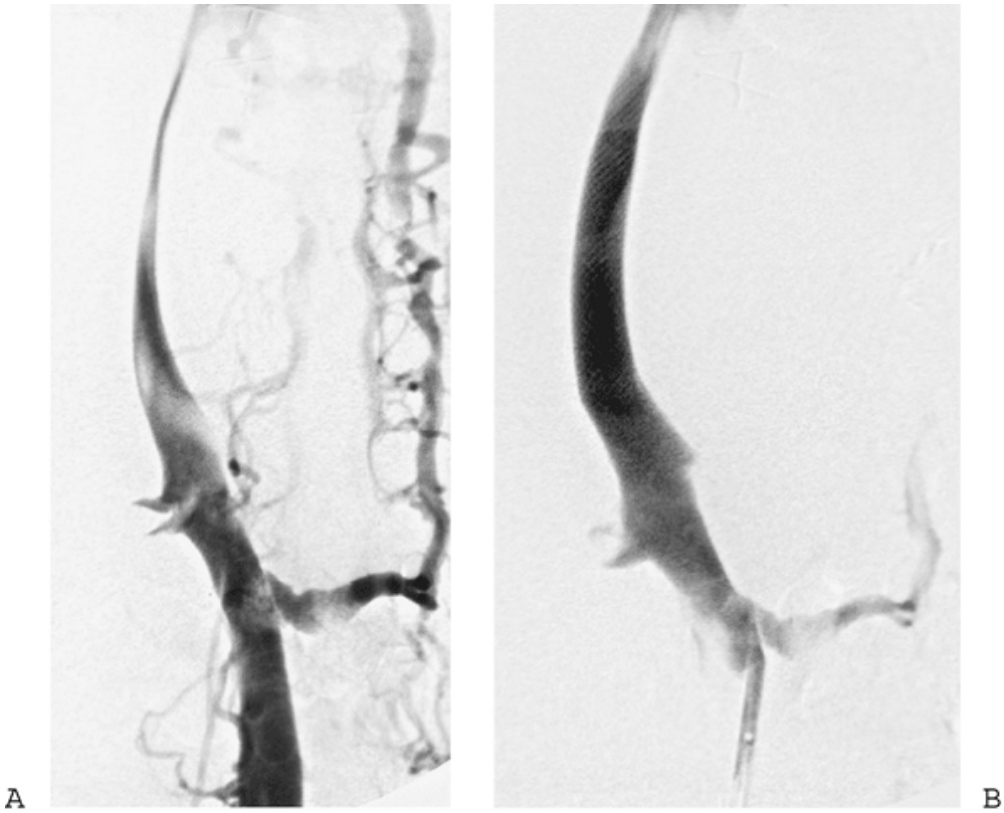
Angioplasty was developed in the 1960s as a minimally invasive approach for treating peripheral atherosclerotic disease. By the mid-1970s, the angioplasty balloon that we use today was developed, permitting vascular dilatation to a much greater diameter than was possible with earlier systems. Further refinements of angioplasty balloons and techniques have led to contemporary balloons that can withstand inflations to a pressure of 20 atm or greater and resist puncture during stent deployment.

Stents were conceived in the 1960s but not introduced for human use until the late 1980s. The original two stents were the Palmaz balloon-expandable stent and the self-expanding Gianturco Z-stent. Both types were used for creation of early TIPS shunts, and both types of stents continue to be used for hepatobiliary indications. The last decade has seen the introduction of a number of new stents, including the Wallstent, the Smart stent, the Zilver stent, and the Luminexx stent to name but a few devices. There are many hepatobiliary uses of angioplasty balloons and metal stents today. These include creation and revision of TIPS shunts, stenting of bile duct occlusions, angioplasty and stenting of hepatic vein and IVC occlusions related to BCS and tumors, and angioplasty and stenting of vascular anastomotic stenoses in the transplanted liver.

Arterial Angioplasty in Hepatobiliary Disease

Hepatic arterial stenoses after liver transplantation occur in up to 11% of cases and typically involve arterial anastomosis (26). Stenosis may lead to liver ischemia, cholangitis, liver necrosis, and ultimately transplant failure even in the absence of secondary arterial occlusion. If detected early, these stenoses can

be dilated with technical success, thus averting the need for surgical revision of the anastomosis (27,28). Once a transplant hepatic artery stenosis progresses to thrombosis, most patients will require retransplantation (29). There are no clear indications for stenting of transplant-related arterial stenoses; however, in the appropriate setting, conversion of a failed angioplasty to a successful stenting would seem appropriate.



▪ **Figure 5.18** Patient with inferior vena cava (IVC) obstruction due to cystic gastric sarcoma metastases. **A:** The IVC is diffusely stenosed, and there are multiple collaterals that communicate with the azygos venous system. **B:** After the IVC has been dilated and stented, there is direct blood flow into the right atrium and nearly complete cessation of flow into the azygos system.

Venous Angioplasty and Stenting in Hepatobiliary Disease

Malignant tumors of the liver can compress and/or invade the IVC, leading to massive lower extremity edema. When IVC obstruction involves the hepatic veins or a portion of the IVC at or above the hepatic veins, the patient may also develop ascites. Angioplasty alone is of little use because elastic recoil of the tumor causes recurrent IVC occlusion. Stenting of the IVC, however, can maintain the patency of the IVC and palliate the symptoms of IVC obstruction (Fig. 5.18A,B). Typically, self-expanding stents such as the Gianturco Z-stent and Wallstent have been used because they are less prone to migration and deformation compared to balloon-expandable stents. The reported series on stenting of the IVC are small, but the clinical success reported by Furui et al. in a series of 16 patients with IVC obstruction due to malignant tumors of the liver who were treated with Gianturco Z-stents was 100%, with no symptomatic recurrence at a mean follow-up of 3.2 months (30). Entwisle et al. also reported

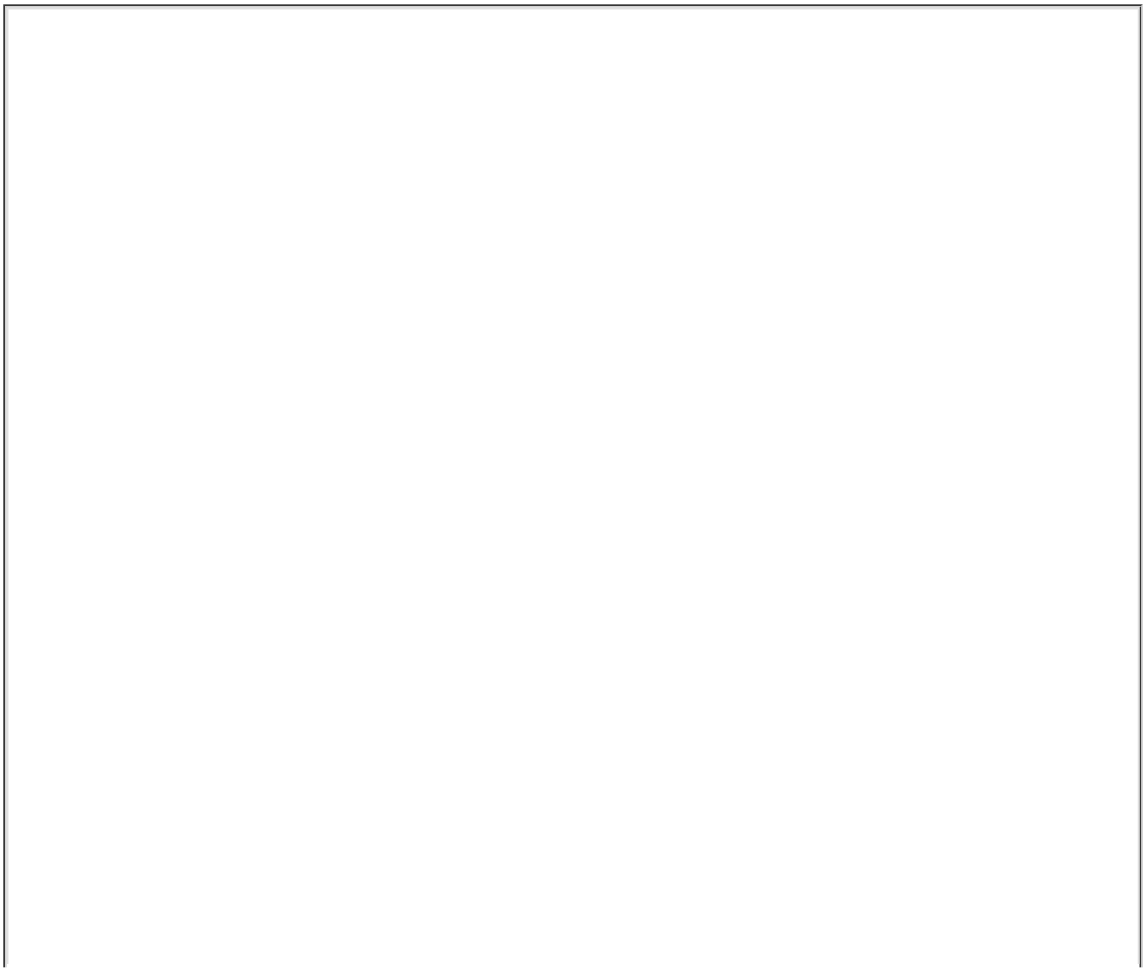
success in using the Wallstent to treat malignant IVC obstruction (31).

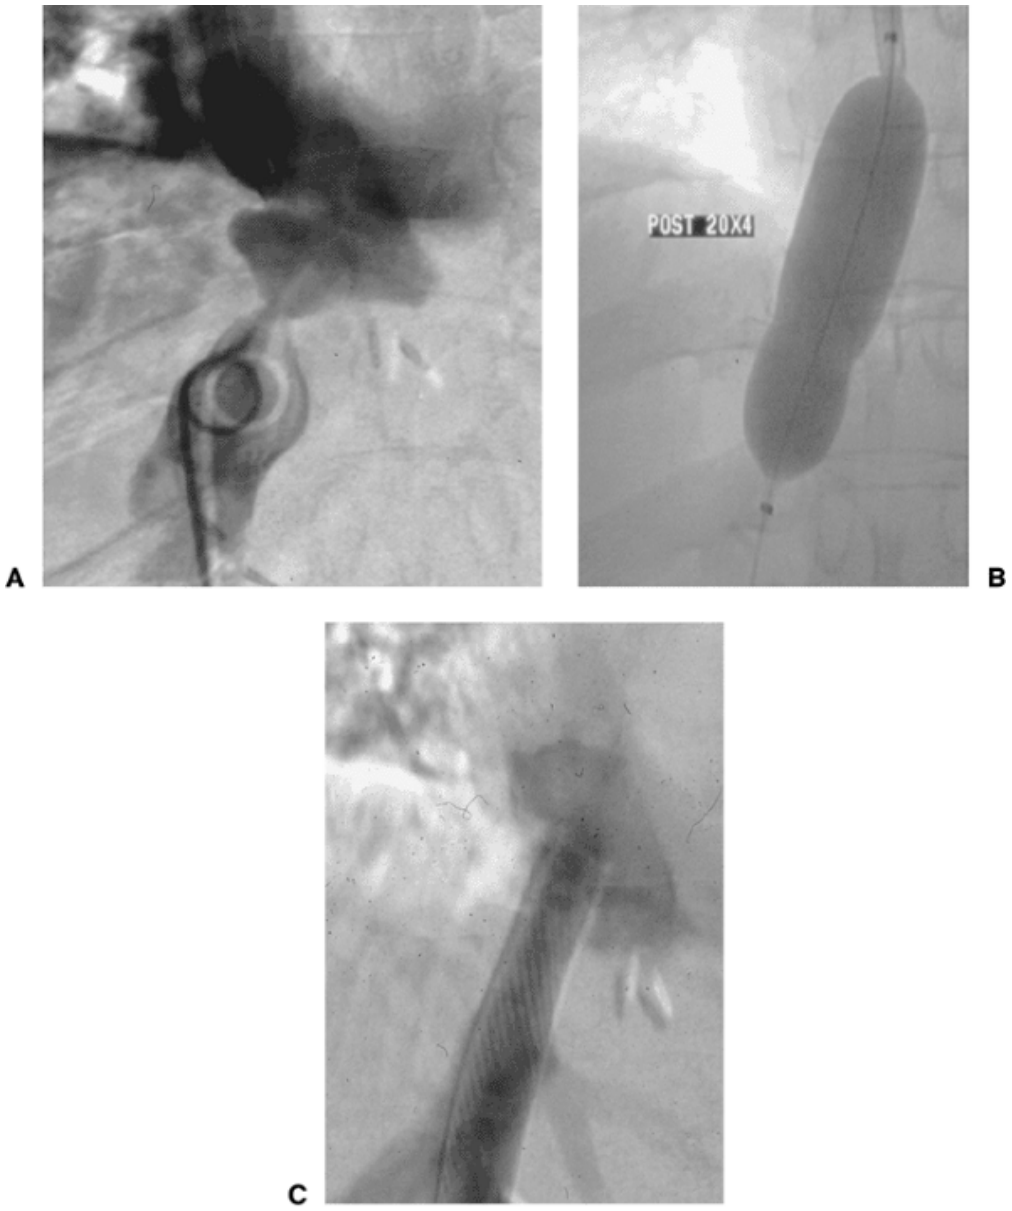
Balloon dilatation and stenting of posttransplant IVC stenosis after liver transplantation (Fig. 5.19A, B and C) has been reported in a small series (32,33,34). These techniques may help patients undergoing liver transplantation avoid surgical revision or retransplantation and should be considered as the first option when hemodynamic IVC stenosis is detected. The only caveat about stenting for this indication is that once placed in the IVC, the stent may complicate the surgeon's approach if retransplantation becomes necessary. In general, once the decision to place a stent is made in concert with the surgeon performing the transplantation, a Wallstent is preferred because it is easily cut with a scissor and, if necessary, the stent wires can removed when imbedded in tissue. The stent wires in a Gianturco Z-stent are difficult to cut and harder to extract once entrapped in tissue.

BCS represents hepatic venous occlusion that often involves the intrahepatic IVC. Venographically, there are many presentations, such as occlusive and nonocclusive thrombus in the hepatic veins, as well as webs in the hepatic veins and IVC. Many of the lesions seen in BCS can be treated using angioplasty and stenting with a high degree of success. The goal is to improve the outflow of blood from the liver and retard the process of hepatic necrosis and fibrosis.

A number of small series have described angioplasty and stenting for IVC occlusions due to BCS. In one report, 32 patients were treated using angioplasty with or without stenting. Technical success for angioplasty

and for stenting was 100%. The primary patency rate for the target stenosis or occlusion for angioplasty was 50%, and for stenting the primary patency rate was 88% (35). Another report described the use of the Wallstent to treat obstructions of the hepatic and suprahepatic IVC, with no restenoses reported in all ten patients (36).





▪ **Figure 5.19** Inferior vena cava (IVC) stricture after transplantation, with angioplasty and stenting. **A:** There is a focal IVC stricture just above the level where the hepatic veins enter the IVC. **B:** A 20-mm angioplasty balloon is used to predilate the stricture. **C:** A Wallstent is placed in the IVC and supports the angioplasty so that blood flow into the right atrium is no longer impeded.

The hepatic vein strictures and occlusions in BCS have also been approached with angioplasty and stenting techniques on a case-by-case basis. It is possible to stent stenoses of the hepatic veins (37) or to recanalize hepatic vein occlusions to "reconnect" the hepatic veins using a stent to support the postangioplasty channel that is created (38) (Fig. 5.20A,B).

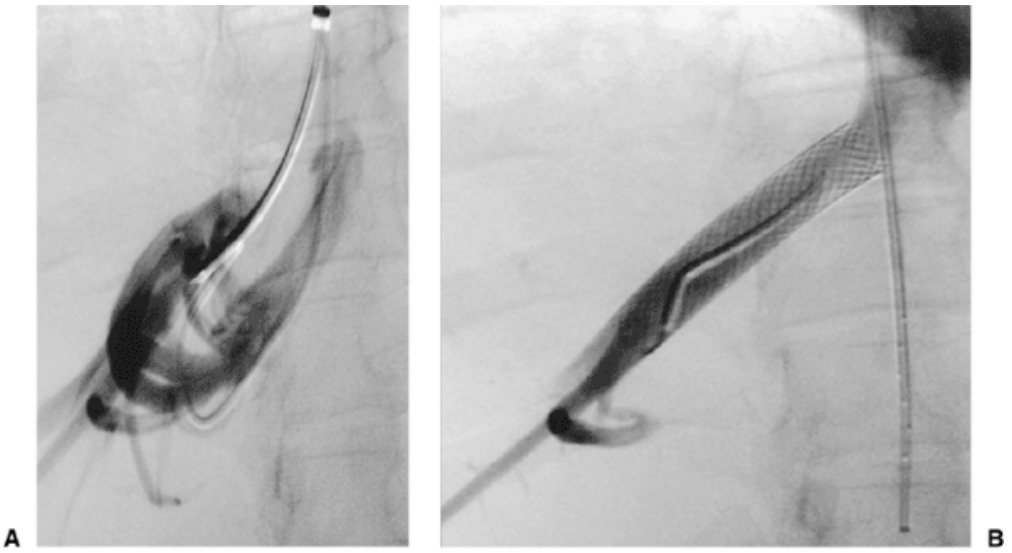
Portal vein strictures can be due to surgery (including transplantation), pancreatitis, or incomplete portal venous thrombosis. Angioplasty (39) and stents (40) have been used successfully to treat these lesions.

Transjugular Intrahepatic Portosystemic Shunt

The TIPS procedure represents the culmination of many percutaneous catheter-based techniques, including CO_2 venography, transvenous pressure measurements, angioplasty techniques, and stenting.

Biliary Balloon Dilatation (Cholangioplasty) and Stenting

Biliary strictures can be divided into benign and malignant types. The percutaneous management of these two types of lesions is distinctly different.



▪ **Figure 5.20** Reanastomosis of the right hepatic vein in a patient with Budd-Chiari syndrome. (Same patient as in Fig. 5.11.) **A:** A puncture is made from the stump of the right hepatic vein into the remaining intrahepatic portion of the right hepatic vein. **B:** After the puncture reconnects the right hepatic vein, the obstruction is balloon dilated and stented, restoring flow from the right hepatic vein into the inferior vena cava.

Benign biliary stricture dilatation

Benign strictures are typically iatrogenic (i.e., caused during surgical bypass, laparoscopic cholecystectomy, common bile duct exploration, or liver transplantation) or rarely due to underlying stone disease or adjacent inflammation such as pancreatitis. Although it is usually possible to dilate a benign biliary stricture, the results are variable. Citron and Martin (41) described 100% technical success rate for the dilatation of intrahepatic biliary strictures and 92% for the extrahepatic biliary tree strictures above the pancreas. The results were poor for intrapancreatic biliary strictures, with only a 33% success rate. The overall restenosis rate, excluding the intrapancreatic strictures, was 29%, which compares favorably with a restenosis rate of 20% to 22% from surgical series (42,43) and other interventional radiology series that reported 20% to 34% recurrence (44,45,46). It is currently the practice of most interventional radiologists to dilate biliary strictures to a diameter of 6 to 10 mm and then leave a biliary drainage catheter across the site for several months. This provides support to the dilated stricture during healing and maintains access for cholangiography before catheter removal to confirm an acceptable result at the dilated

segment.

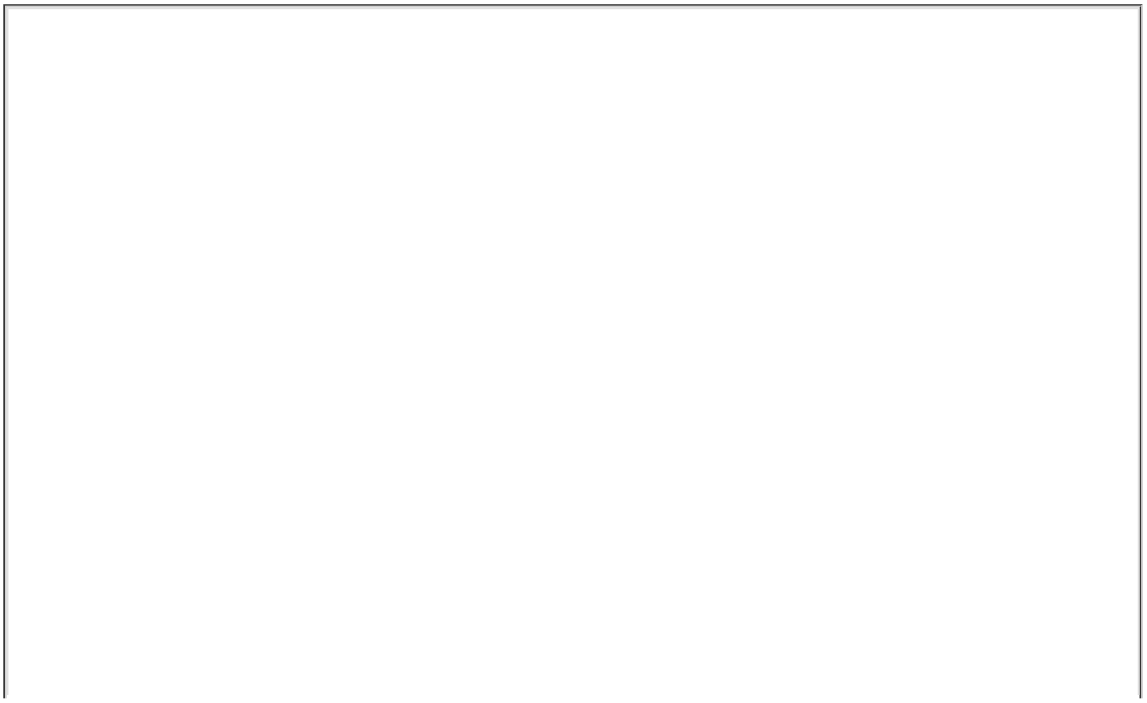
Biliary manometry can be used to assess the likelihood of successful stricture dilatation. Savader et al. (47) found that biliary manometry was a useful tool in predicting the durability of the intervention. The procedure involved a simple pressure measurement in the bile duct a mixture of contrast and saline was infused at a step-up rate every 5 minutes until a rate of 20 mL/minute was reached. Patients whose intrabiliary pressure remained less than 20 cm H_2O during all infusion rates without symptoms of pain, nausea, vomiting, or chills were considered to have "passed" the perfusion test. Patients who passed the perfusion test had a 0.9 probability of patency at 3 years, whereas patients who failed had a 0.45 probability of patency at 3 years. Alternatively, patients could be managed by "clinical trial," converting the supportive biliary catheter to one that resided above the site of dilatation and then capping the tube for several weeks so that it would serve as an access to the biliary tree if necessary. If the patient had nausea, vomiting, fever, chills, bile leakage, or discomfort flushing the catheter, they were considered to have failed the clinical trial. If the patient remained asymptomatic, the tube was removed. With either manometry or clinical trial, patients who were likely to have success and those who were likely to fail after biliary dilatation or surgery were identified.

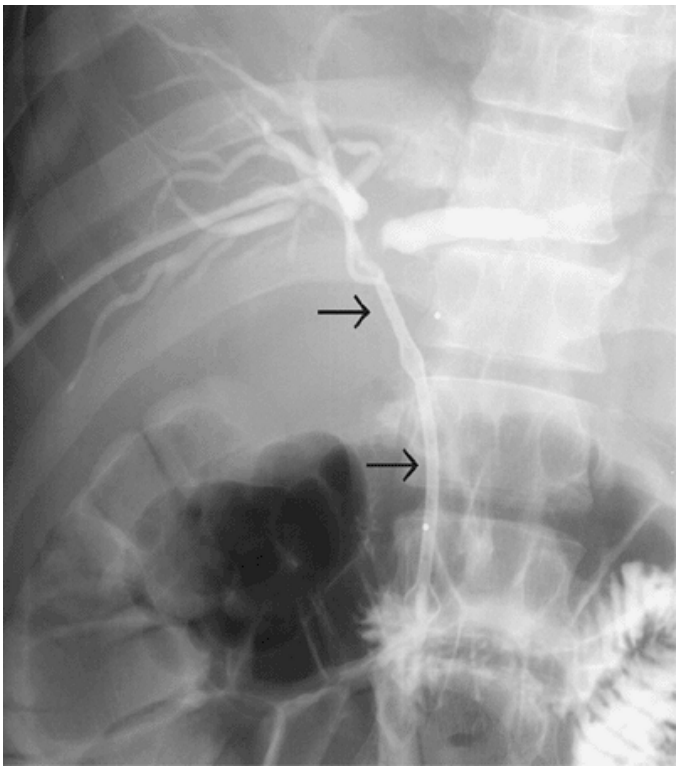
Although the placement of a percutaneous biliary catheter is an essential component of visualizing transhepatic cholangioplasty of benign strictures, there has been no proof that the placement of a permanent metallic stent offers any patency advantage despite the demonstration of a typically superb immediate technical result. In fact, the placement of a metallic biliary stent is usually avoided when treating benign strictures because the durability of treatment is measured in years, whereas metallic biliary stents often occlude within a few months because of a variety of causes, as described in the following text.

Malignant stricture dilatation

Unlike many benign biliary strictures, malignant strictures do not respond favorably to balloon dilatation

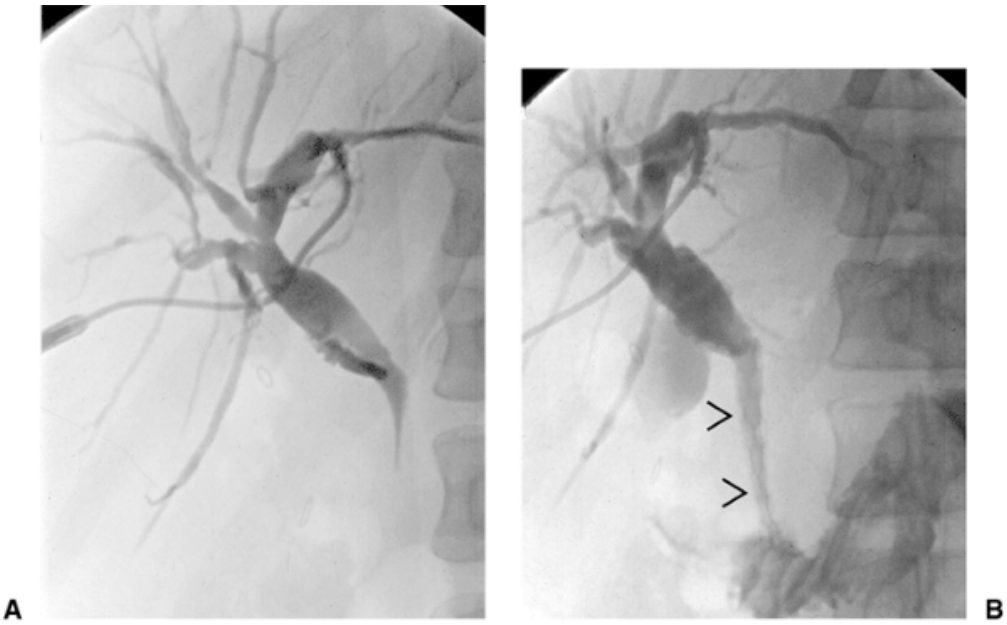
alone because of the mass effect and elasticity of the tumor and adjacent tissues such as enlarged lymph nodes. To achieve an acceptable technical result after balloon dilatation of a malignant biliary stricture, addition of a stent is necessary.





▪ **Figure 5.21** Percutaneously placed internal biliary stent. The stent (*arrows*) resides in the extrahepatic bile duct, with its distal tip entering the duodenum. These tubular plastic stents are particularly prone to occlusion. Furthermore, and as seen in this case, it may be difficult to position this stent accurately if there is a lesion in the porta hepatis or high extrahepatic biliary tree.

Many different stents, both plastic (Fig. 5.21) and metal (Figure 5.22A,B), have been developed for the biliary tree, and they all afford an excellent technical result at the end of the procedure. Unfortunately, these stents are also fraught with early (<30 days) and late (>30 days) complications. In a comparative series, metallic stents had an early occlusion rate of 18%, which was nevertheless better than plastic stents, with a 50% early occlusion rate (48,49). Therefore, endoscopically placed metal stents have a distinct advantage over plastic stents in the first month. A similar comparison was done for percutaneously placed stents, with an early obstruction rate of 19% versus 27% for metal versus plastic stents (50). The median patency of percutaneously placed metal stents was much greater than of plastic stents—272 days versus 96 days, respectively ($P < 0.01$). Nevertheless, stent occlusion remains a problem even for metal stents. Occlusion occurs because of bile salt encrustation, inspissated gastric debris, tumor ingrowth, and epithelial hyperplasia. Therefore, the use of indwelling metallic stents is typically reserved for patients with a life expectancy less than a year, such as those with unresectable pancreatic carcinoma or metastatic adenocarcinoma. For patients with slowly growing malignancy, such as many of those with cholangiocarcinoma, internal metal stents are problematic, and we usually recommend internal–external biliary catheters that can be easily changed every 3 to 6 months over a guide wire using a percutaneous transhepatic approach.



▪ **Figure 5.22** Pre- and post–stent images in a patient with pancreatic carcinoma. **A:** There is abrupt tapering of the distal common bile duct because of obstruction from the pancreatic head mass. **B:** A self-expanding metal biliary stent has been placed, restoring continuity between the biliary system and the duodenum (*arrowheads*).

In summary, benign strictures above the level of the pancreas typically respond to balloon dilatation, and placement of a metallic indwelling stent should be avoided. The cholangioplasty site, however, should be internally supported during the healing process by placing a temporary plastic drainage catheter or

an endoscopically removable plastic stent. Malignant biliary strictures almost always require internal stent placement, and metal stents are preferred over plastic stents because of a relative patency advantage. Nevertheless, all internal stents are prone to occlusion, and internalized biliary stents are recommended for patients with limited life expectancy or those who are willing to accept the likelihood that additional procedures will be needed to treat an obstructed internalized stent.

Thrombolytic Therapy

The use of thrombolytic agents in hepatobiliary disease is not common but can offer dramatic nonsurgical cure for acute portal vein thrombosis (50,51). Thrombolytic agents such as tissue plasminogen activator (tPa) can be infused into the mesenteric venous clot by direct portal vein access, as described previously for transhepatic portography. Alternatively, thrombolytic agents have been delivered into the superior mesenteric artery with transcapillary passage into the venous circulation (52).

Eagerness to treat mesenteric vein thrombosis with thrombolytic agents, however, should be tempered until the cause for thrombosis has been determined and the risk for bleeding while on thrombolytic treatment assessed. It is important to recognize that a number of conditions may cause portal vein thrombosis, and accurate diagnosis and treatment may be necessary before initiating thrombolytic therapy. These conditions include primary disorders of thrombosis, myeloproliferative disorders, and dehydration. Multiple concurrent factors may lead to portal vein thrombosis (53).

Embolotherapy

With the ability to catheterize fourth- and fifth-order hepatic arterial branches, embolotherapy techniques are used frequently to treat hepatic artery injury and AV lesions of the liver. When embolotherapy is coupled with transcatheter delivery of chemotherapeutic agents or radioactive particles, the combined effect offers aggressive ablation of liver tumors. Transhepatic portal vein embolization (PVE) is evolving as a method to hypertrophy a portion of the liver that will remain in the patient after partial hepatic resection.

Embolotherapy of Nonmalignant Lesions of the Liver from the Hepatic Artery

Embolic agents used in the hepatic artery include particulate materials (polyvinyl alcohol [PVA], polyacrylamide microspheres, microfibrillated collagen, and gelfoam particles and pledgets), embolic metal coils, oily agents (Ethiodol and Lipiodol), adhesives, autologous clot, and detachable balloons. Each type of agent is selected for a particular property such as the size of vessel it will occlude, flow rate across the lesion (especially important when treating high-flow AV shunts), and the need for short-term versus permanent occlusion.

AV lesions of the liver are rare. When an AV shunt is guided from the hepatic artery into the portal venous system there may be signs of portal hypertension such as ascites, formation of varices, variceal hemorrhage, or encephalopathy. Venovenous shunts can develop, connecting the portal venous system to the systemic system, with clinical manifestations of encephalopathy, seizures, and heart failure.

Trauma is a well-recognized cause of hepatic AV fistula formation. Using particulate emboli and coils, it is possible to occlude all branches, leading to a complex AV fistula or AV malformation, and provide a durable cure (Fig. 5.23A–C). An example of a venovenous shunt is the persistent ductus venosus, a rare condition in which a persistently patent ductus venosus shunts blood from the left portal vein to the LHV. Careful delivery of embolic coils can permanently occlude this shunt and restore portal flow to the liver (Fig. 5.24A,B).

Aneurysms and pseudoaneurysms of the hepatic artery are uncommon. They may be due to hepatitis, trauma, pancreatitis, tumor, or iatrogenic causes (Fig. 5.25A,B) such as biopsy or biliary drainage. Pseudoaneurysms can also be related to the disruption of the anastomosis of the hepatic artery during liver transplantation. Many of these lesions can be managed with therapeutic transcatheter embolization.

Transarterial Chemoembolization of Malignant Tumors in the Liver

Delivery of embolic agents along with chemotherapy, termed *TACE*, has become one of the methods for palliation of hepatocellular carcinoma, cholangiocarcinoma, hepatic metastases from carcinoid tumors, islet cell tumors, and ocular melanoma. Many chemoembolic concoctions have been promoted over the years. Perhaps the most widely employed techniques call for embolic PVA particles mixed with a three-drug regimen that includes doxorubicin, cis-platinum, and mitomycin-C, although there are also many reports on the use of only one chemotherapeutic agent such as doxorubicin or cis-platinum. The addition of an oily contrast agent (Ethiodol or Lipiodol) is believed to enhance the embolic effect of particles by occluding flow at the sinusoidal level (54,55). The use of oily contrast also helps the interventional radiologist during the administration of the chemoembolic mixture because these oily agents are densely radioopaque and, therefore, easily seen as they enter the hepatic arterial system and tumor (Fig. 5.26A,B).

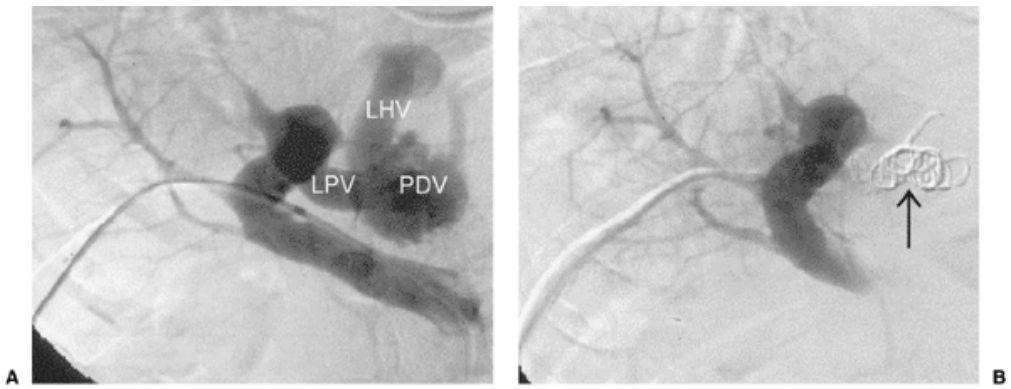
▪ **Figure 5.23** Arteriovenous fistula (AVF) and embolization. This young man sustained a liver laceration 10 years earlier and presented with signs of portal hypertension including ascites and varices. **A:** There is a complex AVF connecting the right hepatic artery (HA) to the right portal vein (PV), with contrast entering the main PV. **B:** Occlusive metal coils and small gelfoam pledgets have been used to perform therapeutic embolization of the AVF. There is no residual PV filling. **C:** Six-month follow-up angiogram. The AVF remains thrombosed. The main HA has returned to near-normal caliber. Intrahepatic collaterals have developed from the left hepatic arterial system to the right during this interval. The patient no longer evidenced signs or symptoms of portal hypertension.

A number of investigations have been performed demonstrating the effectiveness of this multitherapy embolic regimen in the treatment of hepatocellular carcinoma (56,57,58,59). Most reports of TACE for the treatment of unresectable hepatocellular carcinoma note tumor regression in many patients and prolonged periods of tumor stability with minimal treatment-related toxicity. Survival of these patients after TACE is prolonged compared with historical survival data for patients not treated in this way (56,58).

Randomized data has recently become available. Three prospective randomized trials and one meta-analysis confirm the survival advantage of TACE compared with supportive care or bland particle embolization (no chemotherapy) for unresectable hepatocellular carcinoma. Llovet et al. (60) randomized 112 patients, with most of them being infected with hepatitis C virus and classified as Child-Pugh A (70%), into one of three groups—TACE, bland embolization (no chemotherapy), and supportive

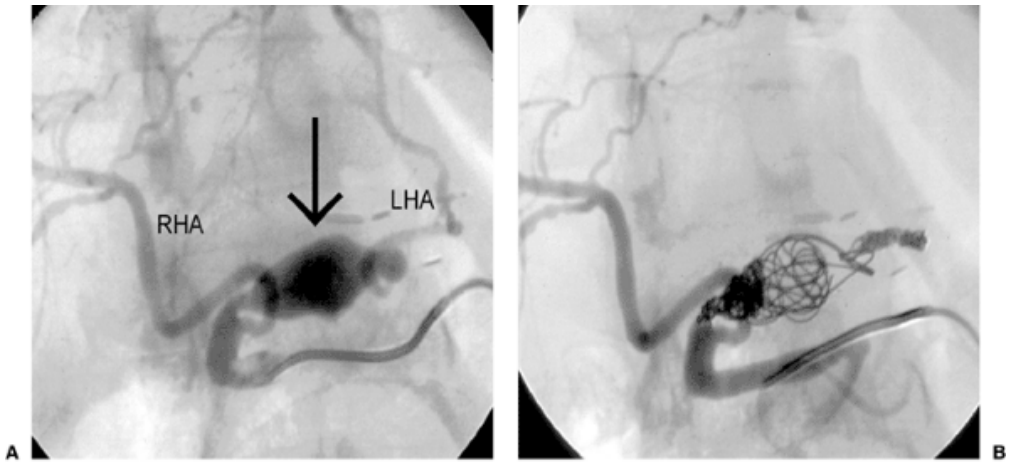
medical therapy. The median tumor size was 5 cm (range 3.9 to 6 cm) and patients with portal vein invasion were excluded. This trial was halted early when a clear survival advantage was seen with TACE compared to supportive therapy. The 1-, 2-, and 3-year survival rates for TACE were 82%, 63%, and 29%, respectively, while the survival rates for supportive therapy were 63%, 27%, and 17% at 1, 2, and 3 years, respectively (*P* = 0.009). Patients receiving TACE also had better survival than those who underwent treatment of their tumor using bland

particle embolization (no chemotherapy). In the study by Llovet et al. the TACE regimen included doxorubicin and Lipiodol while bland particle embolization was performed with gelfoam particles.



▪ **Figure 5.24** Patent ductus venosus (PDV). This patient presented with right-sided heart failure and had several recent seizures. Ammonia levels were elevated. **A:** Transabdominal-transhepatic portal vein catheterization into the right portal vein. Portal venography demonstrates dilatation of the left portal vein (LPV), the presence of a PDV, and flow into the left hepatic vein (LHV). **B:** Transcatheter embolization of the communication branch of the LPV and the PDV has been successful. This patient's cardiac dynamics improved and his ammonia levels normalized.

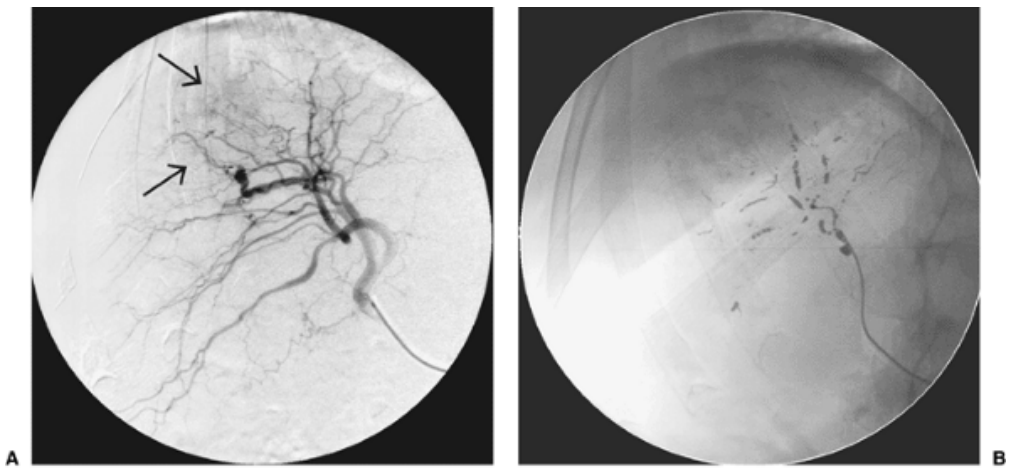
Lo et al. (61) reported a series of patients with unresectable hepatocellular carcinoma who were treated with a cis-platinum and Lipiodol TACE regimen. Most patients were positive for hepatitis B virus (HBV), mean tumor size was 7 cm (range 4 to 14 cm), and patients with portal vein invasion were allowed into the study. Patients were randomized between TACE and supportive therapy. The 1-, 2-, and 3-year survival in the TACE group was 57%, 31%, and 26%, respectively, while survival in the supportive therapy group was 32%, 11%, and 3%, respectively.



▪ **Figure 5.25** Catheterization of the proper hepatic artery followed by therapeutic transcatheter embolization of a left hepatic artery pseudoaneurysm. **A:** This patient had liver transplantation several years earlier, and a hepatic artery pseudoaneurysm was incidentally noted on a computed tomography (CT) scan obtained for other reasons. Hepatic arteriogram showing that the pseudoaneurysm (*arrow*) arises from the left hepatic artery (LHA). The right hepatic artery (RHA) arises proximal to the pseudoaneurysm. **B:** Therapeutic transcatheter coil embolization of the pseudoaneurysm and the short segment of the LHA leading into and away from the pseudoaneurysm. Intrahepatic arterial collaterals from right to left were seen immediately after the occlusion of the proximal LHA.

Yuen et al. (62) reported a comparative trial of 96 patients with hepatocellular carcinoma, with a preponderance of patients who were HBV positive,

randomized between TACE (cis-platinum and Lipiodol and supportive therapy. Although the median tumor size was 3 to 4 cm, the range of tumor size was quite wide and the trial included tumors as large as 20 cm diameter. Patients were mostly classified as Child-Pugh A. The median survival time of the patients receiving TACE was 31.2 months while the control group had a median survival of 14.1 months (P = 0.0126). The 1- and 2-year survival for the TACE group was 86.3% and 78.8%, respectively, while the patients in the supportive therapy group had 1- and 2-year survival of 62.5% and 50%, respectively.



▪ **Figure 5.26** Transarterial chemoembolization of a hepatocellular carcinomas. **A:** There is neovascularity in this region of the right lobe hepatocellular carcinomas (*arrows*). **B:** The injection of the chemotherapeutic agent mixed with embolic particles and Ethiodol (oily contrast material) appears as droplets on the fluoroscopic image. These droplets migrate into the tumor with blood flow until enough occlusion has reduced the flow to the point of sluggishness or stagnation.

A meta-analysis of seven randomized studies of TACE for treating unresectable hepatocellular carcinoma was recently reported by Llovet and Bruix (63). This analysis also demonstrated that TACE offers a survival benefit, with a reduced risk of death at 2 years for TACE compared with supportive therapies (odds ratio 0.42 to 0.53 depending on which trials were included in the analysis).

Although randomized studies now validate the advantages of TACE over supportive therapy, a critical review of this literature shows that there is still much work to do. There is no agreement regarding the optimal chemotherapeutic agent(s), the optimal embolic agent(s), or even whether TACE should be performed as a scheduled series of treatment or only when there is evidence of disease progression. Many of these unresolved issues are highlighted in the recent review by Reidy and Schwartz (64).

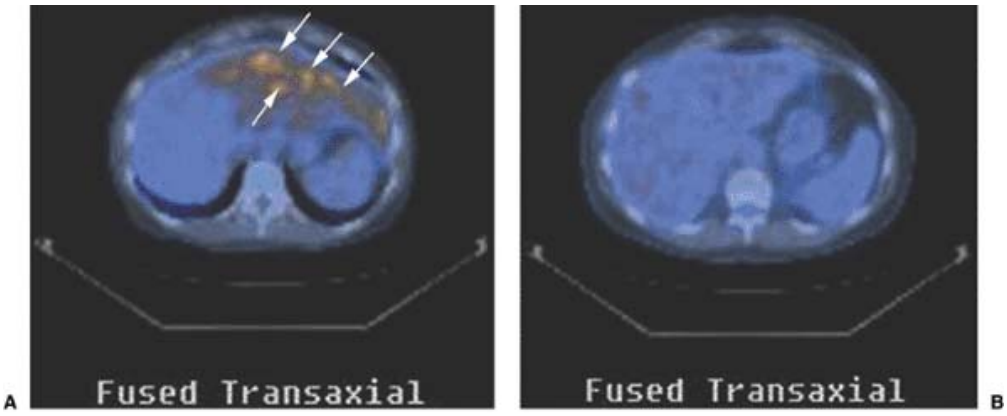
There is no randomized data on TACE for the treatment of unresectable cholangiocarcinoma; however, a recent report by Burger et al. (65) describes encouraging results in a group of 17 patients treated over a 5-year period. Nearly all patients were Child-Pugh A with a TNM staging of II or III. TACE consisted of embolic particles, Ethiodol, and a triple-drug mixture of doxorubicin, cis-platinum, and mitomycin-C. Eleven patients underwent only TACE, four had concurrent chemotherapy, and two had concurrent chemotherapy and radiation therapy. The median survival was 23 months, markedly better than historical reports of survival for patients with cholangiocarcinoma, in which the median survival was approximately 6 months and effective therapy very limited (66,67).

Hepatic metastases from carcinoid tumor respond to TACE, with many reports of tumor shrinkage and control of symptoms related to pharmacologically active metastases. When hepatic metastases from the carcinoid tumor are treated with TACE, the 5-hydroxyindoleacetic acid (5-HIAA) levels associated with the carcinoid syndrome normalize and symptoms resolve or diminish in most patients. Drougas et al. (68) reported an approximate 75% clinical response rate. Symptoms associated with carcinoid syndrome due to hepatic metastases such as diarrhea, flushing, abdominal pain, and malaise were successfully treated in most patients in this study. Additionally, biochemical markers of carcinoid metastases decreased by 60% ± 6% for 5-HIAA, 75% ± 10% for chromogranin A, and 50% ± 7% for neuron-specific enolase at 3 months (mean% ± standard error).

Symptomatic relief and tumor shrinkage have also been reported for a number of other types of pharmacologically active metastases including islet cell malignancies such as gastrinomas, glucagonomas, and

insulinomas. The reported success rate for symptom control after TACE treatment of these biochemically active metastases is reported to range from 90% to 100% (69,70,71,72,73).

Ocular melanoma metastases to the liver have been treated successfully using TACE. In a series of 30 patients, Mavligit et al. (74) reported an actuarial survival of 33% at 1 year, whereas the median survival for patients who treated by other methods is 2 to 6 months (75).



▪ **Figure 5.27** Selective internal radiation therapy (SIRT) of metastatic lung carcinoma to the liver. **A:** Fusion computed tomography/positron emission tomography (CT/PET) of a 52-year-old woman with metastatic lung cancer to the liver. The primary tumor has been removed and metastases to the liver (*arrows*) are the only identified sites of disease. **B:** Fusion CT/PET obtained 5 months after two treatments with SIRT. Whole liver treatment was performed twice, initially with 1.3 GBq of Yttrium 90 resin particles followed 8 weeks later with a second treatment using the same type of particles delivering 1.0 GBq. There was no demonstrable metastatic disease in the liver.

Finally, there has been increasing interest in use of TACE for metastatic colorectal carcinoma to the liver, which, in the United States, affects more people than the combined number of people with hepatocellular carcinoma, and hepatic metastases from carcinoid tumor, ocular melanoma, and islet cell tumors. To date, TACE appears to shrink the size of colorectal metastases, but there is still no clear survival advantage for these patients (76,77,78,79). Fortunately, other systemic and local–regional therapies have evolved for colorectal metastases to the liver. Local–regional therapies including transarterial radioembolization and radiofrequency ablation (RFA) are presented in the following two sections.

Transarterial Radioembolization of Malignant Tumors in the Liver

Intra-arterial delivery of radioactive Yttrium 90 microspheres, referred to as *SIRT*, is one of the more recent additions to the array of percutaneous ablative therapies for hepatic malignancies. Yttrium 90 is a pure β-particle emitter produced by neutron bombardment of Yttrium 89. The half-life of Yttrium 90 is 64.2 hours, and on radioactive decay it releases a β particle with the energy of 0.94 MeV and transforms to stable Zirconium 90. β-Particles released from decay of Yttrium 90 have a mean penetration of 2.5 mm into the tissue and a maximum range of approximately 11 mm. Yttrium 90 can be coupled to a carrier bead made of either resin (SIR-Spheres) or glass/ceramic (TheraSpheres) that are approximately 30 μm in diameter. When delivered through an angiographic microcatheter into the hepatic arteries that feed the liver tumor, these beads lodge in the tumor capillary bed and irradiate the surrounding tissue. Using this technique, between 5 and 50 million spheres are delivered to a tumor in the liver, depending on the type of particle, size of tumor, and dose calculations (80). Radioactive Yttrium 99 particles deliver an extremely high local radiation dose. One GBq (27 mCi) is within the range of a single therapeutic dose delivered during SIRT. Radioactive particles will deposit up to 3,000 Gy in a tumor (81).

The results of Yttrium 90 particle SIRT are impressive. In a small randomized series, the lifespan of those patients with colorectal carcinoma who had one dose of SIRT coupled with systemic chemotherapy was twice as good as that of the chemotherapy arm (82). These patients were treatment naïve and had normal liver function test results, and therefore, were not the usual patients seen in US clinical trials who had already failed prior systemic chemotherapy and had often presented with liver function abnormalities. Yet recent experience shows that even in studies of SIRT in patients who have failed systemic chemotherapy, mean survival is 10.5 months while nonresponders survive only 4 months (83,84,85). Similar results have been seen with cholangiocarcinoma, hepatocellular carcinoma, and metastatic breast, neuroendocrine, lung, and other malignant tumors in the liver (86,87,88,89). It is important to note that response may be characterized in different ways, and follow-up imaging studies may show persistent masses that have little or no residual malignant tissue. Because of this, serum tumor markers and/or imaging studies that also show tumor activity, such as CT fused with positron emission tomography (PET), may give a more reliable assessment of the success of SIRT treatment (Fig. 5.27A,B).

One major and avoidable complication of SIRT is unanticipated shunting of radioactive particles to the lungs. This may happen when there are abundant tumoral artery-to-systemic venous circuits that allow shunting of the SIRT particles around the tumor's capillary bed. The lifetime dose of radiation to the lungs is 30 Gy, and it does not take a significant number of radioactive particles in the pulmonary parenchyma to cause radiation pneumonitis, a possibly lethal complication of SIRT. Shunting of 10% to 20% of the anticipated tumor dose can induce radiation pneumonitis (there are different allowable shunt percentages for SIR-Spheres and TheraSpheres for various technical reasons).

Preliminary visceral arteriogram is performed in advance of anticipated SIRT treatment to assess shunt percentage before delivery of the SIRT particles. At the completion of this arteriogram, Technetium Tc 99m—labeled macroaggregated albumin (Tc 99m MAA) particles are injected into the target hepatic artery. Distribution of the Tc 99m MAA particles in the liver, lung, and viscera simulates the expected distribution of radioactive microspheres. Calculation of scintigraphic activity from the concentration of Tc 99m MAA in the lungs and liver is used to determine the amount of pulmonary shunting.

Other complications related to SIRT include deposition of the spheres in the arteries that supply the gastrointestinal system. Inadvertent radioactive particle embolization in the gut can result in radiation gastritis and enteritis, with possible ulceration and slow mucosal healing. Meticulous pre-SIRT angiography is required, and aberrant visceral supply to the stomach, pancreas, or large or small bowel from the hepatic arterial circulation can often be managed by branch

vessel occlusion with embolic coils or gelfoam pledgets at the time of preliminary diagnostic angiography or immediately before SIRT. Successful occlusion of aberrant visceral branches is usually confirmed during the same Tc 99m MAA distribution study that is performed to assess shunting to the lungs.

Finally, it is possible for appropriately located radioactive particles to induce damage of normal liver tissue, and overdose of particles in the liver can lead to radiation-induced liver dysfunction (90). A recent report that studied the hepatotoxicity of TheraSpheres found that patients with elevated serum bilirubin levels had a higher incidence of SIRT-related liver toxicity. There was also a correlation between higher radiation dosage and liver toxicity, although none of the patients with liver toxicity had confirmation of radiation-induced liver damage, and all toxicities resolved over time (91).

Percutaneous Needle-Directed Tumor Ablation

Having just discussed both transarterial chemoembolization and transarterial

radioablation of hepatic malignancies, it is important to mention an entirely different approach for tumor ablation—percutaneous needle-directed ablative therapies. During the last decade, a variety of ablative approaches have been used, including injection of necrosing agents (e.g., acetic acid, ethanol, hot saline), freezing techniques (e.g., cryoablation), ultrasonic methods, microwave ablation, and, most recently, the widespread use of RFA. All methods aim to deliver a necrosing blow into the tumor by open, laparoscopic, or image-guided placement of a needle or probe that can deliver the therapeutic agent directly into the tumor.

There is no substantial prospective randomized data comparing any of these techniques to each other. However, it is generally recognized that all these techniques can offer successful ablation of tumors less than 5 cm, and the smaller the tumor, the more effective the treatment. Ethanol ablation calls for delivery of 95% ethanol through a needle that has been placed with its tip in the tumor by ultrasound or CT guidance. Delivery of ethanol causes coagulative necrosis, with response rates for tumors less than 3 cm in diameter approaching 100% (92). The 5-year survival rates for patients with hepatocellular carcinomas 3 cm or less in diameter treated with ethanol is 48% (93,94,95).

Fifty percent acetic acid injection is delivered into the center of the tumor through a needle placed percutaneously. Coagulative necrosis, similar in appearance to the results seen with ethanol injection, causes tumor regression. However, for patients with up to four lesions that were not greater than 3 cm in diameter there was better survival at 1 and 2 years (100% and 92%) compared with the results for ethanol (83% and 63%). Furthermore, tumor recurrence was less frequent at 2 years with acetic acid compared to ethanol (8% with acetic acid vs. 37% with ethanol), whereas the 5-year survival rate for patients with hepatocellular carcinoma measuring 3 cm or less in diameter who were treated with acetic acid was 49%, similar to the results for ethanol (96,97).

Cryoablation uses a probe that delivers freezing temperatures to the center of the tumor and causes

tumor death by direct cellular freezing and indirectly through vascular thrombosis and tissue anoxia (98). Initial experience with this technique from a truly percutaneous approach has waned until recently as other ablative techniques have been developed, in part because of the large probe size that was required. Also, unlike RFA, the percutaneous tract cannot be cauterized with the cryoablation probe, so there is the potential for higher bleeding risk with cryoablation.

Now, however, miniaturization has led to more acceptable cryotherapy probe sizes, with diameters in the range of 2.4 to 3.0 mm. There are also some theoretic advantages of cryoablation compared with other percutaneous ablation therapies. There is no limitation from "heat sink" (as encountered with RFA, see in the following text) nor are there chemical dosing or toxicity issues (associated with acetic acid and ethanol injection). Cryoablation, therefore, may return as a viable method for percutaneous tumor ablation in the coming years.

RFA is currently the most widely used percutaneous ablative treatment for liver tumors in the United States. This procedure requires the insertion of a multitined probe into a tumor under ultrasound, CT, laparoscopic, or open surgical access. Then, an electric current is applied to the probe and a sphere of heating ensues proportional to the fourth power of the distance from the electrode. Thermal injury to cells starts at about 41°C, but most tumors in humans require temperatures of 45°C to 50°C for cell death to occur. As with ethanol and acetic acid ablation, larger tumors are more difficult to ablate than smaller ones. Until recently, tumor diameter limit for RFA was approximately 5 cm (99,100,101), but advances in probe design, as well as repositioning the probe to treat a larger volume, has made RFA a reasonable therapy

for tumors that are larger than 5 cm in diameter.

Disease-free survival at 12 to 15 months after RFA of primary and metastatic tumors of the liver without other ablative therapies was approximately 70% from two large series that studied tumors ranging from 1 to 10 cm in diameter (102,103). While this data is from laparoscopic placement of the RFA probe, similar data have been reported for percutaneous hepatocellular carcinomas 3 cm or less in diameter (104). Survival data for percutaneous RFA of hepatocellular carcinomas is comparable to those achieved with ethanol and also acetic acid, with 1- and 5-year survival of 94% and 40%, respectively. Lencioni et al. (105) treated 53 metastases in 29 patients, mostly from colorectal carcinoma. They reported a complete response in 77%, with a recurrence rate of 12%. With a mean follow-up of 6.5 months, 68% of the 53 lesions had no evidence of tumor progression.

A recent report of 1,000 RFA procedures directed at treating hepatocellular carcinoma in 664 patients confirms the effectiveness and safety of this therapy (106). There were 2,082 sessions of RFA to treat 2,140 nodules, with a mean lesion size of 2.6 cm. Of the 1,000 procedures, the major complication rate was 4.0% (40 procedures) with no treatment-related deaths. Major complications included intraperitoneal hemorrhage (four procedures), hepatic infarction in two patients, hepatic abscess in seven patients, and intestinal perforation/penetration in three patients. For the one patient with bile peritonitis, surgical and endoscopic biliary drainage was required.

From this large series of RFA for hepatocellular carcinoma, the long-term outcomes were comparable to other forms of ablative therapy, with 1-, 2-, 3-, 4-, and 5-year survival rates of 94.7%, 86.1%, 77.7%, 67.4%, and 54.3%, respectively, in a patient population in which approximately 80% of the treatment population was hepatitis C–antibody positive and 10% were hepatitis B–antigen positive. Tumor recurrence was seen in just over half the patients (165 of 306 patients) with a median time to recurrence of 1.59 years. Of the 165 patients with recurrence, 137 had three or fewer recurrent lesions and were treated with repeat RFA procedures. It is clear that RFA can be used to treat hepatocellular carcinoma with a low complication rate, and although recurrence is likely in at least half the patients, most of these patients can be retreated.

RFA for hepatic metastases is in evolution, especially given the recent interest in radioablative embolization, as well as ongoing developments in systemic therapies. Nevertheless, in the largest series to date, Lencioni et al. (107) describes the multicenter data for 423 patients with four or fewer colorectal hepatic metastases treated with RFA. The average metastasis size was 2.7 cm, with a mean follow-up of 19 months. Local tumor progression was observed in 25.15% of 525 lesions, and the overall survival rates at 1, 2, 3, 4, and 5 years were 86%, 63%, 47%, 29%, and 24%, respectively. As they noted, these survival rates were substantially higher than those obtained with any chemotherapy regimen, and therefore, this provides indirect evidence that RFA therapy improves survival in patients with limited hepatic metastatic disease. Similar to RFA for hepatocellular carcinoma, RFA for colorectal metastases carries a relatively low major complication rate of approximately 5% (108,109).

One of the potential pitfalls of RFA is the "heat sink" effect in highly vascular tumors or tumors adjacent to large vascular structures, in which blood flow may permit cooling of the vascular portion of the tumor or the portion of the tumor that resides adjacent to the vessel. This heat sink phenomenon may prevent heating of the tumor to the point of tissue death and leave the viable tumor behind (99,110,111,112).

There are many other ablative approaches to liver tumors including microwave ablation, ultrasonic

ablation, and external beam irradiation. Which ablative therapy is best for localized nonresectable hepatic malignancies? At present there is no clear choice of the best

ablative approach for hepatocellular carcinoma (113), though a recent report suggests that the question is not which *single* therapy is best, but how to use combined local ablative therapies for the best outcome. Kitamoto et al. (114) described RFA without or with TACE. They found that combined RFA and TACE gave a markedly increased extent of induced coagulation compared with RFA alone. Although this was a small study, it highlighted the trend that many interventionalists are following, that is, using the ischemic/necrosing effects of TACE to enhance the ablative effects of RFA.

Transhepatic Portal Vein Embolization

Embolization of the portal vein branches of a portion of the liver leads to atrophy of the embolized territory with compensatory hypertrophy of the remaining liver. This technique has been used successfully before surgery for the development of the normal liver before hepatic resection in the treatment of liver tumors when there is doubt that the residual liver would otherwise be sufficient for performing adequate hepatic function (115,116).

There are four important considerations before performing PVE. First, the ratio of the future liver remnant (FLR) to the total estimated liver volume (TELV) should be calculated. Next, consideration should be given to differentiating cases with underlying diffuse liver disease from those without underlying liver disease because this influences the FLR needed to reduce postoperative morbidity and mortality. Although the absolute liver volume necessary after resection for adequate hepatic function has not been pinpointed, an FLR/TELV ratio of at least 25% is recommended in patients with otherwise normal livers, and a ratio of at least 40% is suggested in patients in whom the liver is considered compromised.

A third consideration is the presence of systemic disease, such as diabetes mellitus, that may limit hepatic hypertrophy. Finally, planning the type and extent of resection is important.

PVE using interventional techniques is typically performed by direct transhepatic puncture, entering one of the intrahepatic portal veins from either the left or the right sides (entering the side opposite to the portion of the liver that will be embolized). A vascular sheath is advanced into the portal venous system, and then, using angiographic techniques, selective portal venous imaging and embolization is performed. The latter technique is performed with PVA particles ranging from 300 to 700 μm and platinum microcoils when appropriate. Occasionally, larger PVA particles (up to 1,000 μm) are needed, and at some institutions, other embolic agents such as ethanol, thrombin, fibrin glue, microspheres, cyanoacrylate, ethiodized oil, and absorbable gelatin sponge have been used. The goal is to reduce flow in the target portal vein branches to stagnation or near-stagnation. At the completion of the embolization procedure, the sheath is removed by embolization of the transhepatic tract using microcoils or absorbable gelatin sponge.

Follow-up imaging is performed at 2 to 4 weeks because liver regeneration usually peaks within the first 2 weeks after PVE (117,118,119). Complications of PVE are uncommon but include risks of transhepatic puncture (e.g., intraperitoneal bleeding, hemophilia), portal vein thrombosis, and infection. Overall, a typical increase in the FLR/TELV ratio has been reported in the range of 8% to 12% in various series (120,121,122,123,124,125).

Percutaneous Abscess Drainage

Percutaneous drainage of liver abscesses has been an important component of medical care for many years. Pyogenic liver abscesses typically represent the final common presentation of many pathologic processes including infection that reaches the liver through the portal venous, hepatic arterial, or biliary tract invasion. The right hepatic lobe is involved in three fourths of the cases, and abscesses many be single or

multiple. Typically identified by ultrasound or CT scanning, both techniques are excellent methods for guiding catheter drainage procedures (126). Typically, catheters ranging form 8 to 14 Fr are used to drain pyogenic abscesses of the liver. Drainage volume is recorded regularly, and the tube is removed when little or no drainage persists. Catheter drainage is required for 5 to 7 days in most cases.

There are two controversial areas of percutaneous treatment of pyogenic liver abscesses. First, some believe that aspiration of the abscess along with intake of systemic antibiotics is sufficient for most patients, obviating the need for drainage catheter placement and management. Success rates between 58% and 88% that have been reported with this technique compare favorably with the reported success rates of 69% to 90% for catheter drainage (127,128,129,130,131,132,133). It should be noted, however, that repeat aspiration is required in more than half of the patients (134,135). Rajak et al. (136) found no difference in average time for clinical improvement, mean hospital stay, or average time for complete resolution of liver abscesses for catheter drainage compared with aspiration in a high-risk group of patients. This suggests that aspiration is a useful technique that should be considered, especially when catheter placement may be undesirable (e.g., in a patient with altered mental status who may dislodge the catheter).

The second controversial area is the use of antibiotics alone, without aspiration or drainage. Although this may suffice for patients with small abscesses and few other comorbid conditions, the indications for antibiotics alone have been not established. At the very least, aspiration can be used to obtain a specimen for microbiologic analysis and may suffice as a first-line treatment of pyogenic liver abscesses along with systemic antibiotics (126).

Amebic liver abscess is unusual in the United States but is a widespread problem globally (137). Medical treatment alone is recommended for patients suspected of having amebic liver abscess unless the patient is at high risk of abscess rupture. Risk factors include abscess cavity size greater than 5 cm, left hepatic lobe abscess, or failure to respond to medical therapy in 5 to 7 days (138,139). Typically, aspiration without drainage is recommended (137,140).

Percutaneous Cholecystostomy

The gallbladder may be drained with a catheter for various reasons, including cholecystitis, to gain access for the treatment of biliary stone disease, and for the drainage of the biliary system in the presence of common duct obstruction. Most cholecystostomy tubes are placed for drainage of an infected gallbladder, often in patients with contraindications to cholecystectomy. This is especially true for patients in the intensive care unit in whom acute cholecystitis may present without an obstructing stone (acalculous cholecystitis). For these patients, a cholecystostomy tube will permit effective drainage of the gallbladder while systemic antibiotics are administered. Often, the condition of acalculous cholecystitis will resolve with these measures alone, and the tube can be ultimately removed (141,142,143,144).

Drainage of the gallbladder has historically been accomplished by transhepatic puncture, with the initial passage of the needle through the liver and then into the gallbladder (144,145). Transhepatic gallbladder puncture was considered to be safer than direct gallbladder puncture, as it was commonly believed that there was less risk for bile leakage from the transhepatic approach because the liver would act to tamponade the puncture site during catheter drainage, as well as after catheter removal. Although the practice of transhepatic drainage of the gallbladder persists, it has been shown that a direct transperitoneal access can also been used safely (146), but there is no conclusive proof that a transhepatic route for drainage is necessary.

The procedure of catheter drainage of the gallbladder begins under sonographic or CT

guidance for puncture of the gallbladder, followed by fluoroscopy imaging to confirm that the drainage catheter has been inserted into an acceptable position. At the time of puncture, the bile is examined and sent to the laboratory for culture. An 8- to 14-Fr drainage catheter is inserted over the guide wire, with its tip in the gallbladder, usually using a catheter with a Cope loop design at its tip so that the catheter cannot be dislodged. Drainage volume from the cholecystostomy tube should be charted regularly.

When bile output from the cholecystostomy tube decreases, it could be due to one of three causes. First, the tube may have become intermittently obstructed. Second, the tube may have become dislodged from the gallbladder. Finally, the cystic duct may have opened, allowing the bile to pass down the common bile duct and into the duodenum rather than out through the catheter. The reason for the diminishing bile drainage should be evaluated fluoroscopically, injecting contrast through the cholecystostomy tube and into the gallbladder (if the tube has not become dislodged). If the cystic duct is open, the tube is usually capped for a trial period of internal drainage and ultimately removed. If the cystic duct is not open, external biliary drainage should be continued.

Removal of a cholecystostomy tube is done typically under fluoroscopic control by partially removing the catheter over a guide wire. Contrast is injected during this maneuver to ensure that there is no demonstrable communication between the gallbladder and the peritoneal space. If spillage is noted, the tube is reinserted and checked again in several days, and the procedure of tube removal is repeated with fluoroscopic assessment until there is no bile spillage.

For some patients, obstruction of the cystic duct will persist, typically because of an impacted stone or other fixed obstruction. For patients who cannot tolerate cholecystectomy, the tube may be needed as long-term therapy, with external drainage and regularly scheduled tube changes.

Conclusion

A variety of percutaneous procedures have been developed for the diagnosis and treatment of hepatobiliary disease. These procedures are under constant evolution, with some being incorporated into clinical practice while others have been rendered obsolete. It is admittedly a daunting task for most clinicians to find their way through this labyrinth of imaging and therapeutic options. Therefore, it is increasingly essential that members of the clinical team become familiar with their group of interventional radiologists who understand the risks, benefits, and use of imaging techniques and percutaneous procedures. By developing a close working relationship with their interventional radiology colleagues, the clinical team members will more readily find safe and effective strategies to provide care for patients with hepatobiliary disease.

Annotated References

Hepatobiliary Angiography

Reuter SR, Redman HC, Cho KJ, eds. *Gastrointestinal angiography*, 3rd ed. Philadelphia: WB Saunders, 1986.

The third edition of this classic text remains the contemporary first reference source for the angiographer who seeks information about hepatobiliary angiography.

Liver Biopsy

Siragusa DA, Friedman AC. Imaging-guided percutaneous biopsy of hepatic masses.

Tech Vasc Interv Radiol 2001;4(3):172–185.

One in a series of "technique" monographs, this useful approach to image-guided biopsy of liver masses also provides 54 references including most of the important work in this area published during the last 20 years.

Percutaneous Transhepatic Cholangiography and Biliary Intervention

Kim HS, Lund GB, Venbrux AC. Advanced percutaneous transhepatic biliary access. *Tech Vasc Interv Radiol* 2001;4(3):153–171.

Venbrux AC, Osterman FA Jr. Percutaneous management of benign biliary strictures. *Tech Vasc Interv Radiol* 2001;4(3):141–152.

Wilson MW. The application of metallic stents in malignant biliary obstruction. *Tech Vasc Interv Radiol* 1999;2(1):39–52.

Each of these references comes from the Techniques in Vascular and Interventional Radiology series and provides a hands-on approach and a scientific basis for the use of interventional radiologic techniques in biliary diagnosis and treatment.

Transarterial Chemoembolization of Hepatic Tumors

Llovet JM, Bruix J. Systematic review of randomized trials for unresectable hepatocellular carcinoma: chemoembolization improves survival. *Hepatology* 2003;37:429–442.

Reidy DL, Schwartz JD. Therapy for unresectable hepatocellular carcinoma: review of the randomized clinical trials – I: hepatic arterial embolization and embolization-based therapies in unresectable hepatocellular carcinoma. *Anticancer Drugs* 2004;15:427–437.

Soulen MC. Chemoembolization of hepatic malignancies. *Semin Interv Radiol* 1997;14(3):305–311.

In Michael Soulen's thoughtful review, procedural details, and outcomes for transarterial chemoembolization (TACE) of a variety of hepatic tumors are reviewed in this reference. The article by Llovet and Bruix provides a relatively recent meta-analysis of TACE in the treatment of hepatocellular carcinoma. Reidy et al. offer a current review of TACE for hepatocellular carcinoma and highlight not only the success of this therapy but also many questions that have not been adequately addressed.

Percutaneous Ablation of Liver Tumors

De Sanctis JT, Goldberg NS, Mueller RP. Percutaneous treatment of hepatic neoplasms: a review of current techniques. *Cardiovasc Intervent Radiol* 1998;21:273–296.

Goldberg SH, Dupuy DE. Image-guided radiofrequency tumor ablation: challenges and opportunities—Part I. *J Vasc Interv Radiol* 2001a;12:1021–1032.

Goldberg SH, Dupuy DE. Image-guided radiofrequency tumor ablation: challenges

and opportunities—Part II. *J Vasc Interv Radiol* 2001b;12:1135–1148.

Tateishi R, Shiina S, Teratani T, et al. Percutaneous radiofrequency ablation for hepatocellular carcinoma: analysis of 1000 cases. *Cancer* 2005;103(6):1201–1209.

The review by De Sanctis capitulates the various state-of-the-art tumor ablative techniques through the late 1990s. Goldberg et al. published a 2-part series on radiofrequency (RF) tumor ablation. Part I provides information on the technical aspects of RF ablation, while Part II describes clinical use and outcome for treating tumors in the liver and elsewhere. The recent publication by Tateishi, et al. describes an experience with RFA for hepatocellular carcinoma.

Percutaneous Liver Abscess Drainage

Johannsen EC, Sifri CD, Madoff LC. Infections of the liver: pyogenic liver abscesses. *Infect Dis Clin North Am* 2000;14(3):547–563.

This contemporary review covers all aspects of pyogenic liver abscesses including etiology, clinical presentation, and treatment. It provides comprehensive data for treatment outcomes for aspiration versus drainage.

Chapter 6

Endoscopic Retrograde Cholangiopancreatography

Richard Kwon

David L. Carr-Locke

Key Concepts

- Endoscopic retrograde cholangiopancreatography (ERCP) with therapeutic intervention (endoscopic sphincterotomy, stone extraction, or stent placement) can achieve biliary decompression in more than 95% of cases of biliary obstruction.
- Pancreatitis, the most common complication of ERCP, occurs in approximately 5% of cases, and the rate of this complication does not increase with therapeutic intervention.
- Endoscopic sphincterotomy permanently abolishes the pressure gradient across the sphincter of Oddi but is not associated with long-term biliary complications. Patients with cirrhosis who undergo endoscopic sphincterotomy have a higher-than-average risk of complications.
- In cholangitis, the treatment of choice is emergency ERCP with biliary decompression, which results in lower mortality than does surgical decompression.
- In acute biliary pancreatitis, ERCP is indicated in the care of patients with severe pancreatitis and in those with persistent abnormalities in liver enzyme levels. The low likelihood of recovering a stone from the common bile duct in cases of mild biliary pancreatitis or rapid improvement in liver enzyme abnormalities does not justify the use of routine ERCP.
- ERCP remains the standard of care for the diagnosis of primary sclerosing cholangitis (PSC). Endoscopic therapy for PSC strictures that includes dilatation and stent placement improves outcome in the subset of patients with a “dominant” extrahepatic stricture.
- ERCP is the procedure of choice for the diagnosis and management of biliary complications after cholecystectomy and liver transplantation. Bile leaks have high healing rates with short-term stenting, whereas biliary strictures require an aggressive regimen of endoscopic dilatation and stenting.

Since its inception in 1968 (1), endoscopic retrograde cholangiopancreatography (ERCP) has been an important diagnostic and therapeutic tool in the management of hepatobiliary disease. The advantages of this endoscopic approach to the hepatobiliary system compared with the more invasive percutaneous or open

surgical routes led to a rapid expansion in its applications, including stone extraction, dilatation and stenting of benign and malignant strictures, and management of postoperative complications. With the recent advances in noninvasive imaging, including magnetic resonance cholangiopancreatography (MRCP) and multidetector row computed tomography (MDCT), ERCP has now become mostly a therapeutic procedure.

Indications and Contraindications

Indications

The main indication for ERCP is the evaluation and treatment of suspected biliary obstruction. The broader

indications for the procedure include pancreatic disorders and the need for endoscopic therapy within the biliary or pancreatic ducts (Table 6.1).

Table 6.1. Indications for Endoscopic Retrograde Cholangiopancreatography

Biliary tract disease
Obstructive jaundice
Cholestasis
Cholangitis
Postoperative and traumatic biliary complications, such as bile leak, fistula, stricture
Evaluation of sphincter of Oddi dysfunction by means of manometry
Acquisition of bile for diagnosis of microlithiasis
Sphincterotomy for complications of gallstone disease when the gallbladder will be left in situ
Pancreatic disease
Acute biliary pancreatitis if severe or with persistent biliary obstruction
Suspected pancreatic cancer
Suspected chronic pancreatitis
Endoscopic therapy for known chronic pancreatitis
Evaluation of pancreatic trauma
Pancreatic duct roadmap before surgery

In the evaluation of cholestasis or jaundice, ERCP should be reserved for cases in which a high index of suspicion for obstruction exists. The distinction between obstructive and nonobstructive jaundice can usually be made on clinical grounds alone. Typically, obstructive jaundice leads to biliary dilatation on imaging (ultrasound, MDCT, or MRCP) and elevated liver function test results, particularly the alkaline phosphatase and total bilirubin levels. Instances in which obstruction may not be accompanied by ductal dilatation include obstruction of recent onset (because ductal diameter is partly related to the duration of obstruction) and primary sclerosing cholangitis (PSC). Once the diagnosis of obstructive jaundice is made, the appropriate timing of the ERCP must be determined. Acute cholangitis, characterized by fever, jaundice, and right upper quadrant abdominal pain, requires urgent biliary decompression by ERCP if it does not improve with conservative management. In the setting of biliary pancreatitis, published results

have shown a clear benefit of urgent ERCP (within 24 to 48 hours) in cases of severe biliary pancreatitis (2,3,4), but less so for mild pancreatitis, in which the likelihood of recovering a stone is lower and spontaneous recovery without complications higher.

Sphincter of Oddi dysfunction (SOD) is suspected when biliary or pancreatic symptoms occur or recur after cholecystectomy. SOD is classified into three types (5). The triad of elevation of serum liver enzyme levels, dilatation of the common bile duct (CBD), and poor drainage on a diagnostic cholangiogram is strongly suggestive of the diagnosis of type I biliary SOD, which is treated with empiric sphincterotomy. If only one or two of these three features are present (type II SOD), sphincter manometry is performed on both biliary and pancreatic sphincters. Normal basal sphincter pressure is less than 40 mm Hg, and phasic contractions are usually no higher than 250 mm Hg. Sphincterotomy is indicated and successful when the diagnosis of SOD is accurate. Type III SOD (pain syndrome) has none of the aforementioned features and is usually managed conservatively but sphincter of Oddi manometry may be helpful in proving normalcy.

The growth of laparoscopic cholecystectomy and liver transplantation has led to an increase in the incidence of postoperative complications in the biliary tract. Biliary-type pain, elevated cholestatic liver enzyme levels, or abnormal imaging in the postoperative setting usually constitutes an indication for ERCP.

The role of ERCP in the evaluation of chronic abdominal pain that has defied diagnosis with less invasive testing is questionable and carries the highest risk of post-ERCP complications, especially pancreatitis. The development of MRCP has provided a reliable and safe means of imaging the biliary and pancreatic ductal systems and has therefore lowered the utility of ERCP as a purely diagnostic modality.

Contraindications

The same general contraindications that apply to other endoscopic procedures also apply to ERCP. Refusal by the patient to undergo the procedure or an acute cardiovascular or pulmonary condition are the only true contraindications. A Zenker's diverticulum, esophageal diverticulum, or tight esophageal stricture can complicate passage of a side-viewing duodenoscope. Previous surgery on the upper gastrointestinal (GI) tract (e.g., Billroth II partial gastrectomy) is not a contraindication, although the altered anatomy may render the procedure technically more difficult.

ERCP is not contraindicated during pregnancy, but should be performed judiciously (6,7). With a pregnant patient, radiation exposure is minimized by placement of a lead shield to protect the patient's abdomen, scant use of fluoroscopy, and avoidance of spot radiographs.

History of an adverse reaction to an ionic contrast medium is not a contraindication to ERCP. Systemic absorption of contrast medium injected into the biliary or pancreatic ducts is negligible, and reports of adverse reactions at the time of ERCP are rare (8). In the care of patients with a documented history of a severe reaction (laryngeal edema, anaphylaxis, or vascular collapse), it is our policy to administer glucocorticoids and antihistamines, starting 12 hours before the procedure.

Techniques

Preparation

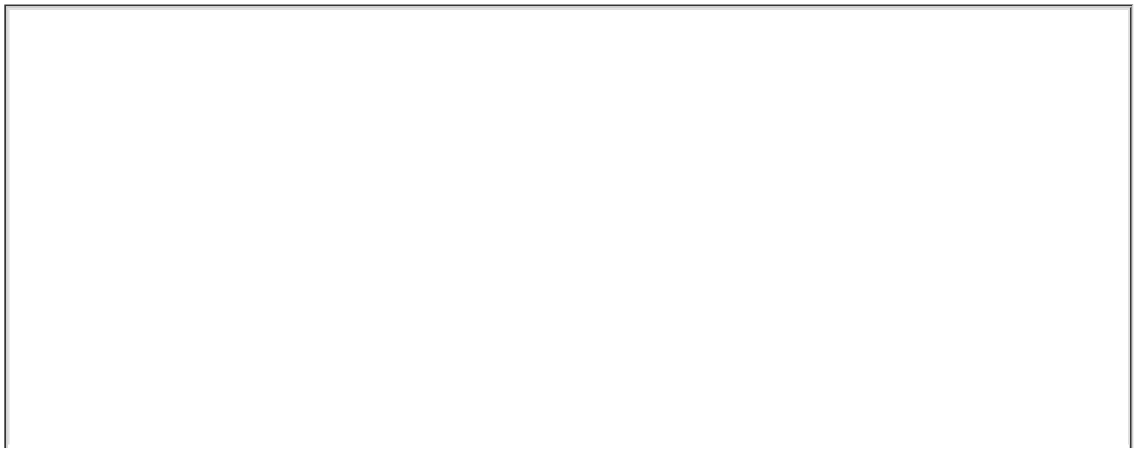
After a detailed discussion about informed consent and addressing the patient's concerns, he or she is placed in the prone “swimmer's” position. A combination of intravenous midazolam and fentanyl provides conscious sedation. The patient is given supplemental oxygen and is monitored throughout the procedure for heart rate, blood pressure, and pulse oximetry. Capnography monitoring is likely to become standard in the near future. Propofol (monitored anesthesia care) and general anesthesia have been used increasingly for ERCP in some centers.

Prophylactic antibiotics are administered according to the guidelines of the American Society for Gastrointestinal Endoscopy (ASGE) (9), although their value has been questioned. If injected contrast does not subsequently drain adequately (because of a stricture or obstruction) and adequate endoscopic drainage cannot be provided, intravenous ampicillin (2 g) and gentamicin (1.5 mg/kg) should be given empirically immediately after the procedure. In the setting of PSC, periprocedural antibiotics are universally recommended because of the propensity of these patients to develop post-ERCP cholangitis.

A “therapeutic” side-viewing duodenoscope is now almost universally used in adults as the standard instrument. It is approximately 13 mm in diameter and contains a 4.2-mm diameter accessory channel. It is carefully passed through the upper GI tract and into the duodenum. Excessive duodenal motility can be suppressed by intravenous administration of 0.2 to 0.5 mg of glucagon. At this time, cannulation of the CBD is attempted using a catheter or sphincterotome. The CBD and ventral pancreatic duct share the papillary orifice in more than 90% of cases. Selective cannulation of the bile duct requires a detailed knowledge of the local anatomy and a range of technical maneuvers that require prolonged training to acquire.

The Normal Cholangiogram

Bile duct cannulation allows the delineation of the biliary tree anatomy, including intrahepatic and extrahepatic ducts, as well as the cystic duct and gallbladder (Fig. 6.1). The muscular wall of the distal CBD can cause smooth tapering or a shelf-like “notch” that may be mistaken for a stricture. A contracted sphincter also can simulate an impacted stone (pseudocalculus sign). Care must be taken to identify the cystic duct because its origin in the CBD is quite variable, which can make the identification of the common hepatic duct and confluence of the hepatic ducts difficult.



▪ **Figure 6.1** Normal postcholecystectomy endoscopic retrograde cholangiogram.

The left and right hepatic ducts fuse 7 to 15 mm below the hilum at the confluence. The left hepatic duct is slightly longer than the right hepatic duct. With the patient in the usual prone position during ERCP, the left hepatic duct is in a dependent position and therefore fills preferentially when contrast material is injected into the CBD. Maneuvers for filling the right hepatic ductal system include tilting the head of the table down 15 to 20 degrees, injecting directly into the right system or through an inflated balloon in the common hepatic duct (occlusion cholangiography), or turning the patient to the supine position.

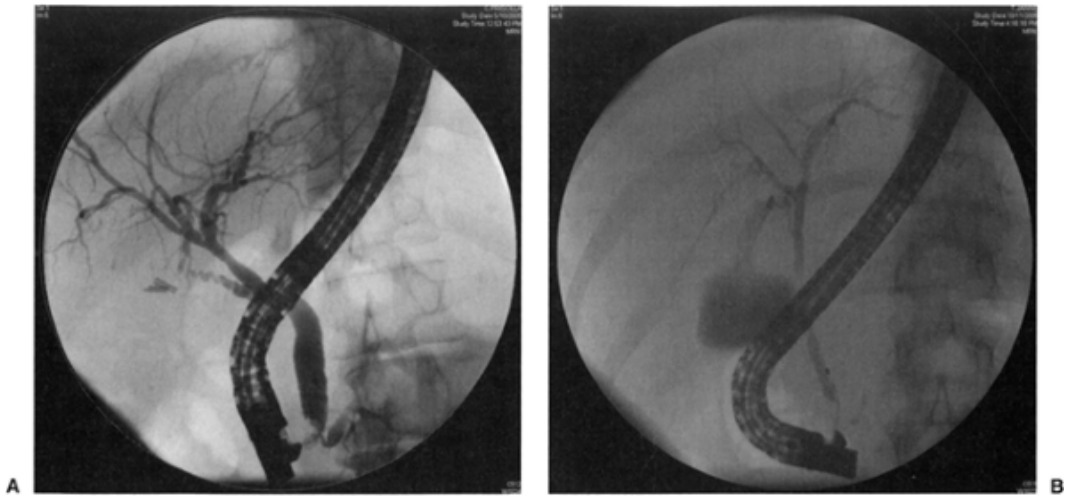
There are many variations in biliary tract anatomy. In approximately 2% of cases, the cystic duct drains into the confluence, so there is no true common hepatic duct. In 1% of the population, the right hepatic duct, or a second abberrant right hepatic duct, drains directly into the gallbladder or the cystic duct. This variant may lead to postoperative complications if the presence of this configuration is not recognized and the aberrant duct is inadvertently clipped or injured during laparoscopic cholecystectomy (Fig. 6.2).

Therapeutic Endoscopic Retrograde Cholangiopancreatography

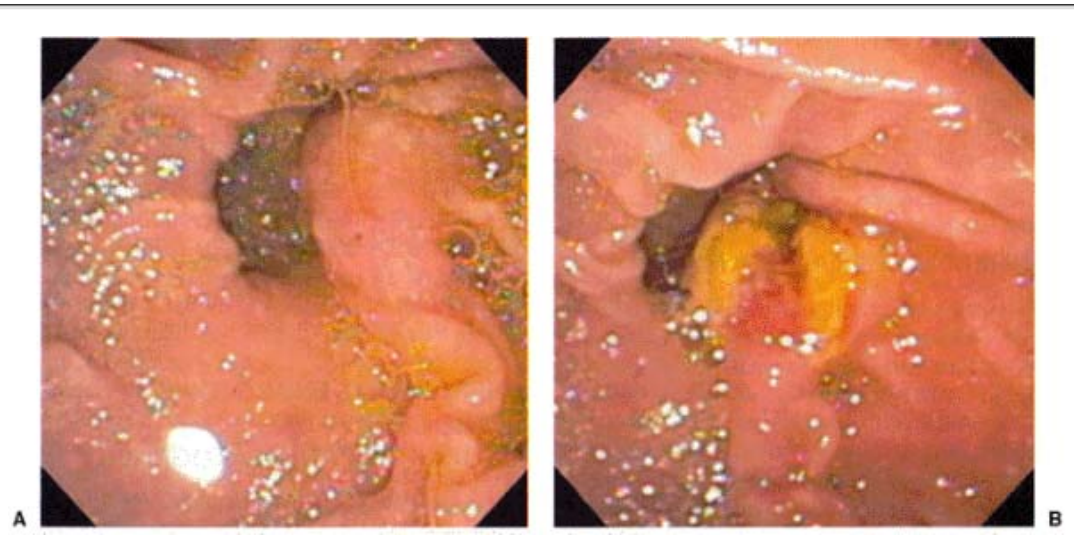
The most important therapeutic ERCP technique and often the first step in a therapeutic procedure is

endoscopic sphincterotomy (ES). A sphincterotome, a plastic catheter with an exposed metal wire at the distal end, is used in the procedure. To perform an ES, the tip of the sphincterotome is bowed to isolate the wire, and is positioned such that only a portion of the bowed wire is in contact with the papilla. A cutting

current is applied in the direction of the bile duct (Fig. 6.3). After ES, the stones can be extracted through the papilla using balloon catheters or Dormia-type baskets (Fig. 6.4A, B). Failure to clear the duct may be due to the shape, number, or size of stones (stones >15 mm being considered large) or to a distal obstruction, such as mass or stricture. These difficult bile duct stones can be extracted in most cases after mechanical lithotripsy (Fig. 6.4E, F, G). This procedure is performed with a specialized basket that is cranked closed against an unyielding metal sheath, fragmenting the stone within the bile duct. Stones refractory to mechanical lithotripsy can be fractured using electric hydraulic lithotripsy (EHL) (see the subsequent text), laser lithotripsy (10), or extracorporeal shock wave lithotripsy (11). Dissolution therapy with solvents has not gained wide acceptance in the United States.



▪ **Figure 6.2 A:** Normal intrahepatic ductal anatomy showing the typical "trifurcation" at the confluence of the right and left hepatic ducts. **B:** Aberrant right hepatic ductal system with a second duct arising close the cystic duct.



▪ **Figure 6.3** Endoscopic views of papilla **(A)** before sphincterotomy and **(B)** after sphincterotomy.

Biliary obstruction can also be decompressed using either plastic biliary stents or self-expanding metal

stents (SEMS), which are placed over a guidewire (Fig. 6.5A, B). When using biliary stents, 10-Fr diameter stents should be placed whenever possible because narrower stents have been shown to have diminished patency rates in clinical trials (mean patency, 144 days for the 10-Fr stent vs. 67 days for the 8-Fr stent) (12). Biliary stents are usually replaced in 2 to 3 months. Metallic stents are reserved for palliation of malignant obstruction or as a last resort in difficult benign strictures.

Tissue sampling from the bile duct can be accomplished using cytology brushes (with or without a guidewire) or small biopsy forceps. Biliary dilatation can be performed with dilating balloons or catheters of gradually increasing diameter, both of which can be passed over a guidewire.

Cholangioscopy

Direct endoscopic visualization of the bile ducts has become possible using thin-caliber cholangioscopes of 3.3 mm diameter or less. The “baby” cholangioscope is passed through the “mother” endoscope and into the bile duct with or without the assistance of a guidewire. The “baby” endoscope has only two-dimensional tip movement and is usually controlled by a second endoscopist. Baby endoscopes have a small accessory channel that allows flushing of the bile duct and passage of a biopsy forceps or other small-caliber device. One of the important applications of cholangioscopy is EHL, which successfully fragments large stones that cannot be extracted using mechanical lithotripsy (13,14). This technique requires direct apposition of a thin electrode

probe against the stone. Electric sparks are delivered in short pulses within a liquid medium, leading to the generation of pressure waves. Care must be taken to avoid injuring the bile duct.

▪ **Figure 6.4** Endoscopic retrograde cholangiopancreatography showing **(A)** a stone in the distal bile duct, **(B)** basket extraction, **(C)** balloon extraction,

(D) a large stone in the bile duct and the sphincterotome positioned for sphincterotomy, **(E)** lithotripsy basket entrapping the stone, **(F)** mechanical lithotripsy crushing the stone, **(G)** basket removal of fragments.

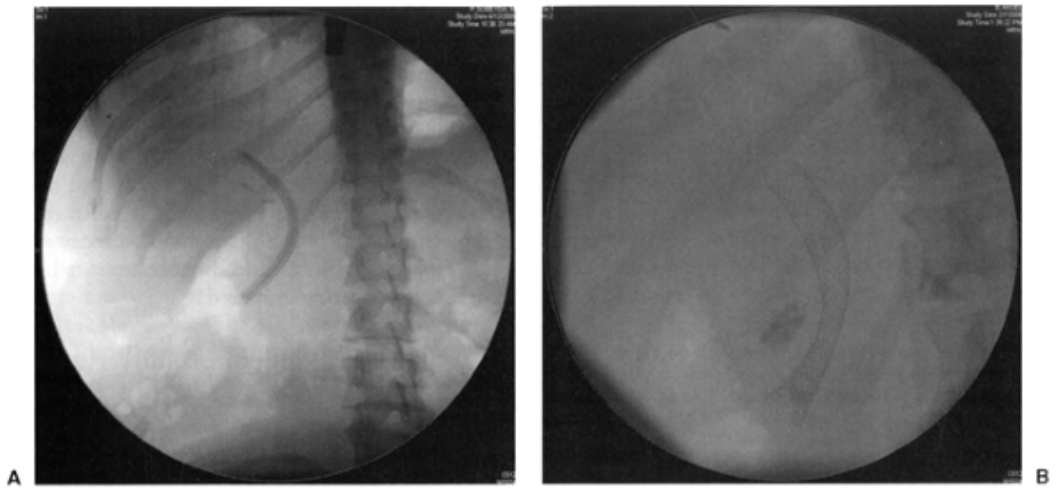
Complications

A consensus conference in 1991 (15) classified ERCP-related complications as mild, moderate, or severe on the basis of clinical criteria, and this grading system has been used in most studies involving ERCP ever since (Table 6.2).

In a study of more than 2,000 ERCPs with ES (16), the mortality rate related to the procedure was 0.4%. The overall complication rate was 9.8%, and severe complications occurred in 1.6% of cases (Table 6.3). The most common ERCP-specific complication was pancreatitis, occurring in 5.4% of patients undergoing sphincterotomy and accounting for more than one half of all cases of complications (13). Only 9 of the 127 (7%) cases of pancreatitis were graded as severe.

Post-ERCP pancreatitis is characterized by abdominal pain and elevated levels of pancreatic enzymes. Predisposing risk factors for pancreatitis include female sex and a normal serum bilirubin level (17), repeated attempts at bile duct cannulation, and “precut” or access papillotomy with a needle knife (16). The incidence of pancreatitis does not seem to differ between purely diagnostic and therapeutic ERCP (17). However, the risk of ERCP-induced pancreatitis in the setting of SOD is increased and has been reported to be as

high as 20% (18). Intravenous infusions of somatostatin, an inhibitor of pancreatic enzyme secretion, and gabexate, a synthetic protease inhibitor (19), and oral allopurinol (20,21) may be effective in the prevention of pancreatitis. Other prophylactic agents are under evaluation.



▪ **Figure 6.5 A:** Two plastic stents in position in bile duct, **(B)** self-expanding metallic stent in bile duct.

Bleeding from the sphincterotomy site is the second most common ERCP-specific complication, occurring in up to 2% of cases (16). Most episodes are evident at the time of sphincterotomy, although delayed hemorrhage can occur up to 2 weeks after ES. Most cases of bleeding can be managed endoscopically with local epinephrine injection, multipolar coagulation, or hemostatic clips. Angiographic embolization is rarely required for severe bleeding associated with the retroduodenal artery, which is in the vicinity of the sphincterotomy site in 4% of patients.

Table 6.2. Grading System for the Major Complications of Endoscopic Retrograde Cholangiopancreatography and Endoscopic Sphincterotomy

Complication	Mild	Moderate	Severe
Bleeding	Clinical (not just endoscopic) evidence of bleeding, hemoglobin drop by <3 g/dL, and no need for transfusion	Transfusion (4 U or less), no angiographic intervention or surgery	Transfusion 5 U or more or angiographic or surgical intervention
Perforation	Possible, or only very slight leak of fluid or contrast	Any definite perforation managed medically for	Medical treatment for >10 d or percutaneous or

	medium, managed with fluids and suction for 3 d or less	4–10 d	surgical intervention
Pancreatitis	Clinical pancreatitis, amylase level at least three times the normal value for >24 h after the procedure, necessitating admission or prolongation of planned admission to 2–3 d	Pancreatitis requiring hospitalization for 4–10 d	Hospitalization for >10 d, hemorrhagic pancreatitis, phlegmon, pseudocyst, or intervention (percutaneous drainage or surgery)
Infection (cholangitis)	>38°C 24–48 h	Febrile or septic illness necessitating >3 d of hospital treatment or endoscopic or percutaneous intervention	Septic shock or surgery
Basket impaction	Basket released spontaneously or by repeated endoscopy	Percutaneous intervention	Surgery
Any intensive care unit admission after a procedure grades the complication as severe. Other rarer complications can be graded by the length of needed hospitalization.			

ES in the setting of cirrhosis carries an increased risk of bleeding, and should therefore be performed judiciously. Multivariate analysis has revealed that

coagulopathy, rather than cirrhosis per se, was the risk factor associated with a threefold increased risk of bleeding (16). Even so, the adjusted odds ratio for all ES complications in patients with cirrhosis was 2.9 (95% confidence interval, 1.5 to 5.9). This high overall rate of complications of ES among patients with

cirrhosis was also demonstrated in a retrospective study conducted in France on a series of 52 patients with cirrhosis (18, Child-Pugh class A; 22, class B; 12, class C) (22). Four of the 52 patients in that series (7.7%), all Child-Pugh class C, died within 5 days of the procedure because of bleeding, perforation, or sepsis. The 1-month mortality rate was 12.5%.

Table 6.3. Complications of Endoscopic Sphincterotomy

Type of complication	Percentage with complication	Percentage with severe complication
Pancreatitis	5.4	0.4
Hemorrhage	2.0	0.5
Perforation	0.3	0.2
Cholangitis	1.0	0.1
Cholecystitis	0.5	0.1
Miscellaneous[a]	1.1	0.3
Any complication	9.8	1.6

[a]Includes cardiopulmonary complications, ductal perforation by guidewire, stent malfunction, antibiotic-induced diarrhea, indeterminate fluid collection, and infection of pancreatic pseudocyst.
Adapted from Freeman ML, Nelson DB, Sherman S, et al. Complications of endoscopic biliary sphincterotomy. *N Engl J Med* 1996;335:909–918, with permission.

If ES is performed on a patient with cirrhosis, admission for observation is prudent. It is recommended that patients with cirrhosis who undergo ES receive preprocedural transfusions of platelets and fresh frozen plasma for correction of coagulopathy and that they receive periprocedural antibiotics.

An alternative to ES in this setting is balloon dilatation of the sphincter, which has shown equal efficacy in CBD clearance and fewer bleeding episodes than ES in patients without cirrhosis (23), but it may be associated with more postprocedural pancreatitis (24). A recent report from Korea showed that sphincter dilatation caused fewer bleeding episodes than did ES in patients with cirrhosis and coagulopathy (25). A recent meta-analysis concluded that balloon dilatation may be the preferred method in patients with an underlying coagulopathy (26).

Perforations are rare but can occur when the sphincterotomy incision extends

beyond the intramural segment of the bile duct into the retroperitoneal space (27). Perforations are usually identified during the procedure but may present afterward with abdominal pain, with or without abdominal distension. The diagnosis is made by the presence of retroperitoneal air on computed tomography (CT) scan, and most can be managed conservatively with antibiotics and nasogastric suction.

Cholangitis occurs as a complication in 1% to 3% of ERCP procedures and usually results from inadequate ductal drainage. Bile should be aspirated before injection of contrast medium into an obstructed biliary system, and the least amount of contrast medium necessary to define the lesion should be injected. If adequate drainage of contrast cannot be accomplished endoscopically, a percutaneous transhepatic drainage procedure is urgently indicated.

Benign or Premalignant Biliary Obstruction

Choledocholithiasis

The annual incidence of gallstone disease in patients with cirrhosis appears to be 2.6% to 5.5%, which is higher than that among the population without cirrhosis. (28). In patients with liver disease and suspected choledocholithiasis, the decision to proceed to ERCP should be made carefully. Trends in liver enzymes in the first 48 to 72 hours after the initial presentation are an important indicator of the likelihood of recovering a stone during ERCP (29). When the results of the liver function tests normalize, the likelihood of finding choledocholithiasis is lower (14%) than that among patients whose liver function test results remain unchanged or increase (90% likelihood of finding a CBD stone by ERCP). Improvement in liver function test results that falls short of normal values is associated with an intermediate prevalence of stones. Imaging studies can help weigh the need for ERCP. Studies have shown that a combination of elevated liver function results and abnormal radiographic findings (e.g., dilated CBD) are more predictive of CBD stones than is either sign alone (30). Transabdominal ultrasonography has high diagnostic accuracy for intrahepatic calculi but depicts only two thirds of CBD stones. MRCP has a sensitivity of greater than 90%, but its accuracy is directly correlated with the size of the stone (31,32,33). Either transabdominal ultrasonography or MRCP is a reasonable first test when choledocholithiasis is suspected because these modalities have a sensitivity greater than 90%. MDCT and virtual cholangiography may be a third option (34). Endoscopic ultrasound has also been shown to be helpful in diagnosing CBD stones (35) but is not yet a primary option. If there is evidence of a stone or abnormal biliary dilatation, then ERCP should be performed. A meta-analysis addressing the subject of predictive factors showed that cholangitis, CBD stones found by ultrasound examination, and preoperative jaundice were the three

strongest predictive indicators of the presence of CBD stones (36).

The role of ERCP in choledocholithiasis is to confirm the diagnosis and extract stones therapeutically, as described earlier. Accomplishing timely biliary drainage is imperative in the setting of cholangitis. If a difficult stone resists attempts at extraction or fragmentation, a plastic stent should be placed across the stone and extraction should be attempted at a later date. Biliary stents have been successful at partial stone disintegration over several weeks to months, likely by mechanical abrasion of the stone. Stone extraction is often easier at subsequent attempts (37). The duct should ultimately be cleared of stones because long-term

indwelling plastic stents are associated with a risk of cholangitis of up to 40% (38).

Before the use of laparoscopic cholecystectomy, many patients with symptomatic choledocholithiasis with minimal or no symptoms attributable to the gallbladder, or those considered poor surgical candidates for open cholecystectomy, were treated with ES alone, and their gallbladders were left in situ. For cholecystitis and choledocholithiaisis in patients with cirrhosis, the high operative morbidity and mortality of cholecystectomy mitigate in favor of endoscopic management of biliary tract disease whenever possible. As noted previously, patients with cirrhosis also have a higher than average risk of bleeding after ES; however, this risk may not normalize even when coagulopathy is corrected before the procedure (39). Long-term follow-up study with high-risk patients showed minimal development of gallbladder complications, and only a few patients needed cholecystectomy (40). There is now growing evidence that elderly patients or those at high operative risk for undergoing laparoscopic cholecystectomy can be treated similarly with ES and observation, with cholecystectomy being reserved for patients who have recurrent biliary symptoms. Advanced cirrhosis with cholecystitis may also be successfully managed with the placement of a long plastic stent from the gallbladder to the duodenum (41,42), which serves as a bridge to liver transplantation.

Sclerosing Cholangitis

PSC is a chronic cholestatic disorder characterized by fibrosing inflammation of the intrahepatic and extrahepatic biliary tree that progressively leads to cirrhosis, portal hypertension, liver failure, and death within a mean of 12 years after diagnosis. There is a strong association with inflammatory bowel disease. ERCP is the standard for diagnosis of PSC, and the availability of this modality has led to the diagnosis of an increased number of cases in the asymptomatic, preicteric phase. Recently, MRCP has been shown to be as accurate as and more cost-effective than ERCP (43,44,45) and may eventually be the diagnostic study of choice.

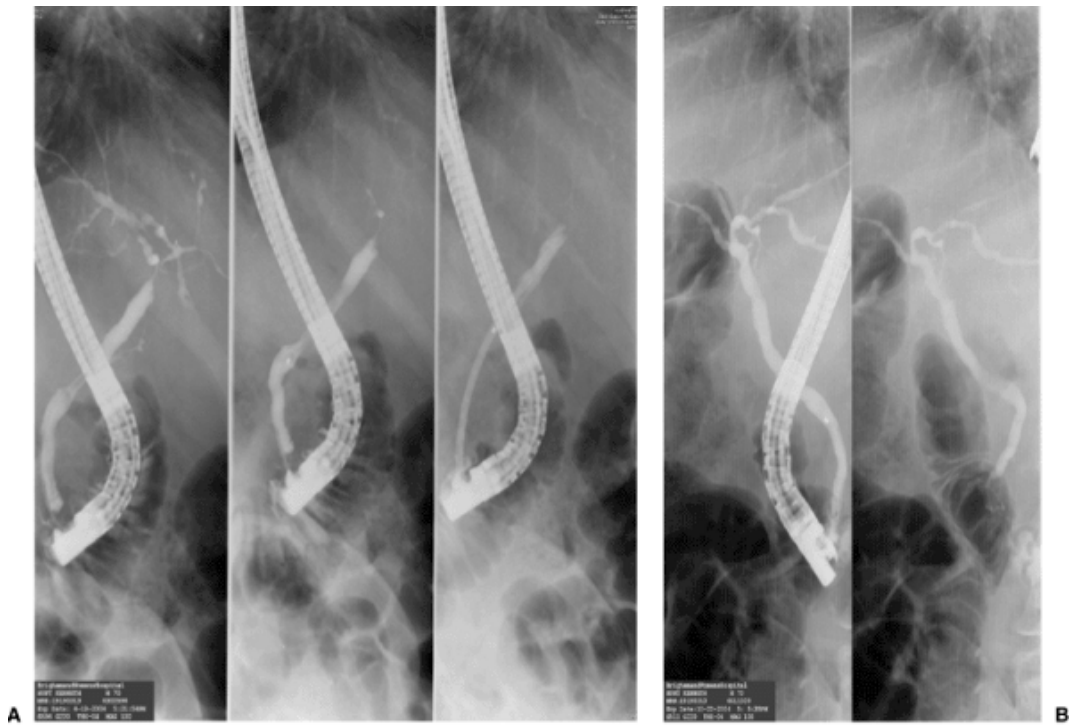
The cholangiogram in PSC shows characteristic diffuse, multifocal strictures of the intrahepatic and extrahepatic ducts, with areas of ectasia that give a beaded appearance (Fig. 6.6A). A rare variant termed *small duct sclerosing cholangitis* involves ducts of such small caliber that cholangiographic findings appear normal. Biliary strictures may prevent opacification of the full ductal system, which can be overcome by occlusion cholangiography with an inflated balloon catheter above the cystic duct entry. However, the same strictures often prevent complete drainage of injected contrast medium, resulting in an increased incidence of post-ERCP cholangitis if antibiotics are not used. Unfortunately, the routine use of antibiotics before and after the procedure does not prevent cholangitis in all cases. Therefore, given the possible complications of obtaining a cholangiogram, ERCP should be performed judiciously on patients with known PSC.

One of the most important and difficult differentiations to be made during cholangiography is that between benign strictures of PSC and cholangiocarcinoma, which arises as a complication of PSC in up to 15% of cases. The onset of weight loss or sudden deterioration of jaundice or pruritus may herald the onset of cholangiocarcinoma and warrants investigation using cholangiography. Brush cytologic examination of strictures at the time of ERCP has a sensitivity of 60% for detection of cholangiocarcinoma (46). The combination of brush cytology, tissue deoxyribonucleic acid analysis, and serum

CA 19-9 and carcinoembryonic antigen level determination was reported to increase the sensitivity and specificity in diagnosing cholangiocarcinoma in patients with PSC (47). To date, routine surveillance of patients with PSC for the development of cholangiocarcinoma has not been recommended.

A number of other conditions can mimic the cholangiographic appearance of PSC (Table 6.4). Biliary tract involvement of autoimmune pancreatitis has been described (48). Cirrhosis of any cause can lead to blunting and thinning of the intrahepatic tree, but intervening dilatation is not usually present. Multifocal liver metastases, lymphoma, and polycystic liver disease can similarly cause multifocal intrahepatic narrowing, and nodal involvement at the porta hepatis can mimic extrahepatic involvement. Acquired immunodeficiency syndrome (AIDS) cholangiopathy associated with opportunistic infection is discussed later (see “Acquired Immunodeficiency Syndrome Cholangiopathy”). Postoperative biliary strictures, which have an ischemic pathophysiologic mechanism, can lead to secondary biliary cirrhosis and have an appearance similar

to that of PSC, but the extrahepatic bile duct distal to the injury is usually normal.



▪ **Figure 6.6 A:** Sclerosing cholangitis affecting the extrahepatic and intrahepatic bile ducts. **B:** The same patient after medical and endoscopic therapy, showing improvement.

The benefit of endoscopic therapy for strictures in PSC is controversial. The rationale for endoscopic therapy is that back-pressure from high-grade strictures is at least in part responsible for the progression of liver disease. The ideal candidate for endoscopic therapy, therefore, has a discrete high-grade extrahepatic obstruction with limited intrahepatic involvement (Fig. 6.3B).

Unfortunately, this sort of “dominant” stricture is seen in only 20% of patients with PSC. The study by a group from Amsterdam has reported significant benefits from short-term endoscopic treatment of 32 patients with a dominant stricture (49). Short-term stenting with a 7- or 10-Fr stent after stricture dilatation resulted in significant improvement in mean scores for pruritus, fatigue, and right upper quadrant pain 2 months after the procedure. Jaundice resolved in 12 of 14 patients. There was evidence that the beneficial effect was durable because no reintervention was needed by 80% and 60% of patients 1 and 3 years after the procedure, respectively. Another group has described a slightly different approach in which balloon dilatation was the primary therapy, repeated yearly or more often if clinical or biochemical markers worsened (50). Stent placement was performed for 4 to 12 weeks only if balloon dilatation was deemed unsatisfactory. A group of 63 patients was therefore observed for a median of 34 months and needed a mean of 2.3 dilatations (range, 0 to 7) and a mean of 2.2 stents (range, 0 to 5). Compared with the predicted survival rate calculated using the Mayo Clinic survival model, this aggressive approach resulted in a significant increase in 1-, 3-, and 5-year survival rates from 92%, 77%, and 65% to 97%, 87%, and 83%, respectively (P = 0.03). Although this study was conducted with historical controls and the results may have been influenced by the concomitant use of ursodiol in the care of all the patients in the study, the results emphasized the potential impact of endoscopic therapy in altering the course of PSC. However, these therapies, even when combined, may not always be successful (51). An analysis of published papers revealed that the predictors of positive clinical and laboratory success include the presence of a dominant stricture, endoscopic therapy, and high serum bilirubin levels (52).

Hemobilia

Hemobilia refers to bleeding into the biliary tree. Today, the most common causes of hemobilia are endoscopic,

surgical, or radiologic procedures directed at the liver and biliary tract. The incidence of hemobilia following percutaneous liver biopsy is between 0.06% and 1% (53). Other causes of hemobilia include blunt or penetrating liver trauma, hepatic or biliary tumors, ascariasis, hydatid disease of the liver, and vascular fistulas. Hemobilia manifests as the classic Sandblom triad of upper GI bleeding, right upper quadrant pain, and jaundice in only 22% of patients (53). If bleeding is brisk, the presentation may be dominated by signs of hemorrhage, which can be severe and sometimes fatal. Slower rates of bleeding lead to clot formation within the bile ducts and can cause pancreatitis, cholecystitis, or cholangitis. If the pressure within the bleeding vessel is low, as in a hepatic vein or portal vein, the flow may be reversed and bile may enter the bloodstream, a rare condition called *bilhemia.*

Table 6.4. Conditions that can Mimic Primary Sclerosing Cholangitis During Cholangiography

Neoplastic disease
Cholangiocarcinoma
Liver metastasis
Porta hepatis lymph node metastasis

Lymphoma
Cirrhosis
Polycystic liver disease
Infectious disease
Ascending cholangitis
Intrahepatic stones with bacterial infection
Multiple hepatic abscesses
AIDS cholangiopathy (cytomegalovirus, *Cryptosporidium*)
Graft versus host disease
Hepatic arterial ischemia
Posttraumatic
Postsurgical, including liver transplantation
Chronic rejection after liver transplantation
Biliary involvement by autoimmune pancreatitis

AIDS, acquired immunodeficiency syndrome.

Ultrasonographic findings can be misleading in hemobilia because blood in the bile duct can be isoechoic to liver parenchyma, so the bile ducts may not be visualized at all. On ERCP, fresh blood or clot often extrudes from the papilla. Cholangiography demonstrates intraductal clots that can appear string-like, if they have formed a cast of the bile duct, or rounded, mimicking bile duct stones. Balloon extraction of the clot during ERCP is an effective means of relieving bile duct obstruction (54). When the bleeding site is in the distal CBD, endoscopic coagulation, injection of diluted epinephrine, or clip application usually achieves hemostasis. However, in most cases of severe hemobilia, bleeding arises from an intrahepatic arteriobiliary fistula that is not amenable to endoscopic therapy. These cases necessitate hepatic arteriography and embolization.

Hepatobiliary Surgery and Complications

Cholecystectomy

Biliary leaks appear to be more common after laparoscopic cholecystectomy than after open cholecystectomy, ranging in incidence from 0.65% to 5% (55,56). Most bile duct leaks after laparoscopic cholecystectomy are from the cystic duct stump, although leakage can occur anywhere in the extrahepatic biliary tract, including the “ducts of Luschka” in the gallbladder bed (Fig. 6.7).

Symptoms of abdominal pain, tenderness, and fever can occur in the immediately postoperative period but are often not recognized until an average of 5 days after surgery. The diagnosis may be made by transabdominal ultrasonography, CT scan, or nuclear scintigraphy (57).

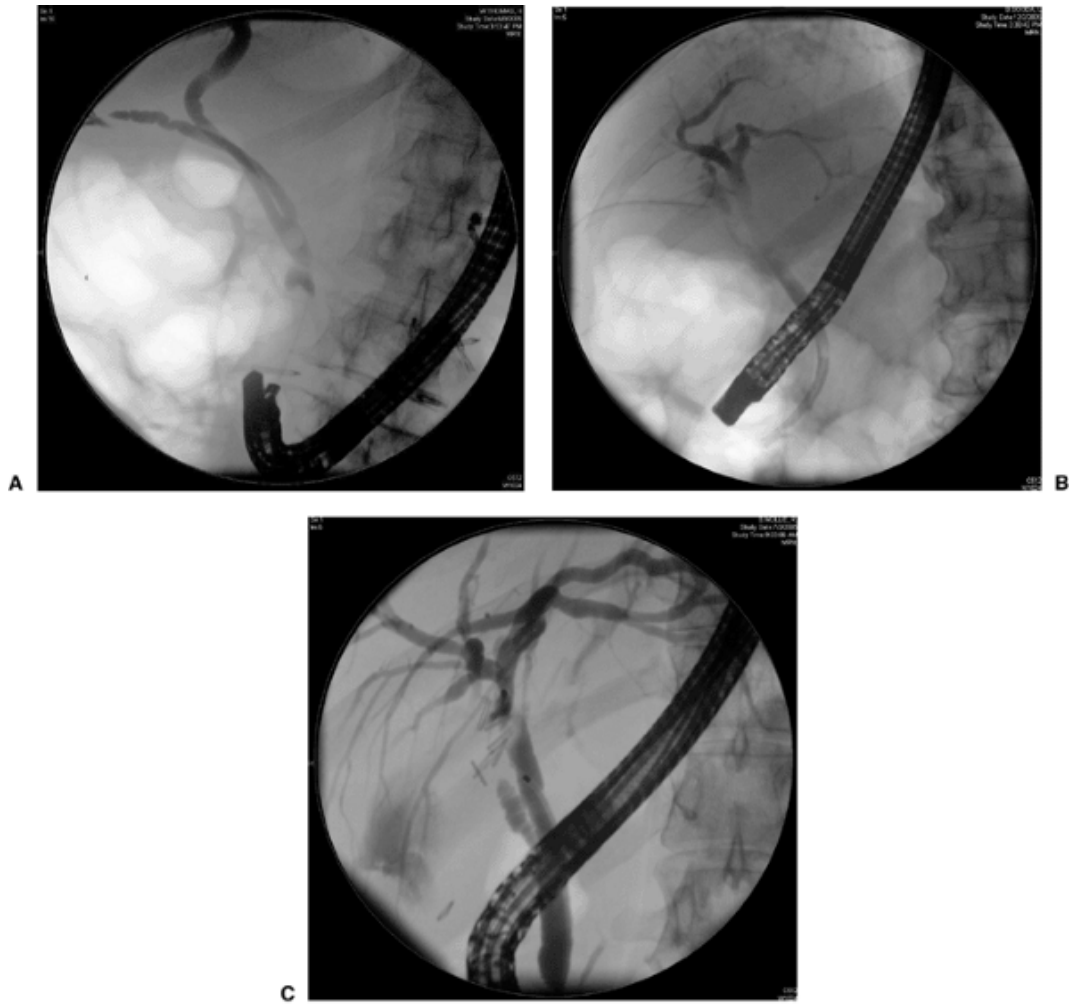
ERCP has three roles in the management of bile leaks. First, ERCP best demonstrates the anatomy and identifies and locates a leak. Second, it helps rule out any potential distal biliary obstruction, such as CBD stones (Fig. 6.8A), which could contribute to the development and persistence of a bile leak. Third, ERCP provides therapeutic options.

Although spontaneous closure of a leak has been described after percutaneous

drainage of the bile collection, most patients need intervention. ERCP is the therapy of choice for bile leaks because it is highly successful and carries less morbidity than does surgical repair. Endoscopic therapy has been shown to achieve closure in more than 90% of patients. When no distal biliary obstruction is found, the least invasive method of treatment is the placement of a 10-Fr stent without sphincterotomy. Placement of a stent across

the duodenal papilla is adequate treatment (58,59) (Fig. 6.8B). More complex bile leaks involving major injury to the CBD, common hepatic duct, or right hepatic duct necessitate stent placement across the injury site if possible for effective resolution and for reduction of stricture formation that may occur later (Fig. 6.8C). Nasobiliary tubes have also been shown to be successful (60). No data exist on the ideal period for stent placement, but 1 to 4 weeks is recommended in most series. At the time of stent removal, repeat cholangiography is not necessary if the patient is clinically well. Surgery may be necessary if, rarely, endoscopic management fails. Endoscopists must be aware of excluded hepatic duct segments that may leak but are disconnected from the biliary tract, as shown by ERCP. A knowledge of segmental intrahepatic ductal anatomy is essential.

▪ **Figure 6.7** Cystic duct leak after laparoscopic cholecystectomy.



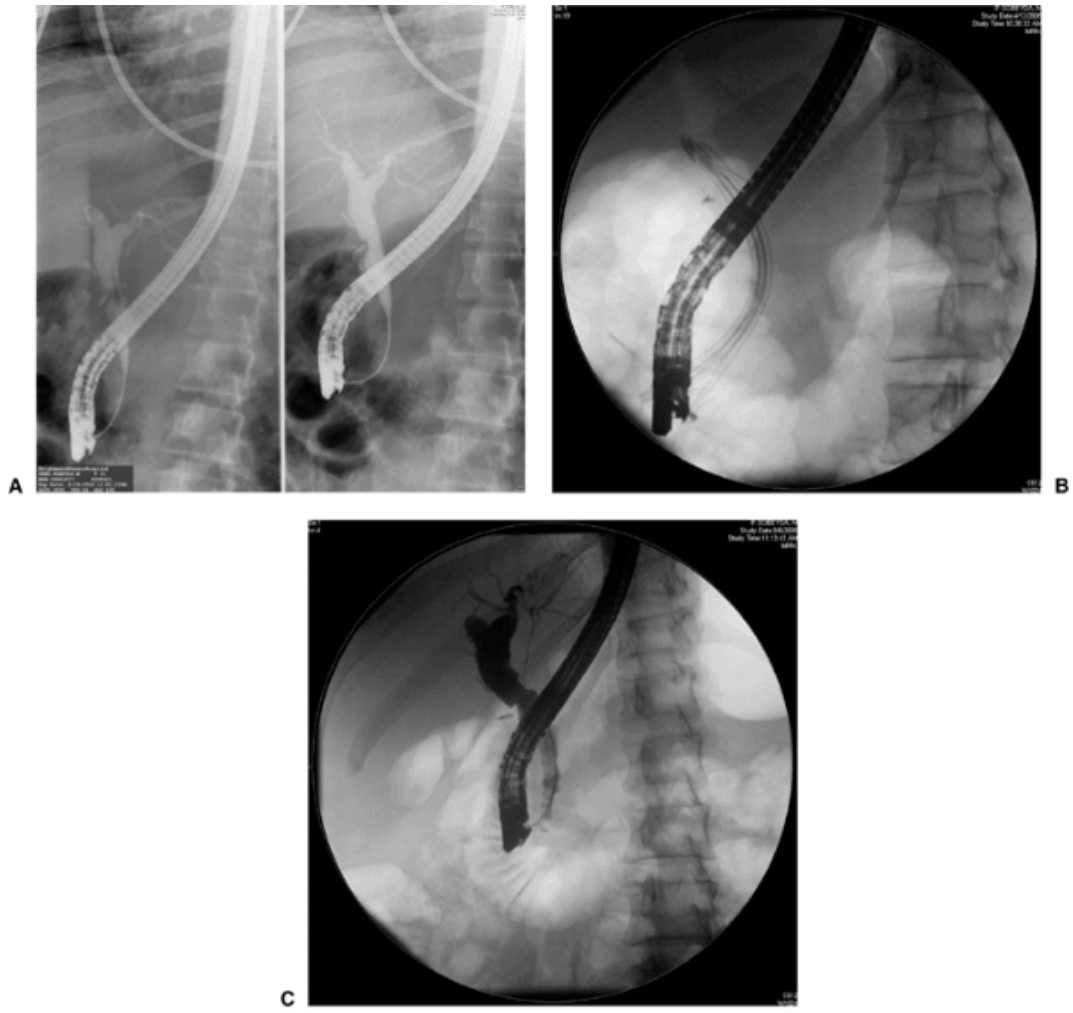
▪ **Figure 6.8 A:** Patient with prior Billroth II partial gastrectomy now with a bile leak after cholecystectomy and a distal bile duct stone; **(B)** short 2-cm 10-Fr diameter plastic stent placed for treating bile leak; **(C)** major common hepatic duct injury showing clips placed partly across the duct and concomitant leak.

Benign bile duct strictures are another complication of laparoscopic cholecystectomy (Fig. 6.9A). Bile duct strictures after laparoscopic cholecystectomy tend to be short (<10 mm) and occur at several well-defined areas: Mid-CBD (42% to 50%), confluence of the right and left hepatic ducts (22% to 41%), common hepatic duct (28%), distal CBD (15%), and cystic duct (20%). Strictures may result from misplacement of a clip or suture during surgery, often across the right hepatic duct or CBD, or after inadvertent ischemic injury to the bile duct, which may evolve over time and, therefore, potentially present late.

Options for therapy include surgery and percutaneous or endoscopic dilatation with stent placement. Surgical management of benign biliary strictures results in a good response in 75% to 93% of patients, with a

stricture recurrence rate of 18% (61). Early surgical referral, no previous repair,

the quality of the proximal duct, and greater distance between the stricture and the confluence are associated with a favorable surgical outcome. Similarly, percutaneous biliary dilatation of benign biliary strictures has a reported success rate between 33% and 100%, with a long-term patency rate of 76% (62). However, several sessions are required to obtain a satisfactory outcome.



▪ **Figure 6.9 A:** Benign bile duct stricture after cholecystectomy in a patient undergoing hydrostatic balloon dilatation; **(B)** four 10-Fr plastic stents placed across the stricture; **(C)** result after 6 months of endoscopic therapy with the resolution of the stricture.

The role of ERCP in the management of benign biliary strictures is well established (63). The guiding principles include clearly defining the stricture, excluding further strictures, and determining the degree of communication between left and right systems. Stricture dilatation is performed with a balloon or with sequential catheter dilators over a guidewire. Previous sphincterotomy eases instrumentation, facilitates placement of multiple stents, and may reduce the incidence of pancreatitis after stenting. After initial dilatation, a single 8- or 10-Fr stent should be placed for an initial period of 6 to 8 weeks to reduce the rate of restenosis (64). Placement of several stents may further reduce the long-term rate of restenosis (Fig. 6.9B). Stent changes every 3 months for up to 1 year are

required to achieve long-term clinical results. Success rates higher than 80% have been reported with this endoscopic regimen (61,62,65). The likelihood of successful endoscopic therapy is based on the age of the stricture. A delay in diagnosis greater than 3 months significantly reduces the success rate (62).

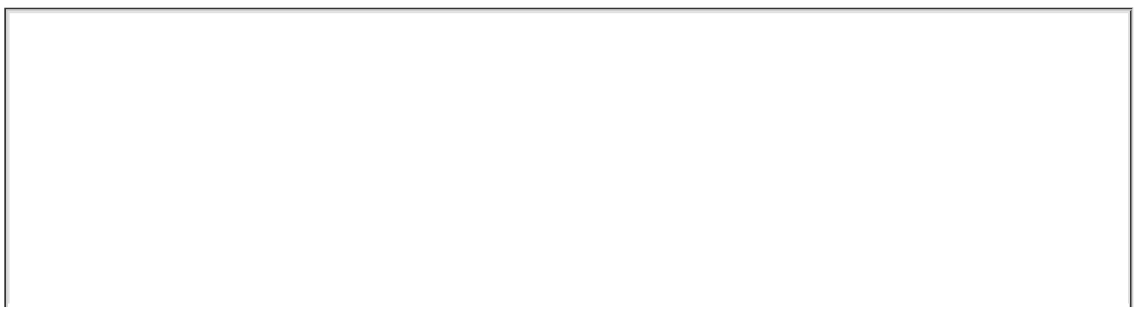
Results of a retrospective study showed similar long-term success rates between endoscopic and surgical interventions (66). These findings suggest that surgery be reserved for patients with complete duct transection, failed previous repairs, failed endoscopic therapy.

The role of SEMS in the management of benign strictures, particularly postoperative strictures, remains unclear. Although there are reports of successes with SEMS in postoperative biliary strictures, concerns about long-term patency have prevented the standard use of the stents (67,68,69). Furthermore, the relative safety and success of surgery means that in suitable patients it may be a more logical alternative to failed endoscopic management with plastic stents unless SEMS seem the only option, in which case a covered stent would be logical.

Liver Transplantation

ERCP plays several roles in the care of patients in the pre- and posttransplantation settings. Preoperatively, ERCP may be used to evaluate the biliary tree and rule out any concomitant biliary disorder such as choledocholithiasis or cholangiocarcinoma. More commonly, however, ERCP is used after transplantation to diagnose and manage postoperative complications (70,71,72). Biliary tract complications after liver transplantation include bile leaks, which tend to occur early in the postoperative period, and strictures, stones, and sphincter dysfunction, which typically occur later (Fig. 6.10).

The biliary ductal anastomosis most often performed during liver transplantation in adults is an end-to-end choledochocholedochostomy with or without T-tube placement. Roux-en-Y choledochojejunostomy is performed in children or adults if there is evidence of biliary tree disease (e.g., PSC) in the recipient, if there is a considerable size mismatch between recipient and donor (e.g., split graft transplantation), or if the free biliary ends do not lie close enough to each other to allow tension-free anastomosis. Bile leaks can occur at the site of either the ductal anastomosis or T-tube insertion. As with postcholecystectomy leaks, posttranplant bile leaks typically manifest early in the postoperative period as pain, fever, or unexplained elevated results of liver function tests. Several factors can contribute to the development of a bile leak in the postoperative period, including local ischemia, tissue preservation problems, technical difficulties, relative obstruction of distal bile flow by debris, a clogged T-tube, or papillary stenosis (73). The mainstay of management is endoscopic clearance of debris after sphincterotomy, with stent placement if necessary. Surgery is indicated in the setting of massive bile leaks.



▪ **Figure 6.10** Stricture of choledochocholedochostomy after liver transplantation (with acknowledgment to Dr. Peter Kelsey, Massachusetts General Hospital.)

Bile leaks at the anastomosis, at the T-tube removal site, or due to parenchymal injury (e.g., a reduced-size graft in a pediatric patient, a graft from a living-related donor, or a split graft) are successfully treated by placement of a transpapillary stent (64). Unless there is evidence of stone or debris obstruction or of papillary stenosis or suspected SOD, sphincterotomy is not necessary.

Biliary strictures after liver transplantation most commonly occur at the choledochocholedochostomy or choledochoenterostomy anastomosis and may manifest any time in the postoperative period. They may be caused by hepatic arterial thrombosis (a major complication of liver transplantation) or ischemic injury after prolonged organ preservation (cold ischemic time >13 hours). Although strictures typically manifest with the signs and symptoms of biliary obstruction, proximal dilatation of the biliary tree on imaging studies is not always seen, likely due to graft disease. The length and diameter of the anastomotic stricture are predictive of the likelihood of success of endoscopic intervention. Short, mildly narrowed strictures are more likely to resolve after endoscopic dilatation or temporary stenting. Longer or multiple strictures often may not be managed successfully with endoscopy alone and may necessitate either surgical reconstruction or retransplantation for definitive treatment.

Papillary stenosis (SOD) can occur in the post-transplantation period. It typically manifests as cholestasis associated with a tightly narrowed terminal CBD segment and proximal dilatation. ES is the treatment of choice.

Choledocholithiasis occurs sporadically in the posttransplantation period. Biliary cast syndrome is a rare form of choledocholithiasis in which sludge and sloughed necrotic biliary epithelial cells or clot form casts within the bile duct. Preservation or ischemic

injury is thought to be the main etiology. Biliary casts may be extracted by ERCP, but an open procedure may be necessary for extensive disease.

Pretransplantation liver disease, particularly PSC, may recur after liver transplantation. Disease recurrence is often difficult to differentiate from ischemic strictures or opportunistic infections in the biliary tract. Recurrent PSC may be suspected when a pattern of multiple strictures in a well-preserved graft is encountered with no apparent vascular or infectious problems. In patients with PSC, the possibility of a malignant stricture should be considered, especially if there is unsuspected cholangiocarcinoma in the explant. Unfortunately, because these patients often undergo Roux-en-Y hepaticojejunostomy as part of the transplantation procedure, an endoscopic approach may be impractical.

Other Postoperative Injuries

Biliary strictures and leaks can also develop after other hepatic, biliary, or pancreatic resections with reimplantation of the bile ducts. Biliary leaks can be successfully managed with stent therapy (74). Although amenable to both dilatation and stenting, strictures may be difficult to access with endoscopy because of surgically altered anatomy or distortion by liver atrophy or hypertrophy (75).

Other Benign Biliary Strictures and Injuries

Trauma

A variety of nonsurgical causes of bile duct injury may necessitate endoscopic management. There have been several reports of successful endoscopic therapy for biliary fistulas resulting from both blunt and penetrating liver trauma (76). Success, however, appears to depend on the nature and location of the injury and the patient's clinical status. Endoscopic therapy, including stent placement, has been described in the successful closure of a fistula between a transjugular intrahepatic portosystemic shunt and the biliary ducts, and in the management of bile leak secondary to liver biopsy and penetrating trauma (77).

Iatrogenic Strictures

Ischemic bile duct strictures have been associated with hepatic arterial infusion of 5-fluorodeoxyuridine (78). Therapy includes withdrawal of the drug and surgical, percutaneous, or endoscopic drainage of the dilated biliary tree. Direct toxic injury to the biliary tree after using formaldehyde or alcohol solutions in the treatment of hydatid disease has also been described.

Chronic Pancreatitis

Biliary strictures accompany chronic pancreatitis in as many as 29% of cases (79). These strictures tend to be relatively long (mean length, 3.9 cm). Clinical manifestations include abdominal pain (65%), jaundice (43%), secondary biliary cirrhosis (15%), and cholangitis (15%). Surgical bypass with choledochoduodenostomy or choledochojejunostomy has been the procedure of choice but is associated with a high morbidity (25%) in alcoholic patients. Endoscopic stent placement is a safe and potentially beneficial alternative therapy. Single biliary stents have shown short-term success in maintaining biliary drainage (80,81) and may even induce the reversal of secondary hepatic

fibrosis (82). Multiple stents may prove more successful than single stents (83). SEMS have also shown preliminary success in maintaining biliary drainage in chronic pancreatitis (84,85,86), but long-term studies of efficacy and safety have not yet been published.

Malignant Biliary Obstruction

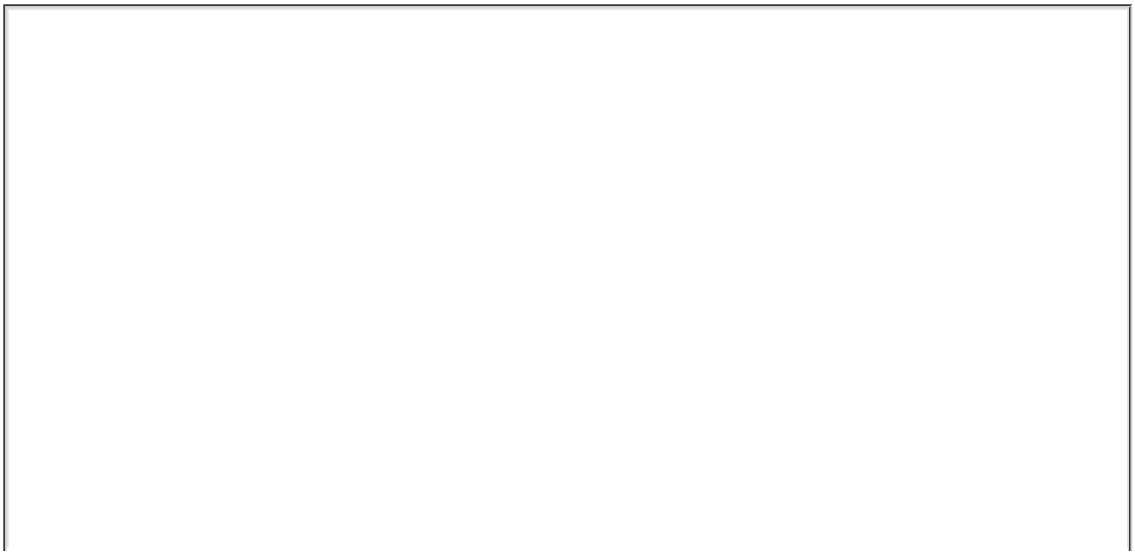
Diagnosis and Staging

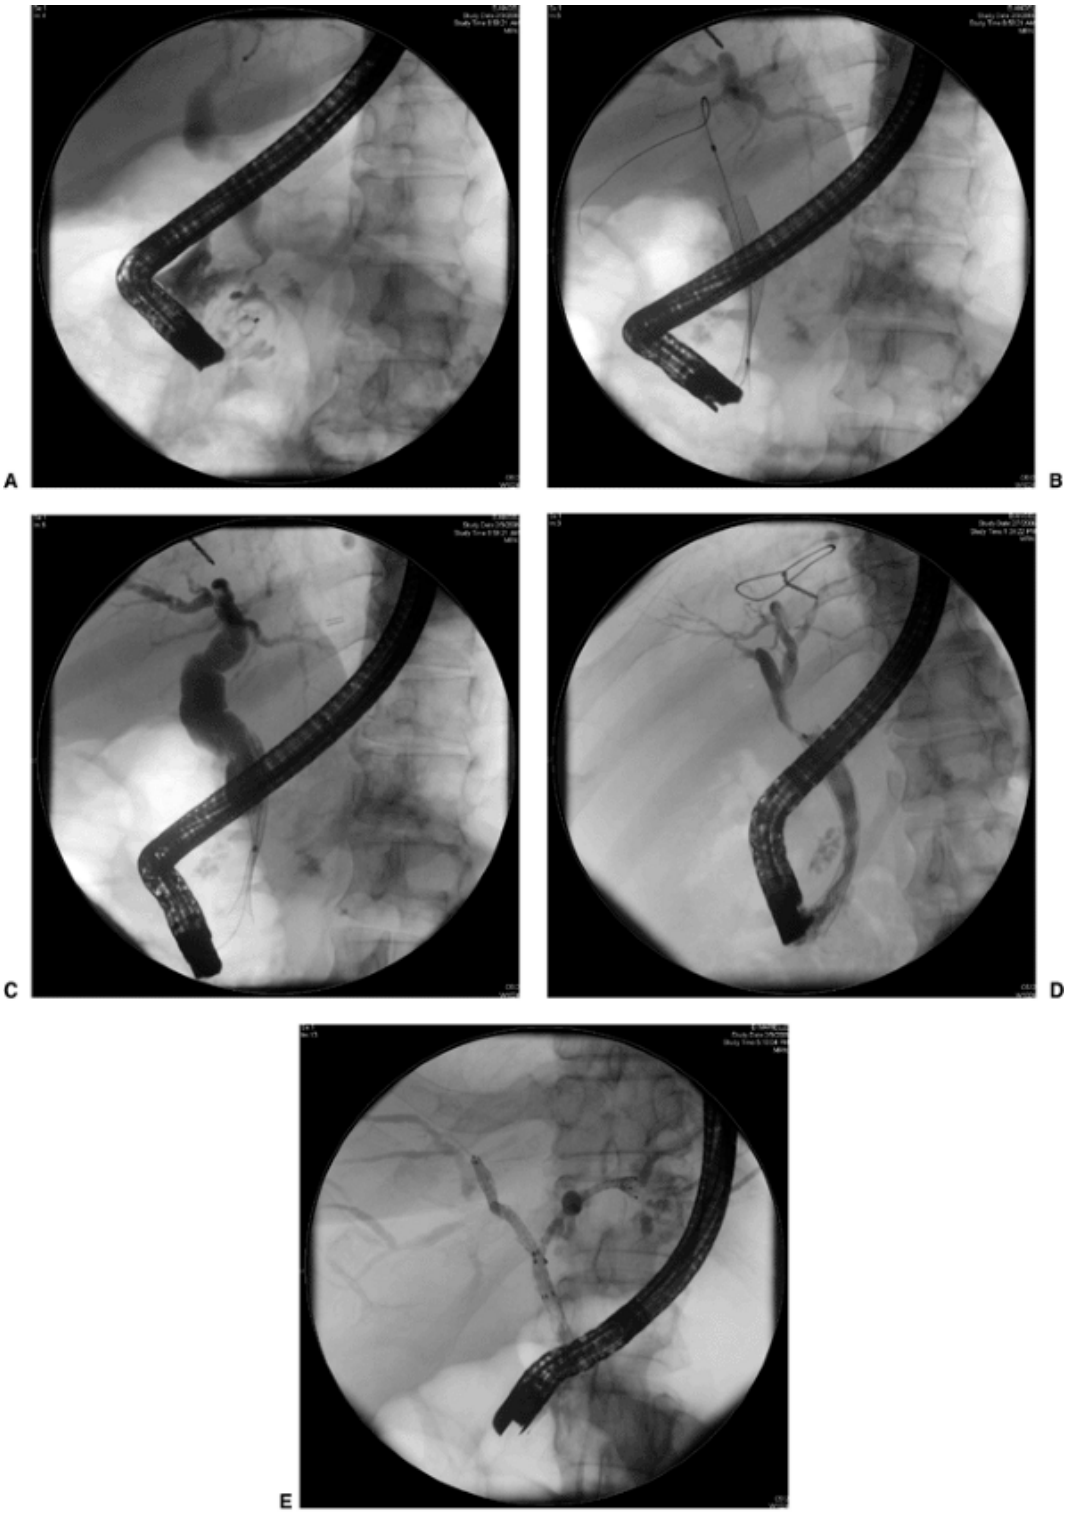
Malignant biliary obstruction is caused by tumors arising in the biliary tree (including papilla) or adjacent organs (e.g., pancreas) or by metastatic lesions. Patients with malignant biliary obstruction usually have progressive cholestasis and pruritus, but fever is rare in the absence of previous intervention.

Signs of biliary dilatation are evident on imaging by ultrasound, MDCT, or MRCP, but the malignancy itself may not be identified easily. Patients with tumors arising in the major papilla or pancreas usually have dilatation of both pancreatic and biliary ducts. The “double-duct” sign (stricture and dilatation of both the biliary and pancreatic ducts) is highly suggestive of a lesion of the head of the pancreas.

ERCP has many roles in differentiating malignant from benign causes of biliary obstruction. Conventional biopsy of lesions involving the papilla or duodenum can be performed in the appropriate setting. After identifying the stricture on cholangiography, a cytology brush can be inserted into the strictured area to obtain specimens for analysis. The sensitivity of brush cytologic examination is highest for primary bile duct tumors, intermediate for pancreatic cancers, and lowest when biliary obstruction is secondary to metastatic malignant disease (87). The sensitivity of brush cytology increases from 40% for one brushing to 62% for three brushings in documented cases of cholangiocarcinoma (88). A small biopsy forceps can be passed under direct visualization (with cholangioscopy) or fluoroscopy into ductal strictures. The overall sensitivity

of cytology increases to 80% when biopsy is used in combination with cytologic brushing (62). Cytologic examination of aspirated bile has the lowest diagnostic sensitivity—34% to 50%. Newer devices for tissue acquisition, including tissue scrapers, are being evaluated and may improve the sensitivity for malignant disease. Bile tumor markers, including K-ras and p53, are under investigation.





▪ **Figure 6.11 A:** Malignant distal bile duct stricture; **(B)** appearance immediately after deployment of a self-expanding metallic stent; **(C)** injection of contrast through the stent to document patency and appropriate position; **(D)** partial occlusion of metallic stent by tumor ingrowth; and **(E)** three metallic stents used to palliate hilar malignancy affecting the right and left hepatic ducts.

Although ERCP is not designed for staging malignant disease of the pancreatic or bile duct, the development of intraductal ultrasonography, in which a high-frequency ultrasound probe is introduced into the bile duct or pancreatic duct through a duodenoscope, may prove to be an important tool in staging early and, possibly, resectable cases of malignant biliary obstruction (89).

Endoscopic Therapy

With malignant obstruction, the major role of ERCP is in the achievement of biliary drainage through plastic or metal stents. Duodenoscopes with larger channels (3.7 and 4.2 mm) are used to deploy 10- and 11.5-Fr plastic stents and SEMS (Fig 6.11A). Technical success rates of 90% have been reported. Inability to gain access to the papilla because of tumor occlusion of the duodenum, surgically altered anatomy (Billroth II or Roux-en-Y anastomosis), or the inability to pass a guidewire across the stricture are the most common causes of technical failure. Endoscopic management of malignant biliary obstruction is superior to both surgical bypass and percutaneous stent placement (90,91). However, in cases in which an attempt at surgical resection is anticipated, preoperative biliary drainage by ERCP has no proven advantage except when there has been previous instrumentation (92,93,94).

Dilatation of distal malignant biliary strictures is usually not necessary for stent deployment, but may be necessary for high-grade or hilar strictures (Fig. 6.11E). If endoscopic attempts are unsuccessful, percutaneous transhepatic cholangiography is used to access the stricture and to place a percutaneous biliary drain through it over a guidewire. The biliary drain can then be replaced with a stent through either percutaneous or endoscopical means. Some experts recommend prophylactic administration of antibiotics to all patients with obstruction, whereas others have argued for selective use of antibiotics when drainage is not established (95).

At the time of the initial ERCP, plastic biliary stents are inserted to allow for diagnosis and tumor staging if these are not already available. Biliary stents are not permanent and require replacement. The optimal time to replace these stents is generally between 3 and 6 months based on low occlusion rates with 10- and 11.5-F stents at 3- and 6-month intervals, respectively (96). An alternative approach is based on close clinical follow-up evaluation and exchange of the stent when there is evidence of occlusion (i.e., low-grade fever, malaise, or dark urine). It is our practice to change biliary stents at 3- to 4-month intervals.

If a malignancy is deemed unresectable, SEMS are used for palliation. When compared to plastic stents, metal stents have better stent patency and are more cost-effective (97,98). Several expandable metal stents are available for use in the biliary tract. These stents can be delivered from a small-caliber (e.g., 8-Fr) catheter system and once released can expand up to 10 mm in diameter. For malignant obstruction of the distal bile duct, the tip of the stent is usually left outside the papilla. For more proximal biliary lesions (e.g., within the common hepatic duct), it is possible for the deployed stent to be laid entirely within the bile duct. For malignant obstruction, the technical success rates for biliary placement of SEMS have been reported to be as high as 95%, with few immediate complications (69). Metal stents can become obstructed by tumor ingrowth or overgrowth and more rarely by sludge and bacterial adherence. These stent blockages can be relieved by diathermic devices, extraction balloon catheters, or the insertion of a standard plastic stent or a second metal stent. Coated SEMS have been developed and may confer the advantage of prolonged patency

compared to uncovered stents.

Adjuvant Therapy

The delivery of adjuvant therapy for malignant biliary obstruction has been investigated. Intrabiliary irradiation has been performed on an investigational basis with iridium 192 wires placed by the percutaneous or endoscopic route. More recent work has focused on the delivery of photodynamic therapy to the bile duct through an ERCP-guided catheter. The use of hematoporphyrin derivatives as sensitizers, followed by intraluminal photoactivation, showed mixed results in producing prolonged biliary decompression, improved survival, and improved quality of life for patients with advanced bile duct cancer (99,100,101).

Other Biliary Disease Infections

Acquired Immunodeficiency Syndrome Cholangiopathy

Patients with human immunodeficiency virus (HIV) infection appear to be uniquely susceptible to disease in the biliary system, because profoundly immunosuppressed transplant recipients are not similarly predisposed. The syndrome that has been termed *AIDS cholangiopathy* clinically describes the condition of

patients with HIV infection, who usually have CD4 counts less than 200/µL, and right upper quadrant pain, dramatic elevation in alkaline phosphatase level (mean value 800 IU/L), and modest hyperbilirubinemia (mean value 1.5 mg/dL) in the absence of stone disease or tumor obstruction (43). Numerous opportunistic pathogens have been found in the bile ducts of these patients, including *Cryptosporidium*, cytomegalovirus, and *Microsporidia* such as *Enterocytozoon bieneusi.* On ERCP, the appearance of the bile duct can vary from classic papillary stenosis with a dilated CBD that tapers distally and markedly retains contrast material, to intrahepatic or extrahepatic sclerosing cholangitis. The response to ES is similarly variable. Patients whose cholangiograms reveal papillary stenosis appear to have a dramatic reduction in pain after sphincterotomy, although levels of alkaline phosphatase remain elevated (102). The role of endoscopic therapy in cases of more diffuse involvement has not been established.

Parasitic Infection

Echinococcosis, caused by the small tapeworms *Echinococcus granulosus* and *Echinococcus multilocularis* is typically managed surgically, but when it is associated with biliary obstruction, ERCP can help in the management. Large hydatid cysts located near the porta hepatis in the liver can cause obstruction by external compression. Smaller hepatic cysts also can rupture into bile ducts and form biliary fistulas. The hydatid membranes can then obstruct the bile duct. These biliary obstructions can be defined by ERCP, and sphincterotomy can lead to successful extraction of hydatid material from the CBD (103,104) or to the resolution of the fistulas.

The biliary manifestations of ascariasis, caused by the large roundworm *Ascaris lumbricoides*, are a result of the worm's propensity to enter narrow orifices such as the papilla. Previous ES is a predisposing factor (105). Migration of the worm into the bile ducts can result in biliary obstruction and acute or chronic

cholangitis. Intraductal worm death may result in fibrosis, stricture, and stone formation. Combined with medical antihelminthic therapy, endoscopic extraction of the worm with a forceps, basket, or snare can be therapeutic.

Fasciola hepatica, a large, hermaphroditic trematode, invades the biliary tract during the acute invasive phase, when the parasite migrates through the liver, and the chronic phase, when the parasite matures and resides in the biliary tract. During the chronic phase, biliary colic, jaundice, and even hemobilia can occur. Worms as large as 13 to 30 mm can be visualized on ERCP. Although fascioliasis can be managed medically, sphincterotomy and balloon extraction of the parasites have also been effective (106).

Liver flukes migrate through the papilla and into biliary ducts, pancreatic ducts, and the gallbladder before ultimately residing in the smallest biliary duct that can accommodate them. *Clonorchis sinensis* is the most common fluke in humans, followed by *Opisthorchis* species. The infection is often asymptomatic but can result in cholestasis, secondary biliary cirrhosis, or superimposed bacterial cholangitis. The presence of liver flukes causes marked proliferation of the biliary epithelium and is associated with an elevated risk of cholangiocarcinoma. ERCP is useful in the diagnosis because it shows filling defects and tapering of the terminal bile ducts, often with a characteristic pattern of multiple cystic dilatations. These cystic dilatations may persist on cholangiograms despite successful medical therapy with praziquantel.

Pediatric Endoscopic Retrograde Cholangiopancreatography

Success and Complications

ERCP in neonates and infants is now possible using specialized smaller duodenoscopes. ERCP in neonates is technically demanding, but the procedure in older children is no more difficult than it is in adults (107). Cannulation rates in neonates and infants are lower than those in adults, ranging from 27% to 95% (107), but comparable in children older than 1 year. The overall complication rate (mainly from pancreatitis) in the pediatric population ranges from 5% to 7%. The same medications are used for conscious sedation but the doses are age adjusted. Some centers use general anesthesia routinely. Lead protection of nonbiliary areas, judicious limitation of fluoroscopy, and efficient endoscopic practices are necessary to minimize radiation exposure.

Indications for Endoscopic Retrograde Cholangiopancreatography in Neonates and Children

The biliary indications for ERCP in neonates and children are listed in Table 6.5. The most important role of ERCP in neonates is in the evaluation of neonatal cholestasis, in which up to 80% of cases are either extrahepatic biliary atresia or neonatal hepatitis. An early diagnosis is crucial because extrahepatic biliary atresia requires early corrective surgery (Kasai operation or hepatoportoenterostomy) to achieve a favorable outcome. In the initial evaluation of neonatal jaundice, ERCP has a sensitivity of 83% to 86% for the diagnosis of biliary atresia and of 93% to 100% for the diagnosis of neonatal hepatitis (108). Biliary atresia has been classified into three categories (78). In type 1, the

biliary tree is not visualized. In type 2, the distal CBD and the gallbladder can be

seen, but the main hepatic and intrahepatic ducts cannot. Type 3 is divided into two subtypes: Type 3a, in which the gallbladder and the complete common duct are visualized with biliary lakes at the porta hepatis, and type 3b, in which both hepatic ductal systems have lakes.

Table 6.5. Biliary Indications for Endoscopic Retrograde Pancreatography in a Pediatric Population

Congenital anomalies
Biliary atresia vs. neonatal hepatitis
Paucity syndrome
Congenital hepatic fibrosis
Biliary strictures due to cystic fibrosis
Congenital biliary strictures
Choledochal cyst
Acquired diseases
Primary sclerosing cholangitis
Biliary obstruction due to parasitic infestation
Cholelithiasis and choledocholithiasis
Biliary obstruction or leaks after liver transplantation
Malignant obstruction of common duct

Another variant of biliary atresia is characterized by a paucity or absence of intrahepatic biliary ducts with a normal or hypoplastic extrahepatic duct. This condition may occur as part of Alagille syndrome. It is important to differentiate this condition from extrahepatic biliary atresia to avoid unnecessary surgery. Another condition to consider with a normal CBD and irregular intrahepatic ducts is congenital hepatic fibrosis. This is a recessive genetic disorder characterized by multiple intrahepatic macroscopic and microscopic bile duct cysts within bands of fibrous tissue.

As in adults, PSC in children is associated with inflammatory bowel disease and other autoimmune disorders. PSC in children can be accurately diagnosed by pruning the peripheral biliary tree and irregular areas of stenosis and ectasia during cholangiography. Endoscopic treatment with balloon dilatation of strictures and clearance of any obstruction results in clinical and laboratory improvement.

Cystic fibrosis is characterized by dilatation, narrowing, and beading of the intrahepatic ducts secondary to focal or multilobular biliary cirrhosis. These abnormalities have been attributed to intrahepatic mucus plugging.

Cholelithiasis is rare in childhood, except for certain ethnic groups, but is associated with chronic hemolytic anemia, short bowel syndrome, congenital anomalies of the biliary tree, cystic fibrosis, neonatal sepsis, prolonged parenteral nutrition, or chronic bile acid malabsorption. Choledocholithiasis occurs only rarely in infants and children and may be associated with biliary tract malformations such as choledochal cysts, chronic liver disease, hemolysis, and infection. Ultrasound and MRCP are often the initial diagnostic procedure. ERCP serves a confirmatory and therapeutic role. ES is the procedure of choice in the management of retained and recurrent bile duct stones and has been performed safely (109).

Choledochal cysts are a congenital malformation of the biliary tract that usually manifest before the patient is 10 years old (110). Patients may present with jaundice, cholangitis, abdominal pain, a palpable mass, or failure to thrive. The classic triad of jaundice, abdominal pain, and a palpable mass is present in only a minority of patients. Type I, the most common, is characterized by the dilatation of the CBD. Type II is a true diverticulum of the CBD. Type III is known as a *choledochocele* and occurs at the papilla. Type IV is characterized by multiple cysts. In type IVA, the cysts are both intra- and extra-hepatic. Type IVB has only extrahepatic cysts. Type V is also known as *Caroli's disease* and is characterized by intrahepatic cysts. ERCP is used to define the biliary anatomy, including any anomalous union between the CBD and the pancreatic duct that may contribute to the pathogenesis of the cysts. ERCP is also used to treat complications of the cysts including CBD stones and sludge. Given a higher risk of biliary malignancies in patients with choledochal cysts, the treatment of these cysts is typically surgical resection, except for cholodochoceles, which do not confer an increased risk of malignancy and can be treated by ES.

Chapter 7
Physioanatomic Considerations

Ian R. Wanless

Key Concepts

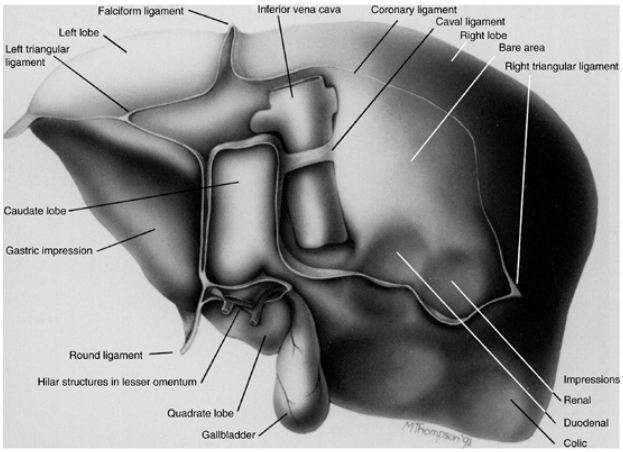
- The branching pattern of large vessels and ducts is used for defining the segmental nomenclature used by radiologists and surgeons.
- Anomalies of the vessels and ducts are of importance to surgeons.
- Bile ducts are supplied by arteries. Arterial injury may lead to ischemic strictures of the ducts, especially after transplantation.
- The liver receives most of the splanchnic blood flow. After severe obstruction at any level of the hepatic vasculature, collateral channels become a source of bleeding and are partly responsible for hepatic encephalopathy.
- The microvasculature of the liver consists of small branches of portal and hepatic veins that interdigitate in a regular pattern, allowing the definition of parenchymal subunits called *acini* or *lobules*.
- Arterioles communicate with portal veins through the periportal end of the sinusoids. In cirrhosis, these communications dilate and, therefore, contribute to portal hypertension.
- Hepatocytes are exposed to gradients of nutrients and waste products, leading to zonal metabolic specialization and zonal variation in the susceptibility to ischemia and drug toxicity.
- The sinusoids are lined by fenestrated endothelial cells that lack basement membranes. This anatomy facilitates rapid exchange between plasma and hepatocytes.
- Hepatic lymph is formed at the sinusoidal level when there is increased sinusoidal pressure, especially with outflow obstruction. This lymph may accumulate as ascites.
- Sinusoidal macrophages (Kupffer cells) are important in host defense.
- Perisinusoidal stellate cells store vitamin A and, when activated, produce collagen that contributes to the pathogenesis of cirrhosis.
- There are two major anatomic forms of chronic liver disease: Cirrhosis and nodular regenerative hyperplasia.
- Nodular regenerative hyperplasia occurs when multiple acini undergo ischemic atrophy and the less-affected acini undergo compensatory hyperplasia.
- Cirrhosis develops when the stromal habitat of hepatocytes is damaged and replaced by dense collagen. The topographic distribution of the resulting parenchymal extinction correlates exactly with the obliteration of small veins.

Anatomic knowledge is required for understanding the normal hepatic physiology and the pathogenesis of disease. This chapter presents a summary of normal anatomy, some physiologic correlates, and a description of the major anatomic abnormalities found in human liver disease. This chapter represents an evolution of the legacy provided by Dr. Aron Rappaport in the earlier editions of this book. Material of current general interest has been retained in this edition. Earlier editions may be consulted for citations of historical interest.

Surface Anatomy

The liver is shaped like a wedge, with its base against the right abdominal wall and its tip pointing to the spleen. The normal liver extends from the fifth intercostal space in the midclavicular line down to the right costal margin. It measures 12 to 15 cm coronally and 15 to 20 cm transversely. The lower margin can usually be felt below the costal margin during inspiration.

Transcutaneous puncture for liver biopsy is commonly located in the midaxillary line in the third interspace below the upper limit of liver dullness during full expiration, commonly in the ninth intercostal space. The median liver weight is 1,800 g in men and 1,400 g in women (1). The adult liver weight is between 1.8% and 3.1% of body weight in 80% of individuals (2,3). Liver weights in fetuses and children are relatively greater, being 5.6% at 5 months gestational age, 4% to 5% at birth, and 3% at 1 year of age (4,5).



• **Figure 7.1** Posterior view of the liver. The marks impressed on the liver surface by neighboring organs mirror its topographic relations. (Drawn by M. Thompson.) (From Wanless IR. Anatomy and developmental anomalies of the liver. In: Feldman M, Scharschmidt BF, Sleisenger MH, eds. *Sleisenger and Fordtran's gastrointestinal and liver disease*, 6th ed. Philadelphia: WB

Saunders, 1997:1056, with permission.)

Impressed by its molding against adjacent organs, William Osler quipped that the liver was present only for packing purposes. Therefore, the superior, anterior, and lateral surfaces are smooth and convex to fit against the dome of the diaphragm. The muscle bundles of the diaphragm often impress grooves in the superior surface. The costal margin often marks a transverse groove on the anterior surface (corset deformity). The posterior surface has indentations from the colon, kidney, and duodenum on the right and from the stomach on the left (Fig. 7.1). Deeper grooves, called *fissures*, are formed where extrahepatic vessels or cords press against the developing liver. Three of these structures, the umbilical portion of the left portal vein (PV), the ductus venosus (ligamentum venosum), and the umbilical vein (ligamentum teres), form the umbilical fissure.

P.183

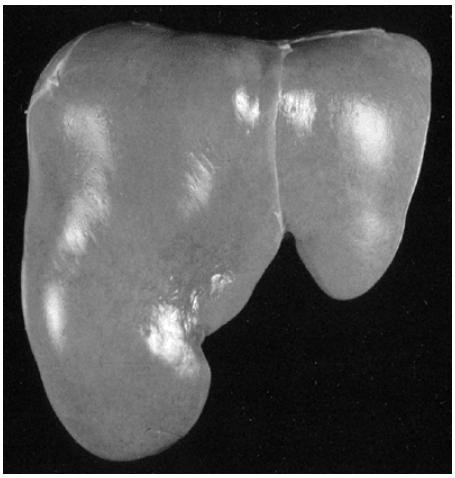
The liver is covered by the fibrous capsule of Glisson (or Walaeus). At the porta hepatis, the connective tissue of the capsule is continuous with the fibrous sheath, which invests the portal vessels and ducts and follows them to their smallest ramifications. The capsular peritoneum reflects onto the diaphragm and continues as the parietal peritoneum. The reflections form the coronary ligaments, the right and left triangular ligaments, and the falciform ligament (Fig. 7.1). These ligaments hold the liver firmly in its place and allow the passage of lymphatics, small vessels, and nerves. There is a large bare area where the liver is attached to the diaphragm and retroperitoneum. The vena cava, being retroperitoneal, lies on the bare area and is held to the liver by a ligament or bridge of the liver parenchyma between the caudate and right lobes.

The falciform ligament connects the liver to the diaphragm and anterior abdominal wall. The lower free edge of the falciform ligament, called *the round ligament*, contains the obliterated umbilical vein. The falciform ligament ascends the anterior surface of the liver, joins the reflections of the peritoneum left of the vena cava, continues posteriorly as the lesser omentum in the fissure of the ductus venosus, and finishes at the hilum. Therefore, the falciform ligament, anteriorly, and the lesser omentum and umbilical fissure, posteriorly, divide the liver into the conventional right and left lobes.

On the posterior surface, the transverse portal fissure contains the hilar vessels and demarcates the conventional right lobe anteriorly from the caudate lobe posteriorly (Fig. 7.1). The quadrate lobe is the portion of the right lobe anterior to the transverse fissure and is delimited on the right by the gallbladder and on the left by the umbilical fissure.

The hepatoduodenal ligament connects the liver to the superior part of the duodenum. It is part of the lesser omentum, which sheathes the hepatic artery (HA), PV, nerves, bile duct, and lymph vessels, all being present within the porta hepatis. In the ligament the common bile duct lies to the right, the HA to the left, and the PV behind them. However, variations in the topography of the HA are common.

There are several variations in the gross anatomy and topography of the liver (6,7). The relative size of the right and left conventional lobes is variable, being equal in size in 7% of individuals and greater on the left in 4% (7). Riedel's lobe is a caudal prolongation of the right lobe, which may give a false impression of hepatomegaly (Fig. 7.2). The falciform left lobe is an elongated lobe that extends laterally and posteriorly like a scythe, found in 19% of individuals (7). Extreme atrophy of the left lobe (4%) may be a result of vascular anomalies occurring early in life (8) or the extinction of parenchyma occurring after acquired vascular obstruction. The left lobe may be attached to the rest of the liver by a narrow pedicle. Accessory livers may be found in the ligaments or mesentery or on the surface of the gallbladder, spleen, or adrenals (6).



• **Figure 7.2** Liver with Riedel's lobe, a prominent caudal extension of the right lobe.

Segmental Anatomy

Division of the liver at the falciform ligament and umbilical fissure does not correspond to the division based on branch points in the vascular supply. Surgical imperative has led to the search for functional divisions within the liver. The anatomic studies of Rex and others (9,10,11,12) demonstrated that the liver can be divided on a different plane into right and left livers (or hemilivers), each with its own blood supply and duct drainage. The right hemiliver comprises 50% to 70% of the liver mass. The liver can be further divided into a total of eight segments on the basis of the vascular or bile duct distribution (7,12,13,14,15,16) (Figs. 7.3 and 7.4). The segmental nomenclature devised by Couinaud has received the widest acceptance. This classification was based on the divisions of the PVs. However, the branching of the PVs to the left lobe is irregular because of the entry of the umbilical vein, making it desirable to adopt a nomenclature based on the divisions of the arteries or ducts, as suggested by Strasberg (17). This can be done without modifying the segments defined by Couinaud and rationalizes the diverse nomenclature used in different parts of the world. The Strasberg nomenclature is summarized in Figures 7.3 and 7.4 and Table 7.1.

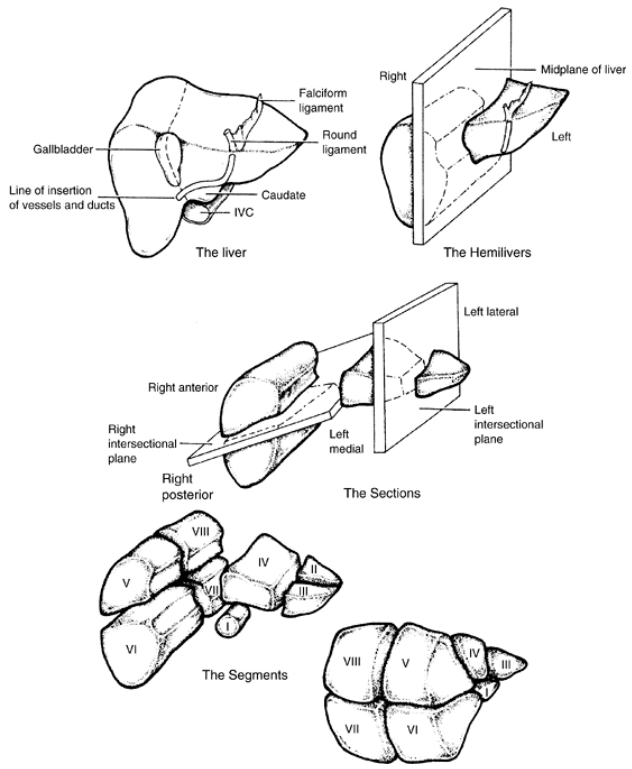
Most hepatic resections can be achieved by division either on Cantlie's line (between the gallbladder

P.184

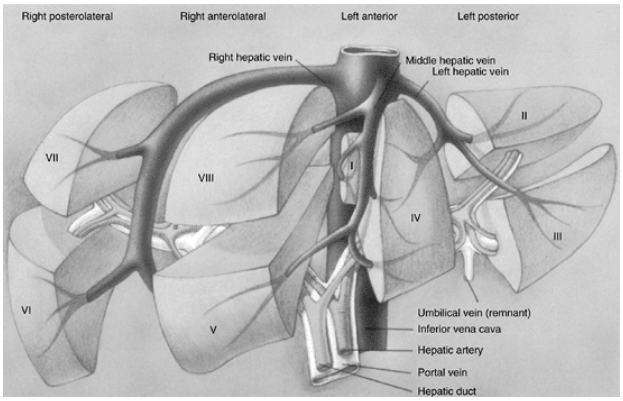
P.185

and vena cava) or near the falciform ligament. Surgical dissection along the planes between segments is relatively bloodless. Because the segments do not have surface landmarks, small resections are usually performed without attempting to identify the segmental

boundaries (16). The segments vary greatly in size and shape among individuals (18), so that each operation is empirical and may be based on ultrasonography (19,20)



• **Figure 7.3** Schematic diagram of the planes of division in the liver. The liver can be visualized as being divided into two hemilivers by the midplane of the liver. The hemilivers are each subdivided into two sections by right and left intersectional planes. Three of the sections are further subdivided into two segments each by intersegmental planes on the basis of the divisions of the ducts and arteries. The left medial section does not have a regular duct and artery division and is therefore called *one segment* (IV). However, for surgical convenience, it is subdivided into posterior and anterior portions (segments IVa and IVb, respectively, not shown). The caudate lobe is a separate segment (I) that is not part of the four main sections. IVC, inferior vena cava. (Courtesy of Dr. Strasberg.) (From Strasberg SM. Terminology of liver anatomy and liver resections: coming to grips with hepatic Babel. *J Am Coll Surg* 1997;184:413–434, with permission.)



• **Figure 7.4** Schematic demonstration of the vascular relations of the segments (drawn by M. Thompson). The segments are numbered using the nomenclature of Couinaud. The remaining elements of nomenclature are those of Strasberg. The midplane extends along Cantlie's line from the vena cava to the gallbladder. The middle hepatic vein runs in this plane. The right and left intersectional planes contain the right and left hepatic veins, respectively. Each section is supplied by one of the four major arteries and bile ducts. The portal pedicles and hepatic veins interdigitate, so they do not lie in the same planes except for the umbilical portion of the left portal vein and the umbilical vein (a medial branch of the left hepatic vein), both of which are found in the umbilical fissure (also known as left intersectional plane). The *sections* of Strasberg coincide exactly with the *segments* of Healey and Schroy. The two *sections* of the right hemiliver correspond to the two right *sectors* of Couinaud. The tertiary structures of Strasberg and of Couinaud are called *segments*; these coincide with the *areas* of Healey and Schroy, except that segment IV is divided into two *areas* by these authors. (Modified from Wanless IR. Anatomy and developmental anomalies of the liver. In: Feldman M, Scharschmidt BF, Sleisenger MH, eds. *Sleisenger and Fordtran's gastrointestinal and liver disease*, 6th ed. Philadelphia: WB Saunders, 1997:1056, with permission.)

Embryology

The liver arises from the hepatic diverticulum of the foregut during the fourth week of gestation (7,21) (Fig. 7.5). As the embryo develops, the blood supply to this region evolves in an elaborate manner to deliver nutrients from three different sources in sequence: Yolk sac, placenta, and gut (7,17).

Hepatocyte precursors, the hepatoblasts, arise from endodermal cells at the advancing front of the diverticulum and invade the mesoderm of the caudal portion of the septum transversum. The vitelline veins traverse the region, bringing blood from the yolk sac and the digestive tube to the heart. As hepatoblasts invade the mesenchyme, they disrupt the vitelline veins, tapping their blood supply. This supply is from the vitelline veins, segments of which later become the PV The hepatic bud is subdivided into cords by new capillaries called *sinusoids*. The sinusoidal flow coalesces into three major hepatic veins. At the time the main hepatic veins are developing, the entire liver is composed of only two lobules, and there is no artery and no left or right bile duct. As the hepatic veins and PVs begin to branch, the branches interdigitate to remain equidistant from each other, and the parenchyma is subdivided into numerous lobules or acini. It has been suggested that the portal and hepatic vessels invade the most ischemic parenchyma that is located at the nodal point of Mall, the point most distant from both PVs and hepatic veins (22,23).

The hepatoblast cords develop into anastomosing tubular structures with central bile canaliculi that

P.186

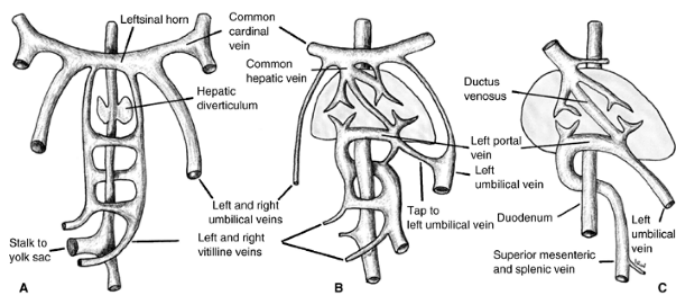
P.187

eventually communicate with the bile ducts. Most hepatoblasts differentiate into hepatocytes, but those adjacent to the portal mesenchyme differentiate into a layer of duct progenitors called the *ductal plate* (24,25). The ductal plate becomes bilayered and gradually forms segments with lumina. These segments form ducts that migrate away from the limiting plate to a more central location in the portal tracts near the PV. Portions of the ductal plate resorb, leaving a complex anastomosing network of ducts that continues to simplify in the weeks after birth (26). The common bile duct, left and right hepatic ducts, and gallbladder develop in the stalk region of the hepatic diverticulum. These ducts are continuous with the ductal plate in the cranial end of the diverticulum. As bile ducts develop, they become highly vascularized by arterioles and capillaries of the periductal plexus.

Table 7.1. Nomenclature for Resections of Liver

	Name of operation	
Portion of liver excised	**Strasberg**	**Couinaud, Goldsmith, and Woodburne**
Single segment	Segmentectomy (e.g., segmentectomy III)	—
Two adjacent segments	Bisegmentectomy (e.g., bisegmentectomy V, VIII)	—
Multiple segments	Segmentectomy (e.g., segmentectomy IV, V, VI)	—
One fourth of liver (e.g., left lateral section)	Left lateral sectionectomy	Left lobectomy (segments II and III), left lateral segmentectomy
One half of liver, right hemiliver	Right hemihepatectomy (may or may not include segment I [e.g., right hemihepatectomy with segment I[a]])	Right hepatectomy (segments V, VI, VII, and VIII), right hepatic lobectomy
One half of liver, left hemiliver	Left hemihepatectomy	Left hepatectomy (segments II, III, and IV), left hepatic lobectomy
Three fourths of liver, right hemiliver, and left medial section	Right trisectionectomy or right hemihepatectomy with left medial sectionectomy	Right lobectomy (segments IV, V, VI, VII, VIII, ± I), extended right hepatic lobectomy, right trisegmentectomy (Starzl)
Three fourths of liver, left hemiliver, and right anterior section	Left trisectionectomy or left hemihepatectomy with right anterior sectionectomy	Extended left hepatectomy, extended left lobectomy, left trisegmentectomy (Starzl)

[a]This comment also applies to left hemihepatectomy and the trisectionectomies.
Modified from Strasberg SM. Terminology of liver anatomy and liver resections: coming to grips with hepatic babel. *J Am Coll Surg* 1997;184:413–434, with permission.



• **Figure 7.5** Drawing to show three stages in the development of the hepatic vasculature. **A:** In the embryo, there are three paired venous beds that drain the placenta (umbilical veins), yolk sac, and intestinal tract (omphalomesenteric or vitelline veins), and the remainder of the body (cardinal veins). These beds converge on the sinal horns before entering the heart. The left and right vitelline veins are joined by three anastomoses to form a ladder-like structure with the intestinal tract intertwined. The extrahepatic portal vein develops from these vessels after selective obliteration of portions of the ladder **(B and C)**. **B:** The left vitelline vein receives a tap from the left umbilical vein. The intrahepatic segment of this tap becomes the umbilical portion of the left portal vein. The flow in this segment reverses after birth and supplies segments of the left hemiliver. As the liver develops, the venous drainage of the parenchyma becomes focused on two vessels, the future right and left hepatic veins, and later the middle vein (not shown), which usually drains into the left hepatic vein. The ductus venosus develops as a through-channel from the left portal vein to the common hepatic vein. The remainder of the portal vein blood perfuses the sinusoids before reaching the hepatic veins. **C:** The vasculature is simplified with the removal of several segments including the most caudal anastomosis between the vitelline veins, the rostral portions of the left vitelline and left umbilical veins, and the right umbilical vein. The right lobe grows faster than the left because the left lobe loses the supply from the left vitelline vein and the left umbilical vein blood is shunted through the ductus venosus. The left umbilical vein actually lies in the midline and later shifts to the right of midline.

The liver occupies most of the abdominal cavity in the third month of gestation, in part because of large masses of sinusoidal hematopoietic cells. Thereafter, the right lobe grows faster than the left lobe but slower than the rest of the body. The liver cell cords remain tubular until birth, when they begin to remodel into double-cell plates and finally into single-cell plates by 5 years of age. Hematopoietic cells are still found in the sinusoids at birth and largely disappear from the liver by 4 weeks of age.

The hepatoblast is a bipotential progenitor cell that is positive for cytokeratin 19 (CK19) and HepPar1. During organogenesis, these cells differentiate into hepatocytes (CK19-negative and HepPar1-positive) and small bile ducts (CK19-positive and HepPar1-negative) (25,27). CK7 is expressed later and its level continues to increase in the weeks after birth. Severe injury to the adult liver causes a return to the pattern of expression seen in hepatoblasts. Therefore, regenerating epithelial cells in the liver have features of both ducts and hepatocytes (28).

Large Vessels of the Liver

The liver receives blood through the PV and through the HA, a branch of the celiac axis. Because the PV drains the blood of an area supplied by the other branches of the celiac axis and by the superior and the inferior mesenteric arteries, the hepatic blood flow depends on the flow in these arteries (29).

Portal Veins

The PV is an afferent nutrient vessel of the liver that carries blood from the entire capillary system of the digestive tract, spleen, pancreas, and gallbladder. It is constant in length, but the branches are variable (30,31) (Fig. 7.6). The PV is formed behind the neck of the pancreas by the confluence of the splenic and superior mesenteric veins. It also receives the superior pancreaticoduodenal vein, the left gastric (coronary) vein, and the cystic vein. Usually the upper 5 cm of the PV is devoid of major branches, allowing easy surgical dissection.

The splenic vein commences with five to six branches that return the blood from the spleen and unite to form a single nontortuous vessel. In its course across the posterior abdominal wall, it grooves the upper part of the pancreas, from which it collects numerous short tributaries. It runs close to the hilum of the left kidney and terminates behind the neck of the pancreas, where it joins the superior mesenteric vein at a right angle. Because of its nearness to the vessels of the left kidney, the splenic vein can be anastomosed to the renal vein. Its tributaries are the short gastric veins, the pancreatic veins, the left gastroepiploic vein, and the inferior mesenteric vein. In the distal splenorenal shunt operation, the short gastric veins are used for collateral drainage of the gastroesophageal varices.

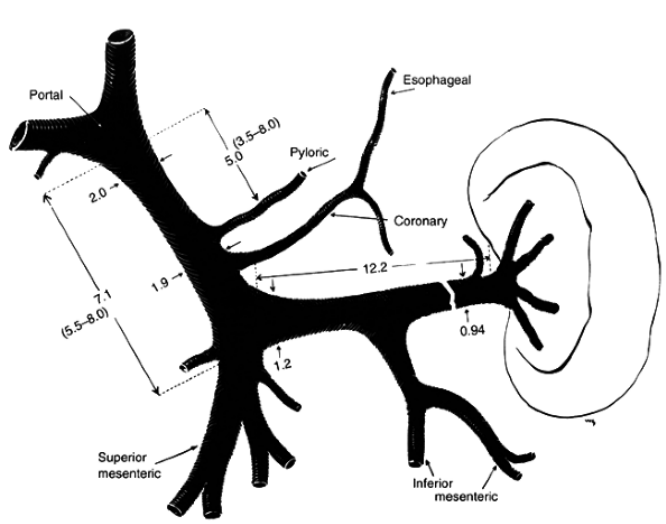
The superior mesenteric vein carries blood from the small intestine, ascending colon, and transverse colon. The inferior mesenteric vein returns blood from the area drained by the superior and the inferior left colic and the superior rectal veins.

An important tributary of the portal trunk is the coronary vein. It runs upward along the lesser curvature of the stomach, where it receives some esophageal veins. In patients with portal hypertension, these enlarge to form varices.

The portal trunk runs in the hepatoduodenal ligament in a plane dorsal to the bile duct and the HA and divides into two lobar veins before entering the portal fissure. The right lobar vein, short and thick, receives the cystic vein. The left lobar vein, longer and smaller, is joined by the umbilical vein and the paraumbilical veins. It connects with the inferior vena cava by the venous ligament. The left lobar vein gives branches to the quadrate lobe and also to the caudate lobe before entering the parenchyma at the left end of the porta hepatis. A separate branch may arise near the bifurcation to supply the caudate lobe. This vein is easily injured during dissection. The paraumbilical veins arise from the umbilical portion of the left PV and travel in the round ligament, where they may become evident as umbilical varices in the presence of portal hypertension. The umbilical vein is easily recanalized in infants, allowing access for blood sampling and angiographic visualization of the portal system.

In addition to the main PV and its branches, the liver receives other veins from the splanchnic circulation, the parabiliary venous system of Couinaud (32). This highly variable plexus includes several veins that arise from the pancreaticoduodenal or pyloric veins and drain into the PV or directly into the inferior surface

of segment IV and less often into other segments. This plexus provides examples of the metabolic effects of proximity to insulin source. Veins arising from the pancreatic region would carry blood with high insulin levels and pyloric veins would carry low-insulin-level blood. Because insulin determines the propensity of the liver to store triglycerides, the anatomy of these veins could explain some examples of focal fatty liver and focal fatty sparing (33).



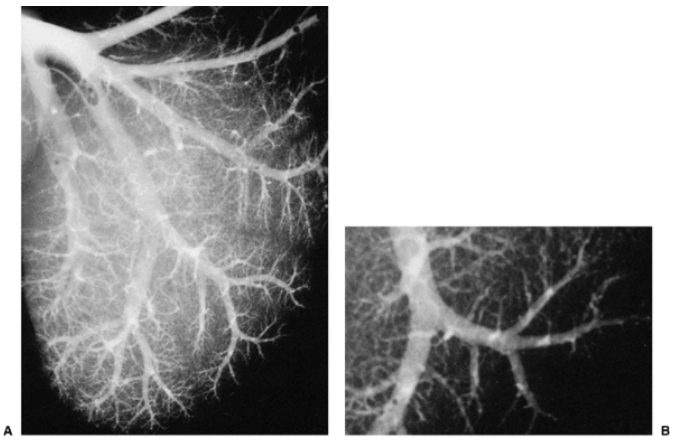
• **Figure 7.6** Measurements of the portal vein and its main branches, in centimeters. (From Gilfillan RS. Anatomic study of the portal vein and its main branches. *Arch Surg* 1950;61:449, with permission.)

Anomalies of the portal venous system are relatively rare. The anterior segment of the right liver is occasionally supplied by a branch of the proximal left PV (34). Preduodenal PV may be a result of the persistence of the most caudad anastomotic channel between the vitelline veins (Fig. 7.5). It may be associated with the duplication of the PV, annular pancreas, duodenal diaphragm, or intestinal malrotation, producing duodenal obstruction (35). Congenital absence of the PV is associated with portosystemic shunting because the superior mesenteric vein and the splenic vein drain directly to the vena cava or left renal vein, usually separately (36). This may be associated with hepatoblastoma or nodular hyperplasia of the liver (often simulating a neoplasm), cardiac anomalies, and biliary atresia. The ductus venosus rarely remains patent after infancy and is associated with hypoplasia of the intrahepatic PV branches, nodular hyperplasia of the liver, atrial septal defect, and hyperammonemia (37).

Atresia of the PV may be a congenital malformation often associated with other vascular anomalies or a response to neonatal injury such as omphalitis or PV thrombosis (38). When PV thrombosis occurs in the neonatal period, the vein does not grow so that in adulthood it appears as a thin fibrous cord (hypoplasia or agenesis). A thrombosed PV may develop numerous irregular intraluminal channels in addition to a leash of collaterals in the porta, giving a radiologic appearance called *cavernous transformation of the PV*.

Hepatic Veins

There are three main hepatic veins. The middle and left veins unite before entering the vena cava in 65% to 85% of individuals (7,39). In 18% of individuals, there are two right hepatic veins draining into the vena cava (20). In another 23%, there is a separate middle or inferior right hepatic vein draining segments V or VI, respectively. The veins have variable branching patterns. There are axial veins with four to six orders of dichotomous branching at acute angles, as well as numerous much smaller branches nearly at right angles (Fig. 7.7).



• **Figure 7.7 A:** Hepatic veins shown on postmortem angiogram. The major rami branch dichotomously and receive smaller branches nearly at right angles. **B:** Magnified portion of **(A)**.

The caudate lobe and adjacent parenchyma are usually drained by one or two small veins directly into the vena cava caudal to the main hepatic veins. When thrombosis of the main hepatic veins occurs, the veins of the caudate lobe are often spared, allowing survival and compensatory hyperplasia of this lobe (40). Anastomoses between branches of the hepatic veins are uncommon in the normal liver (41) but may be more frequent in the presence of diseases with portal hypertension (42). Anastomoses of veins to other lobes become enlarged and may be mistaken for the original hepatic veins on Doppler interrogation. Partial recanalization occurs, often leaving webs in the hepatic veins or vena cava. These webs were formerly thought to be congenital, although most are now considered to be acquired (43,44).

Hepatic Arteries

The common HA is the second major branch of the celiac axis (45). It courses to the right along the upper border of the pancreas in the right gastropancreatic fold, which conducts the artery to the medial border of the hepatoduodenal part of the lesser omentum. It ascends in front of the PV in 91% of humans and to the left of and behind the bile duct in 64% of cases. It gives off the left and the right HAs to supply the corresponding hemilivers. The right and left HAs each divide into two arteries that supply the right anterior and posterior sections and the left medial and lateral sections, respectively. The middle HA arises from the left or right HA and supplies the quadrate lobe.

The cystic artery arises from the right HA in the upper part of Calot's triangle (formed by the cystic duct, common hepatic duct, and inferior surface of liver). The cystic artery divides into a superficial branch that is distributed to the peritoneal surface of the gallbladder and a deep branch that supplies the attached wall of the gallbladder and adjacent liver. In 75% of cases, the artery is single, and in 25%, there are two arteries with separate origins for the deep and superficial branches.

Anomalies of the HA are frequent, occurring in half of the individuals (46). Angiographic studies of the HA demonstrate that the course of the arterial branches in the hilum deviates markedly from that of the PV, and in some cases the arteries may even cross the segmental fissures (47). However, the more distal arterial branches follow the PVs closely, "climbing along them like a vine on a tree" (48).

Anomalies of the HA have gained new importance because of the advent of transplantation, aggressive resections, and intra-arterial chemotherapy. The most important anomaly is a right HA arising from the superior mesenteric artery to supply the entire right liver (14%) (49). Because this vessel may appear in

Calot's triangle, it is at risk during cholecystectomy. The left HA arises from the left gastric artery in 14% to 25% of cases (45,49,50). This vessel enters the liver at the left end of the hilum and may fail to be ligated during resections, leading to hemorrhage. Each of the aberrant arteries may be the only HA so that its injury can damage the liver severely. The PV and HA to segment IV may cross to the left of the umbilical fissure before turning medially and, therefore, may be injured during left lateral segmentectomy. Ducts or small vessels cross this fissure in 20% of cases (13).

There are extensive communications between the ultimate and the penultimate branches of the right, the middle, and the left HAs in the umbilical fossa and in the region around the caudate lobe. The HA is provided with collateral flow through its anastomoses with arteries arising from the celiac axis and superior mesenteric artery. Anastomoses between the left and right HAs may occur. The main collaterals of the common HA are right and left gastrics; right and left gastroepiploics; gastroduodenal, supraduodenal, retroduodenal, superior and inferior pancreaticoduodenals; aberrant HAs; and inferior phrenic arteries (51).

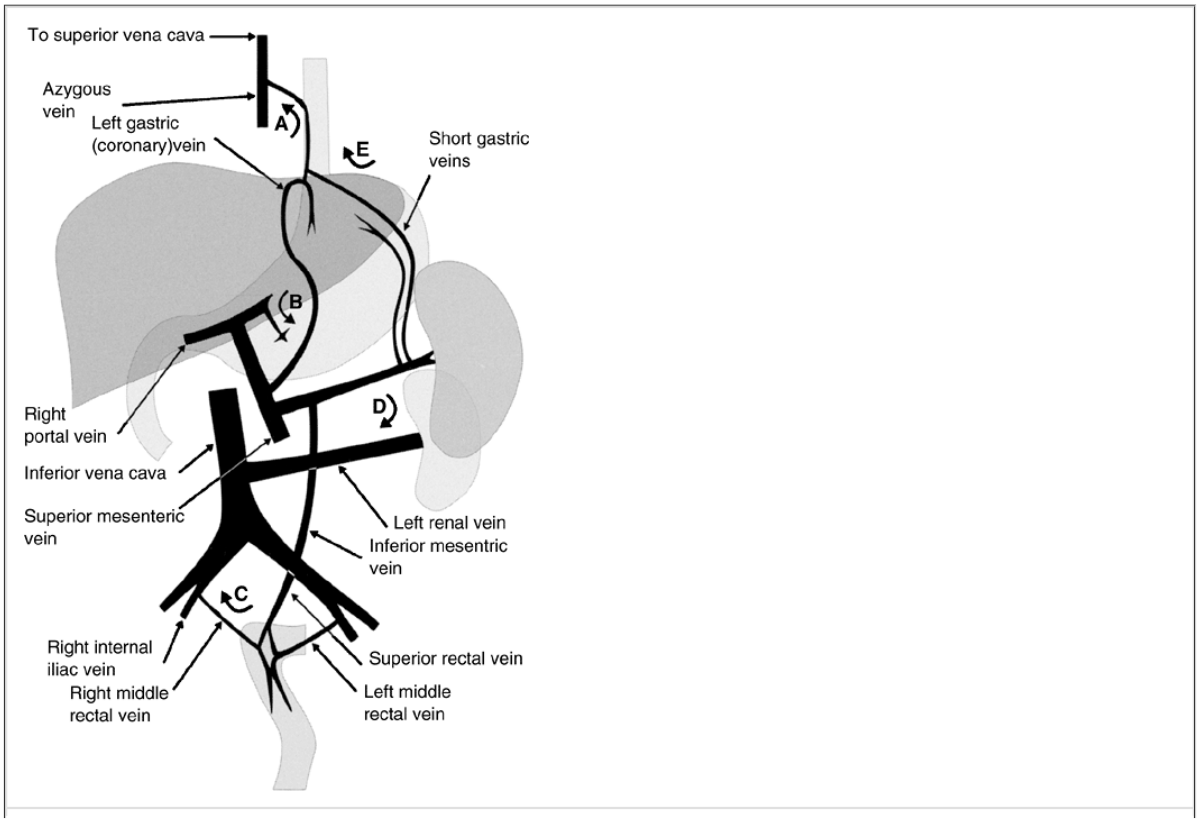
If ligation of an artery is necessary for the control of hemorrhage, ligation of the left or right artery is safe. Ligation of the HA proximal to potential collaterals such as the right gastric artery or gastroduodenal artery is better than ligation of the proper HA. After ligation of an HA, anastomotic channels enlarge and reestablish flow within a day (52).

Hepatic Collateral Circulation

Portal hypertension leads to the development of intra- and extrahepatic venous collaterals (53,54) (Fig. 7.8). Extrahepatic collaterals are important, because when dilated to form varices, they are susceptible to rupture and massive bleeding. Varices in the submucosa of the gastrointestinal tract are most often a problem, especially in the esophagus and stomach but also in the rectum and duodenum and at ostomy sites.

Dilated umbilical or paraumbilical veins are found in 11% of patients with cirrhosis (veins of Sappey) (55). They may cause a venous hum and *caput medusa* at the umbilicus (Cruveilhier-Baumgarten syndrome). Their presence implies high pressure in the left PV and, therefore, intrahepatic vascular obstruction. The direction of flow in lower abdominal wall collaterals is caudad if the inferior vena cava is obstructed, as in some patients with Budd-Chiari syndrome.

Varices may be found at sites where the gastrointestinal tract or pancreas becomes retroperitoneal or adherent to the abdominal wall because of pathologic processes. These "veins of Retzius" establish connections between the portal bed and the ascending lumbar azygos, renal, and adrenal veins.



• **Figure 7.8** Diagram of portal circulation. The most important sites for the potential development of portosystemic collaterals are shown. *A*, Esophageal submucosal veins, supplied by the left gastric vein and draining into the superior vena cava through the azygous vein. *B*, Paraumbilical veins, supplied by the umbilical portion of the left portal vein and draining into abdominal wall veins near the umbilicus. These veins may form a *caput medusa* at the umbilicus. *C*, Rectal submucosal veins, supplied by the inferior mesenteric vein through the superior rectal vein and draining into the internal iliac veins through the middle rectal veins. *D*, Splenorenal shunts: Created spontaneously or surgically. *E*, Short gastric veins communicate with the esophageal plexus. (From Wanless IR. Anatomy and developmental anomalies of the liver. In: Feldman M, Scharschmidt BF, Sleisenger MH, eds. *Sleisenger and Fordtran's gastrointestinal and liver disease*, 6th ed. Philadelphia: WB Saunders, 1997:1057, with permission.)

Within cirrhotic parenchyma, shunts are formed by anastomoses between smaller branches of the portal and hepatic veins, as discussed later (56). These shunts allow blood to bypass the sinusoidal exchange surface, leading to functional impairment. This effect is made worse by the creation of large shunts. In addition, any procedure that decreases portal flow to the sinusoids increases the likelihood of thrombosis, further increasing intrahepatic resistance. Titration of these benefits and liabilities is an important feature of surgical management. Large spontaneous shunts may be beneficial in lowering portal pressure and should not be disturbed without due consideration.

Portosystemic shunting appears to be responsible for reduced peripheral vascular resistance, possibly through the enhanced release of nitric oxide (57). Dilated vascular channels in the lungs lead to intrapulmonary shunting with hypoxemia and increased cardiac output.

Lymphatics

Lymphatic channels are divided into deep and superficial networks (41,58). The former run parallel to the branches of the portal vessels and hepatic veins and the latter are found in the capsule. There are numerous anastomoses between these networks through small branches percolating through the capsule. The superficial lymphatics from the convexity form a dense network that coalesces into 14 groups of lymphatic trunks that drain through the coronary and falciform ligaments, through the diaphragm, and into esophageal and xiphosternal nodes. From the undersurface of the liver, they drain into hepatic hilar nodes. The deep lymphatics following the portal tracts reach the hepatic nodes at the left side of the porta hepatis, and the lymphatics along the hepatic veins drain to lymph nodes near the vena cava. The portal lymphatic trunks drain 80% of the hepatic lymph. The formation of lymph is discussed in the Section "Microanatomy."

Nerves

The liver has a rich sympathetic and parasympathetic innervation (59,60,61). Fibers derive from lower thoracic ganglia, the celiac plexus, the vagi, and the right phrenic nerve to form the plexi about the HA, PV, and bile duct. Most fibers are organized into the anterior and posterior trunks that enter the liver at the hilum. A few fibers enter at hepatic veins and ligaments. The arteries are innervated mainly by sympathetic fibers. The bile ducts are innervated by both sympathetic and parasympathetic fibers. Unmyelinated sympathetic fibers send branches to individual hepatocytes in zone 1. Nerve discharges are propagated from one hepatocyte to another through gap junctions (62).

Most hepatic nerve fibers are aminergic or peptidergic, with a few cholinergic fibers. Intra-acinar cholinergic fibers do occur in the guinea pig. Immunohistochemical studies have demonstrated many other substances in some hepatic nerve fibers, including vasoactive intestinal peptide, neuropeptide Y, glucagon, somatostatin, neurotensin, and calcitonin gene–related peptide. The effects of nerve stimulation are partially mediated by prostaglandins synthesized in nonparenchymal cells of the liver. There may be local baroreceptors capable of detecting sinusoidal hypertension and leading to reflex renal artery vasoconstriction (63,64). Afferent nerves may be responsible for pain when the liver is distended.

Stimulation of the nerve bundles around the HA and PV mainly results in a sympathetic discharge that alters the metabolism and hemodynamics of the liver. Glucose and lactate output are increased. Ketone and urea production, ammonia uptake, oxygen consumption, arterial and portal blood flow, and bile flow are reduced. Sympathetic nerve stimulation may exacerbate the effect of toxins (65). Parasympathetic stimulation is thought to increase glycogen synthesis and reduce glucose release. Hepatic parasympathetic activity has an important effect on skeletal muscle insulin resistance (66). Nerve action is modified by prevailing levels of hormones, especially insulin and glucagon. Resection of the anterior nervous plexus increases the concentration of bile salts and pigments in bile and impedes the accumulation of triglycerides in the liver. The clinical importance of this effect is uncertain. After transplantation, the denervated state of the liver persists (67), although hepatic blood flow and metabolic functions of the liver appear to be normal (68).

Biliary System

The biliary system includes the bile canaliculi, intrahepatic and extrahepatic bile ducts, peribiliary glands, gallbladder, and ampulla of Vater (27). The intrahepatic ducts begin at the bifurcation of the common hepatic duct.

Large Ducts and Gallbladder

The nomenclature of the large intrahepatic ducts will vary with the system used for naming the hepatic subunits (see preceding text). Each hepatic segment has a bile duct draining into a sectoral duct that drains into the right or left hepatic duct, which drains the right or left hemilivers, respectively. Caudate lobe drainage is variable, with ducts usually entering both right and left ducts. The junctions of the segmental, hepatic, and common hepatic ducts are also highly variable (69). The right and left hepatic ducts join to form the common hepatic duct at the right end of the portal fissure. The common hepatic duct is 1 to 5 cm long (mean 2 cm), is 0.4 to 1.3 cm in diameter (mean, 0.66), and is situated to the right of the HA and in front of the PV (70). It is joined by the cystic duct at its right side to form the common bile duct (ductus choledochus) that runs another 5 to 8 cm to the ampulla of Vater. The supraduodenal part of the common bile duct lies in the right border of the lesser omentum. The pancreatic part of the common bile duct passes retroperitoneally

behind the first portion of the duodenum. It then runs in a groove on the posterior surface of the head of the pancreas, anterior to the inferior vena cava. At the left side of the duodenum, it is joined in 70% to 85% of cases by the pancreatic duct (of Wirsung) and forms a common channel of variable length (71). When a dilatation is present, it is called the *ampulla of Vater* (72). The common channel resides within an elevation of the duodenal mucosa called the *major papilla* (of Vater).

The sphincter of Oddi consists of circular muscle fibers that surround the common bile duct in its course through the duodenal wall (73). Circular muscle fibers are also present around the end of the pancreatic duct and around the tip of papilla; longitudinal fibers are also present. The sphincter of Oddi is inhibited by cholecystokinin, assisting the expulsion of bile into the duodenum. An elongated common channel has been associated with congenital bile duct dilatation (74). Bile reflux may occur after papillotomy or surgical anastomoses with the intestine, resulting in recurrent cholangitis.

The gallbladder is a receptacle that receives up to a liter of bile daily, concentrating it by sodium-coupled water transport and expelling it on stimulation by cholecystokinin. The gallbladder is a pear-shaped sac with a volume of 30 to 70 mL and measuring 3 cm in width and 7 to 10 cm in length. Its parts are designated as fundus, body, and neck. It lies on the undersurface of the right liver lobe, with the fundus projecting beyond the inferior border of the liver where the lateral margin of the rectus crosses the costal margin. The body is

directed upward and to the left. Posteriorly, fundus and body are in close relation with transverse colon and duodenum, respectively. Gallstones can perforate into these viscera. The neck of the gallbladder is curved anteriorly and, when enlarged, forms the so-called Hartmann's pouch. The mucosa of the neck forms a spiral valve of Heister that continues into the cystic duct. The spiral valve has the function of regulating bile flow into and out of the gallbladder. The cystic duct measures 4 to 65 mm in length (mean, 30 mm) and 4 mm in average diameter (75).

The arterial supply of the bile ducts comes mainly from many branches of the common HA, especially the retroduodenal artery and the right HA (45,76). The gallbladder may be supplied by one, two, or three arteries. The cystic artery usually arises from the right HA. The veins of the gallbladder are variable, draining into the liver at the gallbladder bed or into the veins from the common bile duct, but eventually draining into branches of left and/or right PV (7). The lymph vessels of the gallbladder, hepatic ducts, and upper parts of the common bile duct empty into the lymph nodes of the hilum. Those of the lower common bile duct drain into nodes near the head of the pancreas.

Nerve fibers supplying the extrahepatic ducts and gallbladder derive mainly from the sympathetic hepatic plexus laced around the HA. These fibers also receive filaments from the right and left vagus nerves. Some nerve fibers deriving from the plexus can be seen running along the common bile duct. Sparse ganglion cells are present in the muscularis and the mucosa of the gallbladder. Their nervous connection with the spinal system is brought about by fibers from the right phrenic and musculophrenic nerves. Because these nerves derive from the third or fourth cervical nerve, the anatomic basis for shoulder pain in gallbladder disease is evident. Vagal stimulation causes gallbladder contraction (77).

Histology of the bile ducts and gallbladder has been reviewed by Frierson (78) and Nakanuma et al. (27). The wall of the extrahepatic ducts is formed by fibrous tissue with elastic fibers; smooth muscle is scanty or absent (79), except at the lower end of the common duct where muscle rings are conspicuous. The gallbladder wall contains abundant smooth muscle and little fibrous tissue. Rokitansky-Aschoff sinuses are outpouchings of the gallbladder mucosa through defects of the muscularis and are found in almost all gallbladders having calculi. The ducts of Luschka are small ducts in the areolar tissues of the hepatic surface of the gallbladder that communicate with intrahepatic bile ducts, but not usually with the gallbladder cavity, and may leak hepatic bile after cholecystectomy.

The mucosa has numerous papillary folds in the gallbladder, distal pancreatic duct, distal common bile duct, and ampulla. The mucosa of bile ducts and gallbladder consist of a single layer of columnar epithelium and a lamina propria. A few goblet cells are present, especially in the ampulla. Somatostatin-containing cells may be present in the ampulla, a possible source for the development of somatostatinomas arising at this site.

Mucous-secreting accessory glands (peribiliary glands) are in the lamina propria of the gallbladder neck and extrahepatic bile ducts and adjacent to the large intrahepatic ducts (80).

Intrahepatic Ducts

The intrahepatic ducts have been defined as ductules (<0.02 mm), interlobular ducts (0.02 to 0.1 mm), septal ducts (0.1 to 0.4 mm), and large ducts (>0.4 mm) (27). These measurements are approximate because the definition is also dependent on the relation to the segmental boundaries and on histologic pattern.

The large and septal bile ducts have a well-demarcated dense fibrous wall and high columnar epithelium with basal nuclei and small mucin droplets. These ducts express the blood group antigens. Interlobular ducts are located near the center of portal tracts and have minimal or no fibrous investment, and

the epithelium is low columnar or cuboidal and lacks mucin. There is a periodic acid-Schiff–positive basement membrane. The ductules are located near the limiting plate and have cuboidal epithelial cells. The presence of a few ductules may be considered normal, but large numbers are a feature of cholestatic or regenerating liver. Throughout the biliary tree, each duct is usually accompanied by an artery of similar diameter, a helpful guide when evaluating the absence of ducts.

The peribiliary glands accompanying intrahepatic large and septal ducts may be located within the walls (intramural) or form clusters outside the fibrous wall (extramural). Intramural glands are mucin rich, and extramural glands may be mucinous or serous, rarely with focal pancreatic acinar differentiation. Peribiliary glands are hypertrophied in patients with *Clonorchis* infestation and may be the tissue source of some cholangiocarcinomas (81). These glands may form retention cysts at the hilum in case of cirrhosis, PV obstruction, and polycystic kidney disease (82), rarely causing obstructive jaundice (83).

Intrahepatic bile ducts are the site of injury in many diseases, resulting in duct destruction, secondary cholestasis, and eventually, cirrhosis in severe cases. In primary biliary cirrhosis, ducts up to 0.3 mm in diameter are destroyed by an immune process. In primary sclerosing cholangitis, the most severely involved ducts are extrahepatic and large intrahepatic ducts, with less severe duct destruction in the smaller branches. Ducts less than 0.1 mm in diameter are the focus in chronic allograft rejection, graft versus host disease, Alagille's syndrome, and reactions to a variety of drugs and toxins. Neonatal biliary atresia, polycystic liver disease, and several other syndromes may be a result of a variety of insults to the developing ducts at the ductal plate stage (84).

The peribiliary vascular plexus is hypertrophied in livers with cirrhosis or with PV obstruction and is especially prominent in congenital hepatic fibrosis, where it may fill on portal venogram and appear to form a duplication of the portal tree (85).

Variations and Surgical Implications

A portion of the right liver may drain into the left duct system in 6% of cases (7). In 25% of cases, a branch of the right duct drains into the left duct (86). The common hepatic duct may receive accessory hepatic ducts. If the common hepatic duct is absent, the right and left hepatic ducts may run separately and join close to the duodenum; the right duct receives the cystic duct. Other variations include a main duct draining into the gallbladder, the cystic duct draining into the right hepatic duct, and the right hepatic duct draining into the cystic duct (7,69,85,87). The cystic duct usually enters the bile duct at an angle but may run parallel or curve behind the duct in a spiral manner. The relations of the large ducts and vessels near the hilum are variable, but the peripheral branches of these structures run together within portal tracts.

Because ducts depend on arterial supply, ischemic necrosis, with or without stricture, may occur in the large bile ducts after transplantation, especially if the HA is compromised. Duct strictures, rupture, and infarction of the gallbladder have also been found after hepatic arterial injection of alcohol or chemotherapeutic agents, possibly because of injury to the peribiliary vascular plexus (27).

Numerous conditions are characterized by congenital or acquired anomalies of the duct system. Aberrant biliary ducts, the vasa aberrantia, form anastomoses between the gallbladder and small ducts in the adjacent liver. These ducts are liable to leak bile after cholecystectomy. Accessory mucous-secreting periductal glands are located all along the duct system. These may develop retention cysts that, rarely, encroach on the duct lumen to produce obstructive jaundice (83). Congenital dilatation of the intrahepatic and/or extrahepatic ducts, known as *choledochal cyst*, is a rare cause of cholangitis or obstructive jaundice, usually presenting in childhood (see Chapter 43). Caroli's disease is a subset of this condition, with dominant dilatation of the intrahepatic ducts. Congenital fibrocystic disease occurs in a variety of anatomic patterns, often with coexistent renal disease. Clusters of dilated ducts within portal tracts, von Meyenburg complexes, are markers of adult polycystic kidney and polycystic liver diseases (88). Biliary atresia, the absence or obliteration of the extrahepatic bile ducts, is one of the most common causes of cirrhosis in childhood.

Anomalies and diseases of the gallbladder have been reviewed by Weedon (89). Absent gallbladder and double gallbladder are rare (0.05% and 0.02%, respectively) (90). Agenesis is associated with other congenital defects of the intestines or bones. Bilobed,

hourglass-constricted gallbladder and that with folded fundus (phrygian cap) or persistent septum favor retention and inflammation. Diverticulum also occurs. The gallbladder can be completely buried in liver substance or attached loosely to it by a mesentery (floating gallbladder).

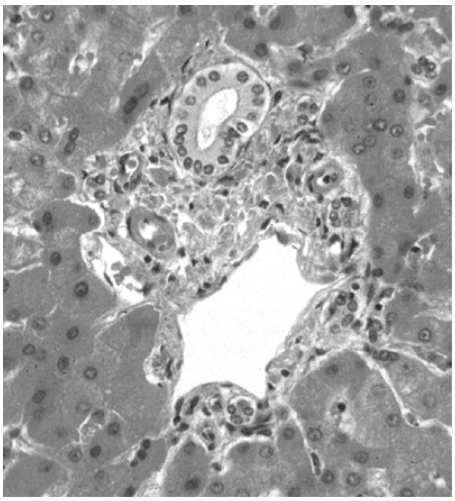
Microanatomy

Normal Human Histology

When viewed histologically, the normal liver displays a uniform arrangement of portal tracts separated by parenchyma composed of hepatocellular plates and

P.194

sinusoids. Terminal hepatic venules are located equidistant from portal tracts, which contain arteries, ducts, nerves, and PVs in a connective tissue stroma (Fig. 7.9). The stroma within portal tracts normally contains a small number of macrophages, plasma cells, and lymphocytes.



• **Figure 7.9** Normal portal tract from human liver, showing several small ducts, two arteries, a portal vein, and occasional lymphocytes (hematoxylin and eosin).

Although often called *portal triads*, the number of each of these elements varies with the size of the tract. In a study of needle biopsies, the number of profiles per portal tract was 2.3 ducts, 2.6 arteries, and 0.7 veins (91). The average minimum diameters were 13 μm for ducts, 12 μm for arteries, and 35 μm for PVs. In healthy infants, the number of ducts per portal tract is less than that in adults. The average number of portal tracts was 19 per biopsy, with a mean biopsy length of 1.8 cm. The interpretation of liver biopsies requires an assessment of sampling error. Biopsies obtained by the transjugular route are half this size, and in fibrotic conditions, the number of portal tracts available is often less than half a dozen.

Hepatocytes

Hepatocytes comprise 65% of the cells in the liver and 80% of hepatic volume. Hepatocytes are polyhedral with a central spherical nucleus. They are arranged in plates, one cell in thickness, with blood-filled sinusoids on each side of the plates (Fig. 7.10) (92). The cytoplasmic membrane has specialized domains providing a canalicular region on the lateral walls and numerous microvilli on the sinusoidal (basolateral) surfaces. The canalicular domains of adjacent hepatocytes are bound together by tight junctions to form bile canaliculi that coalesce and ultimately drain into ducts within portal tracts. Hepatocytes are also attached by gap junctions that have a role in the transmission of nerve impulses from zone 1 to zone 3. Normal and abnormal ultrastructure of hepatocytes has been reviewed elsewhere (90,93).

Endothelial Cells and Sinusoids

The length of a human sinusoid varies from 223 to 477 μm. The diameter of the sinusoids can vary from 6 to 30 μm and can increase to 180 μm when necessary. Zone 1 sinusoids are smaller than those in zone 3 (94). The caliber depends on active contraction of endothelial cells and stellate cells, as well as passive distension (95). Leukocytes are large compared to sinusoidal diameter, so that blood flow compresses the sinusoidal wall, promoting exchange between plasma, subendothelial fluid, and hepatocytes (94).

The sinusoidal surface is covered with a layer of endothelial cells that enclose the extravascular space of Disse (Fig. 7.10). Hepatic sinusoids differ from systemic capillaries in that the endothelial cells are fenestrated, subendothelial basement membrane material is scanty, Weibel-Palade bodies are absent in most species, and intercellular junctions are absent, permitting the passage of large macromolecules including lipoproteins but not chylomicrons (92,96). Fenestrations are grouped into clusters called *sieve plates*. Mean fenestration diameter in the rat is 150 to 175 nm, occupying 6% to 8% of the endothelial surface area (96). The fenestrations can change in size in response to various stimuli, including pressure, neural impulses, endotoxin, alcohol, serotonin, and nicotine (97). They are large in zone 1 and smaller and more numerous in zone 3. Agents that disrupt actin filaments can almost double the number of fenestrations within minutes (97). The permeability of fenestrations has been studied with marker particles. In the rat, liposomes 400 nm in diameter are readily engulfed by hepatocytes. The ability to traverse fenestrations may depend on the deformability or surface charge of the particles (98).

Sinusoidal endothelial cells also differ from continuous endothelial cells in their immunohistochemical phenotypes. Factor VIII–related antigen, *Ulex europaeus* agglutinin I binding, platelet/endothelial cell adhesion molecule-1 (PECAM-1), CD34, and 1F10 are features of continuous endothelial cells but not of sinusoidal endothelial cells (99). Sinu soidal endothelial cells express low-affinity Fc γ-receptors (CD32, FcR), lipopolysaccharide-binding protein complex receptors (CD14), thrombospondin receptors (CD36), class II histocompatibility receptors (CD4), and intercellular adhesion molecule-1 (100,101). During embryogenesis, the transition from

P.195

P.196

continuous to fenestrated phenotype occurs between 5 and 20 weeks' gestation (100). The fenestrated phenotype partially reverts to the continuous endothelial phenotype in chronic hepatitis, cirrhosis, and hepatocellular carcinoma (101), including the expression of CD34,

PECAM-1, and laminin receptors α6 β1 and α2 β1 (99).

This space contains stellate cell processes (*) and hepatocellular microvilli. Note that the microvilli extend into recesses between hepatocytes. The endothelial cells are fenestrated (*arrows*) (transmission electron microscopy [TEM] ×4,840). **B:** Closer view shows endothelial fenestrations and microvilli of a hepatocyte (TEM ×10,000). **C:** Endothelial fenestrations are clustered into sieve plates (scanning electron microscopy [SEM] ×29,400). (From Bioulac-Sage P, Saric J, Balabaud C. Microscopic anatomy of the intrahepatic circulatory system. In: Okuda K, Benhamou J-P, eds. *Portal hypertension: Clinical and physiological aspects.* Tokyo: Springer-Verlag, 1991:17, with permission.) **D:** Hepatocellular plates are one cell in width, with bile canaliculi (*arrow*) visible on the fractured edges of the plates. Hepatocytes (*H*), sinusoids (*S*), and Kupffer cells (*K*) are seen. Collagen fibers have been pulled from the spaces of Disse (SEM ×2,000). **E:** The space of Disse (*star*) contains several stellate cell processes (*) and collagen bundles (*C*). Endothelial fenestrations are labeled (*arrows*). *H*, hepatocyte nucleus (TEM ×6,000). **F:** Sinusoid with a Kupffer cell in the lumen and a stellate cell containing lipid (*) in the space of Disse (TEM × 2,000).

During the development of cirrhosis, the sinusoids also acquire some morphologic features of systemic capillaries; the space of Disse becomes widened with collagen, basement membrane material is deposited, endothelial fenestrations become smaller and less numerous, and hepatocellular microvilli are effaced. These changes, often called *capillarization of sinusoids* (102), likely reduce transport across the sinusoidal walls and explain some of the hepatocellular dysfunction seen in cirrhosis.

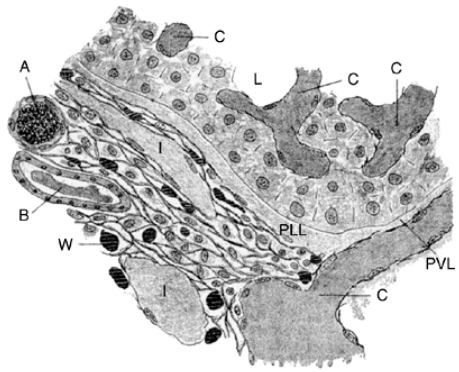
Nitric oxide produced by hepatocytes, Kupffer cells, and sinusoidal and arterial endothelial cells may cause increased sinusoidal blood flow, thereby protecting the liver during various injuries (103,104,105). Increased blood flow may be beneficial by preventing the adhesion of leukocytes and platelets that might otherwise injure the endothelium (60). Nitric oxide production may have a role in the hepatopulmonary syndrome (106) and hepatorenal syndrome (107). Endothelin-1 is produced by activated stellate cells and causes these cells to contract (108). Circulating endothelin-1 may have a role in hepatorenal syndrome (107).

Endothelial cell injury is important in endotoxemia, hypotensive shock, and cold perfusion of donor livers (109,110). Donor livers may develop rounding-up and detachment of endothelial cells that may be responsible for some instances of primary nonfunction after transplantation (111).

It has been suggested that thickening of the space of Disse may contribute to poor transport of materials to the hepatocellular surface (112), as well as possibly contributing to portal hypertension (113). Amyloid fibril deposition may widen the space of Disse dramatically and cause severe atrophy of subjacent hepatocytes. With severe amyloidosis, hepatomegaly, cholestasis, and noncirrhotic portal hypertension have been reported (114). Cellular infiltration within the lumina of sinusoids occurs in Gaucher's disease, mastocytosis, leukemias, and myeloproliferative disorders, but such infiltration does not correlate with the clinical evidence of portal hypertension (115). Obstruction of small veins is more likely to cause portal hypertension in these diseases because sinusoids are distensible and have the ability to regenerate (38).

Formation of Lymph

Most of the hepatic lymph derives from the subendothelial space of Disse, and a minority, perhaps 10%, is formed by leakage from capillaries of the peribiliary plexus. The smallest recognizable lymph capillaries are found in the interstitial tissue in terminal portal tracts and adjacent to terminal hepatic venules (116) (Fig. 7.11). The pathways that connect these lymph capillaries to the space of Disse have been difficult to demonstrate, and it is believed that lymph percolates through the collagen and proteoglycan matrix of the interstitium. Collagen bundles in the space of Disse appear to be continuous with fibers in the portal tracts, marking a submicroscopic channel for lymph flow. Lymph could also flow in the matrix investing the portal inlet venules and arterioles that penetrate the limiting plate.



• **Figure 7.11** Mall's drawing of portal and periportal tissue showing the space of Disse (perivascular lymph space, *PVL*), the space of Mall (perilobular lymph space, *PLL*), and lymph vessel (*I*) after injection with gelatin. The space of Disse is continuous with the space of Mall. In living beings, the space of Mall may be virtual where lymph percolates among interstitial matrix fibers. Also shown are lobule (*L*), sinusoids (*C*), connective tissue fibers (*W*), bile duct (*B*), and artery (*A*). (From Mall, FP. On the origin of the lymphatics in the liver. *Bull Johns Hopkins Hosp* 1901;12:146, with permission.)

Lymphatics have endothelial cells with no basement membrane and no pericytes. PVs can be distinguished from lymphatic channels by the presence of smooth muscle cells surrounding the former (117). The larger lymphatic vessels and trunks have valves.

Because of the large endothelial fenestrations in sinusoidal (and presumably lymphatic) endothelial cells, there is little or no oncotic pressure gradient between the plasma and the subendothelial tissue fluid, and the protein content of hepatic lymph is approximately 80% that of plasma. With a very low oncotic pressure gradient, the main stimulus for the formation of lymph is sinusoidal pressure. A 1-mm rise in efferent pressure doubles the hepatic lymph flow. The liver normally produces 1 to 3 L/day but this may increase to 11 L/day in cirrhosis or extrahepatic outflow obstruction (118). Communication between small bile ducts

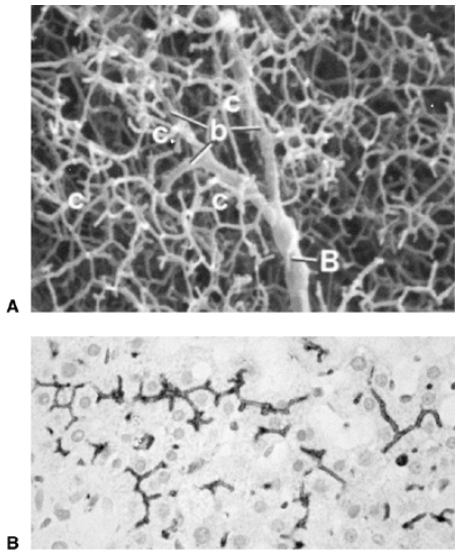
and lymphatics may allow for the increased formation of lymph seen after biliary tract obstruction (119).

Biliary Tree

The biliary tree begins with a network of bile canaliculi that empty into bile ducts (Fig. 7.12). Canaliculi have contractile and secretory properties.

Canaliculi in isolated hepatocyte doublets have been shown to undergo rhythmic contraction thought to represent peristaltic activity in the intact liver (120). These contractile functions are provided by a pericanalicular band of microfilaments composed of actin, myosin II, tropomyosin and α-actinin, and associated proteins, stabilized by a sheath of noncontractile intermediate filaments (121).

The cholangiocytes lining small ducts transport water and solutes under hormonal control (122,123). Peribiliary glands also participate in the concentration of bile. Chloride transport is dependent on the cystic fibrosis transmembrane conductance regulator, explaining the decreased water content of bile, hepatolithiasis, and secondary biliary cirrhosis seen in some patients with cystic fibrosis.



• **Figure 7.12** Bile canaliculi. **A:** Scanning electron micrograph of methacrylate injection cast of rat biliary tree (×860). *B*, terminal twig of the bile duct; *b*, canal of Hering; *c*, bile canaliculi emptying into canals of Hering. (From Murakami T, Itoshima T, Hitomi K, et al. A monomeric methyl and hydroxypropyl methacrylate injection medium and its utility in casting blood capillaries and liver bile canaliculi for scanning electron microscopy. *Arch Histol Jpn* 1984;47:223, with permission.) **B:** Photomicrograph of human liver with slight cholestasis, stained for carcinoembryonic antigen (CEA). CEA is present in the distribution of the bile canaliculi that could not be seen on hematoxylin and eosin.

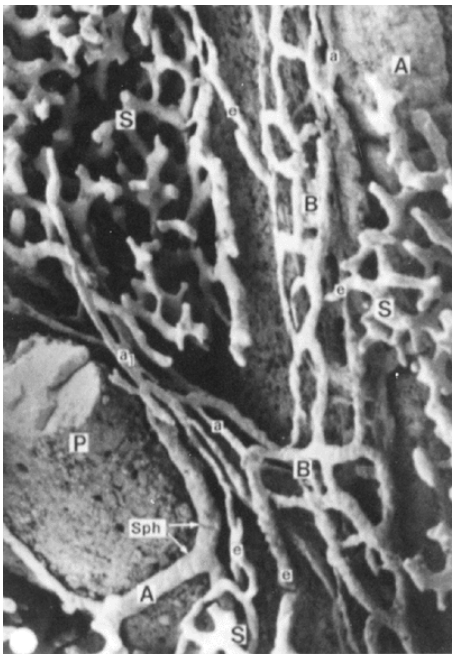
The small bile ducts are supplied by arteries (124) (Fig. 7.13). Terminal branches of the HA supply a general capillary plexus within the

portal tract and a peribiliary vascular plexus and also empty directly into zone 1 sinusoids (125). The general and peribiliary vascular plexi eventually drain into sinusoids through capillary connections known as the *internal roots of the PV*. The peribiliary vascular plexus has been divided into inner, intermediate, and outer layers. The inner layer has fenestrated endothelium, suggesting a role in water exchange. Similar fenestrated endothelium is found in the gallbladder mucosa.

Stellate Cells

The stellate cells (fat-storing cells or Ito cells) are located within the spaces of Disse. Their cytoplasmic droplets normally contain abundant vitamin A, mostly

as retinyl palmitate (126). These cells can be identified by the presence of immunoreactivity for smooth muscle actin, transient autofluorescence, and histochemical affinity for gold and silver. When activated by various cytokines, stellate cells are transformed into myofibroblast-like cells that have reduced vitamin A storage, increased content of myofilaments and α-smooth muscle actin, and increased expression of procollagen gene transcripts. Stellate cells, in their activated state, are the principal hepatic fibroblasts (127,128). Evidence that many forms of hepatic injury activate hepatic macrophages and that these cells release cytokines capable of activating stellate cells has been presented (129). Stellate cells can also secrete matrix metalloproteinases that degrade matrix proteins (130). Activated stellate cells contract under stimulation by sympathetic discharge or endothelin-1 secretion (95,108,131). By this mechanism, stellate cells could exacerbate portal hypertension.



• **Figure 7.13** Scanning electron micrograph of cast blood vessels in the liver of rhesus monkey. Peribiliary arterial plexus (*B*) receives blood from arterial branches (*A*) by means of afferent arterioles (*a*). The plexus supplies sinusoids (*S*) through efferent arterioles (*e*). Note the grooves indicating arteriolar sphincters (*Sph*). Arterioles (a_1) bypass the plexus and empty directly into sinusoids. *P*, portal vein (methyl methacrylate cast ×135). (Courtesy of Dr. T. Murakami, Department of Anatomy, Okayama University, Japan.)

Kupffer Cells

Kupffer cells are the resident macrophages in the liver. They comprise more than 80% of tissue macrophages in the body and 15% of cells in the liver. Although capable of proliferation in situ, they are also recruited from the peripheral blood (127). Kupffer cells reside in the sinusoids, with pseudopodia anchored to endothelial cells or, occasionally, hepatocytes. They may form part of the sinusoidal wall.

Liver-Associated Lymphocytes

A few lymphocytes are normally found in portal tracts and sinusoids even after washout with saline. Portal lymphocytes are 90% T cells with CD4/CD8 ratio of 1.6, whereas sinusoidal lymphocytes are 60% T cells with a CD4/CD8 ratio of 0.4 and 30% natural killer cells (CD56+). Sinusoidal lymphocytes reside in the lumen adherent to Kupffer cells and endothelial cells (127). Many sinusoidal lymphocytes are large, with cytoplasmic granules, and are also called *pit cells* because of the resemblance of the granules to grape seeds (128). Pit cells are most numerous in zone 1 sinusoids. These cells are thought to have a role in killing tumor cells and virus-infected cells. The granules of pit cells contain perforin, a protein that injures cell membranes. Pit cell tumoricidal activity is enhanced by the presence of Kupffer cells (128).

Stroma

Connective tissue stroma supports the capsule, the portal tracts from hilum to periphery, and the sinusoidal walls. The composition of the stroma varies with location. Connective tissue of the capsule and portal tracts is mostly type I and III collagen and elastin. Reticulin fibers, defined by their histochemical affinity for silver, are largely composed of type III collagen and fibronectin (132). They are located in the spaces of Disse, where they give tensile strength to the parenchyma. Type IV collagen forms a basal lamina around small vessels.

Many noncollagenous glycoproteins are present in the matrix, including laminin, fibronectin, tenascin, entactin, vitronectin, undulin, osteonectin, and Von Willebrand's factor (133). Laminin links basement membrane collagen to the integrins attached to endothelial cells and epithelial cells. The function of tenascin is uncertain, but it is mitogenic for a variety of cell types. Vitronectin stimulates fibroblast migration; von Willebrand's factor is found within endothelial Weibel-Palade bodies and in basement membranes (133). Proteoglycans bind to cells and matrix proteins and have roles in matrix–cell and cell–cell interaction.

In scarred livers, there is an absolute increase in many matrix proteins. The bulk of the scar tissue is type I collagen. After

hepatocellular necrosis, the connective tissue framework is rapidly repopulated with hepatocytes in an orderly manner. If regeneration is delayed, the deposition of collagen by stellate cells destroys the framework and prevents restitution to normal.

The stromal collagen is important in the prevention of tears in the blood vessels and sinusoidal walls. Focal dissolution of reticulin leads to parenchymal hemorrhage and blood-filled cysts (peliosis hepatis) (134,135). Mineral oil deposits are present in portal tracts and adjacent to hepatic venules in more than half of human livers and are usually accompanied by a slight mononuclear infiltrate (136).

Three-Dimensional Organization of the Liver

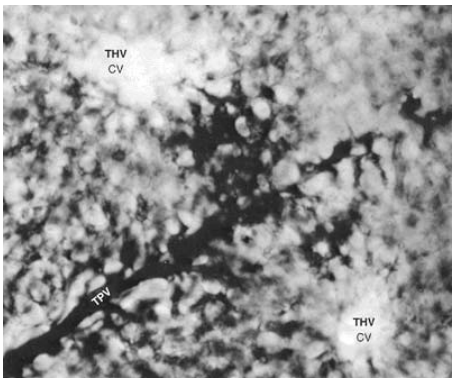
The organization of the hepatic parenchyma has been conceptualized in two contrasting models: The acinus and the lobule (137,138,139). Terminal PVs interdigitate with the terminal hepatic venules, with sinusoids bridging the gaps between these vessels. The terminal hepatic venules can be considered as being in the center of a lobule or the periphery of several acini. The acinar approach is discussed in detail here.

The simple liver acinus is a small parenchymal mass, irregular in size and shape, arranged around an axis consisting of a terminal hepatic arteriole, portal venule, bile ductule, lymph vessels, and nerves that grow out together from a small portal field (Fig. 7.14). The simple liver acinus lies between two (or more) terminal hepatic venules with which its vascular and biliary axis interdigitates. In a two-dimensional view, it occupies sectors of two adjacent hexagonal or pentagonal fields.

The plates and cords of the simple acini are in continuity with adjacent acini in three dimensions; there

P.199

is no capsule separating the acini from one another. It can be assumed that the dividing line between the acini is the watershed of biliary drainage, so that each acinus empties its biliary secretion into the axial bile ductule.

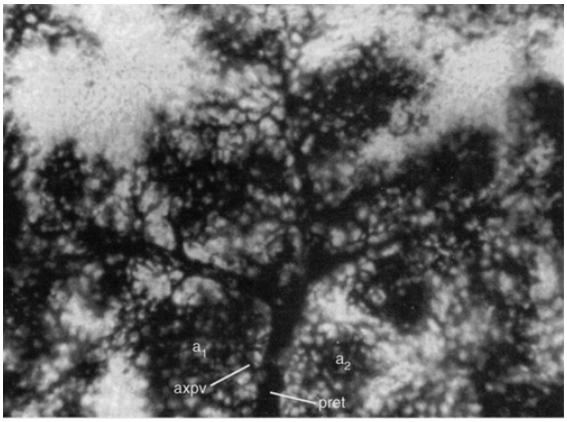


• **Figure 7.14** Liver acinus in humans. The acinus occupies sectors only of two adjacent hexagonal fields and reaches their central veins (*CV*). The terminal portal branch (*TPV*) is injected with India ink and runs perpendicular to the two terminal hepatic venules (*THV*) with which it interdigitates (thick cleared section ×300).

A complex acinus is a clump of tissue composed of at least three simple acini whose axial channels branch in three dimensions from the preterminal stalk (Fig. 7.15). Each of its terminal branches forms the axis of a simple acinus. A sleeve of tissue composed of tiny clumps (acinuli) surrounds the preterminal channels. These acinuli are nourished by axial venules and arterioles branching off the preterminal vessels. Structural and functional unity in a complex acinus can be demonstrated by injecting colored materials (140). The

P.200

axial vessels of the simple acini are always the same color as the parent vessels of the complex acinus. Three or four complex acini form larger clumps of tissue, the acinar agglomerates. Acini or acinuli also form a sleeve of parenchyma around the axial stem servicing the agglomerate.



• **Figure 7.15** Complex acinus in humans. The sinusoids injected with India ink are supplied by three terminal portal branches and their parent preterminal vessel (*pret*). These portal venules help form the axial channels of a complex acinus cut longitudinally. The sleeve of parenchyma around *pret* is formed by acinuli (a_1, a_2); *axpv*, axial portal venule supplying the sinusoids of a_1. The poorly injected *white* areas (in the upper corners) are parts of zone 3 around terminal hepatic venules, which are not shown (150 µm-thick section ×88).

• **Figure 7.16** Group of acinar agglomerates in a human liver injected with India ink. Three large portal branches grow out in different directions from a portal space (*PS*). One of these runs diagonally through the field and represents the axis of an acinar agglomerate. From this portal branch, preterminal (*1*) and terminal (*2*) branches grow out and form the axes of complex and simple acini, respectively (100 μm-thick cleared section ×18).

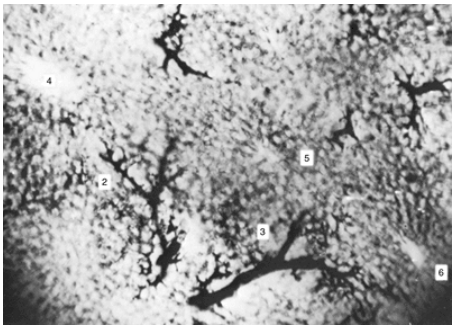
The acinar agglomerate has unity because the main route of vascular supply and the biliary drainage are common to the whole clump, as well as to its subdivisions. The hierarchy can be continued because several agglomerates are supplied by a single macroscopic portal tract. The PVs supplying agglomerates in the human liver are approximately 150 μm in diameter (140) (Fig. 7.16). All branches of the hepatic vein interdigitate with HA and PV branches of similar order; this creates a hexagonal or pentagonal pattern when seen histologically in cross-section (Figs. 7.17 and 7.18).

The acinus is an ideal physiologic unit for understanding many vascular and biliary events in human biology (see discussion on cirrhosis in subsequent text). The conceptual advantage of the acinus is that the blood supply to a portion of the parenchyma and the bile duct draining the same parenchyma reside in the same portal triad. "Thus, structural, circulatory, and functional unity is established in this small clump of parenchyma" (141) (Fig. 7.19). By contrast, the classical hexagonal lobule is supplied by several separate PV branches, arteries, and ducts, each of which also supplies other adjacent lobules (140).

McCuskey (142) notes that all the essential relationships are present within smaller units called *hepatic microvascular subunits*. This concept is validated by the existence of focal degenerative changes that involve portions of parenchyma that are subacinar in size. The smallest useful unit is that in which there is a significant barrier to blood flow between adjacent units.

Recent studies show that PV blood is distributed by numerous small inlet venules, giving a portal supply that is more diffuse and less granular than that pictured by the original description of the acinus (137,138,139). These analyses suggest that isobars of oxygen tension are sickle shaped (Fig. 7.20), with the parenchymal subunits being components of a hedge rather than individual grapes on a vine. Although parenchymal subunits are difficult to visualize in the normal human liver, they become evident in pathologic conditions such as nodular regenerative hyperplasia, in which there is a pruning of the portal venous supply. As with a hedge, when individual portal units are pruned, the remaining units undergo hyperplasia to form an

array of spherical units, revealing the underlying acinar structure. The hierarchical arrangement of simple, complex, and agglomerate acini can be appreciated in livers with prominent atrophy or necrosis (141). In this century-long debate, it is useful to note that parenchymal subunits do not exist in the human liver. The debate concerns the best way to imagine their structure if they did exist.



• **Figure 7.17** Interdigitation of portal and hepatic vein branches. Human liver injected with India ink. Two horizontal terminal portal branches (*2, 3*), forming the axes of acini, interdigitate with three vertical terminal hepatic venules (*4, 5, 6*), around which they arch (cleared thick section × 110).

Hepatocellular Heterogeneity

The liver is anatomically situated to receive high concentrations of nutrients and certain hormones from the intestines and pancreas. Gradients of these substances, as well as oxygen and waste products, are found across the functional units of the liver. These gradients are not constant but vary with cycles of feeding and exercise.

The position of hepatocytes within the acinus is reflected by the specialized functions of these hepatocytes (138,143,144,145) (Fig. 7.21). Zone 1 hepatocytes are adapted to high oxidative activities, having numerous large mitochondria. Dominant processes in zone 1 are gluconeogenesis, β-oxidation of fatty acids, amino acid catabolism and ureagenesis, cholesterol synthesis, and bile acid secretion. Zone 3 is an ideal location for exergonic processes, including glycolysis and lipogenesis. There is a narrow rim of hepatocytes adjacent to terminal hepatic venules that remove ammonia from the blood by synthesizing glutamine. Zone 3 is also the site of general detoxification and biotransformation of drugs.

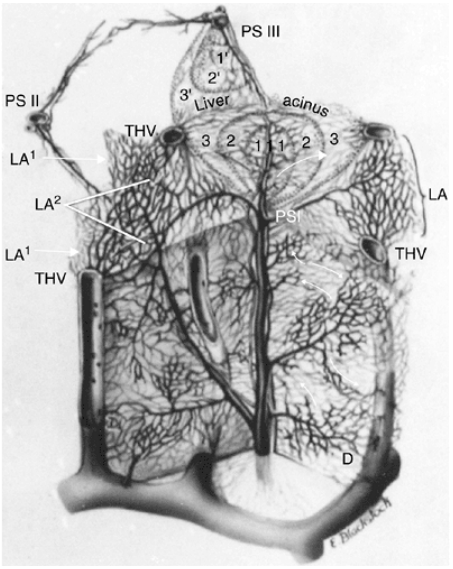
Metabolic zonation is accompanied by gradients of some anatomic features (141). Mitochondria are larger and more numerous and lysosomes and Golgi are more abundant in zone 1. Smooth endoplasmic reticulum is more abundant and nuclear volumes are larger in

zone 3. Endothelial fenestrae are larger and less numerous in zone 1. Kupffer cells, large granular lymphocytes, stellate cells, and sympathetic nerve endings are all more numerous in zone 1. There are also gradients in the composition of matrix proteins (146).

The control of metabolic zonation has been found to operate at the pretranslational level, with a few exceptions. Therefore the gradients of the enzyme protein and the enzyme messenger ribonucleic acid tend to parallel each other. Enzyme expression usually varies during the feeding cycle or changes in oxygen tension, and the zonation is said to be dynamic. It is likely that many signals interact to produce dynamic zonation. Glucose and oxygen gradients each have an effect on various enzymes, and these gradients are interdependent (147,148). The sensors of oxygen gradients may be mediated by heme-containing proteins.

Stable zonation that does not vary with metabolic signals is a result of intercellular or cell–matrix interactions. For example, glutamine synthetase activity

may depend on close approximation of hepatocytes with some element of the venules, although this is controversial (144,149). Metabolic zonation is lost in cirrhosis (150). Glutamine synthetase expression was undetectable in one study (150).

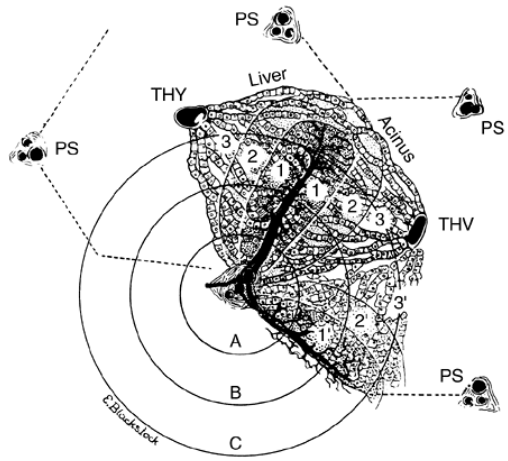


• **Figure 7.18** Vascular and biliary architecture of an acinar agglomerate and the relation of the acini to the adjacent hexagonal lobule. Note the arcuate courses of the terminal portal branches, the irregularly arranged simple acini, and the short portal vessels that form the axes of tiny acinuli constituting the mantle of parenchyma around the longitudinally cut portal space. Intercommunicating paths of acini and acinuli are indicated by *arrows*. *PS I, PS II, PS III*, portal spaces; *LA, LA*^{1}, simple liver acinus; *LA*^{2}, simple acinus penetrating a hexagonal field situated well above the level of origin of the acinus; *THV*, terminal hepatic venule; *D*, channels of Deysach; *1, 2, 3*, circulatory zones of the simple liver acinus.

Although hepatocellular heterogeneity is largely determined by the zonal gradients of environment cues, some heterogeneity occurs because of local genetic aberration. This can be seen in hemochromatosis as iron-free foci within livers that are otherwise diffusely pigmented (151). These represent dysplastic foci with increased risk for the development of hepatocellular carcinoma (152). Clusters of hepatocytes with excess cytoplasmic glycogen occur in patients with various disorders of ureagenesis and in leprechaunism, presumably because of focal genetic variation (153).

Clinical Importance of Hepatocellular Heterogeneity

Metabolic heterogeneity is responsible for zonal injuries that are of diagnostic value to the pathologist. The distribution of necrosis and steatosis in response to chemical injury is often zonal (154). Sharply defined zone 3 necrosis is characteristic of toxicity due to acetaminophen, *Amanita phalloides*, pyrrolizidine alkaloids, and various hydrocarbons such as halothane and carbon tetrachloride. Zone 1 necrosis has been found with allyl alcohol, phosphorus, and high-dose iron ingestion. Zone 2 toxicity is rare in humans but has been produced in animals with ngaione, furosemide, and beryllium. Cocaine toxicity in rodents may affect different zones depending on preexisting enzyme induction (155).

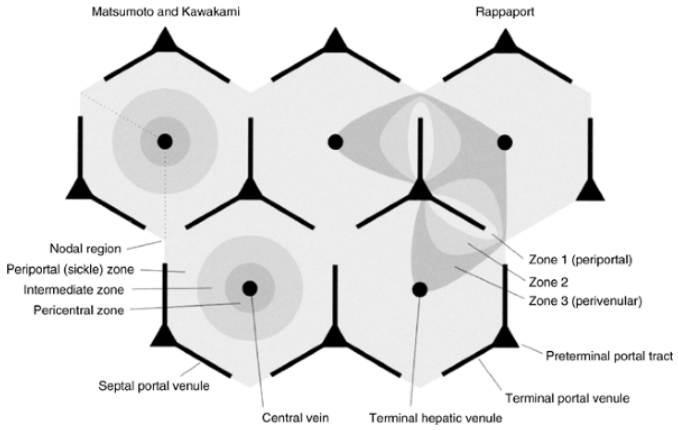


• **Figure 7.19** Blood supply of the simple liver acinus and the zonal arrangement of cells. The acinus occupies adjacent sectors of neighboring hexagonal fields. Zones *1, 2*, and *3*, respectively, represent areas supplied with blood of first, second, and third quality, with regard to substrate, oxygen, and nutrients. These zones center on the terminal afferent vascular branches, terminal bile ductules, lymph vessels, and nerves and extend into the triangular portal field from which these branches crop out. Zones *1′, 2′*, and *3′* designate corresponding areas in a portion of an adjacent acinar unit. In zones *1* and *1′*, portal inlet venules empty into sinusoids. Note that zone *3* approaches the preterminal portal tract, nearly reaching the inner circle (*A*). *PS*, portal space; *THV*, terminal hepatic venules (central veins).

Systemic hypoperfusion generally produces zone 3 necrosis. This pattern may be altered by local factors. For example, in disseminated intravascular coagulation, zone 1 sinusoidal fibrin deposition results in maximum ischemia being located in zone 1 or 2. Zone 2 necrosis has been reported in some patients with hypotensive shock (156). Viral hepatitis usually produces spotty necrosis in all zones but often with an ill-defined zone 3 predominance. Yellow fever often produces zone 2 necrosis. Herpesvirus produces well-demarcated necrosis that does not follow a zonal distribution.

In hemochromatosis, hemosiderin is deposited predominantly in zone 1 hepatocytes. This is useful to

distinguish hemosiderin from lipofuscin, the latter occurring predominantly in zone 3 hepatocytes. Proximity to a source of insulin favors the development of steatosis, as seen after the instillation of insulin in the peritoneal cavity during dialysis and in the case of decreased steatosis in infarcts of Zahn, where PV supply to the tissue is obstructed.



• **Figure 7.20** The acinar structure of the hepatic microcirculation, as conceived by Rappaport (140) and modified by Matsumoto and Kawakami (137). In both models, the margins of the shaded zones represent planes of equal blood pressure (isobars), oxygen content, or other characteristic. The models differ in the shape of the isobars surrounding terminal portal venules. The acinus is bulb-shaped, and the classical hexagonal lobule is comprised of several wedge-shaped portions (called *primary lobules*, indicated by *dotted lines*, upper left), which have cylindrical (sickle-shaped) isobars. The nodal region is the nodal point of Mall (22). (From Wanless IR. Anatomy and developmental anomalies of the liver. In: Feldman M, Scharschmidt BF, Sleisenger MH, eds. *Sleisenger and Fordtran's gastrointestinal and liver disease*, 6th ed. Philadelphia: WB Saunders, 1997:1059, with permission.)

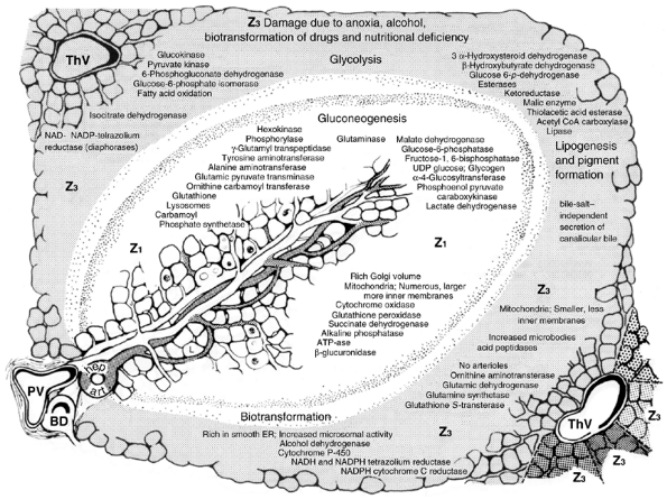
Control of Hepatic Microcirculation

The terminal PVs supply sinusoids directly, giving a constant but sluggish blood flow (140,141). In contrast, arterioles drain into terminal portal venules and zone 1 sinusoids, giving a pulsatile but small volume flow that appears to enhance sinusoidal flow, especially in periods of reactive arterial flow, as in the postprandial state. Groups of sinusoids shift their work asynchronously. The change from the storage phase of inactive sinusoids to flow activity demonstrates, at the microscopic level, the function of the liver as a "venesector and blood giver of the circulatory system" (157).

Arterial flow varies inversely with PV flow. The mechanism of this *hepatic arterial buffer response* is based on the washout of locally produced adenosine (158). When portal venous flow is reduced, adenosine accumulates and causes dilatation of the arterial resistance vessels; the reverse also occurs. The relative contribution of arterial and portal venous flow varies between regions of the liver and with

gravity and other physiologic variables (159). Conductance of PVs increases with distention, causing portal pressure to be little altered by large changes in PV flow (160). In addition to arteriolar tone, local control of the microcirculation may depend on the contraction state of sinusoidal endothelial and stellate cells (95).

Regional blood flow is of practical importance when investigating focal lesions such as focal nodular hyperplasia and neoplasms. The venous and arterial circulation can be differentially imaged by using computed tomography with arterial portography (CTAP) or CT scan with intravenous contrast injection. Hepatocellular carcinoma, hepatic adenomas, metastases, and focal nodular hyperplasia are mostly supplied by arteries and are therefore hypodense with CTAP (161,162). Cirrhotic nodules, dysplastic nodules, and small hepatocellular carcinomas may have a portal venous supply and are usually isodense on CTAP.



• **Figure 7.21** Schematic diagram of various metabolic processes that show zonal differences across the acinus. PV, portal vein; *ThV*, terminal hepatic venule; *D*, bile duct; *A*, hepatic arteriole; NAD, nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate; UDP, uridine diphosphate; ER, endoplasmic reticulum; Z_1, periportal area; Z_3, periacinar and perivenular area. (The latter is derived from portions of zone 3 of several adjacent acini.) (Modified from Rappaport AM, Wanless IR. Physioanatomic considerations. In: Schiff L, Schiff ER, eds. *Diseases of the liver*, 7th ed. Philadelphia: JB Lippincott, 1993:1–41, Jungermann K, Kietzmann T. Zonation of parenchymal and nonparenchymal metabolism in liver. *Annu Rev Nutr* 1996;16:179–203.) (For description see text; for references see both the sources.)

Physioanatomic Aspects of Human Liver Disease

Regeneration of Hepatocytes

The normal liver maintains a constant mass that is determined by the needs of the host. If a partial hepatectomy is performed, the organ grows to regain much of the original mass in 10 days in rodents and in a few weeks or months in humans (163). If a liver is transplanted into a new host, the new liver grows (by mitosis) or shrinks (by apoptosis) to the size of liver expected for the host's body size. Hepatocyte dysfunction, such as chronic cholestasis in primary biliary cirrhosis or primary sclerosing cholangitis, appears to be a signal to initiate cell proliferation because the liver may be twice the normal weight in the early stages of these diseases.

There is controversy about the source of the hepatocytes participating in regeneration. The normal resting liver has a very low mitotic rate. After many types of injury, mitoses become readily visible in hepatocytes from all acinar zones. However, some labeling studies suggested that mitosis is particularly active in the periportal region, giving rise to the hypothesis that hepatocytes are born in zone 1 and migrate in their lifetimes to zone 3 (164). This "streaming liver" concept implies the presence of stem cells, now considered to be located in the smallest radicles of the biliary tree, the canals of Hering (165,166). Cells in this location are thought to be able to differentiate into cholangiocytes and hepatocytes (167,168). It appears that the bulk of cell replacement, in acute and subacute injury models, is by panacinar mitosis. The stem cell and streaming liver mechanisms may be important in severe injury states (169). The stem cell population may be replenished by cells migrating from the bone marrow (170,171,172,173,174).

In a healthy human liver, half the hepatocytes are diploid and the other half are polyploid (175). One third of the hepatocytes are binuclear. The processes of polyploidization and binucleation are irreversible, so that polyploidy increases with age. These processes may protect long-lived hepatocytes against mutation. During a regenerative stimulus, binucleation and polyploidy decrease as binucleating growth is suppressed. Therefore, after regeneration, freshly divided cells have small and uniform nuclei, in contrast to the polyploid resting cells.

Putative signals for the initiation of the cell cycle in hepatocytes include hepatocyte growth factor (HGF), produced in all the major types of nonparenchymal liver cells; epithelial growth factor, produced in the salivary glands and hepatocytes; transforming growth factor-α (TGF-α), produced in the hepatocytes, and tumor necrosis factor (TNF) (see Chapter 2) (176). Endotoxin stimulates TNF secretion, and TNF stimulates Kupffer cells to secrete interleukin-6, which is an important mediator of hepatocellular regeneration. HGF and TGF-β are bound to the extracellular matrix (177). Insulin and glucagon support hepatocyte growth in culture and in vivo, although they are not complete mitogens for hepatocytes. Although the details of this complex system are not fully understood, it is clear that cytokines and growth factors derived from multiple cells types are involved. Therefore, gut-derived endotoxin, pancreatic hormones, activated Kupffer cells, and sinusoidal blood flow will influence hepatocellular regeneration (171).

Table 7.2. Clinical and Anatomic Features of the Major Forms of Chronic Liver Disease

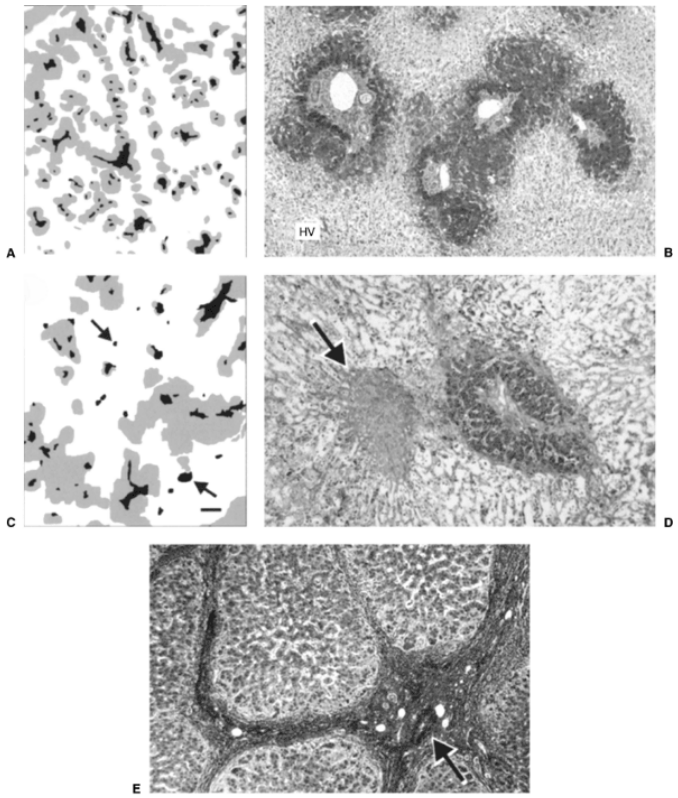
Anatomic	Portal	Hepatocellular	Parenchymal	Fibrous	Obliteration of small	Extrahepatic or large intrahepatic	Obliteration of small hepatic

diagnosis	hypertension	dysfunction	extinction	septa	portal veins	PV block	veins
Cirrhosis, micronodular	++	++	+++	Many, broad	+++	±	+++
Cirrhosis, macronodular	+	±	++	Many, narrow	++	±	++
Cirrhosis, venocentric[a]	++	+	+++	Between hepatic veins, portal tracts not involved	+	±	+++
Cirrhosis, incomplete septal	±	±	+	Moderate, narrow, or incomplete	+	-	+
Cirrhosis, incomplete septal with large portal vein obstruction	+	±	+	Moderate, narrow, or incomplete	+	+	+
Extrahepatic portal vein obstruction[b]	++	±	-	None	+	++	-
Nodular regenerative hyperplasia	±	±	-	None or rare	++	±	±

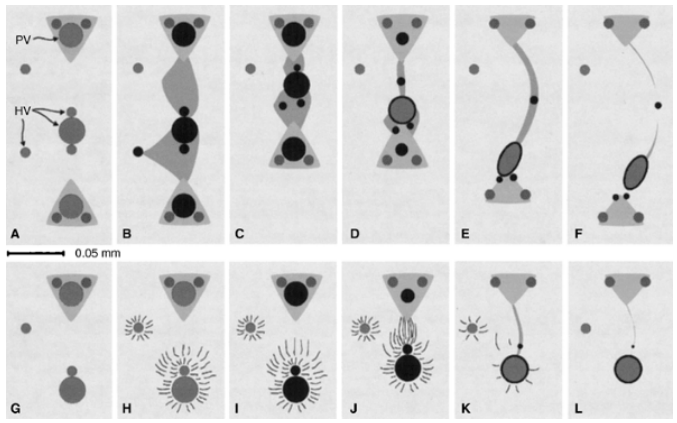
Gradings are for typical examples but gradings can vary within each anatomic category.
[a]Typically seen with Budd-Chiari syndrome.
[b]Examples are Portal vein thrombosis, portal vein agenesis, cavernous transformation of the portal vein.

Pathogenesis of Chronic Liver Disease

Chronic liver disease is usually defined as hepatic injury lasting for at least 6 months. The end stage of chronic liver disease has often been divided in two clinicopathologic forms: Cirrhosis and noncirrhotic portal hypertension, the former being associated with portal hypertension and hepatic dysfunction and the latter with portal hypertension and nearly normal function. Recent anatomic studies have demonstrated that these two categories can be further subdivided (Table 7.2) (38). All types of chronic liver disease are associated with vascular obstruction, and the various anatomic patterns can be explained by the distribution and severity of the obstructive lesions. Each anatomic pattern is the summation of numerous local parenchymal lesions of either atrophy or extinction. Therefore, understanding the pathogenesis of atrophy and extinction is necessary to understand the pathogenesis of each anatomic pattern.



• **Figure 7.22** The histogenesis of cirrhosis. There are two basic types of cirrhosis, venocentric and venoportal. The type of cirrhosis is determined by the distribution of vascular obstruction, as illustrated by these examples with Budd-Chiari syndrome. **A, B:** Venocentric cirrhosis occurs when parenchyma near the obstructed hepatic veins (*HV*) shows contiguous cell loss and fibrosis (extinction) and cirrhotic nodules (*dark tissue*) contain portal tracts with patent veins. The periportal tissue survives because of retrograde portal vein drainage. **C, D:** When hepatic vein obstruction is followed by portal vein thrombosis, retrograde portal vein (PV) flow is not possible and the periportal tissue cannot support hepatocytes. This is shown in **(C)** where portal tracts (*black*) are usually accompanied by periportal tissue (*gray*) except in regions affected by PV thrombosis (*arrows*). In **(D)** the *arrow* indicates a portal tract with obstructed PV and absent periportal tissue. **E:** Venoportal cirrhosis occurs when portal tracts are incorporated into the septa located adjacent to the cirrhotic nodules. Arrow shows obliterated portal vein (**B**, **D**, and **E**: Elastic-trichrome stain). (Modified from Tanaka M, Wanless IR. Pathology of the liver in Budd-Chiari syndrome: Portal vein thrombosis and the histogenesis of venocentric cirrhosis, venoportal cirrhosis, and large regenerative nodules. *Hepatology* 1998;27:488–496, with permission.)



• **Figure 7.23** Diagrammatic depiction of tissue remodeling in chronic hepatitis **(A–F)** and in alcoholic liver disease **(G–L)** during the development and regression of cirrhosis. Normal acini are shown in **(A)** and **(G)**, with the sequence of events leading to small regions of parenchymal extinction in the following panels. Obstructed veins are shown as *black circles*. **B:** Obliteration of small portal and hepatic veins occurs early in the development of cirrhosis in response to local inflammatory damage. The supplied parenchyma becomes ischemic. **C, D:** Ischemic parenchyma shrinks and is replaced by fibrosis (process of extinction). The shrinkage is accompanied by close approximation of adjacent vascular structures. **E:** Septa are deformed and stretched by expansion of regenerating hepatocytes. **F:** As septa are resorbed, they become delicate and perforated before disappearing. Trapped portal structures and hepatic veins are released from the septa and are recognizable as deformed and ectopic remnants. Note the absence of portal veins. In alcoholic disease **G–L**, the sequence of events may differ from other forms of chronic liver disease. **H:** Sinusoidal fibrosis is often prominent before parenchymal collapse, leading to a pericellular pattern of fibrosis. **I, J:** Inflammation and fibrosis lead to hepatic and portal vein obliteration, with secondary condensation of preformed sinusoidal collagen fibers into a septum. **K, L:** After prolonged periods of inactivity, sinusoidal fibrosis and septa are resorbed. (Modified from Wanless IR, Nakashima E,

Sherman M. Regression of human cirrhosis. Morphologic features and the genesis of incomplete septal cirrhosis. *Arch Pathol Lab Med* 2000;124:1599–1607, with permission.)

P.206

P.207

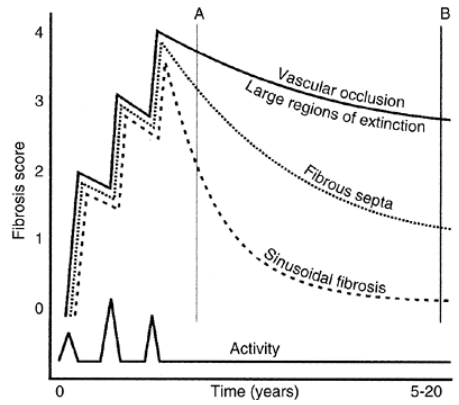
The two-hit vascular model allows one to predict the local parenchymal response to vascular obstruction (178,179). Normal liver parenchyma is supplied by arteries and PVs and is drained by hepatic veins. The dual blood supply, therefore, allows for two levels of ischemia. Mild ischemia may occur when any one of these vessels is obstructed, resulting in atrophy. Severe ischemia occurs when any two of these vessels are obstructed, leading to extinction. The evolution of extinction lesions is illustrated in Figure 7.22.

The histologic appearance of the liver varies with time after injury, with progressive enlargement (nodular hyperplasia) of well-supplied regions of parenchyma, arterial dilatation and growth, and progressive resorption of collagen (178,180). These secondary events complete the genesis of the various patterns of chronic liver disease. Therefore, nodular hyperplasia occurring in the presence of atrophy produces the pattern of nodular regenerative hyperplasia. Nodular hyperplasia occurring in the presence of abundant extinction is the pattern called *cirrhosis*. The pattern of cirrhosis is further modified by the relative involvement of portal and hepatic veins (Fig. 7.23). Resorption of collagen in cirrhotic livers leads to macronodular cirrhosis, incomplete septal cirrhosis, and eventually almost a total regression of cirrhosis (Fig. 7.24). Significant regression presupposes that the activity of disease and the development of new obstructive events are minimized by spontaneous remission or effective therapy.

The mechanism of vascular obstruction in chronic liver disease depends on the nature of the primary disease. In most forms of chronic hepatitis, portal and hepatic vein phlebitis occurs as a bystander effect of inflammation in adjacent tissue (181). In Budd-Chiari syndrome and chronic congestive failure, thrombosis is the cause of the vascular obliteration (179). In chronic

P.208

biliary disease, bile salt injury is likely responsible for the hepatic vein obliteration, and portal inflammation may explain the PV obliteration. In established cirrhosis of any etiology, stasis commonly leads to secondary thrombosis or congestive venopathy of portal and hepatic veins and secondary parenchymal extinction that may be independent of the activity of the original disease (182,183). The significance of these thrombotic and congestive venopathy mechanisms is that they point to mechanisms that might be ameliorated by therapy. Antithrombotic therapy is often recommended in patients with obvious thrombotic disease such as Budd-Chiari syndrome and portal thrombosis (184) but may also be beneficial in other types of progressive liver disease. Congestive venopathy might be ameliorated by β-blockers or porta-caval or transhepatic shunt procedures.



• **Figure 7.24** The time course of the histologic features of cirrhosis in relation to periods of activity. After cessation of activity, various histologic features regress at different rates. The balance of histologic features varies with the duration of low-activity disease, for example, between time points *A* and *B*. At time *B*, cirrhosis cannot be diagnosed histologically, although portal hypertension may remain. (Reprinted with permission, from Wanless IR. Regression of human cirrhosis. In Reply. *Arch Pathol Lab Med* 2000;124:1592–1593.)

The development of extinction in chronic hepatitis may be recognized as bridging necrosis in very active cases. In less active disease, there are clusters of apoptotic and atrophic hepatocytes, often with congestion of the sinusoids. As lesions are fully organized, they are identified by the approximation of hepatic veins to portal tracts after the intervening parenchyma has been resorbed.

The formation of intrahepatic shunts in cirrhosis can be understood from this model. Arterioles from terminal portal tracts normally feed into zone 1 sinusoids. When the local terminal hepatic venule is obliterated, arterial flow seeks a patent channel with lower pressure. If the local PV is patent, it receives the arterial flow by retrograde flow in the zone 1 sinusoids (179). If the local PV is also obstructed, the arterial flow will drain laterally into those sinusoids that connect with a patent hepatic vein, likely the parent of the obstructed terminal hepatic venule. These favored sinusoids dilate and become part of an artery-to-hepatic vein shunt. If the nearest patent hepatic vein is too distant, the parenchyma becomes congested and eventually extinct.

Chapter 8
Bilirubin Metabolism and Jaundice

Allan W. Wolkoff
Paul D. Berk

Key Concepts

- Bilirubin is the final degradation product of heme, which is the prosthetic group of numerous important hemoproteins involved in oxygen transport (e.g., hemoglobin) or metabolism (e.g., P-450 cytochromes). The conversion of heme to bilirubin involves two enzymatic steps: Opening of the heme ring by heme oxygenase to form biliverdin, with the release of both carbon monoxide (CO) and iron, and reduction of biliverdin to bilirubin by biliverdin reductase.
- Healthy adults produce a mean of 4 mg of bilirubin/kg body weight per day. Degradation in the reticuloendothelial system of the hemoglobin of dying erythrocytes generates 80% to 85% of daily bilirubin production. The remainder has multiple sources, including ineffective erythropoiesis in the bone marrow and the turnover of short-lived, nonhemoglobin hemoproteins including the various P-450 cytochromes. Because synthesis and degradation of these cytochromes occurs throughout the body, both heme biosynthesis and the heme oxygenase/biliverdin reductase pathway are widely distributed.
- Bilirubin was long considered simply a biologic waste product. However, biliverdin and bilirubin have antioxidant properties, CO is important in cell signaling, iron plays a key role in the generation of reactive oxygen species, and both heme biosynthesis and heme degradation are tightly regulated. These observations suggest that, hemoglobin degradation aside, heme synthesis and degradation throughout the body may play a role in cellular antioxidant defenses.
- Bilirubin formed in the periphery is kept in solution during transit to the liver by very tight binding to albumin. Once in the liver, it is transported from plasma to bile by four distinct steps: Hepatocellular uptake; binding to specific intracellular proteins; conversion to a water-soluble form by conjugation to glucuronic acids by the uridine-5′-diphosphate glucuronosyltransferase isoform UGT1A1; and the adenosine triphosphate (ATP)-dependent, carrier-mediated transport of the resultant bilirubin monoglucuronide (BMG) and bilirubin diglucuronide (BDG) across the canalicular domain of the plasma membrane into the bile canaliculus.
- Jaundice is the yellow–orange discoloration of the skin, conjunctivae, and mucous membranes that results from an elevated concentration of bilirubin in plasma. Hyperbilirubinemias are usually classified into those that are predominantly unconjugated and those that are mainly conjugated. The latter often, in fact, involve elevations of levels of both the conjugated and unconjugated bilirubin fractions. Instances of hyperbilirubinemia in which other common hepatic biochemical test results are normal often reflect familial hyperbilirubinemias; the combination of hyperbilirubinemia with abnormalities of other hepatic biochemical tests suggests an acquired condition. Exceptions to this rule are not rare.
- The plasma unconjugated bilirubin concentration reflects a balance between bilirubin turnover and hepatic bilirubin clearance (C_{BR}). Unconjugated hyperbilirubinemia can result from increased bilirubin turnover (e.g., hemolysis), decreased bilirubin clearance (e.g., neonatal hepatic immaturity, familial unconjugated hyperbilirubinemias), or situations in which both processes are occurring (neonatal immaturity in infants with glucose-6-phosphate dehydrogenase deficiency).
- Reduced levels of UGT1A1 on either a congenital (Gilbert's and Crigler-Najjar syndromes) or an acquired basis (administration of certain human immunodeficiency virus protease inhibitors) and shunting of blood around the hepatic parenchyma in cirrhosis are the most frequent causes of a reduction in C_{BR}. Hereditary (Dubin-Johnson syndrome) or acquired (hepatocyte injury) deficiencies of the canalicular transport system, or obstruction to the flow of bile down the biliary tract, are the principal causes of conjugated hyperbilirubinemia.
- Application of molecular technology has led to extensive progress in understanding the pathogenesis of the familial hyperbilirubinemias. Gilbert's syndrome and Crigler-Najjar syndrome types I and II were long considered separate diseases, with separate patterns of inheritance. It is now recognized that they all reflect autosomal recessive disorders characterized by mutations of different severity in the gene encoding UGT1A1. Similarly, Dubin-Johnson syndrome is now known to reflect an inherited abnormality in multidrug resistance–associated protein 2 (*MRP2*), encoding an ATP-dependent canalicular plasma membrane transporter for bilirubin conjugates and a number of other non–bile acid organic anions. Of the five familial hyperbilirubinemias, only Rotor's syndrome remains unexplained in terms of molecular pathogenesis.

Bilirubin, a reddish-yellow heme degradation product, is produced principally by the breakdown of the hemoglobin of senescent red blood cells and eliminated from the circulation by the liver. Jaundice, derived from the French *jaune* (yellow), is the yellow–orange discoloration of the skin, conjunctivae, and mucous membranes, which is a consequence of an elevated concentration of bilirubin in plasma. Although mild hyperbilirubinemia may be clinically undetectable, jaundice becomes apparent at plasma bilirubin concentrations of 3 to 4 mg/dL. The threshold for its recognition depends on the patient's normal pigmentation, the lighting conditions under which the observation is made, and the particular fraction of plasma bilirubin whose concentration is elevated. Optimal interpretation of an elevated plasma bilirubin concentration is based on an appreciation of its metabolism, and in particular, its sources and disposition. These are the subjects of this chapter.

Studies of bilirubin chemistry, metabolism, and genetic disorders underwent explosive growth in the 1960s through the 1990s, creating the foundation on which current work in the field is based. Because space limitations restrict the number of references that can be cited in this chapter, readers are frequently referred to review articles for detailed bibliographies of older work in this field (1,2,3,4,5,6,7,8,9,10).

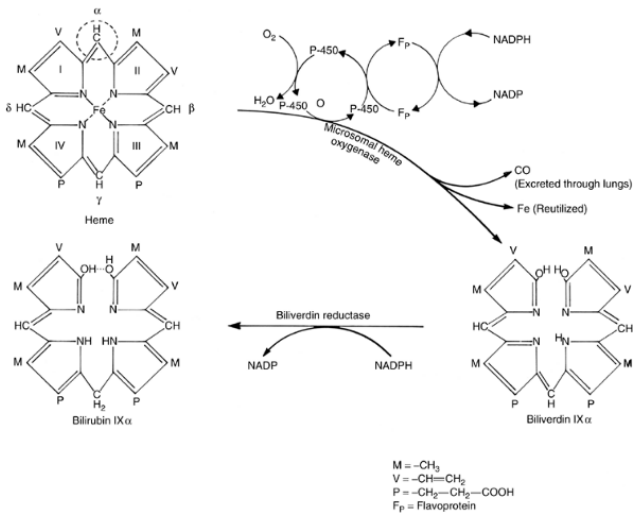
Sources, Structure, and Plasma Transport of Bilirubin

Bilirubin Production from Heme

Bilirubin is the final, common end product of the metabolism of heme, the moiety found in hemoglobin, myoglobin, and other hemoproteins (Fig. 8.1). The formation of bilirubin is the result of a multistep, enzymatic process in which the porphyrin ring of heme is first opened at the α-bridge carbon in a stereoselective, enzymatic oxidative process carried out by the microsomal enzyme heme oxygenase. This step leads to the release of an iron atom and the formation of equimolar quantities of biliverdin, a green tetrapyrrolic pigment, and carbon monoxide (CO) (3,4,11,12,13,14,15). Biliverdin is a water-soluble pigment readily excreted unaltered by the liver. It is the principal bile pigment in many

amphibia, fish, and birds. However, it does not readily cross the placenta. Accordingly, most mammals rapidly and quantitatively convert biliverdin to the reddish yellow pigment bilirubin through a reaction that is catalyzed by the enzyme biliverdin reductase (2,3,8,9,16). Heme oxygenase is present in macrophages throughout the reticuloendothelial system, including Kupffer cells of the liver, and certain epithelial cells, including hepatocytes and renal tubular cells (17). Biliverdin reductase is widely distributed in many cells throughout the body, including macrophages (16). The major sites of bilirubin production are the spleen and other compartments of the reticuloendothelial system, which degrade the hemoglobin of senescent and injured red blood cells. However, the degradation of heme to bilirubin can occur in many sites, including macrophages that migrate into hematomas containing extravasated hemoglobin. Because both heme oxygenase and biliverdin reductase are present in macrophages, the sequential steps in the conversion of heme to bilirubin are readily visualized at the edges of any bruise, where the purplish to green to yellow color changes reflect the conversion of extravasated and deoxygenated hemoglobin first to biliverdin and then to

bilirubin (18,19).

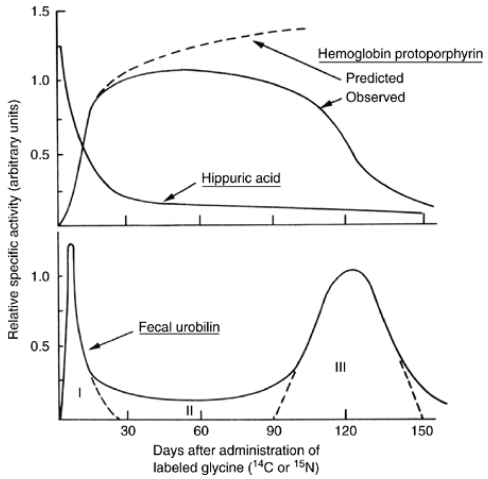


▪ **Figure 8.1** Pathway for the degradation of heme to bilirubin. Stereospecific opening of the heme macrocycle at the α-bridge carbon by the microsomal enzyme heme oxygenase results in the formation of equimolar amount of biliverdin and carbon monoxide. Biliverdin is subsequently reduced to bilirubin by the enzyme biliverdin reductase. MET, microsomal electron transport system; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, nicotinamide adenine dinucleotide phosphate (reduced form). (Reproduced from reference Berk PD, Jones EA, Howe RB. Disorders of bilirubin metabolism. In: Bondy PK, Rosenberg LE, eds. *Metabolic control and disease*, 8th ed. Philadelphia: WB Saunders, 1979:1009–1088, with the permission of the publisher.)

Possible Cytoprotective Effects of the Heme Oxygenase/Biliverdin Reductase Pathway

Although both heme oxygenase and biliverdin reductase were initially considered to function solely as a heme-degradative and waste disposal pathway, the

widespread distribution of these enzymes in cells outside the reticuloendothelial system, the tight control of heme oxygenase activity achieved through the presence of both an inducible (HO-1) and a constitutive (HO-2) form of the enzyme, and the important biologic effects of the several products of heme degradation have led to a growing interest in this pathway (20). In this regard, both biliverdin and bilirubin have proved to be potent antioxidants, CO functions as both a signaling molecule and an important vasoactive regulator, and the iron released during heme degradation contributes to various forms of cellular cytotoxicity by facilitating the formation of reactive oxygen species (ROS). These findings suggest that cells may have evolved a fine control over the heme oxygenase/biliverdin reductase pathway specifically to regulate CO production for signaling and heme consumption and generation of bilirubin and biliverdin for their roles in counteracting intracellular oxidative and nitrosative stress (20,21). The existence of a specific oxidation/reduction cycle in which lipophilic ROS oxidize bilirubin to biliverdin, which is then re-reduced by biliverdin reductase, has been postulated (22) and debated (23). Such a cycle, analogous to the glutathione/glutathione disulfide (GSH/GSSG) cycle for detoxifying soluble oxidants, would permit bilirubin to destroy a 10,000-fold excess oxidants (22).



▪ **Figure 8.2** Relative specific activities of hemoglobin protoporphyrin, fecal urobilin (stercobilin), and hippuric acid after administration of labeled glycine. The early labeled peak of stercobilin is derived from ineffective erythropoiesis and the turnover of heme enzymes; the late peak reflects the death of senescent erythrocytes. The observed specific activity of hemoglobin protoporphyrin is less than that predicted from the continued availability of labeled glycine for hemoglobin synthesis, as determined from the hippuric acid curve. This suggests some random loss of labeled erythrocytes, which may be the source of fraction II of labeled stercobilin. (Reproduced from reference Berk PD, Jones EA, Howe RB. Disorders of bilirubin metabolism. In: Bondy PK, Rosenberg LE, eds. *Metabolic control and disease*, 8th ed. Philadelphia: WB Saunders, 1979:1009–1088, with permission of the publisher.)

Quantitative Aspects of Bilirubin Production

In healthy human subjects, bilirubin production averages approximately 4 mg/kg body weight per day (6 μmoles/kg body weight per day)

(2,5,8,9,14,15,24,25). Hemoglobin from senescent or injured erythrocytes is the source of 80% to 85% of the heme that is eventually catabolized to bilirubin (Fig. 8.2). The remainder has multiple sources, including a component of ineffective hemoglobin production in the bone marrow and the turnover of short-lived, nonhemoglobin hemoproteins such as the various P-450 and b_5 cytochromes, catalase, and peroxidase (1,2,3,8,9,10,25,26,27,28,29,30,31). In normoblastic hemolytic anemias, the bone marrow can increase red blood cell production by as much as eightfold (32), leading to a corresponding increase in the component of bilirubin production derived from erythrocytes (3,5,27). Under these conditions, the amount of bilirubin derived from ineffective erythropoiesis in the marrow may increase

in absolute terms, but the proportion of bilirubin production due to ineffective erythropoiesis remains unchanged (27,28). By contrast, major increases in the fraction of bilirubin production derived from ineffective erythropoiesis may occur in megaloblastic anemias such as those associated with either folate or vitamin B_{12} deficiency, thalassemia, and certain dyserythropoietic anemias (27,28). Increased bilirubin production also occurs in the disorders of heme biosynthesis, including the hereditary erythropoietic porphyrias and lead poisoning (27,28,29). Finally, administration of phenobarbital and other drugs increases the turnover of heme enzymes, notably hepatic cytochrome P-450 isoforms, with a resulting increase in bilirubin production (30,31,33) (see following text).

Structure of Bilirubin-IXα

Naturally occurring bilirubin is designated bilirubin-4*Z*,15*Z*-IXα. This designation indicates that it is derived from protoporphyrin isomer IX, the isomer found in heme and hemoproteins such as hemoglobin, by cleavage of the porphyrin macrocycle at the α-bridge carbon and that the stereochemical arrangement of the 4,5 and 15,16 double bonds places the 5- and 15-bridge carbons is in the *Z* configuration (12,34) (Fig. 8.3). This configuration allows the formation of internal hydrogen bonds between the propionic acid side chain on the B ring and polar groups on the D ring, and between the propionic acid on the C ring and polar groups on the A ring (35). Although bilirubin is frequently depicted as a linear tetrapyrrole, these hydrogen bonds in fact fix the molecule in a "ridge tile" configuration (34,36). This configuration blocks exposure of the molecule's polar groups to aqueous solvents and of the central bridge carbon to attack by diazo reagents and is therefore the basis for both bilirubin's hydrophobic behavior and its slow (indirect) diazo reactivity (reviewed in ref. 12,37) (see following text).

Other Bilirubin Isomers

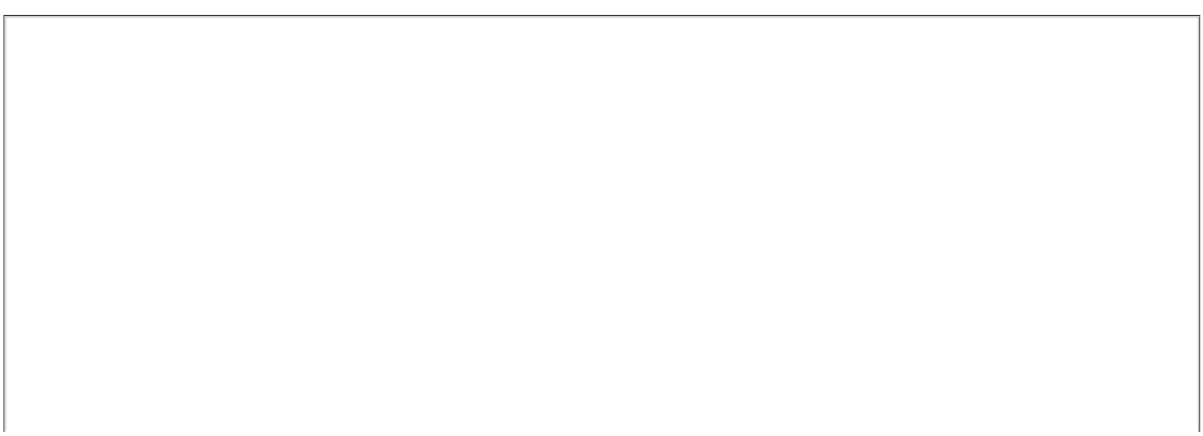
A number of structural (Fig. 8.4A and D) and configurational (stereo-) isomers (Fig. 8.4B and C) of bilirubin are of either physiologic or clinical interest. Opening of the protoporphyrin-IX ring at bridges other than the α-carbon can occur nonenzymatically, leading to the formation, after reduction, of bilirubin-IXβ, IXγ, or IXδ (Fig. 8.4A) (34,38). Stereoisomerization at positions 4 and 15 can lead to the formation of 4*Z*,15*E* and 4*E*,15*E* stereoisomers, respectively (12,34,39), as illustrated in Figure 8.4C and D. None of these isomers can form the internal hydrogen bonds characteristic of bilirubin-4*Z*, 15*Z*-IXα. Accordingly, they behave as more polar molecules, with rapid (direct) diazo reactivity, and can be excreted in bile without conjugation (40,41,42,43). Finally, under certain conditions in vitro, the two nonidentical halves of the bilirubin molecule can dissociate and then reassemble at random (4,12,39). This results in the formation of two symmetric isomers, designated bilirubin-IIIα and XIIIα, in addition to the asymmetric IXα isomer; the ratio of the IIIα:IXα:XIIIα molecules formed is approximately 1:2:1 (Fig. 8.4B). Bilirubin-IIIα and XIIIα *can* form internal hydrogen bonds. They are therefore relatively nonpolar, react slowly with diazo reagents, and require conjugation as a prerequisite to biliary excretion (4,11,12). Recognition of the existence and properties of these various bilirubin isomers has increased the understanding of the biologic properties of the naturally occurring 4*Z*, 15*Z*-IXα form and of the processes involved in its elimination by the liver. However, only the 4*Z*, 15*E* and 4*E*, 15*E* photoisomers, which are formed and readily excreted without conjugation during phototherapy for neonatal jaundice (41,42,43), are of clinical significance.

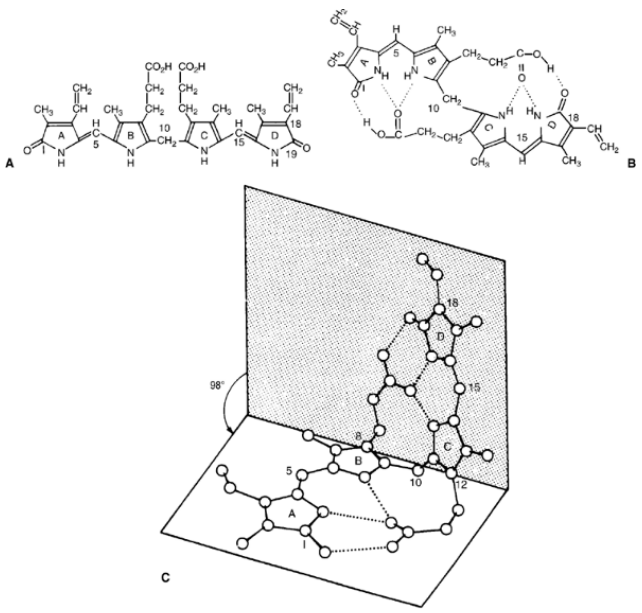
Bilirubin in Plasma

Although the bilirubin molecule contains two carboxyls and several other polar groups, internal hydrogen bonding involving these polar moieties constrains the molecule in a rigid, nonpolar, and, therefore, highly insoluble conformation. As an otherwise insoluble molecule, bilirubin formed in the periphery is transported to the liver tightly bound to albumin, at concentrations that far exceed its solubility in protein-free aqueous solutions (44,45,46). Adult human albumin has one high-affinity binding site for bilirubin and at least one class of lower-affinity sites. Experimental measurements of the affinity of bilirubin for albumin have varied considerably with the methods employed (44), but estimates of K_d for the high-affinity site have been in the micromolar range by several different approaches (44,45,47,48,49,50). The determination of these estimates has been based on the assumption that the affinity of bilirubin for albumin is constant and is independent of the albumin concentration. Under this assumption, until the bilirubin to albumin molar ratio in the circulation exceeds 1:1, virtually all the bilirubin present would be bound to the high-affinity site on albumin, and the unbound bilirubin concentration would remain extremely small. This small, unbound bilirubin concentration (51) is, nevertheless, considered to be an important driving force for hepatocellular bilirubin uptake (see following text). Under this model, if the 1:1 molar ratio of bilirubin to albumin is exceeded, the unbound bilirubin concentration increases rapidly with further increases in total bilirubin. In the neonatal period, increased levels of unbound bilirubin can cross the blood–brain barrier, leading to the serious neurologic consequences of kernicterus (52,53,54). Similar neurotoxicity may rarely occur in adolescents and

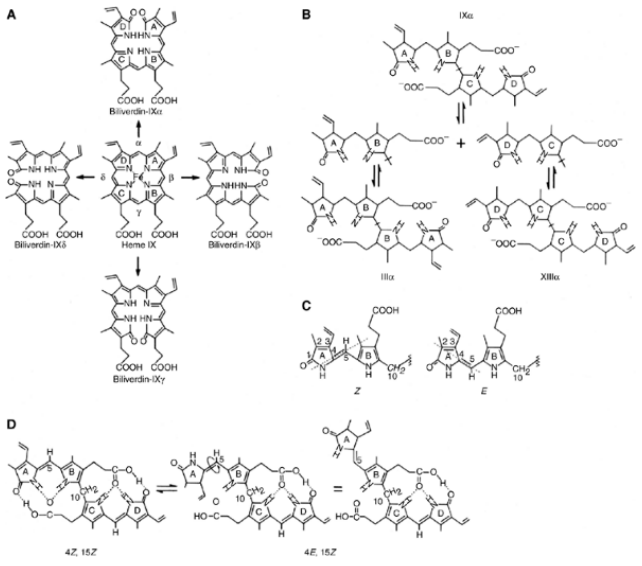
adults who develop sufficiently high concentrations of unconjugated bilirubin such that the critical 1:1 bilirubin to albumin molar ratio is exceeded (55). This is, in fact, the only clinically significant potential toxicity of hyperbilirubinemia. Because the normal albumin concentration is approximately 4 g/dL (600 μM), and a 1-mg/dL bilirubin concentration represents 17.1 μM, the critical 1:1 bilirubin to albumin molar ratio is usually exceeded in otherwise healthy adults only at bilirubin concentrations of 35 mg/dL or more. In catabolic states in which hypoalbuminemia exists, however, the 1:1 ratio may be exceeded at much lower bilirubin concentrations, for example, less than 17 mg/dL in the presence of an albumin concentration of 2 g/dL. Although models of bilirubin binding to albumin that assume a constant affinity independent

of the albumin concentration have been the basis for predictions of bilirubin concentrations at which the risk of kernicterus increases, several recent studies have challenged the basic assumptions of the model, reporting that the affinity of bilirubin for albumin actually varies inversely with the albumin concentration (51,56). This makes calculation of the critical unbound bilirubin concentration, and hence the risk of kernicterus, even more uncertain than earlier. However, the most rapid changes in affinity reportedly occur at quite low albumin concentrations, with only relatively minor further changes occurring as the albumin concentration is increased above 150 μM (56). Therefore, the impact of this new observation on bilirubin–albumin binding within the physiologic range of albumin concentrations, and hence on the risk of kernicterus, is yet to be definitely determined and may be very small. A variety of xenobiotics may displace or otherwise influence the binding of bilirubin to albumin. The resulting increase in the free bilirubin concentration may increase the risk of kernicterus in susceptible individuals (52,57,58,59).





▪ **Figure 8.3** Structure and conformation of bilirubin. **A:** Conventional "linear tetrapyrrole" structure of the naturally occurring isomer of bilirubin, designated bilirubin-IXα. The oxygen functions on the *A* and *D* rings are depicted as the lactam tautomers, and the bridge carbons at positions 5 and 15 are shown in the *Z* configuration. In this configuration the bridge carbons and their attached hydrogens project toward the substituted β positions on the adjacent pyrrole rings, just as in the protoporphyrin ring from which bilirubin is derived. **B:** Planar representation of the three-dimensional conformation of the bilirubin molecule, showing hydrogen bonding (…) between each of the –COOH side chains and the –C–O and –NH groups of the end (A and D) rings of the opposite half of the molecule. These hydrogen bonds, and weaker ones with -NH groups in the B and C rings, hold the molecule in a rigid three-dimensional conformation. **C:** Three-dimensional representation of bilirubin-IXα. The molecule takes the form of a ridge tile (i.e., a tile that fits along the top of a roof), with the ridge line defined by the carbons at positions 8, 10, and 12. Rings *A* and *B* lie in one plane, and *C* and *D* lie in another, with the interplanar angle being approximately 98 degrees. (Reprinted from reference Berk PD, Jones EA, Howe RB. Disorders of bilirubin metabolism. In: Bondy PK, Rosenberg LE, eds. *Metabolic control and disease*, 8th ed. Philadelphia: WB Saunders, 1979:1009–1088, with permission of the publisher.)



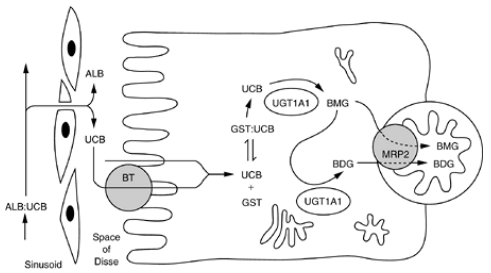
▪ **Figure 8.4** Bilirubin isomers. **A:** Formation of α, β, γ, and δ isomers of biliverdin by nonenzymatic cleavage of the protoporphyrin ring of heme at the α-, β-, γ-, and δ-bridge carbons, respectively. **B: Dipyrrolic scrambling**. This process involves the nonenzymatic dissociation of the bilirubin tetrapyrrole into dipyrrolic units, which may then reassemble at random into symmetric (bilirubin-IIIα and XIIIα) and nonsymmetric (bilirubin-IXα) tetrapyrroles. When this process occurs in a mixture of the C8 and C12 isomers of bilirubin-IXα monoglucuronide, the final products will include IIIα, IXα, and XIIIα isomers of both unconjugated bilirubin and its mono- and diglucuronides. **C: Nomenclature of the Z and E configurational isomers of bilirubin**. If a plane is erected perpendicular to the page along the 4, 5 double bond (illustrated by the *dashed lines*), the *B* ring may be together on the same side of the plane (*Z* [German: Zusammen]) or on opposite sides of the plane (*E* [Entgegen]) from the NH group in the *A* ring. In the *Z* configuration, the meso hydrogen at position 5 is trans to the A-ring lactam hydrogen, whereas in the *E* configuration it is cis. **D: E, Z isomerization at the 4,5 double bond**. In the 4*Z*, 15*Z* configuration, the molecule is rigidly hydrogen bonded. In the 4*E*, 15*Z* configuration, the *A*-ring nitrogen and oxygen groups are not spatially available to form hydrogen bonds with the C12 propionic acid side chain. Because of free rotation about the C5–6 bond, the two 4*E*, 15*Z* structures are equivalent. Analogous geometric isomerization may occur at the 15, 16 double bond. (Reproduced from Berk PD. Bilirubin metabolism and the hereditary hyperbilirubinemias. In: Berk JE, Haubrich MD, Kalser MH, et al. eds. *Bockus' gastroenterology*, Vol. 5. Philadelphia: WB Saunders, 1985:2732–2797, with permission of the publisher.)

Hepatic Disposition of Bilirubin

Because bilirubin is a potentially toxic waste product, its hepatic disposition is designed to eliminate it from the body through the biliary tract. Transfer of bilirubin from blood to bile involves four distinct but interrelated steps: Hepatocellular bilirubin uptake, binding to specific intracellular cytosolic proteins, conjugation with glucuronic acid, and canalicular excretion (Fig. 8.5) (5,7).

Bilirubin Uptake

The fenestrated endothelium that lines the hepatic sinusoids provides the bilirubin–albumin complex with ready access to the extrasinusoidal space of Disse, where it can come into direct contact with microvilli lining the sinusoidal surface of the hepatocytes (5,60,61). In this setting, bilirubin dissociates from albumin and is transported across the hepatocyte plasma membrane into the cell. Numerous in vivo studies of bilirubin uptake kinetics in animals; isolated, perfused livers; isolated hepatocytes; and plasma membrane vesicles have all indicated that bilirubin uptake is concentrative, saturable, and competitively inhibited by other organic anions such as sulfobromophthalein (BSP), implying a protein-mediated, facilitated uptake process (62,63,64,65,66,67,68,69,70,71). Subsequent reports, however, showed that BSP and bilirubin uptake could be dissociated under certain conditions, implying the existence of both shared and separate transport processes (66). Despite an intensive search, the putative bilirubin transporter has not yet been identified, and several candidate transporters (72), including such historical ones as BSP/bilirubin binding protein (BSP/BR-BP), organic anion binding protein (OABP), bilirubin translocase (BTL) (67), and the more recently reported human transporter SLC21A6 (68,69), have failed to withstand closer scrutiny. Recent studies have also identified a purely passive, nonsaturable bilirubin uptake process, but its relative magnitude compared with the saturable process remains to be determined (70). Although transporter-mediated hepatocellular bilirubin uptake is yet to be definitively identified, it appears that unconjugated bilirubin can be exported from the hepatocyte by the human multidrug resistance–associated protein 1 (MRP1) (71).



▪ **Figure 8.5** Hepatocellular transport of bilirubin. Efficient transfer of bilirubin from blood to bile is dependent on normal sinusoidal architecture, plasma membrane transport processes, and intracellular binding and conjugation. Albumin-bound bilirubin in sinusoidal blood passes through endothelial cell fenestrae to reach the hepatocyte surface, entering the cell by both facilitated and simple diffusional processes. Within the cell it is bound to glutathione-*S*-transferases and conjugated by bilirubin-uridine-5′-diphosphate-glucuronosyltransferase (UGT1A1) to monoglucuronides and diglucuronides, which are actively transported across the canalicular membrane into the bile. ALB, albumin; UCB, unconjugated bilirubin; BT, proposed bilirubin transporter; GST, glutathione-*S*-transferase; BMG, bilirubin monoglucuronide; BDG, bilirubin diglucuronide; MRP2, multidrug resistance–associated protein 2. (Reproduced from Berk PD, Wolkoff AW. Bilirubin metabolism and the hyperbilirubinemias. In: Braunwald E, Fauci AS, Kasper DL, et al. eds. *Harrison's principles of internal medicine*, 15 ed. New York: McGraw-Hill, 2001:1715–1720, with the permission of the publisher.)

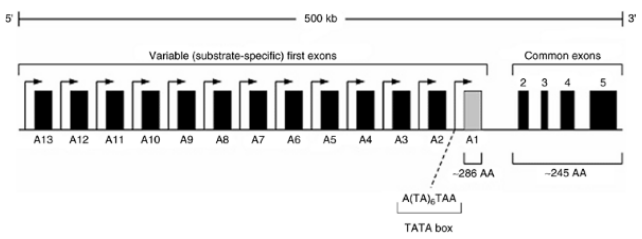
Intracellular Binding

Once within the cell, bilirubin partitions between the cytosol and the lipid bilayer of various intracellular membranes. As with bilirubin binding to albumin

in plasma, the cytosolic bilirubin fraction is kept in solution at concentrations that far exceed its aqueous solubility by binding as a nonsubstrate ligand to a number of proteins, of which the most abundant and best characterized are members of the glutathione-*S*-transferase (GST) superfamily (73,74). This family includes a large number of homodimeric and heterodimeric proteins, previously referred to as *ligandins* (75), that are principally responsible for bilirubin binding. Kinetic analyses suggest that binding to these proteins is not involved in the initial process of cellular bilirubin uptake but does increase net bilirubin sequestration by decreasing bilirubin efflux from the cytosol back into the space of Disse (76). The GSTs have been postulated to play a specific role in presenting bilirubin to the microsomes for subsequent conjugation (4,72).

Bilirubin Glucuronidation

The aqueous insolubility of bilirubin reflects the rigid, highly ordered, molecular structure conferred by internal hydrogen bonding that prevents solvent access to polar components of the molecule. Subsequent conjugation with glucuronic acid residues disrupts this internal hydrogen bonding, rendering the resulting monoglucuronide and diglucuronide conjugates highly soluble in aqueous solutions. The enzyme responsible for bilirubin glucuronidation is the uridine-5′-diphosphate glucuronosyltransferase isoform 1A1 (UGT1A1), which is encoded by the *UGT1* gene on chromosome 2 (77). This gene has a complex structure, and mutations within it are recognized as the cause of three different disorders characterized by unconjugated hyperbilirubinemia: Gilbert's syndrome and Crigler-Najjar syndrome types I and II. The *UGT1* gene (Fig. 8.6) (7) consists of 13 exons (designated A1 to A13) each of which encodes a distinct, substrate-specific binding site for one of the multiple protein isoforms produced by this single gene locus. Initiation of ribonucleic acid transcription at each of these 13 exons is controlled by a separate promoter element immediately upstream of its unique exon. Alternative splicing fuses one of these upstream exons with the four exons (exons 2 to 5) common to all UGT1 protein isoforms. Exon A1 and the four common exons code for the UGT1A1 protein that is responsible for glucuronidation of bilirubin (78) (Fig. 8.6).



▪ **Figure 8.6** Structural organization of the human *UGT1* gene complex. This large complex on chromosome 2 contains at least 13 substrate-specific first exons (A1, A2, etc.), each with its own promoter, that encode the *N*-terminal substrate-specific 286 amino acids (AAs) of the various *UGT1*-encoded isoforms, and common exons 2 to 5 that encode the 245 carboxyl-terminal amino acids common to all the isoforms. Messenger ribonucleic acids (mRNAs) for specific isoforms are assembled by splicing a particular first exon such as the bilirubin-specific exon A1 to exons 2 to 5. The resulting message encodes a complete enzyme, in this particular case bilirubin-uridine-5′-phosphate-glucuronosyltransferase (UGT1A1). Mutations in a first exon affect only a single isoform. Those in exons 2 to 5 affect all enzymes encoded by the UGT1 complex. (Reprinted from Berk PD, Wolkoff AW. Bilirubin metabolism and the hyperbilirubinemias. In: Braunwald E, Fauci AS, Kasper DL, et al. eds. *Harrison's principles of internal medicine*, 15 ed. New York: McGraw-Hill, 2001:1715–1720, with permission of the publisher.)

Canalicular Excretion of Bilirubin

Bilirubin glucuronides are transported across the apical plasma membrane into the canaliculus by an adenosine triphosphate (ATP)-dependent process mediated by a membrane protein initially called *canalicular multispecific organic anion transporter* (*cMOAT*), but now designated *MRP2* (Fig. 8.5) (79,80). MRP2 is a member of the MRP gene family, other members of which pump drug conjugates, as well as unmodified anticancer drugs, out of cells. In mouse models, effective MRP2 function requires the presence of at least one additional protein, radixin, which localizes to the canalicular membrane and directly binds the carboxyl-terminal cytoplasmic domain of MRP2 (81).

Fate of Bilirubin in the Gastrointestinal Tract

Conjugated bilirubin excreted in bile passes through the small intestine without significant absorption and reaches the colon intact (82,83,84,85). There, it is both deconjugated, presumably by bacterial β-glucuronidases (86), and degraded by other bacterial enzymes to a large series of urobilinogens and other products (87,88,89,90), the nature and relative proportions of which depend in part on the bacterial flora (84,91,92). Because of this variability, quantitation of fecal urobilinogen excretion does not provide an accurate measure of heme degradation and bilirubin formation (93) and has largely been abandoned as a clinical test for hemolysis or ineffective erythropoiesis.

Some urobilinogen is reabsorbed from the colon (94), resulting in small but measurable concentrations of urobilinogen in plasma (95). Most of this is re-excreted by the liver, but a small fraction is eliminated by the kidney. Increased urinary excretion of urobilinogen is a consequence of its increased plasma level. This in turn may reflect either increased bilirubin production, with a consequent increased formation and enterohepatic circulation of urobilinogen, or decreased hepatic clearance of urobilinogen. Hence, an elevated urine urobilinogen excretion does not distinguish between hemolysis and liver disease (96).

In the neonatal period, the presence of increased levels of intestinal β-glucuronidase (84,97) may result in the presence of appreciable amounts of unconjugated bilirubin within the distal small intestine and upper colon. Absorption from these sites can give rise to a significant enterohepatic circulation of unconjugated bilirubin (82,83,84), which has been implicated as a contributing factor to physiologic jaundice in the newborn and to the further increase in plasma bilirubin concentrations seen in neonates with intestinal obstruction, delayed passage of meconium, or fasting (86). In severe unconjugated hyperbilirubinemias such as those occurring in Crigler-Najjar syndrome type I or in the jaundiced Gunn rat (see following text), a similar enterohepatic circulation may result from unconjugated bilirubin being excreted both in bile (98,99) and directly across the intestinal lumen into the gut (98). Efforts to reduce unconjugated hyperbilirubinemia in such situations by interrupting the enterohepatic circulation of unconjugated bilirubin with the use of agents such as oral agar, charcoal, or cholestyramine have had at best limited and inconsistent success (84,86,100). Recent reports suggest that oral administration of calcium phosphate with or without the lipase inhibitor orlistat may be an efficient means to interrupt bilirubin enterohepatic cycling to reduce serum bilirubin levels (101,102).

Bilirubin in the Urine

Because of its very tight binding to albumin, the free fraction of unconjugated bilirubin in plasma is too small to permit efficient ultrafiltration at the glomerulus. Consequently, unconjugated bilirubin never appears in the urine no matter what its plasma concentration. By contrast, bilirubin conjugates are appreciably less tightly albumin bound. In the presence of cholestasis, whether secondary to hepatocellular injury or ductal obstruction, bilirubin conjugates formed in the hepatocyte are diverted back to the circulation, where their weaker albumin binding and larger free fraction permit excretion by the kidney, principally by glomerular filtration (103,104,105,106,107). A small degree of tubular reabsorption has been demonstrated, but tubular secretion apparently does not occur (107). The presence of bilirubin in the urine is an absolute indicator of conjugated hyperbilirubinemia.

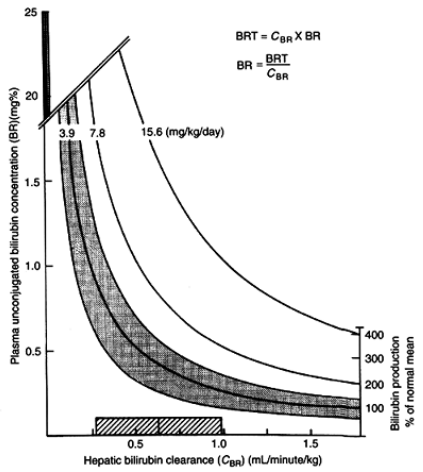
Clinical Physiology of Bilirubin

The quantity of unconjugated bilirubin in plasma, and hence the plasma unconjugated bilirubin concentration, reflects a balance between two processes: Bilirubin production and hepatic bilirubin clearance (Fig. 8.7) (5,24,27,108). This balance is indicated by the relationship:

BR [not asymptotically equal to] BRT/C_{BR},

where BR represents the plasma unconjugated bilirubin concentration, BRT is plasma bilirubin turnover (which closely approximates bilirubin production), and C_{BR} is the rate of clearance of unconjugated bilirubin from plasma by the liver. Measurement of C_{BR}, in units of milliliter per minute per kilogram, is a quantitative test of hepatic function that is, conceptually, analogous to creatinine clearance, a widely used measure of renal function. Both BRT and C_{BR} can be calculated from the area under the curve of an injected tracer dose of radiolabeled unconjugated bilirubin (24,27,108,109). Alternatively, the bilirubin production rate can be estimated by isotope dilution from the specific activity of fecal bile pigments after an intravenous injection of radiolabeled bilirubin (25,26,110), or from measurements of the excretion rate of CO (15,111,112). Although estimates of BRT and C_{BR} by any of these methods are not available as routine clinical measurements, an appreciation of the physiologic implications of these two variables is very useful in interpreting data that *are* readily available in clinical settings. Specifically, the equation indicates that BR is directly proportional to the rate of bilirubin turnover and inversely related

to hepatic bilirubin clearance in a manner analogous to the relationship between glomerular filtration rate and serum creatinine. Moreover, starting from any given baseline values of BRT and C_{BR}, a change in either BRT or C_{BR} will result in a corresponding fractional change in BR. The fractional change in BR will be directly proportional to any fractional change in BRT and inversely proportional to a fractional change in C_{BR} (Figs. 8.7 and 8.8) (27,108). As a result, for any given level of bilirubin production, equal *fractional* changes in hepatic bilirubin clearance can have dramatically different effects on plasma bilirubin concentrations, depending on the initial absolute value of C_{BR}. For example, when bilirubin turnover is normal (e.g., 4 mg/kg per day), reducing bilirubin clearance from a normal mean value of 0.70 mL/minute/kg to a lower mean value of 0.35 mL/minute/kg (a reduction of 50%) will approximately double the serum bilirubin concentration, increasing it by approximately 0.4 mg/dL (from 0.4 to 0.8 mg/dL). This increment may well go unnoticed clinically. By comparison, in a patient whose hepatic clearance is already reduced, a corresponding 50% reduction in bilirubin clearance, for example, from 0.1 to 0.05 mL/minute/kg, will again double the bilirubin concentration. In this instance, however, the interval increase, by approximately 2.7 mg/dL, will be sufficient to be clinically detectable. Similarly, doubling bilirubin production will double the plasma concentration of unconjugated bilirubin. The absolute magnitude of the increase, in milligram per deciliter, will depend on the value of C_{BR}.

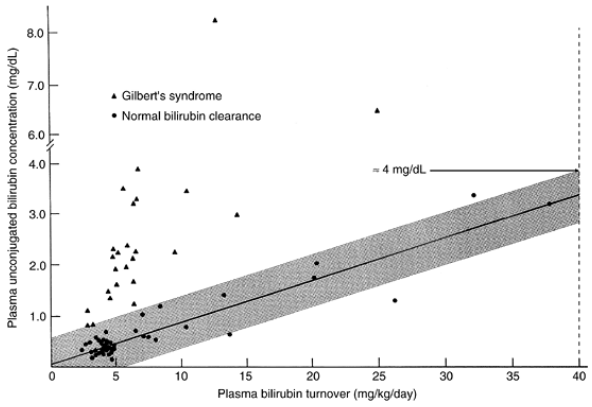


· **Figure 8.7** Relationship between plasma bilirubin turnover (BRT), hepatic bilirubin clearance (C_{BR}), and the plasma concentration of unconjugated bilirubin (BR). Stippled area represents the normal range for bilirubin turnover; bar on the horizontal axis is the normal range (mean ± 2 standard deviations) for C_{BR}. Physiologic evaluation and experimental approaches to therapy. *Ann Intern Med* 1975;82:552–570, with permission of the publisher.)

Measurement of Plasma Bilirubin Concentration

Plasma bilirubin is typically measured in clinical laboratories by some modification of the diazo reaction first described by van den Bergh and Müller in 1916 (113) (reviewed in ref. 114). In this procedure, unconjugated

bilirubin in the sample reacts slowly with the diazo reagent (e.g., diazotized sulfanilic acid) because the central bridge carbon, which is the site of the attack by the reagent, is rendered sterically inaccessible by internal hydrogen bonding within the molecule (Fig. 8.3). In the presence of ethanol, caffeine, or other "accelerators" that disrupt the internal hydrogen bonding, the central bridge carbon becomes more readily accessible to nucleophilic attack and the unconjugated bilirubin molecule reacts more rapidly and completely. Similarly, rapid diazo reactivity is displayed by conjugated bilirubin, in which esterification of propionic acid side chains with glucuronic acid prevents hydrogen bond formation and exposes the central bridge carbon. Accordingly, the "prompt" or *direct-reacting bilirubin* in serum or plasma, considered a measure of the amount of conjugated bilirubin present, is determined a short time (30 to 60 seconds) after the addition of the diazo reagent to the sample in the absence of an accelerator. The *total bilirubin* concentration, a measure of both unconjugated and conjugated bilirubin, is typically measured at some more prolonged interval (e.g., 30 to 60 minutes) after addition of an accelerator substance. The *indirect-reacting* bilirubin, calculated as the difference between the total and the direct-reacting bilirubin, is widely used as a proxy for the amount of unconjugated bilirubin in the sample (114).



· **Figure 8.8** Relationship between plasma bilirubin turnover and the plasma concentration of unconjugated bilirubin. Normal plasma bilirubin turnover is up to 5 mg/kg body weight per day. Higher values indicate increased bilirubin production, usually from hemolysis. When hepatic bilirubin clearance is within the normal range, the plasma unconjugated bilirubin concentration increases linearly with increases in bilirubin turnover, as indicated by the regression line (the stippled area represents ± 2 standard errors of the estimate about the regression line). Extrapolation of the regression line to the maximal rate of steady state bilirubin production indicates the highest level of unconjugated hyperbilirubinemia that can result from sustained hemolysis in an individual with normal hepatic bilirubin clearance. Because the bone marrow can increase erythrocyte production only by about eightfold in response to hemolysis, the maximum sustainable rate of bilirubin turnover is approximately 40 mg/kg per day, and the corresponding value of plasma unconjugated bilirubin is 4 mg/dL. (Reproduced from Berk PD, Martin JF, Blaschke TF, et al. Unconjugated hyperbilirubinemia. Physiologic evaluation and experimental approaches to therapy. *Ann Intern Med* 1975;82:552–570, with permission of the publisher.)

Bilirubin can also be estimated in biologic fluids by direct spectrophotometry because of its intense absorption band at approximately 450 nm (12,115). The method is rapid, requires very small samples, and is therefore often used in neonatal nurseries or in amniotic fluid analyses (116) in which sample availability is limited. The method is nonspecific because turbidity and other yellow–orange materials such as carotenoids interfere. Various devices designed to measure bilirubin levels transcutaneously without blood sampling, by reflectance and/or spectrophotometry, are widely used in neonatal nurseries (see for example ref. 117). Accurate alternative methods also exist for the quantification of individual bilirubin species (118,119), including bilirubin conjugates covalently bound to plasma proteins (i.e., δ-bilirubin, see following text), not only in plasma but also in bile, urine, and other biologic

fluids (120,121,122,123,124,125). Because they are rarely employed outside research laboratories, a description of these technologies is beyond

the scope of this review.

Normal Ranges

Using conventional, diazo-based analytic procedures, the upper limit of normal for *total plasma bilirubin* has been reported to be anywhere between 1.0 and 1.5 mg/dL (17 and 26 μM), and that for the indirect-reacting fraction between 0.8 and 1.2 mg/dL (14 and 21 μM) (2,96,114,126,127). Differences reported reflect both variations in analytic methods and whether the 95% or 99% confidence limit was used to define the normal range. They also reflect the fact that bilirubin concentrations in the healthy population exhibit a log-normal (skewed to the right) rather than a Gaussian (bell-shaped) distribution, which must be accounted for in establishing appropriate normal limits (126).

Many studies have set the upper limit of normal for the *indirect-reacting fraction* at 1.0 mg/dL (17 μM), which is in close agreement with the limits predicted on theoretic grounds from knowledge of the distribution of plasma bilirubin turnover and hepatic bilirubin clearance rates in a healthy population (126). When the total plasma bilirubin concentration is normal, the normal direct-reacting fraction (a proxy for conjugated bilirubin) is traditionally reported to be less than 0.1 mg/dL, or at most less than 0.2 mg/dL (114). Because unconjugated bilirubin does react, although slowly, with diazo reagents even in the absence of an accelerator, even this small direct-reacting fraction *overestimates* the miniscule amounts of conjugated bilirubin actually present (125). Consequently, the calculated indirect-reacting bilirubin *underestimate*s the amount of unconjugated bilirubin present. The proportional magnitude of these errors is greatest at total bilirubin concentrations within or near the normal range. Nevertheless, at virtually any total bilirubin level, if the direct-reacting fraction is less than 15% of the total, the bilirubin in the sample can be considered essentially as being completely unconjugated. Unfortunately, the errors involved appear to be greater with autoanalyzer methods currently in widespread use than they were with manual methods used in the past. "Normal" values for direct-reacting bilirubin have been creeping upward over the years even as more precise chromatographic methods demonstrate that the actual amounts of conjugated bilirubin in normal serum or plasma are vanishingly small. An informal survey several years ago suggested that few large laboratories in the New York metropolitan area set an upper limit of normal for direct-reacting bilirubin as low as 0.2 mg/dL. The most commonly reported upper limit was 0.3 mg/dL, with limits of 0.4 to 0.8 mg/dL being reported not infrequently. Such latitude can lead to considerable error in interpreting the direct- and indirect-reacting fractions as conjugated and unconjugated bilirubin, respectively. Because the presence of even modest amounts of true conjugated bilirubin in serum should alert the clinician to the possibility of significant hepatobiliary pathology, this distinction is of more than academic interest (128). Because conventional bilirubin glucuronide conjugates are water soluble and bind relatively loosely to albumin, they are readily filtered at the glomerulus and excreted in the urine. Accordingly, uncertainty about the clinical significance of a mildly elevated level of direct-reacting bilirubin can often be clarified by a simple dipstick test for bilirubin in the urine. Even minimal degrees of conjugated hyperbilirubinemia are associated with bilirubinuria. A negative dipstick test in the presence of a modestly elevated direct-reacting fraction suggests the presence of either δ-bilirubin (see following text) or an artifact of the diazotization procedure.

With prolonged conjugated hyperbilirubinemia, some of the conjugated bilirubin in plasma binds *covalently* to albumin and produces what is designated the δ-bilirubin fraction (121,122,123,124). Although δ-bilirubin gives a direct diazo reaction, it is not filterable by the glomerulus and does not appear in the urine; it disappears slowly from the plasma with the 14- to 21-day half-life of the albumin to which it is bound. δ-Bilirubin accounts for the sometimes slow rate with which conjugated (direct) hyperbilirubinemia resolves as hepatitis improves or biliary obstruction is relieved. Although δ-bilirubin is not easily measured, its presence can be inferred when an elevated level of direct-reacting bilirubin persists after bilirubinuria resolves.

Hyperbilirubinemia and Jaundice

Hyperbilirubinemia is conveniently classified as *unconjugated (indirect-reacting), or conjugated (direct-reacting) hyperbilirubinemia*. In practice, pure conjugated hyperbilirubinemia is uncommon; in most cases an elevated plasma conjugated bilirubin level is accompanied by an elevation of the unconjugated bilirubin level, resulting in mixed hyperbilirubinemia. In this setting, because the plasma level of conjugated bilirubin reflects renal as well as hepatic clearance of bilirubin conjugates, the ratio of conjugated to total bilirubin is usually not helpful diagnostically. *Another useful characteristic is whether hyperbilirubinemia is the only abnormality of hepatic function or whether other hepatic biochemical tests such as the activities of serum aminotransferases* (*alanine aminotransferase [ALT], aspartate aminotransferase [AST]*), *alkaline phosphatase, or γ-glutamyltransferase are also abnormal*. Absence of abnormalities of other hepatic biochemical tests is one of the features that helps distinguish the *familial*

hyperbilirubinemias from most acquired cases of hyperbilirubinemia. However, certain forms of acquired hyperbilirubinemia such as acquired hemolytic disease and inactive cirrhosis may also occur in the absence of other biochemical abnormalities. The major causes of familial hyperbilirubinemia are listed in Table 8.1.

Table 8.1. The Familial Hyperbilirubinemias

I. Unconjugated hyperbilirubinemias
  A. From increased bilirubin production
    1. Hemolytic anemias
      a. Hemoglobinopathies
      b. Thalassemia syndromes
      c. Enzyme defects
      d. Membrane defects, etc.
    2. Shunt hyperbilirubinemias
      a. Congenital dyserythropoietic jaundice syndromes
      b. Miscellaneous
  B. From defective hepatic bilirubin clearance
    1. Gilbert's syndrome
    2. Crigler-Najjar syndrome
      a. Type I—phenobarbital resistant
      b. Type II—phenobarbital responsive
II. Conjugated hyperbilirubinemias
  A. Dubin-Johnson syndrome
  B. Rotor's syndrome

Causes and Consequences of Hyperbilirubinemia

Unconjugated hyperbilirubinemia

Unconjugated hyperbilirubinemia is the result of any process that increases bilirubin production, decreases bilirubin clearance, or results in both processes acting in concert (3,27,108,109). The reference range for the plasma unconjugated (i.e., indirect-reacting) bilirubin concentration is generally reported to be 0.3 to 1.0 mg/dL, although some laboratories set the upper limit at 1.2 mg/dL and occasionally as high as 1.5 mg/dL. Values above the reference range represent unconjugated hyperbilirubinemia. Although scleral icterus may become detectable when the bilirubin concentration exceeds 2.5 to 3.0 mg/dL, many cases of unconjugated hyperbilirubinemia are subclinical and detectable only by measurement of the plasma bilirubin concentration.

Increased bilirubin production

Hemolysis and increased ineffective erythropoiesis are two of the most common processes responsible for increased bilirubin production. A large number of distinct hereditary hemolytic disorders have been described (129) and result from inherited hemoglobinopathies, enzyme deficiencies,

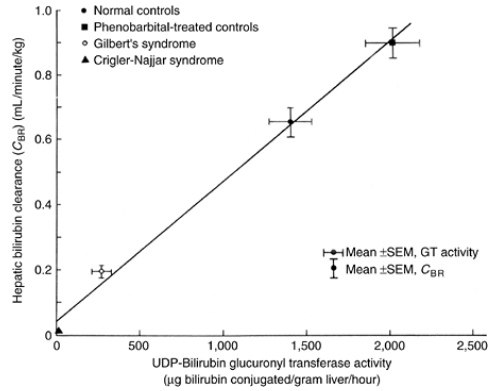
or abnormalities in red blood cell membrane structure. There are also many acquired hemolytic conditions, ranging from pure, specific autoimmune hemolytic anemias to the shortened red cell life spans that accompany many chronic diseases. Excessive ineffective erythropoiesis may occur on a congenital basis, as in any subtype of congenital dyserythropoietic anemia (3,5,28), or on an acquired basis, in disorders such as erythropoietic porphyria, pernicious anemia, and lead poisoning (2,29,129). Transfusion of old bank blood and massive hematomas or pulmonary infarcts can produce unconjugated hyperbilirubinemia by temporarily increasing bilirubin production. Excessive *hepatic* bilirubin production, although seemingly a potential cause of increased plasma bilirubin turnover, has not been convincingly documented as a cause for clinically evident hyperbilirubinemia. Although hepatic heme turnover has been reported to contribute as much as one fourth of the total bilirubin production on the basis of the labeling of plasma bilirubin after administration of radiolabeled heme precursors (see for example refs 130–132), approximately half of hepatic-derived bilirubin is excreted into the bile without transit through the plasma (2,5,24,25,27,110,131,133). This means that hepatic hemes contribute no more than approximately 12% of the plasma bilirubin turnover. Studies documenting a significant discrepancy between the increase in bilirubin labeling from ^{3}H- or ^{14}C-labeled heme precursors and total bilirubin production suggest that the actual percentage of plasma bilirubin turnover derived from hepatic hemes is appreciably lower (134,135). On this basis, hepatic heme turnover would have to increase manyfold to result in a clinically recognizable increase in the plasma unconjugated bilirubin concentration.

Unconjugated hyperbilirubinemia solely due to increased bilirubin production rarely exceeds 4 mg/dL, even in the face of brisk hemolysis (Fig. 8.8) and is generally well tolerated. However, subjects are at an increased risk for the development of pigmented gallstones.

Decreased bilirubin clearance

As noted in preceding text, four distinct processes are involved in hepatocellular bilirubin disposition, and each, if defective, can result in a decrease in hepatic bilirubin clearance. Although the precise mechanism(s) by which bilirubin is taken up by hepatocytes remains unclear, several drugs (e.g., rifampin, flavispidic acid, novobiocin, and various cholecystographic contrast agents) are reported to competitively inhibit the bilirubin uptake process (see ref. 5). The resulting unconjugated hyperbilirubinemia resolves with the cessation of the medication. Reduced hepatic bilirubin uptake (and net clearance) can also result from portosystemic shunting by which blood bypasses the hepatocytes. Although this is most commonly thought

of as occurring through venous channels such as varices, it may also result from capillarization of the hepatic sinusoids—that is, the loss of sinusoidal endothelial fenestrae and increased perisinusoidal matrix deposition—that occurs in cirrhosis. It is also a consequence of an absolute reduction in hepatic blood flow or of abnormalities in the net extraction of bilirubin from the circulation by hepatocytes.



· Figure 8.9 Relationship between the mean values for hepatic bilirubin clearance (C_{BR}) and bilirubin uridine-5′-diphosphate-glucuronosyltransferase (UDPGT) activity in patients with Crigler-Najjar syndrome type I, Gilbert's syndrome, and healthy controls. For the control group, data are presented for both untreated and phenobarbital-treated subjects. The line represents a least-squares fit to the mean values for the four groups. Subsequent data in Crigler-Najjar type II fell on the regression line. Data such as these suggested that Gilbert's syndrome and the two Crigler-Najjar syndromes might all reflect mutations with quantitatively differing effects on a single gene, designated at the time as bilirubin-UDP-glucuronyltransferase. (Modified from Blaschke TF, Berk PD, Rodkey FL, et al. Drugs and the liver. I. Effects of glutethimide and phenobarbital on hepatic bilirubin clearance, plasma bilirubin turnover and carbon monoxide production in man. *Biochem Pharmacol* 1974;23:2795–2806.)

Abnormalities in the binding of bilirubin to its cytosolic binding proteins are at least a hypothetical basis for decreased bilirubin clearance. However, defective glucuronidation is a more common mechanism that results in reduced bilirubin clearance and consequent unconjugated hyperbilirubinemia. Delayed expression of UGT1A1 in neonates is primarily responsible for the physiologic jaundice of otherwise healthy newborns. Peak serum bilirubin levels in this setting are typically less than 5 to 10 mg/dL between days 2 and 5 and decline to normal within 2 weeks. Higher neonatal bilirubin levels that predispose to kernicterus occur in the face of profound prematurity, Gilbert's syndrome (see following text), hemolysis, or both (see for example ref. 136). Three familial disorders of bilirubin conjugation are well recognized: Crigler-Najjar syndrome types I and II and Gilbert's syndrome. These are described in greater detail in following text. Although considered until recently as distinct disorders, these conditions are all now known to result from mutations of different functional severity in the bilirubin-conjugating enzyme UGT1A1. Acquired deficiency of UGT1A1 and consequent unconjugated hyperbilirubinemia also occurs with administration of certain human immunodeficiency virus protease inhibitors such as indinavir and atazanavir (reviewed in ref. 137,138).

Conjugated hyperbilirubinemia

Conjugated hyperbilirubinemias typically reflect abnormalities in hepatocellular excretion of conjugated bilirubin or in biliary tract obstruction. Dubin-Johnson and Rotor's syndromes are uncommon, heritable disorders of conjugated bilirubin excretion. In Dubin-Johnson syndrome, mutations in MRP2 result in deficient canalicular transport of bilirubin conjugates (80,139,140). The molecular defect in Rotor's syndrome remains unknown but produces a phenotype similar in many respects to that of Dubin-Johnson. In both disorders, general hepatocellular function is preserved and liver chemistries other than the bilirubin

concentration are typically normal. Bilirubin concentrations in Dubin-Johnson and Rotor's syndromes are most often between 2 and 5 mg/dL, although values as high as 5 mg/dL for prolonged periods have been described. Extensive clinical experience suggests that conjugated hyperbilirubinemia produces no significant adverse consequences, even if prolonged for months at levels of up to 35 to 40 mg/dL.

Far more common is the defective bilirubin excretion that occurs with a broad spectrum of hepatobiliary diseases. In these conditions, elevations in bilirubin concentration typically occur in association with abnormalities of other hepatic biochemical tests, including elevations in AST and ALT levels, alkaline phosphatase level, and, if severe, reduction in serum albumin level and prolongation of clotting times. This broad category of diseases includes hepatocellular and cholestatic liver diseases, benign postoperative jaundice, mechanical intrahepatic or extrahepatic bile duct obstruction, and a rare group of disorders classified under the rubric of familial intrahepatic cholestasis (141).

Familial Hyperbilirubinemias

The Familial Unconjugated Hyperbilirubinemias

The spectrum of familial unconjugated hyperbilirubinemias is indicated in Table 8.2. This review limits itself to those entities associated with a decrease in hepatic bilirubin clearance: Crigler-Najjar syndrome types I and II and Gilbert's syndrome. Important characteristics of these three entities are summarized in Table 8.2. These were once considered distinct genetic and pathophysiologic entities, with Gilbert's syndrome reportedly an autosomal dominant disorder and Crigler-Najjar type I an autosomal recessive disorder (see for example refs 2,4,5). However, physiologic observations (Fig. 8.9) (142) suggested that the three entities might reflect mutations with quantitatively different impact on the functioning of a single gene. Subsequent molecular findings in the specific syndromes and the observation that one *normal* UGT1A1 allele is sufficient to maintain a normal plasma bilirubin concentrations (77,78) have established that in almost all instances the hereditary unconjugated hyperbilirubinemias are related autosomal recessive disorders.

Crigler-Najjar syndrome type I

Crigler-Najjar syndrome type I is a rare, recessive disorder characterized by profound unconjugated hyperbilirubinemia, with bilirubin concentrations of 20 to 45 mg/dL as a result of mutations in UGT1A1 that result in the near total loss of UGT1A1 enzyme activity (77,78,100,143,144,145,146,147,148,149,150,151). Mutations most often occur in exons 2 to 5 of the *UGT1* gene, affecting the glucuronidation of a wide spectrum of substrates in addition to bilirubin (type Ia). Less often, the mutation occurs in exon 1, and the loss of glucuronidation capacity is largely limited to bilirubin conjugation (type Ib). Crigler-Najjar syndrome type I first appears in the neonatal period, and historically, most patients have succumbed from kernicterus in infancy and early childhood. Patients with Crigler-Najjar syndrome type I do not respond to phenobarbital with a reduction in plasma bilirubin concentrations (2,4,6,8,9,10,11,100,146). Although survival has been extended with the advent of phototherapy, those who survive beyond early childhood remain at substantial risk for late-onset bilirubin encephalopathy, which often sets in after even mild febrile illnesses (see for example refs 100,152). Although isolated hepatocyte transplantation has been used experimentally in a limited number of cases of Crigler-Najjar syndrome type I (153,154), early liver transplantation remains the best hope to prevent brain injury and death (155,156,157,158).

Much of the basis for elucidation of the pathobiology of Crigler-Najjar syndrome type I has arisen from studies that have been performed in the Gunn rat. This mutant Wistar strain of rats was initially described by Gunn in 1938 as having chronic nonhemolytic unconjugated hyperbilirubinemia (159). As in patients with Crigler-Najjar syndrome type I, jaundice in these animals is inherited as an autosomal recessive trait. Heterozygotes are anicteric, and liver histology in the affected rats is normal. Bilirubin glucuronyl transferase activity is undetectable in the livers of these rats (160).

Crigler-Najjar syndrome type II

In contrast to Crigler-Najjar type I, in Crigler-Najjar type II UGT1A1 activity is maintained, although at a minimal level (<10% of normal), and serum bilirubin concentrations typically vary between 6 and 25 mg/dL (146,161,162). Induction of UGT1A1 levels with exposure to phenobarbital can further reduce bilirubin levels by more than 25% (146,163,164,165,166). Depending on the severity of the molecular defect, either basal or phenobarbital-stimulated enzyme activity is sufficient in most cases to prevent the development of kernicterus. Clinically relevant neurologic sequelae can, however, be precipitated in the setting of intercurrent illnesses, fasting, or any other factor that temporarily raises the serum bilirubin concentration significantly above baseline (see for example ref. 55), especially if the resulting bilirubin to albumin molar ratio exceeds 1. Overall, available data in most patients with type II syndrome indicates that in adolescents and adults with normal serum albumin levels, the prolonged exposure to unconjugated bilirubin levels below 16 mg/dL

does not result in neurologic injury. Indeed, most patients in the original reports describing the syndrome were healthy adults, many with college-level education (146,161). To date, a total of 77 different mutations in the *UGT1* gene have been identified in association with either type I or type II Crigler-Najjar syndrome (167). Chain-terminating mutations have been more commonly associated with a Crigler-Najjar type I phenotype, whereas missense mutations have been more frequently observed among less severely affected patients with Crigler-Najjar syndrome type II (167).

Table 8.2. Principal Features of the Familial Unconjugated Hyperbilirubinemias

	Crigler-Najjar Syndrome		
Feature	**Type I**	**Type II**	**Gilbert's syndrome**
Incidence	Very rare	Uncommon	Up to 12% of population
Total serum bilirubin (mg/dL)	18–45 (usually >20), unconjugated	6–25 (usually ≤20), unconjugated	Typically ≤4 in the absence of fasting or hemolysis; mostly unconjugated
Defect(s) in bilirubin metabolism	Bilirubin UGT1A1 activity markedly reduced: Trace to absent	Bilirubin UGT1A1 activity reduced: ≤10% of normal	Bilirubin UGT1A1 activity typically reduced to 10%–33% of normal; reduced hepatic bilirubin uptake in some cases; mild hemolysis in up to 50% of patients
Routine liver tests	Normal	Normal	Normal
Serum bile acids	Normal	Normal	Normal
Plasma sulfobromophthalein removal (percentage retention of 5 mg/kg dose at 45 min)	Normal	Normal	Usually normal (<5%); mildly increased 45-min retention (<15%) in some patients
Oral cholecystography	Normal	Normal	Normal
Pharmacologic responses/special features	No response to phenobarbital	Phenobarbital reduces bilirubin by ≤75% but not to normal	Phenobarbital reduces bilirubin, often to normal
Major clinical features	Kernicterus in infancy if untreated; may occur later despite therapy	Rarely late-onset kernicterus with fasting	None

Hepatic morphology/histology	Normal	Normal	Normal; occasionally increased lipofuscin pigment
Bile bilirubin fractions[a]	>90% unconjugated	Largest fraction (mean 57%) monoconjugates	Mainly diconjugates but monoconjugates are increased (mean 23%)
Inheritance (all autosomal)	Recessive	Recessive	Promoter mutation is recessive; missense mutation often dominant
Diagnosis	Clinical and laboratory findings; lack of response to phenobarbital	Clinical and laboratory findings; response to phenobarbital	Clinical and laboratory findings; promoter genotyping may be helpful; liver biopsy rarely necessary
Treatment	Phototherapy or tin protoporphyrin as short-term therapy; liver transplantation definitive	Consider phenobarbital if baseline bilirubin ≥8 mg/dL	None necessary

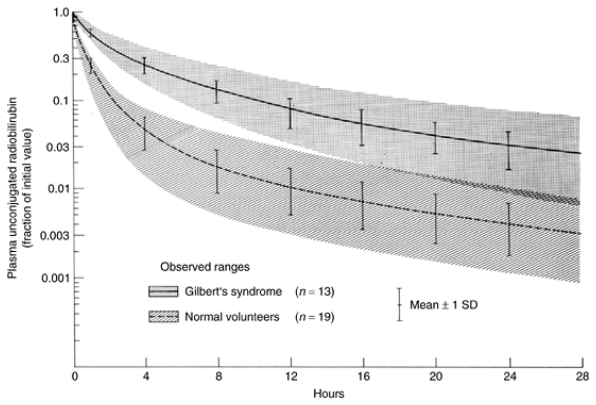
[a]Bilirubin in normal bile: <5% unconjugated bilirubin, with an average of 7% bilirubin monoconjugates and 90% bilirubin diconjugates.
UGT1A1, uridine diphosphate glucuronosyltransferase isoform 1A1.

Gilbert's syndrome

Gilbert's syndrome resides at the other end of the spectrum of disorders of bilirubin conjugation. Originally described in 1901 (168), this condition occurs with a phenotypic prevalence of approximately 8% in the general population and is characterized by a mild, unconjugated hyperbilirubinemia, with bilirubin levels that rarely exceed 4 mg/dL; an otherwise normal liver function; and a hepatic histology that is also normal other than a modest increase in lipofuscin

P.230

pigment in some cases. Other than mild icterus in some patients, physical examination is also unremarkable. Bilirubin clearance is reduced to approximately one third of normal (Fig. 8.10) (169), and some patients also exhibit abnormalities in the plasma clearance patterns of other organic anions such as BSP or indocyanine green (ICG) (64,170), for which the mechanism remains uncertain. By contrast, fasting serum bile acid levels are normal (171). The most commonly recognized molecular defect is the addition of an extra dinucleotide sequence, TA, to the transcription initiation sequence (TATAA box) of the promoter for the A1 exon (172). Therefore, compared with the normal $A(TA)_6TAA$ sequence, an $A(TA)_7TAA$ mutation is commonly found in patients with Gilbert's syndrome. Much less common $A(TA)_5TAA$ or $A(TA)_8TAA$ mutations are also associated with Gilbert's syndrome (173). In individuals homozygous for one of these variants, enzyme activity is decreased to 10% to 35% of normal because of decreased synthesis of a functionally normal enzyme. Homozygosity for the promoter mutation appears to be necessary, but apparently not always sufficient for clinical expression of Gilbert's syndrome because population studies suggest that only about half of $A(TA)_7TAA$ homozygotes have hyperbilirubinemia (174). It has been suggested that additional variables, such as mild hemolysis (reported in up to 50% of patients with Gilbert's syndrome) or a separate defect in bilirubin uptake (7,169,172,173,175), might be among the factors enhancing phenotypic expression.



▪ **Figure 8.10** Observed ranges of plasma radiobilirubin disappearance curves in patients with Gilbert's syndrome and in healthy young adult volunteers. The average curve for each group was calculated by the computer from the mean values, for the group, of the intercompartmental rate constants (λs) of a compartmental model of bilirubin metabolism. The groups do not overlap for the first 16 hours after injection. Estimates of bilirubin clearance (C_{BR}), calculated from the areas under the curves, were reduced to one third of normal in the patients with Gilbert's syndrome. (Reprinted from Berk PD, Martin JF, Blaschke TF, et al. Unconjugated hyperbilirubinemia. Physiologic evaluation and experimental approaches to therapy. *Ann Intern Med* 1975;82:552–570, with permission of the publisher.)

Additional molecular mechanisms result in a phenotype identical to that associated with homozygosity for the $A(TA)_7TAA$ promoter variant (Table 8.3) (172,173). Consistent with the previously noted observation that one *normal* UGT1A1 allele is sufficient to maintain a normal plasma bilirubin concentration, individuals who are heterozygous for one UGT1A1 allele encoding an enzyme with reduced to absent bilirubin-conjugating activity will nevertheless have normal bilirubin concentrations if the second UGT1A1 allele is normal. However, if that second allele has the $A(TA)_7TAA$ promoter variant, the patient will have mild unconjugated hyperbilirubinemia with a

P.231

Gilbert's syndrome phenotype. Additionally, a number of instances have been documented in which mutations in the coding regions of the UGT1A1 gene encode proteins with only mildly reduced enzymatic activity. Such missense mutations, which result in a Gilbert's syndrome phenotype, have thus far been reported only from Japan (176). Inheritance has been either recessive or dominant negative (172,173). If a phenotypic reduction in bilirubin clearance is taken as the operational definition of Gilbert's syndrome, recognition of these alternative genotypes is important for the appropriate interpretation of mild, nonhemolytic, unconjugated hyperbilirubinemia. Although homozygosity for the $A(TA)_7TAA$ promoter variant supports a diagnosis of Gilbert's syndrome, absence of homozygosity for this variant does not exclude Gilbert's syndrome in this setting.

Table 8.3. Alternative Molecular Bases for the Gilbert's Syndrome Phenotype

- $A(TA)_7TAA$ homozygote
- $A(TA)_7TAA$/structural mutation compound heterozygote
- Structural mutation, for example, G71R (homozygous recessive or dominant negative)

The diagnosis of Gilbert's syndrome is most often made clinically on the basis of a mild, unconjugated hyperbilirubinemia in the absence of other causes. Although a definitive diagnosis can be established by assays of UGT1A1 enzymatic activity or by the identification of the homozygous $A(TA)_7TAA$ promoter mutation, elaborate studies, such as liver biopsies, are rarely necessary (177). Provocation tests such as a 48-hour fast or the intravenous administration of nicotinic acid augment the bilirubinemia in patients with Gilbert's syndrome and in healthy controls by a similar proportion and are of limited value in establishing a diagnosis of Gilbert's syndrome (reviewed in ref. 5). Bilirubin levels in simple Gilbert's syndrome in adults are never sufficiently elevated to pose a risk of neurologic damage. However, neonates with *both* Gilbert's syndrome *and* some form of hemolysis are at increased risk of transiently developing dangerous degrees of hyperbilirubinemia (178,179,180,181).

Some patients with Gilbert's syndrome exhibit abnormalities in the hepatic handling of a variety of xenobiotics metabolized by glucuronidation, including menthol, estradiol benzoate, lamotrigine, tolbutamide, rifamycin SV, acetaminophen (5,182), and HIV protease inhibitors (137). The HIV protease inhibitors indinavir and atazanavir produce hyperbilirubinemia by specifically inhibiting UGT1A1 (138). The degree of hyperbilirubinemia is greater with preexisting Gilbert's syndrome. Abnormalities in the glucuronidation of other substrates may be attributable to polymorphisms of other UGT isoforms (182). No significant toxicity has been ascribed to any of these pharmacokinetic abnormalities. Virtually the sole risk from Gilbert's syndrome in adults is associated with exposure to the antitumor agent irinotecan (CPT-11), the active metabolite of which is glucuronidated by UGT1A1. Administration of CPT-11 to patients with Gilbert's syndrome has resulted in severe toxicities, including intractable diarrhea and myelosuppression.

The Familial Conjugated Hyperbilirubinemias

Two inherited disorders characterized by conjugated hyperbilirubinemia without cholestasis, the Dubin-Johnson (183) and Rotor's syndrome (184), have been described. Although a third disorder that had been termed *hepatic storage disease* (185) was also included in this group, more recent evidence indicates that these patients have Rotor's syndrome. These disorders are relatively rare. They are clinically benign, but the establishment of a precise diagnosis is important to differentiate them from other more serious disorders and to save patients from unnecessary anxiety or surgical intervention. There are several additional familial disorders characterized by conjugated hyperbilirubinemia in association with cholestasis. These include benign recurrent intrahepatic cholestasis (BRIC) (186,187), and the progressive familial intrahepatic cholestasis (PFIC) disorders (188).

Dubin-Johnson syndrome

Clinical features

This disorder, independently described in 1954 by Dubin and Johnson (183) and by Sprinz and Nelson (189), is characterized by mild, predominantly conjugated hyperbilirubinemia (Table 8.4). Aside from jaundice, physical examination is normal in most cases, but an occasional patient may be found to have hepatosplenomegaly (190,191). Mild constitutional symptoms similar to those observed in Gilbert's syndrome (i.e., vague abdominal pain, fatigue, and weakness) are common (190,191). However, as in Gilbert's syndrome, these symptoms may be related to the anxiety associated with prolonged diagnostic testing. For the most part, newly detected cases are asymptomatic. Hyperbilirubinemia and clinical icterus are typically increased by intercurrent illness, by the administration of drugs that decrease hepatic excretion of organic anions (notably oral contraceptives), and by pregnancy (192). The condition is rarely observed before the onset of puberty, although occasional cases have been reported in infants (193,194,195). Subclinical cases often become manifest during pregnancy or in association with the initiation of oral contraceptive therapy (192). In contrast to syndromes associated with true cholestasis, pruritus is not seen in Dubin-Johnson syndrome, and serum bile acid levels are characteristically normal (192,196) as are other routine test results of liver function (e.g., serum alkaline phosphatase) (183,191). Useful animal models of the Dubin-Johnson syndrome have been described in mutant Corriedale sheep (197,198,199,200), golden lion tamarin monkeys (201), and in transport-deficient/Groningen yellow (Tr^-/GY) mutant rat strains (80,202,203,204,205,206) and Eisai hyperbilirubinemic rat

(EHBR) (207,208,209) mutant strains. Because of the insights they have provided into the probable pathophysiology of the Dubin-Johnson syndrome, the rat mutants are discussed in detail in following text.

Table 8.4. Phenotypic Features of Dubin-Johnson and Rotor's Syndromes

Feature	Dubin-Johnson syndrome	Rotor's syndrome
First described	1954	1948
Serum bilirubin (mg/dL)	Usually 2–5 mg/dL, predominantly (~60%) direct reacting; less often ≤25 mg/dL total	Usually 2–5 mg/dL, predominantly (~60%) direct reacting; less often ≤25 mg/dL total
Other liver function tests	Normal	Normal
Serum bile acids	Normal	Normal
Appearance of liver	Grossly black; coarse, dark centrilobular pigment	Normal
Physical findings	Jaundice ± hepatomegaly	Jaundice
Urine coproporphyrins	Normal total; >80% isomer I	Markedly increased total; isomer I increased, but always <80%

Inheritance	Autosomal recessive	Autosomal recessive

Frequency

Dubin-Johnson syndrome has been described worldwide in all races, nationalities, and ethnic backgrounds and in both sexes (190,191,210,211,212,213,214). Uncommon on a worldwide basis, the disorder is highly prevalent (1:1,300) among Iranian Jews (191). In this population, its frequent association with a deficiency of clotting factor VII (215,216) appears to represent the coincidental inheritance of the two conditions, because factor VII deficiency is not observed as part of the syndrome in other populations, and is caused by a different genetic mutation (217,218).

Laboratory findings

Serum bilirubin concentration is typically between 2 and *5* mg/dL, but values as high as 20 or even 25 mg/dL have been reported (190,191). Fifty percent or more of total serum bilirubin is direct reacting, and accordingly, bilirubinuria and an increase in the covalently bound bilirubin fraction in plasma are frequently present. The serum bilirubin concentration often fluctuates, and occasional bilirubin determinations may be within normal limits. The results of other routine tests of liver function, including aminotransferases, alkaline phosphatase, and γ-glutamyltransferase activities; serum albumin concentration; cholesterol level; and (except in the Iranian population) prothrombin time are normal. Hematologic studies, including complete blood count, reticulocyte count, and red cell survival studies, are also normal (219), indicating no evidence of hemolysis (18,35,220). Fasting and postprandial levels of the common serum bile acids are normal in most patients with Dubin-Johnson syndrome (192,221), although mild elevations have been described in occasional patients (222).

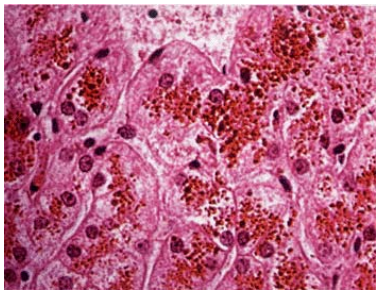
Imaging studies

Cholecystography, even when carried out with supplemental doses of contrast media, does not visualize the gallbladder in Dubin-Johnson syndrome (190,191), but visualization of the gallbladder is sometimes possible 4 to 6 hours after the intravenous administration of iodipamide (220,223). Biliary scintigraphy with agents such as Tc 99m Lidofenin or Tc 99m Disofenin may be helpful in the evaluation of patients with Dubin-Johnson and Rotor's syndromes (224,225,226). In six patients with Dubin-Johnson syndrome, administration of Tc 99m Lidofenin was followed by rapid, intense, homogeneous accumulation of the isotope within the liver without visualization of the intrahepatic biliary tree (224). In most patients with intact gallbladders, this organ was visualized approximately 90 minutes after the injection; in all cases, isotopic activity had reached the intestine within 1 hour of injection. However, in a patient with Rotor's syndrome, as well as in patients with jaundice and hepatocellular disease, administration of Tc 99m Lidofenin resulted in no visualization of the liver, gallbladder, or biliary tract and no accumulation of radionuclide in the intestine over 24 hours of observation. The kidneys visualized intensely in these latter conditions, indicating selective excretion of the radionuclide by this route (224).

Histopathology

Gross examination of the liver from typical patients with Dubin-Johnson syndrome shows it to be intensely pigmented to the point of appearing black in color (189,190). Light microscopy reveals no scarring, hepatocellular necrosis, or distortion of zonal architecture. Instead, the characteristic feature is the accumulation of a coarsely granular pigment, most pronounced in the centrilobular zones (Fig. 8.11) and with a characteristic lysosomal distribution (227). The nature of the pigment has been the subject of some debate, with some authors considering it a lipofuscin and others a melanin derivative. The histologically similar pigment observed

in mutant Corriedale sheep resembles melanin histochemically and incorporates tritium after the infusion of ^{3}H-epinephrine, a finding consistent with a melanin-like origin of the pigment granules (228). A study of Dubin-Johnson syndrome employing electron spin resonance spectroscopy demonstrated differences in the physicochemical characteristics of the Dubin-Johnson pigment when compared with authentic melanin (229). Although the nature of the pigment was not clearly defined, the data were consistent with its being composed of polymers of epinephrine metabolites. The degree of hepatic pigmentation may be variable, both within families and in a single individual with the Dubin-Johnson syndrome. Some of the variability may be genetic, but some may be due to the fact that coincidental diseases, such as viral hepatitis, are associated with the complete disappearance of the pigment from the liver (230). The pigment reaccumulates slowly after recovery from the hepatitic episode (231).

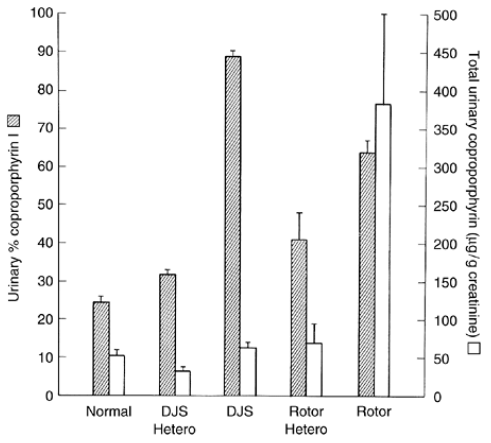


▪ **Figure 8.11** Liver biopsy in Dubin-Johnson syndrome showing coarsely granular pigment most pronounced in the centrilobular region (hematoxylin and eosin, original ×240). (Photomicrograph courtesy of Dr. Kamal G. Ishak, Armed Forces Institute of Pathology.)

Metabolism of organic anions

After intravenous injection, the initial disappearance of organic anions, such as bilirubin, BSP, dibromosulphthalein (DBSP), and ICG, from the plasma is normal (232,233). However, characteristic of Dubin-Johnson syndrome is that the plasma concentration of BSP is higher at 90 minutes as compared to 45 minutes after injection because of reflux of conjugated BSP back into the circulation from the hepatocyte, where it has been conjugated with GSH (191,192,220). This secondary rise is not seen after the intravenous administration of DBSP or ICG, compounds that are excreted into bile by the hepatocyte without further metabolism (232,233). A secondary rise, representing the reflux of conjugated bilirubin, has

been noted after the intravenous administration of unconjugated bilirubin-IXa to patients with this syndrome (229,232). The defect in the excretion of conjugated BSP has been confirmed by direct studies of the plasma clearance of this metabolite (234), consistent with the presence of a selective abnormality in the bile canalicular excretion of conjugated organic anions with normal excretion of bile salts. Studies of BSP metabolism involving continuous infusion of dye support these findings because they show a marked reduction in the calculated secretory transport maximum (T_m) with a normal relative storage capacity (S) (191,192). Although the secondary rise of BSP levels observed after intravenous administration of a single 5 mg per kg dose is highly suggestive of the syndrome, it is not diagnostic and has occasionally been observed in other hepatobiliary disorders (235).



▪ **Figure 8.12** Urinary coproporphyrin in Dubin-Johnson and Rotor's syndromes. The shaded bars represent the percentage of total urinary coproporphyrin excreted as coproporphyrin I. The open bars represent total urinary coproporphyrin excretion; vertical bars represent ± standard error of the mean. Total urinary coproporphyrin excretion is normal to slightly increased in the Dublin-Johnson syndrome (DJS), with a markedly elevated proportion of coproporphyrin I (approximately 80%). Both variables are markedly elevated in Rotor's syndrome. Therefore, with respect to urinary coproporphyrin excretion, the two disorders are distinct. Results in obligate heterozygotes (DJS hetero, Rotor hetero) lie intermediate between the results in healthy individuals and in individuals manifesting the respective disorder. (Reprinted with permission from Berk PD, Wolkoff AW, Berlin NI. Inborn errors of bilirubin metabolism. *Med Clin North Am* 1975;59:803–816.)

Urinary coproporphyrin excretion

Patients with Dubin-Johnson syndrome also have a diagnostic abnormality in urinary coproporphyrin excretion (210,236,237,238). There are two naturally occurring coproporphyrin isomers, I and III. Normally, approximately 75% of the coproporphyrin in the urine is isomer III. In the urine from patients with Dubin-Johnson syndrome, the total coproporphyrin content is normal, but more than 80% is isomer I. Heterozygotes for the syndrome show an intermediate pattern (210,239). The molecular basis for this phenomenon is not yet known.

Animal models of Dubin-Johnson syndrome

The mutant Corriedale sheep was the first recognized animal model of Dubin-Johnson syndrome (197,198,199,200). These animals have grossly black livers and defects in organic anion and coproporphyrin excretion that are identical to patients with the syndrome. Subsequently, two mutant rat models of Dubin-Johnson syndrome were described. These are the TR^- rat strain, also known as *GY*, and EHBR strain (80,202,203,204,205,206,207,208,209). These mutant rat strains exhibit many of the characteristic phenotypic features of the Dubin-Johnson syndrome, including (a) autosomal recessively inherited conjugated hyperbilirubinemia and bilirubinuria, (b) defective biliary excretion of conjugated organic anions with normal bile acid excretion, and (c) normal total urinary coproporphyrin excretion with increased percentage of isomer I. Although these animals do not typically have increased hepatic pigmentation, studies in TR^- animals demonstrate accumulation of lysosomal pigment after infusion of epinephrine metabolites or after feeding a diet high in aromatic amino acids (240). A mutant strain of golden lion tamarins with a Dubin-Johnson phenotype has also been described (201).

Inheritance

The initial descriptions of the Dubin-Johnson syndrome indicated that it was an inheritable disorder (190), and its familial nature has been verified in many subsequent studies (161,211,214,216,220,241,242). Although it was thought to be inherited as an autosomal recessive trait, there was initially no means to detect heterozygous carriers (243). This subsequently became available through the determination of urinary coproporphyrin excretion (210,239). As noted in preceding text, there is a characteristic abnormality in the pattern of urinary coproporphyrin excretion in patients with Dubin-Johnson syndrome (210,236,237). Subsequent studies found that in obligate heterozygotes (e.g., phenotypically healthy parents and children of patients with Dubin-Johnson syndrome), this pattern was intermediate between healthy and affected individuals, consistent with autosomal recessive inheritance (210,239). The pathogenesis of abnormal urinary coproporphyrin excretion in Dubin-Johnson syndrome is not known (244,245).

Genetic defect

The gene responsible for causing Dubin-Johnson syndrome has been identified as *MRP2*, encoding an ATP-dependent canalicular plasma membrane transporter for bilirubin conjugates and a number of other non–bile acid organic anions (246). Mutations in this gene can result in a Dubin-Johnson syndrome phenotype in rats and humans (214,246,247,248,249). Although it is clear that MRP2 plays a major role in the biliary excretion of conjugated bilirubin, even in its absence, bilirubin conjugates are found in bile, implying the existence of other, not yet identified, alternative transport proteins. At least 15 mutations in the MRP2 gene have been described in patients with the Dubin-Johnson syndrome (248). These include four splice site mutations, six missense mutations, three nonsense mutations, and one deletion mutation. As noted in preceding text, as many as 60% of patients with Dubin-Johnson syndrome in an Israeli series had coexistence of clotting factor VII deficiency. It is now known that the gene for factor VII is located on chromosome 13, in contrast to the localization of MRP2 to chromosome 10, which effectively excluded a primary genetic linkage between these two phenotypes.

Treatment

No specific therapy is indicated for Dubin-Johnson syndrome. It is generally considered to be a benign disease requiring only reassurance of the patient and avoidance of invasive diagnostic procedures. Although phenobarbital has been used in an attempt to reduce the serum bilirubin concentration, the results have been highly variable (250,251). Some patients with nonspecific abdominal complaints report amelioration of their vague symptoms during phenobarbital therapy, irrespective of any lowering of the serum bilirubin concentration; however, chronic phenobarbital administration is not recommended.

Rotor's syndrome

Rotor's syndrome characterized by chronic predominantly conjugated hyperbilirubinemia, phenotypically resembling the Dubin-Johnson syndrome (Table 8.4), was initially described in two Philippine families by Rotor et al. in 1948 (184). Although the incidence of Rotor's syndrome remains much less than that of the Dubin-Johnson syndrome, it has a widespread geographic distribution (252,253,254,255).

Clinical and laboratory findings

Patients with Rotor's syndrome are generally asymptomatic, and their conjugated hyperbilirubinemia is most often discovered incidentally. Some individuals describe mild symptoms such as weakness and vague abdominal pain, but pruritus is not a feature. In contrast to the Dubin-Johnson syndrome, hepatosplenomegaly has not been reported. The serum bilirubin concentration is typically elevated to between 2 and 5 mg/dL but may be as high as 20 mg/dL. More than half of the serum bilirubin is direct reacting, and bilirubinuria is typically present. Bilirubin levels often fluctuate in a given individual and may be increased by intercurrent illness. The results of conventional hepatic biochemical tests other than serum bilirubin, such as alkaline phosphatase and aminotransferase activities, serum albumin concentration, and prothrombin time, are typically normal (184,254). The gallbladder usually visualizes on oral cholecystography, in contrast to findings in the Dubin-Johnson syndrome (252,254). Liver biopsy is also normal, and there is no increase in hepatic pigmentation.

Organic anion metabolism

Although Rotor's syndrome phenotypically resembles the Dubin-Johnson syndrome and both disorders were initially considered to be variants of the same entity, detailed studies of BSP and coproporphyrin metabolism have indicated that they are distinct disorders (252,256). In addition, whereas oral cholecystographic agents usually do not visualize the gallbladder in the Dubin-Johnson syndrome, visualization is usual in Rotor's syndrome (254,257). After the administration of a 5-mg per kg dose of BSP, the initial plasma disappearance rate in Rotor's syndrome is markedly reduced and the 45-minute retention is elevated, often to 30% to 50% (256). There is no secondary rise in

P.235

plasma BSP concentration, and conjugated BSP does not accumulate in plasma (256). Studies of biliary excretion failed to document a defect in the transport of either the free BSP or the BSP glutathione conjugate (234). In contrast to Dubin-Johnson syndrome, there is marked retention of ICG and unconjugated bilirubin after intravenous infusion (258). In addition, during constant infusion, the T_m for BSP in Rotor's syndrome was only minimally to moderately reduced, while the relative *S* was reduced by 75% to 90% (256,258). These data are in marked contrast to those in the Dubin-Johnson syndrome in which T_m is virtually 0, while *S* is normal. These results of T_m and *S* for BSP are identical to those that have been described in a phenotypically disorder that had been termed *hepatic storage disease* (185,259). It must be concluded that these two disorders are the same. When plasma BSP disappearance studies were conducted in 11 phenotypically normal obligate heterozygotes for Rotor's syndrome, mildly elevated retention at 45 minutes, averaging 11%, was intermediate between results in patients and healthy controls (256) Similarly, during constant BSP infusion studies, T_m and *S* in obligate heterozygotes were also intermediate between those of patients with Rotor's syndrome and healthy controls (256). These findings, suggesting an autosomal recessive mode of inheritance for Rotor's syndrome, are in contradistinction to similar studies in Dubin-Johnson syndrome, in which the carrier state is not usually detectable by studies of BSP metabolism.

Urinary coproporphyrin excretion

Rotor's syndrome is also differentiated from Dubin-Johnson syndrome with respect to patterns of urinary coproporphyrin excretion (238,252,260). Total urinary coproporphyrin excretion in patients with Rotor's syndrome is increased by 2.5- to 5-fold compared with healthy controls (252,260). The proportion of coproporphyrin I is also increased to an average of 65%. These results are similar to those seen in a variety of acquired hepatobiliary disorders and sharply contrast with those observed in Dubin-Johnson syndrome (261). Obligate heterozygotes for Rotor's syndrome are phenotypically normal and have a coproporphyrin excretion pattern intermediate between that of Rotor's syndrome and healthy controls (252). On the basis of urinary coproporphyrin excretion studies, Rotor's syndrome appears to be inherited as an autosomal recessive characteristic and is clearly distinct from Dubin-Johnson syndrome (Fig. 8.12) (252,260).

Genetic defect

It is clear that Rotor's syndrome is an inheritable disorder distinct from Dubin-Johnson syndrome (252,256,258,260).

P.236

P.237

However, the genetic defect has not yet been elucidated.

Table 8.5. Inheritable Disorders Characterized by Conjugated Hyperbilirubinemia

	Dubin-Johnson	Rotor's	PFIC1	BRIC	PFIC2	BRIC type 2	PFIC3
Gene	*ABCC2*	Unknown	*ATP8B1*	*ATP8B1*	*ABCB11*	*ABCB11*	*ABCB4*
Protein	MRP2	Unknown	FIC1	FIC1	BSEP	BSEP	MDR3
Cholestasis	No	No	Yes	Episodic	Yes	Yes	Yes
Serum γ GT	Normal	Normal	Normal	Normal	Normal	Normal	↑↑
Serum bile acids	Normal	Normal	↑↑	↑↑ during episodes	↑↑	↑↑	↑↑
Clinical features	Mild conjugated hyperbilirubinemia; otherwise normal liver function; dark pigment in liver; characteristic pattern of urinary coproporphyrins	Mild conjugated hyperbilirubinemia; otherwise normal liver function; liver without abnormal pigmentation	Severe cholestasis beginning in childhood	Recurrent episodes of cholestasis beginning at any age	Severe cholestasis beginning in childhood	Recurrent episodes of cholestasis beginning at any age	Severe cholestasis beginning in childhood; decreased phospholipids in bile

PFIC, progressive familial intrahepatic cholestasis; BRIC, benign recurrent intrahepatic cholestasis; MRP2, multidrug resistance–associated protein 2; BSEP, bile salt export pump; MDR3, multidrug resistance protein 3; GT, glucuronosyltransferase.

Treatment

No treatment is required or effective for Rotor's syndrome. Most patients are in any case asymptomatic. In the absence of ill-advised medical or

surgical intervention, life expectancy appears to be normal.

Familial Cholestasis Syndromes

Several familial disorders characterized by conjugated hyperbilirubinemia in association with cholestasis have been described.

Benign Recurrent Intrahepatic Cholestasis

BRIC is a rare disorder characterized by recurrent attacks of pruritus and jaundice and typically presents with an episode of mild malaise, elevated serum aminotransferase levels, followed rapidly by rises in alkaline phosphatase and conjugated bilirubin (bilirubinuria) levels and onset of jaundice and itching (186,262,263,264). Initial episodes may be misdiagnosed as acute viral hepatitis. These episodes typically begin in childhood or young adulthood and can last for several weeks to months. Between attacks, lasting from several months to years, there is complete clinical and biochemical resolution. This disorder is familial and has an autosomal recessive pattern of inheritance. Although BRIC is considered a benign disorder that does not lead to cirrhosis or end-stage liver disease, the episodes can be quite debilitating, resulting in liver transplantation in some patients. Treatment during the cholestatic episodes is symptomatic and there is no means available to prevent or shorten the occurrence of episodes. A gene termed *FIC1* that encodes a protein FIC1, was recently identified and found to be mutated in most patients with BRIC (187). FIC1 is expressed primarily in the small intestine and weakly in the liver. It is a member of a P-type ATPase family that transports aminophospholipids from the outer to the inner leaflet of a variety of cell membranes and has little similarity to genes that have been shown to play a role in bile canalicular excretion of various compounds (187,265,266). How it causes BRIC remains unclear. Interestingly, a second phenotypically identical form of BRIC, termed *BRIC type 2*, has been described resulting from mutations in the bile salt export pump (BSEP), that resides normally on the bile canaliculus (267).

Progressive Familial Intrahepatic Cholestasis

The name PFIC is applied to three phenotypically related syndromes (Table 8.5). PFIC type 1 (Byler disease) presents in early infancy as cholestasis that may be initially episodic (268). However, in contrast to BRIC, Byler disease progresses to malnutrition, growth retardation, and end-stage liver disease during childhood. This disorder is also a consequence of a FIC1 mutation (187). The functional relationship of the *FIC1* protein to the pathogenesis of cholestasis in these disorders is unknown. Two other types of PFIC (types 2 and 3) have been described. Type 2 is associated with a mutation in the BSEP, the same protein that is abnormal in BRIC type 2 (269,270). Type 3 has been associated with a mutation of MDR3, a protein that is essential for normal hepatocellular excretion of phospholipids across the bile canaliculus (271,272). Although all three types of PFIC have similar clinical phenotypes, only type 3 is associated with high serum levels of γ-glutamyltransferase activity (264). In contrast, activity of this enzyme is normal or only mildly elevated in symptomatic BRIC and PFIC types 1 and 2.

Although the primary genetic lesions in the various forms of familial intrahepatic cholestasis do not cause defective bilirubin transport, they do lead to cholestasis and, secondarily, to conjugated hyperbilirubinemia. Studies of these genetic disorders have significantly helped unravel the basic mechanisms of the canalicular bile transport processes. This review covers the mechanism, clinical manifestations, genetics, and treatment of each disease.

This outstanding review evaluates the available information on the phenotypic consequences of multiple genotypes, including many mutations in both the UGT1A1 coding regions and the exon 1 promoter, which have been associated with Gilbert's syndrome and Crigler-Najjar syndromes type I and II. It produces a much clearer picture of the complex interactions among these three conditions.

Kapitulnik J. Bilirubin: an endogenous product of heme degradation with both cytotoxic and cytoprotective properties. *Mol Pharmacol* 2004;66:773–779.

Biliverdin, bilirubin, iron, and carbon monoxide, the biological products of heme degradation, have all been found to have potent biological effects. Furthermore, the rates of heme synthesis and degradation are tightly regulated. This has led to the proposal that heme turnover contributes, on the one hand, to pathogenesis of certain types of cellular injury and, on the other, to antioxidant defenses. This paper reviews this rapidly expanding field of research.

The susceptibility of newborns to bilirubin neurotoxicity is highly variable. Furthermore, neurologic damage sometimes occurs at plasma unconjugated bilirubin (UCB) concentrations well below therapeutic

P.238

guidelines. This paper reviews current information on mechanisms of cellular bilirubin toxicity, and the transport processes determining its access to and accumulation within the central nervous system.

Servedio V, d'Apolito M, Maiorano N, et al. Spectrum of UGT1A1 mutations in Crigler-Najjar (CN) syndrome patients: identification of twelve novel alleles and genotype-phenotype correlation. *Hum Mutat* 2005;25(3):325.

This brief paper, identifying 12 novel UGT1A1 mutations, reviewing the total spectrum of 77 such mutations identified as of early 2005, and exploring genotype–phenotype correlations is a valuable addition to the one by Kodakol et al listed above.

Takeuchi K, Kobayashi Y, Tamaki S, et al. Genetic polymorphisms of bilirubin uridine diphosphate-glucuronosyltransferase gene in Japanese patients with Crigler–Najjar syndrome or Gilbert's syndrome as well as in healthy Japanese subjects. *J Gastroenterol Hepatol* 2004;19:1023–1028.

This meticulous study analyzed both the UGT1A1 promoter and coding regions of 63 Japanese patients with Gilbert's syndrome and 71 healthy Japanese controls. The data indicate clearly that the genetic basis for the familial hyperbilirubinemias differs between Japanese and Caucasian populations.

Chapter 9

Hepatic Histopathology

Zachary D. Goodman

Hala R. Makhlouf

Key Concepts

- Histopathologic examination of a liver biopsy specimen is a source of otherwise unobtainable qualitative information about the structural integrity of the liver tissue, the type and degree of injury, and the host's response to the injury; histopathologic examination also provides a basis for the diagnosis and classification of tumors.
- Histochemical and immunohistochemical stains are extremely helpful in evaluating the liver biopsy specimen.
- Qualitatively different patterns of injury can be used to distinguish diseases that have similar clinical presentations, such as chronic hepatitis, alcoholic or nonalcoholic steatohepatitis, and chronic cholestatic syndromes.
- Specific histologic features may allow precise diagnosis or strongly suggest a specific diagnosis. For example, “ground-glass” cells with positive histochemical or immunostaining for hepatitis B surface antigen indicates chronic hepatitis B infection, or florid duct lesions indicate the early stage of primary biliary cirrhosis.
- Accurate classification of tumors almost always requires histologic examination of tissue obtained by either biopsy or surgical excision.

The liver biopsy is an essential part of the investigation of diseases of the liver. Percutaneous (sometimes laparoscopic or transjugular) needle biopsies provide most of the specimens and the greatest challenge to the surgical pathologist, but open surgical biopsies and resection specimens obtained at laparotomy are also seen from time to time, especially when dealing with tumors, and even in total hepatectomies in

liver transplantation centers. Despite the many advances in laboratory tests, molecular diagnosis, and radiologic imaging techniques, liver biopsies continue to be performed. This is because histopathologic examination of the biopsy specimen is a source of otherwise unobtainable qualitative information about the structural integrity of the liver tissue, the type and degree of injury, and the host's response to the injury; histopathologic examination also provides a basis for the diagnosis and classification of tumors.

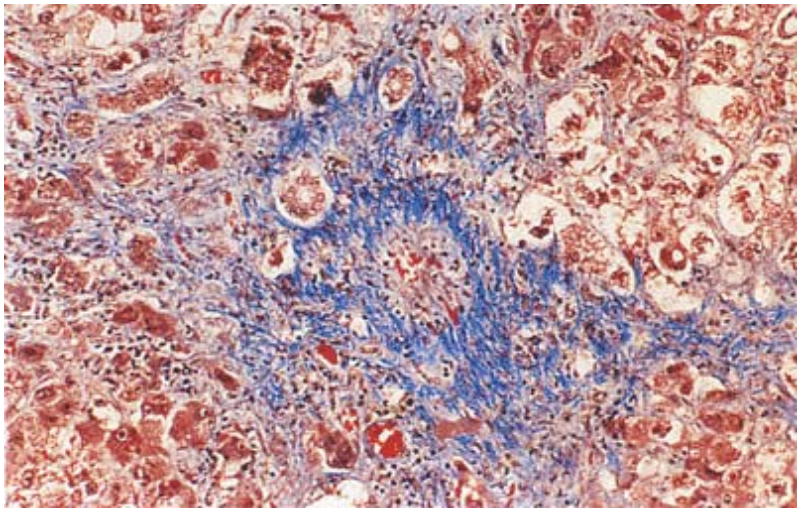
Liver biopsy should only be performed after a thorough noninvasive clinical evaluation. Furthermore, this information, including a history of possible exposure to hepatotoxins and sources of infection, pertinent physical findings, laboratory tests of liver function and integrity, serologic tests to detect infectious agents and autoimmunity, and radiologic studies, when appropriate, should be made available to the pathologist. Many biopsy specimens can be interpreted solely on morphologic grounds, and we recommend that the pathologist first examine the specimen and make initial observations without being biased by the clinical impression and laboratory data. However, after these initial observations, we strongly recommend that the

pathologist review the clinical and laboratory data, preferably with the clinician, and then arrive at the best possible clinical–pathologic correlation as the definitive diagnosis. This will allow the pathologist to avoid embarrassing errors that result from lack of information and will, at the same time, provide the clinician with an interpretation that will allow optimal patient care. In that regard, this chapter emphasizes the morphologic (predominantly light microscopic) aspects of the diseases of the liver, with clinical correlations in some of the major diseases.

Systematic Approach to the Liver Biopsy

The observer evaluating a liver biopsy specimen should always use a systematic approach to histopathologic evaluation. All fragments from a given biopsy specimen should be examined because a focal lesion, such as a granuloma, can be easily missed. In an architecturally normal liver it is best to begin evaluating by locating the terminal hepatic venules (or "central" veins) and then move in the direction of the portal areas. In doing so, changes involving the veins themselves and then the liver cells, bile canaliculi, abnormal deposits in spaces of Disse (e.g., collagen, amyloid), hypertrophied stellate cells, the sinusoids and their contents, and the Kupffer cells should be specifically looked for. The plates of hepatocytes nearest the portal areas should receive special attention, particularly in chronic necroinflammatory or cholestatic disorders. Proliferation of ductules and fibrosis also occur in this region of the acinus. All structures of the portal areas, namely, the connective tissue, bile ducts, veins, arteries, and lymphatics, as well as the inflammatory response (e.g., granulomas and the various types and

relative proportions of inflammatory cells), should be examined. In addition to searching for specific lesions, the absence of various structures in the portal areas such as the destruction and disappearance of bile ducts in primary biliary cirrhosis (PBC) or the obliteration of veins in hepatoportal sclerosis should also be carefully noted.



▪ **Figure 9.1** The Masson trichrome stains type I collagen blue, revealing zone 3 fibrosis in this case of alcoholic liver disease. An occluded terminal hepatic venule can be seen in the center of the field.

Special Histochemical Stains

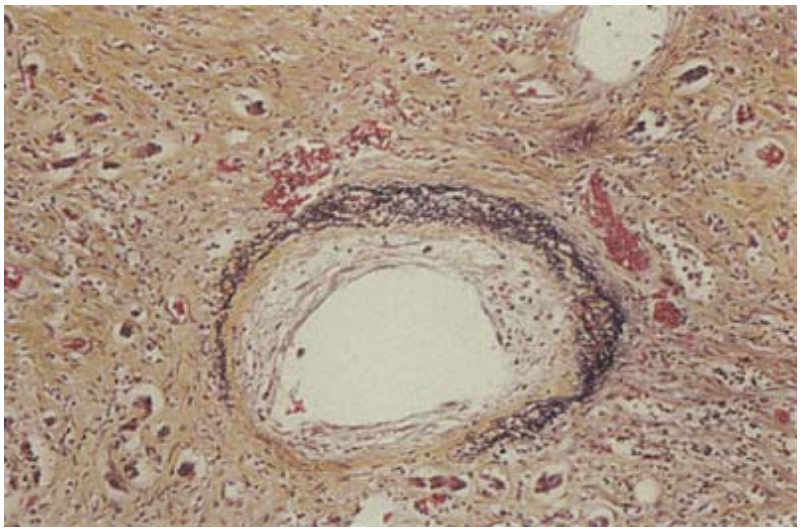
Although most of the observations that lead to a diagnosis are made using the routine hematoxylin and eosin stain, special stains are helpful in evaluating liver biopsy specimens. Staining methods referred to in this chapter can be found in the Armed Forces Institute of Pathology's *Laboratory Methods in Histotechnology* (1).

Fibrosis and connective tissue

Evaluation of the presence, extent, and location of fibrosis is essential in the diagnosis of non-neoplastic liver disease. A Masson trichrome (Fig. 9.1) is useful for demonstrating the degree of fibrosis and cirrhosis in chronic liver disease and is also useful in assessing changes involving arteries and veins, such as the lesions of veno-occlusive disease and hepatic vein thrombosis. A Movat pentachrome stain is particularly useful for vascular lesions because it stains elastica and

acid mucopolysaccharide, in addition to collagen and smooth muscle (Fig. 9.2). Elastic tissue can also be well demonstrated by orcein or

Victoria blue stains that are used to identify ground-glass cells containing hepatitis B surface antigen. A reticulin stain is useful for outlining areas of focal or zonal necrosis (Fig. 9.3), thick liver plates, or nodules of regeneration. It can also be used to demonstrate fibrosis, but in general the Masson stain is preferred because the reticulin stain does not distinguish permanent scarring from stromal collapse.

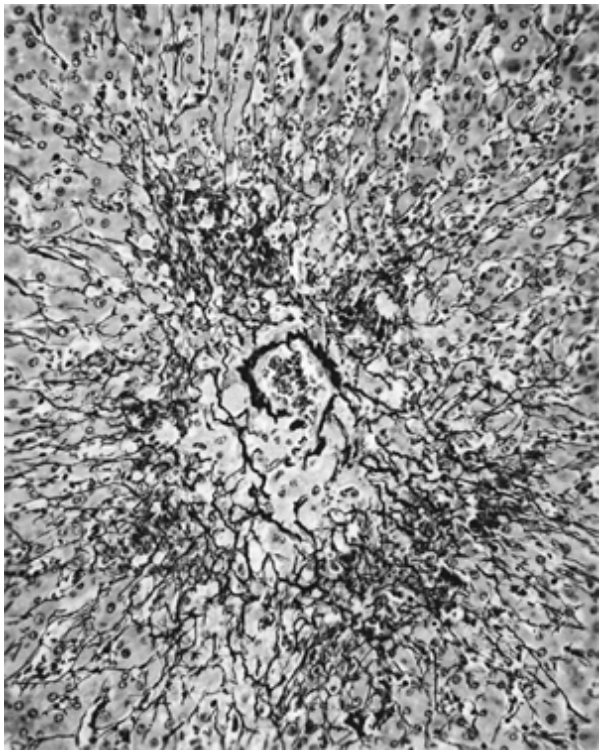


▪ **Figure 9.2** The Movat pentachrome stain shows a partially occluded outflow vein in this case of alcoholic cirrhosis. The elastic tissue in the wall of the vein is black, whereas mucopolysaccharides in the hypertrophied intima are pale blue, and collagen in the cirrhotic scars is yellow green.

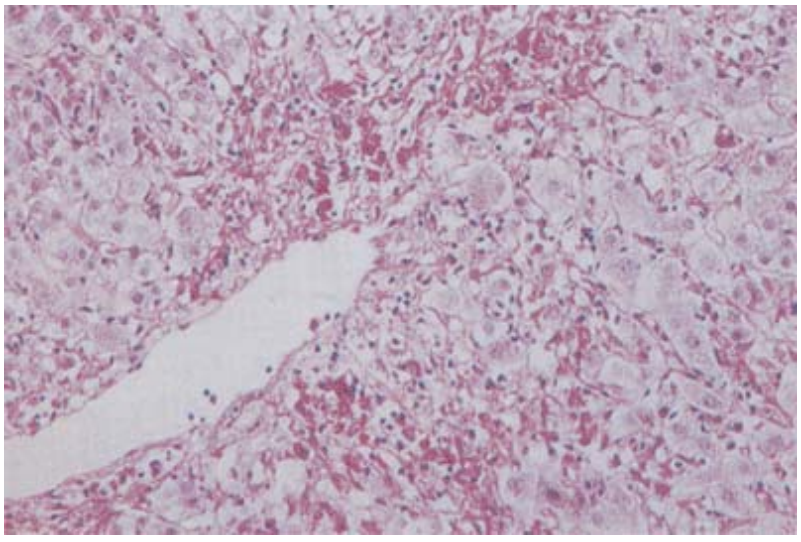
Complex carbohydrates

Complex carbohydrates are readily demonstrated with the periodic acid-Schiff (PAS) stain. This will of course demonstrate glycogen in liver cells or in benign and malignant hepatocellular tumors, but a much more useful stain that should be routinely employed is the PAS stain after pretreatment with diastase (DPAS) to remove the glycogen and unmask other complex carbohydrate–containing substances, including metabolic and synthetic products of the liver, and structural components. The DPAS stain strikingly demonstrates the presence of lipofuscin and other cell debris in Kupffer cells and portal macrophages in acute hepatocellular injury (Fig. 9.4). The Dubin-Johnson pigment in liver cells stains variably with PAS. In type IV glycogenosis, Lafora's disease (myoclonus epilepsy), and cyanamide-induced liver injury, hepatocytes (mainly in zone 1) contain PAS-positive material that resists diastase digestion, but in Lafora's disease and glycogenosis type IV the material can be digested by pectinase. The globules of α_1-

antitrypsin are strongly DPAS positive (Fig. 9.5). PAS is also useful for staining bile duct basement membranes, to demonstrate ductal injury; fibrin (e.g., in disseminated intravascular coagulation); amyloid; starch; amoebae; and most pathogenic fungi.



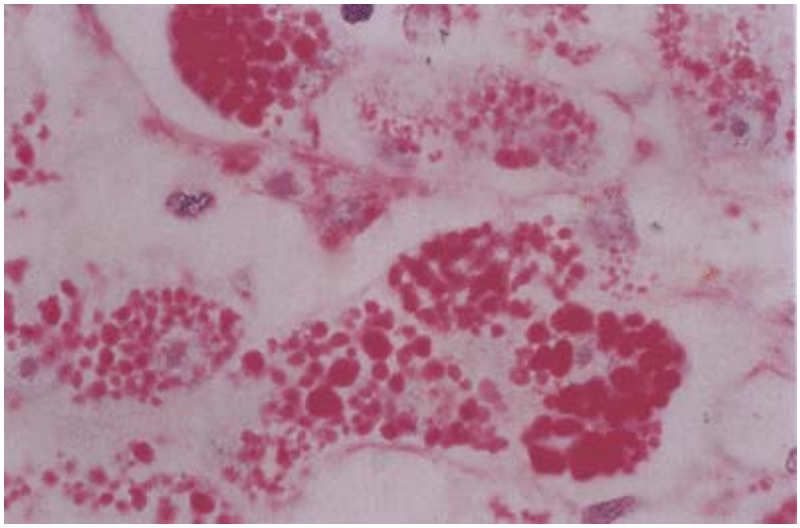
▪ **Figure 9.3** The reticulin stain shows the black-staining type III collagen fibers that support the liver cell plates. A terminal hepatic venule in the center of the field is surrounded by collapsed reticulin, indicating zone 3 necrosis.



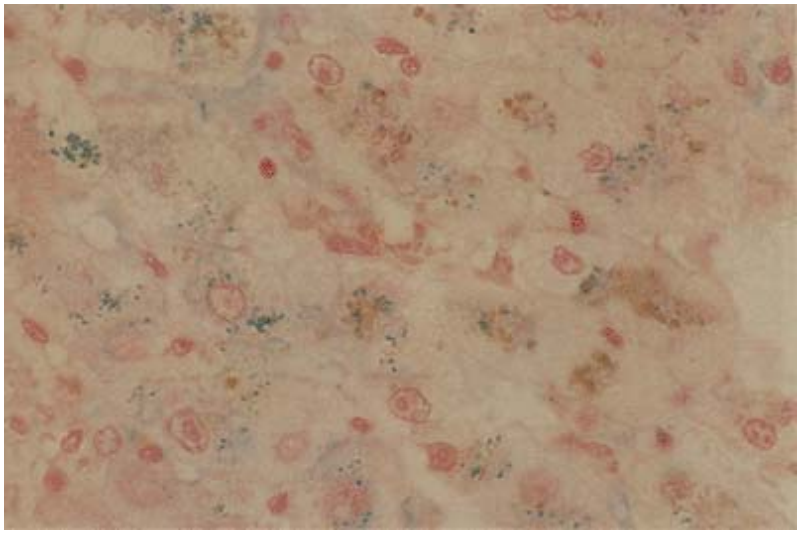
▪ **Figure 9.4** The periodic acid-Schiff stain after diastase digestion to remove glycogen demonstrates the presence of lipofuscin and other cell debris in Kupffer cells in acute hepatocellular injury.

Iron

Iron is readily demonstrated with the Prussian blue stain, which is also useful in bringing out the green color of bile and the golden brown color of lipofuscin, both of which can be masked by overstaining with either eosin or hematoxylin (Fig. 9.6). Copper is specifically best demonstrated by the rhodanine stain (Fig. 9.7), but the orcein and Victoria blue stains, which are technically easier, can also be used because these will stain concentrated deposits of the copper-binding protein, metallothionine. In the past, orcein and Victoria blue were primarily used to demonstrate the ground-glass inclusions of chronic hepatitis B infections (Fig. 9.8), but these have now been largely supplanted by specific immunostains, as discussed later.

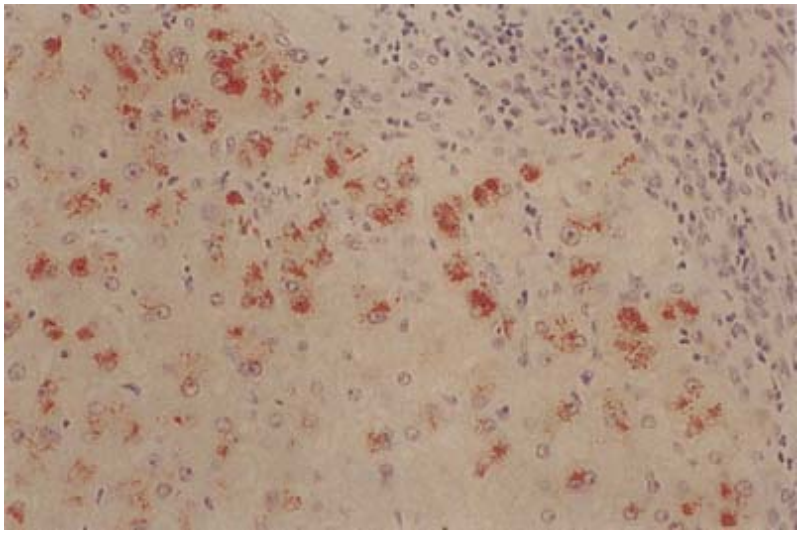


▪ **Figure 9.5** Globules of α_1-antitrypsin are strongly periodic acid-Schiff positive and diastase resistant.



▪ **Figure 9.6** The Prussian blue stain for iron demonstrates hemosiderin (blue granules) and also brings out the green color of bile and the golden brown color of lipofuscin.

Other stains that find occasional use include the Hall's stain for bile; the Fontana's stain for lipofuscin and Dubin-Johnson pigment; the phosphotungstic acid–hematoxylin stain for fibrin or mitochondria; the Congo red, sirius red, or crystal violet stains for amyloid; an acid-fast stain for mycobacteria, schistosome eggs, or the hooklets in the scolices of echinococcal cysts; and the Warthin-Starry stain for spirochetes, leptospira, or the bacilli causing catscratch disease. A Giemsa stain can be useful in studying the morphology of hematopoietic cells or in identifying some microorganisms, such as *Leishmania* or *Cryptosporidia*.

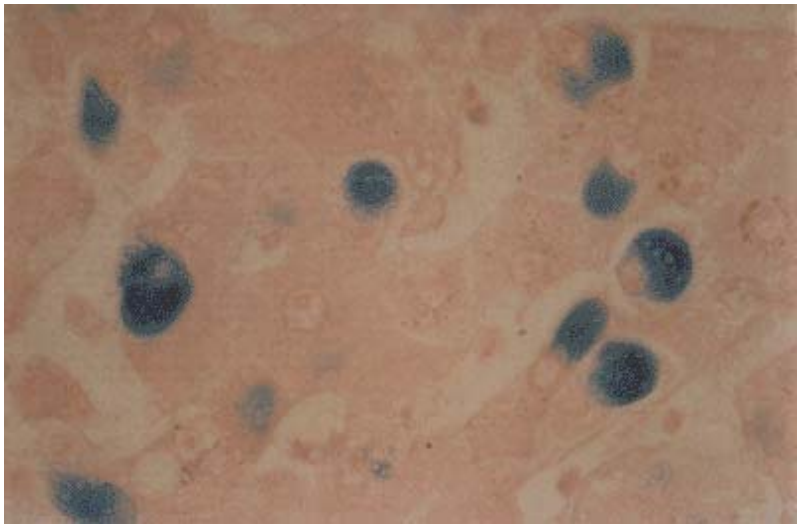


▪ **Figure 9.7** The rhodanine stain demonstrates copper as brick-red granules in liver cells in this case of Wilson disease.

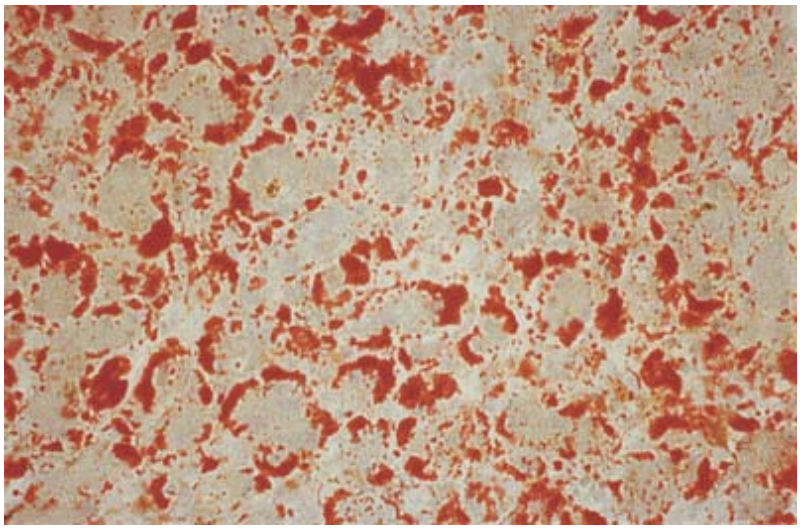
Fat

Fat can be demonstrated histochemically, but this requires unprocessed frozen sections, which must be prepared with a cryostat from fresh or formalin-fixed

tissue. Routine processing exposes the tissue to organic solvents, which will extract lipids and render fat stains useless. However, frozen sections prepared and stained with oil red-O (Fig. 9.9) can be quite useful for demonstrating neutral lipid in liver cells in a variety of conditions or in cells of benign or malignant tumors. This stain may also be used to demonstrate fat globules of stellate cells, cholesterol crystals (which are also birefringent when examined under polarized light), and lipofuscin in liver or Kupffer cells. Cholesterol can be specifically stained in frozen sections by the Schultz modification of the Liebermann-Burchard reaction, a reaction useful for the diagnosis of Wolman's disease or cholesteryl ester storage disease. Metachromatic granules in macrophage cells and bile duct epithelium in metachromatic leukodystrophy are best demonstrated in frozen sections by using stains such as cresyl violet or toluidine blue.



▪ **Figure 9.8** The Victoria blue stain shows cells containing large amounts of hepatitis B surface antigen in a chronic carrier.



▪ **Figure 9.9** Oil red O stain of a frozen section shows microvesicular fat in acute fatty liver of pregnancy.

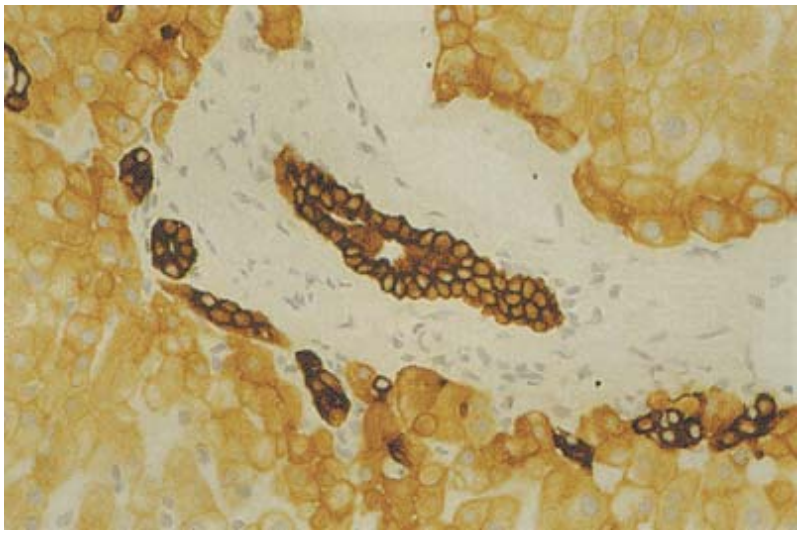
Immunopathology

Immunostains are now routinely utilized in the diagnosis of hepatic neoplasms, but it has fewer practical applications in the study of non-neoplastic diseases of the liver. Nevertheless, these techniques can be

used to demonstrate and characterize normal structural components and a number of histopathologic changes; they can also be used to locate viral antigens and other infectious agents.

In the normal liver, bile duct epithelial cells react with monoclonal antibodies to cytokeratins 7, 8, 18, and 19 (Fig. 9.10), whereas the liver cells react only with monoclonal antibodies to cytokeratins 8 and 18 (2). Bile canaliculi are demonstrated by polyclonal antibodies to carcinoembryonic antigen (CEA) (Fig. 9.11) because of the presence of a cross-reacting biliary glycoprotein. Tumors derived from hepatocytes and bile ducts often maintain the antigenic characteristics of their normal counterparts, but this is not invariable, hence staining patterns must be interpreted in the context of other histologic features.

A few practical applications for immunohistochemistry have been found in the diagnosis of non-neoplastic diseases. In chronic cholestatic disorders, such as PBC, cytokeratin type 7, normally only found in biliary-type cells, appears in periportal hepatocytes (3). Because cytokeratin proteins are a major component of Mallory bodies, antibodies to several high- and low-molecular-weight keratins may be used to demonstrate this pathologic feature, but none is as reliable for this purpose as staining with antibodies to ubiquitin (4), a cellular stress protein that coats the surface of filamentous tangles such as Mallory bodies (Fig. 9.12). Ubiquitin also coats tangles of amyloid filaments, but there are specific antibodies that can be used to confirm the diagnosis of amyloidosis and characterize the different types of amyloids (5).



▪ **Figure 9.10** Immunostain with a cocktail of monoclonal antibodies that react with cytokeratin types 7, 8, 18, and 19. There is strongly positive staining of the bile duct in the center of the portal area and the ductular cells at the edge, whereas hepatocytes

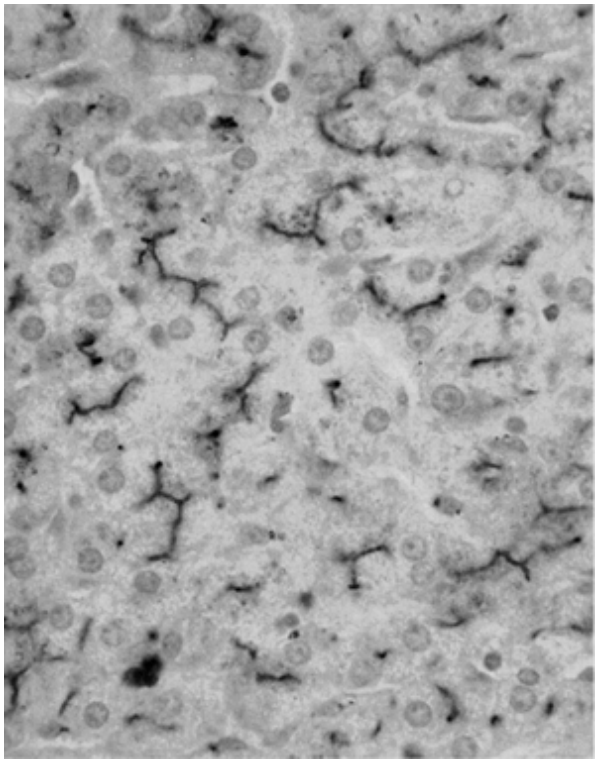
stain only weakly.

Immunostaining for viral antigens in different types of viral hepatitis is extensively used for investigational purposes and, to a lesser extent, for diagnosis. In routine practice, hepatitis B antigens (surface and core) are readily identified with commercially available antisera (Fig. 9.13). Hepatitis D can also be identified in routinely processed tissue, but antibodies are more difficult to obtain. Hepatitis A, C, and E can only be reliably identified in frozen sections, and staining for these is generally limited to research settings. Several viruses, other than those causing viral hepatitis, including herpes simplex virus, Cytomegalovirus (CMV), and adenovirus, can be detected in the liver by using commercially available antisera.

Electron Microscopy

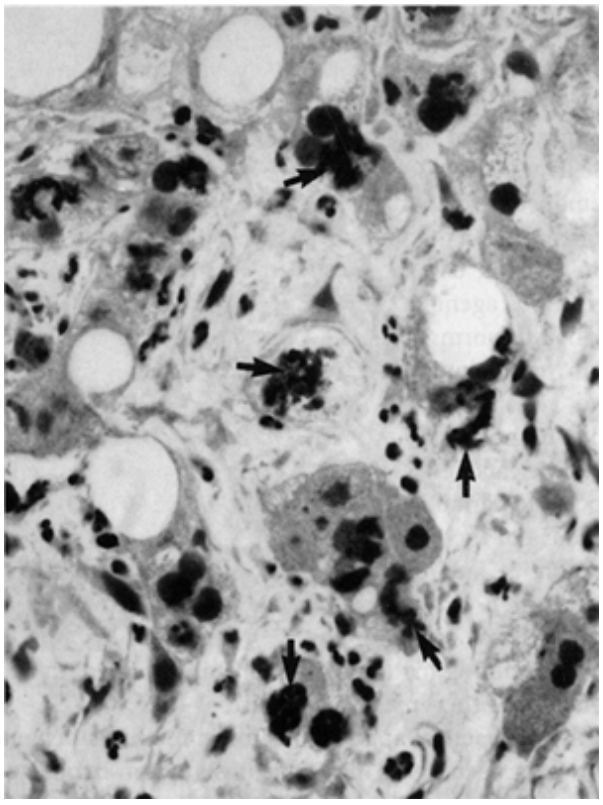
Transmission electron microscopy has many investigational but a limited number of diagnostic applications (6). Its greatest value is in the interpretation of biopsy specimens from patients with known or suspected metabolic disorders, and it can also be helpful in drug-induced and cholestatic diseases and in some infections. Among the metabolic diseases, distinctive or pathognomonic ultrastructural findings are present in hereditary fructose intolerance, α_1-antitrypsin

deficiency, Farber's disease, glycogenoses types II and IV, Gaucher's disease, metachromatic leukodystrophy, Dubin-Johnson syndrome, erythropoietic protoporphyria, Wilson disease, Zellweger syndrome, and many others. Drug-induced injury causes changes in many organelles of the liver depending on the drug, duration of use, and other factors. Many drugs (e.g., phenytoin, phenobarbital) and toxins (e.g., DDT [2,2-bis(*p*-chlorophenyl)-1,1,1,-trichloroethane] and other pesticides) cause proliferation of the smooth endoplasmic reticulum of liver cells ("induced" hepatocytes), which results in a characteristic ground-glass appearance on light microscopy. Megamitochondria, sometimes assuming monstrous forms, are considered typical of drug reactions, while lysosomal phospholipidosis is highly typical of several drugs (e.g., amiodarone). Subtle manifestations of cholestasis due to a variety of causes can be seen ultrastructurally before becoming recognizable by light microscopy. Among infectious agents, viral particles can be visualized directly in herpes simplex, adenovirus, and CMV infections, and both incomplete and complete particles of hepatitis B can be seen in infected liver cells.



▪ **Figure 9.11** Immunostain with polyclonal antibodies to carcinoembryonic antigen demonstrates dark-staining bile canaliculi between hepatocytes.

Scanning electron microscopy has also proved more useful for investigation than for diagnosis. The diagnostic applications of this technique are largely limited to particulate material, especially when x-ray spectrophotometry (also called *electron probe analysis*) is combined with scanning electron microscopy (7). Using this technique, the elements that are present in particulate material, such as talc, Thorotrast, silicone, silica, titanium, gold, and barium sulfate can be positively identified.



▪ **Figure 9.12** Immunostain with antibody to ubiquitin demonstrates dark-staining Mallory bodies (*arrows*) in liver cells in alcoholic hepatitis.

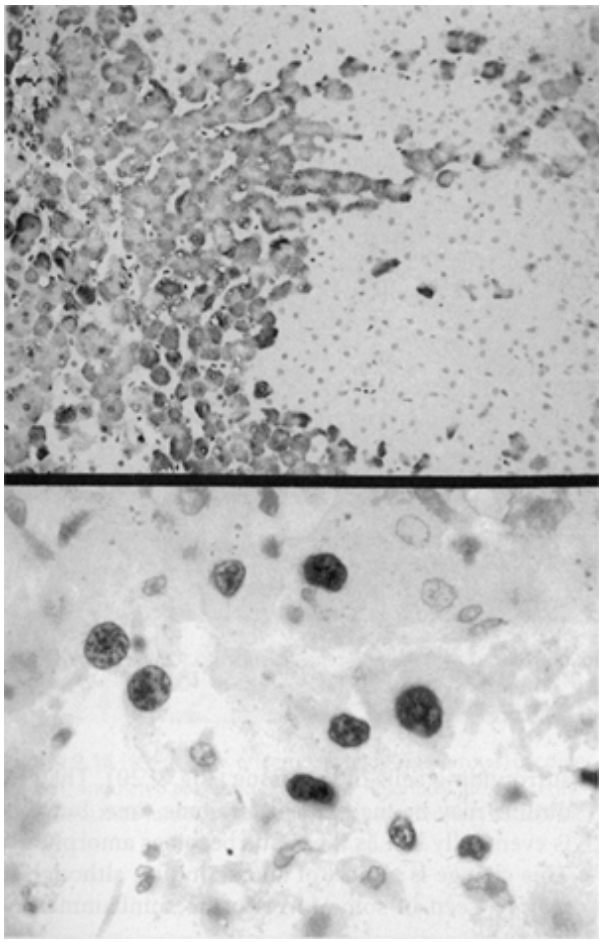
Other Special Techniques

In situ hybridization is used to detect genomic deoxyribonucleic acid (DNA) of the hepatitis B virus (HBV) (8), and there are reports of the use of in situ hybridization and in situ polymerase chain reaction (PCR) to demonstrate the presence of hepatitis C virus (9), but currently, these are essentially research techniques.

Polarizing microscopy is useful in identifying birefringent crystals of talc (Fig. 9.14) in portal macrophages or Kupffer cells in abusers of intravenous drugs (10). The remnants of previous surgery, such as suture material, talc, or starch from glove powder left on the surface of the liver are also birefringent in polarized light, as is silica in multiorgan silicosis (11). Type I collagen has a silvery birefringence, and amyloid has a characteristic apple green birefringence when sections stained with Congo red are examined by polarizing microscopy. Formalin pigment (typically in

blood vessels) and both malarial and schistosomal pigments (in

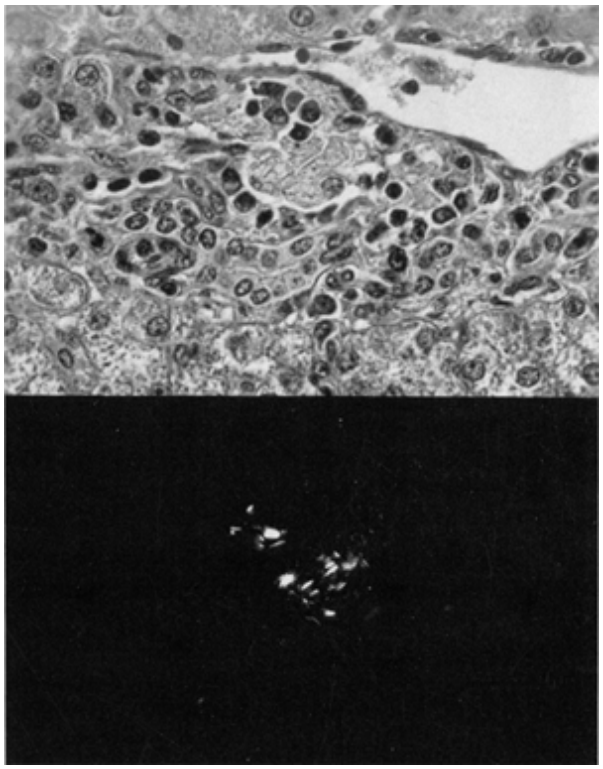
reticuloendothelial cells) are brown to black deposits of acid hematin and are birefringent under polarized light. Cholesterol crystals (e.g., in the livers of patients with Wolman's disease and cholesteryl ester storage disease) in frozen sections, whether stained or unstained, are birefringent, as are cystine crystals in cystinosis. Needle-like uroporphyrin crystals in liver cells can sometimes be visualized by polarizing microscopy of unstained frozen or paraffin sections in porphyria cutanea tarda (12). Red birefringent Maltese crosses and amorphous materials are characteristic of protoporphyrin accumulation in canaliculi or Kupffer cells in erythropoietic protoporphyria (Fig. 9.15) (13).



▪ **Figure 9.13** Immunostains for hepatitis B antigens. Antibody to HBsAg (*top*) shows variable amounts of the antigen in the cytoplasm of some hepatocytes. Antibody to HBcAg (*bottom*) shows the antigen in nuclei of liver cells with replicative virus.

Ultraviolet (UV) microscopy is most useful in confirming the diagnosis in the hepatic porphyrias. However, unfixed, air-dried frozen sections are required, so the usefulness of the technique is limited. Nevertheless,

frozen sections of the liver in porphyria cutanea tarda and erythropoietic protophorphyria reveal red autofluorescence under UV microscopy because of the presence of porphyrins. Vitamin A stored in stellate cells has a green and rapidly fading autofluorescence in UV light, while a granular yellow autofluorescence is characteristic of lipofuscin.



▪ **Figure 9.14** Portal macrophages in the center of field (*top*) contain talc crystals, which are birefringent and easily visualized with polarizing microscopy (*bottom*).

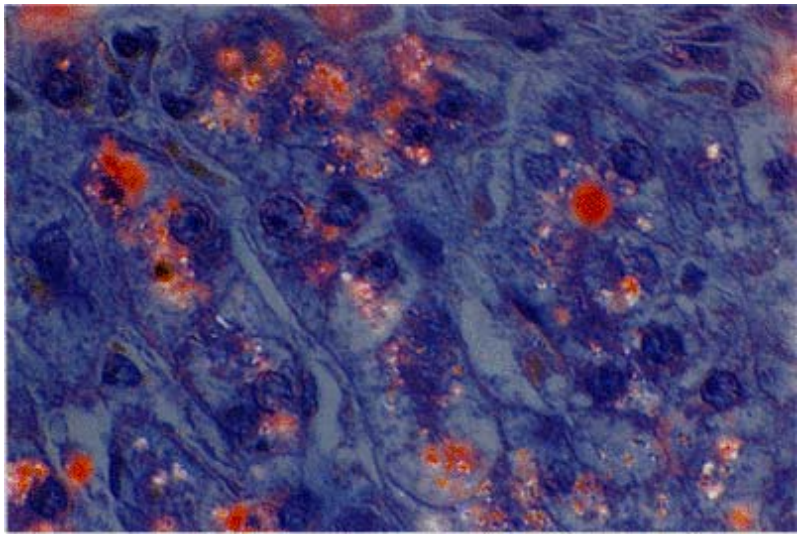
Morphologic Patterns of Injury

Acute Necroinflammatory Disease (Acute Hepatitis)

Acute necroinflammatory disease is typically seen in case of acute infections with the hepatitis viruses, but identical injury may occur with hepatitis-like reactions to a number of therapeutic drugs (see Chapter 33). Hepatocellular injury, leading to cell death, is the predominant morphologic feature of acute necroinflammatory diseases, although the term *necroinflammatory* has become something of a misnomer in view of recent advances in pathobiology. The term *necrosis*, previously used for all forms of cell death, is now applied more selectively to certain

forms of cell death. Many of the injured and dying cells seen in the various forms of hepatitis are actually in the process of apoptosis, while the "inflammatory" component is at times the effector of

apoptosis and at times the response to the hepatocellular injury. Nevertheless, for the purposes of this discussion, the term *necroinflammatory* will be maintained.



▪ **Figure 9.15** Deposits of protoporphyrin are birefringent and appear red in polarized light. Larger deposits show a characteristic Maltese cross.

Several basic lesions are seen in various forms of necroinflammatory injury:

1. *Apoptosis* (14, 15) results in the shrinkage of the hepatocyte, which often has an angular configuration and is more eosinophilic than its neighbors in the liver plate ("acidophilic degeneration") (Fig. 9.16). The nucleus is often pyknotic and deeply basophilic. The cytoplasm of the liver cell develops protuberances that separate and are released into spaces of Disse and sinusoids. The larger cell fragments, which may contain parts of the nucleus, have been termed *apoptotic, acidophilic*, or *hyaline* bodies (Figs. 9.17 and 9.18). The apoptotic bodies are quickly phagocytosed by Kupffer cells or adjoining liver cells, where they undergo degeneration and are reduced to residual bodies.
2. *Ballooning degeneration* refers to the swelling of hepatocytes, often to several times the normal size. Affected cells have an indistinct cell membrane, and the cytoplasm is rarefied (Figs. 9.18

and 9.19). The ballooned hepatocytes eventually undergo lysis, with disappearance or "dropping out." The remnants of these cells attract lymphocytes and, less often, other types of inflammatory cells ("focal necrosis"), as well as hypertrophied Kupffer cells.

3. *Coagulative necrosis* refers to a form of cell death recognized by deeply eosinophilic, granular cytoplasm with loss of the nucleus and discohesion from the surrounding cells of the tissue (Fig. 9.20). The cell outline may be maintained for some time, but this is eventually lost as the tissue becomes amorphous. This change is typical of anoxic injury, although it may be seen in some forms of necroinflammatory injury.
4. *Regeneration*, recognized by enlargement of nuclei and nucleoli, mitoses, binucleation, and thickening of liver cell plates (Fig. 9.21), may be seen shortly after the onset of a necroinflammatory injury such as viral hepatitis. The number of regenerating cells gradually increases as the patient recovers.
5. *Kupffer cell hypertrophy* is characteristic of acute necroinflammatory injuries. Sinusoidal macrophages are normally inconspicuous, but in response to liver cell death, these enlarge as they perform their phagocytic function, and they can be recognized by the presence of cytoplasmic light brown, finely granular lipofuscin presumed to be phagocytosed from necrotic hepatocytes (Figs. 9.21 and 9.22).

Acute necroinflammatory patterns

"Classic" acute hepatitis, typical of the common forms of acute viral hepatitis is characterized by panacinar necroinflammatory disease with spotty necrosis. The appearance of the liver is one of acinar disarray (Fig. 9.23) caused by widespread degeneration and death of individual and small groups of hepatocytes, which display features of both apoptosis and ballooning with focal necrosis. These are seen throughout the acinus in various combinations, and not all hepatocytes in a given acinus

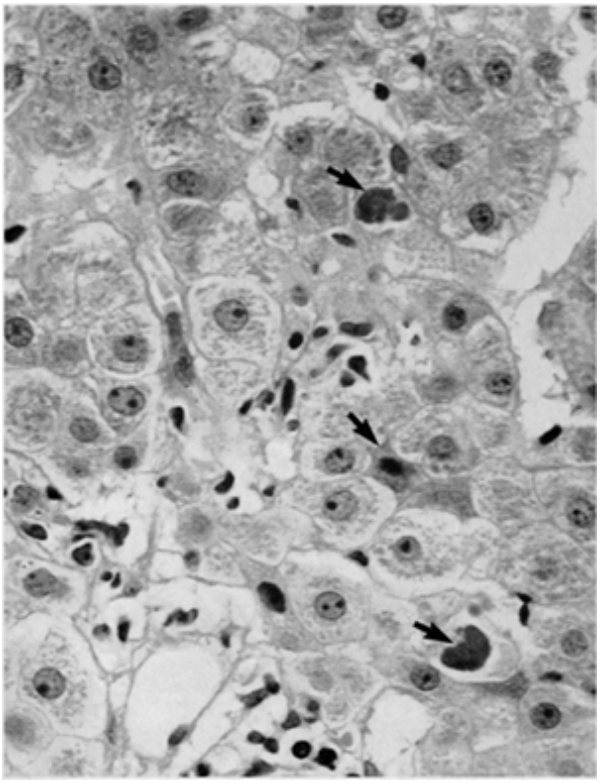
P.255

P.256

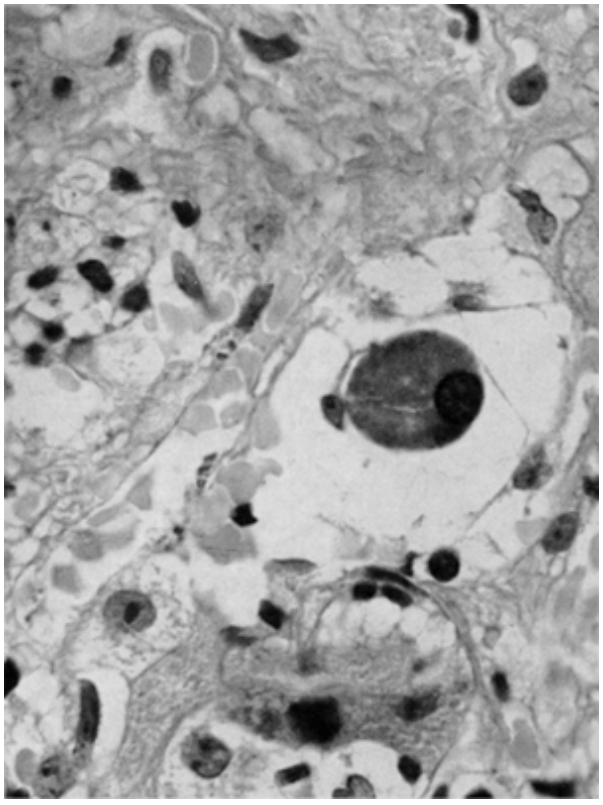
P.257

are affected. Features of regeneration are invariably present, and there is typically an inflammatory response consisting of hypertrophied Kupffer cells and lymphocytes. The portal areas in typical acute hepatitis are usually infiltrated with inflammatory cells. Lymphocytes predominate, but a small number of plasma cells, as well as eosinophils and neutrophils (especially in drug-induced disease), may be present. Occasionally, plasma cells predominate, especially in hepatitis A (16,17). The inflammatory response often extends beyond the confines

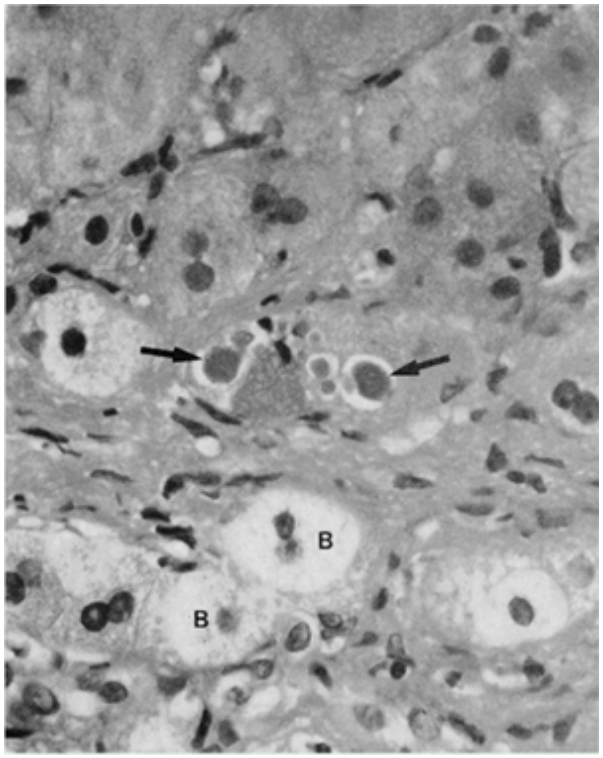
of the portal areas, leading to some blurring of the outline of the limiting plate and creating the appearance of interface hepatitis, as discussed later under chronic hepatitis. This also is especially true in hepatitis A (Fig. 9.24). Cholestasis is not a significant component of the histopathology of "classic" acute viral hepatitis, and when present, it is usually seen as an occasional, haphazardly distributed canalicular bile plug. Occasional cases may reveal abnormalities of the bile ductal epithelium, including swelling, disruption, and infiltration by lymphocytes, which constitute the hepatitis-associated bile duct lesions that are discussed in the section on chronic hepatitis.



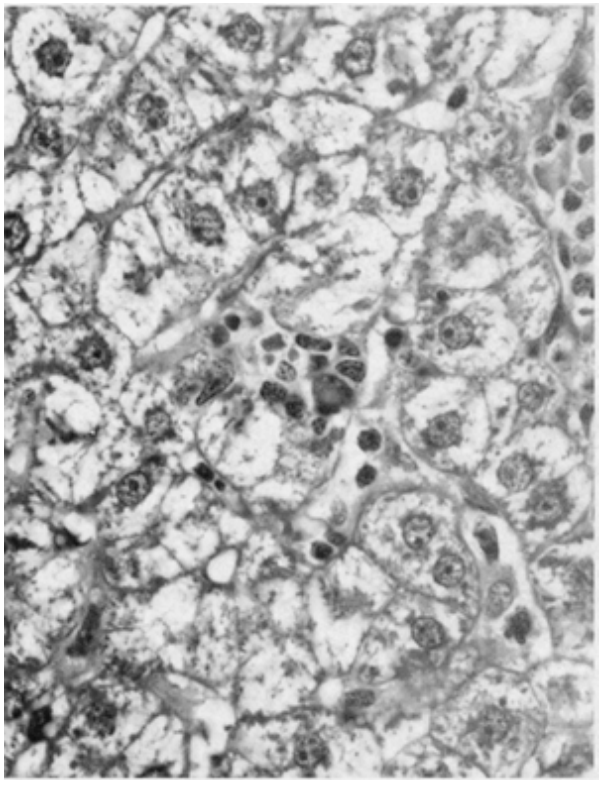
▪ **Figure 9.16** Hepatocytes undergoing apoptosis (*arrows*) become shrunken, angulated and darker than their neighbors (*arrow*, center of field), lose their nuclei and begin to fragment, forming acidophilic bodies.



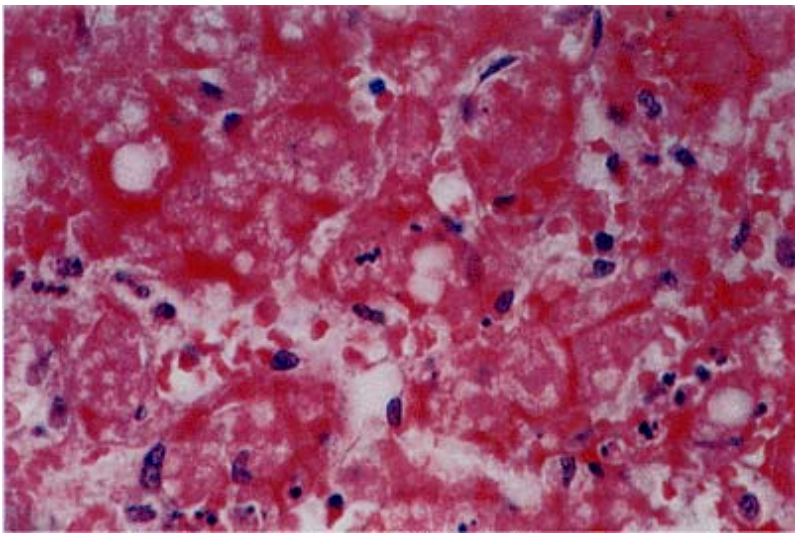
▪ **Figure 9.17** High magnification of an acidophilic body that has been extruded from the liver cell plate into a sinusoid. Most of the degenerated nucleus of the dead hepatocyte remains.



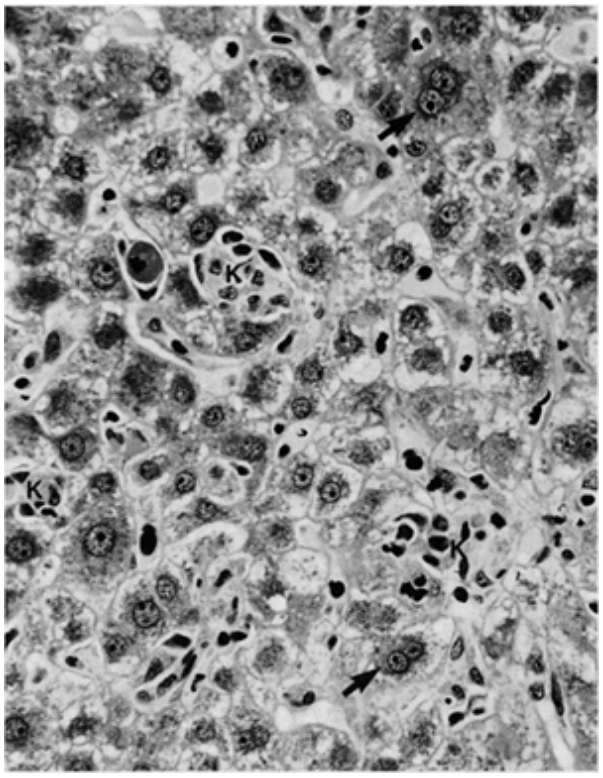
▪ **Figure 9.18** Cellular degeneration and death with apoptotic bodies (*arrows*), and ballooning (*B*).



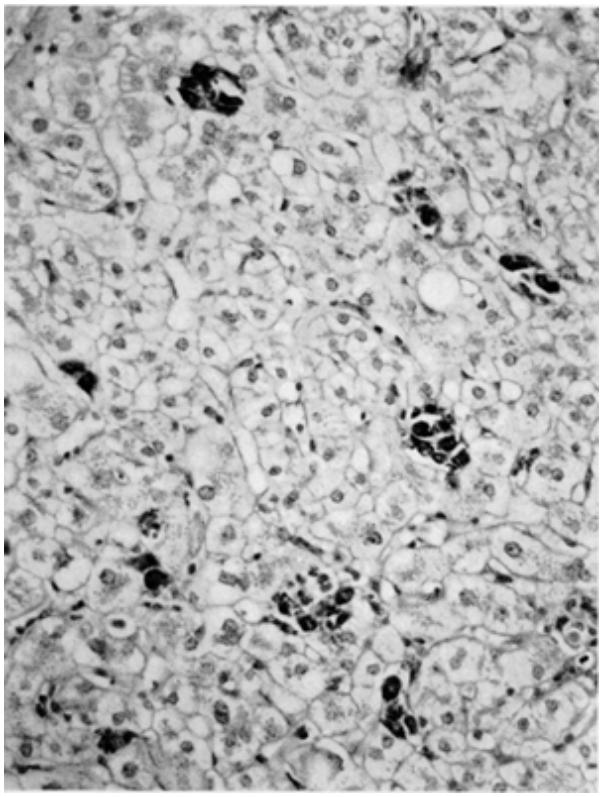
▪ **Figure 9.19** Ballooning degeneration. The hepatocytes are swollen and pale. A cluster of inflammatory cells ("focal necrosis") in the center of the field shows the position where a hepatocyte has disappeared from the tissue.



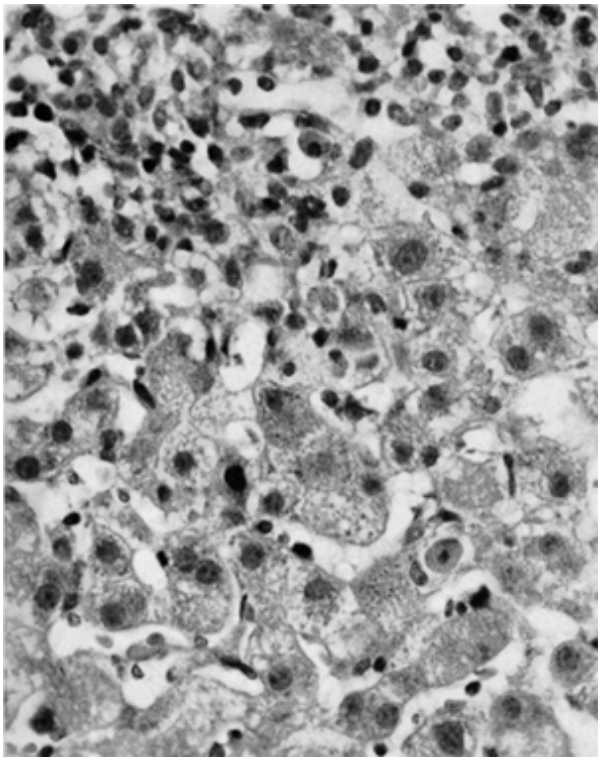
▪ **Figure 9.20** Coagulative necrosis in a case of ischemic injury. The cytoplasm of the necrotic cells is eosinophilic and granular, and the nuclei have disappeared.



▪ **Figure 9.21** Active necroinflammatory injury with regenerating liver cells, recognizable by enlarged nuclei, prominent nucleoli, and binucleate liver cells (*arrows*). Clusters of hypertrophied Kupffer cells (*K*) are present at sites of liver cell dropout.

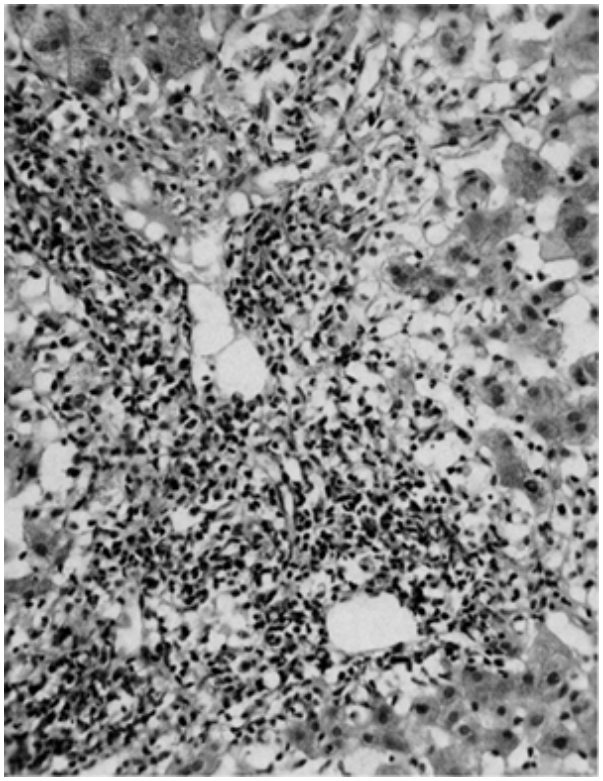


▪ **Figure 9.22** The periodic acid-Schiff stain after diastase digestion demonstrates clusters of hypertrophied, lipofuscin-filled Kupffer cells (dark-staining) at the sites of liver cell dropout.



▪ **Figure 9.23** Acute viral hepatitis. Note acinar disarray, apoptosis, and focal necrosis, Kupffer cell hypertrophy, and lymphocytic infiltrate.

The subsiding phase of viral hepatitis is characterized by a lessening of the injury and inflammation with increased regeneration and repair. The differences between this and the active phase are, however, mainly quantitative. Acinar disarray diminishes and eventually disappears, and the hepatic parenchyma gradually reverts to a normal appearance over a period of several weeks to months, although varying degrees of unrest are still evident. The liver cell plates often appear thickened. Only occasional degenerating cells and small foci of inflammation are evident. A frequent finding is the continuing hypertrophy of Kupffer cells and portal macrophages (Fig. 9.22). They become relatively more conspicuous because the hepatocytes are less swollen, and they now contain variable amounts of hemosiderin in addition to lipofuscin. The portal area inflammatory response gradually diminishes. Uncomplicated viral hepatitis is not followed by any significant periportal or intra-acinar fibrosis.

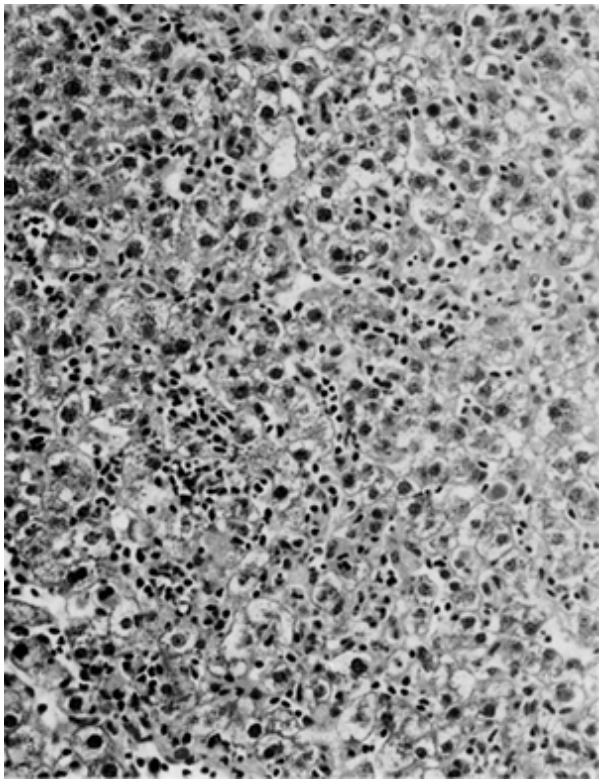


▪ **Figure 9.24** Acute hepatitis A, showing marked portal inflammation with extension into the adjacent parenchyma (interface hepatitis), mimicking the appearance of chronic hepatitis.

Mononucleosis hepatitis is typical of Epstein-Barr virus (EBV) and CMV infections in immunocompetant patients (18,19,20). Similar histology can be seen in reactions to some drugs, especially diphenylhydantoin (21), and we have also observed this reaction on occasion in acute hepatitis B or C, so a complete serologic workup is advisable whenever this pattern of injury is seen. In comparison with "classic" viral hepatitis, the inflammatory response in this variant is more prominent (Fig. 9.25) while the hepatocellular injury is milder. Hepatocellular regeneration is prominent, and mitotic figures are often seen in hepatocytes, Kupffer cells, and

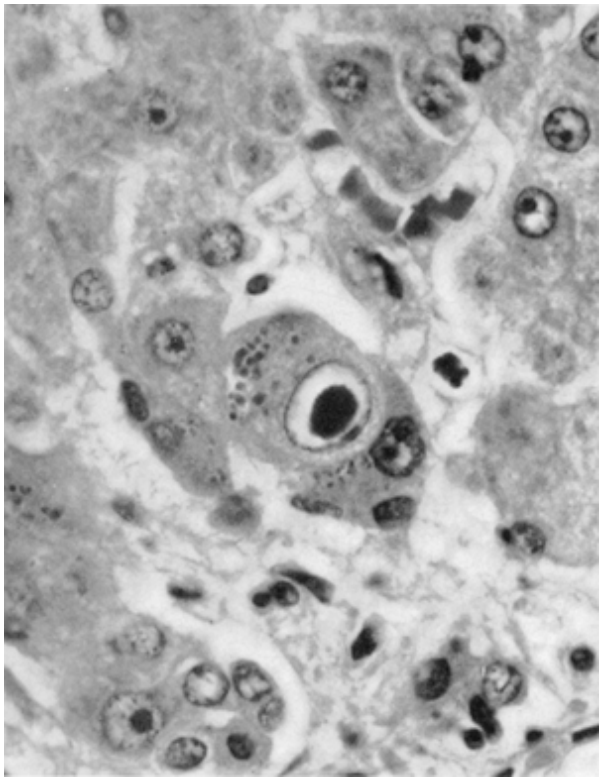
portal mononuclear cells. Apoptosis is present but ballooning is absent or minimal. Kupffer cells are often markedly hypertrophied and sometimes form tiny granulomatoid foci or, rarely, true granulomas. The hepatic sinusoids characteristically contain an increased number of lymphocytes, sometimes closely packed together in a "string of beads" pattern (Fig. 9.25). In CMV infection, cytomegaly and viral inclusions are never seen in immunocompetent patients, but in CMV infections of

the newborn, and of adults who are immunocompromised, characteristic intranuclear and cytoplasmic inclusions (Fig. 9.26) may be present in the bile duct and liver cells.



▪ **Figure 9.25** Infectious mononucleosis hepatitis. There is a prominent sinusoidal mononuclear cell infiltrate along with the hepatocellular injury of an acute hepatitis.

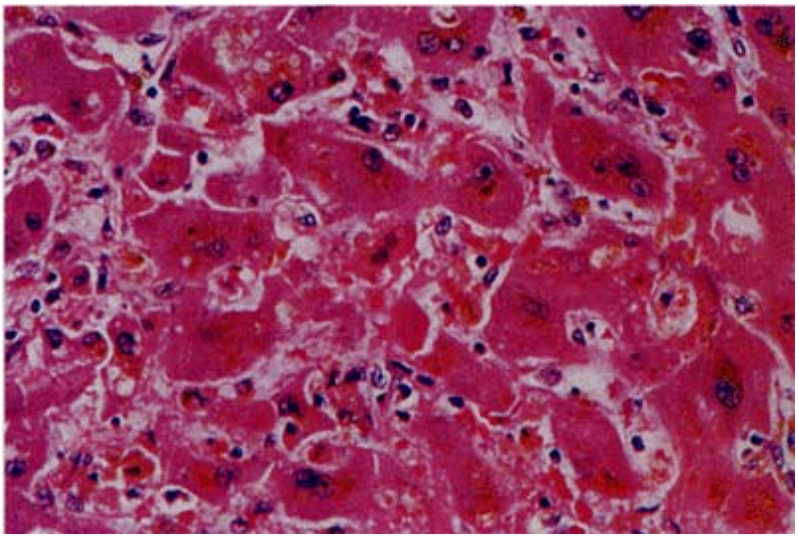
Cholestatic hepatitis, that is, combined hepatocellular and cholestatic injury, is an uncommon complication of most types of acute viral hepatitis, but it is frequent in hepatitis E infection (22). As a pattern of injury, it is more frequently seen in reactions to a number of drugs (23). Synonyms for cholestatic viral hepatitis include "cholangiolitic" or "pericholangitic" viral hepatitis, while drug-induced injury is termed *hepatocanalicular* or *mixed hepatocellular and cholestatic*. The clinical and laboratory findings tend to simulate those of obstructive biliary tract disease. The histopathology of cholestatic hepatitis includes hepatocellular and canalicular bile stasis, often with pseudogland formation, and variable degrees of parenchymal injury (Fig. 9.27). There may be periportal ductular proliferation with infiltration by neutrophils (acute cholangiolitis), as well as many neutrophils in the portal inflammatory infiltrate, but the acinar bile ducts are not involved.



• **Figure 9.26** Cytomegalovirus infection in an immunodeficient host. The large cell in the center of the field has a characteristic intranuclear inclusion and many small cytoplasmic inclusions.

Neonatal giant cell hepatitis typically has features of acute hepatitis with transformation of hepatocytes into multinucleate giant cells. Newborns with this disease typically present with jaundice, and the principal differential diagnosis is between this and extrahepatic biliary atresia (see Chapter 47). The term *idiopathic neonatal hepatitis* is used for most cases in which no cause is found, but the features seen in some neonates with α_1-antitrypsin deficiency may be identical to those seen in a number of other metabolic disorders and infections. The "idiopathic" cases are presumably secondary to undiagnosed viruses because most patients recover without sequellae. Histologically, all the features of acute hepatitis are present, along with significant bile stasis, but the most striking feature is giant cell transformation of hepatocytes (Fig. 9.28). The giant cells appear to result from the fusion of several liver cells to form a syncytium, and there may be up to several dozen nuclei in a single cell. The cholestasis may be quite prominent and there is often extramedullary hematopoiesis. Portal fibrosis and ductular proliferation, typical of biliary atresia, are not seen. Hepatocellular injury with giant

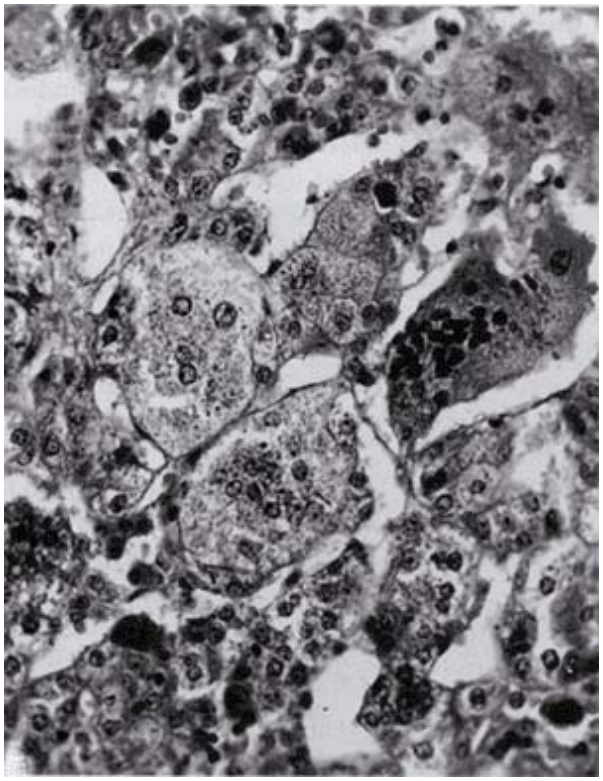
cell transformation also occurs in neonatal hemochromatosis, along with massive iron overload.



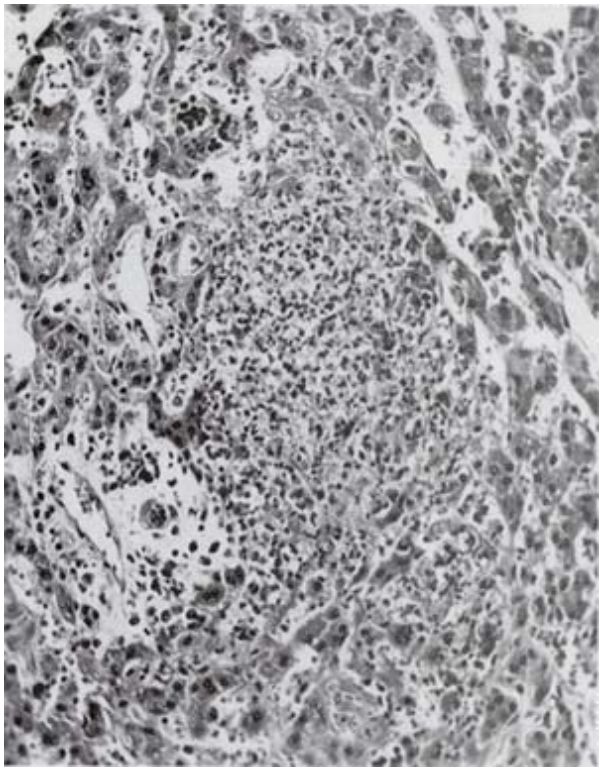
▪ **Figure 9.27** Acute cholestatic hepatitis (combined hepatocellular–cholestatic injury). There is prominent cholestasis, as well as hepatocellular injury, acidophilic bodies, liver cell dropout, and inflammation.

Acute injury with microabscess formation is typical of a number of bacterial infections complicated by sepsis or hematogenous dissemination. This includes diseases caused by both gram-positive and gram-negative organisms, such as listeriosis (Fig. 9.29), melioidosis, and typhoid fever, as well as disseminated mycotic infections such as those caused by *Cryptococcus, Candida*, or *Aspergillus* species. Organisms may or may not be

demonstrable in the lesions. In the immunocompromised host, CMV infection can also lead to this type of tissue response (with or without viral inclusions) in the liver. In all these diseases, lesions typically consist of varying-sized microabscesses, but they sometimes have a granulomatoid appearance. In CMV infection, the lesions are quite small, often only a single degenerating hepatocyte surrounded by neutrophils (sometimes containing an intranuclear inclusion), whereas bacterial and fungal infections may have grossly visible abscesses. In the later stages, lesions may have a purulent center and an organized granulomatous periphery, with variable fibrosis, especially in diseases such as meliodosis or typhoid.



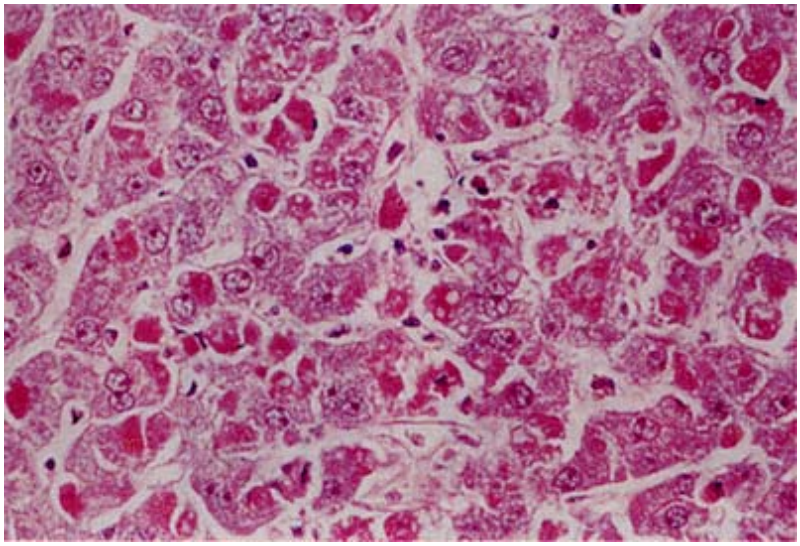
▪ **Figure 9.28** Idiopathic neonatal hepatitis with giant cell transformation. Note the enlarged hepatocytes containing numerous nuclei.



▪ **Figure 9.29** Listeriosis. A microabscess is present in the center of the field because of hematogenous dissemination of the infection.

Not all focal necrosis with a neutrophilic response or microabscess formation is infectious. Focal necrosis with an outpouring of neutrophils is also the characteristic reaction to degenerating liver cells harboring Mallory bodies in steatohepatitis, alcoholic or nonalcoholic. Perivenular focal necrosis with neutrophilic aggregation is an iatrogenic artifact often observed in open surgical biopsy specimens of the liver.

Acute injury with focal coagulative necrosis is seen in some viral infections in children, for example, coxsackie B4 and B9, but more importantly, this type of injury is typical of hepatic involvement in many types of viral hemorrhagic fevers, including yellow fever (Fig. 9.30), dengue, Lassa fever, and others (24). Haphazardly distributed single liver cells or clusters of liver cells are affected by coagulation necrosis, often with little or no inflammatory response. Viral inclusions are not present in any of these diseases.



▪ **Figure 9.30** Yellow fever. Many individual hepatocytes display coagulative necrosis in a haphazard distribution.

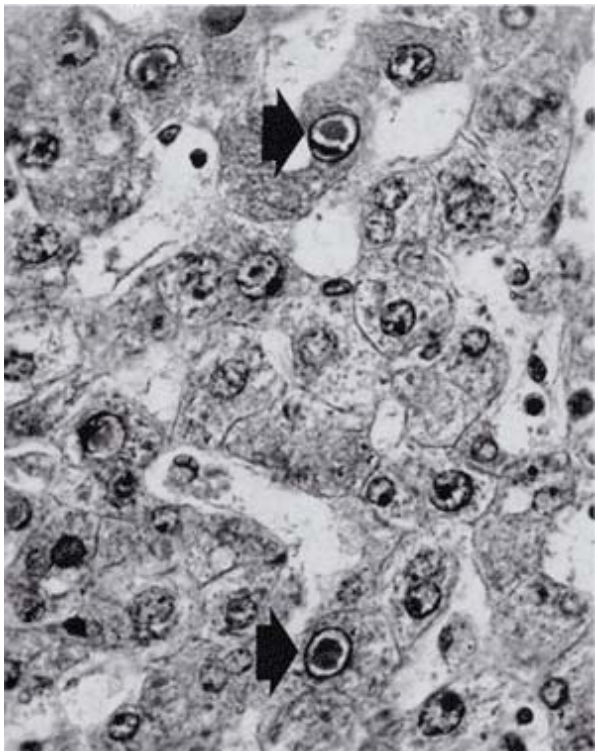
Acute injury with patchy or confluent coagulative necrosis is seen in disseminated herpes simplex hepatitis, whether occurring in neonates, children, or adults (25), both immunocompetent and immunocompromised. Similar findings are rarely seen in adenovirus hepatitis in immunocompromised patients (26). Viral inclusions are most easily identified in the relatively preserved hepatocytes at the margins of the necrotic foci. In herpes simplex, the classical Cowdry type A inclusions are eosinophilic, rounded or irregular, and surrounded by a clear halo with margination of the chromatin (Fig. 9.31). Adenovirus inclusions are more pleomorphic. Some resemble the Cowdry type A inclusions of herpes simplex but many are more basophilic and irregular in contour.

Acute injury with zonal submassive or massive coagulative necrosis is typical of toxic injury from a number of direct hepatotoxins, although it may also be produced by ischemic injury. Among toxins, acetaminophen overdose is by far the most frequent cause of this type of injury (27). The tissue maintains its acinar architecture, but hepatocytes in zone 3 are entirely necrotic (Fig. 9.32), with progressive involvement of zones 2 and 1 with increasing severity of injury. In the most severe cases, only a thin rim of viable hepatocytes surrounds each portal area.

Acute hepatitis with submassive necrosis and stromal collapse can be seen with severe hepatitis of any cause. This pattern of injury is more frequently encountered in biopsy and with surgical material from patients having drug-induced liver disease than in viral hepatitis, partly because patients with acute viral hepatitis are rarely subjected to

biopsy and because drug-induced injury tends, on average, to be more severe than viral

hepatitis, and also because many drugs are preferentially metabolized by hepatocytes of zone 3, thereby having the greatest toxic effects in this part of the acinus. There are patients who have not been exposed to a drug or chemical but develop fulminant liver failure with submassive or massive hepatic necrosis and in whom no evidence for any of the known hepatitis viruses can be found serologically or by PCR for viral DNA or ribonucleic acid (RNA) (27,28). These may be caused by some as yet undiscovered viral agent, but for now they remain enigmatic and unclassified. Finally, autoimmune hepatitis, although considered a chronic disease, often has an acute clinical presentation, and biopsies from the patients with this type of hepatitis may also show an appearance of acute hepatitis with submassive necrosis (29).



▪ **Figure 9.31** Herpes simplex hepatitis. Several of the nuclei have eosinophilic Cowdry type A inclusions surrounded by a clear halo with margination of the chromatin (*arrows*).

Submassive necrosis of any cause is due to the simultaneous death of the hepatocytes of an entire zone or more of the hepatic acini, thereby producing confluent necrosis, lysis of the necrotic tissue, and collapse of the supporting stroma. The necrosis usually involves zone 3 and, less often, zone 2 of the hepatic acini (Fig. 9.33), but viral hepatitis A and

injury due to some drugs and toxins are characterized by necrosis predominantly involving zone 1 (Fig. 9.34). In various planes of the section, acinar zone 3 necrosis may appear to be entirely around the terminal hepatic venule ("centrilobular"), may appear to extend between the terminal venules of adjacent acini, or may extend from the terminal venule to the edge of the portal area. Consequently, when necrosis affects zone 3, the collapsed reticulin framework may extend between adjacent vascular structures, making them appear linked together ("bridging necrosis"), and there may be linkage of portal areas with terminal hepatic venules ("portal–central bridging") or of two or more terminal hepatic venules ("central–central bridging"), both due to submassive zone 3 necrosis.

Acute hepatitis with massive necrosis, the most extreme form of acute hepatocellular injury, may be caused by viral hepatitis or drug-induced liver disease. There is virtually complete loss of hepatocytes (Fig. 9.35), but occasionally, the haphazardly distributed cells can survive, as can a cuff of cells around portal areas. The reticulin framework is usually intact but frequently collapsed because of loss of liver cells, with resultant approximation of portal areas. Variable numbers of inflammatory cells are present in the areas of collapse. These include lymphocytes and plasma cells, as well as a lesser number of eosinophils and neutrophils. Central vein endophlebitis may be present. The collapsed parenchyma contains numerous hypertrophied Kupffer cells with cytoplasm packed with lipofuscin. Zone 1 of the hepatic acinus typically shows proliferation of the putative hepatic stem cells (Fig. 9.36), forming ductules and ductular hepatocytes (30).

Chronic Necroinflammatory Injury (Chronic Hepatitis)

Chronic necroinflammatory disease refers to a morphologic pattern that is seen most often not only in chronic viral hepatitis but also in autoimmune hepatitis, occasional drug reactions, and, in rare instances, some metabolic diseases. As in acute necroinflammatory disease, there is hepatocellular injury and inflammation, but in the chronic diseases, the brunt of the injury tends to be portal and periportal rather than panacinar, and the injury is accompanied by fibrosis that can progress to cirrhosis. Chronic hepatitis, regardless of cause, is characterized by several pathologic changes that are present to a variable extent in each case. These include portal inflammation and sometimes lesions of bile ducts within the portal spaces; periportal injury and inflammation; several forms of degeneration and death by apoptosis of intra-acinar hepatocytes with an associated inflammatory response; and fibrosis that may involve only the portal and periportal areas or that may form septa.

Morphology of chronic hepatitis

Portal inflammation—in all forms of chronic hepatitis the portal areas are variably infiltrated by lymphocytes and plasma cells. Lymphoid aggregates or follicles with

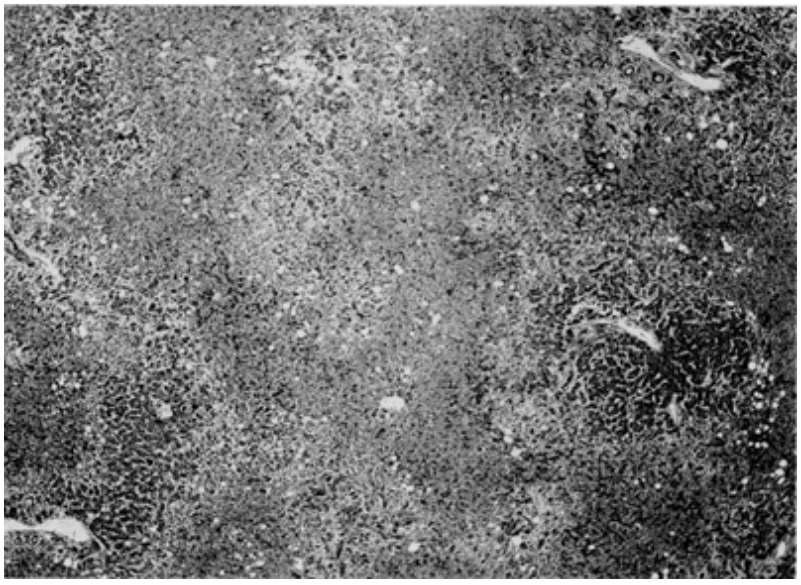
P.262

P.263

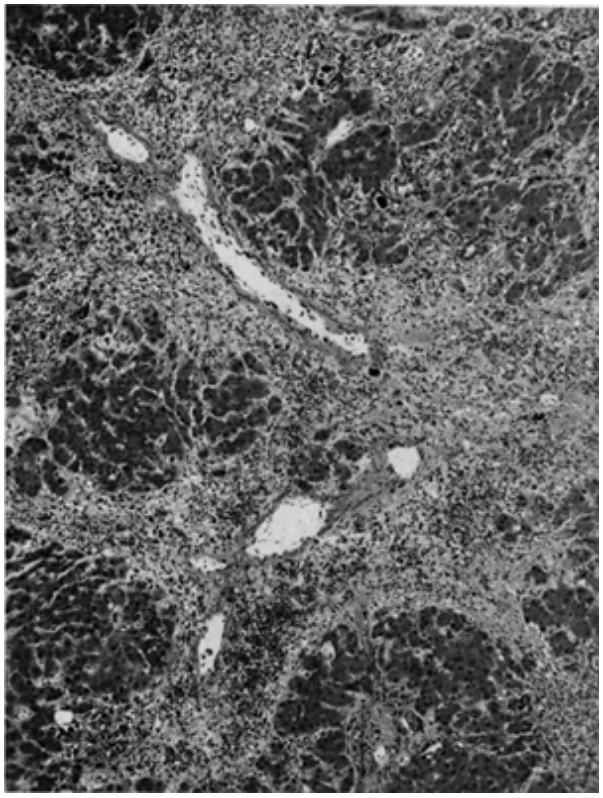
germinal centers may be present and are now considered typical, although not pathognomonic, of chronic hepatitis C (Fig. 9.37). Immunohistochemical studies have shown that even when germinal centers are not apparent by light microscopy, these are true functional lymphoid follicles (31). The germinal centers contain activated B cells surrounded by a follicular dendritic cell network and a mantle zone of B cells, which, in turn, is surrounded by a T-cell zone. Patients with autoimmune hepatitis will often

P.264

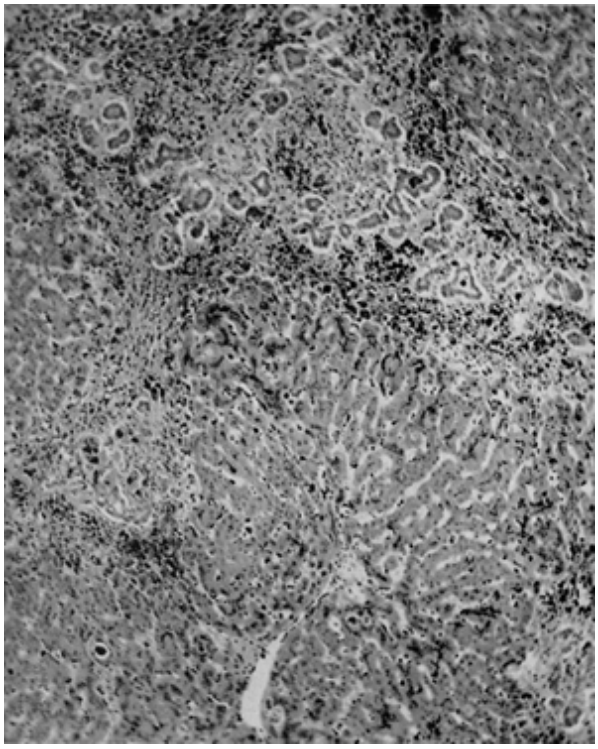
have large numbers or plasma cells in the portal inflammatory infiltrate (Fig. 9.38). Biopsy specimens from patients who are affected by chronic hepatitis through intravenous drug abuse may have birefringent talc crystals in portal macrophages (Fig. 9.14) (10).



▪ **Figure 9.32** Submassive zonal coagulative necrosis in a fatal case of acetaminophen overdose. The necrotic hepatocytes of zones 2 and 3 are present in the section, while some of the zone 1 (periportal) cells survive.

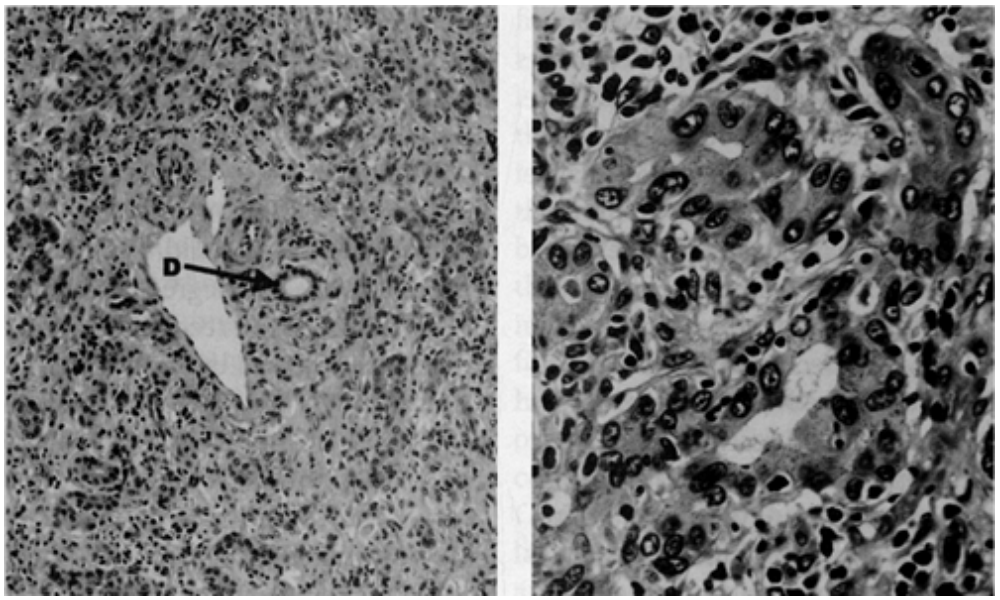


▪ **Figure 9.33** Acute submassive necrosis of acinar zones 3 and 2. Surviving liver cells are predominantly periportal in zone 1 of the acini. In contrast to the coagulative necrosis shown in Figure 9.32, there is a collapse of the stroma where the hepatocytes have been lost.



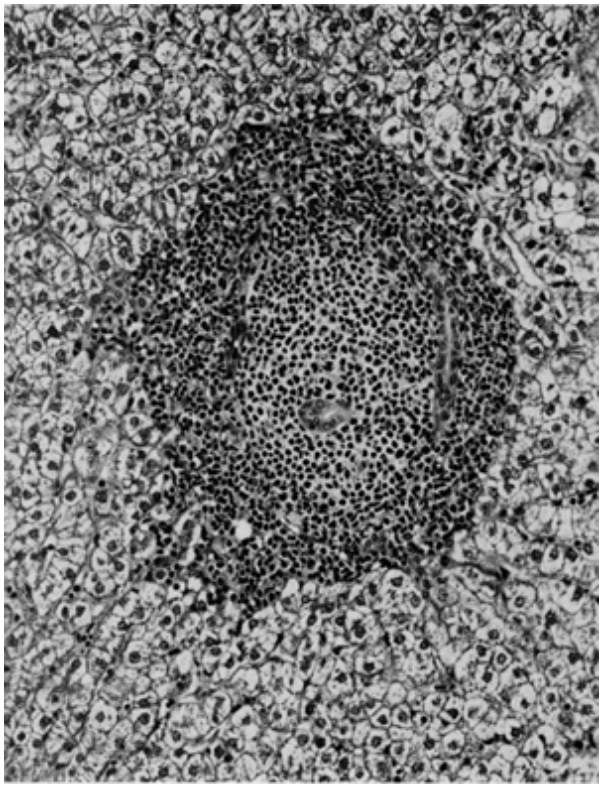
▪ **Figure 9.34** Acute submassive necrosis of zone 1. With the Prussian blue stain, hemosiderin-laden macrophages (dark-staining) are shown to outline the areas of periportal necrosis and liver cell loss.

▪ **Figure 9.35** Acute hepatitis with massive hepatic necrosis. There is loss of all hepatocytes with proliferation of ductules in the collapsed hepatic stroma.

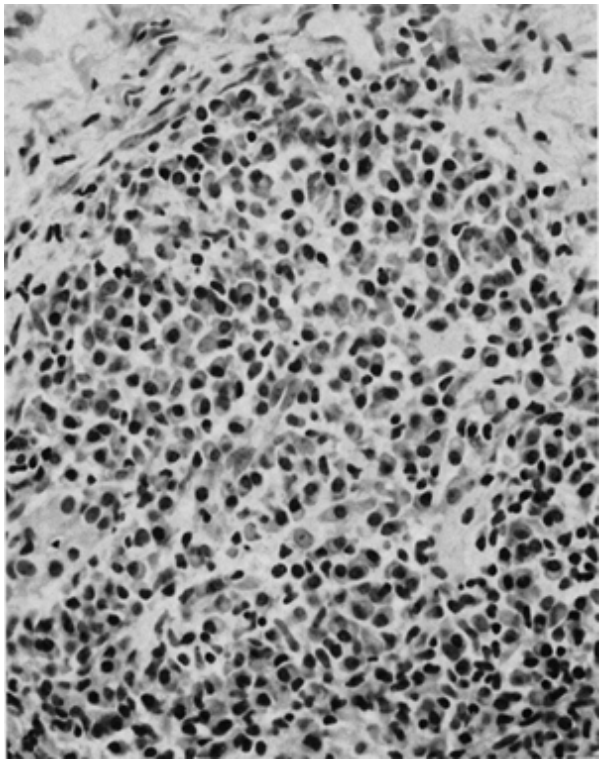


▪ **Figure 9.36** Ductular proliferation in massive hepatic necrosis.

The putative stem cells of the liver have proliferated, forming ductules and differentiating into hepatocytes in a vain attempt to repopulate the liver. The *left panel* has a portal area with an acinar bile duct (*D*) surrounded by collapsed stroma that contains proliferating ductules and inflammatory cells. The *right panel* shows ductules at high magnification. Some of the ductular cells have granular, eosinophilic cytoplasm, indicating differentiation into hepatocytes.



▪ **Figure 9.37** Chronic portal inflammation with a lymphoid aggregate that has a germinal center in a patient with chronic hepatitis C.



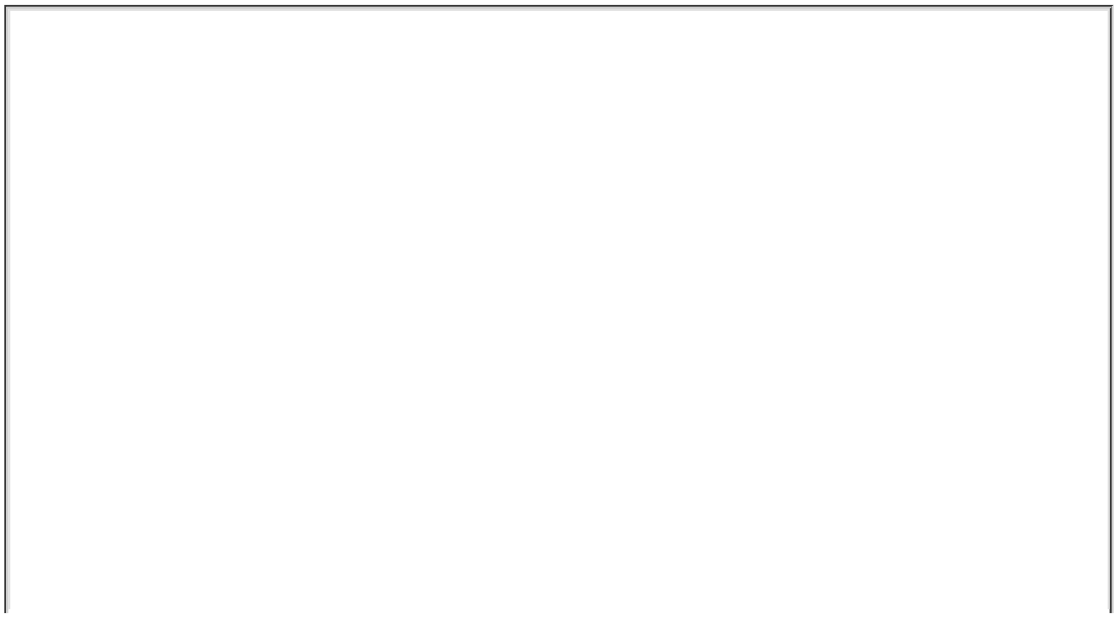
▪ **Figure 9.38** Autoimmune hepatitis with large number of portal plasma cells, recognizable by their eccentric nuclei and clear perinuclear Golgi zone.

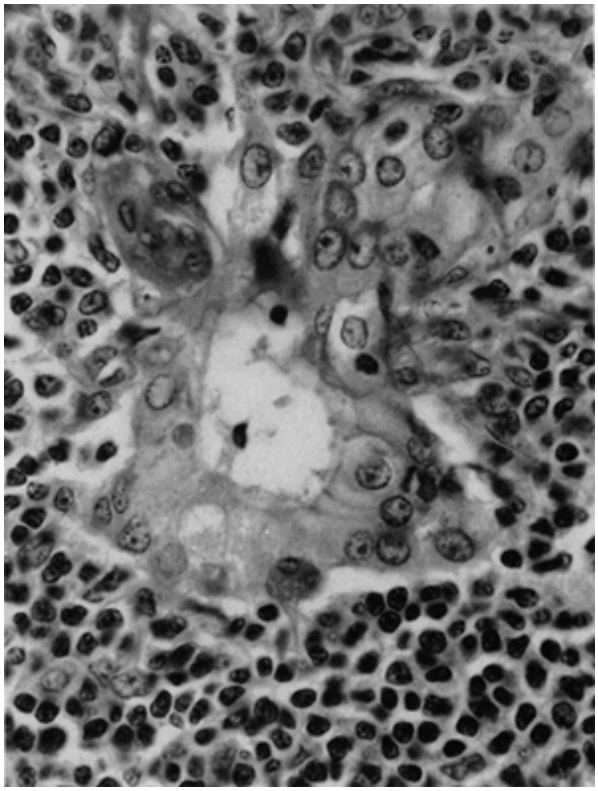
Hepatitis-associated bile duct lesions were first described in chronic hepatitis (32), but lesions may also be found in biopsy specimens of acute hepatitis. The lesion is characterized by swelling, vacuolization, nuclear irregularity, and sometimes, pseudostratification of the biliary epithelial cells (Fig. 9.39). The basement membrane may appear to be ruptured, and lymphocytes, occasional plasma cells, and sometimes, neutrophils infiltrate the duct. The lesion is reminiscent of and sometimes indistinguishable from the "florid duct lesions" of PBC. However, in contrast to the lesions of PBC, the ducts are not destroyed, and so portal areas without ducts are seldom seen and features of chronic cholestasis do not develop. Serial section reconstruction studies (33) have demonstrated that the most frequently observed lesions are actually blind diverticula arising from injured ducts rather than the ducts themselves. The ductal lesions have been seen in all forms of hepatitis, but most commonly in hepatitis C (34).

Interface hepatitis is now the preferred term for the lesion formerly known as *piecemeal necrosis* (35). The original term was defined by an international group as "the destruction of liver cells at an interface between parenchyma and connective tissue, together with a

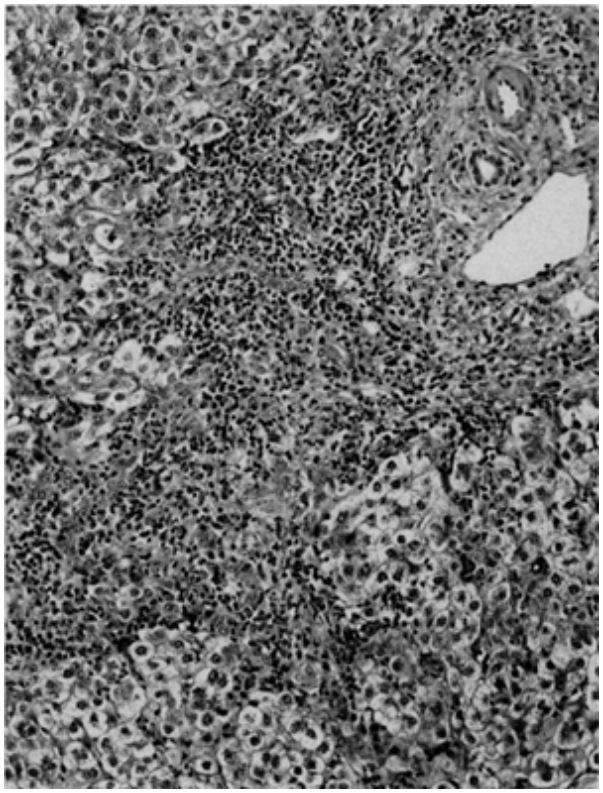
predominantly lymphocytic or plasma cell infiltrate" (36). It is now apparent that the destruction of liver cells is primarily through apoptosis, and because the dead hepatocytes quickly disappear from the tissue, it is the location of the inflammatory component that permits recognition of the lesion, making *interface hepatitis* the more accurate term. *Interface hepatitis* has long been considered to be a key lesion in the progression and pathogenesis of chronic hepatitis, and the degree of periportal injury (mild, moderate, or marked) is still used to grade the degree of activity. Interface hepatitis can be most easily recognized as irregularity of the limiting plate, caused by extension of the portal inflammation through the plate into the periportal parenchyma (Fig. 9.40). The limiting plate becomes irregular and may disappear as the portal area expands. Inflammatory cells surround and invade injured hepatocytes ("emperipolesis"). There may be evidence of hepatocellular degeneration and death, characterized by either acidophilic or ballooning degeneration. As in acute hepatitis, cell death occurs principally by the process of apoptosis, resulting in the formation of apoptotic or acidophilic bodies, which rapidly disappear from the liver

plates or sinusoids. As chronic hepatitis progresses, there is continuous erosion of the hepatic parenchyma, with closer and closer approximation of expanded portal areas, and small groups of hepatocytes ("hepatocytic islets") become trapped in expanded portal zones. The necroinflammatory changes are gradually succeeded by fibrosis, often best appreciated with a Masson or other collagen stain. Delicate collagen fibers laid down in areas of periportal liver cell loss eventually condense into scars. Interface hepatitis may not involve all the portal areas equally in a given biopsy specimen. It may affect either a segment or the entire perimeter of a portal area. Furthermore, even after cirrhosis has developed, interface hepatitis can continue unabated along the fibrous septa, causing further loss of parenchyma and, eventually, clinical decompensation of the cirrhosis.





▪ **Figure 9.39** Hepatitis-associated bile duct lesion with marked epithelial injury and infiltration by chronic inflammatory cells, similar to the florid duct lesions of primary biliary cirrhosis.



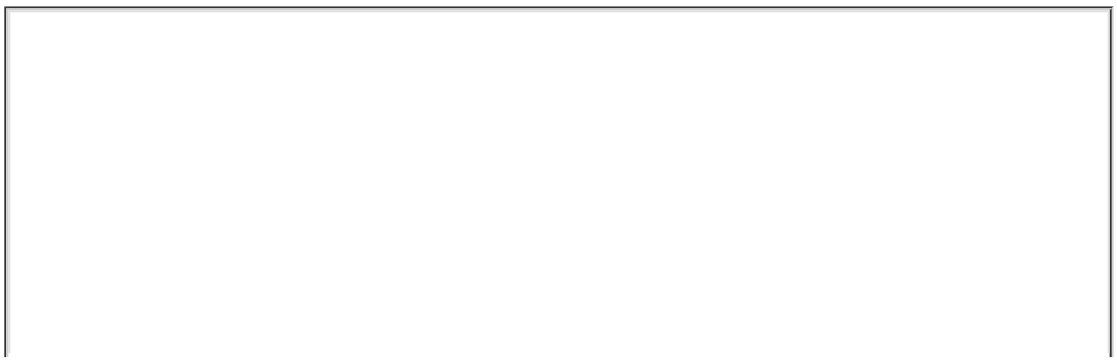
▪ **Figure 9.40** Interface hepatitis ("piecemeal necrosis") can be most easily recognized as irregularity of the limiting plate, caused by extension of portal inflammation through the plate into the periportal parenchyma.

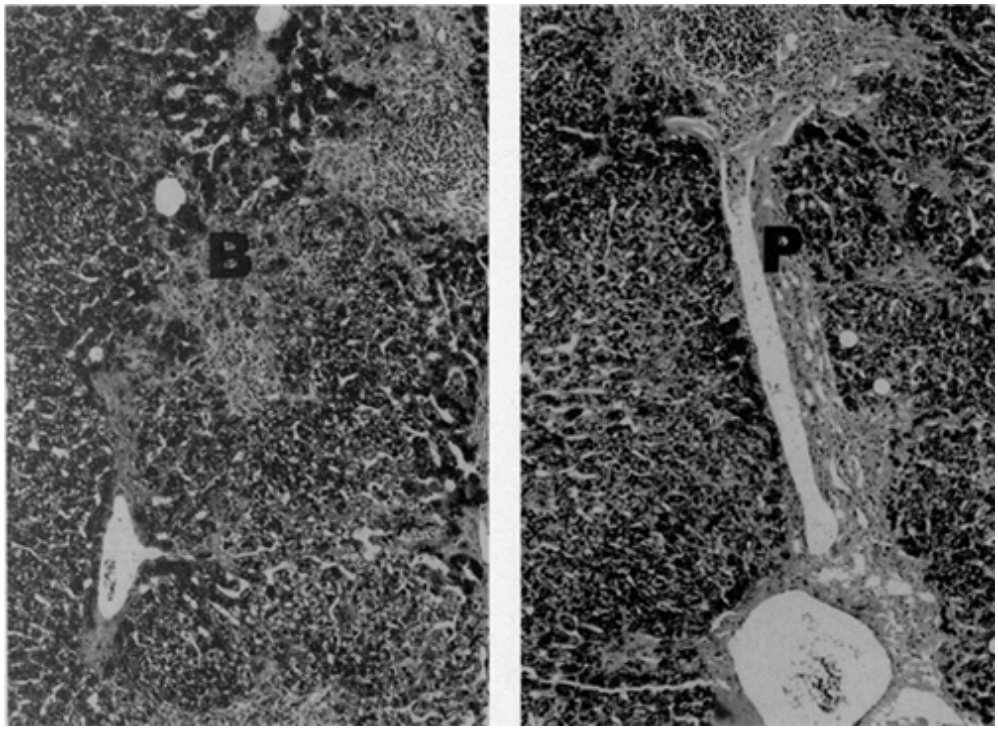
Parenchymal injury, causing intra-acinar necroinflammatory changes, is present to some degree in most biopsy specimens from patients with any type of chronic hepatitis. This is typically multifocal ("spotty") in distribution and consists mainly of apoptosis, as in acute hepatitis. Scattered apoptotic bodies of varied size are observed, as well as focal aggregates of lymphocytes, plasma cells, and hypertrophied Kupffer cells that have scavenged the apoptotic bodies and other debris, producing lesions traditionally called *focal or spotty necrosis*. More severe intra-acinar injury is generally seen when the biopsy is performed during an acute exacerbation of the chronic hepatitis, even if the patient is asymptomatic. Changes typical of acute hepatitis, superimposed on those of chronic hepatitis, may include an increase in the degree of spotty necrosis; ballooning degeneration, often most severe in zone 3, with dropout of hepatocytes and central–central or central–portal bridging necrosis, especially in autoimmune hepatitis; variable cholestasis, often with associated periportal ductular proliferation and infiltration of the ductules by neutrophils; or (in extreme cases) multiacinar necrosis with stromal collapse. There is

simultaneous regeneration of hepatocytes as cells are lost through apoptosis. This is typically seen in the form of two-cell thick plates and an increased number of bi- and trinucleated hepatocytes, but mitotic figures may occasionally be present. There may be some degree of steatosis, generally macrovesicular and of mild to moderate severity, most often in hepatitis C but also in chronic hepatitis of other causes.

Fibrosis is an almost invariable part of chronic hepatitis, although the degree of fibrous tissue deposition is quite variable from patient to patient. Fibrosis is the progressive component of the disease because it is the fibrous scarring that leads to architectural distortion and cirrhosis. It is thought that at least two pathways may lead to the fibrosis of chronic hepatitis. Probably most important in chronic viral hepatitis is the collagen deposition that accompanies the periportal injury of interface hepatitis, causing fibrous expansion of the portal tracts. As the disease progresses, portal–portal fibrous bridges are formed, filling zone 1 between adjacent acini. There may also be formation of "central–portal" and sometimes central–central fibrous bridges, which can develop from superimposed episodes of necrosis involving zone 3. In addition, it is likely that broad areas of fibrosis can result from the healing of bouts of multiacinar necrosis or from ischemic injury due to vascular damage secondary to the inflammation (see Chapter 7). In evaluating needle biopsies, it is important to distinguish tangential cuts through enlarged portal areas, which contain preexisting bile ducts and portal vessels, from true bridging fibrosis, which forms septa through parenchyma that had no preexisting fibrous tissue (Fig. 9.41). The scars of bridging fibrosis contain elastic fibers in addition to collagen. Like scars in any tissue, these tend to contract. Contraction of the fibrous septa in concert with nodular regeneration of the surviving parenchyma produces architectural distortion, and when complete nodules have formed, surrounded by fibrous septa, the result is the development of cirrhosis. Before the architecture is entirely obliterated, parts of the tissue are nodular while whereas adjacent areas maintain an acinar structure, a

state that can be regarded as an "incomplete" cirrhosis. When necroinflammatory changes continue along the septa and within the nodules, this may be considered active cirrhosis, or a term such as *chronic hepatitis with cirrhosis* may be used.





▪ **Figure 9.41** Bridging fibrosis (*B*) is scar tissue that forms across an area of parenchyma that had no preexisting fibrous tissue. It must be distinguished from tangential cuts through fibrotic preexisting portal areas (*P*), which contain bile ducts and arteries.

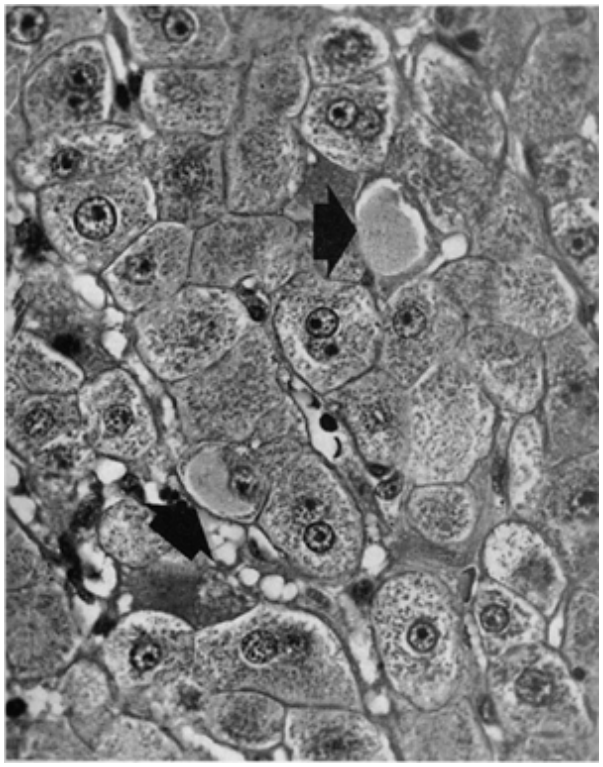
There are several known causes of chronic hepatitis, and although the histopathologic features are similar, there are some noteworthy features that are more characteristic of one type than another. Parenterally transmitted forms of viral hepatitis, which account for at least 90% of cases, are discussed in detail in Chapters 29 and 30. Approximately 5% to 10% of chronic hepatitis is autoimmune (see Chapter 31). Drug-induced liver disease is a rare but well-documented cause of chronic hepatitis (23), and if the other known causes are excluded, this should always be considered and evaluated clinically with a complete drug history. Metabolic diseases, such as Wilson disease, α_1-antitrypsin deficiency, and hemochromatosis are sometimes listed in textbooks and reviews as causes of chronic hepatitis, but because these are usually readily distinguished from chronic hepatitis by liver biopsy and laboratory tests, they are considered separately in this chapter.

Hepatitis B can be diagnosed histologically and distinguished from other causes of chronic hepatitis by demonstration of the virus in tissue. Hepatitis B surface antigen (HBsAg) can be demonstrated by histochemical stains (orcein or Victoria blue, Fig. 9.8) or the more sensitive immunostains (Fig. 9.13) in 80% or more cases of chronic

hepatitis B. Cells containing large quantities of HBsAg have cytoplasm with a uniform finely granular appearance, the so-called ground-glass cells (Fig. 9.42), which are scattered randomly through the liver, often occurring in clusters. The number of ground-glass cells tends to be inversely related to the activity of the hepatitis. Most cells are found in livers with the least active disease, whereas livers with the most activity tend to have the fewest ground-glass cells. In acute hepatitis B, the immune response eliminates antigen-containing cells and immunostains are entirely negative. Conversely, the presence of stainable surface antigen proves a chronic rather than an acute infection, even when there is severe hepatocellular injury. Hepatitis B core antigen (HBcAg) can also usually be immunohistochemically demonstrated in nuclei, and sometimes cytoplasm when there is chronic disease. The presence of core antigen reflects active viral replication, and so the amount of core tends to be directly proportional to the activity of the hepatitis. Patients with recent acute exacerbations will have the most core and will often have HBcAg in hepatocyte cytoplasm and in numerous nuclei. Strains of virus with precore mutations associated with increased disease severity have also been found to have increased cytoplasmic core antigen (37).

Hepatitis C virus cannot currently be reliably demonstrated in routinely processed liver biopsies. There

are, however, histologic features that are characteristic, although not pathognomonic, of chronic hepatitis C (34), and the finding of these features should prompt a serologic evaluation if not already done. Chronic hepatitis C tends to have more intense chronic portal inflammation than other types of chronic hepatitis, often with lymphoid aggregates and sometimes follicles with germinal centers (Fig. 9.37). There is also a greater tendency toward hepatocellular fat accumulation than in other types. Approximately 50% of biopsy specimens have some fat, and in approximately 10% this may be considerable. Patients infected with genotype 3 tend to have even more fat, and it is suggested that this may be due to a cytopathic effect (38). Hepatitis-associated bile duct lesions (see preceding text) may be found in acute or chronic hepatitis of any cause, but they are most frequent in hepatitis C. Severe degrees of bile duct injury can be seen in approximately 10% to 15% of biopsy specimens from patients with chronic hepatitis C (Fig. 9.39). Lesser degrees of duct irregularity and lymphocytic infiltration can be found more often.



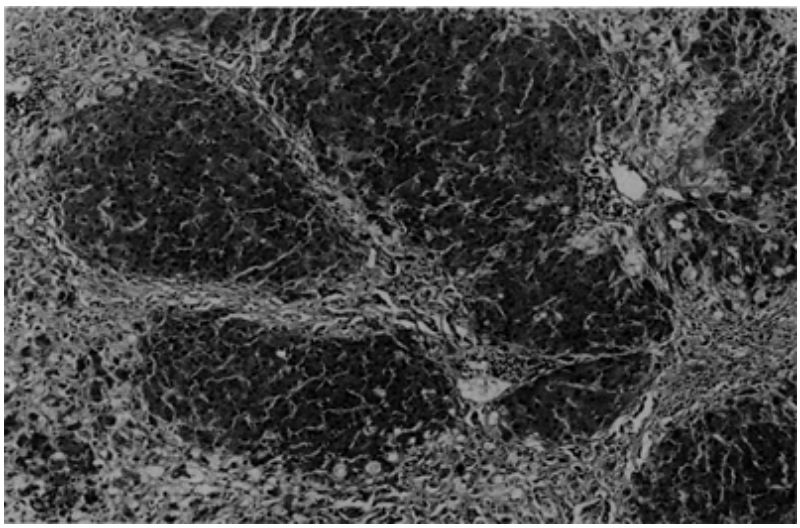
▪ **Figure 9.42** Ground-glass cells (*arrows*) in chronic hepatitis B. The cytoplasm of liver cells containing large quantities of hepatitis B surface antigen (HBsAg) has a uniform finely granular appearance.

Hepatitis D can only infect individuals who are also infected with HBV, which serves as an obligatory helper. Simultaneous coinfection with HBV and hepatitis delta virus (HDV) tends to cause more severe disease than HBV alone, with a higher likelihood of fulminant hepatitis. HDV superinfection of a person with previous chronic HBV infection often causes an acute exacerbation of the underlying chronic hepatitis or deterioration in the clinical status of a previously stable patient, or it may cause fulminant liver failure. Morphologically, HDV superimposed on HBV tends to produce more severe disease than hepatitis B alone, but there are no features that specifically implicate hepatitis D (39). The only way to histologically prove presence of the virus is to demonstrate delta antigen in the hepatocyte nuclei by immunohistochemical staining (although commercial antibodies are not widely available) or to detect antibodies to delta antigen in the blood.

Autoimmune hepatitis tends to be a very severe chronic hepatitis, often with multiacinar collapse and/or cirrhosis at the time of presentation. Numerous plasma cells are often seen in the portal inflammatory infiltrate (Fig. 9.38). About one third of cases have an acute onset, and,

typically, there is severe acute hepatitis-like hepatocellular injury, often with diffuse ballooning of hepatocytes, regeneration with hepatocyte rosette formation, and sometimes, confluent zone 3 hepatocellular necrosis (29). Extensive giant cell transformation (40) is seen in some cases, which have been called *postinfantile giant cell hepatitis* or *syncytial giant cell hepatitis*.

Recurrent chronic hepatitis after liver transplantation may resemble the original disease or may have atypical features. Hepatitis B, before antiviral therapy became established as standard post-transplantation therapy, virtually always recurred and in many cases caused a severe, rapidly progressive disease in immunosuppressed patients. The term *fibrosing cholestatic hepatitis* was proposed for this form of hepatitis B (41). Liver biopsy specimens show numerous ground-glass hepatocytes with massive amounts of intracellular HBsAg and HBcAg, and it is thought that this represents a cytopathic form of viral infection, in contrast to the usual chronic hepatitis B. As the disease progresses, there is portal and diffuse pericellular fibrosis, hepatocyte dropout, and in the late stages, nodular regeneration, producing cirrhosis (Fig. 9.43). Cholestasis in the tissue may be severe, but the patients typically have elevated serum bilirubin concentration even when bile pigment is histologically inapparent, hence the "cholestatic" part of the name. Hepatitis C also recurs, but most patients have histologic features of typical chronic hepatitis. Occasionally, however, patients display features of fibrosing cholestatic hepatitis, except for ground-glass cells (42). It is not clear whether the pathogenesis is the same as that for hepatitis B. Both hepatitis B and C occasionally produce the pattern of fibrosing cholestatic hepatitis in patients who have not undergone liver transplantations but are immunosuppressed or immunodeficient for other reasons (43).



▪ **Figure 9.43** Recurrent hepatitis B with fibrosing cholestatic

hepatitis progressing to cirrhosis 1 year after liver transplantation. The surviving hepatocytes have abundant cytoplasmic hepatitis B surface antigen (HBsAg), producing a ground-glass appearance, and there is canalicular bile stasis.

Grading and staging of chronic hepatitis

The stage of any disease is a measure of how far it has progressed in its natural history, with the end stage resulting in death of the patient or failure of the organ. The grade of the disease is meant to reflect how quickly the disease is progressing to the end stage. In chronic hepatitis the end stage is cirrhosis with clinical decompensation, whereas earlier stages have lesser degrees of fibrosis or cirrhosis. The grade is considered to be the degree of inflammation and hepatocellular injury, which is thought to lead to fibrosis.

The old terminology that classified chronic hepatitis as "chronic persistent hepatitis," implying a benign, nonprogressive disease, or "chronic active hepatitis," implying a disease with a high likelihood of progression to cirrhosis, was a form of grading, but advances in understanding the causes and elucidating the natural history of the diseases that produce this type of liver injury has rendered this terminology obsolete.

There are several methods, currently in use, of expressing the grade and stage of chronic hepatitis. These can be grouped into those that are simple verbal descriptions, those that are relatively simple numeric grades and stages that correspond to the verbal descriptions, and those that use more complicated numeric scoring of histologic features to generate numbers that correspond to the grade and stage. Each method has advantages and disadvantages, and the system used should be appropriate to its suitability for the task at hand. In general, more complex systems have the capability to provide more information than simple ones but are less reproducible.

For routine diagnosis and patient management a simple system of grading and staging is preferred, and we recommend the guidelines that were proposed by a panel of experts convened by the International Association for the Study of the Liver (IASL) in 1994 (44). Grading of chronic hepatitis is accomplished by deciding whether the degree of activity is mild, moderate, or marked. Although this seems rather simple, it is essentially subjective and not highly reproducible between pathologists or even by the same pathologist (45). The principal features used to determine grade are the degree of periportal interface hepatitis ("piecemeal necrosis") and spotty parenchymal injury (Table

9.1). We consider interface hepatitis to be mild when one must search for a foci in the biopsy specimen; moderate when most portal areas have some interface hepatitis, but it extends around less than 50% of the circumference in the majority; and marked when most portal areas have interface hepatitis extending around more than 50% of the circumference. Parenchymal injury is most easily graded using the 10× (medium power) objective of the microscope with the usual 10× ocular lens. At this magnification it is possible to detect acidophilic bodies, ballooned hepatocytes, and clusters of inflammatory cells at sites of focal necrosis, and it is relatively easy to estimate the amount of injury and form an overall impression of the degree of injury. We consider parenchymal injury to be mild when fewer than five injured cells or clusters

of inflammatory cells are seen per 10× field, moderate when there are 5 to 20, and marked when there are more than 20 per 10× field. Portal inflammation can also be considered, but this is more a sign of chronicity than of activity. In grading the overall activity, the chronic hepatitis can be considered as being mild when both interface hepatitis and parenchymal injury are mild or absent, moderate if both interface hepatitis and parenchymal necrosis are moderate or if one is moderate but the other is mild, and marked if interface hepatitis and/or parenchymal injury is marked.

Table 9.1. Grading Activity in Chronic Hepatitis

Grade	Interface hepatitis	Parenchymal injury[a]	Activity
Mild	Found only after diligent search	<5 per 10× field	*Both* interface hepatitis and parenchymal injury are *mild* or less
Moderate	Most portal areas have at least some, but most have <50% of circumference	5–20 per 10× field	*Either* interface hepatitis or parenchymal injury is *moderate*
Marked	>50% of	>20 per 10×	*Either*

	circumference of most portal areas	field	interface hepatitis or parenchymal injury is *marked*

[a]Apoptotic bodies, ballooned cells, inflammatory cell aggregates.

Staging of chronic hepatitis requires assessment of the degree of fibrosis, which requires a Masson trichrome stain for proper evaluation. There is progression in the stage of disease as fibrosis advances from none to fibrous portal expansion, bridging fibrosis, incomplete cirrhosis, and finally to established cirrhosis.

Following the recommendations of the IASL panel (44), the diagnostic line of the pathology report should indicate the cause of the chronic hepatitis and, if known, the grade and the stage. Therefore, the report may read "chronic hepatitis C with mild activity and portal fibrosis"; or "chronic hepatitis B with moderate activity and extensive bridging fibrosis"; or "chronic autoimmune hepatitis with marked activity and established cirrhosis." For those who prefer numbers to words, there are simple numeric scores that generally correspond to verbal diagnoses (Table 9.2), including the Batts-Ludwig (46) and Metavir (47) systems. We prefer the verbal diagnoses because these avoid the false sense of quantification that numbers tend to engender.

Complex numeric systems have also been proposed for grading and staging chronic hepatitis, including the Knodell Histology Activity Index (48), commonly called the *Knodell score*, and its modified form, known as the *Ishak score* (35). For grading, these systems assign numbers to the severity of the necroinflammatory features (e.g., interface hepatitis, confluent necrosis, parenchymal injury, and portal inflammation) and add these numbers to arrive at a grade that can range from 0 to 18. The stage, ranging from 0 to 4, may or may not be added into the Knodell score; in the Ishak score, the stage, ranging from 0 to 6, is reported separately. Numeric scores generated by these systems are useful for investigational studies that involve large numbers of patients requiring statistical analysis. These scores are a good way of showing differences in histologic response between cohorts of patients receiving different forms of therapy, and they have been used successfully in many large clinical trials. However, studies have

shown that there is fairly poor reproducibility for these scores when applied to *individual* liver biopsies, both between different pathologists and by the same pathologist at different times (45,49). When dealing with an individual liver biopsy, the pathologist should avoid complex numeric scores and concentrate on a meaningful verbal report.

Follow-up biopsies from patients who are being treated for chronic hepatitis should be evaluated in the context of their previous biopsies. The biopsy is performed in this clinical setting to see whether the activity of the patient's liver disease has improved or whether there has been progression of fibrosis. The only meaningful evaluation is one that compares the initial biopsy with the follow-up biopsy. It is essential that this be done by a single pathologist (although the clinician may wish to look on) comparing both biopsies together. A comparison of pathology reports

or numeric scores generated at different times can only lead to confusion and incorrect conclusions about the course of the patient's disease.

Table 9.2. Simple Numeric Grading and Staging SystemsT hat Correspond to Verbal Diagnoses

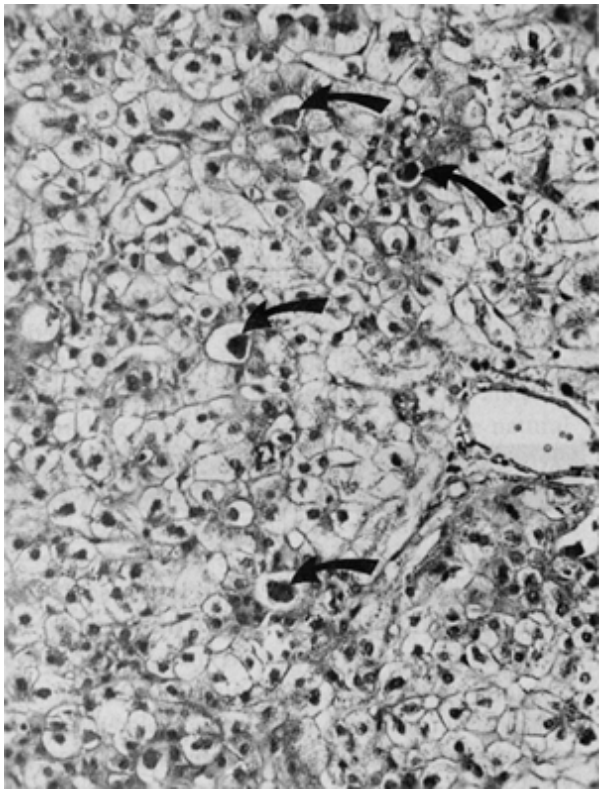
Grade	Metavir (47)	Batts-Ludwig (46)
Chronic hepatitis, minimal	A1	Grade 1
Chronic hepatitis, mild	A1	Grade 2
Chronic hepatitis, moderate	A2	Grade 3
Chronic hepatitis, marked	A3	Grade 4
Stage		
No fibrosis	F0	Stage 0
Portal fibrosis	F1	Stage 1

Few bridges	F2	Stage 2
Many bridges	F3	Stage 3
Cirrhosis	F4	Stage 4

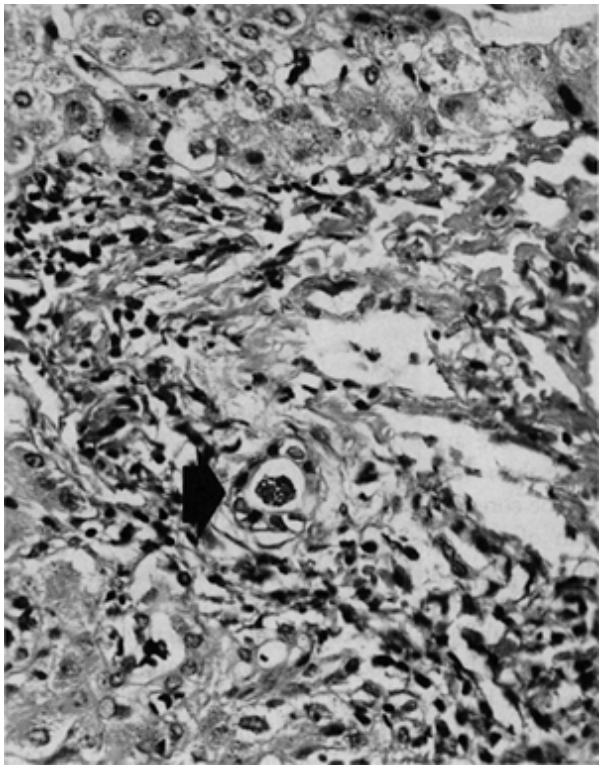
Acute Cholestasis

Cholestasis can be defined as the arrested flow of bile. Morphologically, when there is an acute impediment to bile flow, no matter the cause, bile pigment can usually be found in hepatocytes, canaliculi (Fig. 9.44), and sometimes Kupffer cells, predominantly in acinar zone 3 ("centrilobular"), except when hyperbilirubinemia is minimal. When jaundice is severe, especially in mechanical biliary obstruction, bile pigment may be seen in the lumina of ductules or acinar bile ducts (Fig. 9.45). Bile may be confused with other pigments, particularly hemosiderin and lipofuscin. It is typically a darker brown than the pale yellow lipofuscin. Lipofuscin is more granular and is more likely to be found near the cytoplasmic membrane. Hemosiderin is dark brown, glassy, and usually more refractile than bile or lipofuscin. The Prussian blue stain for iron is useful for identifying bile and so is Hall's stain for bilirubin.

Many disorders, including alcoholic liver disease, drug-induced hepatotoxicity, viral hepatitis, and various developmental and metabolic diseases, can be associated with intrahepatic cholestasis. In general these show features typical of the basic pattern of injury, and cholestasis is a minor component of the picture. This section deals with cholestasis as the predominant feature.



▪ **Figure 9.44** Multiple bile plugs (*arrows*) in zone 3 canaliculi in a patient with an acute onset of cholestatic jaundice.



▪ **Figure 9.45** Bile in an acinar bile duct (*arrow*) in extrahepatic biliary obstruction.

"Bland" cholestasis and cholestatic hepatitis

"Bland" cholestasis refers to an acute cholestatic injury unaccompanied by hepatocellular injury or bile duct injury. The cholestasis caused by some drugs, such as anabolic and contraceptive steroids, is typically "bland," unaccompanied by hepatocellular injury of more than a minimal degree (50). The differential diagnosis, however, includes mechanical biliary obstruction because in the early stages, portal area changes, as noted in the subsequent text, may not be present. In some patients, the cause of the "bland" cholestasis is never found. Benign recurrent intrahepatic cholestasis (BRIC) is a term used for a familial disorder caused by mutations of the *FIC1* gene that is also responsible for progressive familial intrahepatic cholestasis type 1 (PFIC-1) (51). BRIC is characterized by bouts of cholestasis that are self-limited and not followed by fibrosis or cirrhosis. Biopsy specimens show moderate to marked cholestasis and little or no hepatocellular injury. Similar findings

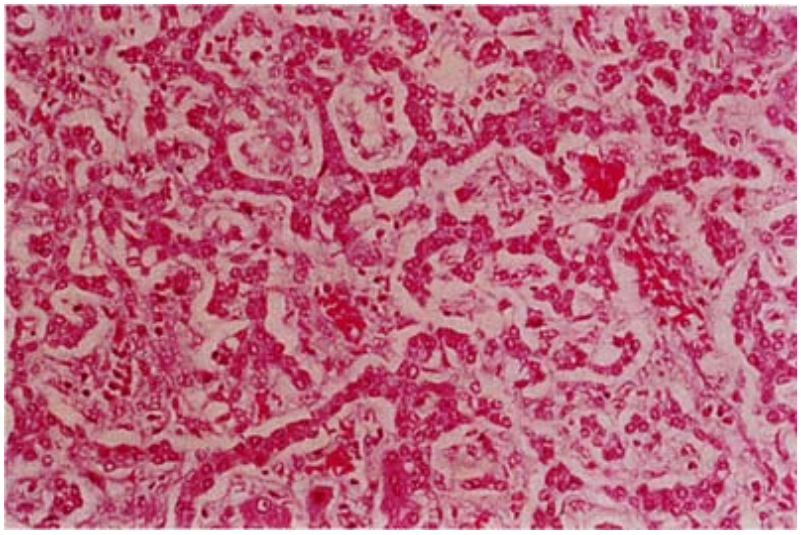
are noted in the syndrome of recurrent jaundice of pregnancy (52).

Cholestatic hepatitis, as noted in the preceding text, is a combined

hepatocellular and cholestatic injury, which may be due to viral hepatitis but which is more often due to drug-induced liver disease (23,50). Acute bile stasis, along with spotty necrosis, hepatocellular ballooning, and/or apoptotic bodies, brings up this differential diagnosis.

Cholestasis with acute cholangitis

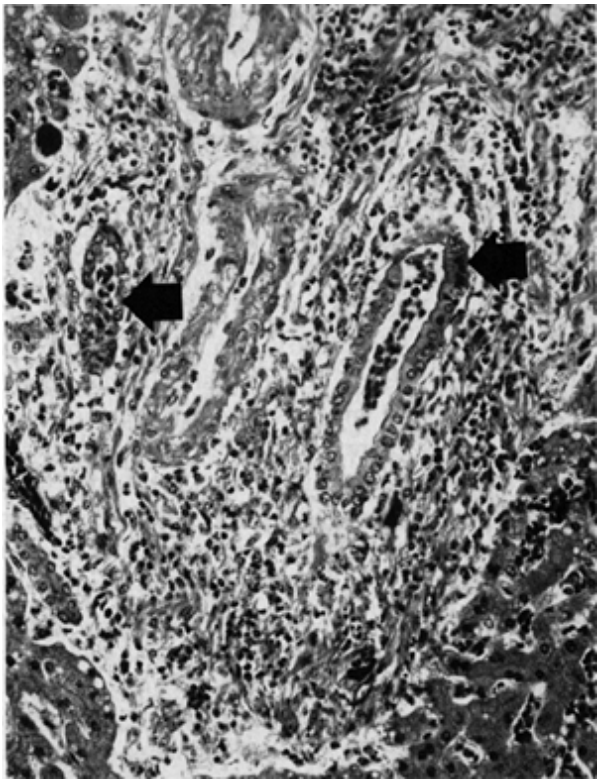
Cholestasis with acute cholangitis is typical of mechanical (large duct) biliary obstruction of any cause, such as choledocholithiasis, neoplasms, strictures (e.g., neoplastic, inflammatory, or postoperative), sclerosing cholangitis, pancreatitis, choledochal cysts, pancreatic pseudocysts, biliary atresia, and several parasitic diseases (e.g., ascariasis, fascioliasis), or even extrinsic pressure from enlarged lymph nodes, tumors, or aneurysms. The key diagnostic feature is acute inflammation (i.e., neutrophils) with epithelial injury of the acinar bile ducts. Bile ducts are usually found adjacent to the corresponding small branches of the hepatic artery with approximately the same diameter. The ducts must be distinguished from ductules or cholangioles, as they have also been called. Reactive ductules ("ductular proliferation") are found at the margins of portal tracts (Fig. 9.46) and should not be confused with bile ducts because changes affecting them do not have the same significance as identical changes in bile ducts (53,54). Ductules, which are usually more angulated than bile ducts, become prominent and appear to proliferate in response to a variety of injuries (55). Neutrophils are commonly situated in and around the reactive ductules, but this does not have the same significance as acute cholangitis, which is characterized by neutrophils in or around the acinar bile duct (Fig. 9.47) and is highly suggestive (but not pathognomonic) of mechanical biliary obstruction. Cholangitis may be present without histologic bile stasis, depending on the degree of obstruction; bile pigment is not usually found without complete obstruction, but acute cholangitis indicates a high likelihood of an obstruction being present. Bile pigment, when present, is seen first in acinar zone 3 and later in zones 2 and 1 as jaundice becomes more profound. Rarely, there is bile in the lumina or epithelium of the acinar bile ducts (Fig. 9.45), but when present, this strongly suggests the presence of obstruction. Other frequent findings include ductular reaction with associated acute inflammation, neutrophilic infiltration of the portal tracts, and bile duct epithelial irregularity or hyperplasia. Severe acute cholangitis is occasionally complicated by rupture, with the development of cholangitic abscesses in the region of the affected bile ducts (Fig. 9.48). Remnants of the disrupted biliary epithelium, bile, and mucin are often located within the abscesses. Xanthomatous cells and foreign body giant cells with phagocytosed bile may also be present. Bile lakes, due to extravasation of bile, and bile infarcts may be seen when there is duct rupture in advanced cases (Fig. 9.49).



▪ **Figure 9.46** Reactive ductules at the margin of an edematous, inflamed portal tract.

Although an acute cholangitis most often denotes extrahepatic biliary tract disease with an ascending infection, there are rare nonobstructive causes,

including toxic shock syndrome, several toxins (e.g., paraquat, methylene diamine, and the toxin of toxic oil syndrome), and a number of drugs (e.g., chlorpromazine, allopurinol and amoxicillin–clavulanate) (56).



▪ **Figure 9.47** Acute suppurative cholangitis in a patient with mechanical biliary obstruction. The portal area is edematous and contains many neutrophils. Neutrophils are present in the lumina of two bile ducts (*arrows*).

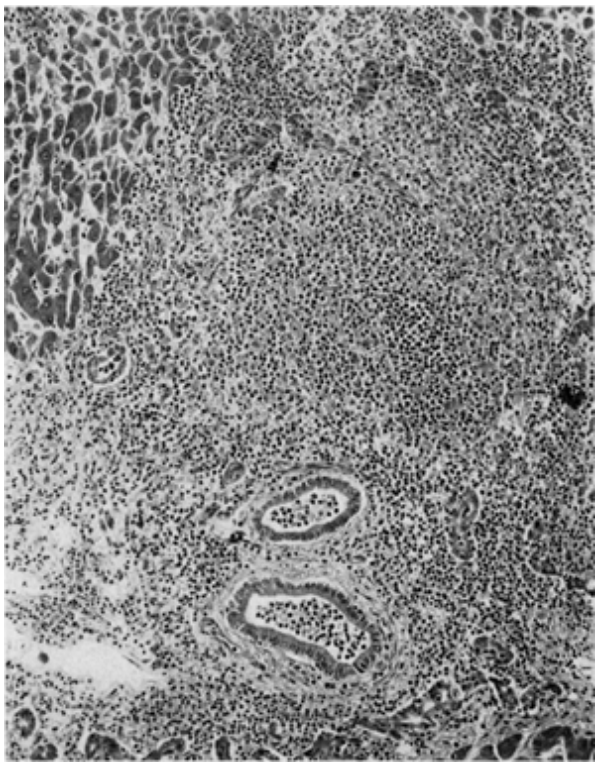
Bile ductular cholestasis

Neutrophils may also be associated with inspissated bile in dilated periportal ductules (Fig. 9.50), a lesion called *bile ductular cholestasis* (57). This lesion is sometimes seen in severely ill patients with sepsis and/or dehydration (57,58), but like other forms of ductular reaction, it does not necessarily indicate mechanical biliary obstruction.

Chronic Cholestasis

Clinical and histologic features of chronic cholestasis appear when there is impaired flow of bile that persists for more than a few weeks. However, most chronic cholestatic disorders are insidious in onset, and chronic cholestasis progresses slowly over the course of years before it becomes clinically apparent. The most reliable histologic sign of chronic cholestasis is the lesion known as *cholate stasis* (53), which is also called *pseudoxanthomatous change, xanthomatous change*, or *feathery degeneration*. These terms refer to a foamy transformation of the cytoplasm of hepatocytes, Kupffer cells, and biliary epithelial cells,

which is seen when there is any type of prolonged (chronic) cholestasis (Fig. 9.51). The affected cells are foamy and often bile stained, as a result of the accumulation of the bile salt and lipid components of bile. Other changes seen in chronic cholestasis include periportal bile pigment, copper accumulation demonstrated with special stains for copper (rhodanine) or by staining for the copper-binding protein, a metallothionein protein within lysosomes (Victoria blue stain) and, in some cases, periportal Mallory bodies. Although there are a number of causes of chronic cholestasis, the most frequent are PBC (see Chapter 24) and primary sclerosing cholangitis (see Chapter 23). Furthermore, in patients who have undergone liver transplantation, allograft rejection can produce bile duct damage and loss, leading to chronic cholestasis.



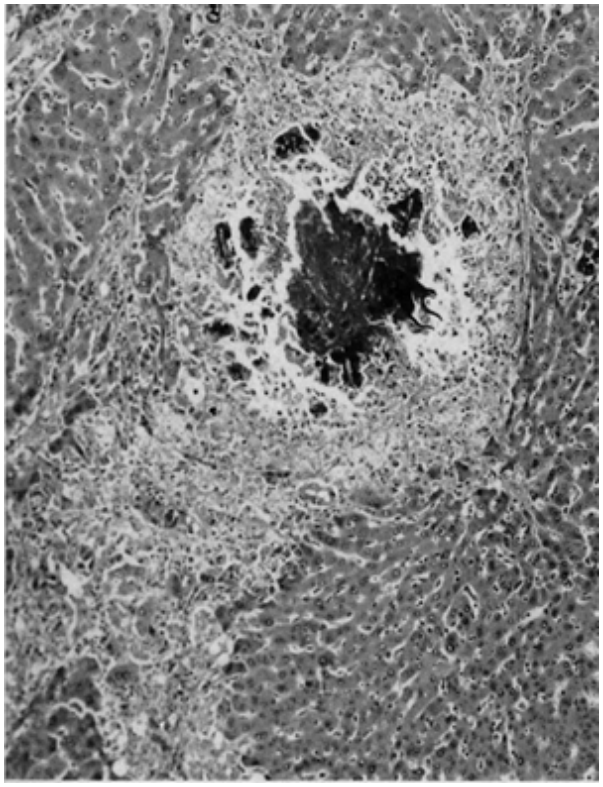
▪ **Figure 9.48** Cholangitic abscess, secondary to ascending cholangitis. The two bile ducts at the bottom of the field are filled with neutrophils.

Primary biliary cirrhosis

The diagnosis of PBC is usually made on the basis of a constellation of clinical, serologic, and histologic findings. In a patient known to have a positive antimitochondrial antibody (AMA) liver biopsy is usually

performed to confirm the diagnosis and assess the stage of disease. In

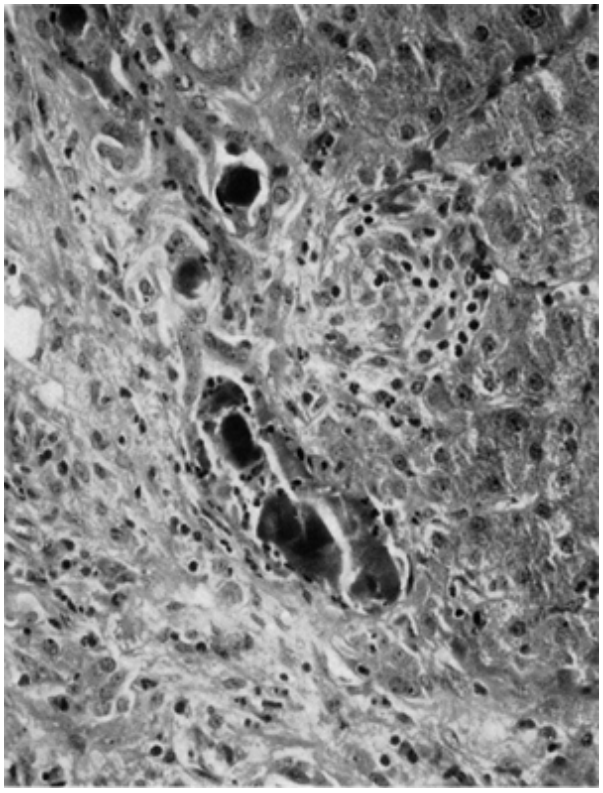
a patient who has not had a complete workup or in whom the AMA is negative, the biopsy may still be diagnostic of the disease.



▪ **Figure 9.49** Bile lake secondary to rupture of a duct and extravasation of bile in mechanical obstruction.

In patients with clinical and laboratory features of chronic cholestasis, particular attention paid to the condition of the acinar bile ducts is critical in histologic evaluation. Ducts affected by PBC show variable chronic inflammation and epithelial injury that lead to destruction of the duct, a lesion called *chronic nonsuppurative destructive cholangitis* (59) or *the florid duct lesion* (60). It is this immunologically mediated destruction of ducts that initiates the disease. Lymphocytes and plasma cells penetrate the basement membrane and insinuate themselves between the epithelial cells, causing destruction of epithelial cells (Fig. 9.52, 9.53) and segments of the basement membrane. Eosinophils and even some neutrophils (despite the fact that it is called *nonsuppurative*) may be present, but it is the lymphocytes that appear to be the primary effectors of the injury. Well-developed lymphoid follicles, sometimes with germinal centers, may be found around or adjacent to the degenerating bile ducts. Epithelioid granulomas (Fig. 9.53), typically less well organized than those of sarcoidosis, are located in the portal areas adjacent to or surrounding the bile ducts, or less often in the

parenchyma, in approximately one third of the cases.



▪ **Figure 9.50** "Bile ductular cholestasis." Periportal ductules are markedly dilated and filled with bile in a patient with bacterial sepsis.

Florid duct lesions are generally considered to be pathognomonic of PBC (53,59,60,61), but they must be distinguished from the hepatitis-associated bile duct lesions (Fig. 9.39) discussed in the preceding text under Chronic Hepatitis. This is most easily accomplished by searching for the features that accompany the destruction of ducts in PBC, namely ductopenia and chronic cholestasis. In chronic hepatitis, loss of ducts is rare and chronic cholestatic features do not develop. The degree of cholangitis in PBC varies greatly from one portal tract to another. Some ducts can appear completely normal, whereas others exhibit striking inflammation and epithelial injury. Therefore, the active diagnostic lesion can be absent in small biopsy samples, and the pathologist is then compelled to apply other criteria and clinical data to the evaluation.

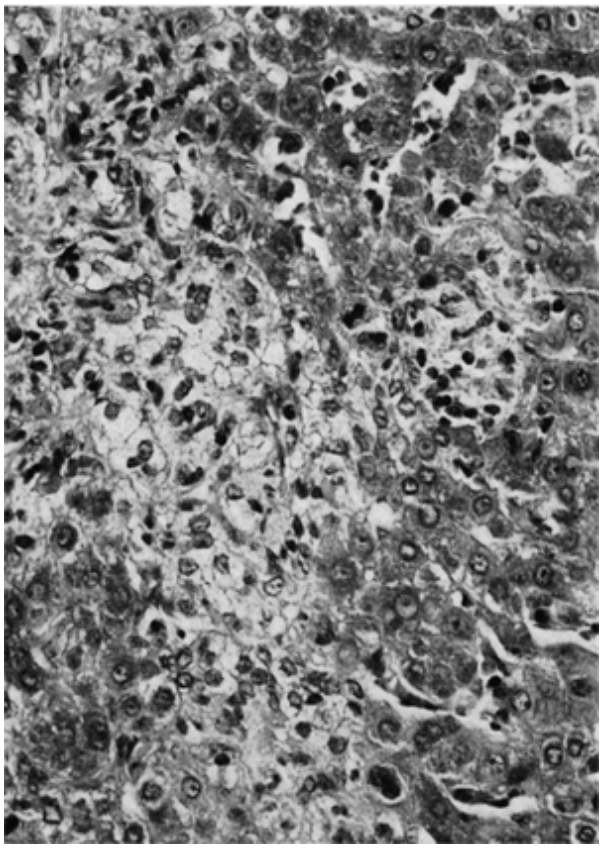
The number of portal tracts lacking acinar bile ducts should be estimated. With the exception of premature infants, a normal liver has a ratio of bile ducts to portal areas of 0.9 or greater (62), usually with the acinar duct running parallel to the hepatic artery branch. In most

patients with PBC, more than half of the portal tracts lack bile ducts, that is, ductopenia (Fig. 9.54), and it is only in the earliest stages that there are no portal areas with missing ducts (62). Also helpful is the frequent presence of periportal bile pigment and cholate stasis (Fig. 9.51).

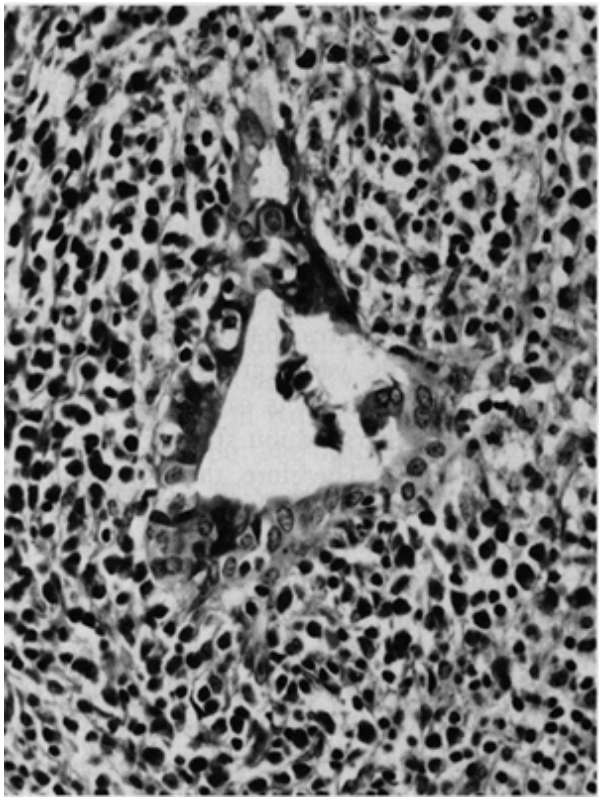
P.274

P.275

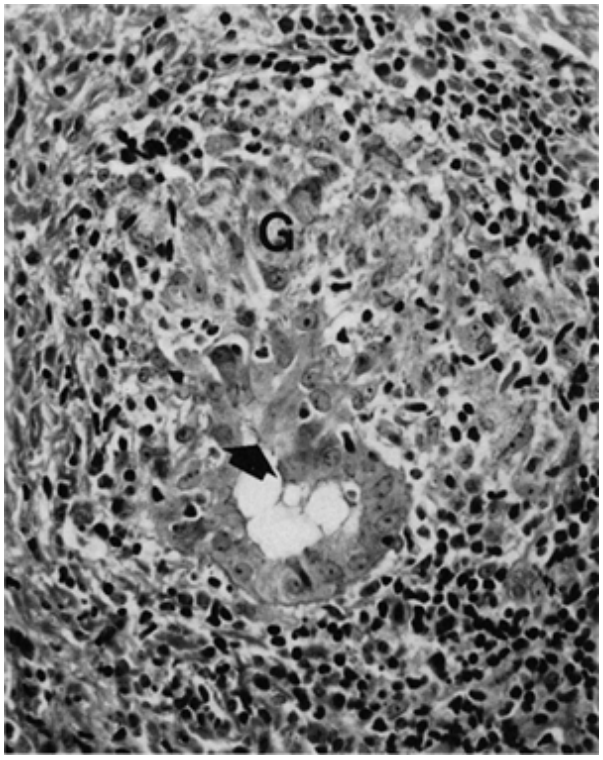
These changes are often subtle and must be sought with care. Small to moderate amounts of copper-binding protein (stainable with Victoria blue) and copper (on rhodanine stain) are frequently detected in hepatocytes in the periportal area (Fig. 9.7). Periportal (zone 1) Mallory bodies, found in 10% to 15% of cases, are further evidence of chronic cholestasis. These are identical to the Mallory bodies of alcoholic and nonalcoholic steatohepatitis except for their location—the Mallory bodies of steatohepatitis are in zone 3.



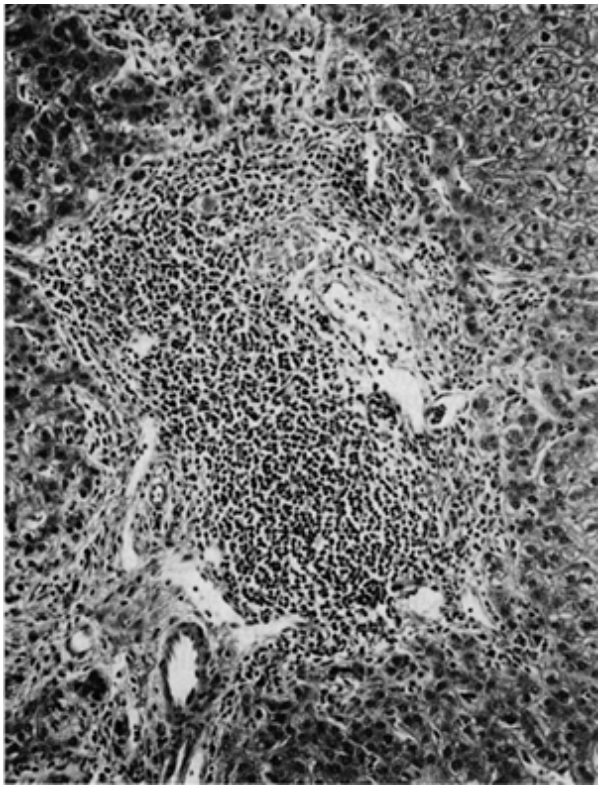
▪ **Figure 9.51** Cholate stasis, indicating chronic cholestasis. The affected cells have pale, foamy cytoplasm because of bile lipid retention.



▪ **Figure 9.52** Florid duct lesion of early primary biliary cirrhosis. The ductal epithelium is infiltrated with inflammatory cells (predominantly lymphocytes), the epithelial cells are severely injured, and the basement membrane is ruptured.



▪ **Figure 9.53** Florid duct lesions of early primary biliary cirrhosis. The duct has ruptured (*arrow*), and there is a poorly formed epithelioid cell granuloma (*G*) adjacent to the damaged duct.

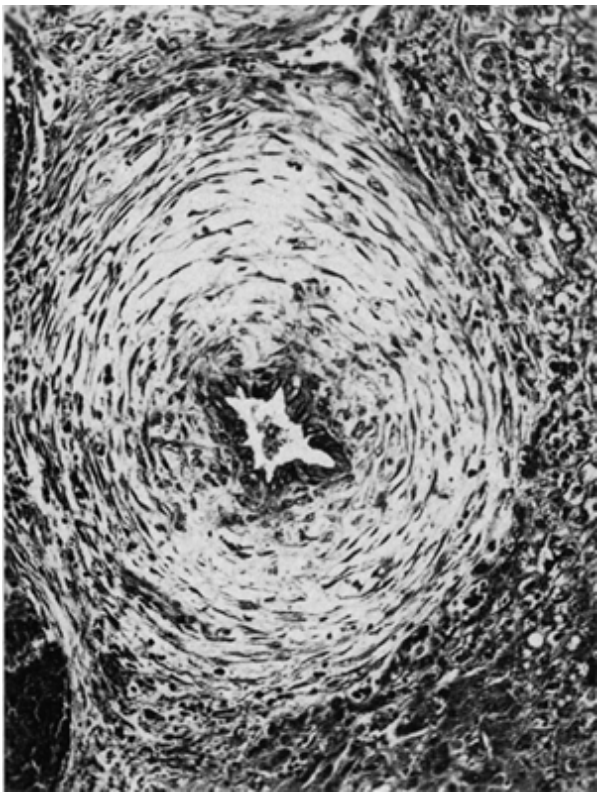


▪ **Figure 9.54** Primary biliary cirrhosis. The portal area lacks a bile duct (ductopenia).

Ductular reaction can be prominent in PBC, particularly in the surrounding portal areas that lack acinar bile ducts. Care must be taken to distinguish the ductules from bile ducts. Hepatocytes are relatively spared, but there is invariably some element of interface hepatitis ("piecemeal necrosis") and hepatitis-like parenchymal injury (61,63). Some investigators have distinguished what they call "biliary piecemeal necrosis," seen in areas of cholate stasis, from "lymphocytic piecemeal necrosis" that is typical of chronic hepatitis (64), but in our experience, these occur together so often that the distinction is not meaningful. There are cases in which the biopsy specimen shows so much hepatocellular injury and interface hepatitis that an overlap syndrome of PBC and autoimmune hepatitis is considered (65,66). In such cases, the clinical and laboratory findings may also suggest both disease processes. However, in our opinion, it is the loss of bile ducts and chronic cholestatic injury that is more significant because bile ducts do not regenerate as readily as hepatocytes and it is chronic cholestasis that leads to cirrhosis in these patients. Therefore, we agree with those who consider the overlap syndrome to be a hepatitic form of PBC (67).

Primary sclerosing cholangitis

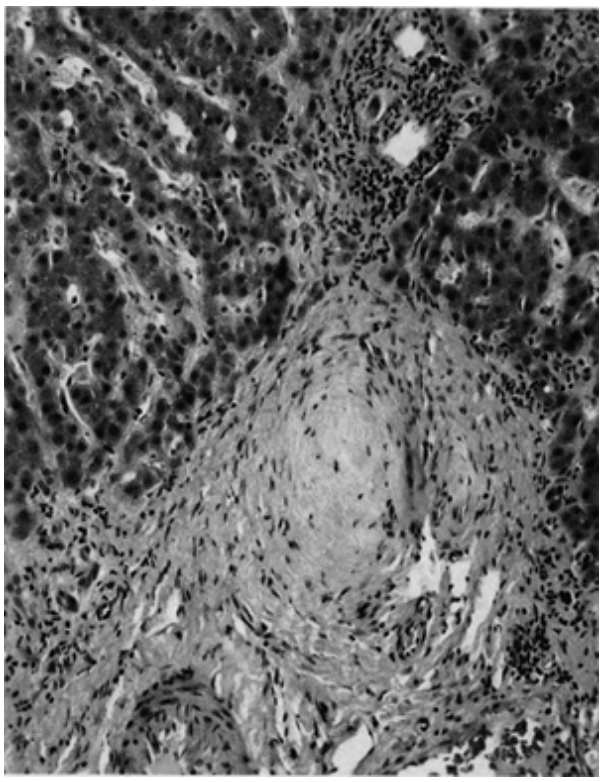
Primary sclerosing cholangitis usually involves the entire biliary tract, but there are occasional cases that affect only extrahepatic or intrahepatic ducts. The extrahepatic ducts are thick and cord-like and have a narrowed lumen. Histologically, a variety of changes may be seen, depending in part on the integrity of the ductal system draining the biopsied area. Changes in the parenchyma are largely due to incomplete chronic mechanical biliary obstruction. Bile pigment is often minimal or absent because obstruction is rarely complete. Clues to the diagnosis can be observed in the portal areas. Some acinar bile ducts may show marked periductal fibrosis with prominent compression and distortion of the epithelium (Fig. 9.55). The epithelium may be almost unidentifiable or even completely atrophic, while a small nodule (cross section of a cord) of fibrous tissue remains in its place (Fig. 9.56). The basement membrane is intact and often thickened. The bile ducts still may be present, but they are often reduced in number or may be totally absent, depending on the stage of the disease. Ductular proliferation is relatively mild compared with that seen in other types of biliary obstruction. Chronic cholestatic features, with cholate stasis and copper accumulation, become increasingly prominent as the disease progresses and may render its distinction from PBC difficult. Furthermore, granulomas, considered a typical feature of PBC, are occasionally present in primary sclerosing cholangitis (68). However, periductal fibrosis is not a typical feature of PBC, while florid duct lesions, in particular the destruction of the basement membrane, are not observed in sclerosing cholangitis.



▪ **Figure 9.55** Primary sclerosing cholangitis. Note the marked periductal fibrosis with compression and atrophy of the epithelium.

Fibrosis follows the loss of bile ducts in both sclerosing cholangitis and PBC, although the mechanism is not clear. In PBC, at least, both ductular proliferation and interface hepatitis, accompanied by collagen deposition, appear to be important (69), but the possible roles of other factors related to chronic cholestasis have not been studied in detail. The fibrosis extends progressively with portal–portal bridging and septum formation, eventually with nodule formation and development of a micronodular biliary cirrhosis indistinguishable from that caused by chronic mechanical obstruction (Fig. 9.57). Staging of disease, if requested, is best accomplished by estimating the degree of fibrosis because any combination of histologic lesions can be found in an individual biopsy specimen. Ludwig

suggested four stages for both PBC (70) and sclerosing cholangitis (71)—stage I (portal), stage II (periportal), stage III (septal), and stage IV (cirrhosis). *Early stage, mid stage*, and *late stage* are also acceptable terms, although they sound less scientific.



▪ **Figure 9.56** Primary sclerosing cholangitis. The acinar bile duct

is replaced by a fibrous nodule.

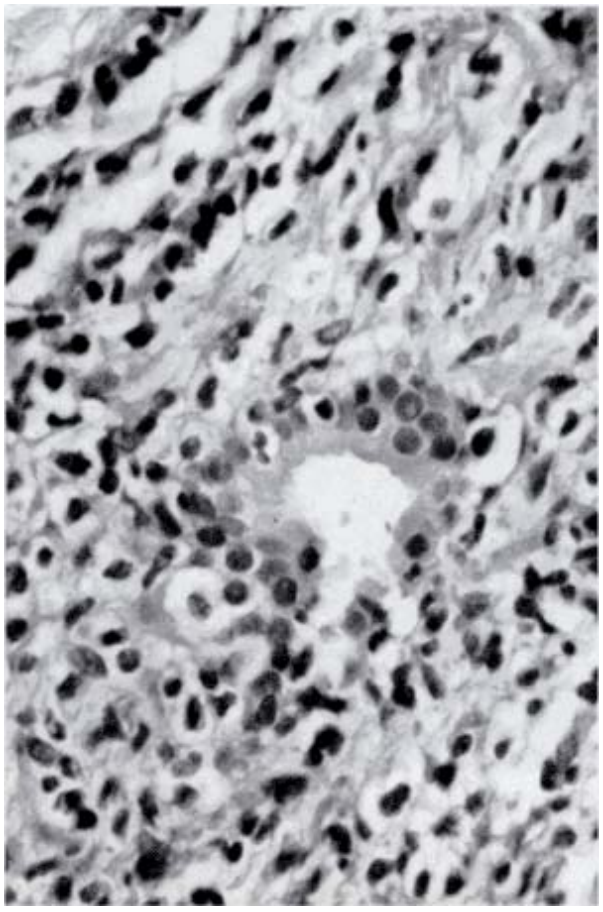
Allograft rejection

Acute (cellular) rejection is an immunologically mediated attack of the host's defenses against the engrafted liver. The principal targets of the attack are the bile ducts and the endothelium of veins and arteries but not of sinusoids. Snover's triad, consisting of mixed portal inflammation (involving lymphocytes, plasma cells, neutrophils, and eosinophils), bile duct damage (Fig. 9.58) (e.g., rejection cholangitis), and endothelialitis (usually affecting portal vein branches and sometimes the central veins, in the form of lymphocytes attached to the luminal surface of the endothelial cells or between the cell and its basement membrane), is considered diagnostic of rejection (72). These features are variable, and diagnostic findings may or may not present on any individual liver biopsy, so the presence of two of the three features is usually considered sufficient for diagnosis. Cholestasis, hepatocyte ballooning, apoptotic or acidophilic bodies, and focal necrosis may also be present. Cellular rejection may be graded according to the international consensus Banff schema (72), but the clinical utility of this is yet to be proved.

▪ **Figure 9.57** End-stage biliary cirrhosis is typically micronodular with chronic cholestatic features in the residual parenchyma and thick bands of collagen between the nodules, imparting a "jigsaw" pattern to the tissue. Bile ducts are absent.

Chronic (ductopenic) rejection refers to the irreversible damage to the engrafted liver through a combination of immunologically mediated injury and ischemia. It typically follows repeated episodes of acute rejection and so is usually not diagnosed until at least several months after transplantation. Rapidly progressive cases are sometimes seen (acute vanishing bile duct syndrome) but are uncommon. The changes of chronic rejection are thought to be partly due to the injury associated with repeated acute rejection and partly due to reduced arterial flow caused by foam cell arteriopathy in large arteries of the graft. Bile ducts require an arterial blood supply, so the loss of the arteries contributes to the loss of ducts. Changes of chronic rejection include bile duct atrophy and pyknosis, loss of bile ducts (ductopenia) with or without loss of hepatic artery branches, and foam cell arteriopathy in larger arteries, particularly those near the hilum (73). The loss of ducts produces features of chronic cholestasis, and zone 3

fibrosis may also occur because of ischemia.



▪ **Figure 9.58** Acute cellular allograft rejection.

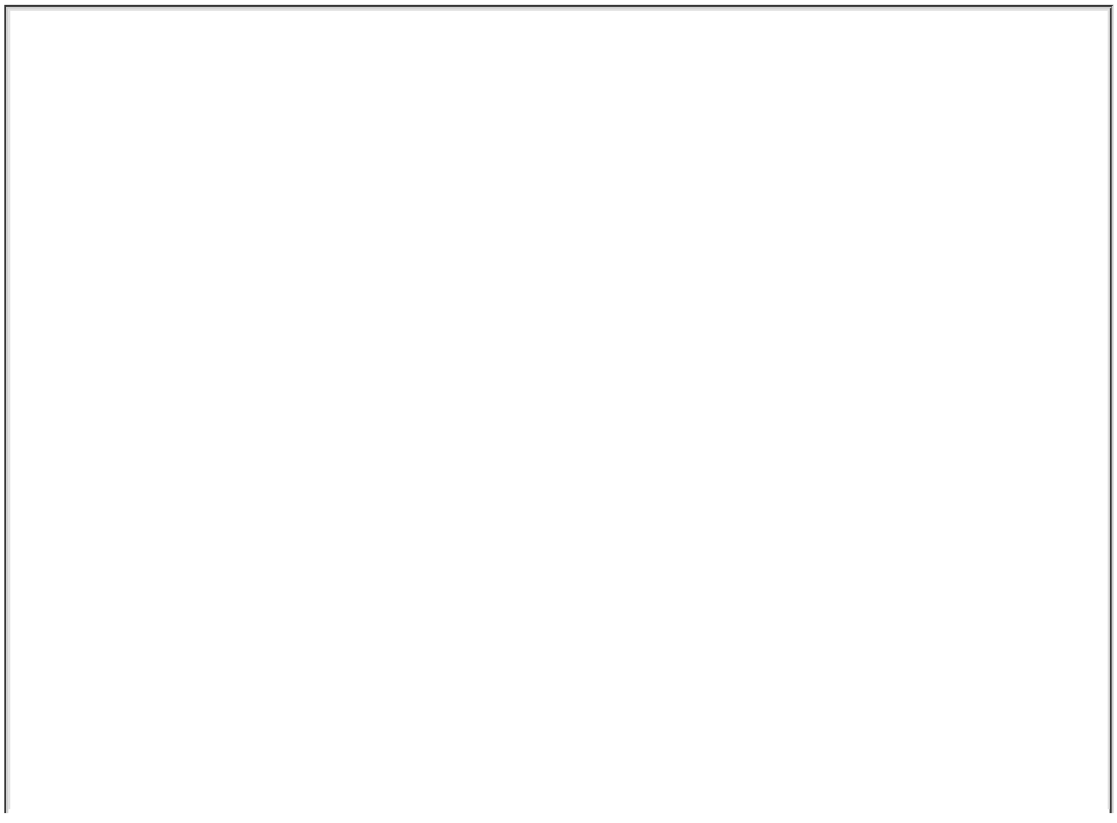
Other chronic cholestatic syndromes

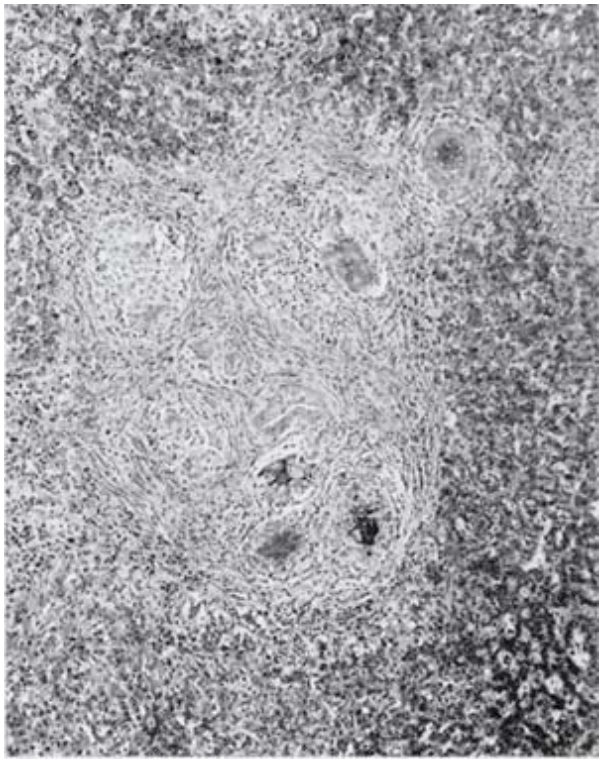
Mechanical obstruction—any of the microscopic changes observed in acute biliary obstruction may be present in biopsy specimens from patients with long-standing obstruction. Additional changes that point to the chronic nature of the process commonly develop when obstruction persists for more than a few weeks. These include periductal sclerosis, cholate stasis, periportal bile stasis, copper accumulation, and sometimes Mallory body formation. Bile becomes inspissated, appearing dark olive green and laminated in sections. Loss of hepatocytes in zone 1 contributes to periportal fibrosis. Cirrhosis may develop when complete or nearly complete obstruction persists for many months, but most patients will be relieved of the obstruction or will develop complications and death before cirrhosis ensues. Biliary cirrhosis is histologically characterized by fibrous septa, linking portal tracts and outlining irregular islands of parenchyma that resemble the

pieces of a jigsaw puzzle (Fig. 9.57).

Extrahepatic biliary atresia in the neonate (see Chapter 47) is more likely to produce secondary biliary cirrhosis than other causes of mechanical obstruction. In this condition, all the morphologic features of acute and chronic biliary obstruction described in the preceding text can be observed, depending on the stage during which a biopsy specimen is obtained. The same criteria for diagnosis of biliary obstruction, described in the preceding text, must be used to differentiate biliary atresia from other cholestatic disorders of the neonate and infant. Some degree of portal fibrosis and ductular proliferation are usually present in biliary atresia and help in distinguishing it from neonatal hepatitis. Diagnostic difficulty may be caused by the presence of giant cell transformation, suggesting hepatocellular injury, in some cases of biliary atresia, but giant cell transformation in neonates should be considered a nonspecific pattern of injury, induced by a variety of hepatic and extrahepatic disorders.

Sarcoidosis sometimes causes a syndrome of chronic intrahepatic cholestasis that can mimic PBC or primary sclerosing cholangitis in many clinical, biochemical, and histologic aspects (72,73,74). In such cases, the liver develops confluent granulomas that destroy bile ducts, cause chronic cholestasis, and may lead to biliary cirrhosis. Although depletion of bile ducts is characteristic, florid duct lesions are uncommon. Granulomatous inflammation in the liver can be found in portal, periportal, and parenchymal areas in the active phase of the syndrome, and the granulomas are better formed and a more dominant feature than those in PBC (Fig. 9.59).





▪ **Figure 9.59** Chronic cholestatic syndrome of sarcoidosis. This portal area has several granulomas and considerable fibrosis but lacks a bile duct.

Secondary sclerosing cholangitis with features nearly identical to primary sclerosing cholangitis may follow mechanical obstruction from a variety of causes, such as surgical manipulation of the biliary tract or tumors of the extrahepatic ducts. Secondary sclerosing cholangitis may also follow chemical injury, such as intra-arterial injection of floxuridine to treat metastatic colon cancer (75) or the injection of formalin into hydatid cysts. Langerhans' cell histiocytosis occasionally affects bile ducts, causing ductal destruction and secondary sclerosing cholangitis (76).

Acquired immunodeficiency syndrome (AIDS) cholangiopathy is a form of secondary sclerosing cholangitis that follows some biliary tract infections such as cryptosporidiosis or CMV in patients with AIDS (77).

Drug-induced chronic cholestasis is an uncommon complication of acute drug injury. A patient with this syndrome develops jaundice, often severe, which does not fully resolve, producing a disorder with some degree of histologic, biochemical, and clinical resemblance to PBC, but not with the insidious onset of the idiopathic forms of chronic cholestasis described in the preceding text. In the early stage there is

an acute cholangitis, while biopsy specimens in the later stages show ductopenia and chronic cholestatic features (78).

Paucity of intrahepatic bile ducts is a term used for congenital diseases that produce chronic cholestasis associated, as the name implies, with absence of the small acinar ("interlobular") ducts (79). The best defined of these is arteriohepatic dysplasia or Alagille syndrome (see Chapter 47). Bile ducts are present at birth but undergo progressive destruction from early infancy to childhood. In later childhood, there is paucity or absence of acinar bile ducts (Fig. 9.60), paradoxically with mild cholestatic features (80,81). Despite the lack of ducts, it is rare to see bile stasis, and progressive fibrosis or cirrhosis is uncommon. By contrast, children who have bile duct paucity without the other anomalies of Alagille syndrome tend to have a much worse disease, often with progression to end-stage liver disease. Such cases are usually idiopathic but are thought to result from various types of in utero injuries that prevent the normal development of acinar ducts, resulting in a diminished number of ducts at birth.

Idiopathic adulthood ductopenia is a term that is suggested for the rare patient who has a chronic cholestatic syndrome with progressive bile duct loss but does not fit into one of the entities listed in the preceding text (82).

Steatosis (Fatty Liver)

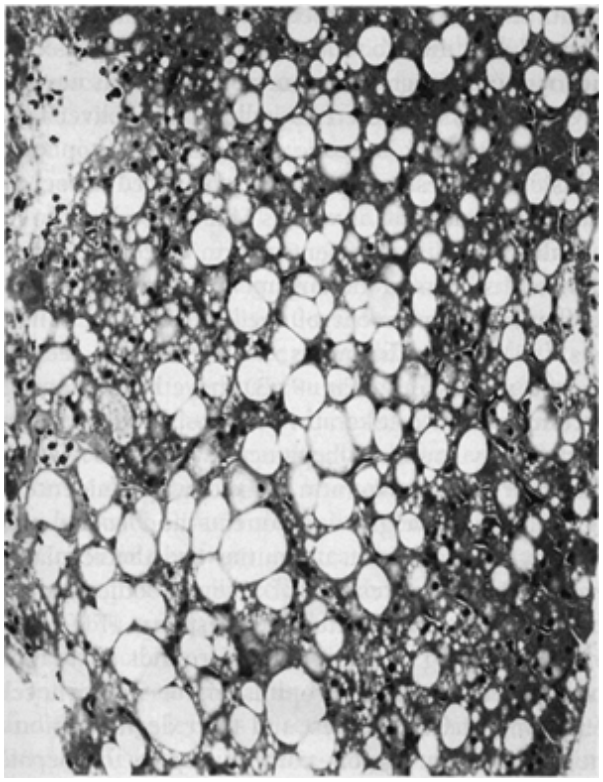
Steatosis can be subclassified into two broad morphologic categories—macrovesicular and microvesicular—on the basis of the size of the fat vacuoles in the liver cells. The distinction is not always sharp, and there are cases where both macrovesicular and microvesicular fat coexist. In general, steatosis is considered macrovesicular when the hepatocytes contain a single large fat vacuole that displaces the nucleus to the edge of the cell, whereas the steatosis is microvesicular when there are numerous small cytoplasmic fat vacuoles that tend to leave the nuclei centrally placed within the hepatocytes. In routinely processed material, the lipid is dissolved by organic solvents, and so frozen sections with special stains (e.g., oil red-O) are necessary to confirm its presence in cases where there is doubt.

▪ **Figure 9.60** Paucity of intrahepatic ducts (Alagille syndrome). This medium-sized, fibrotic portal area lacks a bile duct, but there is very little inflammation or cholestatic features.

Macrovesicular steatosis is a reaction to a wide variety of injuries, many of which are subclinical and might be more properly regarded as a physiologic adaptation manifested as an imbalance between uptake of lipids from the blood and secretion of lipoproteins by the hepatocyte. Most affected hepatocytes contain a single, medium-sized or large, rounded vacuole that displaces the nucleus and cytoplasm to the periphery of the cell (Fig. 9.61). The vacuoles can be as large as or larger than a normal hepatocyte. Conditions often associated with macrovesicular steatosis include malnutrition, diabetes mellitus, obesity, malabsorption, various debilitating disorders, some metabolic diseases, corticosteroid therapy, and exposure to various other drugs and toxins. Steatosis can be the only change, or it may be associated with other lesions. For example,

in chronic hepatitis C, there is often macrovesicular steatosis associated with the other changes described in the preceding text. Steatohepatitis (alcoholic or nonalcoholic), several metabolic diseases (e.g., Wilson disease), and drug-induced injury (e.g., methotrexate) may be associated with fat accumulation, along with other lesions characteristic of the disease. The location of the fat is quite variable; it is usually

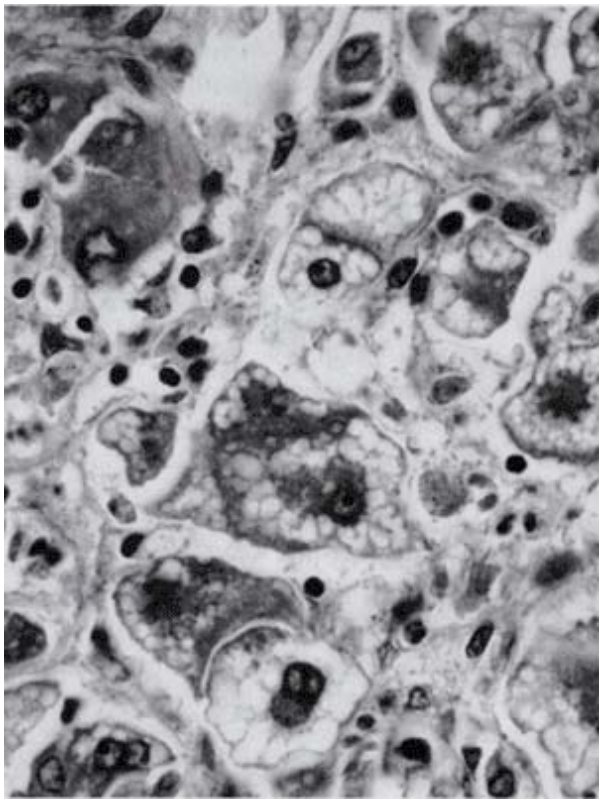
diffuse but can be predominantly in zone 1 or 3.



▪ **Figure 9.61** Macrovesicular steatosis. Most hepatocytes contain a single, large, rounded vacuole that displaces the nucleus and cytoplasm to the periphery of the cell.

Microvesicular steatosis generally connotes a more serious injury than macrovesicular steatosis, although it has been shown that this is a frequent nonspecific finding, especially in autopsy material (83,84). Consequently, a diagnosis of one of the diseases characterized by microvesicular steatosis cannot be made without compatible clinical and laboratory findings. Hepatocytes with microvesicular steatosis show a central nucleus surrounded by sharply defined small vacuoles (Fig. 9.62). Acute fatty liver of pregnancy (85) and Reye's syndrome (86) are well-recognized causes of microvesicular steatosis. A number of metabolic diseases, including fatty acid oxidation disorders, mitochondrial oxidation chain disorders, and urea cycle disorders, are associated with microvesicular steatosis and can mimic Reye's syndrome to varying degrees (87,88). Toxic injury from drugs such as tetracycline, aspirin, valproic acid, antiretroviral nucleoside analogs, and fialuridine can also produce microvesicular steatosis (50,89,90,91). Alcoholic liver injury can also occasionally lead to a toxic microvesicular steatosis, a lesion called *alcoholic foamy degeneration* (92). South American epidemics of hepatitis D and B coinfection are found to have

marked microvesicular steatosis (93) for unknown reasons. Other forms of viral hepatitis, both acute and chronic, may have some degree of microvesicular steatosis, especially if frozen sections and oil red-O stains are used to demonstrate its presence. However, in general fat stains should be reserved for situations in which there is a high clinical suspicion of one of the diseases in which microvesicular steatosis is a cardinal feature, such as acute fatty liver of pregnancy.



▪ **Figure 9.62** Microvesicular steatosis in acute fatty liver of pregnancy. Hepatocytes have a central nucleus surrounded by numerous small fat vacuoles.

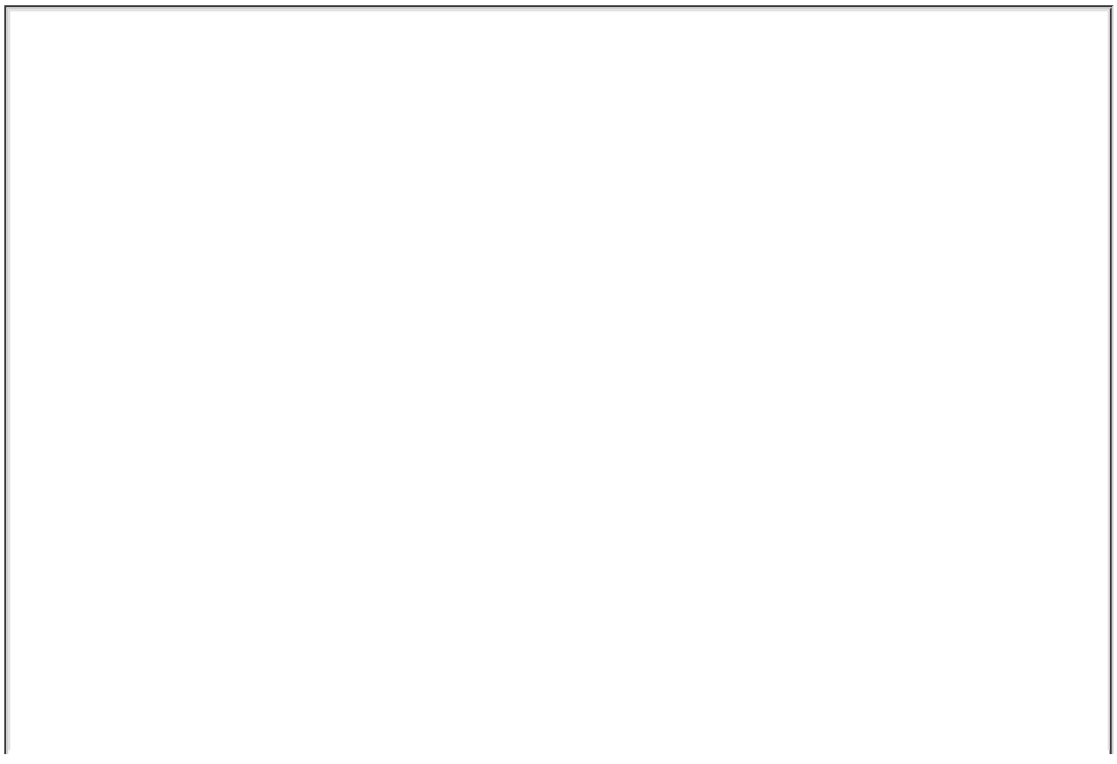
Steatohepatitis: Alcoholic Hepatitis and Nonalcoholic (Metabolic) Steatohepatitis

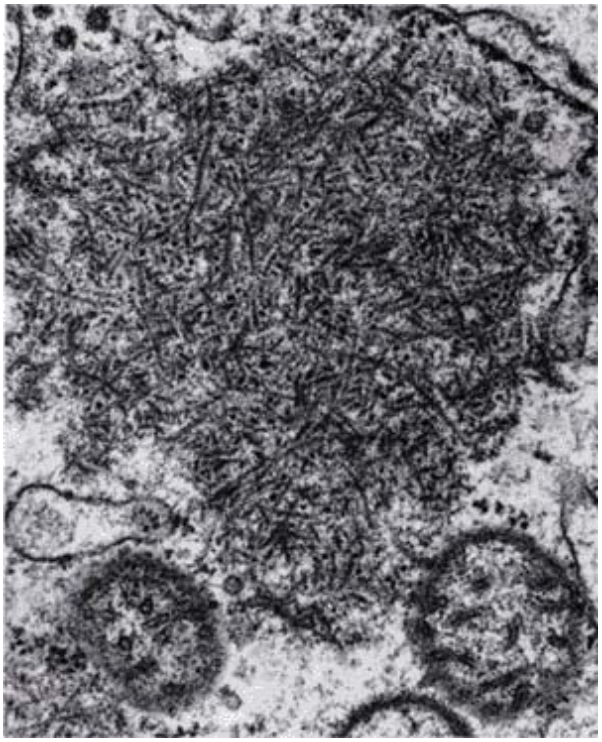
Steatohepatitis

Steatohepatitis is the term used for the morphologic pattern of injury characteristic of the active phase of alcoholic liver disease. Synonyms include alcoholic steatonecrosis, sclerosing hyaline necrosis, and alcoholic hepatitis, when it is found in persons who consume large quantities of alcohol, and fatty liver

hepatitis, metabolic steatohepatitis, and nonalcoholic steatohepatitis, when it occurs in nondrinkers. Because the morphology is so similar, regardless of cause, the term *steatohepatitis* is used here when the lesion is referred to, and alcoholic hepatitis or nonalcoholic steatohepatitis is used for the clinicopathologic entities. Because the pathologist is often unaware of the pertinent clinical information, a diagnosis of steatohepatitis is acceptable until it is known whether the patient consumes alcohol. In patients who are alcoholic, it is presumed that the liver disease represents direct toxicity from ethanol. In those who do not drink, the pathogenesis of the liver disease remains obscure and seems most likely to represent some form of metabolic (probably genetic) disease related to obesity with insulin resistance and/or diabetes (see Chapter 39). It should be emphasized that every liver biopsy specimen with fat and inflammation is not steatohepatitis, despite the name. For example, a patient with preexisting steatosis may have hepatitis-like spotty necrosis and inflammation from an unrecognized drug, undiagnosed virus, or oxidative stress of other unknown cause, but this is not considered steatohepatitis. Only when there are other changes, as described in the subsequent text, is the term *steatohepatitis* appropriate.

Steatohepatitis, whatever the cause, is a chronic lesion that predominantly affects acinar zone 3 (94). Microscopically, this is characterized by a constellation of features that vary in degree and extent from patient to patient. In addition to steatosis (usually macrovesicular but sometimes microvesicular or "mixed"), as noted in the preceding text, there is ballooning of liver cells, most prominently in zone 3. Globular cytoplasmic inclusions, representing enlarged, damaged mitochondria, may be present, as well as Mallory bodies.



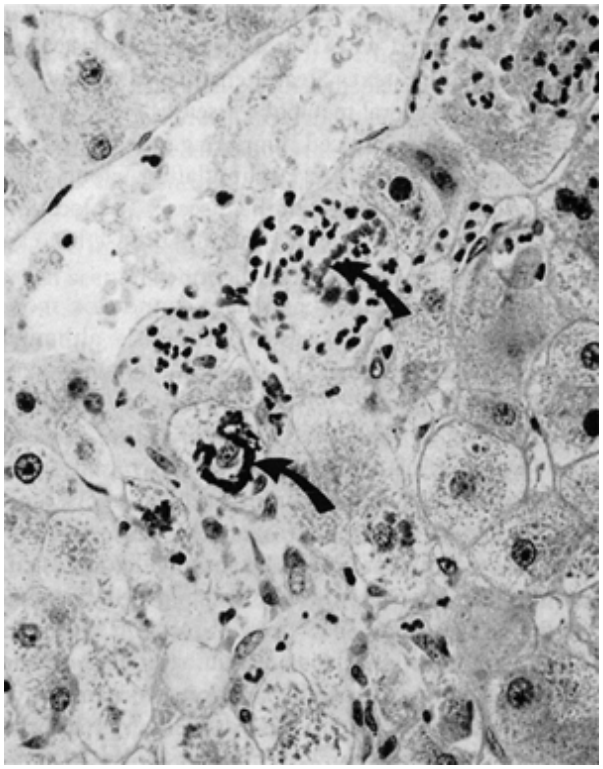


▪ **Figure 9.63** Ultrastructural appearance of a Mallory body. It consists of a tangled mass of intermediate filaments.

Mallory bodies represent a form of cellular injury that results from a derangement of the intermediate filament component of the cytoskeleton of liver cells (95). These filaments, which can be seen by electron microscopy (Fig. 9.63), have been shown to be composed of cytokeratin proteins, both those that are normally found in hepatocytes (types 8 and 18) and other types of keratin, mixed with unidentified high-molecular-weight components and coated with the heat shock protein, ubiquitin, and the regulatory protein p62. The presence of Mallory bodies induces a neutrophilic inflammatory cell response (Fig. 9.64); sometimes a ring of neutrophils surrounds the Mallory body ("satellitosis"). Neutrophils migrate into liver cells containing Mallory bodies, and their degranulation is one of the major factors contributing to the hepatocellular damage (96). Steatosis resolves within 3 to 4 weeks of abstinence from alcohol, while Mallory bodies may take months to disappear. Mallory bodies are

eosinophilic and may be short and irregular or long and rope-like. The cytoplasm around large Mallory bodies is typically empty or rarified (Fig. 9.65), but sometimes it remains eosinophilic and granular (Fig. 9.66), making the Mallory body hard to detect. In mild cases the small Mallory bodies may be few and particularly hard to see (Fig. 9.67), so

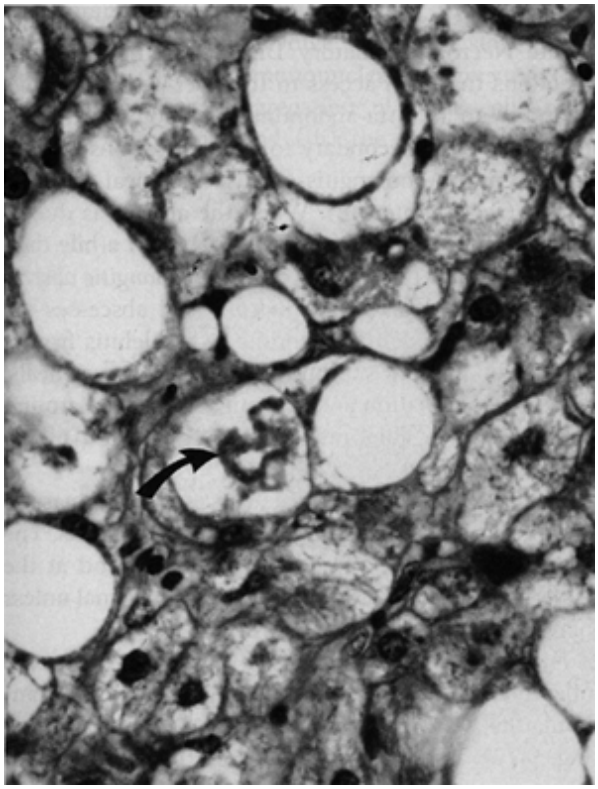
immunostains for ubiquitin (Figs. 9.12, 9.64, 9.68) or p62 protein are particularly helpful in this setting. When Mallory bodies cannot be found despite diligent search, the diagnosis is less certain, but the presence of fat and pericellular fibrosis, described next, strongly suggests steatohepatitis. This is particularly helpful in biopsies from patients with nonalcoholic steatohepatitis, because they tend to have fewer Mallory bodies and less severe active injury than patients with clinical alcoholic hepatitis.



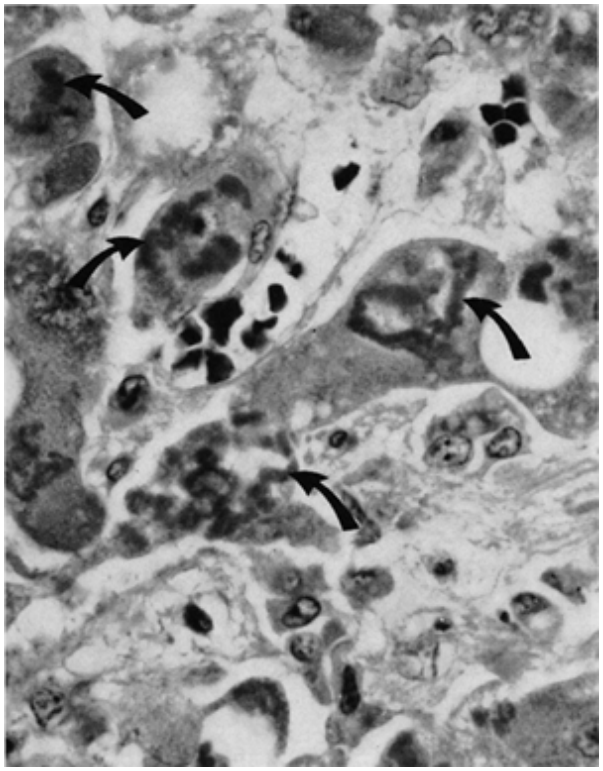
▪ **Figure 9.64** Neutrophilic "satellitosis." In this immunostain for ubiquitin, the dark-staining Mallory bodies (*arrows*) have incited a neutrophilic inflammatory cell response.

Continued activity of steatohepatitis is associated with progressive pericellular fibrosis in acinar zone 3 (Fig. 9.69), with a lattice-like or "chicken-wire" appearance in sections stained with connective tissue stains. Continued scarring also leads to periportal fibrosis and occlusive lesions of terminal hepatic venules (97). With progression of disease, fibrous septa begin to link the chicken-wire fibrosis in zone 3 to extensions of the periportal fibrosis, eventually leading to complete encirclement of islets of hepatic parenchyma. The cirrhosis that develops is usually micronodular (Fig. 9.70), but a macronodular pattern can evolve after alcohol withdrawal. In patients with nonalcoholic steatohepatitis, after cirrhosis develops, the underlying

steatohepatitis may become quiescent with disappearance of fat, active injury, and Mallory bodies, leaving the patient with a histologically cryptogenic cirrhosis (98).



▪ **Figure 9.65** A Mallory body (*arrow*) in a ballooned hepatocyte is easily detected by routine microscopic examination.

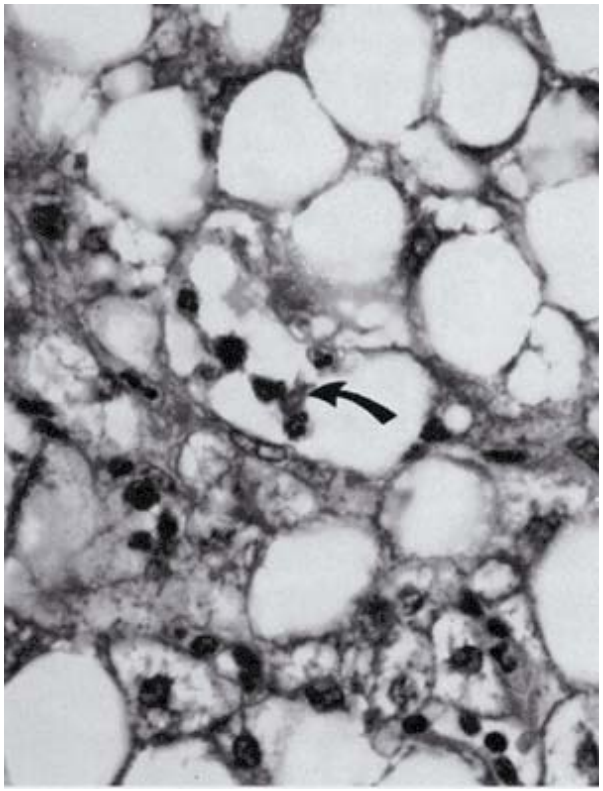


▪ **Figure 9.66** Mallory bodies (*arrows*) in this case of alcoholic hepatitis are less easily seen because the hepatocytes are not as ballooned, but heavy eosin staining brings them out.

Other diseases with features of steatohepatitis

Indian childhood cirrhosis (which occasionally is diagnosed in other countries) is thought to be due to copper toxicity in susceptible children (99). Histologically, the liver shows advanced micronodular cirrhosis with marked copper overload. Fat accumulation is generally mild or absent, but there is considerable hepatocellular injury with ballooning, and Mallory bodies are numerous in many cases.

Drug-induced liver disease from a few drugs may demonstrate Mallory bodies and other features of steatohepatitis (50). Amiodarone and perhexiline maleate are the best characterized of these. Mallory body formation has also been attributed to estrogens, glucocorticoids, calcium channel blockers, and antiretroviral drugs, but the evidence for these is less convincing.



▪ **Figure 9.67** Mallory bodies (*arrow*) in a case of mild nonalcoholic steatohepatitis. The Mallory bodies in this case are all small and thin, making them difficult to find. Note the two neutrophils adjacent to the Mallory body.

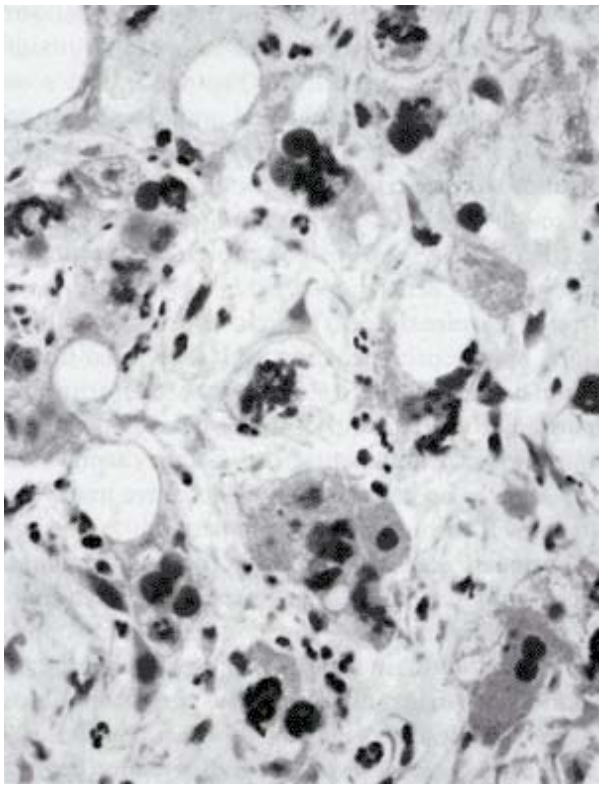
After jejunoileal bypass surgery, some patients developed severe steatohepatitis (100), leading to death from hepatic failure in a few cases. Similarly, steatohepatitis has been reported occasionally in patients with postsurgical short gut syndrome and gastroplasty.

Other diseases with Mallory bodies include chronic cholestatic syndromes such as PBC and primary sclerosing cholangitis, although in these diseases the Mallory bodies are in zone 1 rather than zone 3 and other features of steatohepatitis are lacking. Wilson disease may have Mallory bodies in the cirrhotic stage and can have steatosis as well, making it difficult to distinguish this disease from steatohepatitis. Finally, tumors of hepatocellular origin, including hepatocellular carcinoma, hepatocellular adenoma, and occasionally, focal nodular hyperplasia may contain Mallory bodies in the tumor cells.

Granulomatous and Suppurative Diseases

Space-occupying inflammatory lesions

Abscess is the term used for a collection of neutrophils (i.e., "pus" or purulent inflammation) in a confined space. A microscopic focus of neutrophils may be termed a *microabscess*. This is the typical lesion of some disseminated infections such as listeriosis and salmonellosis, as discussed in the preceding text under "Acute Necroinflammatory Disease". Other bacterial infections that gain access to the liver—blood borne, secondary to an intra-abdominal infection, or through the biliary tract, secondary to mechanical obstruction and ascending cholangitis—cause a typical *pyogenic abscess* (see Chapter 48). When the abscess is due to ascending cholangitis and the remnants of a bile duct can be found in the lesion, the term *cholangitic abscess* (Fig. 9.48) is appropriate. *Pylephlebitic* abscesses are secondary to an acute ascending pylephlebitis from a focus of abdominal suppuration. As an abscess heals, chronic inflammation and scarring can be seen around the edges, with compression and destruction of the hepatic parenchyma.

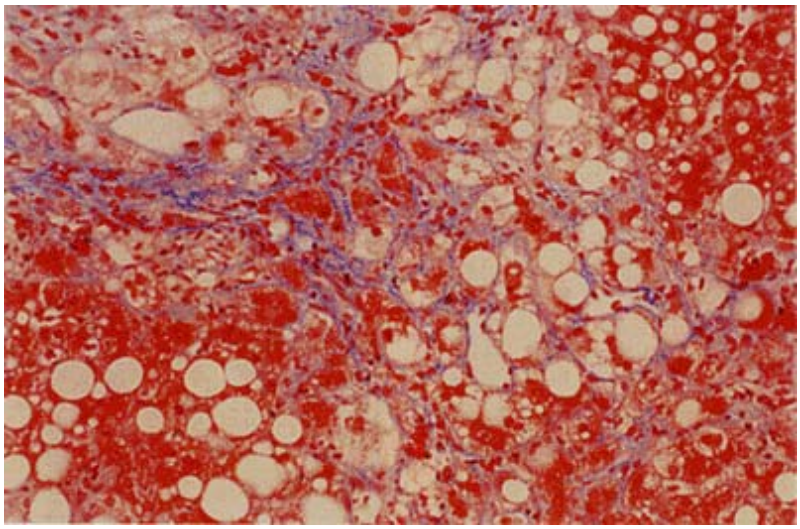


▪ **Figure 9.68** Numerous Mallory bodies in a case of alcoholic hepatitis are easily seen with the immunostain for ubiquitin.

Amebic abscess is not a true abscess. It is a mass of amorphous, necrotic tissue infected with amebas. The amebic trophozoites (Fig.

9.71) can be found at the edges of the lesion, but inflammation is minimal unless there is bacterial superinfection.

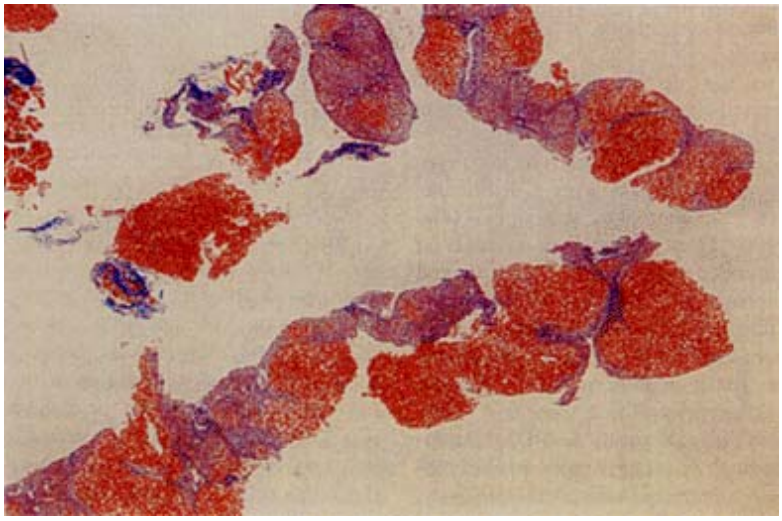
Inflammatory pseudotumor (101) is a mass of chronic inflammatory cells (in particular plasma cells), xanthomatous histiocytes, myofibroblasts, and fibroblasts (Fig. 9.72). Its pathogenesis is uncertain, but at least some cases result from healing abscesses. Some cases are suspected to be true neoplasms, and the term *inflammatory myofibroblastic* tumor is used.



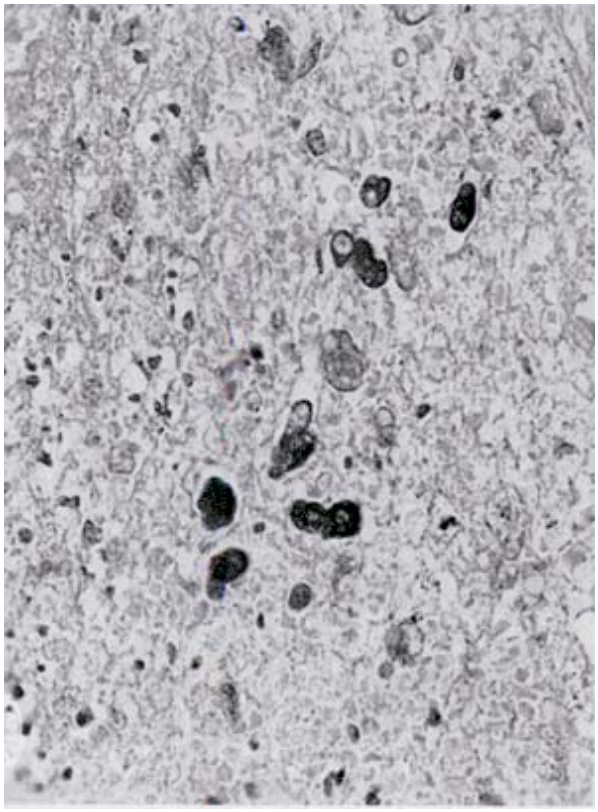
▪ **Figure 9.69** Steatohepatitis with early pericellular ("chicken-wire") fibrosis in acinar zone 3, best appreciated with the Masson stain.

Granuloma is a compact, organized collection of mature mononuclear phagocytes (Fig. 9.73) that may or may not be accompanied by accessory features, such as other types of inflammatory cells, necrosis, or scarring (102,103,104). Granulomatous inflammation is a response to an injury that cannot be contained and eliminated by the usual acute inflammatory response. Granulomas evolve in three stages: (i) An infiltrate of young mononuclear phagocytes, (ii) the maturation and aggregation of these cells into a mature granuloma, and (iii) the potential further maturation of these cells into an epithelioid granuloma (102). A small focus of granulomatous inflammation, consisting of only a few epithelioidhistiocytes, is often called a *granulomatoid focus*. The term *granulomatous hepatitis* should be reserved for cases in which there are both granulomas and necroinflammatory hepatocellular injury, as discussed in the preceding text under Necroinflammatory Diseases. The many causes of hepatic granulomas are discussed in Chapter 52. In the broadest sense, granulomas can be classified as infectious or

noninfectious.



▪ **Figure 9.70** Alcoholic micronodular cirrhosis in a needle biopsy.



▪ **Figure 9.71** Amebic trophozoites (dark-staining) are easily seen with the PAS stain. They are present in the amorphous, necrotic

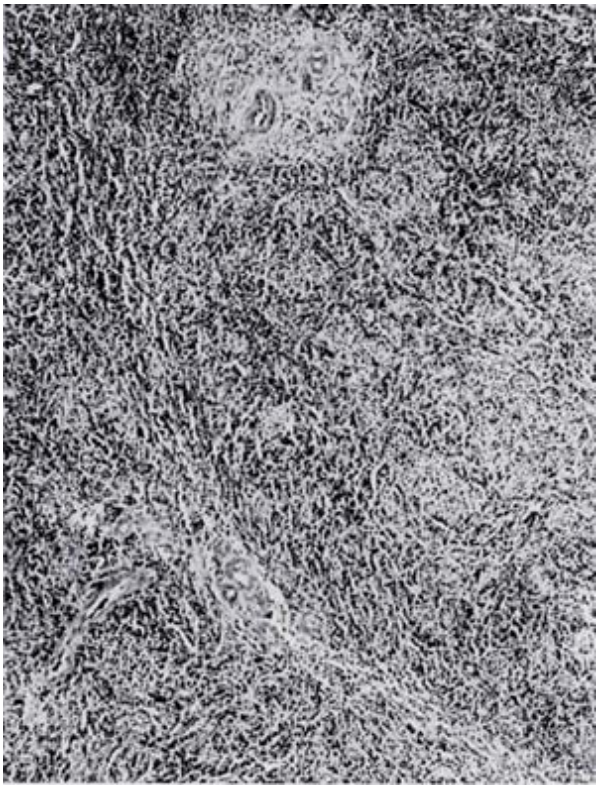
tissue at the edge of an amebic abscess.

Infectious granulomas

Infectious granulomas may be due to any class of organism, and these can sometimes be identified in the tissue or there may be other features to provide a clue to the diagnosis:

Viruses. Granulomatoid foci or, rarely, true granulomas may be seen in the liver in some viral infections, such as infectious mononucleosis and CMV mononucleosis. Other features of mononucleosis hepatitis are invariably present.

Rickettsia. Q fever (*Coxiella burnetii* infection) typically produces granulomas with a distinctive, although not pathognomonic, appearance (Fig. 9.74) (105,106). These lesions have a central fat vacuole surrounded by epithelioid histiocytes and other inflammatory cells. Brightly eosinophilic strands of fibrin form a ring within the granuloma, so these lesions are called *fibrin ring granulomas*. Similar granulomas are described occasionally in patients with a number of other diseases (CMV, EBV, hepatitis A, AIDS, boutonneuse fever, staphylococcal sepsis, toxoplasmosis, visceral leishmaniasis, allopurinol toxicity, giant cell arteritis, Hodgkin's disease, and lupus erythematosus) (103). In each case these are unusual manifestations of the diseases, whereas the fibrin ring granulomas are typical of Q fever hepatitis. The organisms cannot be identified in tissue, but finding fibrin ring granulomas should prompt serologic testing for *Coxiella burnetii*.



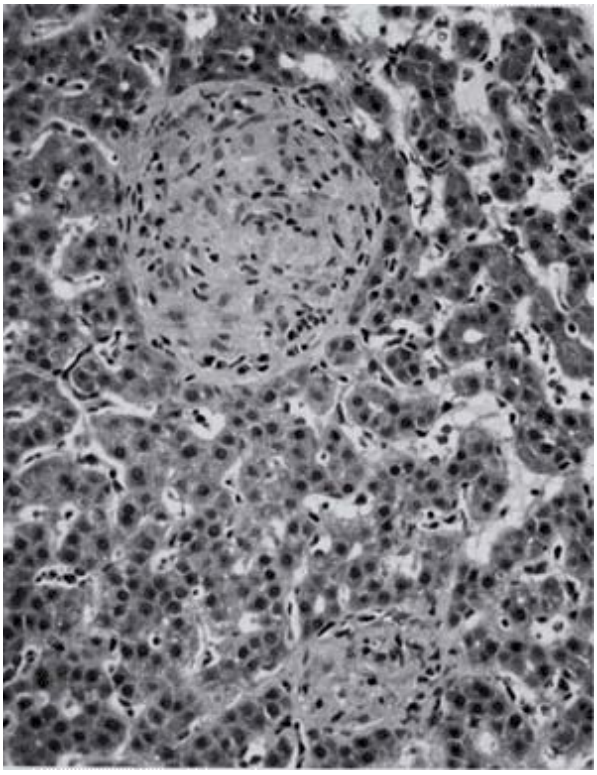
▪ **Figure 9.72** Inflammatory pseudotumor is a mass of inflammatory cells, histiocytes and fibroblasts, presumably the result of a healing inflammatory lesion.

Bacteria. True granulomas are unusual in most bacterial diseases except in brucellosis and occasionally in syphilis; organisms are almost never demonstrable. Microabscesses or ill-formed granulomas that contain neutrophils suggest a bacterial infection such as catscratch disease, melioidosis, tularemia, or typhoid.

Mycobacteria. Caseous necrosis (Fig. 9.75) should suggest miliary tuberculosis, although acid-fast bacilli may be difficult or impossible to find. Absence of caseation, of course, does not exclude tuberculosis. Lepra bacilli are difficult to find in granulomas in tuberculoid leprosy, but they can be demonstrated in large numbers with special stains in untreated lepromatous leprosy in enlarged reticuloendothelial cells that have a foamy cytoplasm (lepra cells) and are clustered in granuloma-like formations (107). Similarly, patients with AIDS

and disseminated *Mycobacterium avium intracellulare* frequently have hepatic involvement with "macrophagic" granulomas composed of hypertrophied, grey–blue macrophages containing hundreds of acid-fast bacilli (Fig. 9.76) (108). Giant cells and

inflammatory cells are generally absent, as is caseous necrosis.



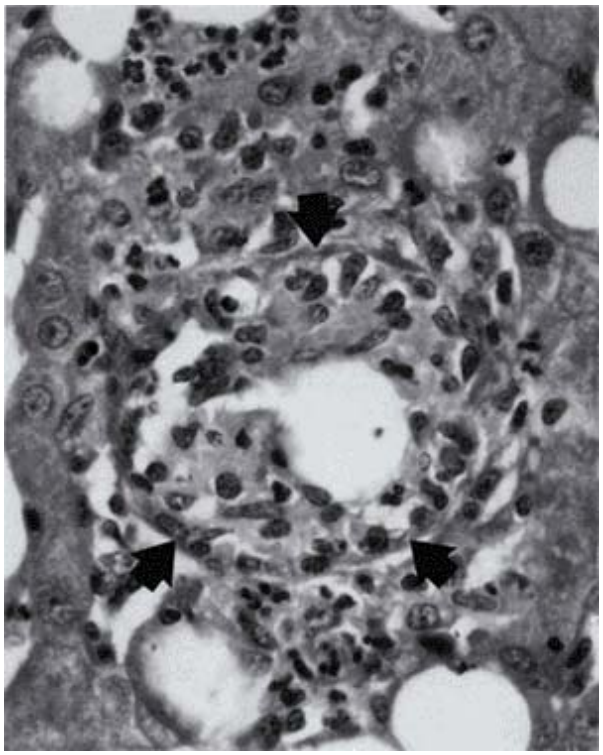
▪ **Figure 9.73** Typical noncaseating granulomas in a patient with sarcoidosis. The granulomas are composed predominantly of epithelioid histiocytes. The smaller granuloma in the lower part of the field probably represents a tangential cut through a larger lesion.

Fungi. Granulomas in the systemic mycoses often contain the fungal spores or hyphae that may be visible with hematoxylin and eosin but are best demonstrated with the Gomori methenamine silver stain (Fig. 9.77).

Protozoa. Organisms in visceral leishmaniasis are usually found in hypertrophied Kupffer cells, but granulomas may be seen, sometimes with central necrosis and sometimes with fibrin rings (103).

Parasites. Several parasitic diseases can involve the liver with a granulomatous response (103). By far the most important of these is schistosomiasis. The granulomas in this disease usually contain intact eggs (Fig. 9.78) or their chitinous remnants. The granulomas in the same biopsy specimen can be of differing ages, from "active" granulomas with many epithelioid cells and eosinophils to round scars containing fragments of egg chitin.

Granular black schistosomal pigment, which is the acid hematin residue from breakdown of host hemoglobin by the parasite, is usually readily identified in the reticuloendothelial cells in livers harboring active granulomas. Other parasitic diseases in which eggs can be found in association with a granulomatous response include hepatic capillariasis, fascioliasis, paragonimiasis, and ascariasis. Visceral larva migrans, usually attributable to the larvae of *Toxocara* species, produces a characteristic lesion in the liver. The granulomas are associated with a massive outpouring of eosinophils and often reveal areas of central necrosis resulting from degeneration and degranulation of eosinophils (Fig. 9.79); there can be Charcot-Leyden crystals in the necrotic foci, but larvae are only rarely identified (109).



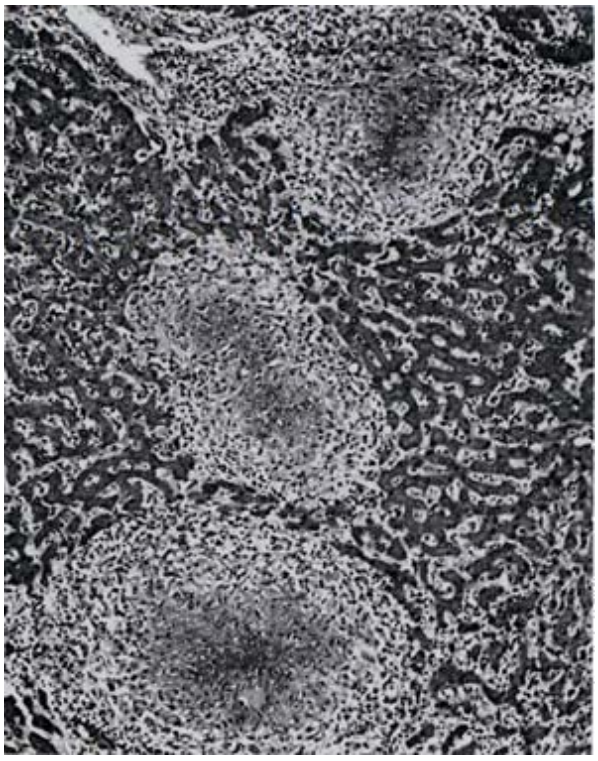
▪ **Figure 9.74** Fibrin ring granuloma in Q fever (*Coxiella burnetti* infection) has a central fat globule surrounded by epithelioid cells and a brightly eosinophilic ring of fibrin (*arrows*).

Noninfectious granulomas

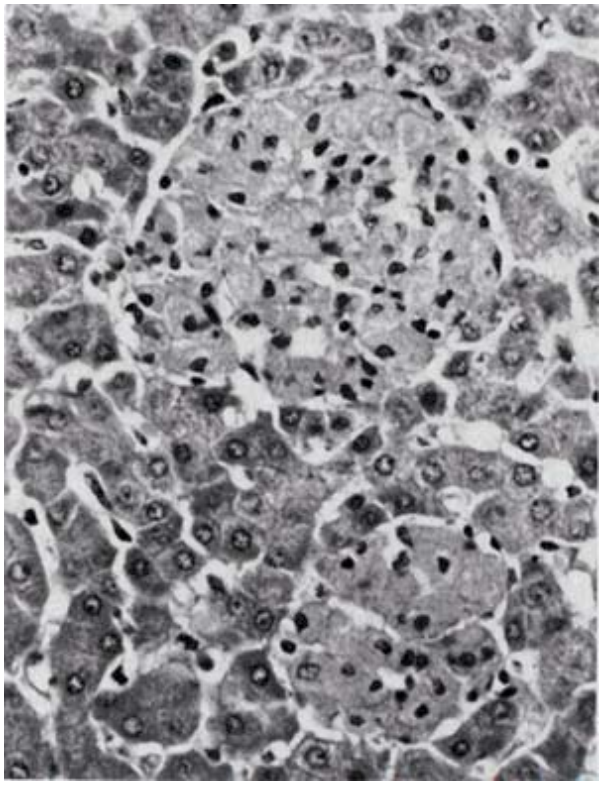
Sarcoidosis is the prototype of all granulomatous diseases. It is always a diagnosis of exclusion, requiring demonstration of granulomas in two or more tissues with exclusion of all known causes of granulomatous disease. At least 90% of patients with sarcoidosis have hepatic

involvement, although in most it is clinically insignificant. Granulomas in sarcoidosis have no specific identifying features, but they do tend to have certain characteristics. The granulomas are scattered

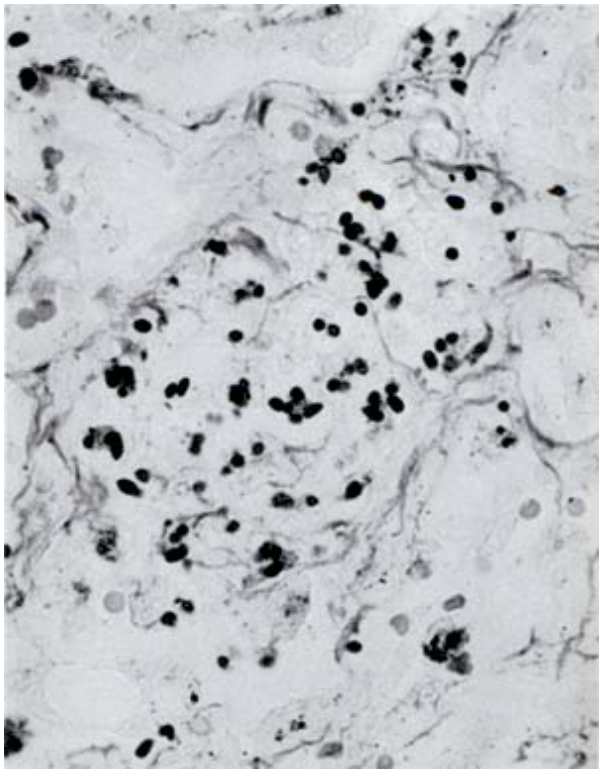
throughout the liver tissue, but most tend to be portal or periportal. Granulomas of all ages are typically present. The earliest lesions consist of small, loosely arranged clusters of a few epithelioid cells within the acini. Older lesions are globular or ovoid and sharply defined (Fig. 9.73), and in cases with severe involvement, the granulomas may be confluent. Young granulomas tend to be composed predominantly of epithelioid cells, often with a few lymphocytes, while giant cells are a sign of aging. The giant cells may contain asteroid bodies (Fig. 9.80), Schaumann bodies, or calcium oxalate crystals. Older granulomas often have many giant cells, and sometimes, when the granulomas have resolved, a few naked giant cells may remain in the tissue. Usually, however, sarcoid granulomas heal by scarring, and often there is a rim of dense collagen around each granuloma (Fig. 9.81). The last remnant is a fibrous nodule, sometimes containing one or two giant cells. The granulomas in sarcoidosis are typically noncaseating, but rarely caseous necrosis may be seen in otherwise typical cases (74).



▪ **Figure 9.75** Miliary tuberculosis with amorphous, caseous necrosis in the centers of the granulomas.

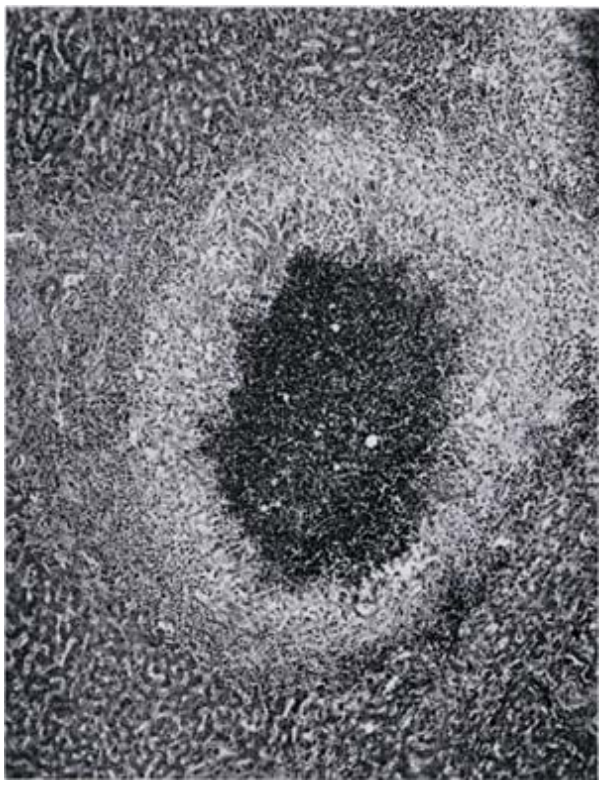


▪ **Figure 9.76** Disseminated *Mycobacterium avium intracellulare* in a patient with acquired immunodeficiency syndrome. The liver contains "macrophagic" granulomas composed of hypertrophied, grey–blue macrophages. Acid-fast stains typically show hundreds of acid-fast bacilli.



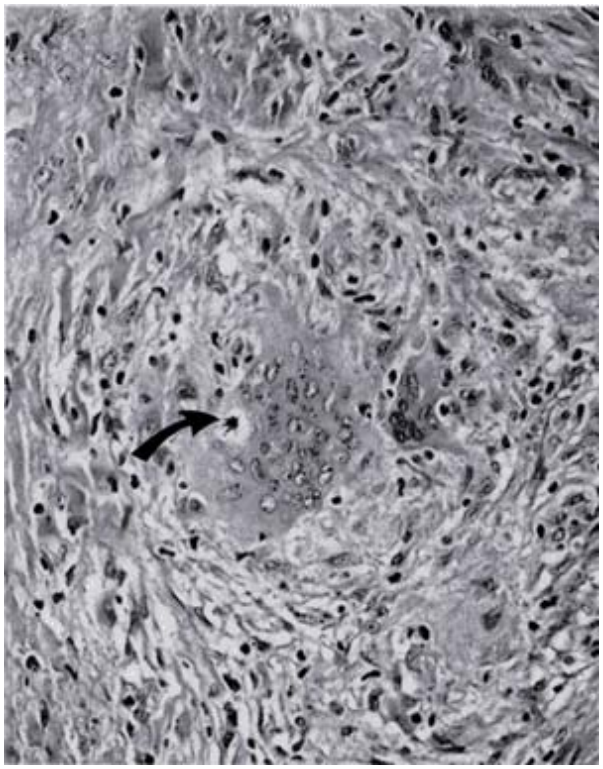
▪ **Figure 9.77** Gomori methenamine silver stain is useful for demonstrating fungal organisms in systemic mycoses. Yeast forms can be seen in this case of histoplasmosis.

▪ **Figure 9.78** Schistosomiasis. This portal granuloma contains an embryonated egg.



▪ **Figure 9.79** Visceral larva migrans. This eosinophilic granuloma consists of a central area of necrotic eosinophils surrounded by a palisade of epithelioid histiocytes and an outer zone that contains many additional eosinophils.

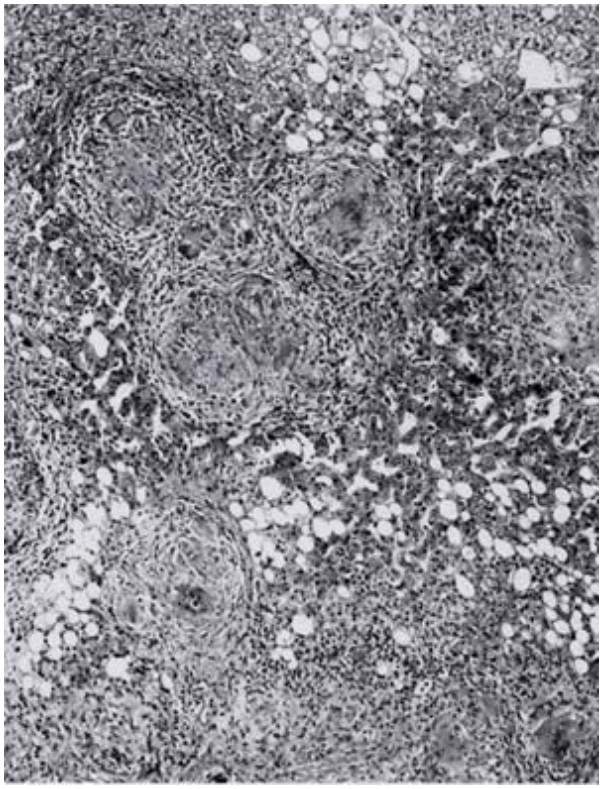
In most patients with sarcoidosis, the hepatic granulomas are clinically silent. An unknown proportion of patients, however, come to clinical attention because of clinical symptoms and signs of cholestatic liver disease, portal hypertension, or abnormal liver test results. Biopsy results in such cases show a spectrum of changes (74). Some patients have only sarcoid granulomas without other associated changes, but the majority show some degree of associated necroinflammatory injury (e.g., apoptosis, focal necrosis, chronic portal inflammation), features of chronic cholestasis (e.g., cholate stasis, bile duct loss), or some combination of these. Extensive portal fibrosis may cause severe bile duct loss leading to a biliary cirrhosis, or there may be fibrous obliteration of portal vein branches, producing portal hypertension.



▪ **Figure 9.80** Sarcoidosis. An old fibrotic granuloma containing several giant cells, one of which has an asteroid body (*arrow*).

In a significant proportion of patients a cause is never found for the sarcoid-like hepatic granulomas, and no extrahepatic granulomas are found to confirm the diagnosis of sarcoidosis. Nevertheless, such cases probably represent the same idiopathic disease, but until the cause of sarcoidosis is discovered, these cases will remain undiagnosed.

Sarcoid-like granulomas can be seen in PBC, chronic berylliosis, brucellosis, drug-induced injury, and in many miscellaneous conditions. Some diseases are characterized by lesions other than the granulomas that suggest the diagnosis. For example, the liver in PBC also reveals chronic cholestasis and cholangiodestructive lesions in portal areas. Drug-induced granulomas can be accompanied by hepatocellular injury or combined hepatocellular and cholestatic injury, as is typical of the liver injury associated with several drugs (23,50).



▪ **Figure 9.81** Sarcoidosis. Old, partially healed granulomas are surrounded by fibrosis and contain both epithelioid histiocytes and giant cells.

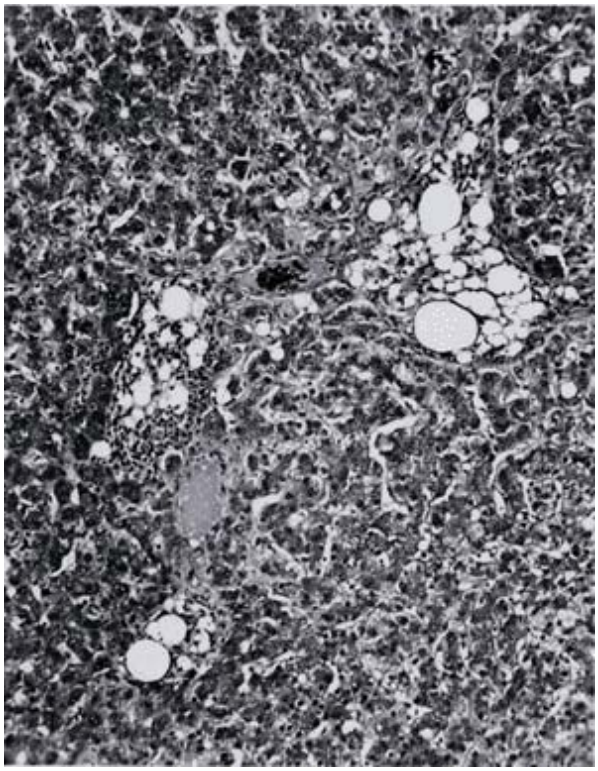
Lipogranulomas in the liver are a common finding, the result of the accumulation of ingested mineral oil (110). They consist of variable numbers of fat vacuoles, histiocytes, mononuclear cells, and sometimes eosinophils or neutrophils, and there can be some associated focal fibrosis (Fig. 9.82). Typically, lipogranulomas are located in portal areas or in the vicinity of terminal hepatic venules.

Metabolic Diseases

Identification of storage products

In the broadest sense, the term *storage* can be used to include various lesions and diseases characterized by the abnormal or excessive accumulation of a metabolite or substance in one of the cellular or extracellular compartments of the liver. This may include storage in hepatocytes, reticuloendothelial cells (Kupffer cells or other macrophages), stellate cells, and other mesenchymal cells, canaliculi, ductules, bile ducts, space of Disse, and other parts of the vasculature. Storage may indicate an inherited metabolic disease (111), or it may be

part of some other process. When an abnormal substance is noted, it can often be identified by its appearance in routine sections and by its reactions with special histochemical stains. Special techniques, such as transmission or scanning electron microscopy, fluorescence or polarizing microscopy, or immunohistochemistry, may help in select cases.



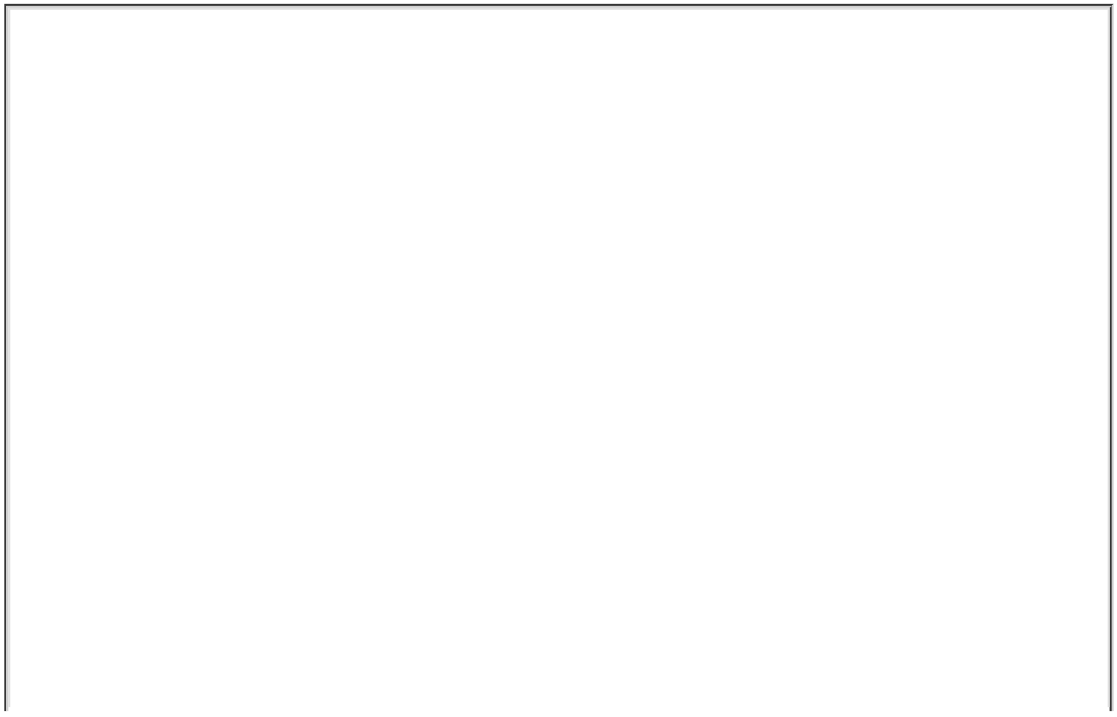
▪ **Figure 9.82** Three small lipogranulomas, composed of mineral oil droplets, macrophages, and chronic inflammatory cells.

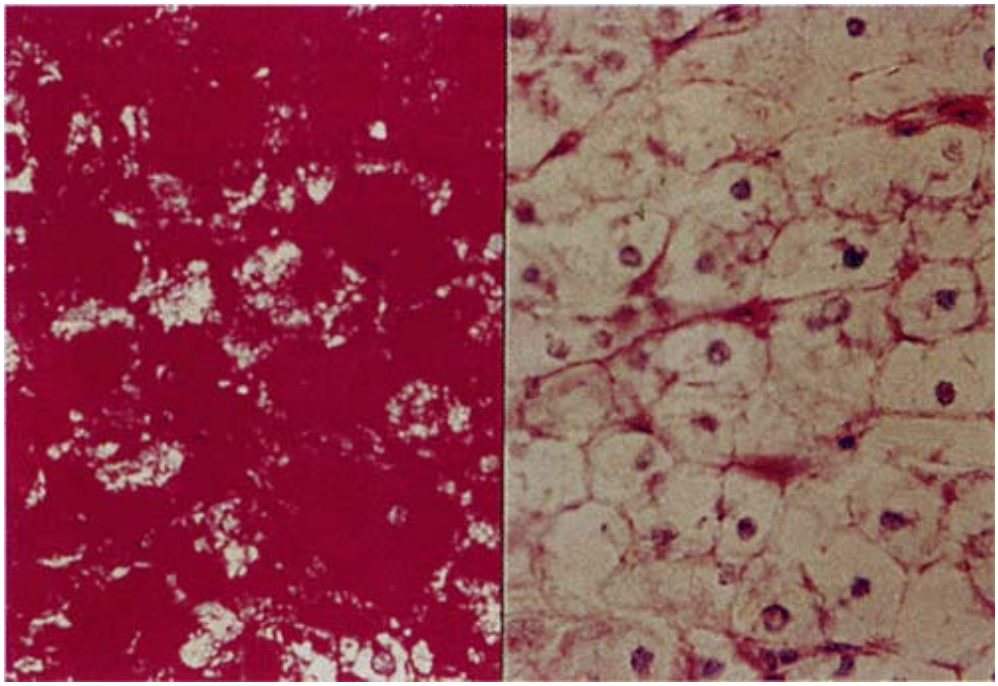
Pigment storage is one of the more common lesions. This can be recognized as brown, green, or black material, which may be stored in hepatocytes, macrophages, or canaliculi. *Bile* pigment varies from brown to green and may be found in canaliculi, ductules, or ducts in cholestatic diseases (see preceding text), which rarely presents an identification problem. Bile pigment in hepatocytes and Kupffer cells can usually be distinguished from other pigments by a characteristic green color in a Hall's stain for bile or by a greenish brown color in a Prussian blue iron stain. *Lipofuscin* pigment varies from dark brown to golden brown. It is found in hepatocytes ("wear and tear" pigment) as a normal part of aging and in increased amounts in patients with chronic drug ingestion and Dubin-Johnson syndrome; it is found in Kupffer cells as the breakdown product of phagocytosed cellular debris when there has been necroinflammatory injury or other forms of tissue necrosis. Lipofuscin stains positively with argentaffin and PAS stains (Fig. 9.4)

and negatively with the iron stain. *Hemosiderin* is brown and coarsely granular and refractile in routine stains. It accumulates in hepatocytes, Kupffer cells, and mesenchymal cells to varying

degrees in hemochromatosis and other iron overload states, and, like lipofuscin, it accumulates in Kupffer cells when there has been necroinflammatory injury. Hemosiderin stains positively with the Prussian blue stain for iron (Fig. 9.6), and so this stain can be easily used in most cases to distinguish the three brown pigments from one another.

Glycogen storage is a physiologic function of the hepatocytes. In the fed state, glycogen can be demonstrated in liver cell cytoplasm with the PAS stain, and predigestion with diastase will abolish the staining. If glycogen storage disease is suspected, a portion of the biopsy specimen should be fixed in alcohol, rather than formalin, because this is the most suitable fixative for the histochemical demonstration of glycogen. In glycogen storage diseases, the glycogen often accumulates to such an extent that the hepatocytes appear swollen and plant-like (Fig. 9.83) (111). Definitive diagnosis, however, depends on the demonstration of the specific enzymatic defect. Type IV glycogen storage disease differs from the other types and is the only type that can be readily diagnosed on liver biopsy (112). This type is associated with the accumulation of an abnormal glycogen molecule, an amylopectin-like material, in hepatocytes. This distinctive material is homogeneous and slightly eosinophilic or even colorless. It typically appears as a circumscribed inclusion (Fig. 9.84) displacing the remainder of the cytoplasm and the nucleus to the periphery and stains intensely with PAS, Best's carmine, colloidal iron, and Lugol's iodine. The inclusions resist digestion with diastase or amylase but can be digested with pectinase.

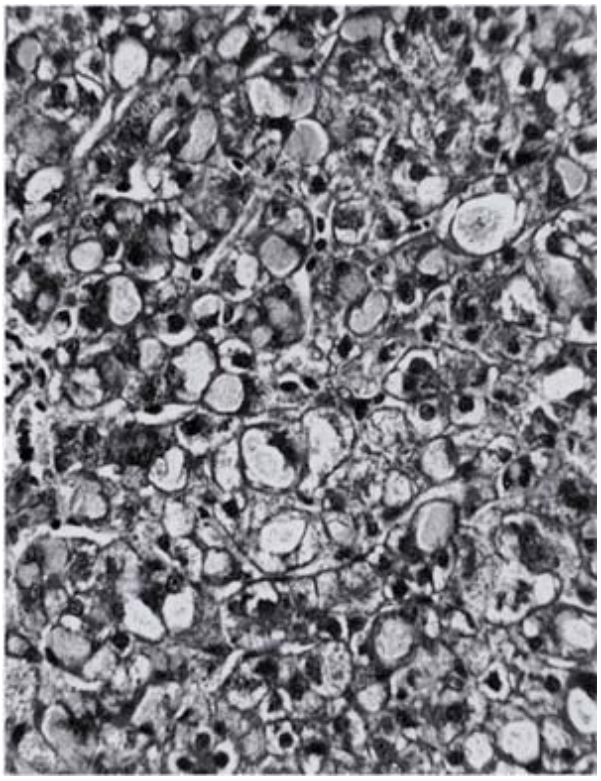




▪ **Figure 9.83** Type I glycogen storage disease. Periodic acid-Schiff stain (*left*) shows that the enlarged hepatocytes are filled with glycogen, which is removed by diastase digestion (*right*), showing the liver cells to have a clear, finely vesiculated cytoplasm.

Proteins and glycoproteins are stored in hepatocytes in several conditions. Proteins stain with eosin in routine hematoxylin and eosin sections, so they can be recognized as storage material when they form discrete cytoplasmic inclusions. *a_1-Antitrypsin (AAT) deficiency* (see Chapter 37) is the best-characterized disorder with protein storage. AAT, a major protease inhibitor (Pi) in serum, is a glycoprotein that is synthesized predominantly by the liver to function as a modulator of the inflammatory response by inhibiting proteases. Individuals with one or both AAT alleles of the "Z" phenotype are unable to transport and secrete newly synthesized AAT molecules normally through the endoplasmic reticulum and Golgi apparatus of the hepatocyte, resulting in low concentrations of AAT in the serum. Faulty secretion of abnormal AAT molecules coupled with defective degradation of these molecules retained in the Golgi apparatus leads to the formation of characteristic eosinophilic globules in hepatocytes (Fig. 9.85) (113). The globules are PAS positive and diastase resistant (Fig. 9.5) due to the carbohydrate moieties of the glycoprotein. These are typically found in patients who are homozygous or heterozygous for PiZ, but they can also occur in other phenotypes, even sometimes in patients with the normal PiM phenotype (114,115). In the noncirrhotic liver, the characteristic AAT globules are located in periportal hepatocytes.

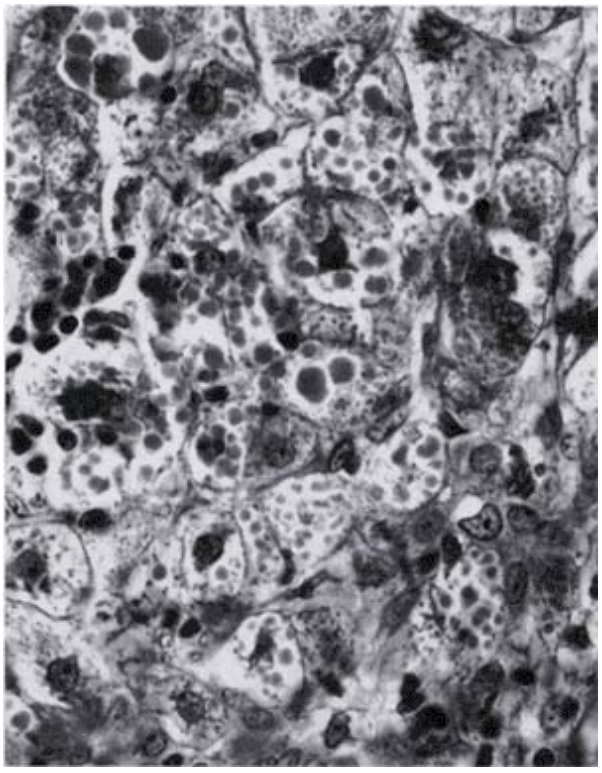
They are round, homogeneous, and eosinophilic, and vary from 1 to 40 μm in diameter. Usually, they are separated from the remainder of the cytoplasm by a halo that is probably artifactual. Immunohistochemical staining can confirm that the globules are composed of AAT but cannot be used to determine the phenotype. PAS-positive globules are usually not detectable in infants younger than 3 months, although some present with neonatal hepatitis or paucity of bile ducts. Liver biopsy specimens from adults with AAT deficiency may reveal only the characteristic globules in periportal regions, or there may be erosion of the limiting plate associated with chronic inflammation and periportal fibrosis, similar to chronic hepatitis of other etiologies, or cirrhosis with globules at the periphery of the nodules.



▪ **Figure 9.84** Type IV glycogen storage disease. The abnormal glycogen metabolite accumulates in cytoplasmic inclusions.

Other protein storage disorders, both inherited and acquired, may produce cytoplasmic inclusions. α_1-Antichymotrypsin deficiency and antithrombin III deficiency are rare, but both are associated with AAT-like PAS-positive globules (116,117). Familial fibrinogen storage disease produces globular inclusions that are eosinophilic but only weakly PAS-positive because of a lower carbohydrate content (118). Plasma protein inclusions (119), consisting of a mixture of circulating proteins imbibed

by hepatocytes from the plasma, are seen most often in hepatic congestion. They are variably PAS positive and may be globular or have a pale eosinophilic appearance that can be confused with the ground-glass inclusions of hepatitis B. PAS-positive, diastase-resistant, ground-glass–appearing inclusions are also seen in patients taking the drug cyanamide (120) (not used in the United States) and in patients with Lafora's disease (myoclonus epilepsy) (121).

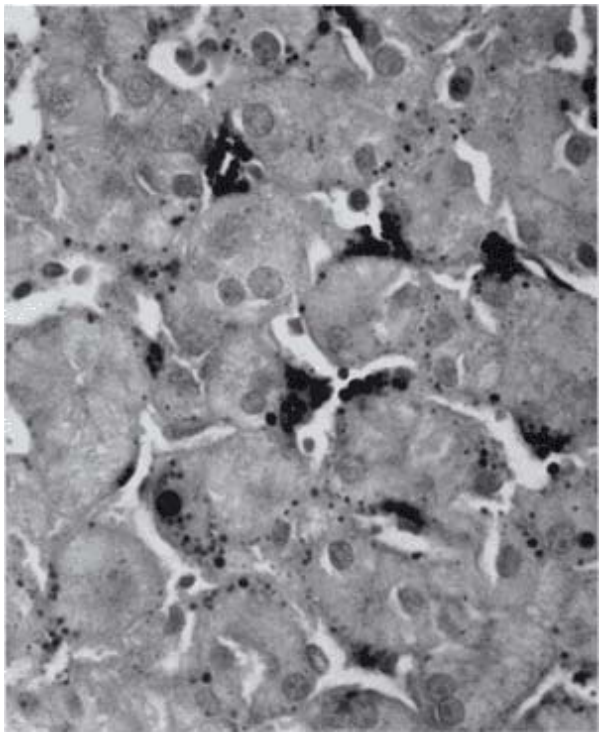


▪ **Figure 9.85** α_1-Antitrypsin deficiency. The hepatocytes contain eosinophilic globules of α_1-antitrypsin stored in endoplasmic reticulum cisternae.

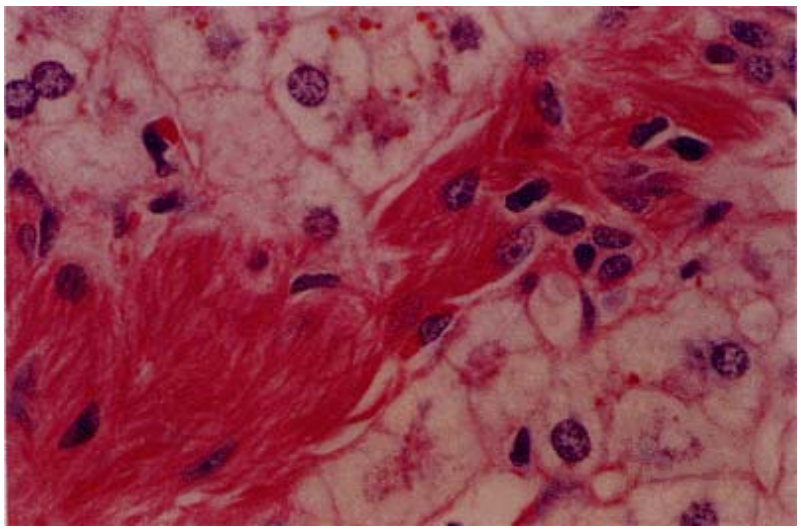
Lipids, glycolipids, sphingolipids, and other phospholipids accumulate in a number of inherited and acquired conditions. Hepatocytes, Kupffer cells, and stellate cells that contain a lipid storage product generally appear clear, vacuolated, or foamy. Triglyceride is by far the most common storage product, and this is discussed separately in the preceding text under Steatosis. All lipids stain positively in unprocessed frozen sections with the oil red O and Sudan black stains. Most, however, do not survive routine processing in organic solvents, so their demonstration requires forethought because a portion of the specimen must be handled separately. To avoid the artifacts of frozen section, the tissue can be postfixed in osmium tetroxide, which stains the lipid black (Fig. 9.86) (122). Cholesterol esters are stored along with triglyceride

in the two forms of lysosomal acid lipase deficiency, Wolman's disease and cholesterol ester storage disease, causing the hepatocytes to appear swollen and pale. Both types of lipid stain with oil red O, but the cholesterol can also be demonstrated in frozen

sections with a Schultz stain (1). Glucosylceramide, a glycolipid, accumulates in Kupffer cells in Gaucher's disease (lysosomal glucocerebrosidase deficiency), producing the distinctive striated appearance of Gaucher's cells. The PAS stain after diastase digestion provides an excellent demonstration of these cells because enough of the carbohydrate component of the storage product survives processing and stains positively (Fig. 9.87). Sphingomyelin accumulates in Kupffer cells in the many variants of Niemann-Pick disease, producing a foamy appearance (Fig. 9.88). Other phospholipids accumulate in both Kupffer cells and hepatocytes in drug-induced phospholipidosis because of chronic ingestion of amphophilic drugs such as amiodarone (50). The Kupffer cells appear foamy, but the hepatocellular phospholipid storage can generally only be recognized by electron microscopy (Fig. 9.89). Vitamin A is stored in stellate cells (formerly called *perisinusoidal lipocytes or Ito cells*), and these become prominent in individuals ingesting excess vitamin A (Fig. 9.90). Lipid globules containing the vitamin A are apparent with fat stains, and vitamin A is autofluorescent in frozen sections. Mineral oils (paraffins) are common in the Western diet, and some are absorbed and stored in portal macrophages or lipogranulomas near terminal hepatic venules (Fig. 9.82). In frozen sections the mineral oil stains a pale salmon with the oil red O stain.



▪ **Figure 9.86** Osmium stain for fat. Lipids stain black when the tissue is postfixed in osmium tetroxide. In this patient with hypervitaminosis A, the stellate cells (perisinusoidal lipocytes) are hypertrophied because of vitamin A storage, and there are a few small triglyceride droplets in hepatocytes.



▪ **Figure 9.87** Gaucher's disease. Striations in the Gaucher's cells are nicely demonstrated by the PAS stain after diastase digestion.

Mucopolysaccharides accumulate in both hepatocytes and Kupffer cells in Hunter and Hurler diseases (Fig. 9.91), other mucopolysaccharidoses, and mucolipidoses. The affected cells appear swollen and finely vacuolated. Colloidal iron, alcian blue, and other stains for mucopolysaccharides are positive, and the PAS stain after diastase digestion is also positive. Oligosaccharides in diseases such as sialidosis are stored in hepatocyte lysosomes, making the liver cells appear vacuolated.

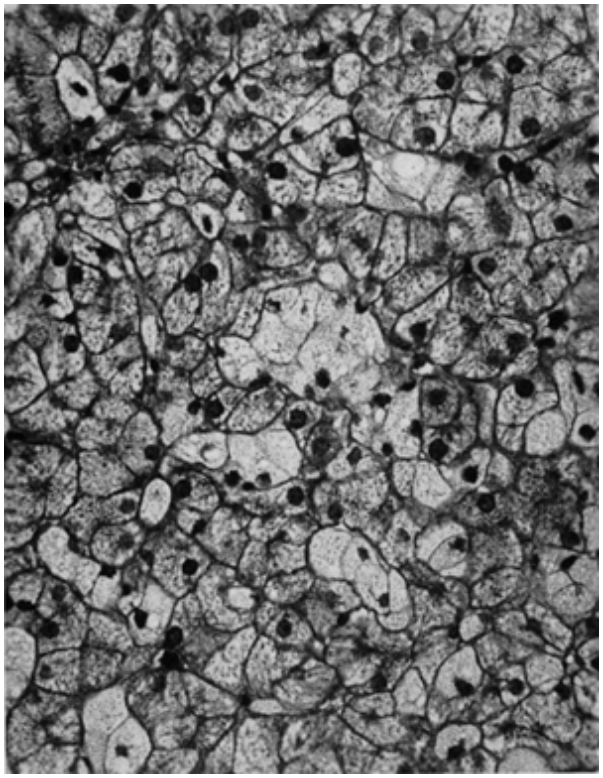
Porphyrins accumulate in the liver in porphyria cutanea tarda and erythropoietic protoporphyria (see Chapter 38). Uroporphyrin crystals in hepatocytes are

P.292

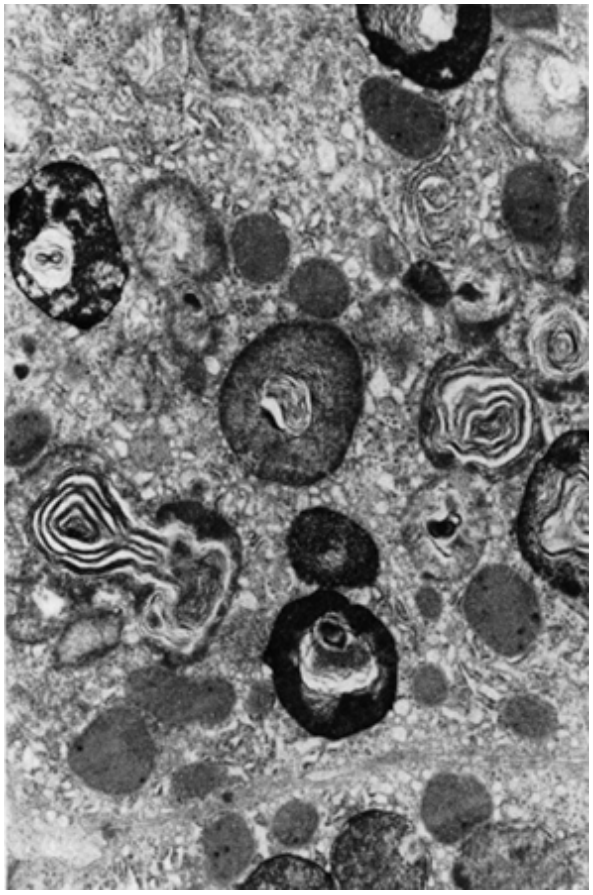
P.293

inapparent by routine stains, but these can sometimes be demonstrated with a ferric ferricyanide stain (123) in patients with porphyria cutanea tarda. Protoporphyrin deposits in erythropoietic protoporphyria appear as brownish red globular masses in hepatocytes and bile canaliculi. They are easily mistaken for bile pigment, but with polarized light they

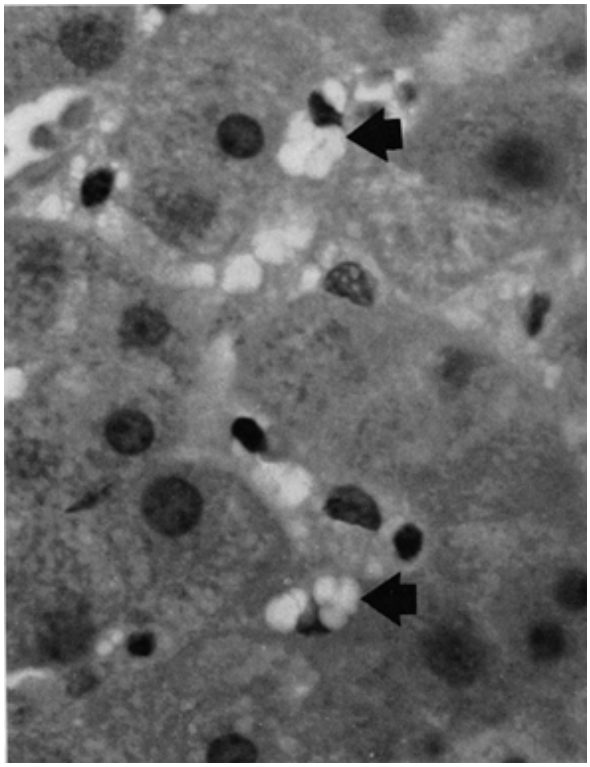
are red with characteristic Maltese cross birefringence (Fig. 9.15) (13).



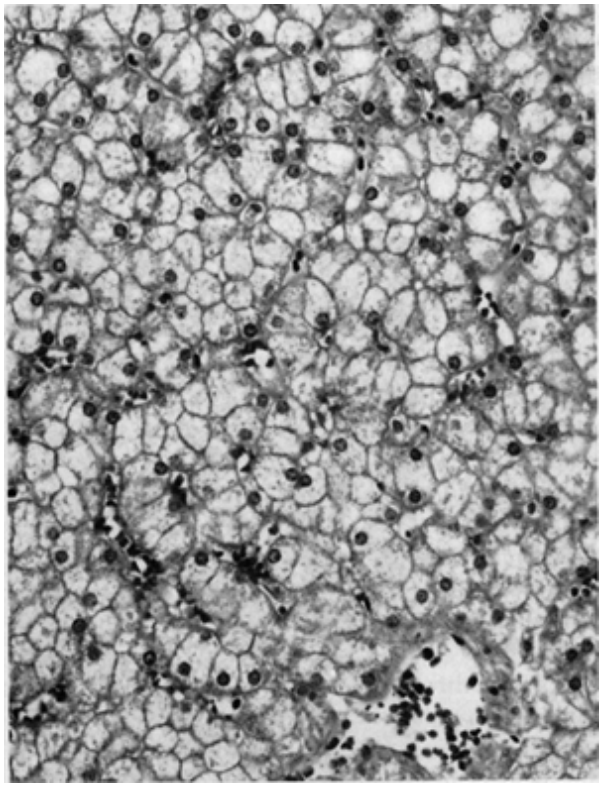
▪ **Figure 9.88** Niemann-Pick disease. Sphingomyelin accumulates in Kupffer cells, giving them a foamy appearance. Liver cells appear normal.



▪ **Figure 9.89** Phospholipidosis in a patient taking amiodarone. Ultrastructurally the hepatocyte cytoplasm contains numerous lamellated whorls of phospholipid.



▪ **Figure 9.90** Hypervitaminosis A. Stellate cells (*arrows*) are engorged with stored vitamin A.



▪ **Figure 9.91** Hurler disease. The stored mucopolysaccharide gives the swollen liver cells a finely vacuolated appearance.

Copper storage in hepatocytes in chronic cholestatic diseases or in Wilson disease is not visible by light microscopy, but it is often found in association with periportal or periseptal lipofuscin granules. Stains for copper, such as rhodanine (Fig. 9.7), are needed for demonstrating storage because it can easily be missed.

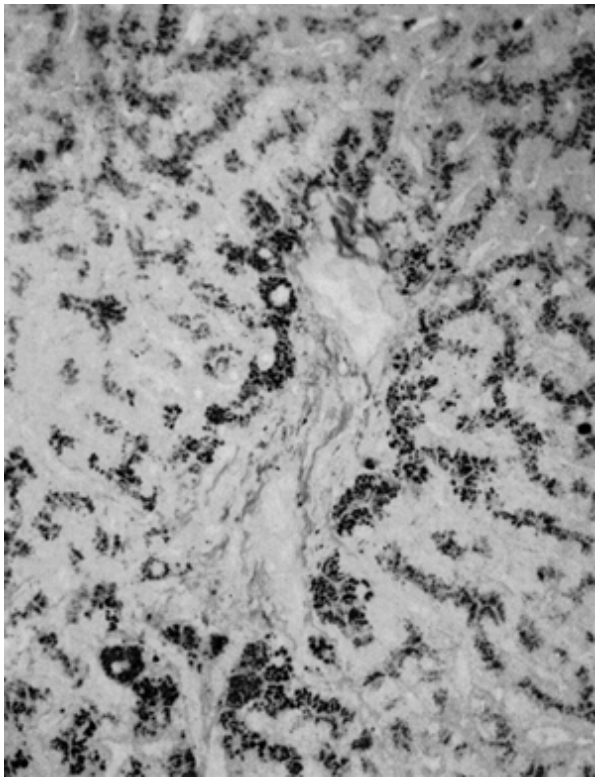
Crystals of various types may be stored in macrophages under special conditions. Many crystals are birefringent with polarized light, and scanning electron microscopy with x-ray spectrophotometry can specifically identify those that are inorganic. In cystinosis, crystals of cystine can be demonstrated with the polarizer in the tissue that has been fixed in alcohol. Birefringent talc crystals (Fig. 9.14) or black, nonbirefringent titanium dioxide pigment granules can sometimes be found in macrophages of some patients who are or had been intravenous drug abusers. Other foreign materials, such as gold (which appears as a black pigment in patients treated with gold for rheumatoid arthritis), thorium dioxide (Thorotrast, a discontinued radiologic contrast material), polyvinyl pyrrolidone (a discontinued plasma expander), and anthracotic carbon (in coal miners), may be found stored in reticuloendothelial cells.

Genetic hemochromatosis

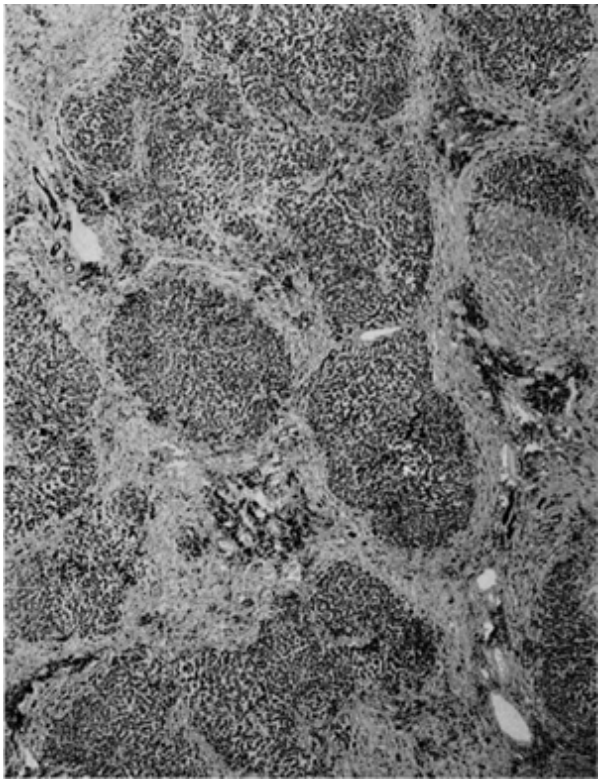
As the most common hepatic storage disease, biopsy diagnosis of hemochromatosis deserves special mention. Gene analysis and quantization of iron concentration in liver tissue obtained by biopsy are now the preferred method for diagnosis (see Chapter 36), but examination of the biopsy specimen is still useful in distinguishing primary from secondary iron overload and in assessing the degree of fibrosis. *Secondary iron overload* is the proper term for nongenetic causes of excess tissue iron. This may be due to multiple blood transfusions, chronic hemolysis, or prolonged dietary overload, but it rarely results in tissue damage except in a few extreme instances. *Hemosiderosis* is the term used for morphologically identifiable iron accumulation in tissue, whatever the cause. Severe hemosiderosis is usually due to genetic hemochromatosis, but it can be secondary to transfusional or dietary iron or chronic hemolysis. In such cases the hemosiderin accumulation is predominantly in reticuloendothelial cells. Excess iron may accumulate in hepatocytes of patients with damaged livers, especially in alcoholic cirrhosis and also in chronic viral hepatitis. Many of these patients are probably heterozygous for genetic hemochromatosis.

In homozygous genetic hemochromatosis, iron accumulates over the course of the patient's life (124). In young homozygous patients, this is detected as a progressive increase in hepatocellular hemosiderin pigment (most prominently in periportal regions) with minimal or no other pathologic changes (Fig. 9.92). As the quantity of iron increases, the cells of zones 2 and 3 become affected. Scattered apoptotic bodies and foci of necrosis are found infrequently. Kupffer cells may ingest small quantities of iron. By middle age in men or after menopause in women, enough iron has usually accumulated to cause hepatocellular necrosis, portal inflammation, and portal and bridging fibrosis. Alcohol and intercurrent liver diseases such as hepatitis C may accelerate iron accumulation. Fibrous septa eventually creep from the portal areas into the surrounding parenchyma. Evidence of regeneration is not apparent in the precirrhotic stage, but a reticulin stain can demonstrate plates greater than one cell in thickness near the portal tracts. The fibrous septa can

show variable ductular proliferation, but inflammation is mild or absent.



▪ **Figure 9.92** Hemochromatosis. This iron stain of a biopsy from a young homozygous patient shows a marked increase in hepatocyte stainable iron (dark granules), most prominently in acinar zone 1. There is no fibrosis as yet.



▪ **Figure 9.93** Micronodular cirrhosis of hemochromatosis. The iron stain shows marked deposition of hemosiderin (dark granules) in liver cells, bile ducts, and mesenchymal cells of the fibrous septa.

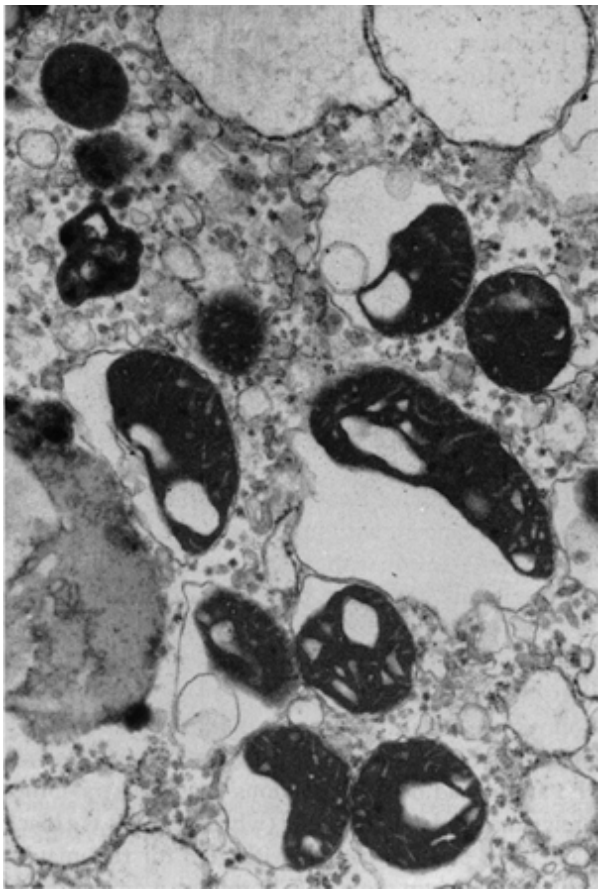
Fibrous bands from adjacent portal tracts eventually join and dissect the parenchyma into irregular micronodules (Fig. 9.93). By this stage there is marked hemosiderin deposition with heavy pigment staining of hepatocytes, bile duct epithelium, ductules, and mesenchymal cells of the fibrous septa and vessels. Relatively less iron is found in Kupffer cells. Regeneration is not usually prominent, but regenerative nodules offer striking contrast to the remaining parenchyma by their lack of stainable iron, so-called iron-free foci (125). Hepatocellular carcinomas that develop in hemochromatotic livers are also devoid of iron, and there is evidence that the iron-free foci represent preneoplastic lesions.

Wilson disease

Tissue damage in Wilson disease (see Chapter 35) is related to excess copper, and the liver is the earliest site of progressive copper accumulation, after which the copper is released into the blood to accumulate in other organs. The histopathologic changes (126,127,128) are not specific and must be evaluated in conjunction with clinical and laboratory findings. Hepatic copper concentration can be measured in the tissue obtained by needle biopsy and can provide a definitive

diagnosis when other tests are equivocal. Biopsy specimens obtained from young siblings of patients with this disease may show little or no hepatic damage. The earliest microscopic lesions include steatosis, periportal glycogenated nuclei, and rare foci of necrosis or apoptotic bodies. Although the hepatic copper content is elevated, copper is usually not histochemically identifiable at this stage, but ultrastructural changes in hepatic mitochondria, thought to be characteristic if not pathognomonic, are present (Fig. 9.94). These include pleomorphism, separation of the inner and outer membranes, enlarged intercristal spaces, and various types of inclusions (6,129). More advanced cases show lesions that resemble chronic hepatitis of other cause. Mallory bodies, with their characteristic neutrophilic response, may be present in the liver cells in zone 1. Copper may be demonstrable in the periportal areas with appropriate stains. A variety of patterns of cirrhosis can develop in the later stages but a macronodular type is the most common (Fig. 9.95). Regenerative foci lack identifiable copper, so absence

of stainable copper in a cirrhotic biopsy, particularly if the sample is small, does not rule out Wilson disease. On the other hand, a large amount of copper in a cirrhotic liver is strongly suggestive of Wilson disease (Fig. 9.7).



▪ **Figure 9.94** Wilson disease. Ultrastructurally, the mitochondria have a dense matrix with separation of the membranes of the cristae.

▪ **Figure 9.95** Wilson disease, end stage. Macronodular cirrhosis is present with large nodules separated by bands of scar tissue.

Vascular Disorders

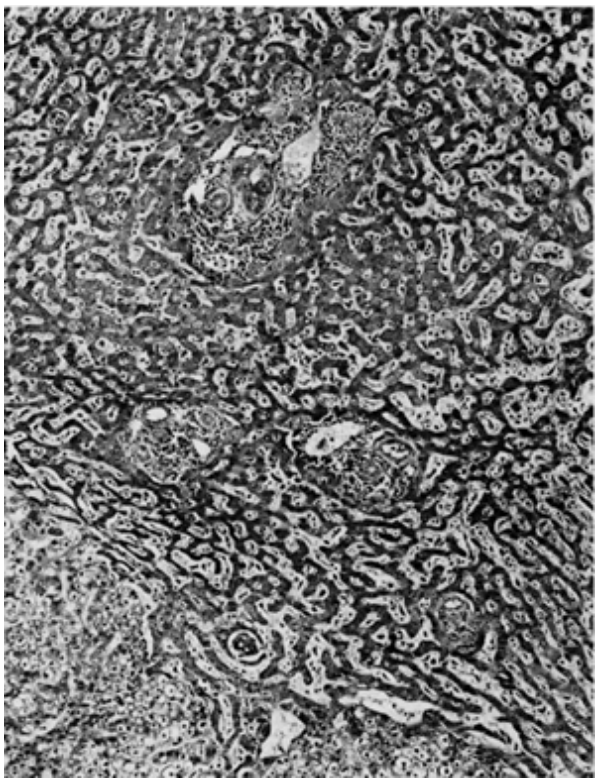
Vascular patterns of injury

Certain patterns of injury in the liver are typical, if not pathognomonic, of a vascular disease. Congestion, atrophy, and coagulative necrosis are all findings that suggest a vascular component to the underlying disorder. A variety of substances, both endogenous and foreign, can be deposited in the vasculature as well.

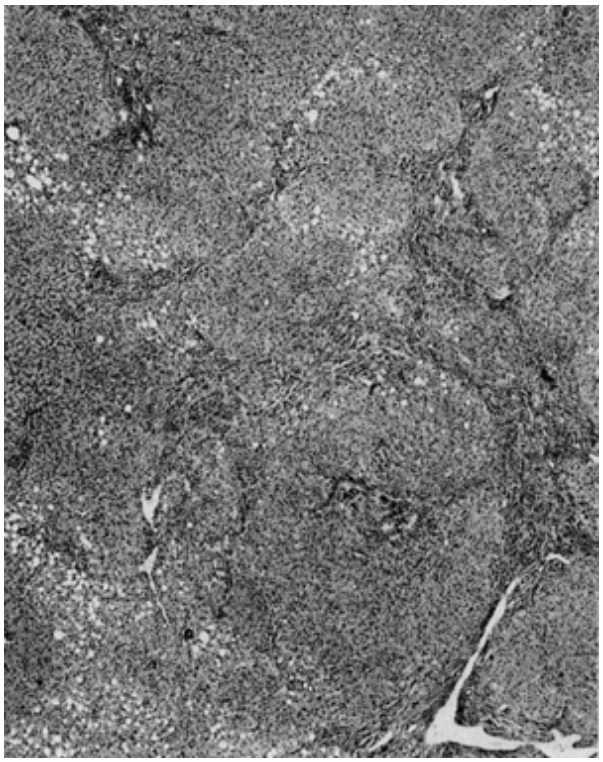
Ischemia. Acute ischemic injury typically produces zone 3 ("centrilobular") coagulative necrosis, similar to that seen in severe injury from certain toxins, such as acetaminophen overdose or mushroom poisoning. Ischemic injury may follow shock, left-sided heart

failure, or right-sided failure associated with hypotension (130,131). Clinically, the presentation may mimic viral hepatitis (ischemic hepatitis) (132). Liver cells that have undergone coagulative degeneration are shrunken, have an intensely eosinophilic cytoplasm, and show nuclear pyknosis or lysis (Fig. 9.20). When an inflammatory response is present, it is invariably neutrophilic. Kupffer cells are hypertrophied and usually full of lipofuscin. Clearing of the dead hepatocytes leads to condensation of reticulin fibers and fibrosis in some cases.

Atrophy. Chronic ischemic injury produces atrophy of acini or liver cell plates. Mild forms of chronic ischemia are a fairly common consequence of aging. Mild portal fibrosis with some periductal fibrosis and reduction in portal vein diameter is a frequent finding in elderly individuals. Often there will be areas in the liver in which vascular structures appear close together, indicating that the acini have atrophied (Fig. 9.96). Extreme forms of this phenomenon can result in hepatoportal sclerosis (also called *idiopathic portal hypertension, noncirrhotic portal hypertension, or noncirrhotic portal fibrosis*) (133) or nodular regenerative hyperplasia (134) when there is heterogeneous blood flow through portal vein branches and hepatic arterioles with atrophy of the affected acini and compensatory hyperplasia of other acini (Fig. 9.97). Both conditions may cause portal hypertension in the absence of cirrhosis. Atrophy of the left lobe and segmental atrophy (Fig. 9.98) (135) are usually due to severe compromise of the vasculature (inflow or outflow) to a portion of the liver, but this may also be due to bile duct occlusion.



▪ **Figure 9.96** Atrophy, secondary to chronic ischemia. Portal areas are fibrotic and close together, indicating atrophy of the acini.



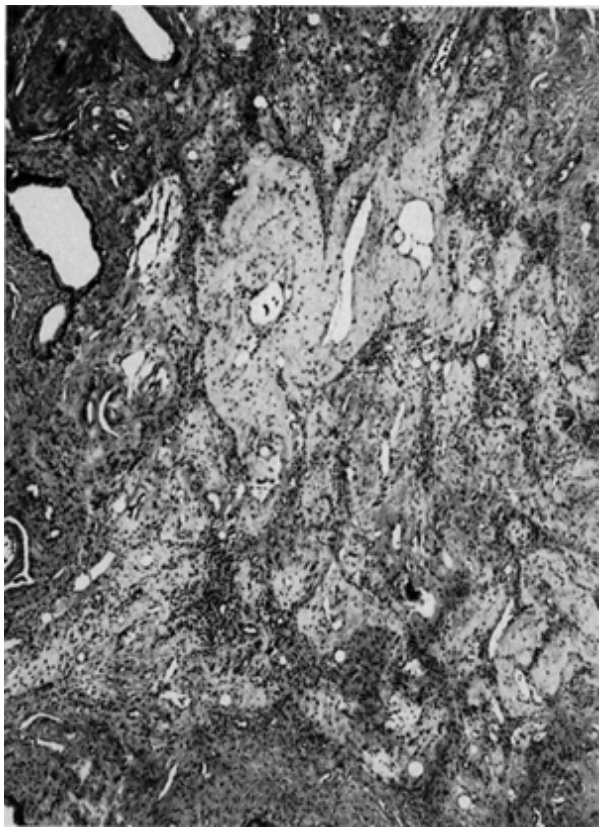
▪ **Figure 9.97** Nodular regenerative hyperplasia. The entire hepatic parenchyma is replaced by hyperplastic nodules separated by atrophic liver cell plates.

Venous outflow obstruction

The terminal hepatic venules ("central veins"), intercalated ("sublobular") veins, hepatic veins, and inferior vena cava form the venous outflow tract, but only the terminal hepatic venules and intercalated veins are commonly sampled by liver biopsy. Obstruction of any portion of the outflow tract can be followed by changes in other vessels, such as sinusoidal dilatation and, rarely, thrombosis of portal venules. Chronic congestive heart failure or constrictive pericarditis can mimic outflow tract obstruction when severe.

Hepatic vein thrombosis (Budd-Chiari syndrome) produces histologic findings that are commonly confused with congestive heart failure or drug-induced injury and must be interpreted with care. Many of the

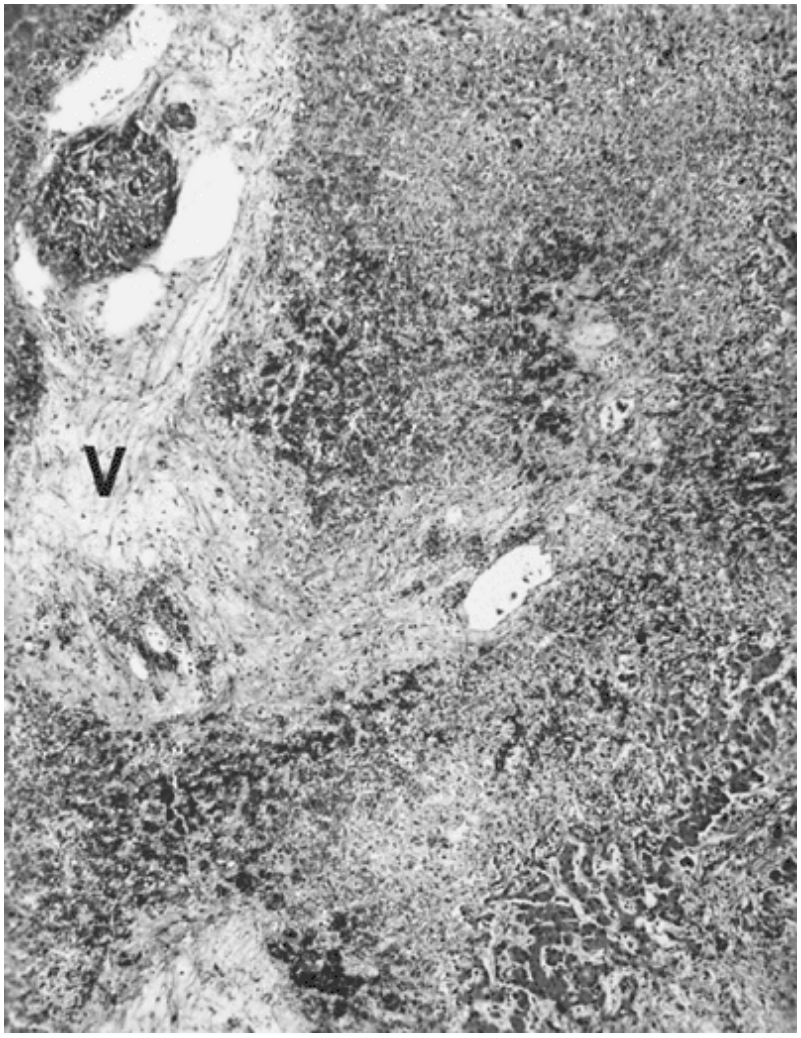
changes do resemble those of congestive heart failure, but differ by showing variability of involvement among acini, particularly well visualized with open (wedge) biopsy specimens. Those acini with acute changes show severe sinusoidal dilatation and congestion, most pronounced in zone 3 (Fig. 9.99), but sometimes extending to the portal tracts. Coagulative degeneration or necrosis is frequently present. Erythrocytes in the congested areas are packed into the spaces of Disse and crowd the degenerating hepatocytes. The terminal hepatic venules and intercalated veins can show thrombosis, recanalized thrombi (Fig. 9.99), and/or fibrous mural thickening, but in a small biopsy specimen the veins that are sampled may be normal. Some acini are injured in a more gradual manner. Progressive sinusoidal dilatation is accompanied by atrophy of hepatocytes. Zone 3 fibrosis can follow either type of injury and can link adjacent terminal hepatic venules. Small portal veins may also become occluded, further augmenting the injury to parts of the liver (136). Other acini are entirely spared. The caudate lobe is often uninvolved because of its separate venous drainage and can undergo compensatory hypertrophy.



▪ **Figure 9.98** Segmental atrophy. The tissue is fibrotic, and there are portal areas and ductules, but hepatocytes are missing, presumably because of chronic ischemia.

Veno-occlusive disease resulting from toxic injury (e.g., from pyrrolizidine alkaloids) or radiation damage to the endothelium of the small outflow produces parenchymal changes that resemble those of Budd-Chiari syndrome, but in the early stages, lesions of the terminal hepatic venules and intercalated veins are distinctive. Intimal edema is followed by the subendothelial deposition of reticulin and collagen fibers and progressive narrowing of the lumen (Fig. 9.100). Extravasated erythrocytes are frequently

situated between the fibers. Inflammation is sparse or absent, and superimposed thrombi are not seen. Cases with severe acute injury may show necrosis of venous walls. With progressive fibrosis of the walls, the veins become difficult to identify, appearing as small hyalinized cylinders. Involvement of hepatic veins or the vena cava does not occur in most cases.

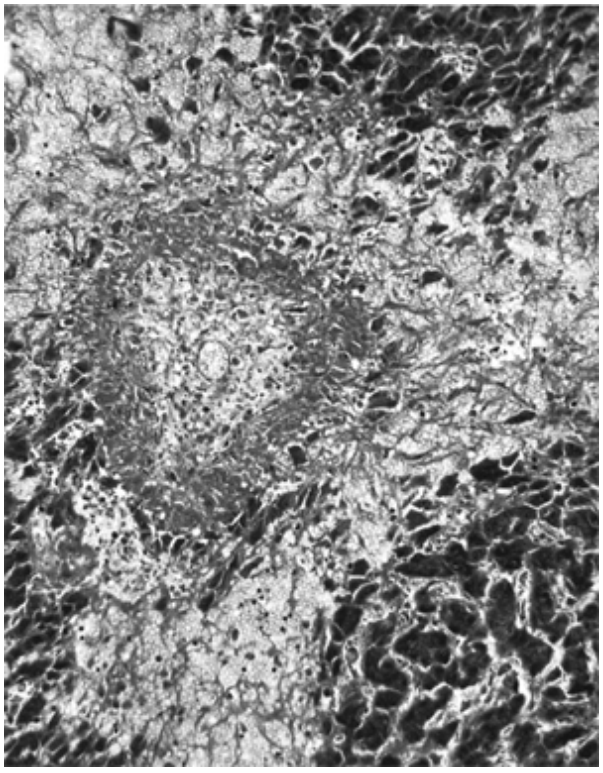


▪ **Figure 9.99** Budd-Chiari syndrome. Organizing thrombus in a large intercalated vein (*V*) is associated with severe sinusoidal dilatation and congestion and necrosis of zone 3 of the surrounding

acini.

Sinusoidal lesions

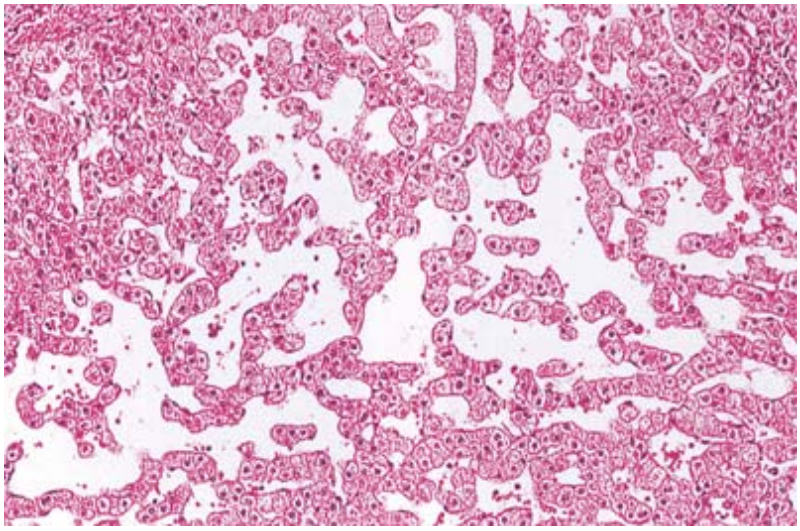
Dilatation of sinusoids is a frequent finding in liver biopsy specimen and is often a nonspecific reaction to systemic disease. Chronic congestive heart failure leads to the gradual development of dilatation and congestion of sinusoids and finally to atrophy of hepatocytes, predominantly in zone 3, with secondary fibrosis (130,131). A characteristic type of periportal (zone 1) sinusoidal dilatation sometimes follows the use of oral contraceptives (137). Liver plates show variable degrees of atrophy (Fig. 9.101). The change affects all acini, unlike the focal sinusoidal dilatation seen sometimes near hepatic masses. Panacinar sinusoidal dilatation can be found in sickle cell disease; the dilated sinusoids are packed with masses of sickled erythrocytes. Variable dilatation, lacking any particular zonal localization, can be associated with other disorders, notably neoplasms and granulomatous diseases. Sinusoidal dilatation of the liver may be a systemic manifestation of a number of neoplasms. A characteristic triad of histologic changes, consisting of focal sinusoidal dilatation, proliferation of ductules, and infiltration of edematous portal areas by neutrophils, has been observed in the vicinity of space-occupying lesions (138).



▪ **Figure 9.100** Veno-occlusive disease associated with Senecio alkaloid toxicity. The efferent vein has a markedly narrowed lumen because of intimal thickening with extravasation of erythrocytes. There is zone 3 necrosis and marked congestion.

Peliosis hepatis is characterized by scattered lakes of blood of varying sizes, which appear to represent an extreme degree of localized sinusoidal dilatation (Fig. 9.102). The pathogenesis of the process is now considered to be due to endothelial injury that allows blood to accumulate in spaces of Disse with resultant formation of the cavities. In the past, peliosis was recognized as a complication of debilitating disorders, such as tuberculosis and malignancies, and was discovered at autopsy as an incidental finding. Currently, the most frequent cause is therapy with androgenic/anabolic steroids (139). Histologically, the peliotic lakes may have an attenuated endothelial lining. Varying degrees of sinusoidal dilatation can be present near some of the lesions, but the term *peliosis hepatis* should not be used for simple sinusoidal dilatation. Bacillary angiomatosis due to *Bartonella henselae* in patients with AIDS (140)

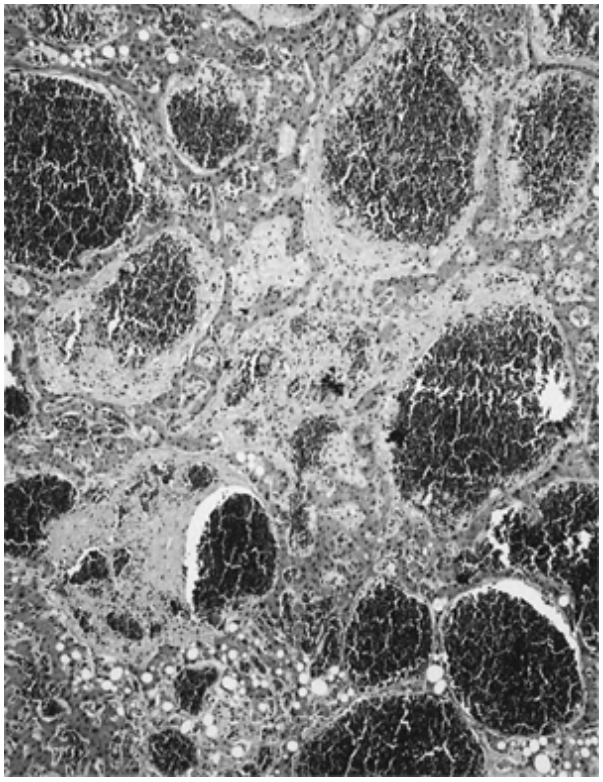
can mimic peliosis, but stains for bacteria typically demonstrate numerous organisms.



▪ **Figure 9.101** Marked periportal sinusoidal dilatation associated with long-term oral contraceptive steroid use. The liver cell plates are atrophic.

Thrombosis of sinusoids with deposition of fibrin thrombi is unusual, but

it happens in some diseases. Patients with toxemia of pregnancy usually have no evidence of liver disease; those who do frequently have deposits of fibrin in periportal sinusoids (141). Occasionally, the deposits are associated with coagulative-type hepatocellular necrosis. Disseminated intravascular coagulation can be associated with a similar pattern of injury, but the sinusoidal fibrin deposition need not be restricted to the periportal areas.



▪ **Figure 9.102** Peliosis hepatis associated with anabolic steroid therapy. Variable-sized lakes of blood are scattered throughout the parenchyma.

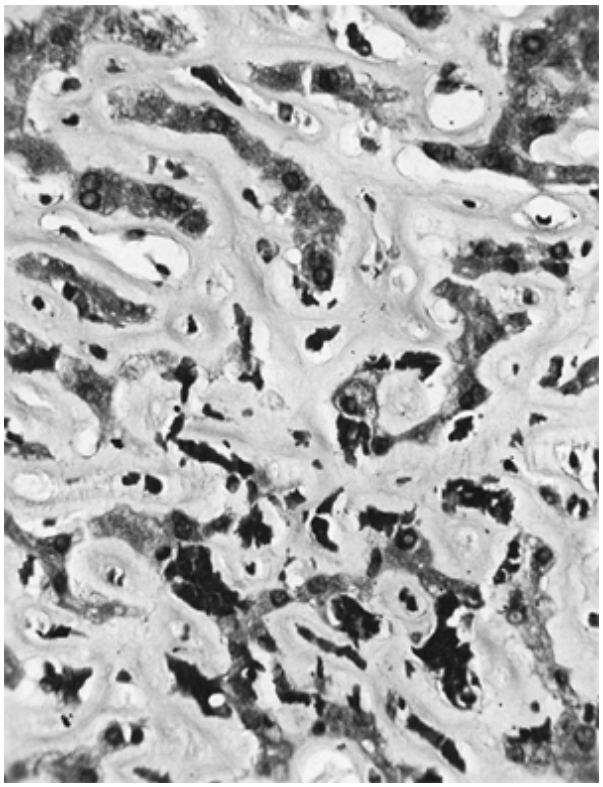
Fibrosis of sinusoids occurs in many chronic diseases. Collagen is deposited in the space of Disse along with laminin, forming basement membranes and leading to capillarization of the sinusoids. The collagen is well demonstrated with a Masson stain, and many components of basement membranes and extracellular matrix can be demonstrated with specific immunostains. Sinusoidal fibrosis is prominent in zone 3 of the acinus in the early stages of alcoholic hepatitis (Fig. 9.69), nonalcoholic steatohepatitis, diabetes mellitus, chronic congestive heart failure, and vitamin A hepatotoxicity.

Amyloidosis

Patients with amyloidosis frequently have hepatic involvement, and liver

biopsy has been advocated as a means of establishing the diagnosis. Amyloid can be limited to the arteries but can also be found in the parenchyma (Fig. 9.103). In both primary amyloidosis (type AL) and secondary amyloidosis (type AA), the eosinophilic material gradually accumulates in the space of Disse (142), eventually leading to atrophy of the hepatic plates. The presence of amyloid can be confirmed by an appropriate stain, either histochemical (e.g., Congo red with apple green dichroism

under polarized light) or immunohistochemical, with a specific antibody to the amyloid.

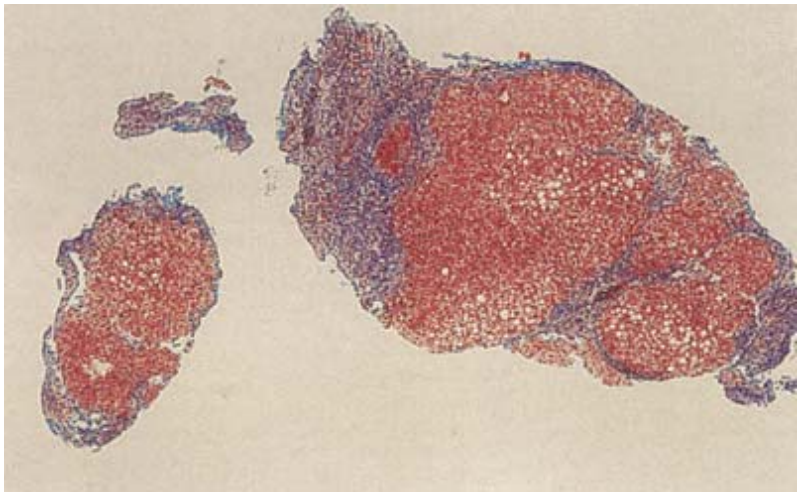


• **Figure 9.103** Extensive intra-acinar amyloid deposition filling the space of Disse between the hepatocytes and endothelial cells, producing atrophy of the liver cell plates.

Cirrhosis

Cirrhosis is defined as a diffuse process characterized by fibrosis and conversion of the normal liver architecture into structurally abnormal nodules (143). Three basic morphologic categories are recognized on the basis of the size of the cirrhotic nodules. The micronodular type includes those cases in which almost all nodules are less than 3 mm in diameter. In the macronodular type, most nodules are greater than 3

mm in diameter and usually show striking variation in size. The mixed pattern is characterized by approximately equal numbers of micro- and macronodules. Regenerative nodules are not essential for the diagnosis of cirrhosis; in both biliary cirrhosis and hemochromatosis, for example, regeneration may be minimal or absent.



▪ **Figure 9.104** Fragmented needle biopsy specimen from a cirrhotic liver. The Masson stain shows collagen of the fibrous septa enveloping and traversing the fragments.

The diagnosis of cirrhosis may be difficult to establish by percutaneous needle biopsy, particularly if the pattern is macronodular. Cutting needles (e.g., Tru-cut) are preferred because these obtain specimens that include the fibrous septa and the parenchymal nodules (Fig. 9.104). Suction techniques (e.g., Menghini needles) are limited by preferential sampling of parenchyma as the biopsy needle rebounds from the fibrous septa. There are, however, a number of microscopic clues to the diagnosis, even in this type of specimen. Suction biopsies from cirrhotic livers are commonly fragmented, and the fragments have rounded edges Fibrous septa can course through the fragments, but these are sometimes represented by thin strips hugging margins of the fragments. Stains for collagen (Fig. 9.104) are frequently necessary to detect them. Such stains are also valuable for distinguishing collapsed reticulin that follows extensive necrosis from fibrosis and for demonstrating thick liver plates in regenerative nodules of the cirrhotic liver. Reticulin stains usually demonstrate a very irregular pattern because of alterations in the growth of hepatocytes. Many cell plates are greater than one cell in thickness,

and the compressed sinusoidal spaces may be nearly invisible. Hepatocytes are pleomorphic, unless the process is entirely inactive. An

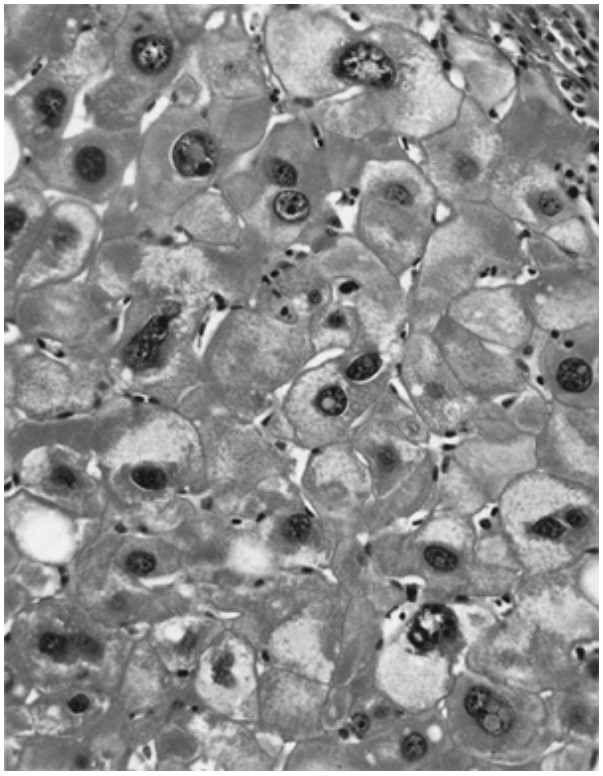
alteration of the spatial relationship between the portal vessels and central veins is typical. Micronodular cirrhosis is less difficult to establish by needle biopsy than is macronodular cirrhosis because the diameter of the biopsy needle usually exceeds that of the small cirrhotic nodules. The capsule of the liver in many noncirrhotic patients is thickened by an increase in fibrous tissue, vessels, and ductules. A small biopsy specimen from such an area (particularly a superficial wedge biopsy) should be interpreted with caution and not diagnosed as cirrhosis.

The morphologic approach in cirrhosis should include an assessment of whether the cirrhosis is fully developed or incomplete, the basic morphologic type (i.e., micronodular, macronodular, or mixed), the degree of activity, and the presumptive cause, if possible. Biopsy specimens showing occasional nodules or extensive fibrosis may be judged to represent early or incomplete cirrhosis, but the designation cirrhosis should be reserved for those with complete loss of acinar architecture. An assessment of the activity should take into account the degree of hepatocellular degeneration and necrosis and the amount of inflammation in the parenchyma of the nodules.

Every effort to establish the underlying cause should be made, although this is not always possible. An etiologic diagnosis can sometimes be established by changes observed in hematoxylin and eosin–stained sections alone (e.g., absence of bile ducts and chronic cholestasis indicating biliary cirrhosis, including cirrhosis secondary to PBC or primary sclerosing cholangitis). Special stains, however, are an important auxiliary technique. Particularly useful are copper stains for Wilson disease and PBC, the PAS stain and immunostains for α_1-antitrypsin deficiency, immunostains of the antigens of hepatitis B, and an iron stain for hemochromatosis.

Putative preneoplastic lesions may be found in cirrhotic livers. Large cell change (liver cell dysplasia) is characterized by nuclear and cytoplasmic enlargement, nuclear hyperchromasia, prominent nucleoli, and occasionally, multinucleation (Fig. 9.105) (144). *Dysplastic nodule* is the term used for grossly or radiologically distinctive nodules that are usually larger than the surrounding cirrhotic nodules and that may differ in color or texture (145). These are classified microscopically as low-grade dysplastic nodules when there are minimal atypical histologic features. They are classified as high-grade dysplastic nodules when there are atypical features in the hepatocytes of the nodule, such as cytoplasmic basophilia, high nuclear/cytoplasmic ratios, nuclear irregularity, and hyperchromasia. High-grade dysplastic nodules often have ill-defined nodules within the large nodule ("nodule-in-nodule" formation), best recognized by compression of surrounding reticulin fibers and different orientation of the liver plates. These are often composed of smaller than normal hepatocytes with high nuclear–cytoplasmic ratios, a feature termed *small cell change* (or *small cell*

dysplasia) (Fig. 9.106). Evidence suggests that this lesion, rather than large cell change, is more likely the precursor of hepatocellular carcinoma in the cirrhotic liver.



▪ **Figure 9.105** Large cell change (liver cell dysplasia) in cirrhosis. Dysplastic cells are large and contain large dark-stained and sometimes irregular nuclei.

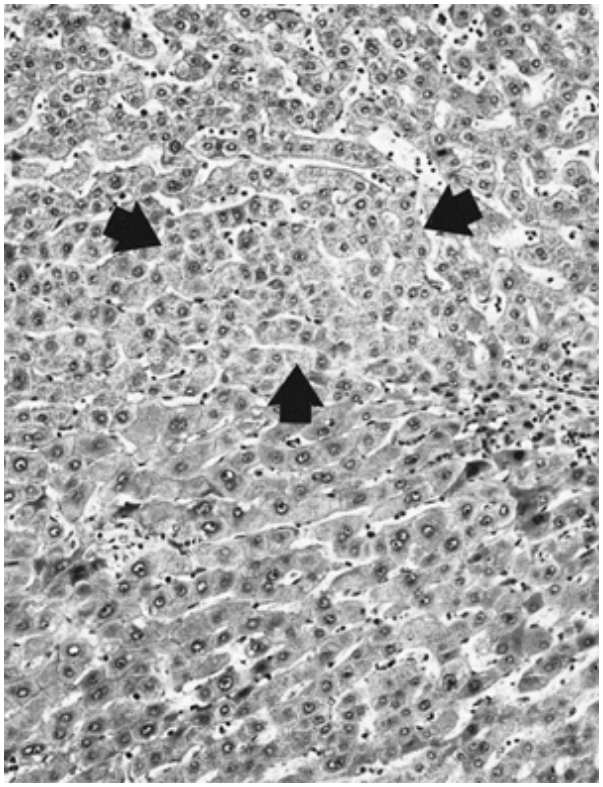
Fibropolycystic Diseases

Lesions and types of cysts

Von Meyenburg complexes or biliary microhamartomas are a common developmental anomaly in the liver (146,147). They are typically found adjacent to normal portal areas and consist of a fibrous stroma that contains several irregular duct-like structures lined by biliary epithelium (Fig. 9.107). These are often somewhat dilated and some may be large enough to be considered cysts. They often contain eosinophilic or bile-stained secretions.

Bile duct cysts are usually solitary and lined by a cuboidal biliary-type epithelium. These are considered to be of developmental origin, and at least some arise from cystic dilatation of a von Meyenburg complex, although in most cases, there are no clues to the

exact pathogenesis of the lesion. The cysts typically contain clear fluid, but become infected and contain pus, or when large, there may be hemorrhage and inflammation secondary to minor trauma.



▪ **Figure 9.106** Small cell dysplasia in a high grade dysplastic nodule. There is a nodular growth of small liver cells with high nuclear/cytoplasmic ratios (*arrows*) within a large cirrhotic nodule.

Ciliated foregut cyst is an unusual type of developmental cyst that is lined by ciliated columnar epithelium (148). These cysts are analogous to bronchogenic cysts of the mediastinum. They are extremely rare in the liver.

Ductal plate malformation refers to the persistence of the embryonic ductal plate in the postnatal liver (147). In embryonic life, before the appearance of the acinar bile ducts, the portal tracts are surrounded by a layer of biliary-type cells, termed the *ductal plate*. This structure normally disappears as the true bile duct develops in the center of the portal area. Persistence of parts of the ductal plate may give rise to von Meyenburg complexes, duct-like structures seen in congenital hepatic fibrosis, and cysts of infantile polycystic disease (Fig. 9.108).

Infantile polycystic disease

Infantile polycystic disease, which is an autosomal recessive disease, is

part of a spectrum of lesions that includes infantile polycystic kidney disease, congenital hepatic fibrosis, and Caroli's disease (149). Expression varies from individual to individual. The liver in childhood polycystic disease is enlarged and firm, but cysts are not usually visible grossly. Microscopic sections show numerous irregular duct-like structures in the portal areas. These have apparent branching and irregular angulated extensions into the acini (Fig. 9.108), and there is often a circular arrangement of the ducts, complete or interrupted, characteristic of the ductal plate malformation. In contrast to congenital hepatic fibrosis, relatively little fibrous tissue is present. The ducts are slightly dilated, but true cysts are rare. They are lined by a simple, low columnar to cuboidal epithelium.

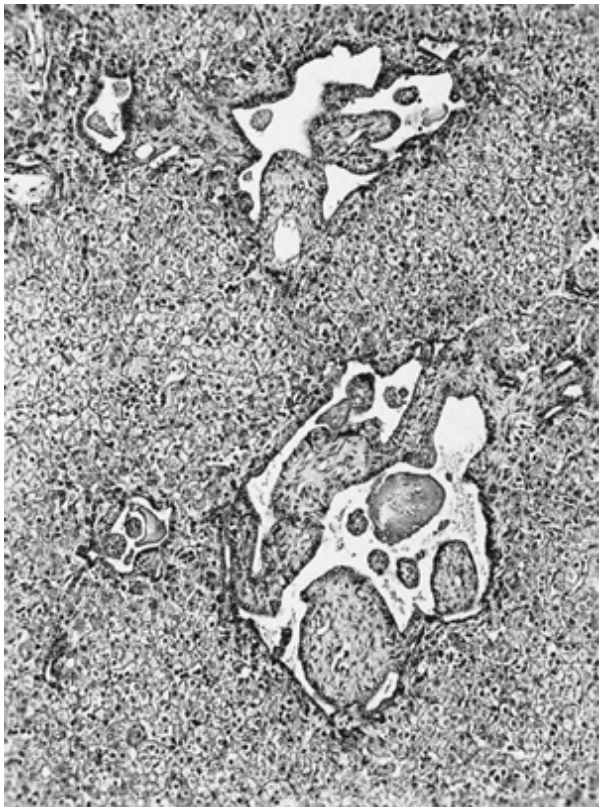
▪ **Figure 9.107** A von Meyenburg complex, which has a dense stroma containing irregular small duct-like structures, a few of which are slightly dilated.

Congenital hepatic fibrosis

In congenital hepatic fibrosis, thick collagenous bands form an extensive network, usually continuous, that links adjacent portal tracts (Fig. 9.109). Numerous bile duct–like structures, some slightly irregular and dilated, are situated in the fibrous septa and sometimes contain mucin or bile. Although they resemble bile ducts, they actually

represent ductal plate remnants. Portal vein branches often appear reduced in size and number, and the sparsity of venous channels might account in part for the portal hypertension. The irregular intervening parenchyma frequently has a "jigsaw"

pattern reminiscent of that seen in biliary cirrhosis. However, unlike cirrhosis, congenital hepatic fibrosis does not show evidence of parenchymal destruction or regeneration. The hepatocytic plates are regular and one cell in thickness, and there is an abrupt transition between the normal-appearing hepatocytes and the collagenous septa.

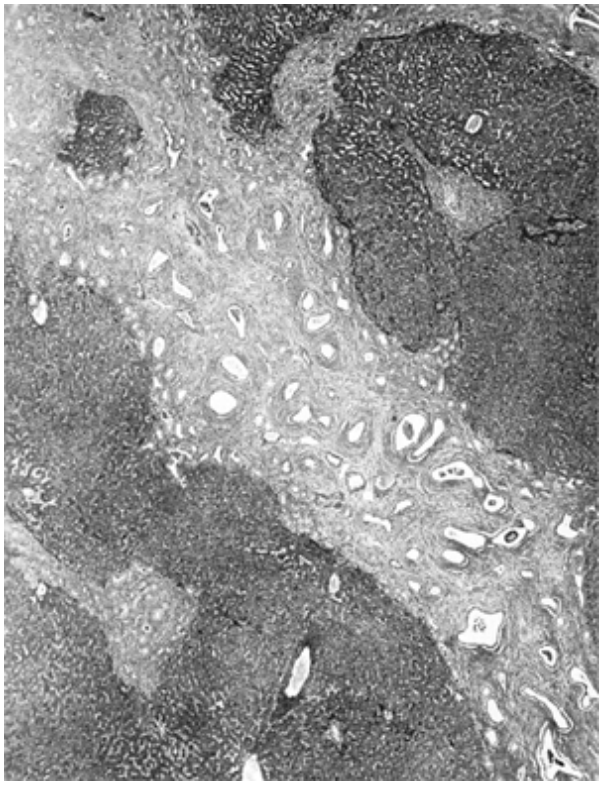


▪ **Figure 9.108** Infantile polycystic disease. The ducts are lined by cuboidal epithelium, show polypoid intraluminal projections, and are for the most part empty. They arise from remnants of the embryonic ductal plate.

Adult polycystic disease

Adult polycystic disease is frequently associated with adult polycystic kidney disease. Numerous cysts, varying from less than 1 mm to more than 12 cm in diameter, are present, containing clear, colorless or straw-colored fluid, unless infected. Microscopically, the cysts appear to originate in the portal areas. They are lined by low columnar to cuboidal

epithelium (Fig. 9.110) and have a collagenous supporting stroma that can be infiltrated by a few inflammatory cells. Von Meyenburg complexes (biliary microhamartomas) are frequently present, and components of the complexes sometimes lie adjacent to the cysts, suggesting that the cysts evolve from progressive dilatation of the biliary channels in the complexes. Occasional cases show many von Meyenburg complexes and no cysts.



▪ **Figure 9.109** Congenital hepatic fibrosis. This Masson stain shows islands of parenchyma separated by irregular bands of fibrous tissue that contain numerous small ductal plate remnants.

Tumors

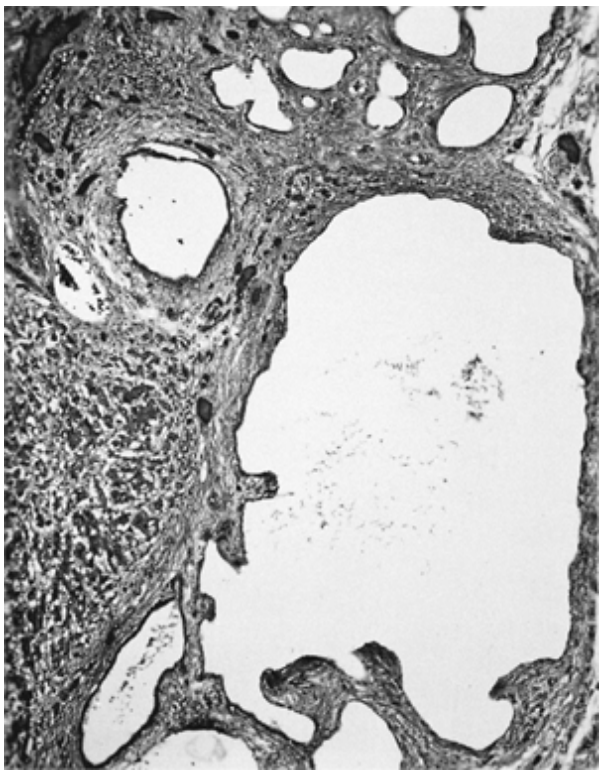
Hepatocellular tumors

Hepatocellular adenoma. This is composed of benign hepatocytes arranged in sheets and cords without an acinar architecture (Fig. 9.111) (150). It is easily mistaken for normal liver if the absence of portal areas is not noticed. The tumor cells are the same size or slightly larger than non-neoplastic hepatocytes and often have a pale cytoplasm because of an increased glycogen and/or fat content. The nuclei are uniform and regular, and the nuclear–cytoplasmic ratio is normal; mitoses are almost never seen. Thin-walled vascular channels are

scattered throughout the tumors, but large arteries are only seen around the periphery. The sinusoids are usually compressed with flattened lining cells, contributing to the sheet-like appearance. Sometimes the sinusoids are dilated, a finding that has mistakenly been called peliosis. Kupffer cells are present but usually inconspicuous, and hematopoietic cells may also be found in sinusoids.

Focal nodular hyperplasia. This is usually a solitary nodule with a typical gross appearance that is extremely useful in making the diagnosis (150). The lesions are well circumscribed but unencapsulated. When on the surface of the liver, they may appear umbilicated. They

are usually of a lighter color than the surrounding liver, ranging from yellow to tan or light brown. The cut surface typically contains a central "stellate" scar with radiating fibrous septa dividing the lesion into nodules.

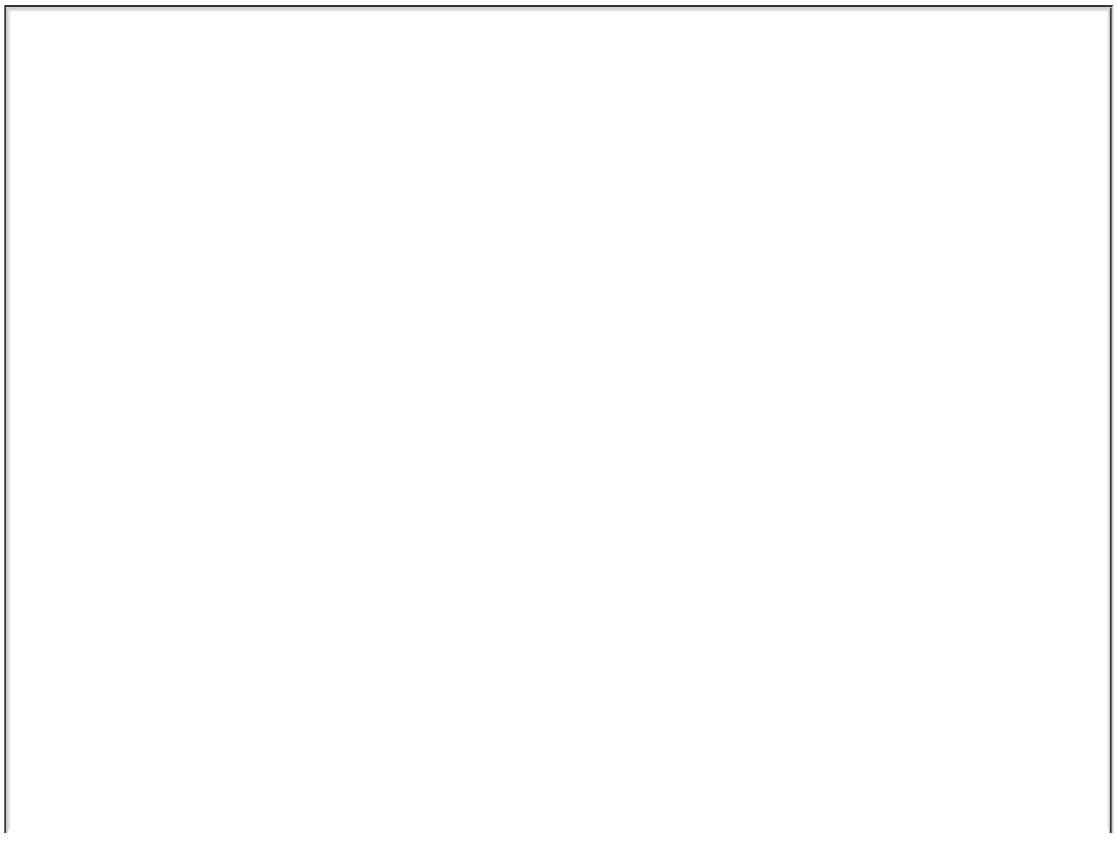


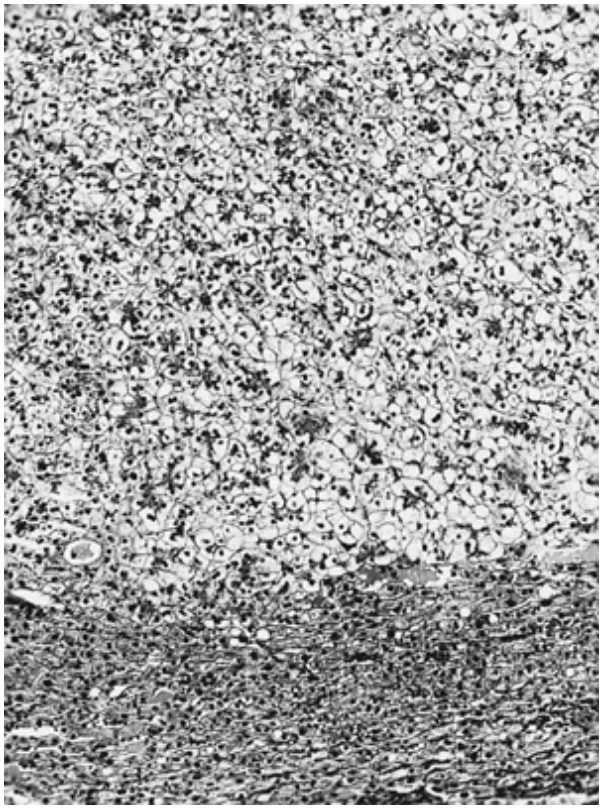
▪ **Figure 9.110** Adult polycystic disease. Multiple cysts of varying size are lined by cuboidal to flattened epithelium.

The microscopic features correspond to the gross pathology. A section through the center of the lesion nearly always shows the central "stellate" scar that usually contains one or more large arteries, often with abnormal intimal or medial fibromuscular proliferation (Fig. 9.112). Proliferating ductules are usually present but true bile ducts are

lacking. Fibrous septa of variable size radiate from the central scar. Between the septa are hyperplastic nodules of normal hepatocytes with cholestatic features, such as cholate stasis, and copper storage, and even bile pigments are usually present to some degree and are occasionally prominent, making the lesion resemble a focal area of biliary cirrhosis. A needle biopsy is easily misinterpreted as cirrhosis unless one is aware that it is from a solitary lesion, but the large artery in an area of scarring provides a valuable clue to the diagnosis.

Hepatocellular carcinoma. The cells of hepatocellular carcinoma resemble normal liver cells to a variable extent (151). In some tumors, the cells are so well differentiated that they are difficult to distinguish from normal hepatocytes or from the cells of hepatocellular adenoma. At the other extreme are tumors with cells that are anaplastic and poorly differentiated, showing only minimal evidence of liver cell origin. Most tumors, however, show definite evidence of hepatocellular differentiation. The tumor cells have distinct cell membranes and an eosinophilic, finely granular cytoplasm. Bile canaliculi are usually present between cells (Fig. 9.113) and, although sometimes hard to find, can usually be seen by light microscopy. Immunostains for CEA are useful for demonstrating canaliculi because of a CEA cross-reacting substance called *biliary glycoprotein I (BGP-1)* located in the canalicular membrane. Bile pigment may be present in tumor cells or in dilated canaliculi and is the most helpful microscopic feature in establishing the diagnosis. The tumor cell nuclei are usually large, producing a high nuclear–cytoplasmic ratio. They show variable degrees of anaplasia and usually have prominent nucleoli.

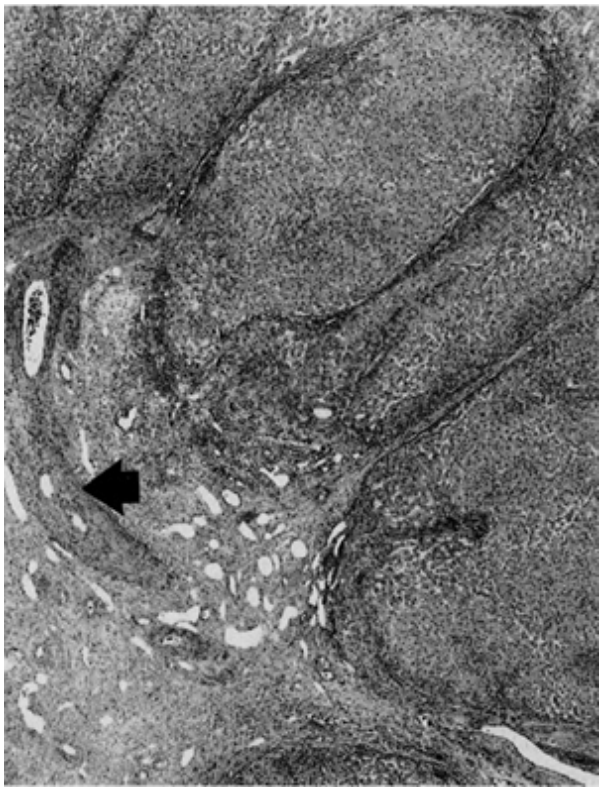




▪ **Figure 9.111** Hepatocellular adenoma, composed of a sheet-like growth of large, pale hepatocytes without acinar architecture. Compressed normal liver tissue is present in the lower part of the picture.

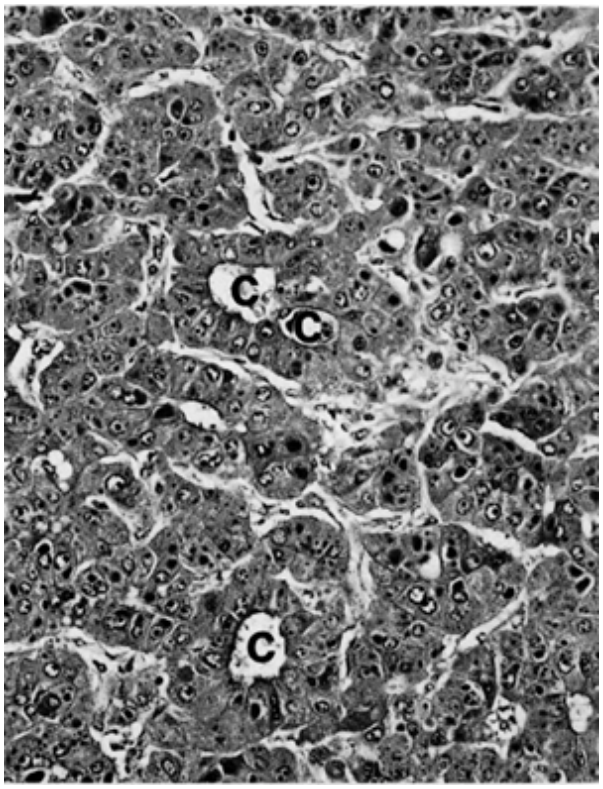
Several histologic growth patterns may be found in hepatocellular carcinoma, and because the cytologic features can be so variable, recognition of one of these patterns can be helpful in arriving at a diagnosis. Most frequent is the trabecular pattern (Fig. 9.114) in which the tumor cells grow in thick cords that attempt to recapitulate the cell plate pattern

of the normal liver. The trabeculae are separated by vascular spaces (sinusoid-like) with very little or no supporting connective tissue. Sometimes the centers of the trabeculae contain dilated canaliculi, producing a pseudoglandular pattern, while solid patterns are produced when the trabeculae grow together, forming sheets of tumor cells.



▪ **Figure 9.112** Focal nodular hyperplasia. A section through the central scar shows an abnormally thickened large artery (*arrow*). Cirrhosis-like nodules surround the central scar.

Fibrolamellar hepatocellular carcinoma. This is usually considered to be a histologic variant of hepatocellular carcinoma, but there is considerable evidence that it is actually a completely different biologic entity, occurring in a different population with a better prognosis than the other types of hepatocellular carcinoma. The pathologic features of fibrolamellar carcinoma are quite distinctive (152). Microscopically, these tumors appear to be well-differentiated hepatocellular carcinomas but instead of trabeculae separated by sinusoids, they are composed of sheets of large polygonal tumor cells separated by abundant collagen bundles arranged in parallel lamellae (Fig. 9.115), hence the name *fibrolamellar*. The tumor cells have a characteristic cytologic appearance with cytoplasm that is deeply eosinophilic and granular due to the presence of numerous mitochondria. Approximately 50% of these tumors have cytoplasmic "pale bodies" that represent intracellular fibrinogen storage.



▪ **Figure 9.113** Moderately differentiated hepatocellular carcinoma with several dilated canaliculi (*C*) easily visible between tumor cells.

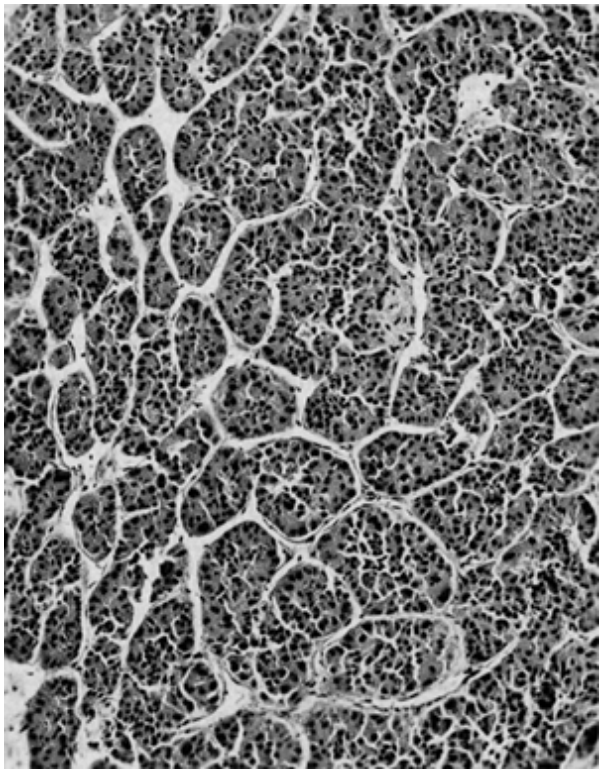
Hepatoblastoma. Epithelial hepatoblastoma is composed of fetal- or embryonal-type liver cells, or both (153). Tumors with predominantly fetal cells mimic fetal liver with a distinctive light-and-dark cell pattern and foci of hematopoiesis (Fig. 9.116). Embryonal cells are smaller and more basophilic with a high nuclear–cytoplasmic ratio. They tend to form acini, tubules, or papillary structures. Mixed epithelial–mesenchymal hepatoblastoma has an epithelial component of either fetal or embryonal cells and also a mesenchymal-like element that may consist of primitive mesenchyme, osteoid (with or without calcification), and rarely cartilage or rhabdomyoblasts. An anaplastic type (small cell undifferentiated) and a macrotrabecular type (hepatocellular carcinoma-like) of hepatoblastoma have also been recognized.

Biliary tumors

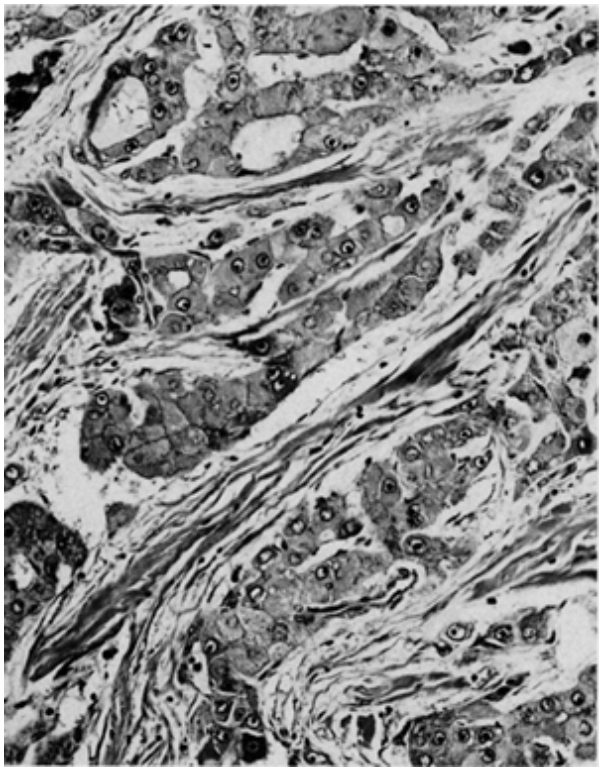
Bile duct adenoma (peribiliary gland hamartoma) is usually a solitary subcapsular nodule, although occasional livers have more than one nodule. The lesions may be up to 4 cm in diameter, but 90% are 1 cm or less. They are composed of a proliferation of small, round, normal-appearing ducts with cuboidal, slightly basophilic cells that have very

regular nuclei and lack any evidence of dysplasia or mitotic figures (Fig. 9.117). There is

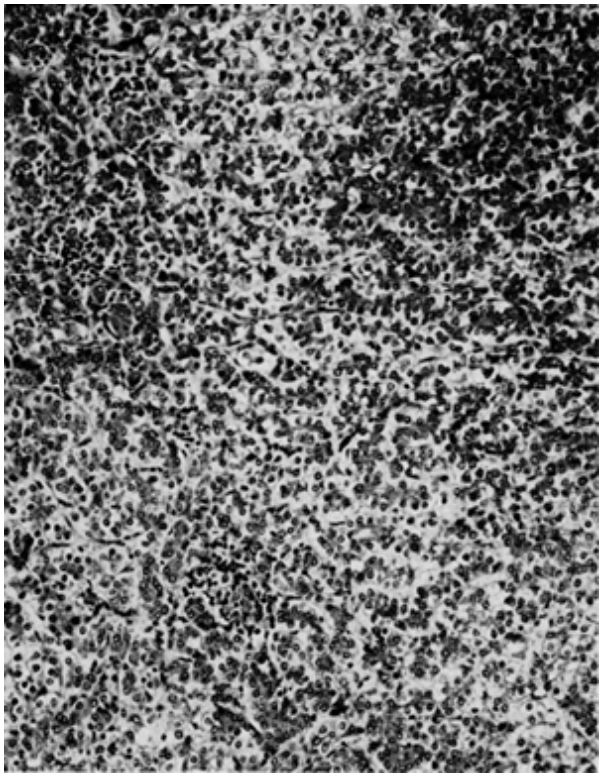
always a fibrous supporting stroma that may be dense and hyalinized. Preexisting normal or inflamed portal areas may be present within the tumor. Although these lesions have traditionally been regarded as benign tumor of bile ducts, recent studies have shown the tumor cells to have the immunophenotype of normal peribiliary glands, indicating that they are actually peribiliary gland hamartomas (154).



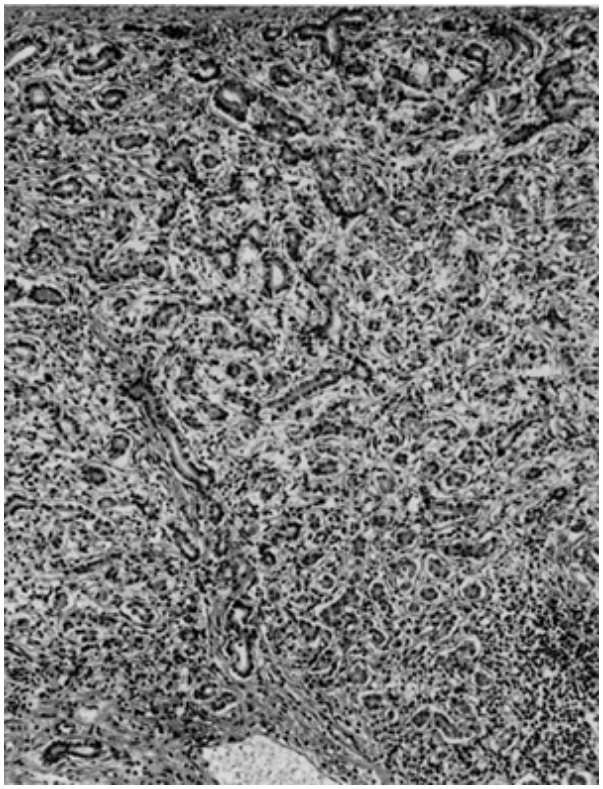
▪ **Figure 9.114** Trabecular growth pattern of hepatocellular carcinoma. The tumor cells form thick cords (resembling islands of cells in cross section), separated by vascular spaces mimicking hepatic sinusoids.



▪ **Figure 9.115** Fibrolamellar hepatocellular carcinoma. The tumor cells are large and polygonal and (in contrast to the trabecular hepatocellular carcinoma) are embedded in a fibrous stroma arranged in parallel lamellae.

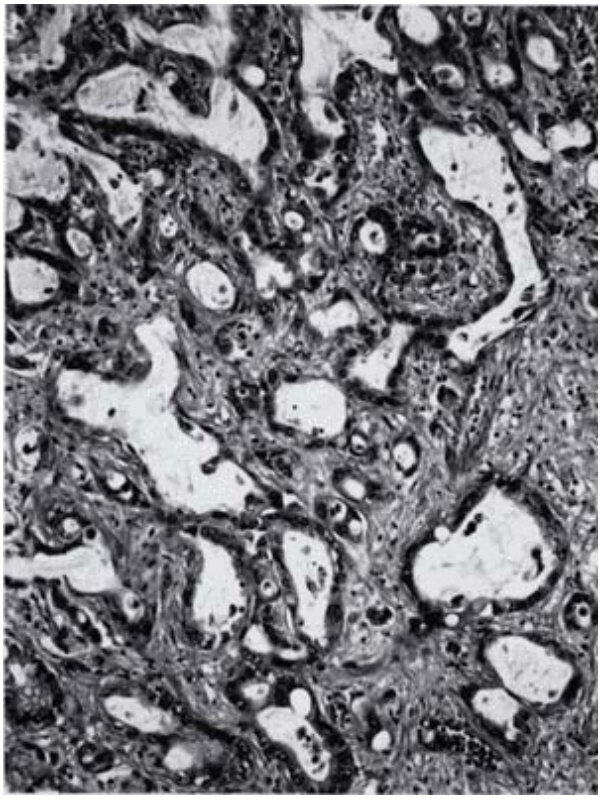


▪ **Figure 9.116** Fetal hepatoblastoma mimics fetal liver with a distinctive "light-and-dark" cell pattern and small clusters of hematopoietic cells.



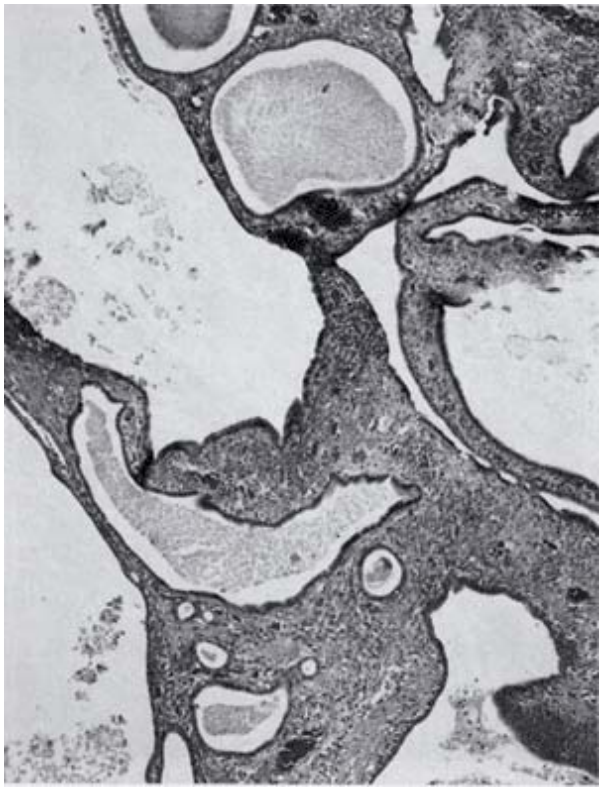
▪ **Figure 9.117** Bile duct adenoma (peribiliary gland hamartoma). The tumor is a localized proliferation of small benign glands in a fibrous stroma.

Cholangiocarcinoma. Microscopically, these resemble adenocarcinomas arising in other parts of the body (155). They are glandular carcinomas (Fig. 9.118) composed of cells resembling biliary epithelium. The cells are low columnar or cuboidal with slightly basophilic cytoplasm and nuclei that are smaller than those of hepatocellular carcinoma; nucleoli are inconspicuous. Mucin can often be demonstrated by special stains but is seldom abundant. There is typically a dense fibrous stroma, which can be helpful in their distinction from hepatocellular carcinoma but not from metastases. Calcifications can sometimes be seen in the fibrous tissue. The tumors are usually well-differentiated gland-forming neoplasms, but they may be poorly differentiated, papillary, or solid, displaying the full range of appearances that can be seen in adenocarcinomas. Occasional tumors show focal squamous differentiation (adenosquamous or mucoepidermoid carcinoma). There are no reliable histologic features distinguishing intrahepatic cholangiocarcinoma from metastatic adenocarcinoma. The diagnosis depends on the reasonable exclusion of an extrahepatic primary.



▪ **Figure 9.118** Cholangiocarcinoma can resemble an adenocarcinoma arising anywhere in the body. There is typically a dense fibrous stroma infiltrated by irregular glands composed of pleomorphic tumor cells.

Biliary cystadenoma and cystadenocarcinoma. These are multilocular cystic neoplasms that arise from intra- and extrahepatic bile ducts (155). Developmental cysts are never truly multilocular (although secondary changes occasionally make them seem so). Cystadenomas and cystadenocarcinomas may occur anywhere in the intra- or extrahepatic bile ducts, but nearly all are partly or totally within the liver. Most are over 10 cm in diameter. Microscopically, biliary cystadenoma has a mucin-secreting columnar epithelium lining the cysts (Fig. 9.119). The lining cells have a pale eosinophilic cytoplasm and basally oriented nuclei, typical of biliary-type epithelium. The epithelium is supported by what has been called a *mesenchymal stroma*. This is compact and cellular, and resembles the stroma of the ovary. Biliary cystadenoma is regarded as a premalignant tumor, and when malignancy develops, it is called *cystadenocarcinoma*. There may only be in situ carcinoma with papillary growth into the cysts, or there may be frank invasive adenocarcinoma.



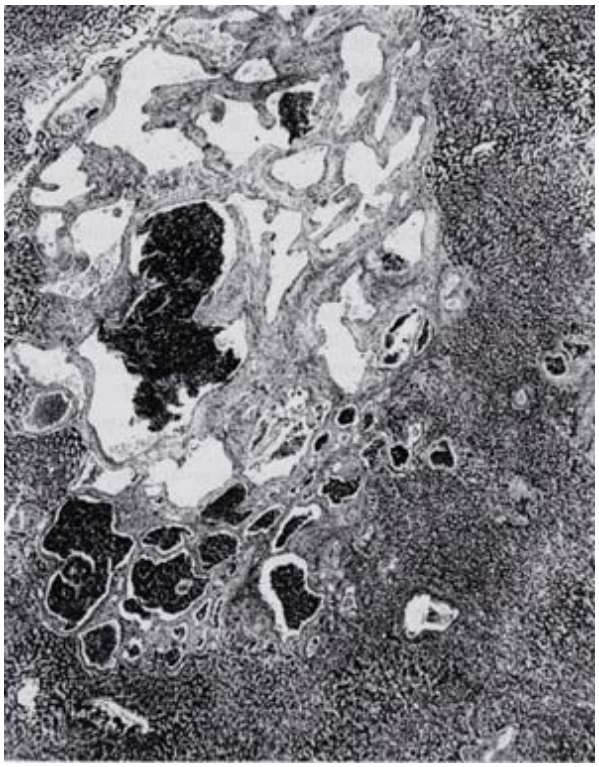
▪ **Figure 9.119** Cystadenoma is a multilocular cystic neoplasm with mucinous epithelium overlying a compact mesenchymal stroma.

Biliary papillomatosis is an extremely rare disease in which multiple benign papillary adenomas, similar to adenomas of the intestinal tract, arise in the bile ducts (154). As with intestinal adenomas, invasive carcinoma may develop.

Hemangiomas and Other Vascular Tumors

Hemangiomas are the only common vascular tumors of the liver. Most are less than 4 cm in diameter, but occasional tumors may be as large as 30 cm. Microscopically these are cavernous hemangiomas with varying-sized vascular channels (Fig. 9.120) lined by flattened endothelial cells (156). They are usually discrete and well demarcated from the surrounding liver, although an occasional hemangioma may contain trapped bile ducts or foci of parenchyma. Variable amounts of fibrous tissue separate the vascular channels. Many consist of thin, delicate strands, while others have large areas of scarring. Fresh and organizing thrombi may be found in the vascular channels. The dynamics of these thrombi are not known, but they are commonly observed in surgically resected hemangiomas. Because of the sluggish blood flow through these tumors, small thrombi are probably constantly

forming and lysing, contributing to the typically heterogeneous appearance by MRI. Fibroblasts can be found growing into a few thrombi and are probably the source of the scarring that results in the "sclerosing hemangioma." In end-stage sclerosed and/or calcified hemangiomas, an underlying vascular pattern can usually still be discerned, providing the clue to the diagnosis.



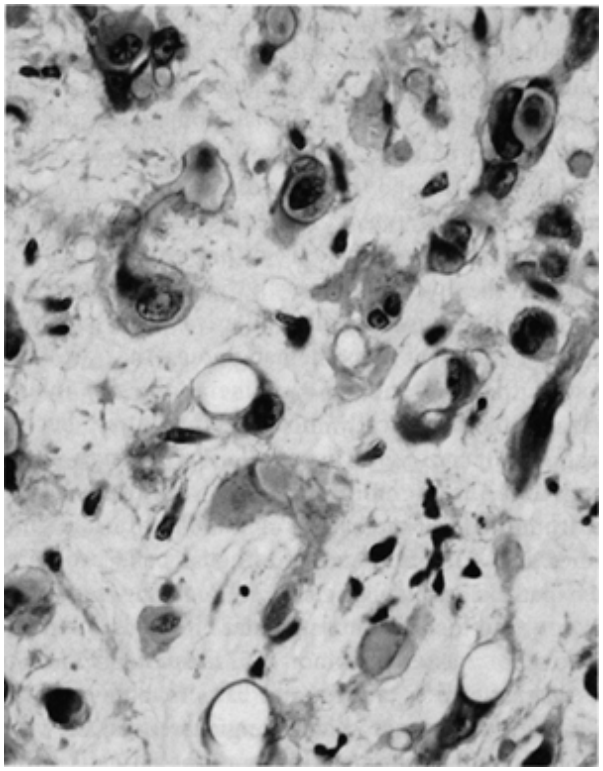
▪ **Figure 9.120** Hemangioma consists of a fibrous stroma containing "cavernous" blood-filled spaces lined by flattened endothelial cells.

Other vascular tumors are exceedingly rare. *Infantile hemangioendothelioma* is a rare tumor that can occur in the liver in infants (156). They consist of small proliferating capillary-like vascular channels, similar to the capillary hemangiomas that are common in the skin and mucous membranes of infants. Although histologically benign, they may become large enough to cause hepatic failure or high-output congestive heart failure due to shunting through the tumor. *Angiosarcoma* is a rare highly malignant tumor in which atypical endothelial cells proliferate in hepatic sinusoids (Fig. 9.121), causing hepatocyte atrophy and formation of vascular channels and sometimes solid masses of tumor (157). *Epithelioid hemangioendothelioma* is an equally rare malignant tumor (although not so aggressive as angiosarcoma), in which plump, epithelioid-appearing endothelial cells

proliferate in the hepatic vasculature, producing a dense fibrous stroma (Fig. 9.122), similar to that seen in cholangiocarcinoma and metastatic adenocarcinoma (157).

Many of these are misdiagnosed as adenocarcinoma or, if the tumor cells are few, as a benign lesion.

▪ **Figure 9.121** Angiosarcoma is a proliferation of malignant endothelial cells that fills the hepatic sinusoids, causing the hepatocytes to atrophy.



▪ **Figure 9.122** Epithelioid hemangioendothelioma is a malignant tumor that forms intracellular capillary lumina and typically produces a dense fibrous stroma as it fills the vascular spaces.

Metastases

Metastases far outnumber primary liver tumors, so that any liver mass is more likely to be metastatic than primary. Only if a tumor is benign or shows clear evidence of hepatocellular differentiation, indicating hepatocellular carcinoma, can it be confirmed that it is primary in the liver. Any other malignancy, particularly an adenocarcinoma, should be presumed to be metastatic. Microscopically, metastases usually resemble the primary tumor. If the primary lesion is known and has been biopsied or excised, comparison of the microscopic appearance of the tumor in the liver with that of the primary will confirm whether the hepatic tumor is a metastasis.

Chapter 10
Mechanisms of Liver Injury

Harmeet Malhi
Gregory J. Gores

Key Concepts

- Apoptosis is a prominent feature of acute and chronic liver disease.
- Various cell types in the liver can be affected by injurious stimuli.
- Death receptor-mediated, mitochondria-dependent cell death is common in liver injury.
- Apoptosis leads to inflammation and injury in acute liver diseases, and in chronic liver diseases sustained apoptosis begets fibrosis.
- Manipulation of apoptotic pathways has wide therapeutic potential.

The liver is in constant cellular flux with careful removal of senescent or damaged cells and controlled repopulation through a progenitor cell compartment. The unique juxtaposition to the intestine, large resting blood flow, and unfiltered contact with portal blood also provides the liver with a unique sensitivity to various gut-derived, diet-derived, or blood-borne insults. Under basal conditions, removal of hepatocytes occurs mainly through apoptosis without reactive inflammation. Liver injury, on the other hand, is associated with cell death, inflammation, and regeneration.

Cell death in the liver can be apoptotic or necrotic or a combination of the two. Historically, apoptosis, or programmed cell death, has been viewed as a carefully choreographed cascade resulting in protease and endonuclease activation. It has been defined morphologically on the basis of characteristic nuclear appearance, the generation of membrane-bound apoptotic bodies (Councilman bodies), and the absence of an inflammatory reaction. Necrotic cell death has been considered the antithesis of apoptotic cell death. It has been defined on the basis of cellular energy depletion, characteristic morphology of cytoplasmic vacuolation, cell swelling, and the presence of an inflammatory reaction. Cell swelling, a cardinal feature of necrosis, results from an inability to maintain ion gradients, such that the process is in fact called *oncotic necrosis*. Over the last few years, with better understanding of both pathways of cell death, these arbitrary morphologic definitions have become less important. It is recognized that both apoptosis and necrosis can be triggered by the same stimulus and occur in the same disease process. Apoptosis has been shown to be a prominent feature of several liver diseases (Fig. 10.1). The dogma has shifted from apoptosis being a physiologic, bland, noninflammatory process to one that is pathologic, occurs in disease processes, and causes liver inflammation, injury, and fibrosis (Fig. 10.2). This

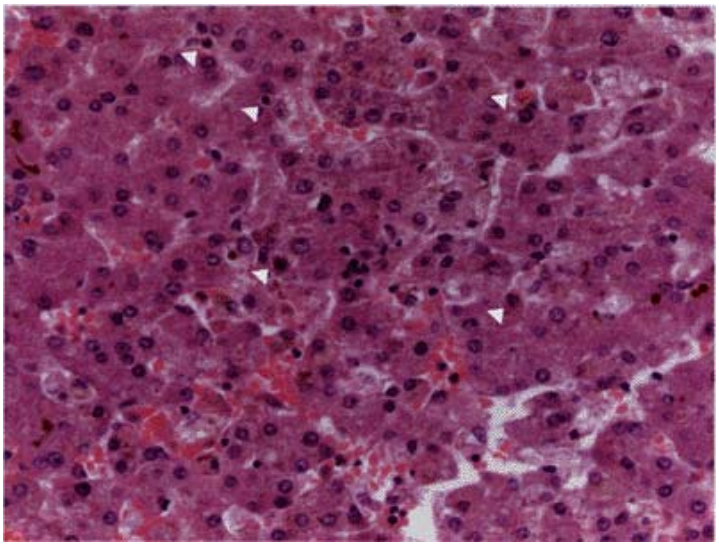
chapter discusses mechanisms of liver injury. It is divided into two sections. The first section provides a general overview of mechanisms of death in the liver. Apoptosis and necrosis are both discussed with emphasis on death receptors (DRs) and the role of mitochondria in cell fate. The second section focuses on liver injury in some common disorders.

Basic Mechanisms

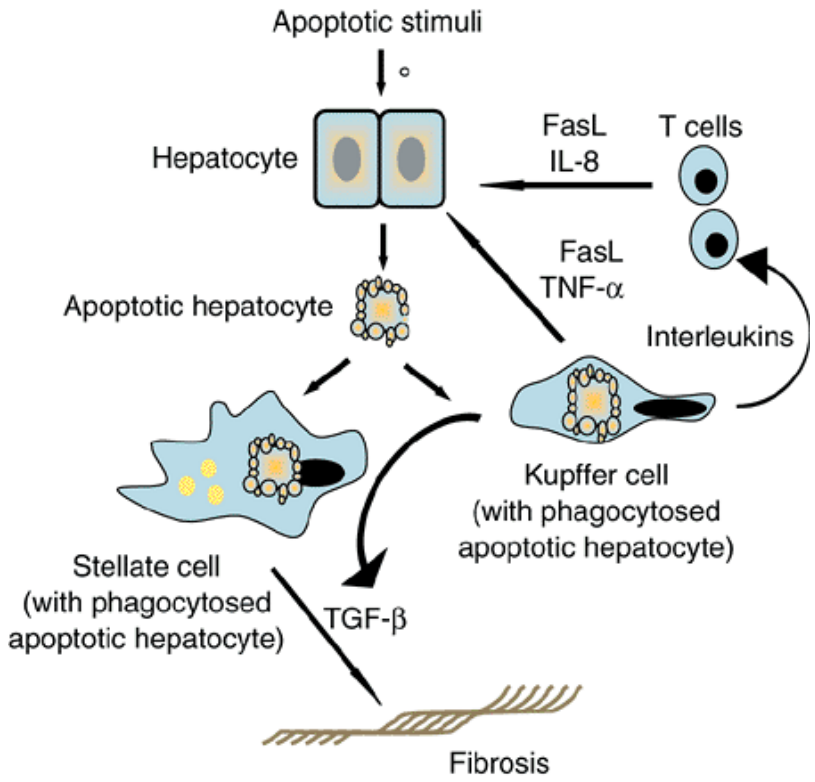
Apoptosis

Liver apoptosis is a prominent feature of most liver disorders, including drug-induced liver disease, viral liver disease, alcoholic liver disease, nonalcoholic liver disease, cholestatic liver disease, and vascular liver disease. Apoptosis of hepatocytes, Kupffer cells, sinusoidal endothelial cells (SECs), hepatic stellate cells (HSCs), and cholangiocytes has been observed in different liver diseases (1,2,3,4,5,6). The initiation of apoptosis occurs by

two fundamental pathways: (i) The DR or extrinsic pathway and (ii) the mitochondrial or intrinsic pathway (7). The extrinsic pathway is triggered by ligation or oligomerization of DRs. The mitochondrial pathway is activated by several intracellular perturbations, including deoxyribonucleic acid (DNA) damage, lysosomal permeabilization, endoplasmic reticulum (ER) stress, chemotherapeutic agents, oxidative stress, toxins, and sustained increases in Ca^{2+} (8). Cells that die through the extrinsic pathway are classified as type I or type II cells. In type I cells, amplification and conduction of death signals occurs exclusive of mitochondrial involvement. In type II cells, DR activation is not sufficient to propagate a lethal signal without mitochondrial involvement. Hepatocytes are type II cells and have an obligate need for mitochondria in cell death (9).



▪ **Figure 10.1** Hepatocyte apoptosis in human liver. Photomicrograph of a hematoxylin–eosin–stained section from the liver of a patient with primary sclerosing cholangitis shows several apoptotic hepatocytes (*white arrow heads*). Condensed nuclei (pyknosis) surrounded by an eosinophilic cytoplasm are seen.



▪ **Figure 10.2** Hepatocyte apoptosis promotes fibrosis. The link between hepatocyte apoptosis and fibrosis is illustrated here. Apoptosis is the proximal event in hepatic fibrosis. Apoptotic hepatocytes are engulfed by stellate cells, leading to their activation, and by Kupffer cells, leading to the secretion of several proinflammatory and proapoptotic cytokines. Kupffer cell–derived cytokines promote stellate cell activation and further promote apoptosis. Activated stellate cells play a key role in fibrosis. IL-8, interleukins-8; TNF-α, tumor necrosis factor α; TGF-β, transforming growth factor β.

In a homeostatic setting, apoptosis is accompanied by activation of phagocytosis, leading to efficient removal of cellular corpses without damage to healthy cells (10). However, apoptosis, if massive or simultaneous, results in liver injury. For example, in the setting of massive apoptosis, such as fulminant hepatic failure (FHF), successful hepatocyte repopulation leads to recovery (11). In such an environment, if hepatocyte repopulation is protracted or delayed, liver injury will result. Apoptosis is harmful not only in a passive sense of inadequate repopulation but also as an active inducer of inflammatory processes. In fact, recent data have established a mechanistic link between liver apoptosis, injury, inflammation, and fibrosis in chronic liver disease (12). Apoptotic body engulfment by phagocytic cells leads to their activation. This results in chemokine secretion, recruitment of leukocytes and inflammatory cells to the liver, and amplification of liver injury. HSCs are activated by phagocytosis of apoptotic

bodies as well, leading to fibrosis (13) (Fig. 10.2).

Death receptors and the liver

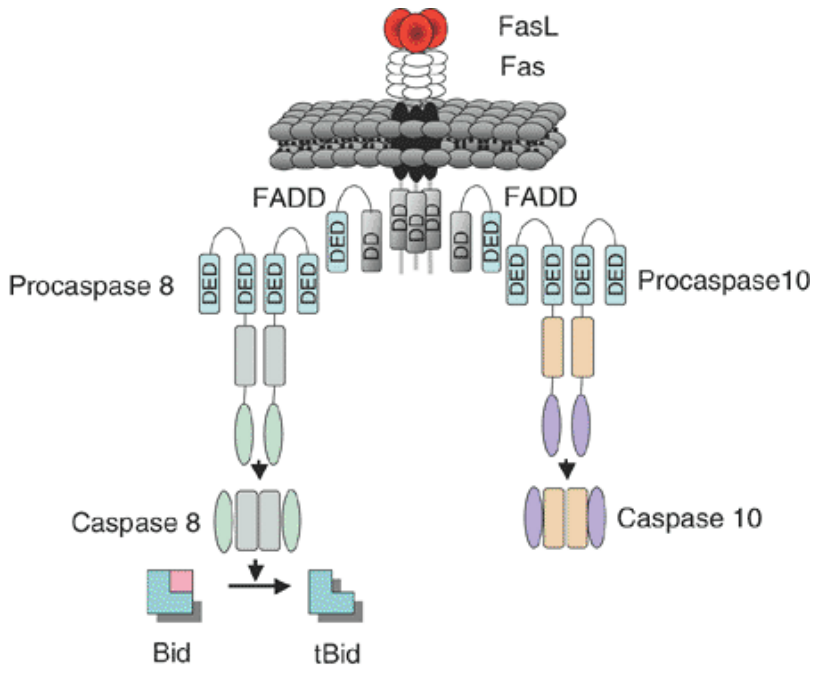
DRs, transmembrane proteins that belong to the tumor necrosis factor (TNF)/nerve growth factor superfamily,

P.315

are essential for ligand–mediated cell death. There are several known death receptors: Fas (CD95/Apo-1), tumor necrosis factor receptor 1 (TNFR1), tumor necrosis factor receptor 2 (TNFR2), tumor necrosis factor–related apoptosis-inducing ligand (TRAIL) TRAIL receptor 1 (TRAIL-R1/DR 4), TRAIL receptor 2 (TRAIL-R2/ DR 5/Killer/ TRICK2), DR 3 (DR 3/Apo-3/TRAMP/WSL-1/LARD), and DR 6. Of these receptors, Fas, TNFR1, and TRAIL are thought to be of significance in liver injury. DRs are activated by engagement with their cognate ligands, Fas ligand (FasL), TNF-α, and TRAIL (Figs. 10.3 and 10.4). Interaction

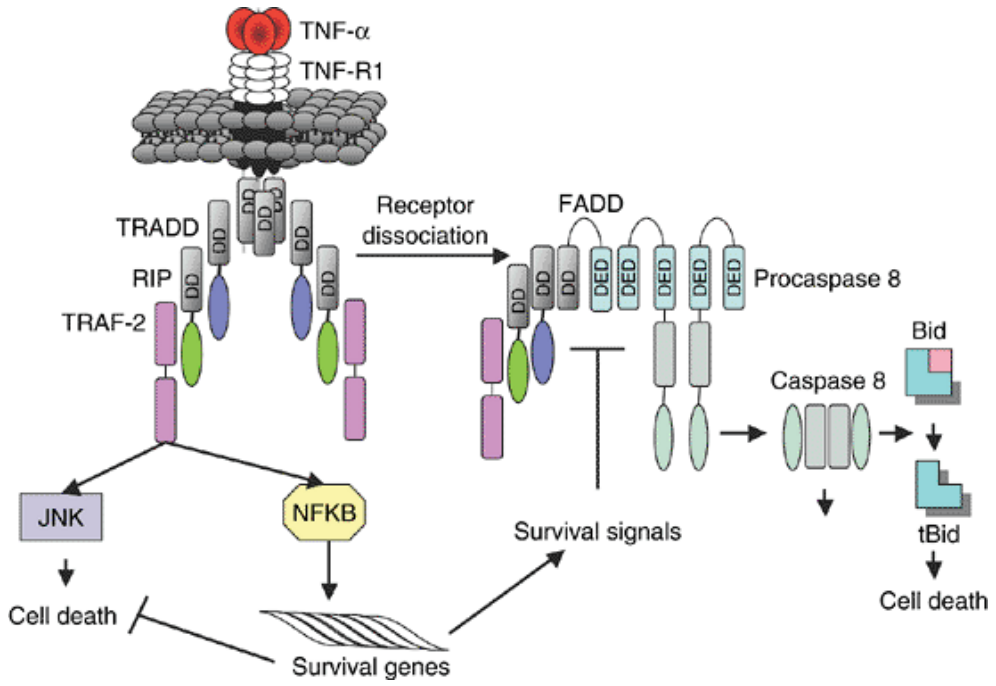
P.316

of these ligands with their cognate receptors triggers intracellular signaling pathways. Receptor ligation brings together the intracellular death domains (DDs) that through adaptor proteins (discussed in the following text) lead to the activation of caspase 8 (an initiator caspase). Once activated, caspase 8 cleaves Bid, a cytoplasmic protein. The cleaved protein, tBid, translocates to mitochondria, leading to its release to mitochondrial effectors of apoptosis, ultimately activating caspases 3 and 7 (effector caspases).



▪ **Figure 10.3** Fas receptor and associated signaling. The Fas receptor is activated on ligation with Fas ligand (FasL). The ligated receptor forms homotypic trimers, leading to intracellular signaling initiated by their intracellular death domains (DDs). The DDs of trimerized Fas associate with the protein Fas-associated death domain (FADD) through its DD. FADD in turn possesses death effector domains (DEDs) that bind and activate procaspase 8 by proteolytic cleavage. Caspase 8 leads to the cleavage of Bid to tBid, a form that translocates to the mitochondria and causes

mitochondrial dysfunction. Caspase 10 is also activated by FADD, but its intracellular targets remain undefined. This conglomeration of proteins is known as the *Fas death-inducing signaling complex (DISC)*.



▪ **Figure 10.4** Tumor necrosis factor receptor (TNFR1) and associated signaling. Ligation of tumor necrosis factor α (TNF-α) to its receptor TNFR1 initiates two distinct set of signals. The initial signaling pathway involves the proteins TRADD (TNFR-associated protein with death domain), receptor-interacting protein (RIP), and TRAF-2 (TNF-associated factor 2), leading to the activation of nuclear factor κB (NFκB) and c-jun *N*-terminal kinase (JNK). Following this the receptor undergoes a conformational change, internalization, interaction with FADD, and activation of caspases 8 and 10 with Bid cleavage.

Fas is expressed by every cell type in the liver, including hepatocytes, cholangiocytes, SECs, stellate cells, and Kupffer cells (6,14,15). Activation of Fas, in most instances, requires binding with membrane-bound FasL-expressing cells or soluble FasL. FasL is expressed in cytotoxic T lymphocytes (CTLs) and natural killer (NK) cells. This provides an efficient means of removal of unwanted hepatocytes, such as virus-infected hepatocytes and cancer cells, by T lymphocytes (16,17). Mice genetically deficient in Fas exhibit hepatic hyperplasia, proving a role for Fas in hepatic homeostasis in healthy individuals (18). The multifaceted role of Fas in hepatic homeostasis and injury is introduced in this section and discussed in greater detail in the subsequent sections.

Although the significance of Fas in liver disease is undisputed, TNF-α plays a significant, if somewhat complementary, role. There is clear overlap in the

spectrum of liver injury associated with TNF-α and Fas, with some features unique to TNF-α receptor–mediated signaling. TNFR1 and TNFR2 are both expressed on hepatocytes, although only TNFR1 expresses a DD and executes the apoptotic program. TNFR1 activation leads to both survival and death signals. Immediate recruitment of TNF receptor–associated protein 2 (TRAF-2) and receptor-interacting protein (RIP) to ligated TNFR1 leads to the activation of nuclear factor κB (NFκB) (19). This transcription factor activates a variety of survival genes (e.g., *Bcl-XL*, *A1*, *XIAP*, and *cFLIP*). Apoptosis is initiated subsequently through the adaptor protein TRADD-mediated caspase 8–Fas-associated death domain (FADD) activation in a receptor-initiated albeit receptor-independent complex (20,21). Therefore, TNFR1 receptor signaling is complex because it usually leads to survival signals but in pathophysiologic states can induce apoptosis.

TRAIL and its receptors add further complexity to DRs and their role in the liver. TRAIL receptors 1 and 2 induce apoptosis through caspase activation, similar to Fas (9,22), whereas TRAIL receptors 3 and 4 are thought to function as decoy receptors, interfering with TRAIL-induced death signaling (23). Traditionally, TRAIL has been thought of as being harmless to normal hepatocytes but efficiently apoptotic in solid tumors (24,25,26). Recent experiments have demonstrated a role for TRAIL in murine hepatocyte apoptosis in several models in hepatitis (27,28). Although circulating TRAIL levels are elevated in human viral hepatitis, a conclusive role in mediating apoptosis has not been established (29). Therefore, TRAIL holds the potential for enhancing therapeutic apoptosis of malignant or virally infected cells without collateral damage.

Lysosomes

Lysosomes are enzyme-filled, membrane-lined or ganelles that along with peroxisomes form the acid vesicle system. The intraorganelle pH of lysosomes is acidic, and lysosomal enzymes optimally function at this acidic pH. Abnormal lysosomal morphology is found in acute and chronic liver diseases. The accumulation of phospholipids in lysosomes (phospholipidosis) is associated with drug-induced liver injury by amiodarone, trimethoprin–sulfamethoxazole, alcohol, and ketoconazole. Lipid accumulation in lysosomes is also a feature of hepatocyte steatosis. Iron, copper, and lanthane are also lysomotropic and toxic to lysosomes.

The extent of release of lysosomal contents (permeabilization) leads to either necrotic cell death, if exuberant, or apoptotic cell death, if the release is controlled. Lysosomal permeabilization may simply involve accumulation of lysomotropic agents with subsequent disruption and release of their content into the cytoplasm. Additionally, reactive oxygen species (ROS), toxic bile salts, sphingosine, free fatty acids (FFAs), ceramide, and TNF-α lead to selective lysosomal permeabilization with subsequent apoptotic cell death. Lysosomal permeabilization leads to the release of lysosomal enzymes into the cytosol, which trigger the mitochondrial pathway of cell death (30,31,32).

Endoplasmic reticulum

The ER is a network of intracellular membranes, the largest membranous organelle in a cell. Its primary functions are to synthesize lipids and proteins. Perturbations that interfere with ER function have been collectively called *ER stressors*. The ER stress pathway is activated by misfolded proteins, glycosylation inhibitors, glucose deprivation, altered glycosylations, ultraviolet (UV) irradiation,

oxidative stress, and alterations in intracellular calcium level. These stimuli lead to accumulation of abnormal proteins, the so-called unfolded protein response (UPR), which is the hallmark of ER stress (33). Sustained ER stress leads to cell death through at least two well-described mediators. Interactions between regulatory ER-localized kinases (e.g., IRE1, PERK, and ATF6) and downstream effectors lead to activation of c-jun *N*-terminal kinase (JNK) (34). JNK then activates the mitochondrial pathway of apoptosis (35,36). Another pathway involves the transcription factor CHOP (c/ebp

homologous protein). The downstream effectors of CHOP are not well defined, but the factor regulates apoptosis transcriptionally and nontranscriptionally through protein–protein interactions (37,38). ER stress is best described in α_1-antitrypsin (α_1-AT) deficiency in which abnormal protein is aggregated in the ER with resultant downstream death signaling (39).

Oxidative stress

Oxygen and oxidative reactions are an essential part of aerobic oxidative phosphorylation, the process that converts nutrient energy into adenosine-5′-triphosphate (ATP), the currency of cellular energy. Oxidative stress is a consequence of this aerobic metabolism. The generation of ROS, (e.g., $O_2^{\cdot-}$, H_2O_2, OH·) and subsequent formation of oxidative products of amino acids, proteins, carbohydrates, lipids, and DNA constitutes oxidative stress. The ROS superoxide ($O_2^{\cdot-}$) also interacts with nitric oxide (NO) to form the reactive nitrogen species, peroxynitrite ($ONOO^-$). Peroxynitrite is a potent oxidizing and nitrating agent. It can nitrate tyrosine residues in several cellular proteins and iron residues in metalloproteins. Given the dependence on aerobic metabolism for energy, cells harbor several antioxidant defense systems to protect themselves from oxidative and nitrative stress. When antioxidant defense systems are overwhelmed, oxidative and nitrative damage ensues. In acute injury models ROS are associated with mitochondrial permeability transition (MPT) in both apoptotic and necrotic cell death. Lipid peroxidation, oxidized DNA, and nitrated proteins are seen in several models of chronic oxidative stress–inducing liver injury (40,41,42,43). Iron overload, copper overload, chronic ethanol consumption, nonalcoholic steatohepatitis (NASH), and viral hepatitis are all associated with oxidative cellular constituent damage. The importance of oxidative stress is further underscored by the well-established use of the antioxidant *N*-acetylcyteine in acute acetaminophen-induced liver failure.

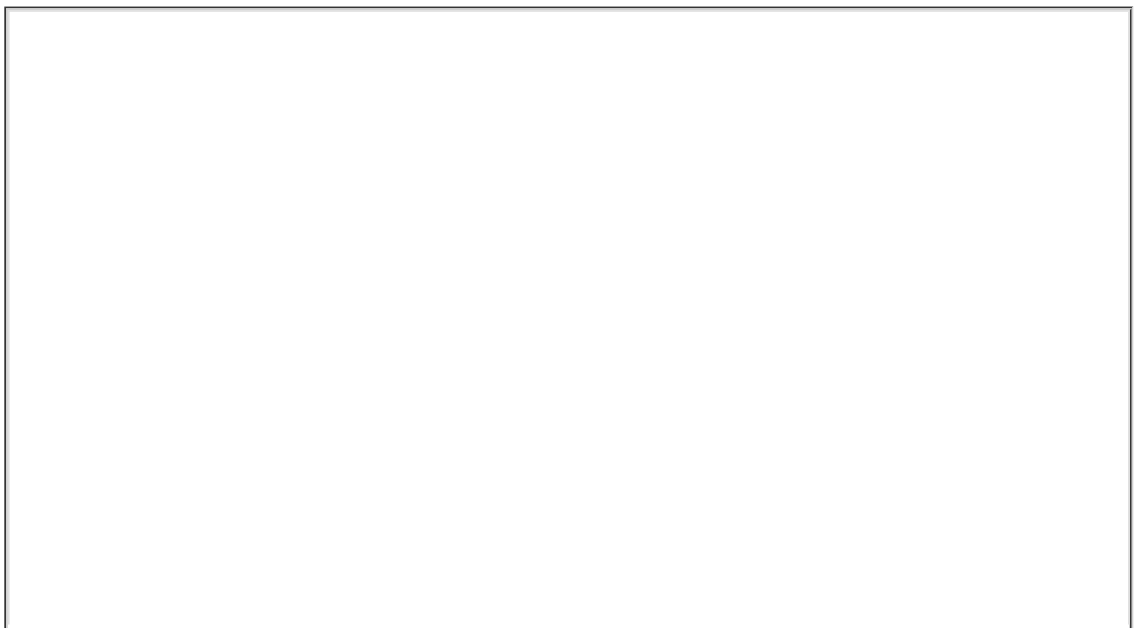
Mitochondria

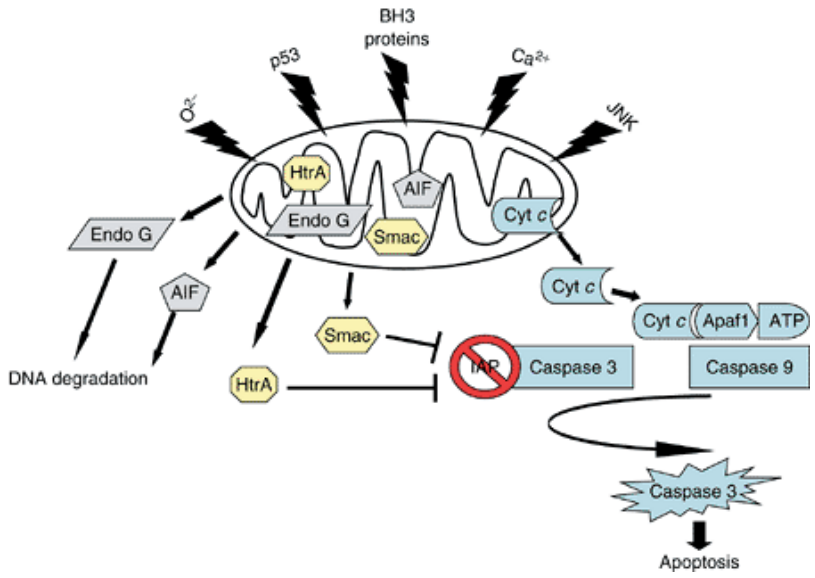
Mitochondria are bound by two membranes, the outer and inner mitochondrial membranes. These two membranes enclose the intermembrane space; the inner membrane is folded into cristae and encloses the mitochondrial matrix. Proapoptotic proteins such as cytochrome *c*, second mitochondrial activator of caspase/direct inhibitors of apoptosis–binding protein with low pI (SMAC/DIABLO), HtrA2/Omi, apoptosis-inducing factor (AIF), and endonuclease G are located within the intermembrane space. The outer mitochondrial membrane is normally impermeable to these proteins, permitting the cell to survive and function. Mitochondrial permeabilization results in the release of these proteins into the cytosol with activation of downstream proteases, culminating in apoptosis (44,45,46) (Fig. 10.5).

Mitochondria are essential for the execution of apoptosis in hepatocytes.

Apoptosis can be divided arbitrarily into three phases, a premitochondrial phase, a mitochondrial phase, and a postmitochondrial phase. The premitochondrial phase is discussed in detail in the section on DRs and other perturbations that culminate in the mitochondria. The end result of the mitochondrial phase is selective mitochondrial permeabilization. This process is regulated by the Bcl-2 family proteins. The Bcl-2 family is divided into pro- and antiapoptotic members. Of the antiapoptotic proteins, Bcl-2, Bcl-XL, and Mcl-1 are important in the liver. The proapoptotic proteins are further divided into multidomain (Bak and Bax) and BH-3 domain only (Bid, Noxa, Puma, Bim, and Bad). Bax is located in healthy individuals in the cytosol but undergoes conformational change and inserts into the mitochondrial membrane to exert its actions. Bak, on the other hand, is an integral mitochondrial protein also activated by conformational change. Bak and Bax then form pores in the outer mitochondrial membrane, leading to permeabilization. The BH-3–only protein Bid is cytosolic and involved in the premitochondrial phase of apoptosis. Its activation is mediated by death receptor–activated caspase 8, and therefore, it serves as a link from the extrinsic to the intrinsic pathway of apoptosis. Bim is activated by its release from cytoskeletal dynein motor complex, and Bad is activated by dephosphorylation. The goal of the proapoptotic members is mitochondrial permeabilization, and the goal of the antiapoptotic members is to prevent just this. The manner in which this occurs is complex and not fully known; it is, however, not just the sum total of the pro- and antiapoptotic signals (47).

Mitochondrial abnormalities, both structural and functional, are associated with liver disorders. Drugs and xenobiotics can inhibit the electron transport chain, uncouple oxidative phosphorylation, impair fatty acid oxidation, damage mitochondrial DNA, and impair mitochondrial DNA repair. Mitochondrial abnormalities in alcohol-induced liver disease are well described (42). Ethanol-driven generation of ROS is associated with oxidative damage to lipids, proteins, and DNA. Moreover, high levels of TNF-α expression, driven by ethanol, also lead to an increase in ROS. Ethanol toxicity, therefore, leads to the MPT that may occur either through DR-mediated pathways or through intrinsic cellular stress. Bile acids, whose levels are characteristically elevated in cholestatic liver diseases, can also trigger mitochondrial dysfunction (48,49,50,51). Similarly, mitochondrial dysfunction is associated with NASH, although the molecular mediators need to be defined (52,53,54).





▪ **Figure 10.5** The role of mitochondria in cell death. Mitochondrial dysfunction is an obligate event in hepatocellular apoptosis. Intrinsic apoptotic stimuli such as p53, calcium, oxidative stress, and c-jun *N*-terminal kinase (JNK), as well as extrinsic apoptotic stimuli (BH-3 proteins), converge on mitochondria. Mitochondrial dysfunction leads to release of several proapoptotic factors. Endonuclease G (Endo G) and apoptosis-inducing factor (AIF) lead to deoxyribonucleic acid (DNA) degradation. Second mitochondrial activator of apoptosis (smac) and HtrA inhibit a set of proteins known as *inhibitors of apoptosis* (*IAP*) leading to the release of caspases 3 and 9. Cytochrome *c* complexes with Apaf 1 and adenosine-5′-triphosphate (ATP) to form the apoptosome that leads to the activation of caspases 3 and 9 that are released from IAP inhibition.

Necrosis

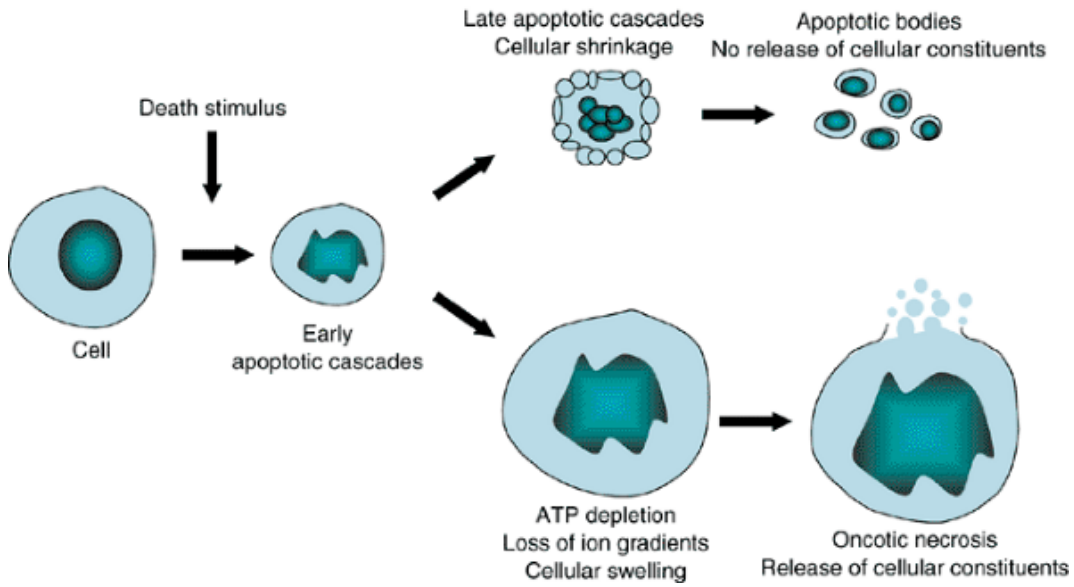
Necrosis has been defined as an energy-independent process, in which cells swell and lyse, releasing their contents. It has been considered "unprogrammed" compared with apoptosis or programmed cell death. The death signaling in necrosis is considered absent or disordered and the cell death equated to the supernova of cellular death phenomenon. Inflammation is viewed as a consequence of phagocytosis of cellular debris and thought to occur more in necrosis because of exuberant release of cellular contents (Fig. 10.6). Although historically viewed as distinct processes, in the last few years, similarities between the two processes have surfaced. Morphologically, hepatocytes with dual characteristics have been observed in vivo in injury models such as ischemia-reperfusion (IR). Regulated, albeit caspase-independent, and death receptor–independent cell death has broadened the definition of necrosis and blurred the erstwhile clear-cut distinction from apoptosis. In addition Fas-mediated necrosis has been described (55). Increasingly, necrosis is viewed as a massive yet programmed cell death (56,57).

Cellular ATP depletion activates necrotic cell death. During ischemia a lack of

oxygen and nutrients leads to a dramatic and absolute inability to generate ATP. This activates processes leading to cellular destruction and necrosis. Exposure to massive ischemia, nitrative/oxidative stress, and xenobiotics can all result in hepatic necrosis (43,58). In some instances the magnitude of noxious stimulus controls the subsequent mode of cell death, with apoptosis resulting from a lesser stimulus and necrosis occurring with the greater magnitude of hepatic insult.

Mitochondria in necrosis

In addition to their role in apoptosis, mitochondria mediate necrotic cell death (Fig. 10.7). MPT, an abrupt increase in the permeability of the inner and outer mitochondrial membranes, occurs in necrosis. This is mediated by the MPT pore, (permeability transition pore [PTP]). The PTP is formed by voltage-dependent anion channel (VDAC) on the outer membrane and adenine nucleotide transporter (ANT) on the inner membrane along with cyclophilin D. The permeability transition leads to dissipation of the electrochemical gradient across the inner mitochondrial membrane, uncoupling of oxidative phosphorylation, and an inability to synthesize new ATP. Calcium and mitochondrial proteins are released as well. Mitochondrial swelling occurs secondary to an increase in membrane permeability, leading to mitochondrial rupture and necrotic cell death (59).



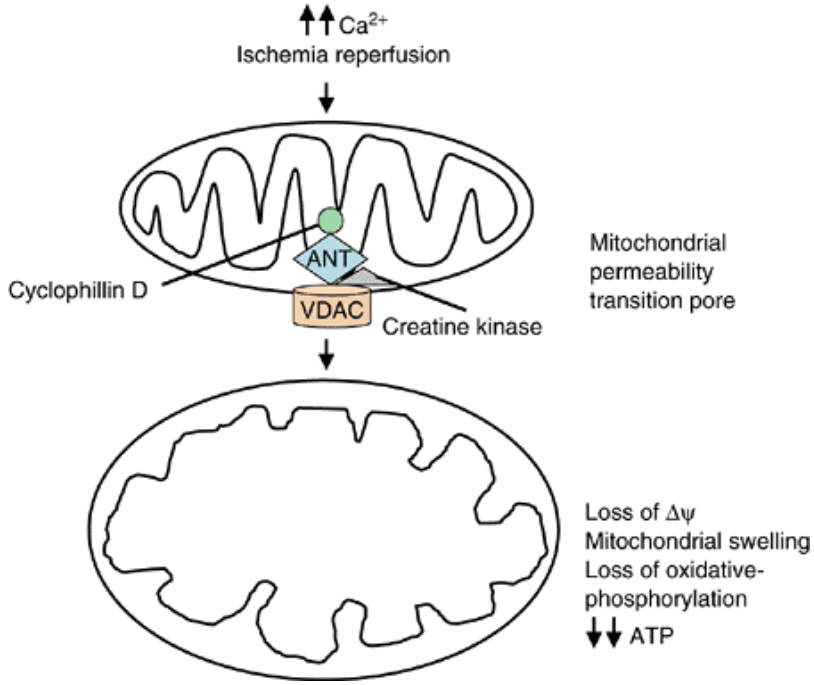
▪ **Figure 10.6** Apoptosis and necrosis are divergent endpoints of common initiating signals. Death-initiating signals lead to activation of early apoptotic signals. In the milieu of adenosine triphosphate (ATP) depletion, loss of ion gradients and cellular swelling ensues. This results in mitochondrial and cellular rupture with release of intracellular content. In a controlled and energy-replete environment, the apoptotic cascade proceeds, leading to nuclear condensation and fragmentation of cells into apoptotic bodies. Physiologically, these apoptotic bodies are engulfed and efficiently removed by Kupffer cells.

Disease Mechanisms

Alcohol-Related Liver Disease

Alcoholic steatohepatitis (ASH) is characterized by steatosis, hepatocyte apoptosis, and acute inflammation. The cellular mechanisms and cytokine milieu leading to alcohol-induced liver injury are well defined. The factors that impart each individual's susceptibility to liver damage are less well understood. In experimental models, ethanol induces changes in mitochondrial and microsomal function with subsequent apoptosis and necrosis (60). Oxidative stress occurs with acute and chronic ethanol ingestion. MPT occurs as a result of oxidative stress, leading to the release of cytochrome *c* and other mitochondrial enzymes,

activation of effector caspases, and apoptosis (61,62). Neutralization of ROS with antioxidants, inhibition of MPT, or inhibition of caspases prevents acute ethanol-induced apoptosis. Oxidative stress also leads to translocation of Bax from cytosol to mitochondria, resulting in mitochondrial dysfunction (63). Induction of cytochrome P-450 2E1 (CYP2E1), a well-known effect of ethanol ingestion, also promotes generation of ROS and may explain how ethanol induces its own toxicity in a feedback loop (60,64). Kupffer cells demonstrate increased expression of CYP2E1 and oxidative stress, and more importantly, they become activated in acute alcohol-mediated liver injury. Once activated, they secrete a number of cytokines, including TNF-α, IL-6, and transforming growth factor β_1 (TGF-β_1) (65,66,67). The role of these inflammatory cytokines is underscored by studies using endotoxinemia to promote TNF-α expression and liver injury and, on the other hand, selective gut decontamination (with antibiotics to reduce portal vein endotoxin levels) with attenuation of both TNF-α signaling and liver injury (65,68). Furthermore, genetic studies in mice demonstrated that TNFR1 is essential for alcohol-induced liver injury (69).



▪ **Figure 10.7** The mitochondrial permeability transition (MPT) pore.

Mitochondria mediate necrotic cell death in the liver. The mitochondrial permeability transition pore (PTP) is formed by voltage-dependent anion channel (VDAC) on the outer membrane and adenine nucleotide transporter (ANT) on the inner membrane along with cyclophilin D. Opening of the PTP leads to mitochondrial swelling, rupture, and release of intermembrane proteins.

Apoptosis occurs in patients with ASH and is correlated with bilirubin, aspartate aminotransferase (AST), and grade 4 steatohepatitis (70,71,72). Hepatic Fas receptor expression is enhanced in ASH, compared with normal livers (70). Studies on sera of patients with ASH have shown increased circulating levels of Fas, FasL, and TNF-α. TNF-α levels correlate with mortality in these patients (73,74,75,76). Hepatocyte apoptosis also correlates with Maddrey's score, a prognostic indicator in acute alcoholic hepatitis. The characteristic inflammatory response occurs secondary to hepatocyte apoptosis and also because of the direct effects of ethanol on Kupffer cells, leading to cytokine production (66). In summary, alcohol-induced liver injury occurs in the setting of oxidative stress and a proinflammatory cytokine environment that together induce hepatocyte apoptosis and consequent inflammation. Apoptosis correlates with the severity of liver injury. Inhibition of the apoptotic signaling pathway holds the potential for future therapies of alcoholic liver disease.

Nonalcoholic Steatohepatitis

Nonalcoholic fatty liver disease (NAFLD), the hepatic component of the metabolic syndrome, has become the most common liver disorder in the United States (77). Hepatocyte apoptosis is a prominent feature of NASH and correlates with disease severity, disease progression, and fibrosis (78). This association underscores the importance of hepatocyte apoptosis and raises the question why only certain steatotic cells die. Recent mechanistic understanding of hepatocyte apoptosis in NASH have elucidated the role of DR ligands, circulating and intrahepatic FFAs, inflammatory cytokines, mitochondrial abnormalities, and genes of fat regulation (53,78,79).

Early pathogenetic studies have described increased Fas and TNFR1 expression in livers of patients with NASH (1). Furthermore, circulating TNF-α levels are also elevated in patients with NASH. This is confirmed by studies in animal models of steatosis, in which apoptosis and inflammation are enhanced after administration of DR ligands, Fas, and TNF-α (80). These data demonstrate the sensitivity of the steatotic hepatocyte to a secondary insult. Insulin resistance, a feature of obesity and the metabolic syndrome, leads to elevated plasma FFA levels. Recent advances have been made in elucidating the cellular mechanisms by which FFA leads to apoptosis in the steatotic hepatocyte, a process termed *lipoapoptosis*. At least two mechanisms have been described. Lysosomal permeabilization by FFA in an in vitro model using HepG2 cells has partially elucidated the role of the intrinsic apoptotic pathway. Indeed, this has been confirmed in patients with NASH who show evidence of lysosomal permeabilization and release of cathepsin B (79). Furthermore, TNF-α expression occurs downstream of, and is partially dependent on, lysosomal permeabilization in this model. A separate in vitro study of the sensitivity of steatotic HepG2 cells to Fas ligand, presumably through upregulation of Fas receptor, provides another piece of the puzzle that integrates

the well-characterized death ligand sensitivity of steatotic livers with the primary metabolic abnormality observed in this syndrome (80). Mitochondria are central to cell death, and FFA-mediated mitochondrial dysfunction in HepG2 cells, as well as primary mouse hepatocytes, has been described as well. One way in which mitochondrial dysfunction can be activated is by a family of signaling enzymes, the mitogen-activated protein kinases (MAPKs). FFA-induced activation of c-JNK, a proapoptotic MAPK, with subsequent JNK-dependent apoptosis in hepatocytes is also an important pathway of FFA-induced lipoapoptosis. Mitochondrial dysfunction in this model results from upregulation of proapoptotic Bcl-2 family proteins (Malhi H, Gores GJ, *unpublished observations*, 2006).

Abnormal mitochondrial structure and function also occur in patients with NASH (53). Megamitochondria with crystalline inclusions, decreased hepatic mitochondrial DNA content, and decreased respiratory chain function occur. CYP2E1 level is increased in patients with NASH, and there is some evidence for increased oxidative stress, which may be stimulated by enhanced FFA-driven mitochondrial β-oxidation. Therefore, the role of mitochondrial abnormalities and oxidative stress as activators of the intrinsic pathway of apoptosis needs to be studied further.

Viral Hepatitis

Hepatitis B virus (HBV) and hepatitis C virus (HCV) cause both acute and chronic hepatocellular infection. In acute viral infection, immune-mediated apoptosis leads to elimination of infected cells, and for chronic infection to be successful, virally infected hepatocytes must evade apoptosis (81). The cell injury in acute infection occurs in two phases. The first phase in acute HBV and HCV infection involves CTL-induced Fas-mediated hepatocyte apoptosis (82,83). The second wave of injury is triggered by apoptosis and occurs as a nonspecific necroinflammatory response that also damages bystander cells that do not express viral antigens (84,85). Also, the virus has a small direct cytopathic effect.

In chronic infection there is ongoing, low-grade, Fas-mediated apoptosis. Apoptosis correlates with histologic severity of chronic hepatitis (86). In sera from patients with chronic HBV and HCV infection sFas levels are increased and correlate with alanine aminotransferase (ALT) levels, histology, and response to therapy (87,88). Furthermore, at the onset of treatment with interferon, sFas levels increase in parallel with ALT values, suggesting enhanced Fas-mediated immune clearance of infected cells (89). Active alcohol consumption in hepatitis C leads to a significant increase in hepatocyte apoptosis that correlates with increased Fas levels, pointing toward a convergence of two distinct apoptotic stimuli on the Fas signaling pathway (90). Not only is there evidence of apoptosis but also soluble markers of apoptosis hold the promise of surrogacy, decreasing the need for repeated liver biopsies (91). It is also clear from several experimental models that HCV proteins regulate apoptosis (92). HCV core protein confers sensitivity to TRAIL-mediated apoptosis in cells previously resistant to its effect (93). Other HCV proteins such as NS3 can activate caspase 8–mediated apoptosis, independent of Fas (94). The inhibition of apoptosis of virally infected hepatocytes possibly provides a mechanism for both viral persistence and development of hepatocellular carcinoma (HCC). Indeed, in a mouse model of hepatic carcinogenesis, the introduction of core E1 and E2 proteins lead to the formation of larger tumors (95,96,97,98,99). In complementary in vitro

experiments, HCV core protein inhibited Fas- and TNF-α-mediated apoptosis in HepG2 cells (100).

Similarly, in chronic HBV infection both Fas receptor and TNFR1 expression are increased in hepatocytes (101). Levels of circulating Fas and TNF-α are increased as well and correlate with severity of infection (88,102). HBV X protein (Hbx) has complex biologic functions in the host, which remain controversial and are reported to attenuate and promote cell death (103,104,105,106,107,108). Therefore, both HCV and HBV infection, although cleared by immune-mediated hepatocyte apoptosis, regulate the apoptotic machinery to establish chronic infections predisposing to hepatocarcinogenesis.

Ischemia-Reperfusion Injury

IR injury occurs during liver transplantation, liver surgery, and hypotensive states. Hemodynamic changes are an integral part of liver transplantation surgery, therefore, understanding the mechanisms of cold ischemia (CI)/warm reperfusion (WR) injury should promote therapeutic strategies to minimize injury and improve allograft function. WR occurs in other forms of liver surgery and hypotensive states. SECs are the immediate target of CI/WR injury, with hepatocyte injury occurring after prolonged periods of ischemia. In contrast, hepatocytes are the primary target in WR injury. Cold storage alone leads to apoptosis of SEC. Use of caspase inhibitors significantly decreases SEC apoptosis and improves survival after orthotopic liver transplantation (OLT) (109). Kupffer cells are activated and secrete numerous cytokines that in turn activate apoptosis and attract inflammatory cells. Depletion of Kupffer cells using gadolinium chloride decreases SEC apoptosis and liver injury in CI/WR (110,111).

IR injury involves hepatocyte apoptosis, which also correlates with the duration of ischemia and the presence of preexisting liver damage (112). Activation of NFκB, TNF-α, and Fas modulate IR-induced hepatocyte apoptosis (113,114). NFκB has a biphasic activation after IR; the initial phase promotes expression of TNF-α, leading to apoptosis and inflammation, and the later phase is protective, such that selective inhibition of activation of the later phase enhances liver injury, and nonspecific inhibition attenuates injury (115). Historically, necrosis and apoptosis both have been thought to mediate IR injury; recent evidence, however, points toward apoptosis as the principal mode of hepatocyte cell death in IR (58,116). In experimental models TNF-α-dependent apoptosis, capsase-dependent hepatocyte apoptosis, and increase in levels of FasL expression were observed (113,117). Stress-activated protein kinases, such as JNK, are also activated soon after OLT (118). Use of JNK inhibitors preserves hepatic architecture and attenuates injury (119). Expression of Bcl-2, an antiapoptotic protein, by several different modalities, protects hepatocytes against ischemic apoptosis and liver injury (120). The use of small interfering ribonucleic acid (siRNA) to decrease the expression of caspases 8 and 3 also reduces IR injury. In summary, IR injury is mediated by apoptosis of both parenchymal and nonparenchymal liver cells. Inhibition of apoptosis in experimental studies has improved the outcomes of OLT; this offers promising interventions to maximize allograft function.

Cholestatic Injury

Cholestasis, an impairment in bile flow and/or secretion, is characterized by an increase in hepatocellular bile acid concentrations. At a cellular level, the effects of hydrophobic bile acids are well understood. Glycine-conjugated

chenodeoxycholic acid (GCDC) is more toxic than taurine-conjugated chenodeoxycholic acid (TCDC) (121,122). Toxic bile acids induce hepatocyte apoptosis in vitro and also in vivo in animal models of extrahepatic cholestasis (bile duct–ligated animal). There is evidence of involvement of the death ligands, Fas and TRAIL, in bile acid–mediated apoptosis (123,124). The importance of Fas receptor in this pathway is proved further by studies in mice deficient in Fas receptor (*lpr*). Following bile duct ligation in these *lpr* mice, hepatocyte apoptosis is attenuated (125). Furthermore, in long-term follow-up in these animals, fibrosis is attenuated as well. This study underscores the importance of the paradigm that hepatocyte apoptosis acts as a fibrogenic stimulus, resulting ultimately in liver cirrhosis.

Fas-induced apoptosis is not the only mechanism of hydrophobic bile acid toxicity. In cholestatic *lpr* mice, hepatocyte apoptosis eventually occurs, although delayed and attenuated when compared to wild type mice. Bax levels and translocation to mitochondria are increased in cholestatic *lpr* mice and explains the onset of apoptosis (5). Inhibition of apoptosis by inhibiting Bid prevents both Fas-dependent and Fas-independent bile acid–induced hepatocyte apoptosis (126). Furthermore, in Fas-deficient cells, the role of TRAIL-R2 in bile acid–induced hepatocyte apoptosis has been unmasked. TRAIL activation by GCDC leads to the recruitment of the classical TRAIL–death-inducing signaling complex (DISC), with activation of caspases 8 and 10, involvement of mitochondria, release of cytochrome *c*, and apoptosis (49).

Primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) are the two commonest etiologies of adult intrahepatic cholestasis. Immune-mediated apoptosis of biliary epithelial cells (BECs) is well defined in PBC (127,128). Pyruvate dehydrogenase complex (PDC), a mitochondrial protein, is expressed on the cell surface membrane of BEC in PBC. Autoantibodies and autoreactive T cells exist against this antigen, perpetuating immune-mediated BEC apoptosis. PDC is normally sequestered in the inner mitochondrial membrane. Although the perpetuation of autoimmune injury in response to PDC is understood, the initial apoptotic stimulus that leads to mitochondrial dysfunction and expression of PDC on BEC surface is unknown. In experimental models it was found that immunoreactive PDC migrated from the mitochondria to the plasma membrane of cells after the induction of apoptosis (3). Therefore, apoptosis plays a role in bile duct injury and in the ensuing hepatocellular injury seen in cholestasis.

Wilson Disease and Hemochromatosis

Wilson disease is characterized by a hepatocellular defect resulting from mutations in a copper-transporting P-type ATPase (ATP7B) with an inability to excrete copper in bile. This leads to copper accumulation in hepatocytes, which is cytotoxic (129). The Long-Evans Cinnamon (LEC) rat is a spontaneous mutant that mimics human Wilson disease (130). This animal shows evidence of chronic oxidative damage, such as lipid peroxidation and DNA strand breaks (131,132). This suggests a role for oxidative stress because copper has redox activity, such as the Fenton and Haber-Weiss reactions, leading to the generation of free radicals and oxidative damage to lipids, proteins, and DNA. In vitro data shows that copper overload also leads to p53-dependent cell death (133).

The course of Wilson disease in humans runs the gamut from FHF to mild chronic hepatitis. In patients with Wilson disease who have FHF, high levels of apoptosis, Fas receptor, and Fas messenger RNA (mRNA) were detected (134). Oxidatively damaged and bulky DNA, indicative of damaged DNA with adduct formation, was

detected in patients with Wilson disease (40,135). Therefore, copper overload causes apoptotic hepatocellular death in patients with Wilson disease.

Oxidative stress is a direct consequence of iron overload because of the redox activity of iron and the generation of oxygen free radicals. As with copper excess, the generation of ROS occurs through Fenton and Haber-Weiss reactions. Oxidative damage to all cellular constituents ensues and, indeed, oxidative DNA adducts are found in patients with hereditary hemochromatosis (41). Although iron is not a direct carcinogen, iron overload is associated with increased risk for the development of HCC (136).

α_1-Antitrypsin Deficiency

α_1-AT is normally secreted predominantly by hepatocytes. Patients with α_1-AT deficiency produce an abnormal variant of the protein, resulting in a failure of hepatocytes to secrete it into the serum. This leads to accumulation of the abnormal protein within hepatocytes. The normal homeostatic response leads to enhanced degradation of the abnormal protein, but in individuals unable to breakdown the accumulated protein, hepatocyte injury ensues. The ER is a major site of degradation of abnormal proteins in the body. Briefly, the accumulation of abnormal α_1-AT in the ER leads to

activation of autophagic processes. Mitochondrial dysfunction and caspase 3 activation occur downstream of this ER stress response (39). The molecular pathways that mediate α_1-AT-induced ER stress and mitochondrial dysfunction are not well defined and are an area for future research.

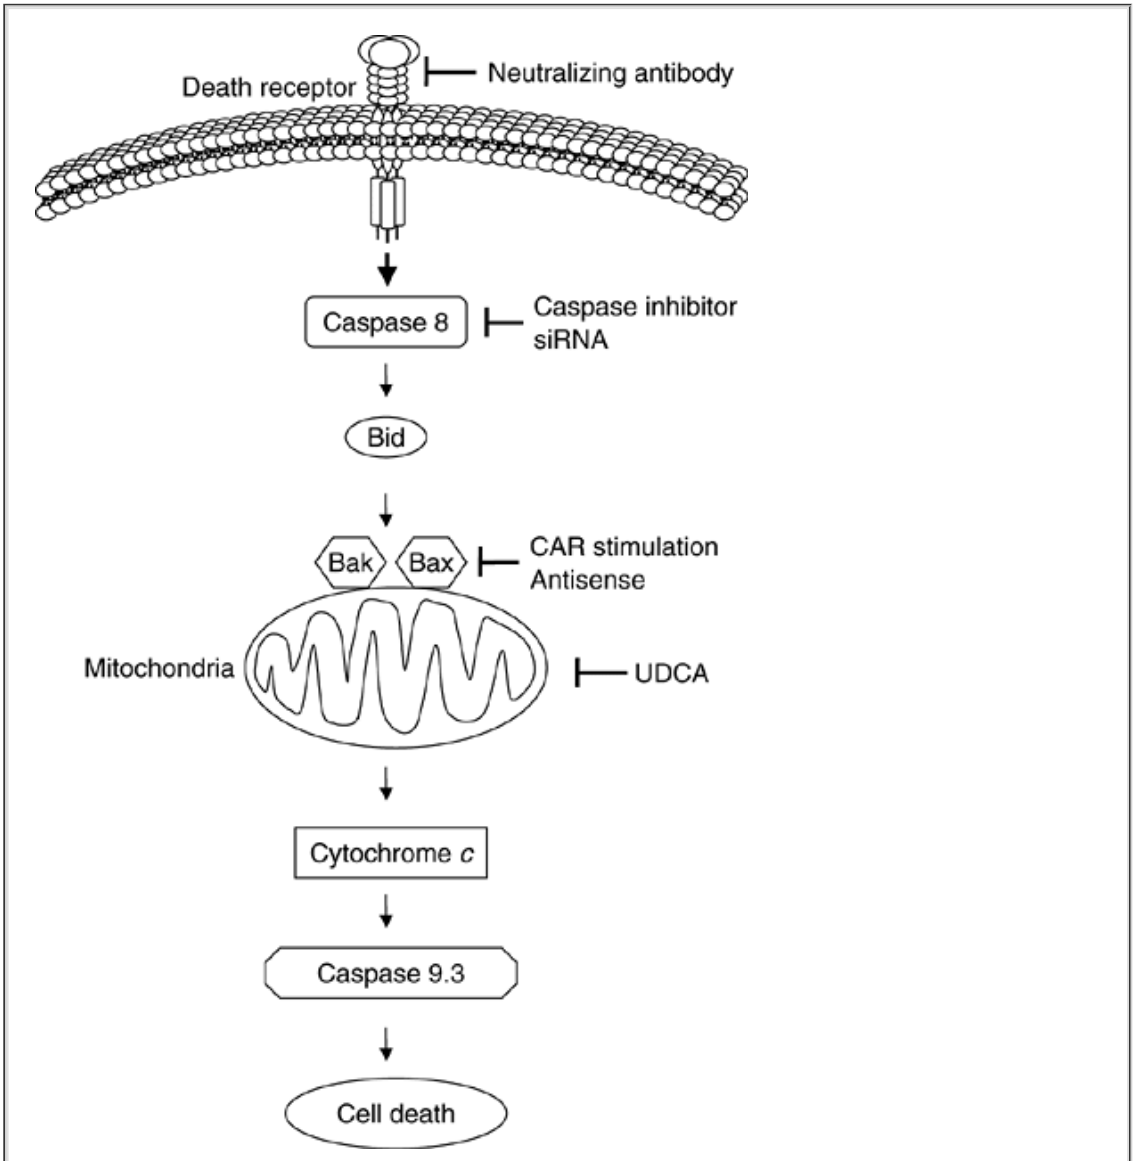
Fulminant Hepatic Failure

Several lines of experimental data and human observations point to the importance of DR-mediated apoptosis in FHF. In a seminal paper Lacronique et al. (137) it was reported that induced massive hepatocyte apoptosis and FHF in mice using an anti-Fas antibody activated the death signaling cascade and rescued livers from apoptosis and animals from death by increasing the expression of antiapoptotic Bcl-2 (137,138). In patients with FHF, levels of both Fas receptor and Fas ligand expression in hepatocytes are high. Fas ligand levels are elevated in infiltrating lymphocytes, circulating lymphocytes, and sera of patients as well. Hepatocyte apoptosis in addition to enhanced Fas expression has been observed in FHF of different etiologies (134,139,140). In addition to Fas, circulating levels of TNF-α and TNF-α receptors are increased in patients with FHF and correlate with the recovery of native liver function (141). Besides activation of NFκB to aid in recovery, the dichotomous role of TNF-α is further developed in FHF, in which it increases the expression of FADD protein, perhaps augmenting Fas sensitivity. In summary, FHF is accompanied by several cytokine changes, of which Fas clearly mediates apoptosis. TNF-α and other cytokines serve dichotomous roles, promoting apoptosis, inflammation, and recovery. Enhancing the milieu in favor of recovery by inhibiting Fas-mediated apoptosis appears to be a promising therapeutic strategy, one that should be developed further with human clinical trials, given the shortage of donor organs.

Therapeutic Implications

Understanding apoptotic cascades in liver disease has unraveled novel therapeutic opportunities (Fig. 10.8). Neutralization of TNF-α in treatment of alcoholic hepatitis has shown early promise (142,143). Ribonucleic acid

interference (RNAi) therapy selectively manipulates a cell's genetic machinery to reduce expression of the protein of interest. Disruption of Fas and caspase 8 gene expression, using RNAi, ameliorated injury and improved survival in experimental FHF and immune-mediated hepatitis (140,144). Increased expression of antiapoptotic Bcl-2 and caspase inhibition protected against FHF (137,145). Similarly, targeted hepatic delivery of NCX-1000, a NO conjugate of urosdeoxycholic acid (UDCA), that selectively releases NO in the liver even after onset of apoptosis protects from acetaminophen (*N*-acetyl-p-aminophenol [APAP])-induced FHF (146). In a model of IR injury, silencing initiator and effector caspases had a salutary effect on the liver (116). UDCA has a dual effect of preventing mitochondrial permeabilization and apoptosis induced by bile acid, ethanol, Fas, and TGF-β_1 (147) and also promoting the activation of survival signals in cells (148). Furthermore, in animal studies an antiapoptotic molecule, IDN-6556 (a pan-caspase inhibitor), reduces cholestatic hepatocyte apoptosis, stellate cell activation, liver injury, and resultant fibrosis (149). At a mitochondrial level, the disruption of proapoptotic Bcl-2 family proteins also prevents bile acid–induced apoptosis (126).



▪ **Figure 10.8** Therapeutic targets in apoptosis. Schematic representation of

potential therapeutic targets in liver diseases. Apoptosis can be inhibited at several levels. Death receptor and ligand interaction can be prevented by neutralizing antibodies. Pharmacologic inhibitors, small interfering ribonucleic acid (siRNA), antisense molecules, modulation of Bcl-2 family pro- and antiapoptotic proteins with nuclear receptor agonists, for example, constitutive androstane receptor (CAR), are all potential therapeutic strategies. Ursodeoxycholic acid (UDCA) has been in clinical use for cholestatic liver disease.

The fact that apoptosis can be modulated temporally after cells have been exposed to apoptotic stimuli is appealing in its applicability to the clinical scenario. Indeed, several studies in experimental models of acute and chronic liver disease have demonstrated amelioration of liver apoptosis and injury and improved survival, with inhibition of apoptosis even after exposure to the apoptogenic stimulus. Future studies should be directed toward development of rational antiapoptotic therapies targeted to the liver.

Canbay A, Higuchi H, Bronk SF, et al. Fas enhances fibrogenesis in the bile duct ligated mouse: a link between apoptosis and fibrosis. *Gastroenterologia* 2002;123:1323–1330.

This article is important because it highlights the principle that sustained hepatic injury leads to sustained hepatocyte apoptosis and attendant fibrosis. Interruption of this process prevents apoptosis and mechanistically links two important observations, that is, apoptosis and fibrosis.

Chapter 11
The Liver in Systemic Disease

Lawrence S. Friedman
Andrew S. Ross

Key Concepts

- Liver disease is highly prevalent in patients with type 2 diabetes mellitus and can range from mild steatosis to cirrhosis and hepatocellular carcinoma. The impact of liver disease on mortality in patients with diabetes is substantial.
- Patients with thyroid disorders, especially hyperthyroidism, commonly have abnormal liver chemistries. Thyrotoxicosis can lead to ischemic hepatic injury, whereas hepatic dysfunction in myxedema may result from right-sided heart failure. Medications used to treat hyperthyroidism can lead to hepatotoxicity.
- Celiac disease may account for otherwise unexplained liver chemistry abnormalities in a substantial number of affected persons.
- Liver disease associated with various rheumatic disorders is commonly the result of the medications used to treat these conditions.
- Liver dysfunction in patients with sickle cell disease results from red cell sickling within hepatic sinusoids and must be distinguished from cholecystitis and choledocholithiasis.
- Hepatic involvement is common in amyloidosis and sarcoidosis. In amyloidosis, hepatic involvement rarely causes clinical manifestations but indicates an ominous prognosis. Hepatic sarcoidosis may occasionally be complicated by cirrhosis and portal hypertension.
- Involvement of the liver by lymphoma is more common in patients with non-Hodgkin's lymphoma than in those with Hodgkin's disease. Rarely, hepatic lymphoma can result in acute liver failure.

The liver interacts in multiple ways with other organ systems and is often involved by systemic disease processes. This chapter reviews the systemic disorders that most frequently involve the liver and includes only those diseases that are not covered in detail in other chapters.

Endocrine Disorders

Diabetes Mellitus

Approximately 17 million people in the United States are affected by type 2 diabetes mellitus, and liver disease is one of the leading causes of death in this patient population (1,2). In fact, the standardized mortality rate for liver disease among patients with type 2 diabetes mellitus is higher than that for cardiovascular disease. Liver disease in patients with type 2 diabetes mellitus can range from nonalcoholic fatty liver disease (NAFLD) to cirrhosis and hepatocellular carcinoma (HCC) (1,3). In addition, evidence suggests that the frequency of chronic hepatitis C is increased among patients with type 2 diabetes mellitus (4).

The most common liver disease associated with diabetes mellitus is NAFLD (1,5,6) (see Chapter 39). It has been estimated that up to 70% of patients with type 2 diabetes mellitus have some form of NAFLD,

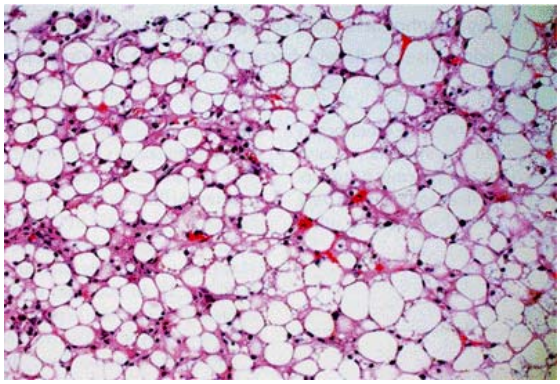
and this rate may reach 100% in patients with both diabetes and obesity (7). Nonalcoholic steatohepatitis (NASH) is almost three times as frequent in persons with type 2 diabetes mellitus as in persons without type 2 diabetes mellitus and is estimated to be present in up to 50% of patients with type 2 diabetes mellitus and NAFLD. Even more alarming is the fact that up to 19% of patients with type 2 diabetes mellitus and NAFLD have cirrhosis (1).

Patients with diabetes and NAFLD typically present with asymptomatic elevations in serum aminotransferase levels; massive hepatomegaly has been described in rare cases. Mild elevations in serum alkaline phosphatase and γ-glutamyl transpeptidase levels have also been described.

Fatty infiltration of the liver in patients with type 2 diabetes mellitus is typically diffuse (Fig. 11.1), although fat accumulation may be focal (1). Steatosis can generally be diagnosed by abdominal ultrasonography, which reveals a diffuse increase in hepatic echogenicity, with focal areas of fat sparing that appear as mass lesions (1,8). Although magnetic resonance spectroscopy can quantify hepatic steatosis, liver biopsy is

required for the detection of NASH and fibrosis.

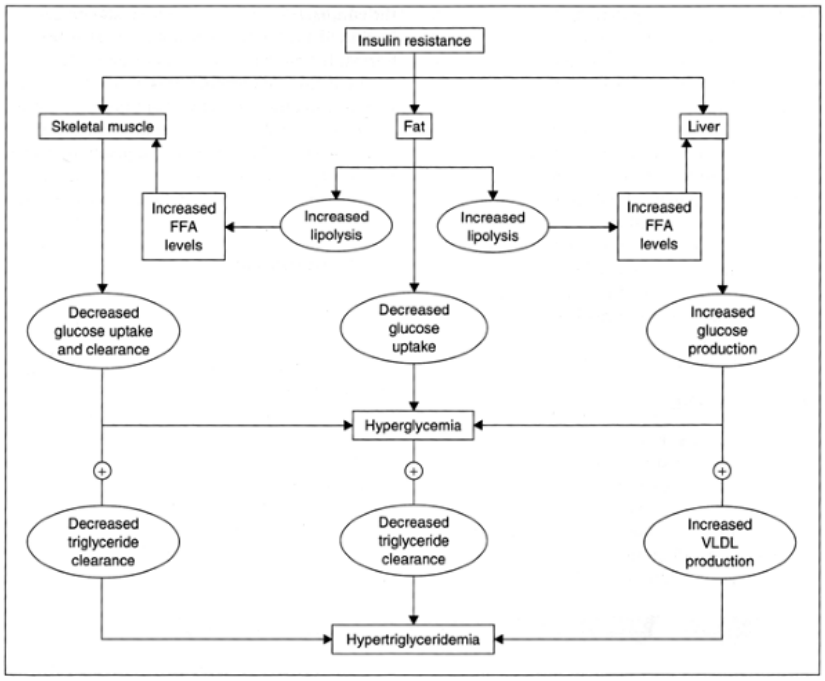
In addition to steatosis, liver biopsy findings in patients with NASH include various combinations of inflammation, Mallory's hyaline, balloon degeneration of hepatocytes, and fibrosis. Nuclear glycogenation, producing a vacuolated appearance of hepatocyte nuclei on light microscopy, may be found in up to 75% of patients with type 2 diabetes mellitus. This feature is not pathognomonic of diabetes and may also occur with bacterial inflammation, tuberculosis, cirrhosis, hepatitis, and Wilson disease, and even in normal livers (1).



▪ **Figure 11.1** Liver biopsy specimen demonstrating severe steatosis in a patient with diabetes mellitus and obesity (hematoxylin and eosin). (Courtesy of John Hart, MD, Chicago, IL: Department of Pathology, University of Chicago Pritzker School of Medicine.)

Insulin resistance and obesity appear to be the common factors that link NAFLD to diabetes mellitus (7,9,10) (Fig. 11.2). The resistance to insulin that characterizes type 2 diabetes mellitus leads to decreased peripheral glucose uptake and enhanced adipocyte lipolysis, in turn leading to increased insulin resistance and further deposition of fat in the liver. The biochemical basis of hepatic lipid deposition in patients with type 2 diabetes mellitus remains to be elucidated. One theory postulates that high circulating levels of insulin lead to defective fatty acid oxidation in the mitochondria, thereby resulting in the intracytoplasmic accumulation of triglycerides within the hepatocytes. An inflammatory response may ensue and result in NASH and, in some cases, hepatic fibrosis and, ultimately, cirrhosis (1). As compared with patients without diabetes who have steatosis, patients with type 2 diabetes mellitus having steatosis may be at increased risk for NASH, likely because of the persistence of insulin resistance (1).

The cornerstones of management of patients with diabetes mellitus and hepatic steatosis are metabolic control and weight loss. Although weight loss is clearly important, the ideal rate of weight reduction in patients with hepatic steatosis is debated. Rapid weight reduction can lead to increased formation and hepatic deposition of free fatty acids. The use of pharmacologic agents to reduce steatosis has been investigated (11). Medications such as pioglitazone, rosiglitazone, and metformin that reduce insulin resistance have been shown to improve liver histopathology, hepatic lipid content, and liver biochemical test results in patients with hepatic steatosis and NASH (12,13,14). Although promising, the use of these agents to treat hepatic steatosis and NASH remains investigational.



▪ **Figure 11.2** Metabolic effects of insulin resistance in skeletal muscle, fat, and liver. The resistance to insulin leads to decreased peripheral glucose uptake and enhanced adipocyte lipolysis, in turn leading to increased insulin resistance and further hepatic fat deposition. FFA, free fatty acid; VLDL, very low density lipoprotein. (From Tolman KG, Fonseca V, Tan MH, et al. Narrative review: hepatobiliary disease in type 2 diabetes mellitus. *Ann Intern Med* 2004;141:946–956. Reprinted with permission.)

In addition to the increased frequency of NAFLD in patients with diabetes mellitus, several epidemiologic studies have suggested that the risk of HCC is increased in patients with diabetes mellitus (1,15,16,17,18,19,20,21,22). Studies from Europe and the United States suggest that the risk of HCC may be increased up to fourfold in patients with diabetes mellitus as compared with subjects without diabetes (16,17,18,19,20,21,22). This risk persists even when patients with viral hepatitis are excluded from analysis, thereby suggesting that diabetes may be an independent risk factor for the development of HCC. Cirrhosis resulting from progressive NASH likely provides the background for the development of HCC among patients with type 2 diabetes mellitus. A proposed mechanism of carcinogenesis in this setting includes the formation of reactive oxygen species in hepatocytes as a result of insulin resistance, enhanced lipolysis, and lipid accumulation within hepatocytes (1).

Data from several epidemiologic studies suggest that the frequency of hepatitis C virus (HCV) infection is higher in patients with diabetes mellitus than in the general population, and some evidence even suggests that HCV may have a causative role in the development of diabetes (1,23,24,25,26,27) (see Chapter 30). Several studies have demonstrated a higher frequency of diabetes among patients with HCV infection than among those infected with hepatitis B virus (HBV). In addition, patients infected with HCV who have undergone liver transplantation have a higher frequency of diabetes than do patients who have undergone transplantation for other diseases. Finally, glucose intolerance improves after eradication of HCV with interferon-based therapy. Together, these data suggest that HCV plays a role in the pathogenesis of diabetes. Although HCV genotype 1 is the most common genotype in patients with type 2 diabetes mellitus and HCV infection, the frequency of HCV genotype 2 is disproportionately represented among patients with type 2 diabetes mellitus and HCV infection as compared with those without diabetes (1). The presence of fatty liver is actually highest among patients infected with HCV genotype 3; treatment with interferon-based therapy has been found to reduce the

degree of steatosis in this population (1). Patients with HCV infection and fatty liver are less likely to respond to antiviral therapy than are those without fatty liver (1).

Patients with diabetes have a two- to threefold increased frequency of cholelithiasis as compared with persons without diabetes. Although comorbid obesity may be a contributing pathogenic factor, diabetes alone has been found to be an independent risk factor for the development of gallstones. The mechanism remains speculative, although sluggish bile flow, perhaps caused by diabetic autonomic neuropathy, has been proposed (1,28). A noncirrhotic form of hepatic sinusoidal fibrosis, termed *diabetic hepatosclerosis* and attributed to microangiopathy, has been described in patients with longstanding diabetes mellitus and

microvascular complications (28).

Thyroid Disease

The liver is the major site of thyroid hormone metabolism. Up to 85% of extrathyroidal deiodination of thyroxine (T_4) to triiodothyronine (T_3) and reverse T_3 (rT_3) occurs in the liver. Moreover, plasma-binding proteins of thyroid hormone, including thyroxine-binding globulin, prealbumin, and albumin, are produced by the liver. In addition, the liver is involved in the conjugation, biliary excretion, and oxidative deamination of T_4. Thyroid hormones are also important for normal hepatic function and bilirubin metabolism; for example, thyroid hormone appears to play an important role in regulating the activity of uridine 5′-diphosphate glucuronyltransferase, the hepatic enzyme that is primarily responsible for the conjugation of bilirubin before hepatic excretion (29,30). A summary of the features of thyroid-related liver disease is shown in Table 11.1.

Table 11.1. Hepatic Abnormalities Associated with Various Thyroid Diseases and Therapies

	Thyrotoxicosis	Hypothyroidism	Propylthiouracil therapy	Methimazole and carbimazole therapy
Aminotransferase elevations	++	+	++	–
Alkaline phosphatase elevation	++	+	–	+
Bilirubin elevation	+	+	–	+
Liver biopsy findings	Lobular inflammation, hepatocyte nuclear changes, Kupffer cell hyperplasia	Centrilobular fibrosis in patients with ascites	Nonspecific hepatocellular injury Hepatocellular necrosis in <1% of patients	Intrahepatic cholestasis
	Rarely, centrilobular necrosis and perivenular fibrosis			
	Nonspecific lobular inflammation, intrahepatocytic cholestasis			
Outcome	Laboratory test result abnormalities and liver biopsy findings are reversible in most patients with restoration of the euthyroid state Rarely, fulminant hepatic failure	Clinical findings and laboratory abnormalities are usually reversible within weeks of initiation of thyroid replacement therapy	Full recovery occurs in most patients with a decrease in dose or cessation of therapy Persistent hepatitis occurs in <1% of patients Rarely, fulminant hepatic failure	Liver test result abnormalities and biopsy findings may persist after therapy is discontinued

–, absent; +, occasional; ++, frequent.

Hyperthyroidism

Elevated serum liver biochemical levels can be seen in 45% to 90% of patients with hyperthyroidism (29). Liver chemistry abnormalities can be highly variable; hypoalbuminemia and increased serum levels of aspartate aminotransferase (AST), alanine aminotransferase (ALT), and alkaline phosphatase have been reported. Mild elevations in serum bilirubin levels can be seen in up to 5% of patients with thyrotoxicosis, but marked elevations are rare. The presence of jaundice should prompt a search for other complications of hyperthyroidism, such as cardiac failure, sepsis, and thyroid storm. Clinically, most patients typically present with self-limited hepatitis, but

massive hepatomegaly and fulminant hepatic failure have been described in patients with severe thyrotoxicosis. In most cases, the hepatic abnormalities reverse after restoration of a euthyroid state (29,31,32).

Hepatic oxygen consumption is increased in patients with thyrotoxicosis, but hepatic blood flow is not increased. As a result, the hepatocytes in the centrilobular area (zone 3) of the hepatic lobule are susceptible to ischemia because zone 3 hepatocytes are farthest away from the hepatic arteriole in zone 1. Ischemic injury to centrilobular hepatocytes probably accounts for most of the liver chemistry abnormalities attributable to hyperthyroidism (see Chapter 41). Conditions often associated with hyperthyroidism, such as congestive heart failure, infection, and malnutrition, likely play a role as well (29,31,32).

Liver biopsy findings in patients with mild hyperthyroidism–related hepatic injury are nonspecific and are more likely to be related to associated high-output cardiac failure or rapid weight loss than to thyrotoxicosis per se (29). Biopsy specimens may reveal lobular inflammation with an infiltrate consisting of polymorphonuclear leukocytes, eosinophils, and lymphocytes; hepatocyte nuclear changes; and Kupffer cell hyperplasia. Some patients may exhibit focal or diffuse centrilobular necrosis and perivenular fibrosis, whereas others may show decreased hepatic glycogen content, steatosis, or vacuolization of hepatocytes.

Liver injury associated with antithyroid therapy

Dose-related elevations in serum AST and ALT levels occur in up to 30% of patients taking propylthiouracil (PTU); peak aminotransferase levels generally occur soon after the initiation of therapy (29,30). The elevated aminotransferase levels typically normalize after a reduction in the dose of PTU. Although aminotransferase levels return to normal in most patients after the discontinuation of PTU, hepatitis may persist in less than 1% of patients, with evidence of hepatocellular necrosis in a liver biopsy specimen. Such an idiosyncratic reaction to PTU typically occurs during the first few months of therapy in women younger than 30 years (33,34). Affected patients usually recover completely after discontinuation of PTU, but fulminant hepatic failure resulting in death or the need for liver transplantation has been reported (35,36,37,38). Patients who experience asymptomatic, mild (less than or equal to two times the normal) elevations in serum aminotransferase levels while taking PTU can continue the drug with close monitoring, but the medication should be stopped immediately if aminotransferase levels rise further. Glucocorticoids have been used to treat patients with severe PTU-related hepatic injury, but controlled studies demonstrating the efficacy of such therapy are lacking (29).

Although less common than PTU-associated hepatotoxicity, cholestatic hepatotoxicity may result from methimazole and carbimazole. Female patients older than 50 seem to be at increased risk. Affected persons typically have elevations in serum bilirubin, alkaline phosphatase, and γ-glutamyl transpeptidase levels. The liver test result abnormalities characteristically occur within 2 to 3 months of the initiation of these agents and may persist up to several months after withdrawal of the drug. Liver biopsy specimens usually reveal intrahepatic cholestasis. Because PTU, methimazole, and carbimazole carry the potential for hepatotoxicity, liver tests should be repeated within 3 months of the initiation of any of these medications (29,30,32).

Hypothyroidism

Hypothyroidism affects every organ system in the body, and the liver is no exception. Decreases in hepatic oxygen consumption and in the production, flow, and excretion of bile have all been demonstrated in

patients with hypothyroidism (29,30,31,32). Clinically, these changes may manifest as cholestatic jaundice. In addition, the reduction in bile salt formation and excretion in patients with hypothyroidism may lead to impaired cholesterol metabolism. The resulting hypercholesterolemia, combined with reduced bile flow and gallbladder hypotonia, leads to an increased risk of gallstone formation in affected persons. Liver biopsy specimens from patients with hypothyroidism-related hepatic dysfunction reveal central congestive fibrosis, which is seen predominantly in patients with coexistent myxedema ascites (39), suggesting that right-sided heart failure may contribute to the liver dysfunction associated with hypothyroidism.

The clinical picture of hypothyroidism can be confused with that of advanced chronic liver disease because of similarities in presenting symptoms and laboratory findings (29,32). Myalgias, fatigue, muscle cramps, and elevated AST and lactate dehydrogenase (LDH) levels (resulting from myopathy in patients with hypothyroidism) are common to both liver disease and hypothyroidism. In addition, myxedema coma and ascites with a high serum–ascites albumin gradient can be seen in patients with hypothyroidism, in whom ascites may be the result of right-sided heart failure or increased permeability of the peritoneal membrane to proteins and mucopolysaccharides. Differentiating hypothyroidism from advanced chronic liver disease is crucial because hepatic dysfunction associated with hypothyroidism typically resolves within weeks of the initiation of thyroid replacement therapy (29,31,32).

Cushing's Syndrome

Excess serum cortisol results in the typical features of Cushing's syndrome: Weight gain, moon facies,

diabetes, and acne. Because obesity is a major clinical feature of this disorder, affected persons may develop mild to severe steatosis or steatohepatitis (29,40). Increased hepatic glycogen deposition and abnormalities in bile flow also have been described in patients with Cushing's syndrome.

Addison's Disease

Destruction of the adrenal glands, resulting in hypocortisolism, may lead to nonspecific elevations in serum levels of AST and LDH. These abnormalities typically return to normal after cortisol replacement. Centrilobular fibrosis has been described in liver biopsy specimens from patients with Addison's disease (29); however, the pathogenesis of this finding remains unclear.

Acromegaly

Organomegaly is characteristic of patients with acromegaly, who typically have hepatomegaly. Liver chemistry levels and liver function are typically within normal limits (29,41).

Celiac Disease

Although the manifestations of celiac disease (also known as *celiac sprue* or *gluten-sensitive enteropathy*) were once thought to be confined to the gastrointestinal tract, important extraintestinal manifestations of celiac disease have now been recognized. Liver chemistry abnormalities, typically characterized by mild elevations in serum levels of AST and ALT, have been described in up to 55% of patients with celiac disease, and elevations in the level of serum alkaline phosphatase have been described in approximately 5% of cases (42). Conversely, celiac disease has been diagnosed in as many as 9% of patients with otherwise unexplained liver chemistry abnormalities (43,44,45), and it has been suggested that testing for celiac disease be included in the evaluation of otherwise unexplained liver chemistry abnormalities (42). Liver biopsy specimens from patients with celiac disease and abnormal liver chemistries typically reveal nonspecific findings. In most cases, the liver chemistry abnormalities resolve after the institution of a gluten-free diet (42,43,46).

The mechanism leading to liver chemistry abnormalities in patients with celiac disease is uncertain. One theory suggests that increased permeability of the small intestine leads to the delivery of toxins to the liver through the portal circulation. Another theory suggests that chronic small bowel inflammation is the cause (42).

In addition to nonspecific liver biochemical elevations, celiac disease has been associated with other liver diseases. Epidemiologic data suggest that the frequency of primary biliary cirrhosis (PBC) in patients with celiac disease is 3%, whereas the frequency of celiac disease in patients with PBC is 6% (47,48,49). Other studies have suggested a possible relationship between celiac disease and primary sclerosing cholangitis (PSC), as well as autoimmune hepatitis and nodular regenerative hyperplasia; these links are weaker than those found between celiac disease and PBC (50,51). In contrast to the nonspecific hepatitis associated with celiac disease, the disease courses of PBC, PSC, and autoimmune hepatitis do not appear to be altered by the initiation of a gluten-free diet (42), although liver dysfunction and ascites have been reported to reverse (52).

Rheumatic Diseases

The frequency and clinical significance of hepatic abnormalities in rheumatic (collagen vascular) disorders are poorly defined, in part because liver biopsy is usually not performed in patients with mild liver biochemical test result abnormalities. In addition, the medications used to treat collagen vascular disorders may cause hepatotoxicity, and distinguishing drug-induced liver disease from liver disease associated with

the underlying systemic rheumatic disease may be difficult (53). Table 11.2 summarizes the typical features of liver disease associated with the various collagen vascular disorders.

Systemic Lupus Erythematosus

Hepatic involvement in systemic lupus erythematosus (SLE) has been difficult to characterize (53,54,55). Initially, hepatic manifestations of SLE were thought to be rare. However, a retrospective observational study performed by Runyon et al. in 1980 (56) described hepatomegaly in up to 39% of 238 patients with SLE, with associated jaundice in 24%. Overall, 21% of these patients had abnormal liver biochemical test and liver biopsy results that could not be explained by other causes.

Hepatic involvement in SLE may be caused by the underlying disease, a coexisting disorder, or medications. Differentiating autoimmune hepatitis (formerly called *lupoid hepatitis*) from SLE-related hepatic manifestations is based in part on the detection of smooth muscle antibodies in the serum of patients with autoimmune hepatitis; these antibodies are rare in patients with SLE (57). This distinction is important because patients with autoimmune hepatitis typically have more serious, progressive liver disease as compared with patients who have hepatic involvement in SLE. Coexisting liver disease such as viral hepatitis and PBC can be seen in patients with SLE (53).

Table 11.2. Hepatic Manifestations of the Major Collagen Vascular Diseases

Disease	Clinical and biochemical features	Histology
Systemic lupus erythematosus	Hepatomegaly	Steatosis
	Jaundice	Chronic hepatitis
	Raised ALT level	
Rheumatoid arthritis	Raised alkaline phosphatase level	Kupffer cell hyperplasia
	Raised γ-glutamyl transpeptidase level	Steatosis
Polymyositis	Jaundice	Chronic hepatitis (rare)
	Raised alkaline phosphatase level	Primary biliary cirrhosis
Sjögren's syndrome	Raised aminotransferase and/or alkaline phosphatase levels	Primary biliary cirrhosis Chronic hepatitis
	Jaundice	Cryptogenic cirrhosis
Scleroderma	Hepatomegaly	Cirrhosis
	Prolonged prothrombin time	Primary biliary cirrhosis
	Jaundice	
	Raised aminotransferase and/or alkaline phosphatase levels	
Antiphospholipid antibody syndrome	Budd-Chiari syndrome	Nodular regenerative hyperplasia
	Hepatosplenomegaly	

	Jaundice	
	Raised ALT level	
Polyarteritis nodosa	Raised ALT and AST levels	Lymphocytic infiltration in the intima and media of hepatic arteries

ALT, alanine aminotransferase; AST, aspartate aminotransferase.

Hepatomegaly is the most consistent clinical finding in patients with hepatic manifestations of SLE (53,58,59). Jaundice and splenomegaly have also been described. Nonspecific liver biochemical abnormalities with mild elevations of serum AST, ALT, bilirubin, and alkaline phosphatase levels have been described.

The most common hepatic histologic finding in patients with SLE is steatosis, often not attributable to glucocorticoid use or other risk factors for steatosis (53,60,61). Additional histologic findings include granulomatous hepatitis, centrilobular necrosis, chronic hepatitis, and, in rare cases, cirrhosis. Other reported findings in patients with SLE include microabscesses from bacterial infection, hemosiderosis from blood transfusion, and drug toxicity.

Patients with SLE and other rheumatic diseases such as juvenile rheumatoid arthritis (RA) are especially susceptible to salicylate toxicity from prolonged high-dose salicylate therapy (62,63). Salicylate hepatotoxicity in patients with SLE is characterized by diffuse hepatocyte injury, disruption of the limiting plate, stellate cell activation, a plasma cell–predominant chronic portal infiltrate with occasional lymphoid follicles, and fibrosis. A more acute pattern of salicylate injury is characterized by ballooning of centrilobular hepatocytes, scattered acidophilic bodies, and moderate portal inflammation.

Successful treatment of SLE or discontinuation of offending medications typically leads to improvement in associated hepatic biochemical and histologic abnormalities (53). Criteria for treating SLE-related liver disease are not well defined. Liver biochemical abnormalities improve in most patients treated with glucocorticoids. In patients who have persistent abnormalities in liver test results despite treatment, a thorough evaluation, including liver biopsy, should be considered. Attention should be paid to the patient's medication history, particularly salicylate use.

Rheumatoid Arthritis

Abnormalities in liver chemistries, primarily elevated serum alkaline phosphatase and γ-glutamyl transpeptidase levels, have been reported in up to 6% of patients with RA (53,55,64,65,66). Elevated alkaline phosphatase levels may also be of bone origin. Liver biopsy findings from patients with abnormal liver chemistries and RA are nonspecific and include Kupffer cell hyperplasia, steatosis, and a periportal mononuclear cell infiltrate (67,68). As in patients with SLE, medications used in the treatment of RA, such as methotrexate, gold salts, nonsteroidal anti-inflammatory drugs, glucocorticoids, methotrexate, and other disease-modifying antirheumatic drugs, may result in hepatotoxicity that is difficult to distinguish from hepatic disease caused by RA.

Relapsing Polychondritis

Relapsing polychondritis (RP) is an uncommon, multisystem disorder that is characterized by recurring inflammation of cartilaginous tissues, including the nasal, auricular, and laryngotracheobronchial cartilage. Associated autoimmune disorders have been described in up to 35% of affected patients. Comorbid liver diseases, including PBC and HCV infection, have been

described in patients with RP; however, these associations are infrequent, at the level of case reports (69).

Myositis

Polymyositis is an inflammatory myopathy, which when associated with a characteristic rash is known as *dermatomyositis*. These conditions can occur as isolated disorders but are associated with other rheumatic diseases in up to 30% of affected persons (53). Both dermatomyositis and polymyositis can occur as a paraneoplastic syndrome in approximately 10% of cases. Because these disorders cause autoimmune destruction of muscle tissue, elevated levels of serum ALT, AST, and LDH can often be seen. These abnormalities are usually associated with elevated levels of serum creatinine kinase, and because patients may also have nonspecific constitutional symptoms at presentation, primary liver disease may be suspected. In fact, liver involvement in patients with inflammatory myositis is rare. A possible association between myositis and PBC has been suggested (64), but case reports describing this association are confounded by the presence of other rheumatic disorders thought to involve the liver. Patients with polymyositis or

dermatomyositis and elevated levels of alkaline phosphatase should undergo serologic testing for PBC with antimitochondrial antibodies (53).

Sjögren's Syndrome

Among 300 patients with primary Sjögren's syndrome (keratoconjunctivitis sicca) investigated for liver involvement by Skopouli et al. 7% had abnormal liver biochemical test results (70). Of these patients, 6.6% had antimitochondrial antibodies, 92% of whom had features of PBC. Although the exact frequency of PBC in patients with primary Sjögren's syndrome is unknown, an overlap between the two conditions has been well described, perhaps related to the similar underlying pathogenic mechanisms of the two diseases (65,71) (see Chapter 24). Patients with primary Sjögren's syndrome and abnormal liver chemistries should undergo testing for antimitochondrial antibodies (53). HCV infection can be associated with lymphocytic sialadenitis, which superficially resembles Sjögren's syndrome.

Scleroderma

Although hepatic involvement in scleroderma is rare, limited cutaneous scleroderma, or the CREST (calcinosis cutis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) syndrome, has been described in 3% to 17% of patients with PBC (72,73,74). The prevalence of PBC in patients with scleroderma is unknown. Scleroderma typically precedes PBC by a mean of 12 years (onset at age 36 years vs. 48 years). Raynaud's phenomenon is the most common presenting symptom. Anticentromere antibodies are relatively specific for the CREST syndrome and have been found in the serum of 10% to 29% of patients with PBC but in up to 100% of patients with both PBC and CREST syndrome. Up to 90% of patients with scleroderma and PBC also have evidence of Sjögren's syndrome; the acronym "PACK" (PBC, anticentromere antibodies, CREST, and keratoconjunctivitis sicca) has been used to describe this constellation (74).

Primary Antiphospholipid Antibody Syndrome

Primary antiphospholipid antibody syndrome (APS) is defined by the clinical features of recurrent arterial or venous thrombosis, recurrent pregnancy loss, and thrombocytopenia in the presence of antiphospholipid antibodies (anticardiolipin antibodies and the lupus anticoagulant). The diagnosis of APS requires the detection of antibodies on two separate occasions 6 months apart. The hepatic manifestations of APS are usually related to vascular abnormalities (53). Several cases of hepatic vein thrombosis (Budd-Chiari syndrome) have been reported in patients with APS (75,76). In addition, one report suggests a role for antiphospholipid antibodies in the pathogenesis of nodular regenerative hyperplasia of the liver (77), which is characterized by diffuse micronodular transformation of hepatic parenchyma resulting in elevated liver chemistries and portal hypertension (see Chapter 40).

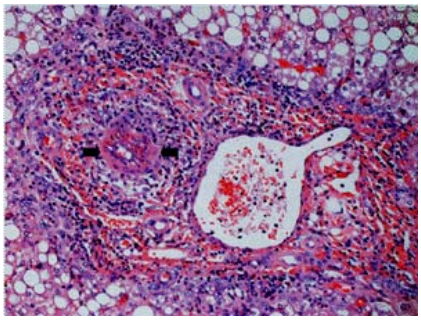
Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is a systemic vasculitis that primarily affects small- and medium-sized arteries. PAN is found in association with chronic HBV infection in over 50% of cases (78) (see Chapter 29). Nevertheless, PAN is a rare complication of HBV infection and occurs in only 1% to 5% of infected persons. Laboratory abnormalities in patients with PAN typically consist of mild elevations in serum levels of AST and ALT; cholestasis is a rare finding (79). Percutaneous liver biopsy specimens in patients with PAN rarely reveal the characteristic lymphocytic infiltration in the intima and media of the hepatic arteries (78), but this finding can be observed on larger specimens obtained at autopsy in up to 50% of patients (Fig. 11.3). Progressive liver disease in patients with PAN is usually not caused by PAN per se, but rather by chronic HBV infection (80,81). Treatment with an antiviral agent and plasma exchange has been recommended (82).

Adult Still's Disease

Rarely, adult patients may present with a syndrome that clinically resembles juvenile RA. Common presenting

symptoms of adult Still's disease include intermittent fever, pleuritis, seronegative polyarthritis, lymphadenopathy, splenomegaly, and pericarditis. Liver involvement in Still's disease is common; hepatomegaly may be identified in up to one half of affected persons (55). Elevated serum aminotransferase levels, up to five times normal, may be seen in up to 92% of patients, and increased serum alkaline phosphatase and bilirubin levels have been described in up to 65% of patients. Although liver biochemical abnormalities associated with Still's disease typically resolve with the initiation of treatment with salicylates, glucocorticoids, or other immunomodulators, fulminant hepatitis requiring liver transplantation has been described in rare cases (83).



▪ **Figure 11.3** Liver biopsy specimen from a patient with hepatic involvement in polyarteritis nodosa revealing a lymphocytic infiltrate in the intima and media of the hepatic artery (*arrows*) (hematoxylin and eosin). (Courtesy of John Hart, MD, Chicago, IL: Department of Pathology, University of Chicago Pritzker School of Medicine.)

Psoriasis

Several studies have reported an increased risk for the development of cirrhosis among persons with psoriasis (84,85). Although patients with psoriasis are often treated with hepatotoxic medications such as methotrexate (see Chapter 33), liver disease has been found to develop in patients with this disorder in the absence of medications, alcohol use, or viral hepatitis (86). The development of cirrhosis in patients with psoriasis has been attributed to the associated NASH (86). Several studies have suggested that insulin resistance may play a role in the pathogenesis of psoriasis (87) and, therefore, may be a pathogenic factor common to psoriasis and associated liver disease.

Sickle Cell Disease

Homozygous sickle cell anemia, or sickle cell disease (SCD), is estimated to affect 1 in 600 African American children. Liver biochemical abnormalities are universal in patients with SCD; most patients have elevated serum levels of unconjugated bilirubin secondary to ongoing hemolysis and elevated AST levels. Elevated serum alkaline phosphatase levels are rarely of hepatic origin (88).

Patients with SCD may commonly present with one of several acute hepatic syndromes that manifest clinically as fever, right upper quadrant pain, and jaundice (Table 11.3). The differential diagnosis includes *acute sickle hepatic crisis* (ASHC), *sickle cell intrahepatic cholestasis* (SCIC), cholecystitis, choledocholithiasis, and acute viral hepatitis (88). Patients with ASHC typically present with elevated serum levels of AST and ALT that are usually no higher than 300 U/L and serum bilirubin levels no higher than 15 mg/dL. The syndrome, caused by hypoxic injury to the hepatocytes from sinusoidal sickling, is self-limited and usually resolves within 14 days of providing therapy with intravenous fluids and analgesics. Liver biopsy is typically not required to make the diagnosis of ASHC (89,90,91).

In contrast to ASHC, SCIC is a rare complication of SCD that carries an ominous prognosis (88,92). The presenting clinical symptoms and signs are similar to those of ASHC. In addition, acute renal failure is usually found in patients with SCIC, and progressive encephalopathy, coagulopathy, and death are common.

SCIC may present as fulminant hepatic failure. ASHC is differentiated from SCIC on the basis of clinical and laboratory findings. In patients with SCIC, serum AST and ALT levels are usually greater than 1,000 U/L, and serum bilirubin levels also are strikingly high because of a combination of hemolysis, renal failure, and intrahepatic cholestasis. The underlying pathophysiology of SCIC is also related to sickling of red blood cells within the hepatic sinusoids and resulting anoxic hepatocyte damage. Liver biopsy specimens typically show ballooning of hepatocytes, sickled red blood cells in hepatic sinusoids, and intracanalicular cholestasis (Fig. 11.4). Treatment is largely supportive with the use of exchange transfusion (88,92,93,94,95), although successful liver transplantation for SCIC has been reported (96).

Table 11.3. Acute Hepatic Syndromes Associated with Sickle Cell Disease

Syndrome	Clinical findings	Laboratory findings	Treatment	Outcome
Acute sickle hepatic crisis	RUQ pain Nausea	Elevated AST and ALT levels	IV fluids Analgesia	Self-limited; complete

	Fever Jaundice Tender-hepatomegaly	(<300 U/L) Elevated bilirubin level (<15 mg/dL)		resolution in most patients
Sickle cell intrahepatic cholestasis	RUQ pain Nausea Vomiting Fever Jaundice	Markedly elevated AST and ALT levels Elevated alkaline phosphatase and lactate dehydrogenase levels Markedly elevated bilirubin level Prolonged prothrombin time Elevated creatinine level Leukocytosis	Exchange transfusion Liver transplantation	Usually fatal, although successful treatment with exchange transfusion and/or liver transplantation has been reported
Hepatic sequestration	RUQ pain Tender hepatomegaly	Falling hematocrit value	Exchange transfusion	Full recovery in most patients
		Liver chemistries typically normal		
Symptomatic cholelithiasis	Fever RUQ pain Jaundice	Elevated AST and ALT levels Leukocytosis Elevated bilirubin level	IV antibiotics Cholecystectomy Endoscopic retrograde cholangiopancreatography or common bile duct exploration for choledocholithiasis	Full recovery in most patients Postoperative acute chest syndrome in up to 10%

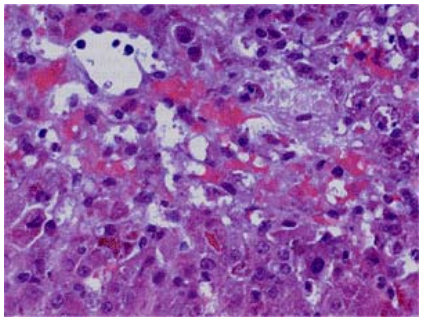
RUQ, right upper quadrant; AST, aspartate aminotransferase; ALT, alanine aminotransferase.

Patients with SCD are particularly prone to the development of pigmented gallstones, which develop in up to 58% of patients with SCD (88,97). Approximately 17% of patients are found to have choledocholithiasis at the time of cholecystectomy. In patients with SCD, acute cholecystitis or choledocholithiasis may be difficult to distinguish from ASHC. Because the prevalence of cholelithiasis in this patient population is very high, abdominal ultrasonography has limited specificity for diagnosing acute cholecystitis, although biliary scintigraphy may be helpful (98). Given the diagnostic difficulties, patients with SCD, gallstones, and symptoms suggestive of biliary pain or acute cholecystitis should be considered for cholecystectomy. However, cholecystectomy is not without risk in patients with SCD; the development of acute chest syndrome has been described in up to 10% of patients with SCD who undergo elective surgery (88,99).

Other acute liver diseases can be seen with increased frequency in patients with SCD. Sickling can lead to thrombosis within the hepatic veins and the Budd-Chiari syndrome (100). Although the frequency of hepatitis A is not reported to be increased in Western populations of patients with SCD, some reports have suggested that the course is more likely to be fulminant in patients with SCD than in those without SCD (101). Finally, hepatic sequestration crisis, in which sequestration of red blood cells within the liver leads to

massive hepatomegaly and a falling hematocrit value, has been described in patients with SCD. Although death from hepatic sequestration has been described, this syndrome is typically reversible with exchange

transfusion (88,102).



· Figure 11.4 Liver biopsy specimen obtained from a patient with severe sickle cell intrahepatic cholestasis. Note the presence of "ballooning" hepatocytes, cholestasis, and sickling of the red blood cells within the hepatic sinusoids (hematoxylin and eosin). (Courtesy of Gregory Lauwers, MD, Boston, MA: Department of Pathology, Massachusetts General Hospital.)

Chronic liver disease associated with SCD is also common. Autopsy series reveal cirrhosis in up to 29% of patients who die of complications from SCD (88,103). Most cases of chronic liver disease associated with SCD are thought to be secondary to hepatic iron overload after numerous blood transfusions or from infection by HBV or HCV acquired by the transfusion of contaminated blood products before the implementation of universal blood screening (88). Since the implementation of universal screening of donated blood in the United States, the incidence of viral hepatitis in patients with SCD has decreased substantially.

Amyloidosis

There are three major categories of amyloidosis, all of which may have hepatic manifestations. Primary or light-chain amyloidosis (AL) includes amyloidosis related to multiple myeloma. In secondary amyloidosis (AA), the amyloid fibrils form as a result of proteolytic cleavage of serum amyloid protein A, an acute-phase reactant. Causes of secondary amyloidosis include RA, osteomyelitis, tuberculosis, Hodgkin's disease and other lymphomas, familial Mediterranean fever, long-term heroin abuse, subclinical ankylosing spondylitis, and lepromatous leprosy. Familial amyloidosis is a rare disorder that includes type I familial amyloid polyneuropathy (FAP), an autosomal dominant disease caused by a mutation on chromosome 18 that leads to hepatic production of a variant prealbumin, transthyretin. The disease is manifested by a progressive mixed chronic polyneuropathy (sensory, motor, and autonomic) that presents after the age of 20 years and is invariably fatal. Early recognition is important because liver transplantation has been demonstrated to halt the progression of and even improve the neurologic symptoms (104).

Regardless of the type (AL, AA, FAP), the hepatic manifestations of amyloidosis are similar (105,106,107). Although hepatic amyloidosis is common and rarely causes clinical manifestations, it carries an ominous prognosis. The median survival in patients with biopsy-proven hepatic amyloidosis is 9 months, with 5- and 10-year survival rates of 13% and 1%, respectively. Clinical symptoms of hepatic amyloidosis are nonspecific and include weight loss, fatigue, abdominal pain, anorexia, early satiety, and nausea. Hepatomegaly is the most common physical finding in affected patients, and its presence is associated with a higher likelihood of abnormal liver chemistries.

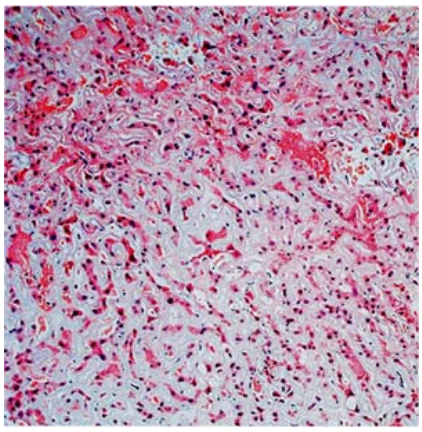
Abnormalities in liver chemistries are common in patients with hepatic amyloidosis. A series from the Mayo Clinic (106) described an elevated serum alkaline phosphatase level in 86% of patients with hepatic amyloidosis, with a level greater than 500 U/L in most cases. Levels of serum AST and bilirubin were found

to be elevated in 37% and 21% of cases, respectively, and the prothrombin time was prolonged in some cases.

The diagnosis of hepatic amyloidosis can be made by percutaneous liver biopsy, but this procedure has been reported to be associated with an increased bleeding risk in patients with hepatic amyloidosis (106,108). Amyloid appears as a pale pink homogenous amorphous protein on a liver biopsy specimen stained with hematoxylin and eosin (Fig. 11.5). Up to 95% of patients suspected of having hepatic amyloidosis have evidence of amyloid deposition on fat pad aspirate or bone marrow biopsy. Because the demonstration of hepatic involvement rarely changes the management, biopsy of lower-risk sites is usually warranted when the diagnosis of hepatic amyloidosis is in question.

Management of hepatic amyloidosis is limited primarily to supportive care or treatment of the underlying predisposing condition (106,108). A trial (109) comparing regimens containing melphalan, prednisone, and colchicine in patients with primary amyloidosis found that median survival was significantly longer in

patients treated with a combination of melphalan and prednisone than in those treated with colchicine alone or a regimen containing all three drugs. Liver transplantation may be of benefit in patients with FAP.



▪ **Figure 11.5** Liver biopsy specimen from a patient with hepatic amyloidosis. Notice the deposition of the amorphous pale pink protein throughout the parenchyma (hematoxylin and eosin). (Courtesy of John Hart, MD, Chicago, IL: Department of Pathology, University of Chicago Pritzker School of Medicine.)

Sarcoidosis

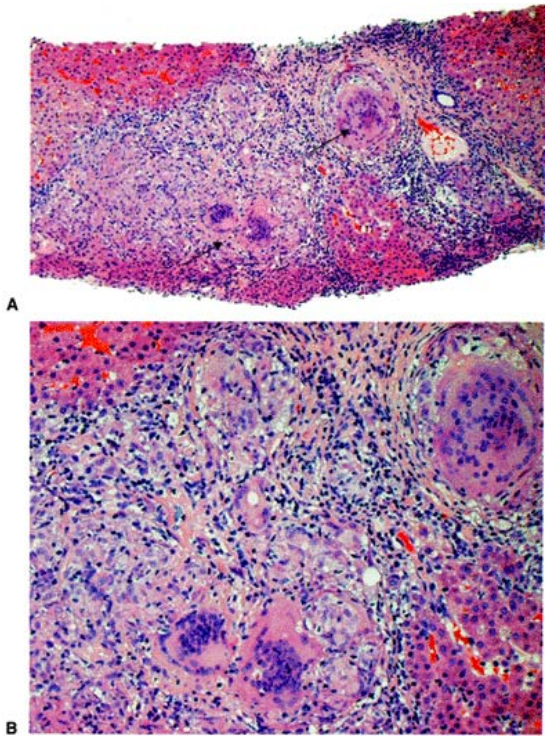
Sarcoidosis is a chronic systemic disorder of unknown etiology that is characterized by an accumulation of T lymphocytes and macrophages with granuloma formation in affected organs (see Chapter 52). Hepatic involvement is common in sarcoidosis and occurs in approximately 75% of all patients; however, liver dysfunction secondary to hepatic sarcoidosis is uncommon (110).

Physical findings are typically absent in patients with hepatic sarcoidosis. Evidence of mild hepatomegaly can be demonstrated by ultrasound or computed tomography in up to 50% of patients (110). The presence of splenomegaly and ascites does not always imply portal hypertension or hepatic involvement in patients with sarcoidosis. Splenomegaly is most commonly caused by granulomatous infiltration rather than portal hypertension. Ascites in patients with sarcoidosis can be related to cor pulmonale resulting from progressive pulmonary disease, hypoalbuminemia resulting from hepatic dysfunction, or, rarely, peritoneal sarcoid involvement.

Usually, serum immunoglobulin G levels are raised, the serum bilirubin level is normal, and the alkaline

phosphatase level is mildly elevated. Serum aminotransferase levels may or may not be elevated. The most common histopathologic finding in hepatic sarcoidosis is the presence of noncaseating granulomas, which typically predominate around portal tracts (111) (Fig. 11.6A,B).

In less than 1% of patients with hepatic sarcoidosis, progressive destruction of the intrahepatic bile ducts may lead to chronic intrahepatic cholestasis (112,113,114). Men are affected more commonly than women and may present with jaundice, pruritus, and constitutional symptoms such as fever and generalized malaise. Levels of serum alkaline phosphatase and γ-glutamyl transpeptidase are markedly elevated, and liver biopsy may reveal intracellular and intracanalicular cholestasis, portal inflammation, and fibrosis, in addition to noncaseating granulomas. Although an association may exist between sarcoidosis and PBC, antimitochondrial antibodies are not present in patients with sarcoidosis-related chronic intrahepatic cholestasis, and testing for antimitochondrial antibodies is recommended because of the similar clinical presentations of the two conditions. Other causes of cholestasis in patients with sarcoidosis include sarcoid involvement of the extrahepatic bile ducts, common bile duct compression by hilar lymphadenopathy, and pancreatic sarcoidosis (115,116).



▪ **Figure 11.6 A:** Low-power view of a liver biopsy specimen obtained from a patient with hepatic sarcoidosis. Noncaseating granulomas are seen (*arrows*). **B:** High-power view of the same specimen demonstrating multiple noncaseating granulomas (hematoxylin and eosin). (Courtesy of John Hart, MD, Chicago, IL: Department of Pathology, University of Chicago Pritzker School of Medicine.)

Cirrhosis and portal hypertension may develop in the later stages of hepatic sarcoidosis (110,117,118). Portal hypertension, often resulting from granulomatous phlebitis of intrahepatic veins, can develop in the absence of cirrhosis in up to 50% of patients (110,119). In approximately 25% of patients, portal hypertension is related to secondary biliary cirrhosis, although associated PBC or PSC may be present in rare cases. Patients with biliary cirrhosis secondary to hepatic sarcoidosis present with findings typical of chronic cholestasis, including hypercholesterolemia,

xanthomata, and osteomalacia. Treatment with glucocorticoids or low-dose methotrexate usually does not delay the progression of the liver disease but may improve constitutional symptoms and result in a decrease in the size of the liver if hepatomegaly is present (114,120). Treatment with ursodeoxycholic acid may improve cholestasis (121).

Fat-soluble vitamin deficiency, hypercholesterolemia, and the complications of portal hypertension require treatment. In patients with portal hypertension related to hepatic sarcoidosis, complications such as bleeding esophageal varices may be the initial clinical presentation. Management of esophageal varices associated with sarcoidosis includes nonselective β-blockers and endoscopic therapy (see Chapter 16). A transjugular intrahepatic or surgical portosystemic shunt may be considered in appropriate candidates (110). Patients with end-stage liver disease should be considered for liver transplantation (see Chapter 53).

Lymphoma

The liver is part of the reticuloendothelial system and may be involved by lymphomas. Although hepatic lymphomatous involvement is relatively common (122), life-threatening complications of lymphomas involving the liver are rare. A summary of the hepatic manifestations associated with lymphoma is shown in Table 11.4.

Hodgkin's Disease

Malignant hepatic infiltrates containing Reed-Sternberg cells have been described in up to 14% of patients with Hodgkin's disease diagnosed on clinical grounds and in up to 50% of patients diagnosed at autopsy; the frequency of hepatic involvement in Hodgkin's disease increases with disease progression (122,123,124). Patients with Hodgkin's disease may present with hepatomegaly, which occurs in approximately 9% of patients with stage I to II disease and in 45% with stage III to IV disease. Liver biochemical testing may reveal a mild increase in the serum ALT level and a moderate increase in the alkaline phosphatase level.

Neither physical findings nor abnormal liver chemistry results predict the presence of a Hodgkin's infiltrate in the liver. By definition, Hodgkin's disease involving the liver signifies stage IIIE or IV disease and has implications for prognosis and therapy. Therefore, patients in whom hepatic involvement is suspected should undergo liver biopsy (122,123,124).

Table 11.4. Hepatic Manifestations of Hodgkin's Disease and Non-Hodgkin's Lymphoma

	Hodgkin's disease	Non-Hodgkin's lymphoma
Clinical features	Hepatomegaly: Frequency increases with disease progression	Hepatomegaly: Common
	Jaundice: Usually related to intrahepatic biliary obstruction	Jaundice: Typically results from extrahepatic biliary obstruction at the level of the porta hepatis
	Acute liver failure: Rare	Acute liver failure: Rare, but more common than in Hodgkin's disease
Liver chemistries	Mild elevations of alanine aminotransferase and alkaline phosphatase levels are common	Aminotransferase levels may be elevated two to three times normal
	Elevated bilirubin levels can be seen	Mild elevations in alkaline phosphatase and bilirubin levels can be seen
Biopsy findings	Usually nonspecific: Lymphocytic infiltrate without histiocytes in the portal tracts; focal hepatocyte necrosis; Kupffer cell hyperplasia; slight iron deposition; moderate-to-severe steatosis; pleomorphic cell infiltrates; and noncaseating granulomas	Lymphomatous infiltrate; histology depends on the type of lymphoma
	Reed-Sternberg cells in rare cases	

Hepatic histologic abnormalities occur in up to 60% of patients with Hodgkin's disease and generally are nonspecific. In a series (123) of 308 patients with Hodgkin's disease who underwent 459 liver biopsies, Reed-Sternberg cells, which are diagnostic of Hodgkin's disease, were found in only 2.4% of liver biopsy specimens. Other findings included a lymphocytic infiltrate without histiocytes in the portal tracts (56%), focal necrosis (24%, but present on a repeat biopsy specimen in only 35% of the original group), Kupffer cell hyperplasia (52%), slight iron deposition (23%), moderate-to-severe steatosis (20%), pleomorphic cell infiltrates (4%), and noncaseating granulomas (2%). Thirty percent of patients had a normal biopsy result.

Jaundice, when present, is typically the result of intrahepatic biliary obstruction (125), although cholestasis in the absence of extrahepatic obstruction or significant tumor infiltration has been described. The cause of jaundice in such cases is unclear but may represent a paraneoplastic phenomenon, defect in hepatic microsomal function, or the vanishing bile duct

syndrome (126) (see Chapter 9). In rare cases, patients may present with jaundice and evidence of hepatic Hodgkin's disease on a liver biopsy specimen and no evidence of disease in peripheral lymph nodes (127). Such cases tend to be seen with the mixed cellularity and lymphocyte-depleted subtypes of Hodgkin's disease and have a poor prognosis. Jaundice has been shown to resolve in some patients after successful treatment of the underlying Hodgkin's disease, but persistent jaundice despite remission of the primary disease in other patients implies that permanent hepatic injury may have occurred (127).

Non-hodgkin's Lymphoma

Lymphomatous infiltration of the liver is more common in non-Hodgkin's lymphoma (NHL) than in Hodgkin's disease (122). Hepatic involvement with NHL has been described in liver biopsy specimens in up to 53% of cases (and an even higher percentage at autopsy), is more common with small-cell varieties than with large-

cell types, and has implications for staging, treatment, and prognosis (128). Liver biochemical test results may be abnormal (primarily an increase in serum alkaline phosphatase), and hepatomegaly may be detected. Rarely, NHL can present as a primary hepatic lymphoma (129). Apart from human immunodeficiency virus–associated lymphomas, primary hepatic lymphoma has a better prognosis than NHL because of the possibility of cure with successful resection. The yield of laparotomy for detecting hepatic involvement in NHL is higher than that for laparoscopy and for percutaneous needle biopsy of the liver, although the yield of needle biopsy may be increased with the use of ultrasound guidance (128).

Jaundice is rare in patients with NHL and in the past was considered a terminal occurrence (125). Jaundice secondary to extrahepatic biliary obstruction is more common in NHL (1.2%) than in Hodgkin's disease (0.3%), and biliary obstruction occurs most commonly at the porta hepatis, although primary lymphomatous involvement of the bile ducts has been reported in rare cases. In patients with NHL and jaundice, gallstones and pancreatic adenocarcinoma must be excluded. Evaluation may include computed tomography, magnetic resonance cholangiopancreatography, endoscopic retrograde cholangiopancreatography, endoscopic ultrasound, and laparotomy.

Acute Liver Failure Secondary to Lymphoma

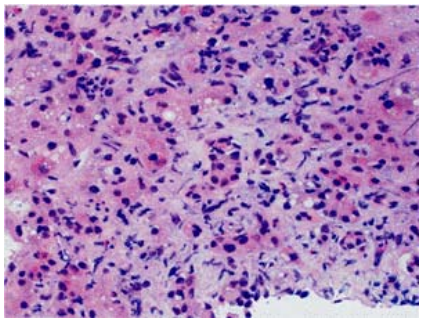
Rarely, malignant infiltration of the liver with lymphoma can cause acute liver failure (ALF) (122,127,130) (see Chapter 21). Malignant infiltration accounted for 0.44% of all cases of ALF seen at King's College Hospital from 1978 to 1995 (130). NHL accounted for 50% and Hodgkin's disease for 17% of the malignant causes of ALF in this series. Most patients in the King's College Hospital series presented with "hyperacute" liver failure (encephalopathy within 7 days of jaundice in the absence of previous liver disease), whereas the remainder evolved more slowly but within 28 days. Prodromal symptoms usually occurred 2 to 4 weeks (range, 5 days to 2 months) before the onset of liver failure; the most common prodromal symptoms were malaise (50%), weight loss (39%), right upper quadrant pain (39%), and fever (33%). Palpable lymphadenopathy was detected in five of nine patients with NHL; all patients had a firm palpable liver two to five fingerbreadths below the right costal margin, a rare finding with other causes of ALF. Laboratory tests could not distinguish these patients from those with ALF from other causes, and most patients had a rapid clinical deterioration, with death from multiorgan failure occurring in 94% of patients at a median of 6 days (range, 1 to 54 days) from admission. Histologic evaluation by needle biopsy of the liver or at autopsy demonstrated that the malignant infiltration was spread diffusely through the liver parenchyma, with large areas of necrosis in both infiltrated and noninfiltrated areas.

The pathogenesis of ALF caused by lymphomas and other malignancies includes massive hepatic replacement by nonfunctioning malignant cells, release of cytokines by tumor cells, Kupffer cell activation, and ischemia from engorgement of hepatic sinusoids with leukocytes and platelets. Prompt diagnosis with liver biopsy and treatment of the underlying malignancy during the prodromal period are the keys to a chance for a successful outcome. Differentiation of these patients from those with nonmalignant causes of ALF is essential because liver transplantation may be life saving in the latter but is contraindicated in the former.

Myelofibrosis with Myeloid Metaplasia

Myelofibrosis with myeloid metaplasia is a chronic myeloproliferative disorder that results from a clonal stem cell defect and leads to ineffective erythropoiesis, myelofibrosis, and extramedullary hematopoiesis. Portal hypertension with associated esophageal varices and ascites has been described in up to 7% of patients with this disorder (131). The mechanism appears to be increased portal flow resulting from the massive splenomegaly that can accompany myelofibrosis, in addition to thrombotic obstruction of the small intrahepatic portal veins (132,133). Patients with complications of portal hypertension can usually be managed successfully with splenectomy, although endoscopic variceal band ligation has been reported to be useful

in a small number of patients with myeloid metaplasia and bleeding esophageal varices (134,135,136).



▪ **Figure 11.7** Liver biopsy specimen demonstrating an inconspicuous infiltrate in a patient with

systemic mastocytosis. Immunostaining subsequently revealed the infiltrate to be composed primarily of mast cells (hematoxylin and eosin). (Courtesy of John Hart, MD, Chicago, IL: Department of Pathology, University of Chicago Pritzker School of Medicine.)

Stauffer's Syndrome

Stauffer's syndrome refers to paraneoplastic intrahepatic cholestasis occurring in the setting of a renal cell carcinoma (137,138,139,140). By definition, patients with Stauffer's syndrome have no evidence of liver metastasis or other causes of biliary obstruction. A paraneoplastic increase in serum alkaline phosphatase levels (with or without jaundice) has been described in up to 21% of patients with renal cell carcinoma and is thought to occur as a result of the production of cytokines, such as interleukin-6 and granulocyte-macrophage colony-stimulating factor, by the tumor (141). Elevations in serum bilirubin and alkaline phosphatase levels may normalize after nephrectomy, but the diagnosis of Stauffer's syndrome portends a poor overall prognosis.

Systemic Mastocytosis

Systemic mastocytosis is characterized by mast cell hyperplasia. The disease can involve multiple organ systems; the liver is involved in up to 61% of cases (142). Hepatosplenomegaly can be seen in up to 41% of patients with systemic mastocytosis involving the liver, and liver biochemical abnormalities, including elevated serum levels of aminotransferases, alkaline phosphatase, γ-glutamyl transpeptidase, and 5′-nucleotidase, have been described in up to 54%. Elevated serum alkaline phosphatase levels and hepatosplenomegaly have been found to correlate with the presence of mast cell infiltration on a liver biopsy specimen (Fig. 11.7). Portal fibrosis can be seen on liver biopsy specimens from affected persons, but cirrhosis has not been described, although portal hypertension has been reported, presumably from various combinations of increased portal venous flow (secondary to splenomegaly) (142), nodular regenerative hyperplasia, mast cell portal venous infiltration, and sinusoidal obstruction syndrome (119).

This paper provides a detailed review of the hepatic abnormalities found in patients with celiac disease. It also highlights the importance of testing for gluten enteropathy in patients with otherwise unexplained liver chemistry abnormalities and provides ample evidence to support this practice.

Abraham S, Begum S, Isenberg D. Hepatic manifestations of autoimmune rheumatic diseases. *Ann Rheum Dis* 2004;63:123–129.

This paper reviews the broad spectrum of liver diseases that can be associated with the various rheumatic diseases and the drugs used to treat them. The authors point out that, although hepatic manifestations of autoimmune disease are rare, the presence of liver chemistry abnormalities should prompt a thorough workup for potentially treatable coexistent liver disease.

Banerjee S, Owen C, Chopra S. Sickle cell hepatopathy. *Hepatology* 2001;33:1021–1028.

This article provides a concise and clinically helpful overview of both acute and chronic liver diseases that are seen in patients with sickle cell disease, including acute sickle hepatic crisis and sickle cell intrahepatic cholestasis. Many of the acute hepatic syndromes that are associated with sickle cell disease can have similar clinical appearances, and this paper describes the features that differentiate these disorders.

Blich M, Edoute Y. Clinical manifestations of sarcoid liver disease. *J Gastroenterol Hepatol* 2004;19:732–737.

This article describes the hepatic manifestations commonly found in patients with sarcoidosis. As a systemic granulomatous disease, sarcoidosis often affects the liver, although hepatic involvement is rarely symptomatic. The authors provide a detailed mechanistic explanation for the development of portal hypertension, cirrhosis, and cholestasis as a result of granulomatous involvement of the liver.

Tolman KG, Fonseca V, Tan MH, Dalpiaz A. Narrative review: hepatobiliary disease in type 2 diabetes mellitus. *Ann Intern Med* 2004;141:946–956.

This paper critically reviews the association between type 2 diabetes mellitus and liver disease. The potential role of insulin resistance in the pathogenesis of diabetes-associated liver disease is explored in detail, and

the association between hepatitis C and diabetes mellitus is discussed.

Chapter 12

Hematologic Disorders and the Liver

Jeffrey I. Zwicker

Reed E. Drews

Key Concepts

- In liver disease, red blood cells (RBCs) acquire membranes that are rich in cholesterol, with diminished membrane fluidity and impaired ability to repair oxidatively damaged RBC membrane phospholipids that arise during normal RBC senescence. As a consequence, altered peripheral blood RBC morphologies occur (target cells, echinocytes, acanthocytes, spur cells, and stomatocytes) and RBC survival is shortened. This form of "extrinsic nonimmune hemolytic anemia" is accentuated by hypersplenism when splenomegaly due to portal venous hypertension ensues from severe hepatocellular dysfunction.
- Patients with primary RBC abnormalities that are either inherited (e.g., thalassemia, sickle hemoglobinopathies) or acquired (e.g., myelodysplastic syndromes, paroxysmal nocturnal hemoglobinuria) can develop liver disease. Frequently, this relates to management of the hematologic disorder, such as RBC transfusions resulting in viral hepatitis or iron overload. However, the primary hematologic disorder itself can cause intrahepatic disease, as in sickle cell disease in which intrahepatic sickling causes ischemia with development of focal necrosis, portal fibrosis, and cirrhosis or hepatic sequestration crisis. Chronic hemolysis also produces hepatobiliary complications from pigmented gallstones.
- Myeloproliferative disorders (MPDs), including polycythemia vera, essential thrombocythemia, chronic myelogenous leukemia, and agnogenic myeloid metaplasia (AMM), are all associated with extramedullary hematopoiesis. EMH may occur in any organ, including liver and spleen. With increasing liver EMH, palpable hepatomegaly develops, with portal vein hypertension arising from increased splanchnic flow due to splenomegaly and/or EMH-associated intrahepatic obstruction. Portal vein thrombosis and Budd-Chiari syndrome from thrombotic occlusion or partial occlusion of hepatic veins and the inferior vena cava are complications of MPD; these should suggest the possibility of latent MPD if it is not already evident. PNH, another acquired hematopoietic disorder, can cause recurring hepatic vein thrombosis and Budd-Chiari syndrome, although the mechanism of thrombotic diathesis in PNH is unknown.
- Thrombocytopenia is common in chronic liver disease. Thrombocytopenia can relate to "distributional" factors, with platelet sequestration in a spleen that is enlarged because of portal vein hypertension. However, reduced level of thrombopoietin, which is produced constitutively by the liver, is the chief cause of thrombocytopenia from chronic liver disease. Immune or nonimmune processes causing underproduction thrombocytopenia and/or platelet destruction may accompany acute and chronic liver diseases. In HELLP (hemolysis with a microangiopathic blood smear, elevated liver enzyme levels, and low platelet concentration in pregnancy) syndrome, complications include hepatic failure,

hepatic infarction, and hepatic hematoma with or without rupture.

- The basis of coagulopathy of liver disease is often multifactorial including thrombocytopenia, factor deficiency (both antigenic and functional), and accelerated fibrinolysis. Despite the progressive nature of coagulopathy associated with advancing liver disease, the degree of coagulopathy has not been shown to be predictive of bleeding outcomes, and therefore, administration of plasma products is most appropriately reserved for instances of active bleeding or invasive procedures.
- In placebo-controlled trials, antifibrinolytic agents have been shown to decrease bleeding complications associated with orthotopic liver transplantation.

The pathologic processes affecting the liver often have profound influences on hemostatic and hematopoeitic systems. This intricate relationship is in part related to the vital function that the liver plays in synthesizing components of the coagulation pathways but also reflects the wide range of influence the liver has on hematopoeitic cells such as red blood cells (RBCs) and platelets. Conversely, patients suffering from many primary hematologic disorders such as sickle cell disease (SCD), myeloproliferative diseases (MPDs), and paroxysmal nocturnal hemoglobinuria (PNH) often suffer hepatic complications. This chapter describes the reciprocal nature of the disease affecting these two organ systems.

Red Blood Cell Abnormalities Caused by Liver Disease

In liver disease, RBCs undergo membrane changes that shorten their survival. Shorter RBC survival defines hemolysis. Because liver disease, rather than immunologic processes, causes these RBC membrane changes, anemia accompanying liver disorders represents a form of "extrinsic nonimmune hemolytic anemia." When severe hepatocellular dysfunction produces portal venous hypertension and splenomegaly, hypersplenism can increase RBC destruction (1,2).

Laboratory signs of hemolysis include increased concentrations of serum indirect bilirubin and lactate dehydrogenase and decreased concentration of serum haptoglobin. Hemolysis in the absence of liver disease generally yields total serum bilirubin concentrations no higher than 5 to 6 mg/dL, but total bilirubin levels in hemolysis superimposed on hepatocellular dysfunction may exceed 7 mg/dL. The chief site of RBC loss is extravascular, within the liver and spleen. Therefore, laboratory signs of intravascular hemolysis (e.g., increased concentrations of plasma free hemoglobin, hemoglobinuria, and hemosiderinuria) are absent.

RBC membrane changes occurring in liver disease yield altered peripheral blood RBC morphologies, including target cells, echinocytes (burr cells), acanthocytes, spur cells, and stomatocytes (Fig. 12.1). As in hyperlipidemia, target cells (Fig. 12.1A) in liver disease (particularly cholestatic liver disease) arise from increased lipid deposition on RBC membranes, resulting in expanded RBC membrane surface area in relation to RBC cytoplasm (1,2). In contrast to thalassemic target cells, which are microcytic with RBC mean cell volumes (MCVs) less than 80 fL, the target cells from liver disease are macrocytic, with MCVs ranging from 100 to 110 fL. Notably, alcoholism induces macrocytosis, independent of liver disease and folate and/or cobalamin deficiency (3). This relates to RBC membrane changes caused by aldehyde adducts from acetaldehyde, a metabolite of alcohol (4,5). Echinocytes (named after sea urchins, which they resemble) have small undulating crenations or serrations uniformly distributed over the entire RBC membrane surface (Fig. 12.1A). While echinocytes can appear as artifacts on blood smears, particularly when albumin concentrations are low, they are common in advanced renal failure and liver disease. In liver disease, the echinocyte morphology may arise from abnormal high-density lipoprotein interacting with receptors on the RBC

membrane surface (6). In contrast to echinocytes, *acanthocytes*

display only a few "thorny" spicules, projecting at irregular intervals from the RBC membrane surface (Fig. 12.1B). *Spur cells* are acanthocytes that have more spherocytic shapes and blunted spicules (Fig. 12.1C), caused by RBC membrane loss from splenic molding (2,7). Increased RBC membrane proteolytic activity, caused by a circulating factor present in spur cell plasma, may contribute to spur cell formation (8). Although hypersplenism accentuates spur cell formation, prompting the consideration of splenectomy in patients with *spur cell hemolytic anemia*, liver transplantation is the definitive intervention (9). *Stomatocytes*, when seen in large numbers on peripheral blood smear (and therefore not likely related to smear artifact), indicate acute ethanol intoxication or severe liver disease, particularly that caused by alcohol (10). With their "mouth-shaped" areas of central pallor (Fig. 12.1B), stomatocytes are RBCs with reduced surface area in relation to volume, en route to becoming spherocytes. Regardless of specific RBC morphology, abnormal RBC shapes and shorter survivals in the setting of liver disease appear to relate to RBC membranes rich in cholesterol, with diminished fluidity and impaired ability to repair oxidatively damaged RBC membrane phospholipids that arise during normal RBC senescence (1,11).

Liver Disease Caused by Red Blood Cell Abnormalities

Patients with primary RBC abnormalities that are either inherited (e.g., thalassemia, sickle hemoglobinopathies) or acquired (e.g., myelodysplastic syndromes, PNH) can develop liver disease. Frequently, this relates to management of the hematologic disorder, such as RBC transfusions resulting in viral hepatitis or iron overload. However, the primary hematologic disorder itself can cause intrahepatic disease, as in SCD. Chronic hemolysis causing pigmented gallstones can also produce hepatobiliary complications.

In SCD, vaso-occlusive complications from the sickling process yield hepatic abnormalities because of ischemia, independent of SCD management. "Sickle cell hepatopathy" (12) refers to hepatic dysfunction arising from the collective effects of

vaso-occlusion and disease management (e.g., viral hepatitis and iron overload). Patients with homozygous hemoglobin (Hb SS) are more likely to develop sickle cell hepatopathy than are patients with the compound heterozygous hemoglobinopathies Hb SC and Hb S β-thalassemia. Cirrhosis is a frequent consequence (13).

In SCD, it is predominantly the level of unconjugated bilirubin that is elevated, with levels less than 6 mg/dL, correlating with lactic dehydrogenase (LDH) levels caused by chronic hemolysis. Aspartate aminotransferase (AST) levels correlate with LDH levels as well, also caused by hemolysis. With sickle hepatic crisis, bilirubin levels may double, and a rise in alanine aminotransferase (ALT) levels reflects hepatic injury (12). Because vascular complications affecting bone can cause high alkaline phosphatase levels, serum 5'-nucleotidase levels are better indicators of hepatic injury, correlating with ALT and γ-glutamyltransferase levels (14). Hyperammonemia in patients with cirrhosis may be accentuated by zinc deficiency, which results from renal tubular losses of zinc in sickle cell nephropathy (15) and deferoxamine therapy of iron overload (16). Zinc is a cofactor of the urea cycle enzyme, ornithine transcarbamylase, and zinc supplementation may benefit patients with SCD who develop zinc deficiency (17,18). Hepatic dysfunction in SCD may contribute to low protein C and protein S levels, thereby increasing the risk of stroke (19,20).

Hepatic histologic findings in SCD include intrasinusoidal sickling with proximal sinusoidal dilatation, Kupffer cell hyperplasia with erythrophagocytosis, hemosiderosis, focal necrosis, portal fibrosis, regenerative nodules, and cirrhosis (13). Radiologic assessments generally show hepatomegaly (presumably because of hyperplasia of the reticuloendothelial system) and either a small, atrophic spleen, as in Hb SS, or an enlarged spleen with infarcts, as in Hb SC and Hb S β-thalassemia. Magnetic resonance imaging (MRI) shows decreased signal intensity in the liver and spleen (before atrophy) because of iron deposition.

Acute sickle hepatic crisis (12), arising from ischemia caused by sinusoidal obstruction, presents as right upper quadrant pain, nausea, low-grade fever, tender hepatomegaly, and worsened jaundice, with aminotransferase and bilirubin levels less than 300 IU/L and 15 g/dL, respectively. Supportive treatment with intravenous hydration and analgesia generally improves symptoms and liver biochemical abnormalities within several days to weeks. However, acute sickle hepatic crisis can evolve to intrahepatic cholestasis if sickling within hepatic sinusoids leads to ischemia, hypoxia, and intracanalicular cholestasis in damaged, swollen hepatocytes. Leukocytosis, markedly worsening hyperbilirubinemia, renal failure, coagulopathy, and encephalopathy suggest this complication. Aminotransferase and bilirubin levels (mostly conjugated) may be strikingly high, exceeding 1,000 IU/L and 15 g/dL, respectively. Exchange transfusions and management of the accompanying coagulopathy can save lives (21,22).

Hepatic sequestration crisis (12), due to sequestration of large numbers of RBCs in the liver (as well as spleen and lung vasculature), presents as right upper quadrant abdominal pain with a rapidly enlarging liver and declining hematocrit (Hct) levels. Liver biochemistries may not necessarily worsen. Management includes improving oxygenation (including hyperbaric oxygen), transfusing packed RBCs, and considering exchange transfusions, particularly if pulmonary complications ensue with progressive hypoxia. With resolution of hepatic sequestration crisis, hepatic size regresses and Hct levels rise, reflecting mobilization of "undigested" sequestered RBCs from liver to peripheral blood. If the Hct level rises substantially ("reverse sequestration"), hypervolemia, hypertension, heart failure, and intra cerebral hemorrhage may occur, resulting in death (23).

Although hydroxyurea therapy decreases the frequency of vaso-occlusive pain crises and acute chest syndrome, it may not affect the frequency of hepatic sequestration crises (24). For patients with end-stage liver disease from SCD who are candidates for liver transplantation, exchange transfusions can maintain Hb S levels below 25%, in an

effort to reduce vaso-occlusive sickling damage to the graft (25).

Myeloproliferative Disorders and the Liver

MPDs, including polycythemia vera (PV), essential thrombocythemia (ET), chronic myelogenous leukemia (CML), and agnogenic myeloid metaplasia ([AMM] alias idiopathic myelofibrosis), are all associated with extramedullary hematopoiesis (EMH). EMH may occur in any organ, including liver and spleen. Of the various MPDs, EMH is most pronounced in AMM and least notable in CML. Whereas untreated CML always transforms into acute leukemia, PV and ET can eventually transform into fibrotic states called *postpolycythemic myeloid metaplasia* (*PPM*) and *post-thrombocythemic myeloid metaplasia* (*PTM*), respectively. With increasing liver EMH, palpable hepatomegaly can develop, with portal vein hypertension arising from increased splanchnic flow caused by splenomegaly and/or intrahepatic obstruction associated with EMH. Complications include ascites, esophageal and gastric varices, gastrointestinal bleeding, hepatic encephalopathy, portal vein thrombosis, and Budd-Chiari syndrome from thrombotic occlusion or partial occlusion of hepatic veins and the inferior vena cava (26,27,28). When splenectomy is performed in AMM, hepatic EMH may increase substantially, presumably as compensation for the loss of EMH in the spleen. The consequences include increasing hepatomegaly, worsening liver biochemistries (chiefly, alkaline phosphatase, bilirubin, and γ-glutamyltranspeptidase), and acute

hepatic failure (29). In contrast, splenectomy in CML is generally well tolerated without hepatic complications.

Development of the Budd-Chiari syndrome should always raise suspicion of an underlying MPD (28) with or without an accompanying hypercoagulable state, including factor V Leiden, prothrombin gene mutation, antiphospholipid antibodies, antithrombin deficiency, protein C deficiency, and protein S deficiency (30). Latent MPD may be detected in individuals with "idiopathic" Budd-Chiari syndrome by assessing various attributes of the MPDs, including spontaneous erythroid colony formation in the presence of low serum erythropoietin levels, increased megakaryocyte colony growth, and clonal karyotypic abnormalities evident by X chromosome inactivation patterns (31). Alternatively, molecular techniques can identify the acquired single gain-of-function point mutation (Val617Phe, V617F) involving Janus kinase 2 (JAK2) present in 65% to 97% of patients with PV, 23% to 57% of those with ET, and 43% to 57% of those with AMM (32).

Paroxysmal Nocturnal Hemoglobinuria and Hepatic Vascular Complications

PNH is an acquired hematopoietic disorder characterized by a defect in the glycosylphosphatidylinositol (GPI) anchor due to an abnormality in the *phosphatidylinositol glycan A* (*PIG-A*) gene. As a consequence, hematopoietic cells derived from PNH cells partially or completely lack certain GPI-linked proteins, including regulators of complement activation, CD59 (also called *membrane inhibitor of reactive lysis, protectin*, and *membrane attack complex inhibitory factor*) and CD55 (decay accelerating factor). Venous thrombosis of any site, including hepatic veins, can complicate PNH, although it is not known whether dysregulated complement activation (versus other mechanisms) contributes to this thrombotic diathesis.

Acute thrombosis in PNH is managed in a manner similar to venous thrombosis in other settings (33). Recurring hepatic vein thrombosis ultimately causes cirrhosis, and development of the Budd-Chiari syndrome portends a poor prognosis (34). Thrombolysis in hepatic vein thrombosis can improve long-term outcomes (35).

Thrombocytopenia in Liver Disease

Thrombocytopenia is common in chronic liver disease, although thrombocytosis may

arise when liver disease occurs with one or more known causes of "reactive" increases in platelet production (e.g., acute bleeding, iron deficiency, bacterial infection, or malignancy), asplenia, or hyposplenia. Thrombocytopenia can relate to "distributional" factors, with platelet sequestration in a spleen that is enlarged because of portal vein hypertension. However, reduced levels of thrombopoietin, which is produced constitutively by the liver, is the chief cause of thrombocytopenia from chronic liver disease (36). Additional causes of underproduction that may worsen thrombocytopenia in chronic liver disease include suppression or damage of bone marrow by viral infections (e.g., varicella, parvovirus, Epstein Barr virus, or human immunodeficiency virus), drugs, or toxins (e.g., alcohol, chemotherapy, or radiation therapy); nutritional deficiencies (e.g., folate or cobalamin); and acquired disorders of hematopoiesis (e.g., bone marrow aplasia or hypoplasia, or myelodysplastic syndromes).

Immune or nonimmune processes may destroy platelets, as is the case in idiopathic immune thrombocytopenic purpura, drug-induced thrombocytopenia, alloimmune destruction of platelets (e.g., posttransfusion, post-transplantation), disseminated intravascular coagulation (DIC), antiphospholipid antibody syndrome, physical destruction of platelets (from cardiopulmonary bypass, giant cavernous hemangiomas), thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP-HUS), HELLP (hemolysis with a microangiopathic blood smear, elevated liver enzymes, and low platelets in pregnancy) syndrome, and infection-associated thrombocytopenia. In sepsis, thrombocytopenia results from immune-mediated platelet destruction, hemophagocytic histiocytosis, and DIC (37).

Transfusion for massive blood loss, as may happen in patients with bleeding varices from portal vein hypertension, can cause "dilutional" thrombocytopenia. In one study, 75% of patients transfused with 20 or more RBC units in 24 hours developed platelet counts less than 50,000/μL, whereas none of the patients receiving less than 20 RBC units developed platelet counts below this level (38). Dilutional thrombocytopenia is distinguishable from posttransfusion purpura (PTP), which is an uncommon immune-mediated transfusion reaction that occurs primarily in women sensitized to a foreign platelet antigen by pregnancy. Patients sensitized by prior platelet or platelet-containing RBC transfusions are also at risk. The most common antigen implicated in PTP is human platelet antigen 1a (HPA-1a), formerly named *PIA1*. In PTP, severe thrombocytopenia arises 5 to 10 days after transfusion of platelets or platelet-containing RBCs and lasts days to weeks (39).

When thrombocytopenia is detected, examining peripheral blood smears allows clinicians to dismiss spurious thrombocytopenia, arising from platelet clumping in vitro. This arises from either insufficient

anticoagulation of the collected blood sample (excess ethylenediaminetetraacetic acid [EDTA]) or EDTA-dependent agglutinins.

Hemolysis with Microangiopathic Blood Smear, Elevated Liver Enzymes, and Low Platelets in Pregnancy

About 15% of pregnant women with pre-eclampsia (i.e., hypertension, proteinuria, and edema in pregnancy) develop thrombocytopenia; up to one third of these women experience severe thrombocytopenia with platelet counts less than 50,000/μL (40). As defined in a large case series, HELLP syndrome is the presence of microangiopathic hemolysis, with platelet counts less than 150,000/μL, serum LDH greater than 600 IU/L, and serum AST greater than 40 IU/L (40). Most patients present with midepigastric or right upper abdominal pain and nausea and/or vomiting. A small number of patients are asymptomatic (40). Patients with pre-eclampsia tend to have more frequent and severe thrombocytopenia, and signs of DIC occur in nearly 20% of patients (40). While HELLP syndrome can complicate pre-eclampsia, 15% to 20% of

patients with HELLP do not have hypertension or proteinuria (40). Hence, HELLP syndrome and pre-eclampsia may have separate etiologies, as underscored by the finding that fetuses of some women affected by HELLP syndrome have long-chain 3-hydroxyacyl-coenzyme A dehydrogenase deficiency (LCHAD) (41). LCHAD contributes to the acute fatty liver of pregnancy (41). However, in contrast to HELLP syndrome, acute fatty liver of pregnancy is not typically associated with thrombocytopenia unless DIC occurs (42).

Hematologic manifestations of pre-eclampsia and HELLP syndrome usually develop in the third trimester of pregnancy. In most patients, delivering the fetus is effective treatment, with hematologic abnormalities usually resolving within 3 days. However, 30% of women with HELLP syndrome develop hematologic abnormalities postpartum, usually within 48 hours of delivery, although sometimes it takes as long as 7 days after delivery. In both antepartum and postpartum HELLP, parenteral corticosteroids (betamethasone or dexamethasone) achieve more rapid improvement in clinical and laboratory parameters (43). When given antepartum, corticosteroid therapy can help delay parturition. In some patients, however, clinical and laboratory manifestations of HELLP worsen or do not improve after 3 days. In such patients, HELLP syndrome is indistinguishable from TTP-HUS, and plasma exchange should be initiated promptly, particularly if neurologic symptoms or signs and/or renal failure appear (44).

Additional complications of HELLP syndrome include hepatic failure (also seen in acute fatty liver of pregnancy), hepatic infarction, and hepatic hematoma with or without rupture. Antithrombin III levels decline as thrombocytopenia worsens (45), and underlying procoagulant states (e.g., antiphospholipid antibodies and factor V Leiden) may influence the risk of hepatic failure and infarction (46,47,48), marked by substantial elevations in the levels of aminotransferases. As platelet counts fall below 20,000/µL, patients face significant risks of hepatic hematoma. Although platelet transfusion may be advisable, there is no evidence that prophylactic platelet transfusions prevent this complication. Computed tomography (CT) and MRI are more sensitive than ultrasonography in detecting hepatic hematoma (49). When hematomas are contained, treatment is supportive; with rupture, patients may require orthotopic liver transplantation (50).

Decreased Synthesis of Coagulation Factors

The liver is the site of synthesis of coagulation factors. Prolongation of clotting tests (i.e., prothrombin time [PT], partial thromboplastin time [PTT]) is apparent only when levels of plasma coagulation factors are severely depressed (<30% to 40% of normal). The sensitivity of the PT as a marker of liver dysfunction reflects the relative influence of coagulation factors with shorter half lives including factor VII (4 to 6 hours) and factor V (12 hours). With advancing disease there are additional decrements in other factors including factors II, IX, and X.

Expression of factor VII on hepatocytes appears to be depressed even in the early stages of liver disease (51), but a measurable decline in circulating plasma levels usually represents more advanced disease (52). This has led to the evaluation of circulating factor VII as a prognostic marker (53) and eventually to the adoption of PT prolongation as an indicator of severity of disease (54,55). More recently, the prognostic Model for End-Stage Liver Disease (MELD) includes the international normalized ratio (INR) as an independent variable (56). INR reflects the ratio of an individual's PT relative to the standardized PT of the thromboplastin reagent to reduce the interlaboratory variability of PT measurements. However, INR was developed to monitor the hemostatic effects of oral anticoagulants and not the degree of liver dysfunction. In fact, studies have shown that in liver failure INR failed to identify a standardized PT independent of the thromboplastin reagent used (57).

Factor VIII is synthesized by both endothelial cells and hepatocytes, which accounts for the lack

of correlation between plasma concentration and the degree of liver dysfunction. Indeed, factor VIII levels are often elevated in patients with advanced liver disease, although the biological basis for this increase is not clear (58). Factor VIII is an acute-phase reactant and its increased concentrations are commonly seen in inflammatory disorders or acute infection; however, in the case of liver disease the levels do not appear to correlate with similar changes in other inflammatory markers such as C-reactive protein (59). It has also been hypothesized that elevations in von Willebrand's factor or low-density lipoprotein receptor–related protein levels observed in liver disease can stabilize circulating factor VIII, resulting in increased concentrations (60). Alternatively, portal hypertension after long-standing liver disease results in an increased number of sinusoidal endothelial cells that synthesize factor VIII (60).

Functional Deficiencies of Coagulation Factors

The activity of multiple coagulation factors including factors IX, VII, X, and prothrombin is dependent on the vitamin K–mediated conversion of glutamic acid into γ-carboxyglutamic acid in the *N*-terminal region of the proteins. Vitamin K deficiency has been implicated as a factor contributing to the coagulopathy of liver disease because of malabsorption and antibiotics usage. Vitamin K is derived from both dietary sources (green vegetables) and intestinal microflora synthesis. The absorption of Vitamin K requires pancreatic enzymes for its liberation from protein complexes and bile salts to facilitate its incorporation into micelles. Predictably, vitamin K absorption is impaired in cases of severe pancreatic insufficiency or extrahepatic biliary obstruction (61,62), but, in cases of intrinsic liver disease, the contribution of vitamin K deficiency appears to be relatively minor.

In severe hepatic disease, there are circulating coagulation factors that are deficient in γ-carboxyglutamic acid, which are commonly due to altered hepatocyte function. In one study, over 90% of patients with liver disease had detectable levels of circulating undercarboxylated prothrombin irrespective of bleeding symptoms or prolongation of PT. Treatment with vitamin K did not correct the prothrombin activity, suggesting that vitamin K deficiency was not the underlying etiology (63). Abnormally carboxylated forms of prothrombin (des-carboxyprothrombin) have also been documented in patients with hepatocellular carcinoma, which may be due to altered gene expression of the γ-carboxylase enzyme in the malignant clones (64,65). Nevertheless, vitamin K is administered to about 25% of hospitalized patients with cirrhosis in an attempt to correct the underlying coagulopathy (66). Although such a practice is considered low risk, with an incidence of anaphylaxis of roughly 3 per 10,000 intravenous doses (67), the benefit of vitamin K has not been evaluated in any randomized controlled trial (68). In a few small studies there has been some laboratory improvement in either PT or the amount of des-carboxyprothrombin in patients treated with vitamin K (59,69).

Functional abnormalities affecting fibrinogen are also well described in patients with advanced liver disease. Clot formation is dependent on the conversion of fibrinogen to fibrin, which is affected by the number of sialic acid residues present on the fibrinogen molecule. In liver failure, there is an increased fibrinogen sialylation, which impairs the ability of fibrin monomers to polymerize (70,71,72).

Consumptive Coagulopathy

The hemostatic abnormalities apparent in advanced liver disease extend beyond the synthesis of functional procoagulants in the hepatocyte. The deposition of fibrin polymers, which represents the final step in the coagulation pathway, depends on the delicate balance of coagulation factor activation, inhibition, and disintegration. In advanced liver disease, perturbations in each of these hemostatic components have been demonstrated.

Laboratory abnormalities that suggest a consumptive coagulopathy, otherwise referred

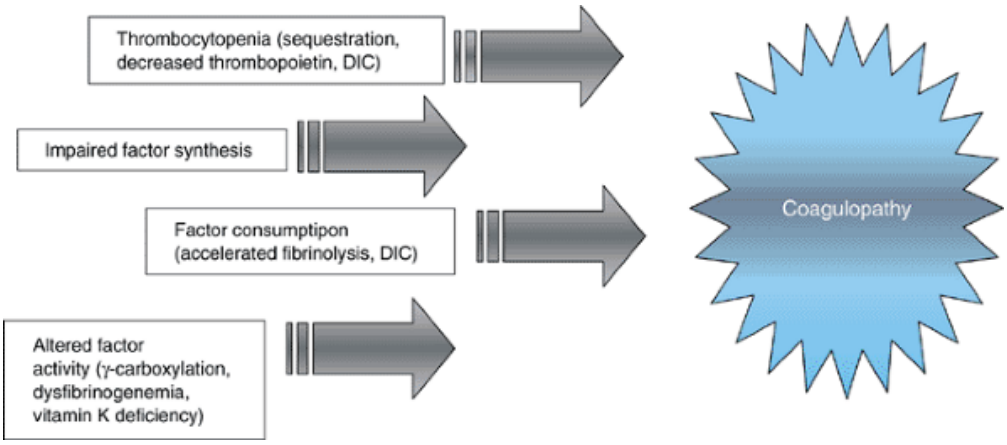
to as *DIC*, can be observed in patients with advanced liver disease (73,74). However, there is an on-going debate as to whether DIC is the consequence of advanced liver disease, a laboratory artifact, or the result of a heightened susceptibility to a secondary insult such as infection (74,75,76,77). Supporting evidence of on-going consumption has been the shortened survival of radiolabeled fibrinogen that improves after heparin administration (78), elevated plasma concentrations of fibrin by-products such as d-dimer (79) and fibrinopeptide A (80), and the inability to normalize factor levels after plasma infusions (81). On the other hand, many of the laboratory abnormalities suggestive of DIC such as thrombocytopenia, prolongation of PT, low fibrinogen levels, and elevated d-dimer concentration can occur in the setting of advanced liver failure even in the absence of on-going consumption (76). For instance, laboratory markers of fibrin degradation, such as d-dimer and fibrin split products, can be attributed to impaired hepatic clearance or accelerated fibrinolysis.

Accelerated fibrinolysis in cirrhosis was first described in 1914 by Goodpasture (82). He observed that blood samples taken at autopsy from four patients

with cirrhosis displayed rapid fibrin clot dissolution (hours) compared to the normal rate (days). He astutely concluded that "fibrinolysis is the activity of normal proteolytic ferments of the blood, operating by virtue of a diminuation or absence of the normal antiproteolytic substances." Abnormalities of the fibrinolytic pathway in advanced liver disease have since been attributed to a delay in hepatic clearance of plasmin activators such as tissue plasminogen activator (83,84) or to decreased synthesis of plasmin inhibitors including plaminogen activator inhibitor-1 (83,85,86), α_2-antiplasmin (84,87), and thrombin-activatable fibrinolysis inhibitor (88,89). Ascitic fluid also contains fibrinolytic activity, and its re-entry into circulation is a postulated mechanism underlying systemic hyperfibrinolysis (90). Factor XIII is also necessary for fibrin polymer cross-linking and its levels may be reduced in patients with cirrhosis (91,92). Distinction between consumptive coagulopathy and hyperfibrinolysis is difficult in advanced liver disease but may be clinically relevant because the treatment with an antifibrinolytic agent can be therapeutically useful in one circumstance and relatively contraindicated in the other. Moreover, in a study of 112 patients with cirrhosis and varices but without a history of upper intestinal bleeding, the only clinical or laboratory variable that predicted an initial bleeding episode was hyperfibrinolysis (93).

Clinical and Laboratory Evaluation of Coagulopathy

Bleeding is a major complication and one of the principal causes of death in patients with cirrhosis (94,95). Although prothrombin activity is a component of the Child-Pugh's scoring system and reflects generalized liver dysfunction, coagulopathy itself is not an independent risk factor for variceal bleeding (96,97). In situations in which bleeding is not attributed to the vascular sequelae of portal hypertension, bleeding symptomatology may be helpful in identifying the underlying hemostatic defect. Mucosal sites of bleeding such as epistaxis or bleeding gums indicate an abnormality involving primary hemostasis due to either qualitative or quantitative platelet deficiencies. Soft tissue hematomas or intracranial hemorrhage may reflect inefficient fibrin clot deposition due to either factor deficiencies or accelerated fibrinolysis. Generalized oozing at venipuncture sites often heralds the development of a more severe coagulopathy such as DIC or severe hypofibrinogemia.



▪ **Figure 12.2** Multifactorial basis of coagulopathy in patients with advanced liver disease. DIC, disseminated intravascular coagulation.

Laboratory evidence of coagulopathy is common in patients with advanced liver disease. However, in the absence of bleeding or anticipated invasive procedure, corrective measures are usually not indicated because the risk of spontaneous bleeding does not correlate with the degree of PT or PTT prolongation (93,98). In fact, thrombosis is not infrequent in patients with advanced liver disease, and a patient should not be considered therapeutically "auto-anticoagulated" in this setting (99). The hemostatic basis for thrombosis in this setting is often multifactorial, including decreased synthesis of natural anticoagulants such as antithrombin, protein C, and protein S; decreased hepatic clearance of activated coagulation factors; or, possibly, high levels of circulating factor VIII. There is also evidence that levels of von Willebrand's factor protease are decreased in patients with cirrhosis, which may predispose patients to microangiopathic thrombosis, but this association has not been established (100).

The differentiation of the various causes of coagulopathy in patients with advanced liver disease is often complicated by the presence of more than one hemostatic abnormality (Fig. 12.2 and Table 12.1). An isolated elevation of PT may be the initial laboratory

abnormality to reflect severe hepatic dysfunction. Prolongation of both PT and PTT can be seen in deficiencies (functional or antigenic) of common pathway coagulation factors, dysfibrinogenemia or low fibrinogen, and/or DIC. Thrombin time (TT) can be used to diagnose dysfibrinogenemia, but prolongation also occurs in the setting of low levels of fibrinogen or elevated levels of fibrin split products, which interfere with fibrin polymerization. Hyperfibrinolysis is characterized by a shortened euglobulin clot lysis time, but this assay is most accurately performed in specialized laboratories. Measurement of factor V activity may be useful in differentiating between decreased hepatic factor synthesis and vitamin K deficiency (either dietary or a functional) because factor V does not require vitamin K–mediated γ-carboxylation. The diagnosis of DIC is often difficult in patients with advanced liver disease because many of the diagnostic laboratory parameters (i.e., elevated d-dimer level, fibrin split products, hypofibrinogenemia, thrombocytopenia) can be attributed to other pathologic processes or delayed clearance of activated coagulation factors. Factor VIII levels may be helpful in distinguishing between synthetic factor deficiencies and consumption. As previously discussed, endothelial cells also synthesize factor VIII, and therefore, its levels can be elevated even in advanced liver disease. Similarly, the onset of coagulopathy can

provide insight into the underlying etiology because a fairly rapid time course (days to weeks) of hemostatic abnormalities supports the diagnosis of DIC over chronic liver disease.

Table 12.1. Coagulation Assay Characteristics of Coagulopathies Associated with Liver Disease

Condition	PT	PTT	TT	Clot lysis time
Factor VII deficiency	+	-	-	-
Factor II, V, X deficiencies	+	±	-	-
Dysfibrinogen or hypofibrinogen	+	±	+	±
Hyperfibrinolysis	-	-	-	+
Disseminated intravascular coagulation	±	±	±	-

+, abnormal; -, normal values; PT, prothrombin time; PTT, partial thromboplastin time; TT, thrombin time.

Correction of Coagulopathy in Bleeding Patients

Fresh frozen plasma

Fresh frozen plasma (FFP) is generated by ultracentrifugation of whole blood and can be stored up to 1 year at -18°C FFP contains all coagulation factors and can be used to replace deficient factors. A dose of 10 to 20 mLkg typically increases coagulation factors by 20% immediately after transfusion. But volume expansion often limits the total increase for any given coagulation factor to 20% to 30% above baseline (101). This is especially relevant in cases of variceal bleeding in which volume expansion could have the undesirable effect of increasing portal pressures (102).

Although FFP administration is useful in temporizing a hepatic coagulopathy, routine use of FFP in the absence of bleeding does not have demonstrated benefit (103). In the only randomized trial addressing this issue, 20 patients with paracetamol overdose were randomized to receive FFP versus no treatment. Prophylactic administration did not result in an improvement in bleeding outcomes (104). Other assessments of the relative benefit of FFP versus pathogen-reduced products also failed to demonstrate a benefit of one product over another in liver disease (103).

Cryoprecipitate

Cryoprecipitate is generated from FFP that is thawed at cold temperatures. It is enriched in high-molecular-weight proteins including fibrinogen, von Willebrand's factor, factor VIII, and factor XIII. It is most commonly used as replacement therapy for hypofibrinogenemia or dysfibrinogenemia and contains approximately 250 mg of fibrinogen per unit. In general, one unit of cryoprecipitate per 10 kg of body weight will increase plasma fibrinogen by 50 mg/dL. Transfusion with cryoprecipitate is

recommended in the bleeding patient when the plasma fibrinogen level falls below 80 to 100 mg/dL.

Prothrombin complex

Vitamin K–dependent factors (e.g., prothrombin; factors VII, XI, X; and protein C and S) can be concentrated using aluminum hydroxide or barium sulfate. However, these concentrates also contain small quantities of thrombogenic activated factors. Thrombotic complications are particularly frequent in patients with liver disease, which has limited the utility of prothrombin complex in this setting (105).

Antifibrinolytics

ε-Aminocaproic acid (EACA), aprotinin, and tranexamic acid are antifibrinolytic agents that inhibit plasminogen activation. They may have a role in managing hemostatic complications during liver transplantation but their use in cirrhosis is limited because of the difficulty in excluding DIC, which is a contraindication to therapy.

Recombinant factor VIIa

Activated VIIa binds to tissue factor, which in turn activates other coagulation factors including factors IX and X. Recombinant factor VIIa (rFVIIa) has been

used to treat bleeding patients in a variety of settings including hemophilia, cardiac surgery, trauma, and warfarin overdose. In advanced liver disease, potential applications include prophylaxis before liver biopsy, variceal bleeding, increased intracranial pressure, and liver transplantation. However, there are limited data to support the use of rFVIIa in these settings. Its potential role in liver biopsy and transplantation is discussed in the subsequent section.

A single large randomized trial investigated the potential benefit of rFVIIa in conjunction with endoscopic therapy for variceal bleeding (106). A total of 245 patients with cirrhosis complicated by upper gastrointestinal bleeding were randomized to rFVIIa versus placebo before endoscopy. rVIIIa failed to show any benefit in any endpoint including failure to control bleeding within the first 24 hours, prevention of rebleeding, early or late mortality, red cell requirements, or even active bleeding at first endoscopy. Therefore, the routine use of rFVIIa cannot be recommended in this setting. The administration of rFVIIa is currently being explored as rescue therapy in cases of uncontrolled variceal bleeding.

Coagulopathy Management in Liver Biopsy and Transplantation

Liver biopsy

Liver biopsy is common in the diagnostic evaluation of patients with liver disease. Following transcutaneous biopsy, intraperitoneal hemorrhage occurs in less than 5% of cases and the mortality rate is less than 0.5% (107,108,109,110,111). Mindful of the potential for bleeding complications, patients who are considered "high risk" on the basis of an abnormal coagulation profile, often receive FFP prophylactically. However, it is not clear from the literature that mildly abnormal hemostatic indices are predictive of bleeding outcomes in this patient population (107). In a prospective study of 200 consecutive patients who underwent laparoscopic biopsy and subsequent observation, there was no difference in terms of platelet count or PT among those patients who had prolonged bleeding at the biopsy site, as shown in Table 12.2 (110). Several retrospective studies have similarly failed to identify an association between PT and bleeding complications (108), although in one study the bleeding rates doubled in those patients with an INR equal to 1.5 or more compared to 1.3 to 1.5 (112). Other biopsy methods such as transjugular approach or biopsy site plugging with gelatin or

foam appear to have favorable bleeding outcomes in patients with coagulopathy but absolute indications for their use have not been established. On the basis of the available data, the British Society of Gastroenterology issued guidelines on the safety of percutaneous liver biopsy in patients with coagulopathy, as shown in Table 12.3 (113).

Table 12.2. Bleeding Outcomes in Patients with Abnormal Coagulation Profiles Undergoing Liver Biopsy

Study	Definition of major bleeding	Biopsy route	Bleeding with abnormal PT	Bleeding with normal PT
Ewe (107)	Directly visualized liver bleeding time. Major bleed >12 min	Lap	4/93 (4.3%)	4/85 (4.7%)
Riley (114)	Intraperitoneal bleeding	PC + plug	1/20 (5%)	NR
Tobin (115)	Decrease in hematocrit	PC + plug	1/100 (1%)	NR
McVay (116)	Hemoglobin decrease by 2 g/dL	PC	4/65 mild coagulopathy; 0/11 moderate (5.3% total)	4/100 (4%)
Papatheodoridis (117)	Requiring transfusion	TJ	0/112	0/45
Bruzzi (118)	Undefined	TJ	0/31	0/19
Smith (119)	Intraperitoneal hemorrhage detected clinically and by computed tomography	TJ	3/203 (1.5%)	0/168

PT, prothrombin time; Lap, laparoscopic biopsy; PC, percutaneous; NR, not recorded; TJ, transjugular.
Table adapted from Segal JB, Dzik WH. Paucity of studies to support that abnormal coagulation test results predict bleeding in the setting of invasive procedures: an evidence-based review. *Transfusion* 2005;45(9):1413–1425 (120).

Orthotopic liver transplantation

Bleeding complications are frequent in liver transplantation and directly correlate with the morbidity and mortality of the procedure (121). The mechanisms underlying coagulopathy of liver transplantation can be divided into three surgical stages:

Preanhepatic, anhepatic, and postanhepatic stages.

In the *preanhepatic* stage of transplantation, the liver is surgically isolated. Bleeding during this stage may correlate with underlying coagulopathy, portal hypertension, and complexity of surgical intervention (122,123), although other analyses have failed to even

identify coagulopathy as a risk factor for intraoperative blood loss (124). Bleeding during *anhepatic* stage is characterized by oozing in the previously dry surgical bed. Laboratory findings suggestive of DIC have been demonstrated in earlier series but later studies have not confirmed significant changes in PTT or PT before reperfusion of the donor graft, which may be due to improved surgical techniques (125,126,127,128). Hyperfibrinolysis during the anhepatic stage is well documented and appears to correlate with an increase in circulating tissue-type plasminogen activator (t-PA) levels in the absence of hepatic clearance (129). Accelerated fibrinolysis also frequently complicates the postanhepatic stage, which has led to the evaluation of antifibrinolytic agents in liver transplantation.

Table 12.3. British Society of Gastroenterology Guidelines on the Management of Patients with Coagulopathy Requiring Percutaneous Liver Biopsy

British Society of Gastroenterology guidelines for percutaneous liver biopsy

- Platelet count and prothrombin time should be checked in the week prior, provided that the patient's liver disease is stable.
- If platelet count is >60,000/mm^3 then the biopsy can be safely performed. If the platelet count is 40,000–60,000/mm^3 then platelet transfusion may increase the count enough for the biopsy to be performed safely by the percutaneous route. If, however, platelet transfusion does not increase or the platelet count is <40,000/mm^3 then alternative biopsy methods such as plugged, transvenous (transjugular), or laparoscopic liver biopsy can be tried (*Recommendation grade B*).
- If the prothrombin time is <4 s prolonged, then percutaneous biopsy can be safely undertaken. If the prothrombin time is 4–6 s prolonged then a transfusion of fresh frozen plasma may bring the prothrombin time into the desired range. If the prothrombin time is >6 s prolonged then other biopsy methods should be tried (*Recommendation grade B*).
- Post liver biopsy observation should continue for 6 h, and if at the end of this period there have been no complications then the patient may be discharged. The patient should, however, have a responsible person to stay with on the first postbiopsy night and should be able to return to hospital within 30 min should the need arise (*Recommendation grade B*).

Definition of Grade B recommendation: Requires the availability of clinical studies without randomization.

Grant A, Neuberger J. Guidelines on the use of liver biopsy in clinical practice. British Society of Gastroenterology. *Gut* 1999;45(Suppl 4):IV1–IV11.

Aprotinin has been evaluated in 137 patients who underwent orthotopic transplantation (130,131). Patients were randomized to high-dose or regular-dose aprotinin versus

placebo. Intraoperative blood loss was significantly lower (44% to 60%) in the aprotinin-treated patients, which was reflected in a decreased number of red blood cell transfusions. However, differences in postoperative mortality were not observed. Other antifibrinolytic agents appear to have similar efficacy in liver transplantation (132,133,134). There have been several case reports of thrombosis after administration of aprotinin in liver transplantation (135), which has led some centers to question its empiric use (131). However, on the basis of the data taken from prospective randomized trials, the observed thrombosis rate does not appear to differ appreciably from the placebo-treated patients (Table 12.4) (136).

Table 12.4. Thrombosis Rates in Randomized Trials Using Antifibrinolytic Agents in Liver Transplantation

Antifibrinolytic agent	Number of patients	Hepatic artery thrombosis	Overall thrombosis
Aprotinin	493	3 (0.6%)	8 (1.6%)
Tranexamic Acid	157	7 (4.5%)	9 (5.7%)
ε-Aminocaproic acid	42	2 (4.8%)	2 (4.8%)
Placebo	264	7 (2.7%)	7 (2.7%)

Adapted from Porte RJ. Antifibrinolytics in liver transplantation: they are effective, but what about the risk-benefit ratio? *Liver Transpl* 2004;10:(2):285–288.

rFVIIa was recently evaluated in a prospective, randomized trial for patients undergoing liver resection in noncirrhotic patients (137,138). Two hundred and four patients were randomized to either 20 or 80 μg/kg of rFVIIa versus placebo. Perioperative red blood cell transfusion and intraoperative blood loss was not significantly reduced in the rFVIIa-treated patients. Similar findings were shown in two randomized, placebo-controlled trials of patients undergoing orthotopic liver transplantation (107). The number of RBC units transfused and intraoperative blood loss was similar in the rVIIa- and placebo-treated groups. On the basis of these randomized studies, the routine use of rVIIa in hepatic transplantation cannot be recommended.

Annotated References

Banerjee S, Owen C, Chopra S. Sickle cell hepatopathy. *Hepatology* 2001;33:1021–1028.

This paper is a comprehensive review of hepatobiliary complications accompanying sickle cell disease (SCD), including acute sickle hepatic crisis, hepatic sequestration crisis, sickle cell intrahepatic cholestasis, cholelithiasis, and multitransfusion hepatopathy from iron overload and viral hepatitis. The authors review the role of abdominal imaging studies in distinguishing the various pathophysiologic processes impacting liver function in patients with SCD, findings on liver biopsy, and the effects on the liver of treatments used in managing patients with SCD, including hydroxyurea,

bone marrow transplantation, and liver transplantation.

This is the initial description of impaired carboxylation of prothrombin present in over 90% of patients with hepatic disease.

Bosch J, Thabut D, Bendtsen F, et al. Recombinant factor VIIa for upper gastrointestinal bleeding in patients with cirrhosis: a randomized, double-blind trial. *Gastroenterology* 2004;127:1123–1130.

A total of 245 patients with upper GI bleeding were prospectively randomized to eight doses of FVIIa or placebo. There was no difference between the two groups in terms of control of bleeding after the first dose of FVIIa, failure to prevent rebleeding, or 5-day mortality.

Chitale AA, Sterling RK, Post AB, Silver BJ, Mulligen DC, Schulak JA. Resolution of spur cell anemia with liver transplantation: a case report and review of the literature. *Transplantation* 1998;65:993–995.

This paper describes a young patient with hemochromatosis, alcohol abuse, decompensated cirrhosis, and spur cell anemia whose spur cell anemia persisted after portal decompression by transjugular intrahepatic portosystemic shunt for recurrent bleeding esophageal varices. However, spur cell anemia resolved after orthotopic liver transplantation, suggesting an integral role for diseased liver, rather than spleen, in the development of red blood cell membrane changes accompanying liver disease.

Peck-Radosavljevic M, Wichlas M, Zacherl J, et al. Thrombopoietin induces rapid resolution of thrombocytopenia after orthotopic liver transplantation through increased platelet production. *Blood* 2000;95:795–801.

To clarify the contributions of platelet production, platelet consumption, coagulation activation, and splenic sequestration to thrombocytopenia in liver disease, the authors studied thrombopoietin (TPO) serum levels and markers of platelet production, platelet activation, and coagulation activation before and 14 days after orthotopic liver transplantation (OLT) in 18 patients with advanced liver cirrhosis. With increased TPO serum levels and increased bone marrow production of platelets, platelet counts normalized in most patients within 14 days of OLT, irrespective of the change in spleen size assessed by computed tomography volumetry. This underscores decreased TPO production in the cirrhotic liver as an important etiologic factor for thrombocytopenia in liver disease.

Segal JB, Dzik WH. Paucity of studies to support that abnormal coagulation test results predict bleeding in the setting of invasive procedures: an evidence-based review. *Transfusion* 2005;45:1413–1425.

This reference is a detailed analysis of the current literature on the bleeding rates associated with invasive procedures including liver biopsies. The authors conclude that there is insufficient evidence to suggest that an abnormal coagulation profile is predictive of bleeding outcomes.

Chapter 13
Nutrition and the Liver

Alan L. Buchman
Kevin Korenblatt
Samuel Klein

Key Concepts

- Energy expenditure is close to that predicted in patients with acute hepatitis and stable cirrhosis but is increased with respect to lean body mass. Energy expenditure is also increased in patients with hepatocellular carcinoma and in those with ascites.
- Both protein synthesis and metabolism are impaired in patients with hepatic dysfunction. Specifically, visceral protein synthesis is decreased, and therefore, serum albumin and prealbumin are not useful in the assessment of nutritional status.
- Patients with cirrhosis exhibit peripheral insulin resistance and hyperglycemia, and even overt diabetes may develop.
- Protein-energy malnutrition (PEM) is common in patients with chronic liver disease and is often related to the severity of the underlying liver disease. Malnutrition is associated with increased infection risk, multiple organ complications, esophageal variceal hemorrhage, and increased post-transplantation morbidity and mortality.
- Vitamin A, D, and E deficiency may develop in patients with chronic cholestatic disease such as primary biliary cirrhosis.
- Many patients with metabolic syndrome also develop nonalcoholic steatohepatitis (NASH).
- Hepatic dysfunction associated with the use of parenteral nutrition may more likely be the result of malabsorption rather than direct toxicity from the parenteral nutrient solution. Choline deficiency has been invoked as a primary cause for the hepatic steatosis that develops, and experimental data suggests a second hit, such as that from endotoxin, may be necessary for the development of more progressive liver disease.
- Some patients with alcoholic hepatitis, as well as those with cirrhosis, may have improved morbidity and survival with the institution of either enteral or parenteral nutritional support.
- Protein restriction should not be considered routine in patients with cirrhosis because most patients will tolerate an increased amount of standard dietary protein without development of or worsening of encephalopathy. Portosystemic encephalopathy should be aggressively treated using standard therapy before instituting dietary protein restriction. Select patients with hepatic encephalopathy may benefit from use of high branched-chain/low aromatic amino acid formulas.
- Because of ineffective gluconeogenesis, a continuous glucose or dextrose supply should be provided to the patient with hepatic failure awaiting liver transplantation. Post-transplantation indications for nutritional support are similar to other nontransplantation postoperative indications.

The liver serves many critical metabolic and nutritional functions. It is the major site for (i) the synthesis of key plasma proteins, such as albumin and coagulation factors; (ii) urea synthesis needed for normal nitrogen and ammonia metabolism; (iii) glucose production to maintain glucose homeostasis and prevent hypoglycemia; (iv) lipoprotein production and export of water-insoluble triglycerides from the liver as water-soluble very low density lipoprotein (VLDL)–triglyceride particles into the bloodstream; (v) ketone body production, which provides fuel for the brain during energy or carbohydrate restriction; (vi) catabolism of metabolic regulatory hormones, such as insulin; and (vii) production of inflammatory markers, such as C-reactive protein. These diverse metabolic functions require a considerable amount of energy. Although the liver represents only approximately 2% of body weight, it accounts for approximately 20% of the body's resting energy requirements. Serious liver disease not only impairs hepatic function but also has considerable extrahepatic metabolic effects on glucose (insulin resistance and impaired glucose tolerance), lipid (increased lipolytic rates), and protein (decreased protein synthesis and increased amino acid oxidation rates) metabolism (1). Therefore, liver function, nutrition, and metabolism are integrally related, and abnormalities in one have adverse effects on the other.

Metabolic and Nutritional Principles

Energy Intake and Absorption

The average person ingests approximately 50 million calories, composed of approximately 2,000 kg of protein, 8,000 kg of carbohydrates, and 2,500 kg of fat, during his/her lifetime. Therefore, the balance between energy intake and energy expenditure is carefully regulated to permit normal growth during childhood and pregnancy and prevent large changes in body composition during adulthood. Food intake is controlled by a complex interaction of peripheral and central systems that determines the size, content, and frequency of feedings (2). These regulatory mechanisms must integrate daily short-term bursts of energy intake (meals and snacks) with long-term energy requirements and body composition. The regulation of energy intake is further complicated by the influence of external environmental cues, which can override endogenous regulatory signals and cause under- or overconsumption of energy.

Patients with cirrhosis often experience alterations in nutrient intake, which can lead to weight loss. Several mechanisms contribute to decreased food intake, including decreased sensation to salty, bitter, sweet, and sour tastes; dysgeusia due to vitamin A or zinc deficiency (3,4); early satiety associated with ascites; medication-induced anorexia or nausea; and psychological or neurologic impairment that alter eating behavior (5). Alcohol intake can account for more than 50% of daily energy intake in some patients with alcoholic liver disease. Excessive alcohol is metabolized in part by the microsomal ethanol oxidizing system, which generates a wasteful energy cycle by producing heat without energy production (6).

Malabsorption can also contribute to weight loss in patients with liver disease, even when appetite is unchanged. Chronic cholestasis and decreased bile acid secretion reduces the formation of mixed micelles, which impairs fat (7,8) and fat-soluble vitamin absorption (9). Malabsorption can also be caused by lactulose therapy, which can exacerbate steatorrhea (8), and by small bowel bacterial overgrowth (10,11,12,13), which occurs because of impaired small bowel motility (14,15,16,17) and prolonged intestinal transit (11,18,19). Some patients with alcoholic liver disease have serious malabsorption because of pancreatic insufficiency or direct alcohol-induced injury of the small intestine.

Energy Metabolism

Energy is constantly required for normal organ function, metabolism, heat production, and muscular work. Resting energy expenditure (REE) is the amount of energy consumed during postabsorptive resting conditions and represents approximately 70% of total daily energy expenditure (TDEE). The thermic effect of feeding is the amount of energy expended during consumption and processing of ingested food and represents approximately 10% of TDEE. The energy expenditure of physical activity depends on the intensity and duration of daily activities but normally represents approximately 20% of TDEE.

An assessment of energy requirements is necessary to make appropriate decisions about dietary intake and nutritional therapy in patients with liver disease. The Harris-Benedict equation developed in 1919 (20) is

still a useful tool for estimating REE in adult men and women:

Men: REE = 66 + (13.7 × W) + (5 × H) - (6.8 × A)

Women: REE = 665 + (9.6 × W) + (1.8 × H) - (4.7 × A)

where *W*, weight in kg; *H*, height in cm; *A*, age in years.

The Harris-Benedict equation generates estimates of REE that are usually within 10% to 15% of measured values for healthy subjects (21). However, the values are less reliable in obese (tends to overestimate REE) or very lean (tends to underestimate REE) patients. In addition, hypocaloric feeding decreases REE to values that are 15% to 20% below those expected for actual body size, whereas metabolic stress, such as inflammatory diseases or trauma, increase energy requirements.

The effect of liver disease on energy requirements is confusing because of conflicting data from different studies. Patients with liver disease have been reported to have low, normal, and high resting metabolic rates (14,22,23,24). Part of the inconsistency across studies can be attributed to how the data are expressed and the clinical condition of the patient. For example, in patients with either acute hepatitis or stable cirrhosis, energy expenditure is normal when it is expressed with respect to body surface area but is increased when it is expressed with respect to lean body mass (15,25). Energy expenditure is also increased in patients who have hepatocellular carcinoma, in relation to tumor size (26,27). Patients with severe disease, such as those with acute hepatic failure, usually have a marked increase in energy expenditure (28,29). Energy expenditure is increased in patients with ascites and decreases after ascites is removed by paracentesis (30).

Energy expenditure can be determined by indirect calorimetry, which measures whole body oxidation of fuels. This is usually performed by using a metabolic cart to assess oxygen consumption and carbon dioxide production and can be helpful in certain patients, such as those with increased energy requirements (e.g., closed head injury, burn, and trauma), decreased energy requirements (e.g., cachexia), difficulty weaning from mechanical ventilation, and fluid overload, making it difficult to determine dry weight. However, the values obtained by indirect calorimetry require an experienced operator and carefully calibrated equipment used under appropriate conditions to obtain reliable results. Indirect calorimetry can be used to estimate basal energy expenditure, derived from oxygen and carbon dioxide consumption using the Weir equation [basal energy expenditure (kcal/day) = (3.941 × VO_2 [L/day]) + (1.106 × VCO_2 [L/day])] (31). Because oxygen phosphorylation allows continuous adenosine triphosphate (ATP) synthesis at the respiratory chain level, a close relationship exists between energy metabolism and oxygen consumption. The rate of ATP utilization determines the overall rate of substrate oxidation, and therefore, oxygen consumption. Indirect calorimetry is performed over a 20- to 30-minute period while the patient is at rest, but not sleeping; extrapolation to daily energy expenditure is undertaken. Indirect calorimetry is portable and noninvasive, and may be performed on spontaneously breathing or mechanically ventilated (FIO_2 60%) patients (Figs. 13.1A and B). In patients with cirrhosis, the liver comprises 20% to 30% of the whole body energy expenditure. Hypo- or hypermetabolism occur when the estimated energy expenditure varies by more than 10% of that predicted on the basis of the Harris-Benedict equation (20).

Data from studies that evaluated substrate oxidation by using indirect calorimetry suggests that cirrhosis shifts basal fuel use from carbohydrate to fat oxidation, presumably because of diminished hepatic glycogen stores and hepatic glucose production (15,16,25). In general, stable patients with liver disease or cirrhosis require approximately 30 kcal/kg per day.

Starvation

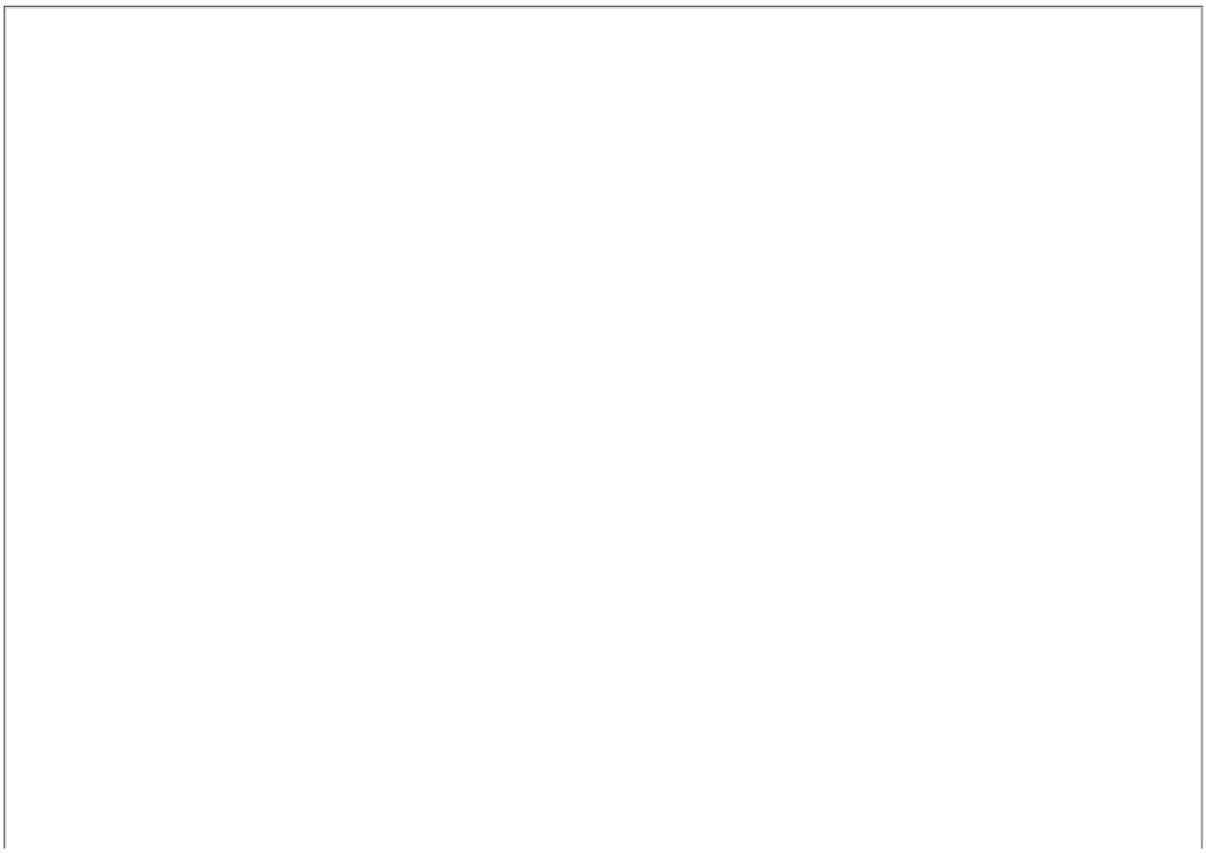
During starvation, an integrated series of metabolic adaptations occur that require important metabolic alterations for survival, including hepatic glycogenolysis and gluconeogenesis to maintain plasma glucose concentrations, decreased urea production in the liver to conserve body nitrogen, increased lipolysis and fatty acid release into plasma to provide tissues with fuel, and conversion of fatty acids to ketone bodies in the liver to provide a source of fuel for the brain and spare oxidative glucose requirements. Patients with cirrhosis have accelerated metabolic response to short-term starvation, manifested by a greater decline in hepatic glucose production, presumably related to decreased hepatic glycogen, and increased lipolysis of adipose tissue triglycerides (32).

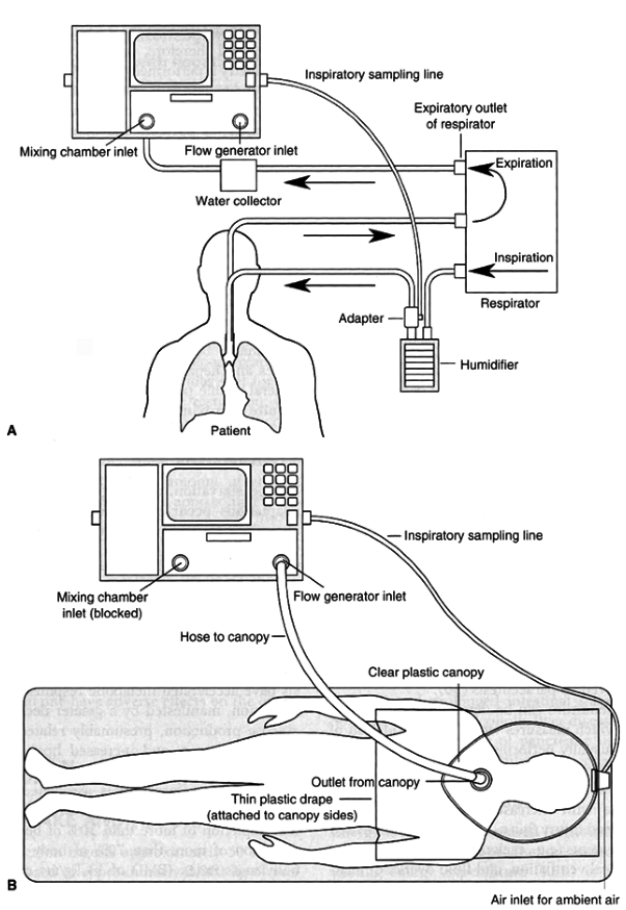
Death from starvation is associated with a body weight loss of more than 35% of body weight, protein depletion of more than 30% of body protein, fat depletion of more than 70% of body fat stores, and body mass index (BMI) of 13 kg/m^2 or less for men and 11 kg/m^2or less for women (33,34,35). Therefore, the duration of survival during starvation depends on the amount of available body fat and lean tissue mass and appropriate hepatic adaptations, which are compromised in patients with liver disease.

Protein Metabolism

Proteins are composed of a combination of 20 different amino acids, which are considered to be essential because the body cannot synthesize the carbon skeletons. Other amino acids are nonessential because they can be made from endogenous compounds. In some disease states,

nonessential amino acids may become "conditionally essential." For example, cysteine is essential in patients with cirrhosis because the trans-sulfuration pathway, which provides a sulfur group from methionine to cysteine, is impaired (36). The defect in trans-sulfuration affects methionine metabolism, which can lead to hypermethioninemia (37,38,39,40,41,42).





· Figure 13.1 A: Indirect calorimetry in a spontaneously breathing patient. **B:** Indirect calorimetry in a mechanically ventilated patient. (Reprinted with permission from Buchman AL. *Practical nutritional support techniques*, 2nd ed. Thorofare, NJ: Slack Inc., 2004.)

The liver is an important site for amino acid and ammonia metabolism. Transamination reactions are catalyzed by transaminases or aminotransferases (e.g., alanine transaminase [ALT] and aspartate transaminase [AST]), which interconvert a pair of amino acids with a pair of keto acids. An increase in serum transaminase concentration is a sign of liver injury and represents its

leakage from injured hepatocytes into the bloodstream. Ammonia, which is toxic to the central nervous system, is formed by oxidative deamination of glutamate in the liver, amino acid deamination in the kidneys, and intestinal bacterial production, and is absorbed and delivered to the liver through the portal vein. The liver rapidly removes ammonia from the circulation by formation of glutamate, glutamine, and urea. However, these metabolic processes can be impaired in patients with cirrhosis, causing an increase in circulating ammonia, which may contribute to hepatic encephalopathy (43).

A major function of the liver is to synthesize and secrete proteins that are necessary for normal metabolic function into the systemic circulation. Hepatic synthesis of albumin, which is necessary for maintaining normal intravascular oncotic pressure and transporting nutrients, and the synthesis of fibrinogen and clotting factors, needed for normal coagulation, are impaired in patients with advanced cirrhosis (44,45). In addition, steatohepatitis is associated with a lower rate of hepatic VLDL-apolipoprotein B production than in obese patients without steatohepatitis (46).

Muscle wasting occurs frequently in patients with cirrhosis (47). Skeletal muscle protein breakdown is often accelerated and nonoxidative leucine disposal is decreased in patients with cirrhosis (48). These alterations in amino acid metabolism can contribute to muscle wasting by enhancing protein breakdown in conjunction with diminished availability of amino acids for muscle protein synthesis.

Protein requirements are affected by the amount of nonprotein calories consumed, overall energy requirements, and protein quality. Inadequate amounts of any of the essential amino acids result in inefficient utilization. In general, approximately 15% to 20% of total protein requirements should be in the form of essential amino acids in healthy adults. The metabolic stress of illness often increases protein requirements by increasing protein catabolism and metabolic rate. Therefore, daily protein requirements in patients with serious liver disease who do not have encephalopathy (approximately 1.0 to 1.2 g/kg) may be greater than the protein requirements in the healthy adult population (approximately 0.8 g/kg) (Table 13.1) (49).

Nitrogen balance is calculated as the difference between nitrogen intake, in the form of amino acids or protein, and nitrogen losses in urine, stool, skin, body fluids, and nonprotein nitrogen. Nitrogen balance can be used to estimate protein balance because approximately 16% of proteins consists of nitrogen, and it is assumed that all the body nitrogen is incorporated into proteins. A positive balance (intake greater than losses) represents anabolic conditions and a net increase in total body protein content, whereas a negative balance demonstrates net protein catabolism. For example, a negative nitrogen balance of 1 g/day represents a 6.25-g/day (16% of 6.25 g protein = 1 g nitrogen) loss of body protein, which is equivalent to a 30-g/day loss of hydrated lean tissue. Total dietary nitrogen intake (grams) can be calculated by dividing the total protein intake (grams) over a 24-hour period by 6.25. Total urinary nitrogen (TUN), or urine urea nitrogen (UUN) + 4 to account for nonurea nitrogen losses (collected over the same 24-hour period as dietary intake), is then subtracted from the total nitrogen intake to arrive at the nitrogen balance. In practice, nitrogen balance studies tend to be artificially positive because of overestimation of dietary nitrogen intake and underestimation of losses caused by incomplete urine collections and unmeasured outputs.

Table 13.1. Recommended Daily Protein Intake

Clinical condition	Protein requirements (g/kg ideal body weight/d)

Normal	0.75
Metabolic "stress"[a]	1.0–1.5
Hemodialysis	1.2–1.4
Peritoneal dialysis	1.3–1.5
Continuous dialysis	1.7–2.0

[a]Including patients with liver disease who have encephalopathy.
Additional protein requirements are needed to compensate for excess protein loss in patients with burn injuries, open wounds, and protein-losing enteropathy or nephropathy. Lower protein intake may be necessary in patients with chronic renal insufficiency not treated by dialysis and in patients with liver disease and hepatic encephalopathy.

It is important to consider the patient's nutritional status when interpreting nitrogen balance data. When a person ingesting a low-protein diet is refed protein, nitrogen excretion does not rise proportionately to intake and there is retention of administered nitrogen. This gain during early refeeding is caused by a rapid accumulation of nitrogen in the liver and to a lesser extent in kidneys and muscle. However, the early retention of nitrogen is not sustained and nitrogen content decreases markedly within 4 to 7 days. In contrast, when a person ingesting a high-protein diet decreases his or her protein intake, the previously high urinary nitrogen loss continues for a few days despite the reduced intake, resulting in a negative nitrogen balance. Similarly, initial nitrogen loss after injury is greater in well-nourished than in malnourished patients. Therefore, a "labile" nitrogen pool of approximately 60 g contributes to short-term alterations in nitrogen balance. It must also be understood that a positive nitrogen balance requires a positive energy balance to avoid catabolism of skeletal muscle protein (50), although a positive nitrogen balance does not necessarily indicate adequate nitrogen utilization because protein metabolism is impaired in cirrhosis and end-stage liver disease.

Glucose Metabolism

After a person fasts overnight (12 hours), the liver produces approximately 2 mg of glucose/kg body weight (51). Adequate hepatic glucose production is critical because certain tissues, such as bone marrow, erythrocytes, leukocytes, renal medulla, eye tissues, and peripheral nerves, cannot metabolize fatty acids and require glucose (approximately 40 g/day) as a fuel, whereas other tissues, such as the brain, prefer glucose (approximately 120 g/day) as a fuel. Severe liver disease and cirrhosis can compromise the liver's capacity for glucose production (52).

Hepatic glucose production is an important determinant of basal plasma glucose concentrations. Therefore, impaired insulin-mediated suppression of endogenous hepatic glucose output can cause basal hyperglycemia and contribute to the development of diabetes. Excess fat in the liver (nonalcoholic fatty liver disease [NAFLD]) is associated with insulin resistance and features of the metabolic syndrome, including abdominal fat accumulation, diabetes, hypertriglyceridemia, low serum high-density lipoprotein (HDL) concentrations, and hypertension (53,54,55,56,57). Data from one study found that lean men with excessive intrahepatic fat content (approximately 11% of liver volume) had impaired insulin-mediated suppression of endogenous glucose production compared with lean men who had low liver fat content (approximately 2% of liver volume) (58). Moreover, moderate weight loss decreases intrahepatic fat content and normalizes hepatic insulin sensitivity (59).

The mechanisms underlying the relationships among hepatic fat, insulin resistance, and dyslipidemia are not known. It is possible that increased release of fatty acids from adipose tissue in obese persons simultaneously causes insulin resistance, dyslipidemia, and increased hepatic fat content. Excessive release of free fatty acids (FFAs) into plasma can impair the ability of insulin to stimulate muscle glucose uptake (60) and suppress hepatic glucose production (61,62) and can increase hepatic VLDL-triglyceride production and plasma triglyceride concentration (63). Therefore, increased hepatic fat content, insulin resistance, and dyslipidemia may be a sequelae of excessive fatty acid availability that can track together. However, it is also possible that increased hepatic fat itself has independent pathophysiologic effects by increasing intrahepatic fatty acids, which stimulate glucose production (61); fat metabolites, such as diacylglycerol and fatty acyl CoA; and ceramides, which impair insulin signaling in skeletal muscle (64).

Patients with cirrhosis exhibit resistance to insulin-mediated glucose metabolism in skeletal muscle. Despite normal endogenous hepatic glucose production (65,66,67), hyperglycemia or overt diabetes has been reported in 15% to 30% of patients with cirrhosis (68). Pancreatic β-cells are unable to secrete sufficient insulin to overcome peripheral insulin resistance (69), although prolonged hyperinsulinemia related to decreased insulin metabolism may actually account for the insulin resistance (70). Insulin resistance resolves after liver transplantation (71).

Lipid Metabolism

Lipids serve as a source of energy; structural components of cell membranes; precursors for steroid hormones, prostaglandins, thromboxane, and leukotriene synthesis; and carriers of essential nutrients. Plasma lipoproteins are molecular complexes of lipids and apolipoproteins that permit the transport of water-insoluble lipid species in the bloodstream. These complexes consist of a hydrophobic lipid core containing triglycerides and cholesterol esters with an outer surface of more hydrophilic phospholipids, free cholesterol, and apolipoproteins. One or more apolipoproteins are associated with each particle. Lipoproteins comprise a spectrum of particles of differing lipid content, apolipoproteins, and sizes and are commonly classified as chylomicrons, VLDL, low-density lipoprotein (LDL), and HDL on the basis of their floatation in an ultracentrifuge. VLDLs, produced by the liver, are the major endogenous triglyceride-rich lipoproteins. Obesity and NAFLD are associated with increased rates of hepatic VLDL-triglyceride production, which decrease with moderate weight loss (72).

Dietary lipids are composed mainly of triglycerides: Long-chain triglycerides (LCTs), which contain fatty acids that are more than 12 carbons in length, or medium-chain triglycerides (MCTs), which are 6 to 12 carbons in length. MCTs do not require bile acids for absorption and are released directly into the portal vein after intestinal absorption. The use of MCTs can be beneficial in patients who have disorders of fat digestion (e.g., pancreatic insufficiency, biliary obstruction), fat absorption (e.g., celiac sprue, short bowel syndrome), or lipid transport (e.g., intestinal lymphangiectasia, abetalipoproteinemia), or in those who require a reduction in lymphatic flow (e.g., chylous ascites, thoracic duct fistula) (73). However, MCTs are more ketogenic than LCTs and should not be given to patients with cirrhosis, particularly those with portal–systemic shunts.

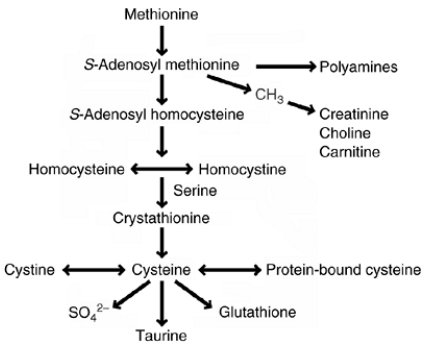
Major and Trace Minerals

Major minerals are inorganic nutrients that are required in large (>100 mg/day) quantities and are important for maintaining ionic equilibrium, water balance, and normal cell function. In patients with cirrhosis, excess whole body sodium exacerbates edema and ascites (74), and hypokalemia can precipitate encephalopathy (75).

Micronutrients

Micronutrients consist of trace elements and vitamins, which are constituents of enzyme complexes that regulate metabolic processes. Trace minerals are inorganic nutrients that are required in small (<100 mg/day) quantities. Normal intake of certain trace elements can be toxic to patients with cholestatic liver disease because these elements are excreted in the bile. For example, the recommended daily parenteral intake of manganese in patients with chronic liver disease can cause excessive manganese deposition in basal ganglia, causing extrapyramidal and Parkinson-like symptoms (76). Manganese should not be provided to patients with cholestasis. Copper intake should also be restricted in patients with cholestasis because it is primarily excreted through the biliary route, although no case of copper toxicity in patients who require parenteral nutrition has been described.

Choline is a particularly important micronutrient for the liver. Cirrhosis develops in the chronically choline-deficient rats (77), Rhesus monkeys (78,79), and Macaque monkeys (80). Hepatocellular carcinoma can also develop in a significant percentage of rats provided a chronic choline-deficient diet (81,82). In cirrhosis, choline deficiency may develop because of impaired methionine metabolism through the hepatic trans-sulfuration pathway (Fig. 13.2) (37,38,83). Hypermethioninemia develops and methionine plasma clearance is reduced after intravenous injection (39,42,83). Plasma free choline, glutathione, carnitine, taurine, and cysteine concentrations are decreased (84,85,86). Sulphate excretion is slowed in patients with cirrhosis; this also suggests impaired capacity of the trans-sulfuration pathway (41,42). The impairment in the trans-sulfuration pathway appears to be at the level of the trans-sulfuration of homocysteine to betaine (86). Ethanol also increases choline metabolism (87). Supplementation of the diet with choline in one study in monkeys prevented the development of hepatic fibrosis (88), although another study in baboons failed to confirm these findings (89); polyunsaturated lecithin and phosphatidylcholine (both containing choline) prevented the development of alcoholic fibrosis in the livers of baboons (90,91). Data from one study suggest that phosphatidylcholine supplementation decreases portal hypertension and ascites, improves response to hepatic encephalopathy, and decreases mortality compared with standard therapy alone (92).



· **Figure 13.2** The trans-sulfuration pathway.

Vitamins

Vitamins are organic compounds that are required in small (<100 mg/day) quantities. Body stores of water-soluble vitamins are usually much smaller than those of fat-soluble vitamins. Therefore, clinical symptoms of vitamin deficiencies usually occur more rapidly for water-soluble than for fat-soluble vitamins. Patients with liver disease are at particularly high risk for certain vitamin abnormalities.

B Vitamins

Patients with alcoholic liver disease have decreased serum concentrations of vitamins B_1 (thiamine), B_2 (riboflavin), and B_6(pyridoxine), and folic acid (93,94). Serum vitamin B_{12} concentration may be elevated because of its release from injured hepatocytes (93,94).

Vitamin A

Serum vitamin A concentration can be decreased in patients with cholestatic liver disease, such as primary biliary cirrhosis, and in patients with hepatocellular carcinoma (95,96). However, the decrease in serum concentration may be due to its defective mobilization from the liver rather than decreased intake or absorption (97). Low serum concentration of vitamin A can also be caused by decreased retinol-binding protein synthesis (98) and does not necessarily correlate with hepatic concentration (99). Plasma concentrations of retinol and retinyl esters decrease when hepatic stores are depleted. Vitamin A supplementation is essential in patients with alcoholic liver disease, in which dark adaptation difficulties are manifest. Abnormal dark adaptation or night blindness in conjunction with low serum vitamin A concentrations can be corrected by 4 to 12 weeks of treatment with 25,000 U of retinol per day (100). During replacement therapy, serum vitamin A concentrations should be monitored to avoid vitamin A toxicity, although it would take months or years of supplementation at this dose to cause toxicity in deficient patients (101). Both vitamin A and zinc deficiency are more prevalent in patients who

have portosystemic shunting for reasons that are not clear (102). Abnormal serum vitamin A concentrations in patients with severe liver disease often normalize within 2 weeks of liver transplantation (103).

Vitamin A toxicity, which is rare, is manifested by mild elevations in serum aminotransferase concentrations, hepatomegaly, dry skin, pruritus, brittle nails, hair loss, gingivitis, cheilosis, skeletal pain, pseudotumor cerebri, headache, anorexia, and fatigue. Serum retinol concentration is usually elevated but may initially be normal in some patients (104). The capacity of retinol-binding protein to transport vitamin A is exceeded, and the excess circulates as retinyl esters bound to plasma lipoproteins (105). Ito cells are the major storage site for retinyl esters (106). As such, these cells are increased in number in hypervitaminosis A (107) and can transform into fibroblasts, which produce type III collagen and fibrosis (108,109). Liver disease in patients with vitamin A toxicosis may take anywhere between 2 months and 1 year to resolve because of the prolonged half-life of vitamin A in the hepatic tissue (up to 60 days) (110,111,112,113,114,115,116). Discontinuation of vitamin A supplementation is the only effective therapy for vitamin A toxicity, but sometimes the liver disease progresses despite stopping vitamin A.

Vitamin D

Low serum 25-hydroxyvitamin D concentrations are observed in patients with chronic cholestasis, particularly primary biliary cirrhosis, because of vitamin D malabsorption (117,118). Patients with chronic liver disease may also fail to obtain sufficient sunlight exposure, which decreases vitamin D production (119). Vitamin D deficiency may also occur in patients with hemochromatosis, but blood levels of vitamin D increase after venesection therapy to remove excess iron (120). Patients with alcoholic cirrhosis have impaired hepatic 25-hydroxylation (121,122) and are at particularly high risk for osteoporosis, which can develop in approximately 50% of these patients (123).

Because vitamin D enhances intestinal calcium absorption (124), low concentrations of this vitamin are associated with decreased calcium absorption (123). Although supplementation with 25-hydroxyvitamin D increases calcium absorption, this formulation is no longer commercially available in the United States; oral 1,25-dihydroxyvitamin D is used instead (125). Vitamin D deficiency may persist after liver transplantation (126).

Decreased bone mineralization (osteomalacia) may occur because of vitamin D deficiency. Several case series have shown that osteomalacia developing in patients with primary biliary cirrhosis may be successfully treated with vitamin D supplementation (127,128,129). Bisphosphonate therapy may be useful in these patients. Other series, however, have reported that the prevalence of osteomalacia was extremely low but that the primary metabolic bone disease was osteoporosis, resulting from increased bone resorption (130,131,132). Data from one clinical study suggest that osteoporosis in some patients with primary biliary cirrhosis is unresponsive to vitamin D therapy and can progress to fractures (133,134). Other studies have shown that bone mineral density (BMD) increased in patients with alcoholic liver disease who were treated with large doses of vitamin D (50,000 IU/day of cholecalciferol or 25 to 50 mg/day of 25-hydroxyvitamin D) (135). Despite the use of medications such as prednisone, which has adverse effects on bone, liver transplantation increases BMD in children undergoing the procedure because of biliary atresia (136).

Vitamin E

Vitamin E deficiency has been described in patients with chronic cholestatic liver disease including primary biliary cirrhosis. Malabsorption appears to be the primary pathophysiology (137). The serum concentration, however, may not accurately reflect vitamin E status because this vitamin is primarily lipid bound. Therefore, vitamin E status should be determined from the ratio of serum vitamin E concentration to total serum lipid (i.e.,

cholesterol, triglycerides, phospholipids) concentration. A ratio of less than 0.5 mg/g or a serum vitamin E to total serum cholesterol concentration ratio of <235 µmol/mmol is considered evidence of deficiency (138,139). However, serum vitamin E to lipid ratio may not predict hepatic stores of the vitamin (140), although interestingly, serum vitamin E concentration alone correlates well with hepatic stores in patients with cirrhosis (141). Vitamin E deficiency may manifest in a neurologic syndrome that includes weakness and proximal muscle wasting, areflexia, and decreased proprioceptive and vibratory sensation (142) and hemolysis (143). Deficiency can be corrected with oral vitamin E supplementation of 400 to 1000 mg daily.

Vitamin K

Vitamin K deficiency is relatively uncommon in patients with cholestatic liver disease and when it occurs, it is usually found in conjunction with other fat-soluble vitamin deficiencies (e.g., vitamin A or E). Measurement of the prothrombin time is an insensitive indicator of vitamin K status and may often remain normal despite decreased plasma vitamin K_1 (phylloquinone) concentration (144). Vitamin K is a

cofactor for γ-glutamylcarboxylase, an enzyme that converts glutamate residues into γ-carboxyglutamate. Deficiency results in impaired carboxylation of prothrombin, producing abnormal prothrombin with no coagulant effect. Vitamin K deficiency has been associated with the development of metabolic bone disease, and supplementation with vitamin K_2 (vitamin form—menaquinone) leads to an increase in BMD in women with cirrhosis (145). This same study also suggested vitamin K_2 supplementation may have a preventive effect for hepatocellular carcinoma (146).

Trace Metals

Zinc

Zinc is required for the release of vitamin A from hepatic storage in retinol-binding proteins and therefore, zinc deficiency may promote vitamin A deficiency (147,148). Zinc supplementation may alleviate abnormalities in dark adaptation in some patients with cirrhosis (149). Zinc supplementation in patients with cirrhosis and low blood zinc concentration has been shown to increase the zinc concentration, improve urea kinetics, and alleviate encephalopathy (150). This finding suggests that low plasma zinc concentration is important in the pathophysiology of insulin resistance in cirrhosis and in improving glucose tolerance (151). Measurement of zinc in blood to detect deficiency may, however, be problematic. It is bound to albumin, and lower albumin concentration results in lower plasma zinc concentration (152); there is no known conversion factor to account for the low albumin level caused by decreased hepatic synthetic function. Therefore, reliance on plasma or serum zinc concentration may overestimate the prevalence of zinc deficiency in patients with significant hepatic dysfunction. Measurement of leukocyte zinc concentration may better reflect tissue stores (152). Increased renal zinc loss has been described in several studies in patients with either alcoholic-related or nonalcoholic liver disease and in patients with cirrhosis (153,154). In addition, intestinal zinc absorption may be impaired in some, but not all, patients with cirrhosis (155,156,157). After liver transplantation, serum zinc concentration increases and renal loss decreases in many patients (158).

Selenium

Serum hepatic selenium concentrations may be decreased in patients with cirrhosis, as well as in those with chronic hepatitis (159,160). Selenium deficiency has been associated with reversible cardiomyopathy, neuropathy, myopathy, macrocytosis, and pseudoalbinism. However, these have not been described in association with selenium deficiency in patients with liver disease (161,162). Burk et al. found that plasma glutathione peroxidase (GSH-Px) and selenoprotein P, two selenoproteins, were unaffected by low plasma selenium concentrations, suggesting that in patients with cirrhosis, low selenium concentration may itself not be a valid indicator of selenium deficiency (163), although other investigators have found both decreased plasma selenium and GSH-Px concentrations in patients with cirrhosis (164,165). Therefore, until selenium deficiency can be better defined in patients with hepatic dysfunction, routine supplementation cannot be recommended.

Malnutrition

Ingestion and absorption of a nutritionally adequate diet are necessary to maintain health. An imbalance between nutrient intake and requirements can lead to malnutrition, manifested by alterations in metabolism, organ function, and body composition. Malnutrition can be caused by specific mineral and micronutrient deficiencies. For example, inadequate iron consumption can cause iron deficiency and anemia, and inadequate vitamin D consumption can cause tetany, muscle weakness, and osteomalacia. Replacement of the deficient nutrient usually corrects the biochemical and functional abnormalities. However, prolonged micronutrient deficiency can cause irreversible organ damage. Malnutrition can also be caused by inadequate macronutrient intake. *Primary protein-energy malnutrition* (*PEM*) is caused by inadequate protein and energy consumption and usually affects children and elderly persons because of poor access to appropriate foods. Primary PEM includes several well-known deficiency syndromes described in children, such as kwashiorkor, marasmus, and nutritional dwarfism (Table 13.2). *Secondary PEM* represents fat and muscle depletion that

accompanies illness or injury and is caused by alterations in nutrient intake, digestion, absorption, or metabolism.

Table 13.2. Characteristics of Protein-Energy Malnutrition Syndromes in Children

Characteristic	Kwashiorkor	Marasmus	Nutritional dwarfism
Weight for age (% expected)	60–80	<60	<60
Weight for height	Normal or decreased	Markedly decreased	Normal
Edema	Present	Absent	Absent
Mood	Irritable when picked up	Apathetic when alone	Alert
Appetite	Poor	Good	Good

Specific micronutrient deficiencies and both primary and secondary PEM can affect liver structure and function. For example, choline deficiency causes hepatic steatosis (166). Both primary and secondary PEM can cause steatosis, abnormal liver biochemistries, hepatomegaly, and hepatic inflammation (167). In fact, abdominal distention observed in children with kwashiorkor is a consequence of hepatomegaly, in conjunction with intestinal dilatation and weak abdominal muscles. Ascites is not caused by PEM alone and is an indication that other pathogenic factors are involved. Hepatic steatosis is more marked when there is concomitant inflammatory stress, such as in children with kwashiorkor or patients with infection. For example, more than 40% of hepatocytes can have fatty infiltration in kwashiorkor (168). Increased liver biochemical test results occur in approximately 10% to 15% of patients who have anorexia nervosa (169). Serum alanine aminotransferase is the serum aminotransferase whose levels are most frequently elevated. Data from clinical reports have found that some patients with anorexia nervosa have serum aminotransaminase concentrations that are 20 times greater than the upper limits of the normal range. The mechanism responsible for the marked increase in liver biochemical test results is not clear. Histologic evaluation of liver tissue abnormalities in patients who have anorexia nervosa and abnormal liver biochemistries has detected a range of liver abnormalities, including subtle portal inflammatory infiltration to more severe ballooning of hepatocytes, accumulation of glycogen, and hepatic steatosis.

Nutrition support improves nutritional status when secondary PEM is mainly caused by anorexia and inadequate food intake. Although both structural and functional abnormalities associated with primary PEM are often reversible by nutritional therapy, prolonged primary PEM can cause irreversible changes in organ function and growth. Nutrition support is unlikely to restore muscle mass in patients who have acute or chronic inflammatory

stress because alterations in metabolism contribute to muscle wasting, which is unlikely to resolve until the underlying inflammatory illness is effectively treated.

Nutritional Assessment

Specific mineral and micronutrient deficiencies

Single mineral, vitamin, and trace mineral deficiencies often cause specific clinical abnormalities, which can be diagnosed by a comprehensive medical evaluation. Therefore, an appropriate history and physical examination, and laboratory tests can be used to diagnose specific nutrient deficiencies (Tables 13.3, 13.4 and 13.5) (170).

Protein-energy malnutrition

The diagnosis of PEM is different in adults compared with that in children because adults do not grow in height. In children, PEM results in growth and developmental delay. Therefore, pediatric growth charts are useful tools to help diagnose PEM in children because undernutrition stunts growth (170). The severity of PEM in children can be assessed by using the Waterlow classification, which determines a child's weight for height (wasting) and height for age (stunting) relative to normal median values (Table 13.6) (171).

Making a diagnosis of PEM in adults may be difficult because there is no universally accepted measure of nutritional status. All current parameters used to assess PEM are affected by illness and injury, so it is difficult to separate clinical influences from the influences of inadequate nutrient intake on markers of nutritional

status. In addition, nutritional assessment markers have been validated by determining their correlation with clinical outcome. Therefore, current nutritional assessment techniques identify patients who are at high risk for complications and mortality but do not necessarily identify patients who will benefit from nutritional therapy.

Table 13.3. Assessment of Mineral Deficiency

		Laboratory evaluation	
Mineral	**Symptoms or signs of deficiency**	**Test**	**Comment**
Sodium	Hypovolemia, weakness	Urinary sodium	May not represent body stores
Potassium	Weakness, paresthesias, arrhythmias	Serum potassium	May not represent body stores
Magnesium	Weakness, twitching, tetany, arrhythmias, hypocalcemia	Serum magnesium 24 h urine magnesium Urinary magnesium	May not represent body stores, urine is preferred May not represent body stores
Calcium	Osteomalacia, tetany, arrhythmias	Serum ionized calcium Dual-energy x-ray absorptiometry	Reflects bone calcium content
Phosphorous	Weakness, fatigue, hemolysis, respiratory muscle insufficiency	Plasma phosphorus	May not reflect body stores

Table 13.4. Assessment of Trace Mineral Deficiency

		Laboratory evaluation	
Trace Mineral	**Symptoms or signs of deficiency**	**Test**	**Comment**
Copper	Anemia, neutropenia, osteoporosis	Serum copper Plasma ceruloplasmin	May not reflect body stores Acute-phase reactant
Iodine	Hypothyroidism, goiter	Urine iodine Thyroid-stimulating hormone	Reflects recent intake Reflects thyroid function
Iron	Microcytic hypochromic anemia	Serum iron and total iron-binding capacity	Poor measure of body stores; high specificity when levels are low; poor sensitivity
Manganese[a]	Hypercholesterolemia, dementia, dermatitis	Serum manganese	May not reflect body stores
Selenium	Cardiomyopathy, myopathy, pseudoalbinism, macrocytosis	Serum selenium Blood glutathione peroxidase activity	May not reflect body stores
Zinc	Growth retardation, delayed sexual maturation, alopecia, acro-orificial skin lesion, diarrhea, mental status changes	Plasma zinc, leukocyte zinc	May not reflect body stores

[a]Manganese toxicity, manifested as extrapyramidal and parkinsonian-like symptoms, can occur in patients with chronic liver disease who are receiving long-term parenteral nutrition.

History and physical examination

We believe the best approach for evaluating nutritional status is to perform a careful *history and physical examination*. The history should assess

whether changes in body weight have recently occurred. Unintentional weight loss is associated with adverse clinical outcome. However, assessment of weight loss is complicated in patients with liver disease because of the confounding influence of edema and ascites on body weight. A loss of 10% or more of body weight within 6 months is associated with a poor clinical outcome (172). A diet assessment should be made to determine whether there has been a change in food intake, which can account for weight loss. Appetite, gastrointestinal function, and physical function should be reviewed to determine reasons for inadequate intake and whether alterations in nutrient intake were severe enough to lead to compromised function.

The physical examination should include a determination of BMI, which is calculated as weight (in kilogram) divided by height (in meter) squared. The assessment of BMI can help identify patients at increased risk for medical complications (Table 13.7). An estimate of "dry weight" in patients who have edema or ascites is necessary to obtain a valid estimate of the risk. Patients who are extremely underweight (BMI < 14 kg/m^2) are at high risk for nutrition-related medical complications and death and should be considered for hospital admission to receive nutritional therapy. The physical examination should search for evidence of fat and muscle wasting, decreased muscle strength, dehydration (e.g., hypotension, tachycardia, postural changes, mucosal xerosis, decreased axillary sweat, and dry skin), and fluid overload (e.g., edema, ascites).

Serum albumin concentration

In healthy adults, approximately 14 g of albumin is produced by the liver daily, which represents approximately 5% of the total 300 g body pool of albumin. Newly synthesized albumin has a half-life of approximately 20 days. Approximately one third of the total albumin pool is located in intravascular space and two thirds in extravascular space; approximately 5% of the intravascular albumin pool exchanges with extravascular albumin every hour, so there is a constant exchange of albumin between the two pools.

Serum albumin concentration has been used as a measure of nutritional status because children who have kwashiorkor have low albumin concentrations, and hypoalbuminemia is associated with an increase in medical complications and mortality in adults (173). Low serum concentrations of these proteins can help identify patients who are seriously ill. However, serum protein concentration is not a good marker of nutritional status because illness or injury, not malnutrition, is responsible for hypoalbuminemia in sick patients (174).

Inflammation and injury decrease albumin synthesis, increase albumin degradation, and increase albumin transcapillary losses from the plasma compartment. In fact, prolonged protein-energy restriction in patients with anorexia nervosa (175) or in human volunteers (176) causes a marked decrease in body weight, but not hypoalbuminemia. Although fasting or inadequate protein and energy intake decreases the rate of albumin synthesis, serum albumin concentration does not usually decline because of albumin's large body pool size (300 g) and slow turnover rate (20-day half-life), a compensatory decrease in albumin degradation, and the transfer of extravascular albumin to the intravascular compartment (177,178).

Table 13.5. Assessment of Vitamin Deficiency

		Laboratory evaluation	
Vitamin	**Symptoms or signs of deficiency**	**Test**	**Comment**
A (Retinol)	Night blindness, Bitot's spots, keratomalacia, follicular hyperkeratosis, xerosis	Serum retinol	Reflects recent intake and body stores
D (Ergocalciferol)	Rickets, osteomalacia, osteoporosis, bone pain, muscle weakness, tetany	Serum 25-hydroxyvitamin D	Reflects body stores
E (α-tocopherol)	Hemolysis, retinopathy, neuropathy	Serum tocopherol Serum tocopherol: total lipid ratio	Reflects body stores Ratio is preferred test
K (Phylloquinone)	Easy bruising and bleeding, abnormal clotting	Prothrombin time	Not specific for vitamin K
B_1 (Thiamine)	Beriberi, cardiac failure, Wernicke's encephalopathy, peripheral neuropathy, fatigue, ophthalmoplegia	RBC transketolase activity	Reflects body stores
B_2 (Riboflavin)	Cheilosis, sore tongue and mouth, eye irritation, seborrheic dermatitis	RBC glutathione reductase activity	Reflects body stores
B_3 (Niacin)	Pellagra (dermatitis, diarrhea, dementia), sore mouth and tongue	Urinary *N*-methyl-nicotinamide	Reflects recent intake
B_5 (Pantothenic acid)	Fatigue, weakness, paresthesias, tenderness of heels and feet	Urinary pantothenic acid	Reflects recent intake
B_6 (Pyridoxine)	Seborrheic dermatitis, cheilosis, glossitis, peripheral neuritis, convulsions, hypochromic anemia	Plasma pyridoxal phosphate	Reflects body stores
B_7 (Biotin)	Seborrheic dermatitis, alopecia, change in mental status, seizures, myalgia, hyperesthesia	Plasma biotin	Unknown
B_9 (Folic acid)	Megaloblastic anemia, glossitis, diarrhea	Serum folic acid; RBC folic acid	Reflects body stores and recent intake Reflects body stores
B_{12} (Cobalamin)	Megaloblastic anemia, paresthesias, decreased vibratory or position sense, ataxia, mental status changes, diarrhea	Serum cobalamin, methylmalonic acid Serum methylmalonic acid	Reflects body stores Tests functional block in enzyme
C (Ascorbic acid)	Scurvy, petechia, purpura, gingival inflammation and bleeding weakness, depression	Plasma ascorbic acid Leukocyte ascorbic acid	Reflects recent intake Reflects recent stores

RBC, red blood cells.

The relationship between serum albumin concentration and nutritional status is particularly confounded in patients with liver disease. It is likely that

low plasma albumin concentrations in patients with liver disease is primarily caused by inflammation, which increases transcapillary losses of albumin from intravascular to extravascular compartments (179), and by decreased albumin synthesis in select patients with advanced cirrhosis. In fact, many patients with cirrhosis have normal or high rates of albumin synthesis (180).

Table 13.6. Waterlow Classification of Protein-Energy Malnutrition in Children

	Normal	Mild	Moderate	Severe
Weight for height (wasting)				
Percent of median NCHS standard	90–110	80–89	70–79	<70
Standard deviation from the NCHS median	+*Z* to -*Z*	-1.1 *Z* to -2 *Z*	-2.1 *Z* to -3 *Z*	<-3 *Z*
Height for age (stunting)				
Percent of median NCHS standard	95–105	90–94	85–89	<85
Standard deviation from the NCHS median	+*Z* to –*Z*	–1.1 *Z* to –2 *Z*	–2.1 *Z* to –3 *Z*	<–3 *Z*

NCHS, National Center for Health Statistics; *Z*, 1 standard deviation.

Serum prealbumin concentration

Prealbumin, which is a component of the retinol-binding prealbumin complex and serves as a transport protein for thyroid hormones, has also been proposed as a measure of nutritional status. It has been hypothesized that prealbumin is a better marker of nutritional status than albumin because prealbumin has a much shorter half-life (2 to 3 days) than albumin (approximately 20 days). Prealbumin is synthesized by the liver and catabolized by the kidneys. Serum prealbumin concentration is an unreliable index of nutritional status in patients with liver disease because its serum concentrations decrease in patients with liver disease or inflammation and increase in patients with renal failure (181).

Creatinine–height index

The amount of creatinine excreted in urine provides an index of skeletal muscle mass (182,183) and has been used as a marker of nutritional status. Every day, a small portion (approximately 2%) of creatine, which is distributed primarily in skeletal muscle, is converted by an irreversible, nonenzymatic reaction to creatinine in the liver. Creatinine is subsequently excreted unchanged in urine. The creatinine–height index (CHI) is determined by measuring urinary creatinine excretion for 24 hours in relation to the patient's height while the patient is consuming a creatine- and creatinine-free diet. It is not known whether CHI is decreased in patients with liver disease because of decreased hepatic creatinine synthesis.

Table 13.7. Classification of Nutritional Status by Body Mass Index in Adults

Body mass index (kg/m^2)	Nutritional status
<16.0	Severely malnourished
16.0–16.9	Moderately malnourished
17.0–18.4	Mildly malnourished
18.5–24.9	Normal
25.0–29.9	Overweight
30.0–34.9	Obese (class I)
35.0–39.9	Obese (class II)
>40.0	Obese (class III)

Immune competence

Delayed cutaneous hypersensitivity (DCH) is altered by severe malnutrition, and patients suffering from severe PEM can become anergic. Up to 60% of patients with cirrhosis and more than 90% of patients with acute hepatic failure are anergic (184). However, a large number of clinical factors also influence DCH, making it a poor marker of malnutrition in sick patients with liver disease. Cirrhosis, hepatitis, infection, uremia, immunosuppressant therapy, and surgery impair DCH in the absence of malnutrition.

Malnutrition in Patients with Liver Disease

PEM is common in patients with chronic liver disease. However, the criteria used to diagnose PEM are affected by liver disease itself, so the presence and severity of malnutrition is often related to the clinical stage of liver disease (185,186). For example, a survey conducted in more than 1,400 patients with cirrhosis found that 20% of patients with Child-Pugh A cirrhosis and 60% of those with Child-Pugh C cirrhosis had PEM (186). PEM is a nearly universal finding in patients awaiting liver transplantation (187,188).

Although indicators of nutritional status do not necessarily reflect adequacy of nutrient intake, these indicators can be useful prognosticators of clinical outcome in patients with liver disease. PEM is associated with an increased risk of infections, multiple organ complications, esophageal variceal hemorrhage, and increased mortality before transplantation, and increased risk of infection, prolonged hospitalization, and mortality after transplantation (188,189,190,191,192,193,194,195,196). Muscle wasting in patients with alcoholic cirrhosis is associated with increased postoperative mortality (197). Malnourished patients undergoing liver transplantation are twice as likely to have treatment-refractory ascites and not as likely to survive as those who are not judged to be malnourished (185,188).

Metabolic Syndrome and Nonalcoholic Liver Disease

Metabolic syndrome represents a constellation of metabolic abnormalities that are risk factors for coronary heart disease. The notion of a metabolic syndrome was first considered by Vague more than 50 years ago, who noticed that an increase in upper body fat, which he called *masculine or android obesity*, was observed commonly in obese men and was associated with diabetes, coronary heart disease, and gout (198).

The metabolic syndrome concept continued to advance and was been defined by the National Cholesterol Education Program as having three or more of the following characteristics: (i) Abdominal obesity (waist circumference >102 cm in men and >88 cm in women), (ii) increased fasting blood glucose level (>100 mg/dL), (iii) increased serum triglyceride levels (≥150 mg/dL), (iv) low serum HDL-cholesterol concentration (<40 mg/dL in men and <50 mg/dL in women), and (v) increased blood pressure (≥130/85 mm Hg) (199). The prevalence of the metabolic syndrome in adults increases directly with age. In the United States, the prevalence of the metabolic syndrome is approximately 7% in those aged 20 to 29 years and increases to approximately 45% in those aged 60 years and older (200). Many obese patients with metabolic syndrome also have NAFLD (201,202), and it has been suggested that NAFLD should be considered a component of the metabolic syndrome (203). In fact, the presence of metabolic syndrome may predict concurrent NAFLD (204). The mechanism responsible for the close relationship between metabolic syndrome and NAFLD is not clear, but it likely involves increased release of FFAs into the bloodstream, which can cause increased hepatic fatty acid uptake and triglyceride accumulation, increased hepatic glucose production, impaired insulin-mediated skeletal muscle glucose uptake, and increased hepatic VLDL-triglyceride production (62,205,206,207). Moreover, increased amount of intrahepatic fat itself can impair hepatic insulin action (58) and stimulate VLDL-triglyceride secretion by providing a source of fatty acids for triglyceride production (208).

Weight loss is the cornerstone of therapy for patients with the metabolic syndrome and NAFLD. Moderate weight loss ameliorates the metabolic abnormalities associated with both the metabolic syndrome and NAFLD. The results from several studies suggest that a gradual loss of 10% or more of body weight can correct abnormal liver chemistries and decrease liver size, fat content, and some features of steatohepatitis (209,210,211). Gastrointestinal surgery is the most effective approach for achieving weight loss in extremely obese patients. The gastric bypass procedure is the most common bariatric surgical procedure performed in the United States, accounting for more than 70% of all bariatric procedures. Currently, more than 140,000 gastric bypass procedures are performed each year in the United States; on average, obese patients who undergo gastric bypass lose about two thirds of their excess weight or approximately 30% of their initial weight (212). However, rapid and marked loss after very low calorie diets (213) or fasting (214) has been associated with an increase in hepatic inflammation and fibrosis, and even liver failure.

Parenteral Nutrition–Associated Liver Disease

Two forms of PN-associated liver disease have been described, one in which cholestasis predominates and the other in which steatosis (both micro- and macrovesicular) predominates. The former is more prevalent in infants, especially those who have been delivered preterm, and the latter predominates in adults, although there is overlap. Cholestasis is associated with hepatocyte ballooning, Kupffer cell hyperplasia, bile duct plugging, and, in infants, extramedullary hematopoiesis. Initially, inflammation is generally minimal, with limited periportal lymphocyte infiltration, although this may progress to steatohepatitis with hepatocyte necrosis and pericellular fibrosis, bile duct hyperplasia and proliferation, and eventual progression to cirrhosis and hepatic failure.

Serum hepatic aminotransferase concentrations (i.e., AST, ALT) often increase to between 1.5 and 3.0 times normal within 2 to 3 weeks of beginning PN (215), although it should be recognized that these laboratory tests are both insensitive and nonspecific indicators of hepatic dysfunction and hepatic histopathology in this population (216). The elevation in AST and ALT levels is generally transient and may be related to a combination of cytokine release potentiated by the underlying illness and the absence of oral intake and portal nutrient absorption. Serum bilirubin concentration is rarely elevated in adults, although it may be observed in preterm infants. In these individuals, the incidence of PN-associated liver disease ranges between 15% and 85% across various centers, although in the largest study of 42 infants, Sondheimer et al. described an incidence of 67%, with 13% having progressed to hepatic failure after only 6 weeks of PN (217). In adults, the prevalence of significant liver enzyme abnormalities (defined as elevations in the levels of at least two of the three enzymes—ALT, AST, or alkaline phosphatase—to >1.5 times the upper limits of normal for >6 months) was 55% at 2 years, 64% at 4 years, and 72% at 6 years in a group of 90 (57 with histologic data)

patients (218). The percentage of patients who developed more complicated liver disease with one or more of six characteristics—serum bilirubin concentration more than 3.5 mg/dL for at least 1 month, ascites, hepatic encephalopathy, variceal hemorrhage, factor V concentration less than 50%, or portal fibrosis or cirrhosis on biopsy—was 26% at 2 years, 39% at 4 years, 50% at 6 years, and 53% at 8 years. Elevation of serum bilirubin concentration may be an ominous sign in adults; the time between onset of this observation and death was a median of 10.8 months in one study (219). All patients with a total serum bilirubin concentration more than 3.6 ± 1.2 mg/dL eventually died within 6 to 12 months.

Pathophysiology

Patients with the least residual functional intestine are at greatest risk for development of total parenteral nutrition (TPN)-associated liver disease and subsequent death from hepatic failure (220). This observation suggests that the more severe the malabsorption, the greater the risk for liver disease.

Nutrient absorption and metabolism differ significantly between orally ingested nutrients and those that are intravenously infused. After absorption of orally ingested nutrients into the portal circulation, nutrient remnants undergo hepatic first pass metabolism. Subsequently, metabolized products are circulated systemically through the right side of the heart and eventually to the kidneys where additional metabolism, reabsorption, or excretion may occur. Intravenously infused nutrients bypass the portal circulation. These are first transported to the heart and then subsequently to the liver through the hepatic artery rather than through the portal vein. A sulfur amino acid, methionine, is normally metabolized to cysteine and other metabolites through the hepatic trans-sulfuration pathway. Cysteine concentration increases after an oral and enteral methionine load (221). However, when methionine is infused intravenously, serum cysteine is nearly undetectable (221).

There are several other products of the trans-sulfuration pathway for which methionine is a substrate, including carnitine and choline (222,223,224,225). Although carnitine concentrations are decreased by approximately 50% from normal in patients who receive long-term TPN compared with a decrease to 10% of normal in case of true carnitine deficiency (222,223,224), carnitine supplementation does not reverse either steatosis or liver test abnormalities (225,226). Therefore, it is unlikely that carnitine deficiency is a cause for TPN-associated liver disease.

Plasma free choline concentration is below normal in more than 90% of patients who require TPN (227). Choline is required for the synthesis of VLDL, which transports triglycerides from the liver. During choline deficiency, hepatic triglyceride accumulates because there is insufficient VLDL to transport the triglyceride from the liver. A significant negative correlation exists between plasma free choline concentration and AST/ALT in patients who require long-term TPN (227). Choline supplementation ameliorates hepatic steatosis and leads to improvement in AST, ALT, and alkaline phosphatase levels in patients who require long-term TPN (228,229). Choline deficiency may be a necessary but insufficient cause for the progression of steatosis to steatohepatitis and more severe forms of TPN-associated liver disease. A second hit, such as lipid peroxidation, may be required (230,231). In a choline-deficient rodent model, Eastin et al. found that animals treated with endotoxin (lipopolysaccharide [LPS]) had significantly worse hepatic aminotransferase abnormalities, as well as steatohepatitis, when compared with choline-sufficient animals treated with LPS that exhibited minor biochemical abnormalities and no histologic changes (232). Methionine metabolism is impaired and its concentration in the blood increased because of what appears to be an ineffective hepatic trans-sulfuration pathway with regard to the metabolism of its intravenously infused form (84,221). Studies in rabbis have suggested that this buildup of methionine may have additional toxic effects on the liver (233).

Plasma free choline concentration is also decreased in infants who require TPN (234), and in addition to malabsorption and lack of choline in TPN, this may be related to an incompletely developed hepatic trans-sulfuration pathway (235,236). This may also result in taurine deficiency, although taurine-supplemented TPN was not shown to result in a decreased incidence of hepatic abnormalities (237,238,239). Oral taurine supplementation results in an increased taurine to glycine conjugated bile acid ratio (240), although this has not been demonstrated with intravenously infused taurine. Infants also have additional risk factors for the development of TPN-associated liver disease. These include an increased incidence of infections and antibiotic use, many surgical procedures, hypoxia, hypotension, and many blood transfusions (241,242).

Several nutrient toxicities have also been implicated in the development of TPN-associated liver disease. These including dextrose overfeeding (>50 kcal/kg per day), which leads to an increased portal insulin to glucagon ratio (243,244). The increased insulin concentration inhibits mitochondrial carnitine acyltransferase, which is the rate-limiting factor for fatty acid oxidation (245), and increases hepatic acetyl-coenzyme A concentration and induction of acetyl-coenzyme A carboxylase, which stimulates fatty acid synthesis (246,247).

Massive lipid emulsion infusion (>2.5 to 3.0 g/kg per day) has been associated with lipid overload

syndrome and hypoxia, thrombocytopenia related to disseminated intravascular coagulation, cholestasis, and death (248,249), although two retrospective reviews have suggested that hepatic aminotransferase abnormalities are more likely when the lipid emulsion infusion exceeds 1.0 g/kg per day (218,219). It has been hypothesized that the large concentration of plant sterols (phytosterols) contained in lipid emulsion results in decreased bile acid secretion and decreased secretory function in isolated rat hepatocyte couplets (250). However, it remains unclear whether the increased serum phytosterol concentration observed in patients on TPN who receive lipid emulsion is the cause of, rather than the result of, decreased hepatic phytosterol metabolism from other factors including those discussed in the preceding text. Despite the association of phytosterolemia and lipid emulsion dose with TPN-associated liver disease, reduction of the lipid emulsion infusion has not resulted in alleviation or resolution of TPN-associated hepatic derangements (251). There has been no randomized placebo-controlled trial to implicate a causal relationship between lipid emulsion infusion at conventional doses and hepatic abnormalities.

Several case reports have suggested a role for manganese toxicity in the development of TPN-associated liver disease (252,253,254). However, given that the excretion route for manganese is through the biliary tract, the likelihood is that manganese accumulates in the liver in patients with preexisting cholestasis. Aluminum contamination, once a problem in TPN solutions and a cause of cholestasis in animal models (255,256,257), has largely been eliminated; specific components of TPN such as calcium, potassium, phosphate, and sodium salts may still contain significant aluminum contamination. However, the overall contribution of aluminum contamination to the TPN solution is negligible (258,259). Copper toxicity resulting from TPN has not been described as a potential etiology for TPN-associated liver disease. However, given that the primary route of excretion for copper, like manganese, is through the biliary system, these trace metals should be withheld from the TPN solutions in patients with cholestasis.

Treatment of Total Parenteral Nutrition–Associated Liver Disease

Few therapies for TPN-associated liver disease are available. Carbohydrate and lipid overfeeding should be avoided. Intravenous choline currently remains an investigational therapy. Ursodeoxycholic acid has been described in a single case report and in a case series of nine patients in adults (260,261) and in a retrospective review and two open-labeled studies in neonates (262,263,264). Although cholestasis was not eliminated, one study reported a significant decrease in the serum bilirubin concentration in neonates who were given 15 to 45 mg/kg per day (262). In another study, the use of metronidazole was associated with improvements in response to hepatic derangements, but the patients studied also had active Crohn's disease and were overfed, two factors that may also lead to abnormal hepatic aminotransferases (265).

Intestinal transplantation is an option for patients with progressive and irreversible TPN-associated liver disease. It must be recognized, however, that in many patients exhibiting an elevation in hepatic aminotransferase levels the disease may not progress to the more severe stage. Currently, other than residual bowel length, there are no known predictors that are useful in estimating the likelihood of development of progressive fibrosis and eventual hepatic failure. Early stages of TPN-associated liver disease may be reversible with isolated intestinal transplantation as absorption improves (266). However, patients with cirrhosis or portal hypertension require combined liver/small intestine transplantation for survival. It is important that such patients be referred early to a transplantation center that is experienced not only in intestinal transplantation but also in the medical management of patients with intestinal failure. An argument could be made that all patients with intestinal failure should be seen in specialized centers regardless of their need for transplantation, given that mortality is lower in such centers (267). In the United States, 74% of all patients on the transplantation list awaiting the availability of a small intestine also require a liver (268). Furthermore, among patients in the waiting list who are in need of combined small intestine/liver transplantation, the mortality is 55% (269). Post-transplantation survival is also inferior in patients undergoing combined small intestine/liver transplantation when compared with those who receive an isolated small intestinal graft (Table 13.8) (270,271).

Nutritional Management of Patients with Liver Disease

Alcoholic Hepatitis

The use of standard amino acids, usually given with hypotonic dextrose through a peripheral vein, has been reported in several prospective randomized controlled trials (PRCTs) involving patients with alcoholic hepatitis (272). Nutritional therapy often improved the response of standard markers of nutritional status and liver chemistries but did not affect morbidity and mortality. The clinical efficacy of peripheral parenteral amino acids in alcoholic hepatitis has been evaluated by

several groups (273). Most studies found improved histology or liver biochemistries in patients who received parenteral amino acids, and one study claimed that survival was improved. Some studies evaluated the use of nutritional therapy in conjunction with corticosteroids in patients with alcoholic hepatitis. One PRCT compared patients randomized to peripheral parenteral nutrition (PPN) (50 g glucose and 35 g amino acids daily), oxandrolone, the combination of PPN and oxandrolone, or no treatment for 21 days. Child-Pugh score improved significantly in those who received PPN with oxandrolone, but mortality rates were similar in all groups (274,275). Mendenhall et al. studied the effect of the combination of oxandrolone with a branched-chain amino acid (BCAA)-supplemented formula in patients with moderate or severe alcoholic hepatitis (276). On an intention-to-treat basis, mortality rates were similar in both treated and control groups of patients with severe alcoholic hepatitis. A subgroup analysis that included only those subjects with markers suggesting either advanced liver disease or moderate malnutrition found that hepatic function was improved. In addition, a significant reduction in 1- and 6-month mortality rates was observed in subjects who received nutritional therapy. Enteral tube feeding was compared to prednisolone (40 mg/day) in a group of 71 patients (80% with cirrhosis) who developed alcoholic hepatitis. Short-term mortality (during treatment) was similar between the two groups but was greater in the steroid group at 6 weeks; this was primarily related to infections (277).

Table 13.8. Survival Data for Small Intestine and Liver/Small Intestine Transplantation

Transplantation type	Number of transplantations	Months post-transplantation	Survival Survival rate	95% confidence limits
Intestine alone	351	12	83.41	(79.10,87.72)
		36	64.67	(58.40,70.93)
		48	58.34	(51.41,65.27)
Liver/intestine	317	12	60.37	(54.73,66.01)
		36	49.46	(43.47,55.44)
		48	46.38	(40.29,52.47)
Multivisceral	253	12	69.39	(63.33,75.44)
		36	55.67	(48.56,62.77)
		48	54.65	(47.40,61.91)

Based on Organ Procurement and Transplantation Network (OPTN) data as of December 5, 2005. This work was supported in part by Health Resources and Services Administration contract 231-00-0115. Alcoholic Cirrhosis

The results of several PRCTs evaluating oral and enteral tube feeding in patients with alcoholic cirrhosis demonstrate that aggressive feeding can be given safely and may have clinical benefits (278,279,280). Oral or enteral tube feedings resulted in the delivery of the desired nutrient level and often provided twice the protein and calories ingested ad lib by the control group. Feedings were usually well tolerated and no serious adverse events were described. Patients who received nutritional support had evidence of improvements in hepatic function (as assessed by hepatic function studies and liver biochemistries), response to hepatic encephalopathy, and Child-Pugh classification, and sometimes improved survival in patients fed with a BCAA-enriched formula.

Several PRCTs have found that enteral nutrition support in patients hospitalized for complications of cirrhosis was well tolerated and improved liver function, response to hepatic encephalopathy, and Child-Pugh score (278,279,281,282,283). In addition, one study found a trend toward decreased in-hospital mortality (3 to 4 weeks) in patients with cirrhosis and PEM who were given enteral tube feeding with a BCAA-enriched formula (mean intake = 2,115 kcal/day; mortality 12%) compared with an ad lib hospital diet (mean intake = 1,320 kcal; mortality 47%) (283). However, the difference between groups may have been exaggerated by the unusually high mortality rate observed in the control group.

Hepatic Encephalopathy

Most patients with cirrhosis can tolerate an increasing amount of standard protein without worsening encephalopathy. Protein restriction should not be considered routine; in fact, protein requirements are increased in patients with end-stage liver disease. Portosystemic encephalopathy can and should be aggressively treated using standard therapy before protein restriction is instituted. Ingestion of excessive dietary protein has been identified as the precipitating factor for the development of hepatic encephalopathy only in 7% to 9% of patients (283). Adults require 1.0 to 1.5 g/kg per day of protein on the basis of their dry body weight and children may require, depending on their age, 2.5

to 3.0 g/kg per day to avoid a catabolic state. Dietary protein content should be incrementally increased as encephalopathy alleviates in those patients for whom protein restriction is necessary until the tolerance point is established. Several studies have suggested amelioration in hepatic encephalopathy when vegetable protein–based diets are prescribed (284,285,286,287). The efficacy of vegetable protein–based diets in ameliorating hepatic encephalopathy is probably not related to their amino acid composition because this diet is similar in BCAA composition to meat protein–based diets but is more likely related to the fiber content and stool-bulking properties of such a diet. Fecal volume and weight increase with a vegetable protein diet (284). Although the methionine content of animal protein–based meals is substantially greater than that contained in vegetable protein–based meals, methionine concentration was not reduced in patients with cirrhosis who were fed a vegetable protein diet (284,287). This may be related to decreased methionine metabolism through the trans-sulfuration pathway. A diet based solely on vegetable protein, however, is unpalatable and, therefore, not practical. Vegetable protein should, however, be incorporated into the usual diet.

Lactulose is a synthetic disaccharide that consists of galactose and fructose, neither of which is hydrolyzed by the human enterocyte. Fecal nitrogen excretion is enhanced with lactulose (288). This appears to be related to the enhancement of nitrogen retention by excreted colonic flora (289). Similar effects were observed in patients with cirrhosis who were fed vegetable protein diets (290), as well as in patients who received soluble-fiber (pectin) supplementation (291). Soluble fiber is fermented by colonic bacteria to short-chain fatty acids, among other metabolic products.

The use of formulas with high concentrations of BCAAs (e.g., leucine, isoleucine, and valine) and small amounts of aromatic amino acids (AAAs) (e.g., phenylalanine, tyrosine, and tryptophan, Table 13.9) has been proposed in patients with hepatic encephalopathy on basis of the observation that the ratio of plasma BCAAs to AAAs is reduced in patients who have cirrhosis (292). According to the false neurotransmitter hypothesis, restoration of a normal BCAA to AAA ratio in the plasma would lead to decreased AAA transport across the blood–brain barrier and, subsequently, lower serotonin synthesis in the brain (293,294).

BCAA-enriched liquid formulas, which contain approximately 35% of total amino acids in the form of BCAAs, may be useful in a small percentage of patients with cirrhosis who are truly intolerant to increasing dietary protein. As much as 80 g of protein given as BCAA-enriched solutions has been tolerated in patients who could not tolerate 40 g of standard dietary protein (295). The large expense of BCAA-enriched solutions discourages their use in most settings. The clinical efficacy of parenteral BCAA-enriched TPN solutions in patients with acute hepatic encephalopathy has been evaluated in nine PRCTs. Five of these trials were reviewed using meta-analytic methodology to pool data across studies (296). Patients who received BCAA-enriched solutions demonstrated a statistically significant improvement in mental recovery from high-grade encephalopathy during short-term (7 to 14 days) nutritional therapy. Considerable heterogeneity in mortality rates between studies precluded meaningful aggregation of mortality data. Although the pooled analysis of trials suggest a beneficial effect of BCAA-enriched formulas as primary therapy in patients with acute hepatic encephalopathy, the studies have several shortcomings that limit enthusiasm for this relatively expensive therapy. The control groups usually received suboptimal, and possibly harmful, nutritional support consisting of high-dextrose solutions without amino acids, and there is considerable heterogeneity in study design. Only one study compared BCAA-enriched TPN with a standard amino acid TPN solution. None of the studies reported on complications associated with nutritional therapy and none evaluated whether short-term benefits of nutritional therapy led to a long-term reduction in complications. A more recent review of the same studies included in the meta-analysis by Naylor et al. albeit with some additional data; Gluud; and Ericksson and Conn concluded that BCAA use had no effect on mortality and that current evidence-based literature did not support the routine use of BCAAs (297,298,299). Data from a more recent 1-year double-blind randomized multicenter trial of 174 patients found that treatment with oral BCAA supplementation significantly reduced length of hospital stay, mortality, and anorexia, and improved the Child-Pugh score, although compliance was poor (300). A Cochrane database review of the use of BCAA in patients with chronic hepatic encephalopathy identified 11 randomized trials that included a total of 556 patients (301). A significant improvement was seen with BCAA use in terms of severity of hepatic encephalopathy, although this positive outcome was generally observed only in studies of poor methodological quality; mortality was unaffected. The concept that increasing the plasma BCAA to AAA ratio leads to decreased encephalopathy has been questioned by some investigators because brain uptake of BCAA in some patients with cirrhosis may be similar to that in healthy controls (302) and may be a better correlate of hepatic function than the degree of encephalopathy in others (303,304).

Nutritional Support of the Peritransplantation Patient

The indications for the provision of nutritional support in the patient with hepatic failure awaiting transplantation, as well as the transplant recipient after

transplantation, are the same as those of other perioperative patients. Hypoglycemia is a life-threatening complication of hepatic failure due to impaired gluconeogenesis and increased glucose uptake caused by hyperinsulinemia, and patients may require a continuous glucose or dextrose supply (minimum 150 to 200 g/day). Intervention should be provided rapidly in malnourished patients because moderately severe and severe malnutrition are risk factors for poor wound healing, wound dehiscence, infection, and death postoperatively (188,189,190,191,192,193,194,195,196) or in patients who are unable to meet their daily nutritional requirements. There is however a paucity of data to support the effect of perioperative enteral supplements, tube feeding, or parenteral nutrition on transplant outcome. Nasoenteric feeding is the simplest measure and can be safely accomplished even in patients with esophageal varices. (305), although there are risks for aspiration and sinusitis. Oral intake should be encouraged unless contraindicated, even with supplemental tube feeding. A nasoenteric tube can remain in place for

up to 4 to 6 weeks. Bolus or overnight feeding through a percutaneously inserted gastrostomy tube may also be undertaken. In patients with ascites, a large-volume paracentesis should be undertaken before percutaneously inserted gastrostomy tube placement (306,307).

Sodium restriction is necessary in patients with ascites or edema, although free water should not be restricted in the absence of severe hyponatremia (sodium <120 meq/L).

Table 13.9. Parenteral and Enteral Branched-Chain Amino Acid Formulas

A. PARENTERAL

	Increased essential amino acids				Increased Branch-Chain Amino Acids

After liver transplantation, the indications for parenteral nutrition include the inability to utilize the gastrointestinal tract for feeding because of postoperative ileus, enterocutaneous or biliary fistulas, and so on. In general, most liver transplantation patients can safely receive tube feedings within 18 to 24 hours of transplantation (308). Jejunostomy tubes for postoperative feeding can be placed safely during the transplantation procedure (309).

Annotated References

Als-Nielsen B, Koretz RL, Kjaergaard LL, et al. Branched-chain amino acids for hepatic encephalopathy. *Cochrane Database Syst Rev* 2003;(2):CD001939.

These investigators identified 11 randomized trials through the Cochrane Hepatobiliary Group Controlled Trials Register, pharmaceutical companies, manual searches of biographies and journals, contacts with authors of trials, and other online searches that included 556 patients. Overall, BCAA significantly increased the number of patients who had improvement in response to hepatic encephalopathy, although there was no evidence that the use of BCAA affected other morbidity or survival. In addition, the trials in which benefit was observed in hepatic encephalopathy were generally of poorer quality in which there were breakdowns in randomization or blinding of the investigator and/or research subject.

Buchman AL, Dubin M, Moukarzel A, et al. Choline deficiency: a cause of hepatic steatosis associated with parenteral nutrition that can be reversed with an intravenous choline chloride supplementation. *Hepatology* 1995;22:1399–1403.

These investigators demonstrated in a 15-patient placebo-controlled trial that intravenous choline supplementation for up to 24 weeks leads to the resolution of hepatic steatosis in patients who required parenteral nutrition. The resolution of hepatic steatosis was associated with decreases in serum ALT and alkaline phosphatase concentrations. This study suggests choline is an essential nutrient for patients who require parenteral nutrition.

Cavicchi M, Beau P, Crenn P, et al. Prevalence of liver disease and contributing factors in patients receiving home parenteral nutrition for permanent intestinal failure. *Ann Intern Med* 2000;132:525–532.

These investigators retrospectively evaluated 90 long-term home TPN patients who had received TPN for a median of 6 months (range 3 to 132 months). The prevalence of complicated liver disease, primarily indicative of portal hypertension, was 26% at 2 years and 50% at 6 years. After a median of 26 months, 17 patients showed evidence of hepatic fibrosis and 5 patients had developed cirrhosis after a median of 37 months. Twenty-two percent of all deaths were caused by liver failure in this home TPN group. Patients with the least residual intestine and those who received more than 1g/kg per day of lipid emulsion were at greatest risk for the development of chronic cholestasis.

Eastin CE, McClain CJ, Lee EY, et al. Choline deficiency augments an antibody to tumor necrosis factor-α attenuates endotoxin-induced hepatic injury. *Alcohol Clin Exp Res* 1997;21:1037–1041.

These investigators showed that a choline-deficient diet leads to the development of hepatic injury in a rodent model but that the administration of endotoxin in the presence of choline deficiency was necessary to provoke the development of steatohepatitis and hepatic necrosis; endotoxin injection alone resulted in increased serum TNF concentration but was not associated with hepatic abnormalities.

Horowitz JH, Rypins EB, Henderson JM, et al. Evidence for impairment of transsulfuration pathway in cirrhosis. *Gastroenterology* 1981;81:668–675.

These investigators administered an oral loading dose of methionine and then measured the plasma elimination half-life, as well as methionine metabolic products obtained through the hepatic trans-sulfuration pathway, in normal volunteers and in patients with cirrhosis. In the patients with cirrhosis the basal plasma methionine concentration was significantly elevated, clearance was delayed, and urinary sulfate elimination was impaired. Homocystine, cystathionine, homoserine, and cystine did not accumulate in plasma or urine, which suggested that the block in the hepatic trans-sulfuration pathway in cirrhosis is above the level of homocystine synthesis.

Madden AM, Morgan MY. Resting energy expenditure should be measured in patients with cirrhosis, not predicted. *Hepatology* 1999;30:655–664.

These investigators compared estimated resting energy expenditure from indirect calorimetric measurements with several formulas for energy expenditure, including the Harris-Benedict equation and others, in 100 patients with cirrhosis and 41 controls. They found that estimates of energy expenditure were generally elevated even in patients with stable cirrhosis compared to controls, although the formula both over- and underestimated REE by 460 to 424 kcal/day. Therefore, REE should be estimated by indirect calorimetry if available when determining nutritional requirements. The amount of fat=free mass was actually the strongest predictor of REE.

Petrides AS, Stanley T, Matthews DE, et al. Insulin resistance in cirrhosis: prolonged reduction of hyperinsulinemia normalizes insulin sensitivity. *Hepatology* 1998;28:141–149.

Using a euglycemic insulin-clamp technique, these investigators found that insulin-mediated glucose uptake was significantly increased, which was accounted for entirely by the impairment of nonoxidative glucose disposal in 8 patients with stable cirrhosis when compared with healthy volunteers. When nonoxidative glucose disposal was normalized during octreotide infusion over 96 hours, insulin-mediated glucose utilization also became normal. This suggests that chronic hyperinsulinemia is a cause for insulin resistance in cirrhosis.

Chapter 14
Hepatic Fibrosis

Scott L. Friedman

Key Concepts

- Hepatic fibrosis is a reversible wound-healing response characterized by the accumulation of extracellular matrix (ECM) or "scar"; it follows chronic, but not self-limited, liver disease. The ECM components in fibrotic liver are similar, regardless of the underlying cause.
- Activation of hepatic stellate cells is the central event in hepatic fibrosis. These perisinusoidal cells and related myofibroblasts from intra- and extrahepatic origins orchestrate an array of changes including degradation of the normal ECM of liver, deposition of scar molecules, vascular and organ contraction, and release of cytokines.
- Not only is hepatic fibrosis reversible, but it is also increasingly clear that cirrhosis may be reversible as well. The exact stage at which fibrosis/cirrhosis becomes truly irreversible, and its biological determinants, are not known.
- Antifibrotic therapies have entered clinical trials. Emerging therapies will be targeted to those patients with reversible disease. The paradigm of stellate cell activation provides an important framework for defining therapeutic targets. Currently, the most significant impediment to drug development is the lack of robust noninvasive markers of fibrosis to accurately assess response to therapy.

Fibrosis is a reversible scarring response that occurs in almost all patients with chronic liver injury. Ultimately, hepatic fibrosis leads to cirrhosis, characterized by nodule formation and organ contraction. The causes of cirrhosis are multiple and include congenital, metabolic, inflammatory, and toxic liver diseases (Table 14.1).

It is essential to understand the molecular underpinnings of fibrosis because the fibrotic response underlies all the complications of end-stage liver disease, including portal hypertension, ascites, encephalopathy, synthetic dysfunction, and impaired metabolic capacity. Therefore, fibrosis is deleterious both by its direct effects on cellular function and by its mechanical contribution to increased portal resistance.

This chapter reviews the significant progress made toward elucidating the cellular basis of hepatic fibrosis and how these insights are leading to advances in the diagnosis and treatment of chronic liver disease.

The Biologic Basis of Hepatic Fibrosis

General principles

1. *Hepatic fibrosis is a wound-healing response* in which the damaged regions are encapsulated by extracellular matrix (ECM), or scar. In all circumstances, the composition of the hepatic scar is similar. The cells and soluble factors participating in this response in the liver are also similar to those involved in parenchymal injury to the kidney, lung, or skin. This understanding has helped to identify underlying mechanisms and will likely lead to new therapies for fibrotic diseases of many organs including the liver.
2. *Myofibroblast-like cells produce hepatic fibrosis regardless of the underlying cause*. As discussed in the subsequent text, the activated hepatic stellate cell is the

key cellular source of these myofibroblasts, but additional origins of fibrogenic cells may include peribiliary fibroblasts, bone marrow, and even transdifferentiation from epithelial cells. How stellate cells and related cells are activated in response to so large a variety of hepatic insults—from inborn metabolic defects to chronic viral hepatitis—is being increasingly revealed.

Table 14.1. Causes of Fibrosis and Cirrhosis

1. **Presinusoidal fibrosis** Schistosomiasis
   Idiopathic portal fibrosis
2. **Parenchymal fibrosis**
   A. Drugs and toxins Alcohol
      Methotrexate
      Isoniazid
      Vitamin A
      Amiodarone
      Perhexiline maleate
      α-Methyldopa
      Oxyphenisatin
   B. Infections
      Chronic hepatitis B, C
      Brucellosis
      Echinococcosis
      Congenital or tertiary syphilis
   C. Autoimmune disease
      Autoimmune hepatitis
   D. Vascular abnormalities
      Chronic passive congestion
      Hereditary hemorrhagic telangiectasia
   E. Metabolic/genetic diseases
      Wilson disease
      Genetic hemochromatosis

α_1-Antitrypsin deficiency
Carbohydrate metabolism disorders
Lipid metabolism disorders
Urea cycle defects
Porphyria
Amino acid metabolism disorders
Bile acid disorders

F. Biliary obstruction
Primary biliary cirrhosis
Secondary biliary cirrhosis
Cystic fibrosis
Biliary atresia/neonatal hepatitis
Congenital biliary cysts

G. Idiopathic/miscellaneous
Nonalcoholic steatohepatitis
Indian childhood cirrhosis
Granulomatous liver disease
Polycystic liver disease

3. **Postsinusoidal fibrosis**
Sinusoidal obstruction syndrome (veno-occlusive disease)

3. *Hepatic fibrosis follows chronic, not self-limited injury*. For example, patients surviving fulminant hepatitis do not develop scarring despite an abundance of fibrogenic stimuli, unless chronic injury follows. Moreover, even fibrosis associated with sustained injury is often reversible. The reason for fibrosis reversibility, even in chronic liver disease, is not certain, but may be related to the relative activity of matrix-degrading enzymes and their inhibitors, as well as the relative extent of collagen cross-linking.

4. *Fibrosis occurs earliest in regions in which injury is most severe*. This is especially true in chronic inflammatory liver disease due to alcohol or viral infection. For example, pericentral injury is a hallmark of alcoholic hepatitis, and the development of pericentral fibrosis (also known as sclerosing hyaline necrosis or perivenular fibrosis) is an early marker of likely progression to panlobular cirrhosis.

Extracellular Matrix Composition of the Normal Liver and Hepatic SCAR

ECM refers to the array of macromolecules comprising the scaffolding of normal and fibrotic liver. The components of hepatic ECM include several families of structural and supporting molecules: Collagens, noncollagen glycoproteins, matrix-bound growth factors, glycosaminoglycans, proteoglycans, and matricellular proteins. Of the 20 types of collagens characterized thus far, 10 have been identified in the liver. Remarkable progress has been made in identifying new members of these families and in understanding how these molecules interact in a defined, stoichiometric manner to affect cell behavior (see ref. 1 for review). Matrix molecules are also recognized in a variety of new roles, including their identification as transmembrane transducers of extracellular

signals.

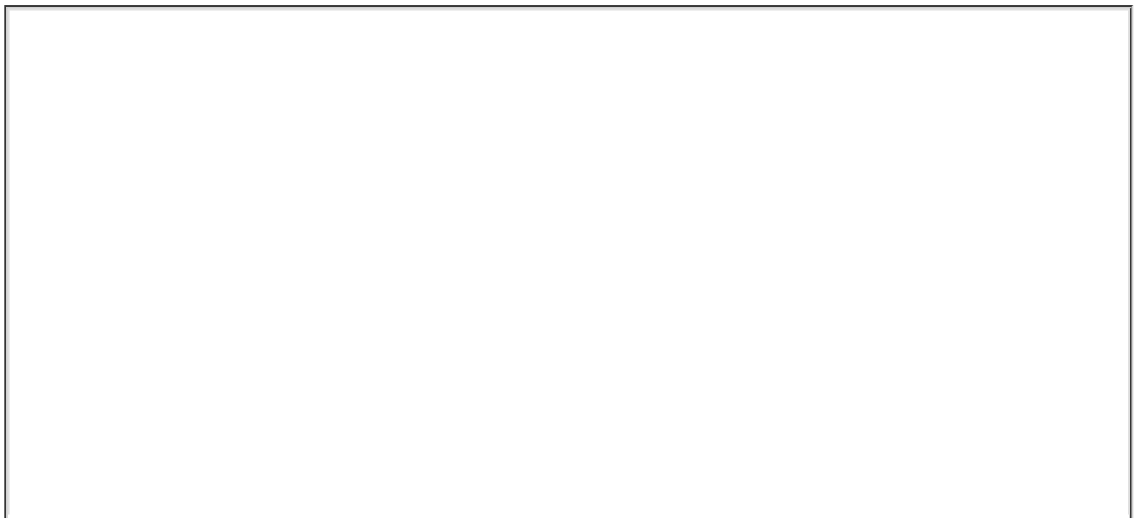
In the normal liver, so-called fibril-forming collagens (types I, III, V, and XI) are largely confined to the capsule, around large vessels, and in the portal triad, with only scattered fibrils containing types I and III collagen in the subendothelial space. Smaller amounts of other collagens including types VI, XIV, and XVIII can be found. Glycoproteins and matricellular proteins are also present, including subendothelial deposits of fibronectin, laminin, tenascin, secreted protein, acidic and rich in cysteine (SPARC), and von Willebrand's factor. Proteoglycans primarily consist of heparan sulfate proteoglycans including perlecan, as well as small amounts of decorin, biglycan, fibromodulin, aggrecan, glypican, syndecan, and lumican (1).

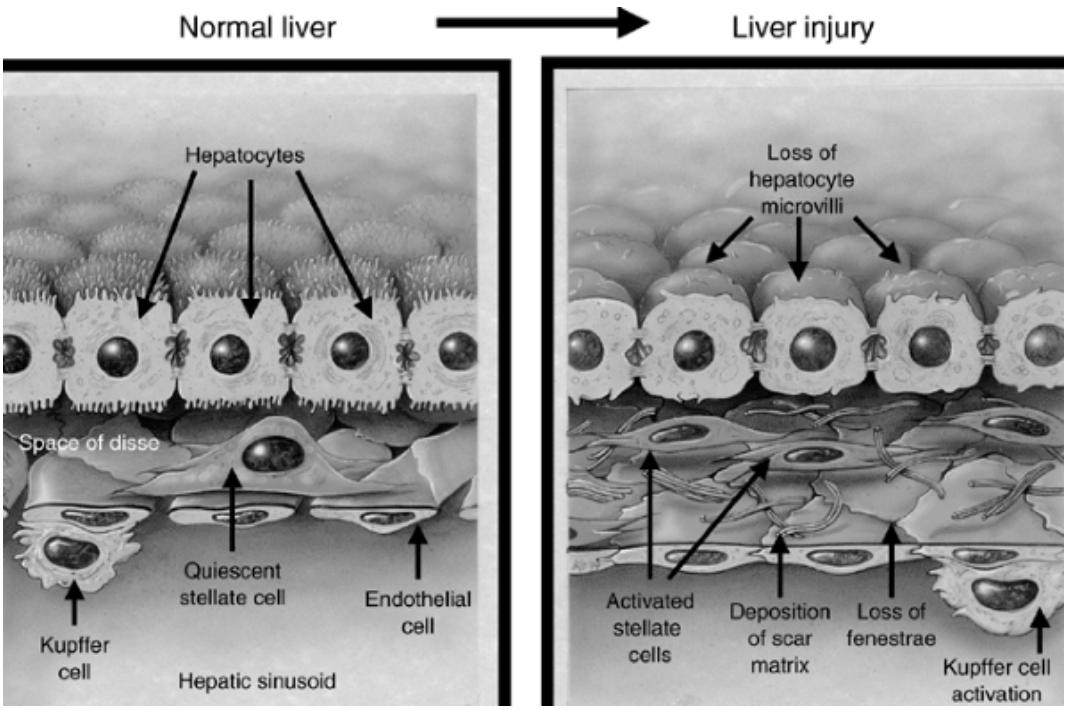
The fibrotic liver is characterized by both quantitative and qualitative differences in the matrix composition compared to the normal liver; as noted, these changes are similar regardless of the type of liver injury. Total collagen content increases 3- to 10-fold, although the collagen is not "abnormal" in sequence or structure. Overall, there is a marked increase in "interstitial matrix" that is typical of the healing wound, which includes fibril-forming collagens (types I, III, and V) and some non–fibril-forming collagens (types

IV, VI), several glycoproteins (e.g., cellular fibronectin, laminin, SPARC, osteonectin, tenascin, and von Willebrand's factor), a large number of proteoglycans and glycosaminoglycans (e.g., perlecan, decorin, aggrecan, lumican, fibromodulin), and related receptors, including dystroglycan (2).

Biologic Activity of Extracellular Matrix in Liver

ECM is a dynamic regulator of cell function and not an inert "ground substance." Early, subendothelial matrix accumulation leading to "capillarization" of the subendothelial space of Disse is a key event and may be more important than overall increases in matrix content (Fig. 14.1). The basement membrane constituents within the subendothelial space may be essential for preserving the differentiated functions of hepatocytes, hepatic stellate cells, and endothelial cells. Replacement of the normally low-density matrix by interstitial matrix directly perturbs hepatocyte function and could explain the synthetic and metabolic dysfunction that is characteristic of more advanced fibrosis and cirrhosis. This high-density matrix also activates stellate cells (3) and leads to a decrease in fenestrations of sinusoidal endothelial cells, which could impair the transport of solutes from the sinusoid to hepatocytes.





▪ **Figure 14.1** Matrix and cellular alterations in hepatic fibrosis. Changes in the subendothelial space of Disse as fibrosis develops in response to liver injury include alterations in both cellular responses and extracellular matrix composition. Stellate cell activation leads to an accumulation of scar (fibril-forming) matrix. This in turn contributes to the loss of hepatocyte microvilli and sinusoidal endothelial fenestrae, which results in the deterioration of hepatic function. Kupffer cell (macrophage) activation accompanies liver injury and contributes to the paracrine activation of stellate cells. (From Friedman SL. Molecular regulation of hepatic fibrosis, an integrated cellular response to tissue injury. *J Biol Chem* 2000;275:2247–2250, with permission.)

In liver injury, an increase in cellular fibronectin levels is among the first matrix alterations seen within this region. A consequence of this change is the activation of hepatic stellate cells and acceleration of fibrosis (See "Cellular Sources of Extracellular Matrix").

Altered cellular behavior induced by matrix alterations is typically mediated by cell membrane receptors. *Integrins*, a large family of homologous membrane linker proteins, are the best characterized type of ECM receptor. Integrins are noncovalent αβ heterodimers that consist of a large extracellular domain, a membrane-spanning domain, and a cytoplasmic tail (see refs 4,5,6 for reviews and references therein).

Integrins control many cellular functions including gene expression, growth, and differentiation. A growing number of α and β subunits have been identified, with each combination having a different cellular and ligand specificity. For many integrins, the tripeptide sequence Arg-Gly-Asp (RGD) present within the ligand is recognized by the receptor; this property underlies the experimental use of competitive RGD antagonists as therapies to block integrin function in a variety

of diseases including hepatic injury and fibrosis (See "Therapy of Hepatic Fibrosis").

Several integrin and nonintegrin receptors have been described in situ on hepatocytes and nonparenchymal cells (7,8,9,10,11,12). Upregulation of $\alpha_6\beta_1$ and $\alpha_2\beta_1$ receptors (10), both of which bind laminin, has been reported in experimental fibrosis. Studies have also defined the integrin phenotypes of the cell types isolated from the liver. In particular, stellate cells express integrin receptors for collagen and laminin (7,8,9,12), which may contribute to their activation and proliferation in response to the deposition of these matrix components during injury.

In addition to integrins, a growing number of other adhesion proteins and cell matrix receptors have been characterized, including cadherins and selectins, which mediate interactions between inflammatory cells and the endothelial wall (13). For example, upregulation of a tyrosine kinase receptor, discoidin domain receptor 2 (DDR2), has been identified during stellate cell activation, which signals in response to fibrillar collagens, leading to enhanced matrix metalloproteinase (MMP) expression and cell growth (14). The DDR family is the only family of receptor tyrosine kinases whose ligands are ECM molecules rather than peptide ligands, and their upregulation could be a critical requirement to perpetuate liver fibrosis.

ECM can also indirectly affect cell function through the release of soluble growth factors (cytokines), which is in turn controlled by local metalloproteinases. These include platelet-derived growth factor (PDGF), hepatocyte growth factor (HGF), connective tissue growth factor (CTGF), tumor necrosis factor α (TNF-α), basic fibroblast growth factor (bFGF), and vascular endothelial cell growth factor (VEGF) (1). Controlled release from ECM is a key mechanism for regulating cytokine activity because it provides a local, accessible source that is tightly regulatable through the actions of proteases and their inhibitors. In addition, ECM can regulate the activity of proteases through specific binding to collagens or fibronectins (1).

Cellular Sources of Extracellular Matrix in Normal and Fibrotic Liver

The identification of the cellular sources of ECM in hepatic fibrosis has been a significant advance that laid the groundwork for defining mechanisms of fibrosis and potential therapies. The *hepatic stellate cell* (previously called *lipocyte*, *Ito*, *fat-storing* or *perisinusoidal cell*) is the primary source of ECM in the normal and fibrotic liver. In addition, related mesenchymal cell types from a variety of sources may also make measurable contributions to total matrix accumulation, including classical portal fibroblasts (15,16,17) (especially in biliary fibrosis), bone marrow–derived cells (18), and fibroblast-derived epithelial–mesenchymal transition (EMT) (19). EMT is a well-characterized response of the kidney (19) to injury, but its role in liver injury has been less convincing.

Hepatic stellate cells are resident perisinusoidal cells in the subendothelial space between hepatocytes and sinusoidal endothelial cells (see refs 20 and 21 for reviews). They are the primary sites for storing retinoids within the body. Stellate cells can be recognized by their vitamin A autofluorescence, perisinusoidal orientation, and expression of the cytoskeletal proteins desmin and glial acidic fibrillary protein. In strict terms, "stellate cells" may represent a

heterogeneous population of mesenchymal cells with respect to cytoskeletal phenotype, vitamin A content, and localization (22), but collectively they are the key fibrogenic cell type in the liver. Moreover, the remarkable plasticity of stellate cell phenotype has been documented in vivo and in culture, precluding a strict definition based only on the cytoskeletal phenotype (23,24). Stellate cells with fibrogenic potential are not confined to the liver and have been identified in the pancreas, for example, where they contribute to desmoplasia in chronic pancreatitis (25) and carcinoma (26).

Studies in situ in both animals and humans with progressive injury have defined a gradient of changes within stellate cells that are collectively termed *activation* (see subsequent text). Stellate cell activation refers to the transition from a quiescent vitamin A–rich cell to a highly fibrogenic cell characterized morphologically by the enlargement of rough endoplasmic reticulum, diminution of vitamin A droplets, ruffled nuclear membrane, appearance of contractile filaments, and proliferation. Cells with features of both quiescent and activated cells are often called *transitional cells*. As noted in the preceding text, proliferation of stellate cells occurs in regions of greatest injury, which is typically preceded by an influx of inflammatory cells and is associated with subsequent ECM accumulation.

Stellate cells have now been characterized in many human liver diseases. Alcoholic liver disease is the best studied example, with numerous reports documenting features of activation in situ (see ref. 27 for review); activation may occur even in the presence of steatosis alone without inflammation (28). Activated stellate cells have also been observed in viral hepatitis (29). In hepatocellular carcinoma, activated stellate cells contribute to the deposition of tumor stroma (30). Stellate cells have been characterized in a number of other human diseases including vascular disease, hematologic malignancy, biliary disease, mucopolysaccharidosis, acetaminophen overdose, leishmaniasis, allograft rejection, and in drug abusers.

Remarkably, very few studies have defined the cellular or matrix composition of congenital hepatic fibrosis, an entity whose pathogenesis is not clear. Current theories suggest that as in adults, congenital hepatic fibrosis

represents a final common pathway of fetal hepatic injury, whether from biliary malformations, viral infections (especially Cytomegalovirus), or other insults, with the stellate cell playing a significant role (31). Interestingly, the genetic knockout of a homeodomain transcription factor, Lhx2, leads to a congenital hepatic fibrosis–like picture (32), raising the intriguing but unproven suggestion that a similar genetic defect could underlie the human condition. Very few studies have examined specific mediators in this disease (33). It is unclear why fibrosis develops in weeks to months in utero, whereas it requires months to years in adults (See "Fibrosis Progression and Reversibility").

ECM production by sinusoidal endothelial cells, although less than that by stellate cells, is nonetheless an important component of early fibrosis. Like stellate cells, there is considerable heterogeneity of this cell type in normal and fibrotic livers. Endothelial cells from a normal liver produce types III and IV collagen laminin syndecans and fibronectin (34). After acute liver injury, increased expression of cellular isoforms of fibronectin by these cells is a key early event because their appearance creates a microenvironment that activates stellate cells.

Degradation of Extracellular Matrix

Degradation of extracellular matrix represents a key component of hepatic fibrosis for at least two reasons: (i) Early disruption of the normal hepatic matrix by matrix proteases ("pathologic" matrix degradation) hastens its replacement by scar matrix, which in turn has deleterious effects on cell function (See "Biologic Activity of Extracellular Matrix") and (ii) in established fibrosis in patients with chronic liver disease, there is an urgent need to resorb the excess wound matrix ("therapeutic" matrix degradation) in hopes of arresting or reversing hepatic dysfunction and portal hypertension. Because fibrosis reflects a balance between matrix production and degradation, this balance must be shifted in favor of degradation for any antifibrotic therapy to succeed.

There has been significant progress in elucidating the fundamental mechanisms of matrix remodeling and how these apply to hepatic fibrosis. An enlarging family of MMPs (also known as matrixins) has been identified, which are calcium-dependent enzymes that specifically degrade collagens and noncollagenous substrates (see refs 35 and 36 for review). Broadly, these fall into five categories based on substrate specificity: Interstitial collagenases (MMP-1, 8, 13) (37), gelatinases (MMP-2 and 9) and fibroblast activation protein (38), stromelysins (MMP-3, 7, 10, 11), membrane-type MMPs (MMP-14, 15, 16, 17, 24, 25), and a metalloelastase (MMP-12). Metalloproteinases are regulated at many levels to restrict their activity to discrete regions within the pericellular milieu. Inactive metalloproteinases can be activated through proteolytic cleavage by either membrane-type 1 matrix metalloproteinase (MT1-MMP) or plasmin and inhibited by binding to specific inhibitors known as *tissue inhibitor of metalloproteinases* (*TIMPs*). The stoichiometry and molecular basis for these interactions has been greatly clarified. For example, MT1-MMP and TIMP-2 form a ternary complex with MMP-2, possibly including $\alpha v\beta_3$ integrin, which is essential for optimal MMP-2 activity (36). Plasmin activity is controlled by its activating enzyme, uroplasminogen activator, and a specific inhibitor, plasminogen activator inhibitor 1, and can be stimulated by active transforming growth factor β_1 (TGF-β_1). Therefore, net collagenase activity reflects the relative amounts of activated metalloproteinases and their inhibitors, especially TIMPs. In addition to TIMPs, other protease inhibitors may affect the net degradative activity, including α_2-macroglobulin.

In the liver, "pathologic" matrix degradation refers to the early disruption of the normal subendothelial matrix, which occurs through the actions of at least four enzymes: *MMP*-2 (also called *gelatinase A* or *72-kDa type IV collagenase*) and *MMP-9* (*gelatinase B* or *92-kDa type IV collagenase*), which degrade type IV collagen; *membrane-type MMP-1 or 2*, which activates latent MMP-2; and *stromelysin-1*, which degrades proteoglycans and glycoproteins and also activates latent collagenases. Stellate cells are a key source of MMP-2 (34), MMP-13 in rodents (37), and stromelysin (34). Activation of latent MMP-2 may require interaction with hepatocytes (39,40). Markedly increased expression of MMP-2 is characteristic of cirrhosis (34,37). MMP-9 is locally secreted by Kupffer cells (36). Remarkably, Kupffer cells may exert a dual role in matrix degradation that differs between fibrosis progression and regression (41). Disruption of the normal liver matrix is also a requirement for tumor invasion and desmoplasia (42).

Failure to degrade the increased interstitial or scar matrix is a major determinant of progressive fibrosis. *MMP-1* is the main protease that can degrade type I collagen, the principal collagen in the fibrotic liver. However, the sources of this

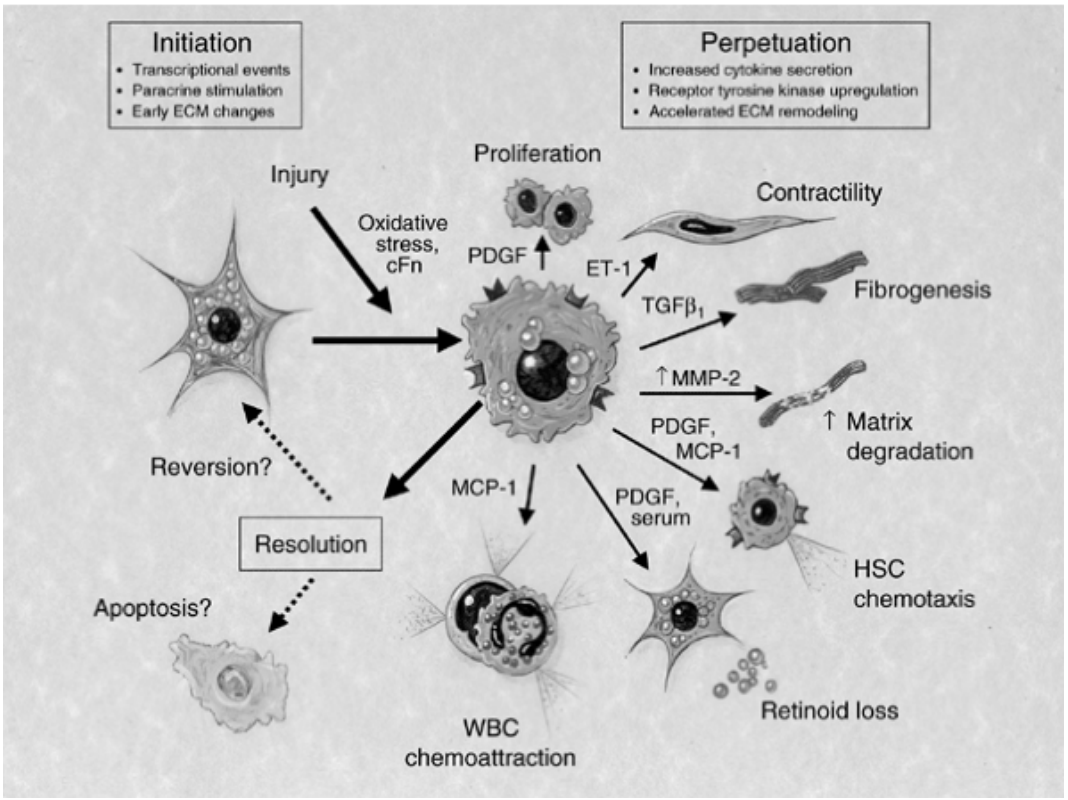
enzyme are not as clearly established as for the type IV collagenases. Stellate cells express MMP-1 messenger ribonucleic acid (mRNA), but little enzyme can be detected (43). More importantly, progressive fibrosis is associated with marked increases in TIMP-1 (44,45) and TIMP-2 (46), leading to a net decrease in protease activity and, therefore, more unopposed matrix accumulation. Stellate cells are the major source of these inhibitors (35). Sustained TIMP-1 expression is emerging as a key reason for progressive fibrosis, and its diminution is an important prerequisite to allow for reversal of fibrosis (see

P.400

subsequent text). Unique mechanisms of TIMP-1 regulation in stellate cells (47) offer the potential for selective inhibition of TIMP-1 expression to accelerate the resorption of scar matrix in patients with liver disease.

Stellate Cell Activation, The Central Event in Hepatic Fibrosis

It is useful to frame the pathophysiology of hepatic fibrosis around the mechanisms of hepatic stellate cell activation because this cell type is the major source of ECM. Activation consists of two major phases, *initiation* (also called a *preinflammatory stage*) and *perpetuation* (20) (Fig. 14.2). Initiation refers to early changes in gene expression and phenotype, which render the cells responsive to other cytokines and stimuli, while perpetuation results from the effects of these stimuli on maintaining the activated phenotype and generating fibrosis. Initiation is largely due to paracrine stimulation, whereas perpetuation involves autocrine and paracrine loops.



▪ **Figure 14.2** Phenotypic features of hepatic stellate cell activation during liver injury and resolution. Following liver injury, hepatic stellate cells

undergo "activation," during which they are transformed from quiescent vitamin A–rich cells into proliferative, fibrogenic, and contractile myofibroblasts. The major phenotypic changes after activation include proliferation, contractility, fibrogenesis, matrix degradation, chemotaxis, retinoid loss, and white blood cell (WBC) chemoattraction. Key mediators underlying these effects are shown. The fate of activated stellate cells during the resolution of liver injury is uncertain but may include reversion to a quiescent phenotype or selective clearance by apoptosis. ECM, extracellular matrix; cFn, cellular fibronectin; PDGF, platelet-derived growth factor; ET-1, endothelin-1; TGF-β_1, transforming growth factor β_1; MMP-2, matrix metalloproteinase-2; MCP-1, monocyte chemoattractant protein-1; HSC, hepatic stellate cell. (From Friedman SL. Molecular regulation of hepatic fibrosis, an integrated cellular response to tissue injury. *J Biol Chem* 2000;275:2247–2250, with permission.)

Initiation of stellate cell activation

The earliest changes in stellate cells are likely to result from paracrine stimulation by all neighboring cell types, including sinusoidal endothelium, Kupffer cells, hepatocytes, and platelets. As noted in the preceding text, early injury to endothelial cells stimulates the production of cellular fibronectin, which has an activating effect on stellate cells (48). Endothelial cells are also likely to participate in the conversion of TGF-β from the latent to active, profibrogenic form. Sinusoidal endothelial cells, normally fenestrated to allow rapid bidirectional transport of solutes between sinusoidal blood and parenchymal cells, may rapidly lose their fenestrations on injury and express proinflammatory molecules including intercellular adhesion molecule-1, VEGF, and adhesion molecules (42,49). Together with stellate cells, they activate angiogenic pathways in response to hypoxia associated with local injury or malignancy (42,50,51,52).

Hepatic inflammation, Kupffer cell infiltration, and activation also play prominent roles (53,54). Influx of

Kupffer cells coincides with the appearance of stellate cell activation markers. Kupffer cells can stimulate matrix synthesis, cell proliferation, and release of retinoids by stellate cells through the actions of cytokines (especially TGF-β_1) and reactive oxygen intermediates/lipid peroxides. Hepatic macrophages, most of which are likely to represent Kupffer cells, also have a complex role in matrix degradation in the liver (55).

Early stimulation of stellate cells by lipid peroxides in vivo may be important in many forms of liver fibrosis, particularly hepatitis C, nonalcoholic steatohepatitis (NASH), and iron overload (56). In fact, there is an increased prevalence of heterozygosity for mutation of the hemochromatosis gene in patients with NASH, suggesting a potentially synergistic relationship between fat and iron overload (57). Additionally, fibrosis is more likely among patients with NASH who are obese, which correlates with increased hepatic steatosis (58). Because antioxidant levels are typically depleted in cirrhotic liver as fibrosis advances, their loss could further amplify the injurious effects of lipid peroxides.

Hepatocytes, as the most abundant cells in the liver, are a potent source of these

fibrogenic lipid peroxides. There is an in situ correlation between the presence of aldehyde adducts and collagen gene expression by stellate cells (59), and peroxides stimulate collagen synthesis by cultured stellate cells (60). Steatosis in NASH and hepatitis C virus (HCV) correlates with increased stellate cell activation and fibrogenesis (61), possibly because fat represents an enhanced source of lipid peroxides. In culture, the activation of stellate cells is provoked by the generation of free radicals and is blocked by antioxidants (62).

Whereas hepatocyte necrosis associated with lipid peroxidation is considered a classical inflammatory and fibrogenic stimulus, recent findings also implicate apoptosis, or programmed cell death, in the fibrogenic response. Apoptotic fragments released from hepatocytes are fibrogenic toward cultured stellate cells (63) and activate Kupffer cells (64). Also, Fas-mediated hepatocyte apoptosis in vivo in experimental animals is fibrogenic (65).

Platelets are often overlooked as a paracrine stimulus, but, in fact, they are a potent source of growth factors and are present within the injured liver (66). Potentially important platelet mediators include PDGF, TGF-β_1, and epidermal growth factor (EGF).

Perpetuation of stellate cell activation

Perpetuation of stellate cell activation involves at least seven discrete changes in cell behavior: (a) Proliferation, (b) chemotaxis, (c) fibrogenesis, (d) contractility, (e) matrix degradation, (f) retinoid loss, and (g) white blood cell (WBC) chemoattractant and cytokine release. Either directly or indirectly, the net effect of these changes is to increase the accumulation of ECM. For example, proliferation and chemotaxis lead to increased numbers of collagen-producing cells, but there is also more matrix production per cell. Cytokine release by stellate cells can amplify the inflammatory and fibrogenic tissue responses, and matrix proteases may hasten the replacement of normal matrix with a matrix typical of the wound "scar."

1. *Proliferation*. PDGF is the most potent stellate cell mitogen identified (67). Induction of PDGF receptors early in stellate cell activation increases responsiveness to this potent mitogen (68). Downstream pathways of PDGF signaling have been carefully characterized in stellate cells (69). In addition to proliferation, PDGF stimulates Na^+/H^+ exchange, providing a potential site for therapeutic intervention by blocking ion transport (See "Therapy of Hepatic Fibrosis") (70). Transgenic expression of PDGF-C in mice leads to both hepatic fibrosis and carcinoma (71). Other compounds with mitogenic activity in stellate cells and a potential role in fibrogenesis include VEGF (51), thrombin and its receptor (72,73), EGF, TGF-α, keratinocyte growth factor (74), and bFGF (75). Signaling pathways for these and other mitogens have been greatly clarified in stellate cells, offering many potential sites for therapeutic intervention (see ref. 69).
2. *Chemotaxis*. Stellate cells can migrate toward cytokine chemoattractants (50,69) mediated by a number of transmembrane receptors (69,76,77), which is characteristic of wound-infiltrating mesenchymal cells in other tissues as well. Chemotaxis of stellate cells explains in part why stellate cells align within inflammatory septae in vivo.
3. *Fibrogenesis*. Increased matrix production is the most direct way by which stellate cell activation generates hepatic fibrosis. Among the components of

the hepatic scar, collagen type I is the best studied, and numerous reports describe the regulation of the collagen I gene in stellate cells.

The most potent stimulus for collagen I production is TGF-β_1, which is derived from both paracrine and autocrine sources; TGF-β_1 also stimulates the production of other matrix components including cellular fibronectin and proteoglycans (78). TGF-β_1 stimulates collagen in stellate cells through a hydrogen peroxide–, p38 mitogen-activated protein kinase (MAPK)-, and CCAAT/enhancer binding protein-β (C/EBPβ)-dependent mechanism (79,80). TGF-β expression is increased in patients with chronic hepatitis C, emphasizing the potential importance of this cytokine in chronic liver disease (81). Similarly, serum levels of TGF-β correlate with the risk of veno-occlusive disease after bone marrow transplantation (82). Also, stellate cell responsiveness to TGF-β_1 is increased during activation by enhanced ligand binding to its cognate receptors (78). Signaling molecules downstream

of TGF-β include a family of bifunctional molecules known as *Smads*, on which many extracellular and intracellular signals converge to fine-tune and additionally enhance the effects of TGF-β downstream of its receptors during fibrogenesis (83,84). The response of Smads in stellate cells differs between acute and chronic injury to further favor matrix production (85). Smads 2 and 3 elicit distinct signaling responses that favor stellate cell activation and fibrogenesis (69), whereas Smad 7 is inhibitory, making it an attractive molecule to utilize in antifibrotic therapies (86) (see subsequent text).

Continued understanding of collagen gene transcription, translation, and mRNA stability have emphasized the many sites of regulation that may affect collagen production (87,88,89,90).

Lipid peroxidation products are emerging as important stimuli to ECM production (91), particularly when derived from hepatocytes (62). Their effects may be amplified by the loss of the antioxidant capacity of stellate cells as they are activated (92). These important insights have provoked efforts to use antioxidants as therapy for hepatic fibrosis (See "Therapy of Hepatic Fibrosis"). Stimulation of fibrogenesis may be especially critical to the pathogenesis of NASH, wherein fat provides a large reservoir of potential reactive oxygen species (93,94,95). In addition to TGF-β_1, CTGF (now referred to as CCN2) is also a potent TGF-β-regulated fibrogenic cytokine (96,97).

4. *Contractility*. Contractility of stellate cells may be a major determinant of early and late increases in portal resistance during liver fibrosis. Activated stellate cells impede portal blood flow by both constricting individual sinusoids and contracting the cirrhotic liver because the collagenous bands typical of end-stage cirrhosis contain large numbers of activated stellate cells (see ref. 98 for review).

   As stellate cells become contractile, they have increased expression of the cytoskeletal protein, α-smooth muscle actin. If smooth muscle actin is required for contraction, then inactivating it could represent a therapeutic target for treating portal hypertension.

   The major contractile stimulus for stellate cells is endothelin-1, whose receptors are expressed on both quiescent and activated stellate cells but whose subunit composition may vary (98). On activation, the receptor

expression does not increase, unlike that of PDGF receptors, but there is a shift in the type of endothelin receptor that predominates, combined with increased sensitivity to autocrine endothelin-1 (99,100). Increased endothelin levels result from increased endothelin-converting enzyme (ECE) activity because of stabilization of the ECE mRNA (101). Contractility of stellate cells in response to endothelin-1 has also been documented in vivo (102).

Another key contractile mediator in activated stellate cells is angiotensin II, which is synthesized by activated stellate cells in a nicotinamide adenine dinucleotide phosphate (reduced form) (NADPH)-dependent pathway (103,104,105). These findings are particularly relevant to human disease because antagonism of this pathway is an attractive antifibrotic therapy using a variety of safe, well-tolerated medications that are already available (106) (See "Therapy of Hepatic Fibrosis"). Contraction may also be induced in activated stellate cells by vasopressin (107), substance P (108), and atrial natriuretic peptide (109).

Locally produced vasodilator substances may counteract the constrictive effects of endothelin-1 (110,111). Nitric oxide, which is also produced by stellate cells, is a well-characterized endogenous antagonist to endothelin. During acute endotoxemia, stellate cell production of nitric oxide is increased. In vivo studies suggest that carbon monoxide also mediates sinusoidal relaxation through its effects on stellate cells (100,112).

5. *Matrix degradation*. Quantitative and qualitative changes in matrix protease activity play an important role in the ECM remodeling that accompanies fibrosing liver injury (see "Extracellular Matrix Degradation"). Stellate cells express virtually all the key components required for pathologic matrix degradation and, therefore, play a key role not only in matrix production but also in matrix degradation.

6. *Retinoid loss and nuclear receptor signaling*. As stellate cells are activated, they lose their characteristic perinuclear retinoid (vitamin A) droplets and acquire a more fibroblastic appearance. In culture, retinoid is stored as retinyl esters, whereas as stellate cells are activated, the retinoids are released outside the cell as retinol, suggesting that there is intracellular hydrolysis of esters before export (113). However, it is unknown whether retinoid loss is required for stellate cells to be activated, and which retinoids might accelerate or prevent activation in vivo. For example, one retinoic acid analog, 9-*cis*-retinoic acid, stimulates hepatic fibrosis in rats by increasing the activation of latent TGF-β_1 (114).

   Several nuclear retinoid receptors have been identified in stellate cells (115,116,117,118), molecules that bind intracellular retinoid ligands and regulate gene expression, but it is uncertain whether they play a regulatory role in fibrogenesis. The question has important clinical implications as efforts to use retinoids therapeutically are being developed (See "Therapy of Hepatic Fibrosis"). Recently, peroxisome proliferator-activated receptors (PPARs), in particular PPARγ, have been identified in stellate cells, and their expression increases with activation (116). Ligands for this newly identified nuclear receptor family downregulate stellate cell activation (116,119). Similarly, farnesoid X receptor (FXR) not only regulates a range of genes regulating choleresis but, in stellate cells, may also drive antifibrotic pathways alone or by converging with PPARγ signaling (115,120,121).

In contrast, PPARβ ligands stimulate stellate cell proliferation (117).

7. *Inflammatory signaling and WBC chemoattraction*. Stellate cells are assuming an increasingly central role in our understanding of hepatic inflammation. They can amplify the inflammatory response by inducing infiltration of mono- and polymorphonuclear leukocytes. Activated stellate cells produce chemokines that include monocyte chemoattractant protein-1 (110), CCL21 (29), regulated on activation, normal T cell expressed and secreted (RANTES), and CCR5 (122). They also express toll-like receptors (123), indicating a capacity to interact with bacterial lipopolysaccharide, which in turn stimulate stellate cells (124). Stellate cells can also function as antigen-presenting cells (125) that can stimulate lymphocyte proliferation or apoptosis (126). In addition to this mononuclear cell chemoattractant, stellate cells produce neutrophil chemoattractants, which could contribute to the neutrophil accumulation characteristic of alcoholic liver disease.

In addition to regulating leukocyte behavior, stellate cells may also be affected by specific lymphocyte populations. For example, CD8 cells harbor more fibrogenic activity toward stellate cells than CD4 cells (127), which may explain in part the increased hepatic fibrosis seen in patients with HCV/human immunodeficiency virus (HIV) coinfection, in which CD4/CD8 ratios are reduced, compared to that in patients monoinfected with HCV alone.

Transcriptional regulation of stellate cell activation

There have been many advances in dissecting pathways of membrane and intracellular signaling and transcriptional gene regulation in activated hepatic stellate cells that are too numerous to detail here (128). As noted in the preceding text, the growing number of transcription factors and signaling molecules may regulate stellate cell behavior, including PPARα, β and γ (117,129), cysteine- and glycine-rich protein 2 (CRP-2) (130), retinoid receptors (131), nuclear factor-κB (NF-κB) (123), Jun D (128), Krüppel-like factor 6 (132), Foxf1 (133), Lhx2 (32), and MEF2 (134), among others (128,129).

Disease-Specific Mechanisms Regulating Hepatic Fibrosis—Hepatitis C Virus and Nonalcoholic Steatohepatitis

In addition to generic mechanisms of fibrogenesis common to all experimental and human liver disease, there has been progress in elucidating disease-specific mechanisms, in particular in HCV and NASH. A recent study has raised the possibility that stellate cells might be infected by HCV by identifying the expression of putative HCV receptors in activated stellate cells, including CD80, low-density lipoprotein receptor, and C1q (135). Moreover, adenoviral transduction of HCV nonstructural and core proteins induces stellate cell proliferation and release of inflammatory signals (135). The E2 protein of HCV can interact directly with CD81, a stellate cell plasma membrane receptor (136). Moreover, hepatocytes in culture that support HCV replication generate paracrine factors that also stimulate stellate cells (137). In HCV-infected liver, chemokines and their receptors are upregulated, stimulating lymphocyte recruitment (29). HCV proteins may also interact directly with sinusoidal endothelium (138). A ductular reaction with portal expansion also correlates with fibrosis progression

(139). Steatosis and apoptosis in HCV may accelerate fibrosis (140), even in patients without NASH, and steatosis has emerged as an important determinant of fibrosis progression in HCV (141).

The rising prevalence of obesity in the United States and Western Europe is associated with an alarming increase in NASH (58) leading to advanced fibrosis and cirrhosis and accelerated mortality (142). Leptin, a circulating adipogenic hormone that is proportionate to the adipose mass in circulating blood, has been clearly related to stellate cell fibrogenesis (143,144,145) and requires sympathetic neurotransmission (146). Sources of fibrogenesis are likely to be both endocrine and autocrine, associated with enhanced signaling through the leptin receptor, which is upregulated during stellate cell activation (143,147). Concurrently, downregulation of adiponectin in obesity, a counter-regulatory hormone, may amplify the fibrogenic activity of leptin. This possibility is supported by findings in mice lacking adiponectin, which have enhanced fibrosis after toxic liver injury (148).

Clinical Aspects of Hepatic Fibrosis

Fibrosis Progression and Reversibility

The rate of progression of fibrosis in an individual patient with chronic liver disease cannot be predicted with certainty. However, some general rules apply:

1. *Fibrosis usually requires at least several months to years of ongoing insult*. Three exceptions in adults are sinusoidal obstruction syndrome (SOS) (previously referred to as veno-occlusive disease), subfulminant drug-induced liver injury, and mechanical biliary obstruction, in which fibrosis can progress more rapidly. In SOS, a dramatic deposition of ECM in pericentral zones associated with activated stellate cells can

follow within weeks of myeloablative therapy, leading to rapid onset of ascites and possibly death. In infants with neonatal obstruction, fibrosis can also develop in utero or within weeks of birth. Mechanisms underlying these examples of "fulminant fibrosis" remain obscure, but stellate cell activation and upregulation of fibrogenic cytokines accompany these fibrotic states as they do in more common forms of hepatic fibrosis.

In contrast to these relatively rare forms of "fulminant" fibrosis, in patients with HCV infection, the median time to overall progression has been estimated at 30 years (149), ranging from 13 to 42 years, depending on the presence of other risk factors. Risk factors for more rapid progression include alcohol abuse, older age at the time of infection, steatosis (as reflected by elevated body mass index), immunosuppression, and male gender. Importantly, the progression does not correlate with viral load or genotype, strongly implicating host response and genotype as determinants of fibrosis progression. In fact, there is increasing appreciation of host genetic determinants that influence fibrosis (150), and large-scale efforts are under way within the commercial sector to define "gene risk signatures" through whole-genome analysis of single nucleotide polymorphisms in patients with HCV and nonalcoholic fatty liver disease (151). Similar studies in animals have successfully identified "fibrogenic loci" whose gene products may modulate the inherent fibrotic response (152).

2. *The severity of inflammation, necrosis, and injury usually correlate with the rate of progression*, as documented in studies of alcoholic liver disease and hepatitis C (153,154,155). Indeed, patients with persistently normal alanine aminotransferase and HCV are less likely to progress (156), indicating decreased overall necroinflammation during the course of their disease.

3. *Concurrent hepatic insult by more than one agent is synergistic for the progression of fibrosis*. This has been especially well documented in patients with HCV infection who abuse large amounts of alcohol but is also true for those with viral coinfection, including hepatitis B virus (HBV) with either HCV or hepatitis delta virus (HDV) (157), as well as HCV with HIV (149,158).

   Iron overload, whether primary or secondary, is a risk factor for fibrosis progression (94). In genetic hemochromatosis and rodent models of iron overload, a threshold iron concentration of 22,000 μg/g of dry weight has been identified. Higher iron content also correlates with increased inflammation and fibrosis in HCV (159) and synergizes inflammation. Increased steatosis is also associated with increased fibrosis in patients infected with HCV (160) or in those who have NASH (161). Other risk factors for fibrosis in patients with NASH include older age, obesity, and presence of diabetes mellitus (162,163,164).

4. *The exact moment when fibrosis becomes irreversible is not known*, in terms of either a histologic marker or a specific change in the matrix composition or content. Dense cirrhosis, with nodule formation and portal hypertension, is generally considered irreversible, but more intermediate lesions can show remarkable reversibility. It is important to consider the possibility that even advanced stages of fibrosis/cirrhosis might be reversible as clinical trials of antifibrotics emerge. Moreover, just as fibrosis may progress over decades, the reversal of fibrosis may also require many years, a fact that will influence the design of antifibrotic trials. Irreversibility may be conferred by the density and acellularity of the septal scars, leading to the loss of sources of interstitial collagenases.

   Reversibility of cirrhosis has now been well documented in a number of diseases including HCV, HBV, HDV, and alcoholic liver disease (165,166,167,168). In mechanical biliary obstruction due to chronic pancreatic disease, surgical decompression can also lead to the reversal of fibrosis (169), a finding supported in animal models (170).

   Animal studies have also yielded significant insight into the mechanisms of fibrosis regression. Sustained experimental liver injury by carbon tetrachloride (CCl_4) leads to delayed reversibility because of thick collagen bands, high levels of TIMP-1, and significant collagen cross-linking by tissue transglutaminase (171), whose expression is increased in activated stellate cells (172). A major role of TIMP-1 is to inhibit the apoptosis of activated stellate cells, thereby allowing these fibrogenic cells to persist in the injured liver (173), with sustained NF-κB signaling providing an intracellular molecular signal to preserve this activated state (174,175). Mice that overexpress TIMP-1 in the liver indeed have a delayed regression of experimental fibrosis (176), reinforcing its role in preventing reversibility. In addition, extracellular survival signals, some of which are bound to surrounding ECM, may further prevent apoptosis.

5. *Host genotype is an intrinsic determinant of fibrosis progression*. In addition

to rapid advances in identifying host genes that regulate the risk of fibrosis progression, characterization of the host immune factors contributing to fibrosis could represent an important insight into the pathogenesis of fibrosis in humans. In HCV infection, the predominance of a Th1 cytokine response has been correlated with more severe injury and fibrosis (177,178). Studies in mice suggest that the immune phenotype is a key determinant of fibrosis in schistosomiasis (179) and toxic liver injury (180). Fibrosis is also accelerated in patients with HCV who are coinfected with HIV (158), further implicating a role of the immune system in modulating fibrosis. In contrast, estrogen in women may provide some protection against fibrosis (181) because fibrosis progression is slower in women than in men (182).

Diagnosis and Assessment of Hepatic Fibrosis

Accurate assessment of the extent of fibrosis is essential to guide management and predict prognosis in patients with chronic liver injury. Histologic assessment of a liver biopsy specimen remains the "gold standard" for quantifying fibrosis, with increasing interest in the use of noninvasive markers to allow more frequent sampling and avoid the risks of percutaneous biopsy.

Histologic and morphometric methods

Three methods of assessment of histologic fibrosis are in widest use—the Ishak score (183), the Metavir score (184), and the Desmet/Scheuer staging system (185). Each relies on progressive development of periportal, then septal fibrosis, and finally nodule formation. The key distinguishing feature is the presence of two cirrhotic stages (5 and 6) in Ishak, and only one (F4) in the Metavir system. Interobserver variation is low in both systems, especially if pathologists have been "trained" before the use of these systems. However, sampling error may exceed 30%, as demonstrated by a study in which laparoscopic biopsies were obtained from both lobes of patients with HCV, yet 33% of the 124 patients had differences of at least one stage between the two lobes (186). Two key features determining the accuracy of liver biopsy are length and width, with a minimum of 2.5 cm generally required to achieve reproducible sampling. In a study from Paris using the Metavir scoring system, 65% of biopsies 15 mm in length were categorized correctly, which increased to 75% for a 25-mm liver biopsy specimen (187). This same study estimated, using "virtual" biopsy lengths, that biopsy specimens only 4 cm or greater in length would reliably avoid sampling error (187). This is not possible, of course, but it emphasizes that liver biopsy is unlikely to completely overcome the inherent problems of uneven distribution of fibrosis in the liver, combined with inadequate sample size, a problem amplified by increasing reliance on the use of radiologists to obtain liver biopsies using automated devices that are especially narrow. At best, a biopsy captures only 1/50,000th of the liver, and therefore, some sampling error would seem inevitable. Morphometric and computerized systems (187) may yield data that is continuous rather than discontinuous, but if the tissue sample is not adequate, or there is uneven distribution of fibrosis, then these quantitative methods will not enhance the quality of the data obtained.

Immunohistochemical and in situ mRNA hybridization methods to identify specific matrix components or α-smooth muscle actin (to reflect the extent of stellate cell

activation) can be employed for experimental studies, and these methods may have some clinical utility in assessing fibrosis progression (188,189). Semiquantitative or real-time polymerase chain reaction can be used to measure mRNA transcripts for several cytokines and matrix components, for example, PDGF and TGF-β_1. This method has potential utility for analysis of liver biopsy because it may be more sensitive in assessing fibrogenesis than the evaluation of tissue sections stained for ECM. Moreover, even when accurate, this method reflects mRNA levels and not protein levels, and the two may not always correlate.

Noninvasive methods

There is an urgent need for a noninvasive diagnostic procedure for liver fibrosis because this is currently the main limitation of drug testing in clinical trials. Assessment of fibrosis progression can be valuable in HCV for at least four reasons: (a) The actual stage of fibrosis will indicate the likelihood of response to interferon-α or interferon-α/ribavirin because patients with advanced stages of fibrosis (Metavir F3 or F4) generally have a lower response rate to antiviral therapy; (b) if little fibrosis progression has occurred over a long interval, then treatment with antiviral therapy may be deemed as less urgent, and it may be safe to await more effective and/or better tolerated therapy; (c) the approximate time to the development of cirrhosis can be estimated; and (d) as antiviral and antifibrotic therapies are refined, they will be most appropriately tested in "proof-of-principle" trials in patients who are at highest risk for progression in the absence of any treatment. This would not, however, indicate if/when clinical liver failure would eventuate, which may be delayed for up to a decade or more after the establishment of cirrhosis (190). Accurate prediction of fibrosis progression will help identify those patients in whom the efficacy of an antifibrotic drug will be more easily uncovered in a controlled trial compared to placebo-treated control patients who have similar risk factors.

There has been considerable effort to identify serum markers as noninvasive measures for the diagnosis of hepatic fibrosis (191,192,193). Although their accuracy and predictive value are improving, they cannot yet supplant direct analysis of the liver. The *ideal fibrosis marker* is one that is specific, biologically based, noninvasive, easily repeated in all patients, well correlated with disease severity and outcome, and not confounded by comorbidities or drugs. Although this ideal has not yet been reached, progress can be anticipated on the basis of the progress to date and the intense interest in this area.

Serum markers of matrix molecules or modifying enzymes

There has been considerable effort to identify serum markers as noninvasive measures of hepatic fibrosis.

Although their accuracy and predictive value are improving, they cannot yet supplant direct analysis of liver. Thus far, no serum test has emerged as the perfect marker of fibrosis.

Serum markers have some limitations:

- They typically reflect the rate of matrix turnover, not deposition, and therefore tend to be more elevated when there is high inflammatory activity.

In contrast, extensive matrix deposition can go undetected if there is minimal inflammation.

- None of the molecules is liver specific, so concurrent sites of inflammation may contribute to serum levels.
- Serum levels are affected by clearance rates, which may be impaired because of either sinusoidal endothelial cell dysfunction or impaired biliary excretion.
- They are surrogates, not biomarkers.

Currently, there are three commercial serum marker systems that have been most extensively validated, the Fibrospect (Prometheus Laboratories) (191), the FibroTest (marketed in the United States by Labcorp) (193), and the European Liver Fibrosis Study Group panel, utilizing a diagnostic algorithm and assays developed by Bayer-Chiron Diagnostics (192). In addition, a growing list of other noninvasive tests have been developed using a variety of standard serum hematologic or chemistry parameters in varying combinations (194,195,196,197,198).

To date, there are few discernible differences among the three major serum assays, and their value can be summarized as follows: (i) The tests are extremely accurate (>95%) in determining the near absence (F0 or F1) of fibrosis in HCV or presence of cirrhosis, but not intermediate stages; therefore, in select clinical circumstances, the findings from these tests may obviate the need for biopsy or help guide decisions about treatment with antiviral combinations; less is known about their value in patients with other forms of liver disease apart from HCV, but data are beginning to emerge; (ii) they suffer from a variable but significant number of indeterminate outcomes (up to 50% with the FibroTest); (iii) there is no evidence that any test can discern changes in fibrosis content over time in an individual patient; (iv) however, these tests are proving valuable in cohort studies, in which mean changes in serum values among a group of patients will correlate with changes in fibrosis.

Overall, the serum assay approach remains promising, in part because these tests may represent an "integrated" readout of liver activity rather than a minute sampling of the type obtained by conventional liver biopsy. Continued refinements are likely, and they already have established an important niche, especially in patients who have a high risk of complications from liver biopsy or in those with liver disease not under the care of a hepatologist/gastroenterologist (e.g., patients coinfected with HCV/HIV).

Proteomics and glycomics

A different approach is the analysis of patterns of either protein or glycoprotein peaks, as assessed by mass spectroscopy of serum samples (199). These methods clearly represent "surrogate" markers, and in fact, the identities of the peaks are generally not known. Nonetheless, impressive correlations have been reported, particularly a study from Belgium (200) combining serum "glycomics" with one of the noninvasive serum assays, the "FibroTest."

Novel imaging technologies

These strategies currently include efforts to assess the metabolic activity of a cell, to image hepatic scar (201), and/or to directly image or quantify fibrogenic

cells. The best developed among these, the "FibroScan," is a noninvasive device resembling an ultrasound device that measures the elasticity of the liver when applied over the right upper quadrant (202). The test's accuracy is compromised if there is significant overlying adipose tissue, as may be the case in patients with NASH. Recent studies indicate a good ability to discriminate cirrhosis from earlier stages, and its accuracy may be enhanced when combined with other noninvasive serum assays (203). Nonetheless, there is no evidence that changes in fibrosis over time can be detected in individual patients.

In summary, there remains a compelling need for noninvasive markers that accurately reflect the matrix content of the tissue and have better prognostic accuracy than standard clinical and laboratory indices such as Child-Pugh or Model for End-stage Liver Disease (MELD) classifications, which are only applicable to patients with cirrhosis.

Therapy for Hepatic Fibrosis

General considerations

The improved understanding of mechanisms underlying hepatic fibrosis makes effective antifibrotic therapy an emerging reality. However, treatment will remain a challenging task, and thus far no drugs have been approved as antifibrotic agents in humans. Therapies will have to be well tolerated over decades, with good targeting to the liver and few adverse effects on other tissues. Combination therapies may prove synergistic rather than additive, but agents must first be tested individually to establish safety and "proof of principle." It is uncertain whether antifibrotic therapies will require intermittent or continuous administration. For

putative agents, evidence of a direct antifibrotic effect must be established in experimental models rather than by only an indirect effect by abrogating the injury. Candidate therapies must be effective in a liver that is already damaged—as in clinical liver disease—rather than only before the onset of injury. Antifibrotic therapies also carry the theoretical concern that inhibiting the scarring response will prevent the encapsulation of injured regions, leading to extension of tissue damage. In reality, however, antifibrotic therapies only need to downregulate the scar response to be effective, and in patients with cirrhosis it is the scarring, not injury, that usually leads to liver failure.

Antifibrotic therapies—rationale and specific agents

The paradigm of stellate cell activation provides an important framework to define sites of antifibrotic therapy (Table 14.2) (see ref. 20 for review). The rationale is as follows: (a) Cure the primary disease to prevent injury; (b) reduce inflammation or the host response to avoid stimulating stellate cell activation; (c) directly downregulate stellate cell activation; (d) neutralize proliferative, fibrogenic, contractile, and/or proinflammatory responses of stellate cells; (e) stimulate apoptosis of stellate cells; and (f) increase the degradation of scar matrix, either by stimulating cells that produce matrix proteases, downregulating their inhibitors, or by direct administration of matrix proteases.

Table 14.2. Therapeutic Strategies for Hepatic Fibrosis

Reducing injury and inflammation	**Inhibiting properties of activated stellate cells**
Antiviral therapy for viral hepatitis	Antiproliferative
Antihelminthic therapy for schistosomiasis	PDGF receptor antagonists
Chelation/venesection, treatment of metabolic disease	Sodium exchange inhibitors
Angiotensin II type I receptor antagonists, ACE inhibitors	HMG CoA reductase inhibitors
Hepatoprotectants	Plasmin/thrombin receptor antagonists
Caspase inhibitors	Anticontractile
HGF/HGF mimetics	Endothelin/endothelin receptor antagonists
Attenuating stellate cell activation	Nitric oxide donors
Interferon-α	Antifibrogenic
Antioxidants	Collagen synthesis inhibitors
Vitamin E, PDTC	TGF-β inhibitors (soluble receptors, neutralizing antibodies)
Angiotensin II type I receptor antagonists	HGF/HGF mimetics
Cytokine-directed therapy	AT receptor antagonists
TGF-β antagonists	ACE inhibitors
Endothelin receptor antagonists	Integrin

HGF	CTGF/CCN antagonists
PPARγ agonists	Smad 7 agonists
FXR agonists	**Promoting specific apoptosis of hepatic stellate cells**
Aldosterone antagonists	Gliotoxin
Pentoxyphylline	NGF agonists
	TIMP antagonists
	Degrading scar matrix
	Direct collagenase administration
	Inhibitors of transglutaminase or collagen cross-linking
	TIMP antagonists
	TGF-β inhibitors

ACE, angiotensinogen converting enzyme; HGF, hepatocyte growth factor; PDTC, pyrrolidine dithiocarbamate; TGF-β, transforming growth factor β; PPAR, peroxisome proliferators activated receptor; FXR, farnesyl X receptor; PDGF, platelet-derived growth factor; HMG CoA, 3-hydroxy-3-methyl-glutaryl coenzyme A; NGF, nerve growth factor; AT, angiotensin; CTGF, connective tissue growth factor; CCN, *C*ysteine rich 61/*C*onnective tissue growth factor, *N*euroblastoma overexpressed; Smad 7, mothers against DPP homolog 7; TIMP, tissue inhibitor of metalloproteinase.

1. *Cure the primary disease*. The most effective way to eliminate hepatic fibrosis is to clear the primary cause of liver disease. This includes abstinence in alcoholic liver disease, removal of excess iron or copper in precirrhotic genetic hemochromatosis or Wilson disease, clearance of HBV or HCV in chronic viral hepatitis, eradication of organisms in schistosomiasis, or decompression in mechanical bile duct obstruction. Not to be overlooked, weight loss in patients with NASH (204), or even those with HCV who are overweight, may improve histology and is a simple recommendation.

Similarly, reversal of jejunoileal bypass-related hepatic fibrosis and cessation of methotrexate may also prevent progression to cirrhosis. Identification of the pathogenetic mechanisms underlying primary biliary cirrhosis and sclerosing cholangitis could lead to the elimination of bile duct injury and periductular fibrosis.

2. *Reduce inflammation and immune response*. Reduced fibrosis has been reported in patients with HCV successfully treated with pegylated interferon-α and ribavirin (166), presumably through its effect on viral replication and liver injury. Sustained viral clearance will likely be associated with marked regression of fibrosis, so that long-term follow-up of patients successfully cleared of HCV may show more dramatic reversal of disease than at early time points. Importantly, some antifibrotic effect is observed even in the absence of viral clearance (205). In experimental biliary fibrosis interferon-α also reduces fibrosis (206), raising the possibility of a direct antifibrotic mechanism in addition to its antiviral effect.

   A number of agents have anti-inflammatory activity in vitro and in vivo, which may eliminate the stimuli for stellate cell activation. Corticosteroids have been used for decades to treat several types of liver disease, in particular autoimmune hepatitis (207). Their activity is solely as anti-inflammatory agents, with no direct antifibrotic effect on stellate cells. Antagonists to TNF-α or NF-κB modulators have some rationale, as do a growing number of biologically active agents currently used in other chronic inflammatory diseases, in particular inflammatory liver disease. Pentoxyphylline may exert its antifibrotic activity by downregulating TNF-α signaling (208). Other efforts to neutralize inflammatory cytokines include RGD antagonists, which may limit immunologic injury (209,210).

   The renin–angiotensin system may also amplify inflammation through the generation of oxidant stress, and therefore, either angiotensin-converting enzyme antagonists and/or angiotensinogen II type I receptor antagonists may have an anti-inflammatory and antifibrogenic activity (211,212).

   Ursodeoxycholic acid has a beneficial effect on fibrosis in primary biliary cirrhosis (213,214), possibly in part due to its anti-inflammatory activity. Similarly, a nitric oxide–releasing derivative of ursodeoxycholic acid reduces inflammation, fibrosis, and portal pressure in an animal model (215).

   A new class of drugs, broadly referred to as *hepatoprotectants*, are showing considerable promise in preclinical and clinical studies, including HGF, HGF deletion variants, and HGF synthetic mimetics (216,217,218), as well as insulin-like growth factor (219), and a small-molecule caspase inhibitor that improves aspartate aminotransferase levels in patients with chronic HCV and is currently in clinical trials (220). The exact mechanism of HGF's antifibrotic activity is uncertain but may include inhibition of TGF-β_1 activity. Trials in large animals and humans are anticipated, with careful monitoring planned to screen for potential hepatocarcinogenesis because HGF is an hepatocyte mitogen.

3. *Inhibit stellate cell activation*. Reducing the transformation of quiescent stellate cells to activated myofibroblasts is a particularly attractive target, given its central role in the fibrotic response. The most practical approach is to reduce oxidant stress, which is an important stimulus to activation. Antioxidants, including α-tocopherol (vitamin E), suppress fibrogenesis in

some (221), but not all (222), studies of experimental fibrogenesis. Other antioxidants can also reduce stellate cell activation in culture (223), which provides a rationale for antioxidant trials in humans, although, as noted in the preceding text, more potent formulations than those currently available may be required.

Silymarin, a natural flavonoid component of the milk thistle *Silybum marianum*, has sparked interest as a potential antifibrotic therapy. The compound functions as an antioxidant and may decrease hepatic injury by both cytoprotection and inhibition of Kupffer cell function (223,224). A single human trial in patients with cirrhosis has reported a slight survival advantage in patients with alcoholic cirrhosis who have Child-Pugh A disease (225), but larger, carefully controlled studies are under way to definitively assess its efficacy.

The cytokine interferon-γ has inhibitory effects on stellate cell activation in animal models of fibrosis (226). However, a clinical trial of interferon-γ did not show the expected antifibrotic benefit in patients with HCV, possibly because only patients with advanced fibrosis were enrolled and the treatment period (1 year) may have been too short.

Interferon-α, in addition to its antiviral effect, can downregulate stellate cell activation and fibrogenesis directly through well-defined molecular pathways, and suppress experimental fibrosis (227). Current long-term low-dose interferon-α trials in HCV nonresponders, including Hepatitis C Antiviral Long-term Treatment Against Cirrhosis (HALT-C) (228) are based in part on this mechanism of action, and if these trials succeed the drug may emerge as the first *bona fide* antifibrotic in humans. Inhibition of collagen gene expression in experimental models may also be accomplished using synthetic oligonucleotides to inhibit collagen promoter activity (229).

Great excitement was generated by an uncontrolled trial of interleukin 10, which reported an antifibrotic effect in patients with advanced HCV (230). The finding was particularly exciting because of parallel studies in animals and cultured stellate cells suggesting a direct antifibrotic activity of the agent (231,232,233,234). However, a controlled clinical trial showed no benefit, possibly because the drug markedly increased HCV viral load (235).

PPARγ nuclear receptors are expressed in stellate cells, and synthetic PPARγ ligands (thiazolidinediones) downregulate stellate cell activation (116,236). Given

their widespread use in diabetes, second- and third-generation thiazolidinediones (i.e., lacking the hepatotoxicity seen with first-generation agents such as troglitazone) are now being tested in clinical trials for both NASH and other fibrotic liver diseases. FXR ligands appear to have similar effects and small-molecule agonists are under study in preclinical models with evidence of antifibrotic activity (120).

Leptin, produced by activated stellate cells (237), not only affects lipid metabolism but also directly influences wound healing. In fact, animals deficient in leptin have reduced hepatic injury and fibrosis (238,239). On the basis of this finding, the discovery of adiponectin, a natural counter-regulator to leptin, may lead to the use of this agent in fibrosis, particularly in association with NASH (147,148).

Progress in understanding transcriptional regulation has offered the opportunity to block stellate cell activation by inhibiting the activity of histone deacetylases (HDACs), enzymes critical for modifying chromatin during gene transcription (240). Highly specific HDAC inhibitors offer the potential for selectively blocking stellate cell activation with tolerable safety and good efficacy (241), but none has reached clinical use. Similarly, modulation of intracellular proteins including transcription factors remains an elusive target for antifibrotic therapy.

Herbal therapies and products derived from natural compounds that are commonly used in the Far East are increasingly being tested under controlled, scientifically rigorous conditions (242) and some show promise of efficacy, in particular Sho-saiko-to (243), *Salvia miltiorrhiza* (244), and a green tea polyphenol (245).

4. *Neutralize proliferative, fibrogenic, contractile, and/or proinflammatory responses of stellate cells*. Significant advances in growth factor biology will benefit the treatment of hepatic fibrosis through the development of antagonists to cytokines and their receptors. In particular, many proliferative cytokines including PDGF, FGF, and TGF-α signal through tyrosine kinase receptors, inhibitors of which are already undergoing clinical trials in other tissues (246). Because the intracellular signaling pathways for these receptors are well understood, inhibitors to signaling models are being explored in vivo or in cultured stellate cells, including γ-linoleic acid and lipoxygenase inhibitors (247), and PPARγ pathways (see preceding text). Others include inhibitors of 3-hydroxy-3-methyl-glutaryl coenzyme A reductase (248); pentoxyphylline, which inhibits PDGF receptor signaling (249), and compounds that elevate intracellular cyclic adenosine monophosphate levels (250) or block ion transporters, including pirfenidone (70,251).

   The recent success in developing Gleevec, a safe, effective, small-molecule tyrosine kinase antagonist in human leukemia and mesenchymal cell tumors (252,253), augurs well for the potential of this approach in other indications, including liver fibrosis. In fact, Gleevec is antifibrotic in experimental liver fibrosis (254). Other orally available, low-molecular-weight small molecules are under development to block cytokine receptor or intracellular signaling. One such compound is a selective inhibitor of Rho-mediated focal adhesions, which can reduce experimental liver fibrosis (255). Antisense to PDGF B chain also blocks experimental hepatic fibrosis (256). Because siRNA technology is increasingly becoming clinically applicable, this approach may merit further evaluation.

   Inhibition of matrix production has been the primary target of most antifibrotic therapies to date. This has been attempted directly by blocking matrix synthesis and processing, or indirectly by inhibiting the activity of TGF-β_1, the major fibrogenic cytokine. Inhibitors of collagen synthesis such as HOE 077, which blocks the enzyme prolyl hydroxylase, were among the first antifibrotic compounds tested in liver diseases, but success with this agent has been modest. The emerging importance of translational regulation of collagen gene expression (87,257,258,259) could lead to specific translational inhibitors with therapeutic value. Colchicine generated excitement at one time because of its apparent efficacy in a small group of patients (260); however, a more recent study in alcoholic cirrhosis showed

no benefit (261).

TGF-β antagonists are being extensively tested because neutralizing this potent cytokine would have the dual effect of inhibiting matrix production and accelerating its degradation (see ref. 78). Animal and culture studies using soluble TGF-β receptors or other means of neutralizing the cytokine, including monoclonal antibodies and protease inhibitors to block TGF-β activation, have established proof of principle (20,262,263). Concerns that inhibiting TGF-β may alter hepatocellular growth or apoptosis will need to be considered as these antagonists reach clinical trials, but in other tissues there is great promise for this approach. A number of even newer TGF-β antagonists are also being developed and may undergo testing soon. These could include recombinant Smad 7, which antagonizes TGF-β activity in stellate cells (264).

Rapamycin, an immunosuppressive drug used after liver transplantation has the added benefit of inhibiting stellate cell proliferation (265), which could attenuate the accelerated fibrosis progression in patients with recurrent HCV; however, the enthusiasm for using rapamycin has been tempered by a reported increase in hepatic artery thrombosis (266).

Relaxin, a natural peptide hormone that mediates parturition, has been developed as an agent that decreases collagen synthesis by stellate cells and

increases matrix degradation in vitro and in vivo (267). Stellate cells also express relaxin receptors (268), which might represent an attractive target for antagonism.

Because endothelin-1 is an important regulator of wound contraction and blood flow regulation mediated by stellate cells, antagonists have been tested as both antifibrotic and portal hypotensive agents. Bosentan, a mixed endothelin A and B receptor antagonist, has antifibrotic activity and reduces stellate cell activation in experimental hepatic fibrosis (269). This and other endothelin antagonists remain attractive drug development targets (270). Alternatively, the delivery of nitric oxide to an injured liver may have the same therapeutic effect as inhibiting endothelin-1 (215,271).

Halofuginone, an anticoccidial compound, has antifibrotic activity by blocking collagen expression and has been used in a number of models of tissue fibrosis, including the liver (272).

The potential utility of retinoids (vitamin A) as antifibrotic therapy has been limited by inadequate knowledge about their regulatory role in stellate cell activation and by toxicity concerns. Although stellate cells export retinoid as they activate, it does not follow that restoration of cellular retinoid will prevent activation. In fact, some retinoids may accelerate fibrosis by augmenting membrane injury as in hypervitaminosis A (273).

5. *Stimulate stellate cell apoptosis*. Attention is increasingly focused on how liver fibrosis regresses, and in particular, the fate of activated stellate cells as fibrosis recedes. Mounting evidence indicates that both reversal of the activated stellate cell phenotype and apoptosis are possible. In particular, as liver fibrosis is decreased, there is selective cell death of activated stellate cells (45). This exciting observation has led to animal studies using gliotoxin, which provokes selective apoptosis of stellate cells in culture and

in vivo, leading to reduced fibrosis (274,275). A TIMP-1 neutralizing antibody has antifibrotic activity in experimental liver fibrosis (276). Similarly, inhibition of Iκβ, whose net effect is to increase NF-κB signaling in stellate cells, may accelerate apoptosis (175). Apoptosis can also be provoked by the disruption of integrin-mediated adhesion (210) or through the use of tumor necrosis factor-α-related apoptosis-inducing ligands (TRAILs) (277). Stellate cells contain several families of apoptotic mediators, including Fas/FasL, TNF receptors, nerve growth factor receptors (278), and Bcl/Bax, so that additional targets to promote apoptosis will likely be exploited in the future (279).

6. *Increase the degradation of scar matrix*. This component of treatment is very important because antifibrotic therapy in human liver disease will need to provoke resorption of existing matrix in addition to preventing deposition of new scar. As noted in the preceding text, TGF-β antagonists have the advantage of stimulating matrix degradation by downregulating TIMPs and increasing net activity of interstitial collagenase (see ref. 35 for review). Retinoids may also stimulate matrix degradation but concerns over toxicity limit their utility. Relaxin can directly increase matrix degradation (280).

   Direct expression of metalloproteinases in animal models of hepatic fibrosis has begun to confirm that matrix can be resorbed by the expression of exogenous enzymes (281,282). Although this may seem impractical in humans, the data establishes the important proof of principle that matrix is responsive to degradation. Moreover, an experimental study has affirmed the importance of matrix degradation in the regression of hepatic fibrosis by demonstrating that a genetically altered mouse expressing mutant collagen resistant to degradation displays delayed regression of fibrosis after liver injury (283).

Future Prospects

Continued progress can be anticipated in unraveling the molecular regulation of fibrosis and its treatment. Rapid advances in gene therapy, tissue-specific targeting, and high-throughput small-molecule screening of cytokine inhibitors are likely to benefit the diagnosis and therapy of hepatic fibrosis. Methods have been developed for stellate cell–specific targeting in animal models (284), which could lead to successful directed therapy to minimize toxicity of antifibrotics and for use as novel diagnostics. New insights into the regulation of growth and apoptosis could have direct implications for stellate cell behavior in liver injury. Sequencing of the human genome and use of high throughput methods begun to yield genetic polymorphisms that predict the rate of fibrosis and patterns of multi-gene expression that have clinical or therapeutic implications, respectively. Additionally, there is tremendous interest in herbal and natural antifibrotic remedies, particularly in the Far East, where many such compounds are undergoing clinical trials. Accelerating progress is certain, once methods of noninvasive diagnosis are established that enable rapid assessment of fibrosis in clinical trials, and ultimately in clinical practice.

Chapter 15

Portal Hypertension and Nonsurgical Management

Jaime Bosch

Gennaro D'Amico

Juan C. García-Pagán

Key Concepts

- Portal hypertension is the most common and lethal complication of chronic liver diseases; it is responsible for the development of gastroesophageal varices, variceal hemorrhage, ascites, renal dysfunction, portosystemic encephalopathy, hypersplenism, and hepatopulmonary syndrome.
- Portal hypertension is defined by a pathologic increase in portal pressure, in which the pressure gradient between the portal vein and inferior vena cava (the portal pressure gradient [PPG]) is increased above the upper normal limit of 5 mm Hg. Portal hypertension becomes clinically significant when the PPG increases above the threshold value of 10 mm Hg (e.g., formation of varices) or 12 mm Hg (e.g., variceal bleeding, ascites). PPG values between 6 and 10 mm Hg represent subclinical portal hypertension.
- PPG is determined by the product of blood flow and vascular resistance within the portal venous system. Portal hypertension is initiated by an increased resistance to portal blood flow and aggravated by an increased portal venous inflow. The site of increased resistance to portal blood flow is the basis for the classification of portal hypertension: Prehepatic (e.g., portal vein thrombosis), intrahepatic (e.g., cirrhosis), and posthepatic (e.g., hepatic vein thrombosis, heart disease).
- Increased resistance in cirrhosis represents not only disruption of the liver's vascular architecture by liver disease but also a dynamic component resulting from the active contraction of vascular smooth muscle cells, myofibroblasts, and hepatic stellate cells. Active contraction is caused by decreased production of vasodilators such as nitric oxide (NO) and by increased release of endogenous vasoconstrictors. Increased hepatic vascular tone is the basis for the use of vasodilators to treat portal hypertension in cirrhosis.
- Portal inflow is increased by splanchnic vasodilatation, which is caused by an increased release of local endothelial factors and humoral vasodilators. Splanchnic vasodilatation can be counteracted with vasoconstrictors and β-blockers, which is why these drugs are used to treat portal hypertension.
- Portal pressure is most commonly assessed clinically by measuring the hepatic venous pressure gradient (HVPG), which is the difference between the wedged hepatic venous pressure (WHVP) and free hepatic venous pressure (FHVP), at hepatic vein catheterization. The HVPG accurately reflects the portal pressure in both alcoholic and viral cirrhosis. HVPG has to be above 10 mm Hg for varices to develop and above 12 mm Hg for variceal bleeding. The threshold values define "clinically significant portal hypertension."

- Bleeding from ruptured esophageal or gastric varices is a major complication of portal hypertension and a frequent cause of death. Approximately 40% of patients with compensated cirrhosis have varices at the time of diagnosis. The rate of formation of varices is approximately 5% per year, so varices develop in most patients during long-term follow-up. The risk of bleeding increases as the pressure and size of the varices increase and as the thickness of the variceal wall decreases. These parameters determine the tension of the variceal wall; rupture and bleeding occur when wall tension increases above the elastic limit of the varices.
- Most drugs used to treat portal hypertension are vasoconstrictors, which act primarily by reducing portal and collateral blood flow. This group includes vasopressin, terlipressin, the somatostatins, propranolol, nadolol, and other β-blockers.
- Vasodilators that decrease the portal pressure include isosorbide-5-mononitrate (IMN), which acts as an NO donor, and adrenergic antagonists, such as clonidine, prazosin, and carvedilol. A common problem with vasodilators is that they cause arterial hypotension, which in turn may enhance sodium retention and aggravate renal dysfunction in patients with cirrhosis and ascites.
- In combination therapy, a vasoconstrictor and a vasodilator are administered together. The combination prevents most of the adverse effects of the vasodilator and enhances the fall in portal pressure caused by the reduction in blood flow induced by the vasoconstrictor. Drug combinations with proven clinical efficacy are vasopressin plus nitroglycerin and propranolol or nadolol plus IMN.
- Continued drug therapy with propranolol or nadolol is highly effective in preventing first bleeding in patients with varices. This treatment should be given to all patients with medium or high variceal bleeding risk (patients with medium or large varices or those with small varices and red color signs or with poor liver function—Child-Pugh B and C) who have no contraindications to β-blockers. Therapy should be maintained indefinitely and is relatively well tolerated; the rate of discontinuation because of side effects or poor tolerance is 15%. Patients with high-risk varices and contraindications to β-blockers should be treated with endoscopic band ligation.
- During acute variceal hemorrhage, general supportive therapy (including antibiotic prophylaxis of bacterial infections and a very conservative use of blood transfusion) is essential to reduce mortality. The prognosis is worse in patients with advanced liver failure or with early (first-week) rebleeding. Terlipressin has proved effective as a first-line treatment in arresting variceal bleeding and reducing mortality from variceal hemorrhage. Somatostatin is also effective. Drug therapy has been shown to be as effective as and safer than emergency endoscopic therapy. Drug therapy should be started early on arrival at the emergency room or even during transfer to the hospital. Endoscopic therapy is established after confirming that esophageal varices are indeed the source of bleeding (66% of bleeding episodes in cirrhosis). Endoscopic band ligation is the endoscopic treatment of choice for acute esophageal variceal bleeding; however, endoscopic injection sclerotherapy can be used in the acute setting if endoscopic band ligation is technically difficult. It is recommended to maintain drug therapy for 2 to 5 days (even if the bleeding is apparently controlled by endoscopic therapy). Endoscopic variceal obturation with tissue adhesives is recommended for acute fundal gastric variceal bleeding.
- Failures of medical treatment should be managed aggressively with emergency surgery or transjugular intrahepatic portosystemic shunting (TIPS), preferably using expanded polytetrafluoroethylene (ePTFE) covered stents. Because of higher rates of morbidity and mortality, rescue derivative surgery should only be considered in low-risk patients (Child-Pugh score <8).

- Patients who survive an episode of variceal bleeding are at high risk for rebleeding. Medical treatment with β-blockers ± isosorbide mononitrate is as effective as endoscopic band ligation in preventing rebleeding. The best results are obtained when HVPG is reduced by at least 20% of the baseline value or below 12 mm Hg. The combination of IMN and propranolol or nadolol significantly increases the number of patients in whom the target reduction in portal pressure is achieved.
- Combination of β-blockers and band ligation is probably the best treatment option, especially in patients who have bleeding while under either therapy alone. Patients who rebleed despite combined endoscopic and pharmacologic treatment may be treated by TIPS or surgical portosystemic shunt; TIPS is the only option in nonsurgical candidates. All Child-Pugh class C patients should be considered for liver transplantation.

Portal hypertension is a common clinical syndrome, defined by a pathologic increase in the portal venous pressure, in which the pressure gradient between the portal vein and inferior vena cava (IVC) (portal perfusion pressure of the liver [PPG]) is increased above normal values (1 to 5 mm Hg). When the PPG rises above 10 to 12 mm Hg, complications of portal hypertension can arise (1,2,3,4). Therefore, this value represents the threshold for defining portal hypertension as being clinically significant.

The importance of this syndrome is defined by the frequency and severity of complications: Massive upper gastrointestinal bleeding from ruptured gastroesophageal varices and portal hypertensive gastropathy (PHG), ascites, renal dysfunction, hepatic encephalopathy, arterial hypoxemia, disorders in the metabolism of drugs or endogenous substances that are normally eliminated by the liver, bacteremia, and hypersplenism (5). These complications are major causes of death and the main indications for liver transplantation in patients with cirrhosis.

This chapter provides a background on the most important aspects of the pathogenesis, evaluation, and treatment of portal hypertension.

Etiology of Portal Hypertension

Portal hypertension can be caused by any disease interfering with blood flow at any level within the portal venous system. According to anatomic location, the diseases causing portal hypertension are classified as prehepatic (diseases involving the splenic, mesenteric, or portal veins), intrahepatic (acute and chronic liver diseases), or posthepatic (diseases interfering with the venous outflow of the liver) (5) (Table 15.1). Cirrhosis of the liver is by far the most common cause of portal hypertension in the world, followed by hepatic schistosomiasis. All other causes account for less than 10% of cases, which is why these cases are sometimes referred as *noncirrhotic portal hypertension*.

Prehepatic Portal Hypertensive Syndromes

Prehepatic portal hypertension is an infrequent condition in which increased portal pressure is caused by obstruction of the portal venous tree before it enters the liver. The site of obstruction may be limited to the splenic or mesenteric veins, but most commonly the portal vein is involved. Obstruction may be caused by congenital abnormalities or, more usually, by various underlying diseases that affect a part or all of the vessels of the portal venous system. In all these conditions, it is essential to obtain accurate anatomic information about the site and extent of the obstruction because it may affect therapeutic decisions.

Portal vein thrombosis

Portal vein thrombosis (PVT) is the most frequent cause of prehepatic portal hypertension. In children, a history consistent with omphalitis or umbilical catheterization can be often obtained. In adults, thrombophilic factors have been identified in approximately 60% and local

factors in 40% of patients with PVT (6,7). Several of these risk factors are frequently associated (8). However, despite a complete thorough investigation, up to 30% of episodes of PVT remain idiopathic. The spontaneous formation of erythroid colonies in culture increases the likelihood of the diagnosis of latent myeloproliferative disorders not detected by conventional criteria (9). This may be further facilitated by the recent identification of the *Janus kinase 2* (*JAK2*) gene mutation as a molecular marker of myeloproliferative disorders (10,11). Local factors include local inflammatory/infectious disorders (e.g., pancreatitis, cholecystitis, cholangitis, and appendicitis), local injury to the portal venous axis (e.g., splenectomy, abdominal trauma, surgical portacaval shunting, and other intra-abdominal surgical procedures). Other associated with PVT are the use of oral contraceptives, pregnancy, and inflammatory and malignancy states (6). The presence of these factors do not exclude the presence of systemic risk factors (8).

Table 15.1. Etiology of Portal Hypertension

Prehepatic
Splenic vein thrombosis
Portal vein thrombosis
Congenital stenosis of the portal vein
Extrinsic compression of the portal vein
Arteriovenous fistulae (splenic, aortomesenteric, aortoportal, and hepatic artery–portal vein)[a]
Intrahepatic
Partial nodular transformation
Nodular regenerative hyperplasia
Congenital hepatic fibrosis
Peliosis hepatis
Polycystic disease
Idiopathic portal hypertension
Hypervitaminosis A
Arsenic, copper sulfate, and vinyl chloride monomer poisoning
Sarcoidosis
Tuberculosis
Primary biliary cirrhosis
Schistosomiasis
Amyloidosis
Mastocytosis
Rendu-Osler-Weber syndrome
Liver infiltration in hematologic diseases
Acute fatty liver of pregnancy
Severe acute viral hepatitis
Chronic active hepatitis
Hepatocellular carcinoma
Hemochromatosis
Wilson disease

	Hepatic porphyrias
	α_1-Antitrypsin deficiency
	Cyanamide toxicity
	Chronic biliary obstruction
	Cirrhosis from hepatitis B and C virus infection
	Alcoholic cirrhosis
	Alcoholic hepatitis
	Veno-occlusive disease
Posthepatic	
	Budd-Chiari syndrome
	Congenital malformations and thrombosis of the inferior vena cava
	Constrictive pericarditis
	Tricuspid valve diseases

[a]This is the only instance in which portal hypertension is not initiated by an increased resistance to portal blood flow.

Cirrhosis may be considered as a local factor promoting PVT. The prevalence of PVT in patients with cirrhosis without associated hepatocellular carcinoma ranges between 0.5% and 26% (12). The concomitant existence of thrombophilic factors in patients with cirrhosis has been suggested to be a relevant risk factor for PVT (13). Other factors that are involved are endoscopic sclerotherapy, the use of vasoactives drugs, past history of variceal bleeding, and a low platelet count (12).

In most adult cases, chronic PVT is diagnosed after an episode of bleeding from ruptured esophageal varices or during routine evaluation (e.g., abdominal evaluation, ultrasonography, or upper endoscopy), whereas in children it is more frequently diagnosed after detecting splenomegaly. Variceal bleeding is much better tolerated in patients with prehepatic portal hypertension than in those with cirrhosis because the former do not have liver failure. Ascites and encephalopathy may develop following bleeding, although infrequently. In these cases, a diagnosis of concomitant liver disease should be considered.

Portal biliopathy, defined as the abnormalities of the extrahepatic and intrahepatic bile ducts observed by imaging techniques in patients with portal cavernoma (14), has been identified in over 80% of patients after long-standing portal vein obstruction (15). It is attributed to biliary compression by the peribiliary collaterals composing the cavernoma. Despite the high rate of biliary tract abnormalities, clinical consequences are infrequent (16), although increased serum alkaline phosphatase levels can be commonly found. However, some cases may develop severe, life-threatening manifestations (e.g., cholecystitis, cholangitis, and obstructive jaundice).

In some rare cases, the diagnosis is made in the acute phase of the disease, and the manifestations of acute portal vein obstruction are mixed with those of the initiating factor, such as recent surgery or abdominal infection. Patients may present with abdominal pain and fever. Diarrhea, ileus, and gastrointestinal bleeding resulting from intestinal infarction may be present. The severity of these symptoms is variable. The clinical suspicion of portal thrombosis should prompt ultrasonographic examination of the portal system. The identification of solid echoes within the portal vein and the absence of flow signals when pulsed Doppler equipment is used confirm the diagnosis. Echo enhancement may be useful. Magnetic resonance imaging (MRI) and helical computed tomographic (CT) scan are very useful, although not mandatory if ultrasonography clearly

shows PVT. When these noninvasive techniques do not demonstrate the site and extent of PVT, other diagnostic procedures, such as angiography, should be used. Angiography is also used in select cases, especially when a surgical approach is being considered. Retrograde wedged hepatic venography with the use of carbon dioxide as contrast agent may also be useful.

In the chronic phase, PVT is associated with the development of new vascular channels that bypass the obstruction, so that the portal vein takes on the appearance of a cavernoma. This is best shown by angiography but is also recognized on abdominal ultrasonography.

Patients with portal vein obstruction exhibit the same hemodynamic abnormalities as those with any other type of portal hypertension. These patients exhibit a hyperdynamic state, with increased blood volume and cardiac output and reduced arterial pressure and peripheral vascular resistance (17). The splanchnic circulation is also hyperdynamic, with increased inflow of blood into the portal venous system. Serum biochemistry shows either no abnormalities or a mild elevation in the concentration of globulins, and the hematologic examination may disclose a variable degree of hypersplenism, evidenced by leukopenia, thrombocytopenia, and anemia.

In acute PVT spontaneous recanalization is extremely infrequent. However, over 50% of patients receiving early anticoagulation achieve portal recanalization (18). Therefore, after the diagnosis of acute PVT early anticoagulation is mandatory. It is recommended to maintain patients on anticoagulation for at least 6 months (18). It, however, seems wise to maintain long-term anticoagulation in patients with an identified underlying prothrombotic disorder, with recurrent episodes of thrombosis, or a familial history of venous thrombosis (8). This is also true for patients with chronic PVT where, although recanalization is not expected to occur, anticoagulation has been shown to prevent the progression and recurrence of thrombosis without increasing the risk or severity of gastrointestinal bleeding (19), provided adequate treatment to prevent variceal bleeding is also established.

Direct thrombolytic therapy through a catheter introduced into the portal vein (either percutaneously or by a transjugular approach) may be useful in some cases of PVT. However, there are no studies evaluating whether this invasive approach offers advantages over early anticoagulation. Our own experience with direct thrombolysis has been disappointing.

In the absence of large specific studies, pharmacologic treatment with nonselective β-blockers, endoscopic band ligation, or the combination of both methods is used for preventing first variceal bleeding (8). Acute episodes of gastrointestinal hemorrhage are treated in the same manner as in patients with cirrhosis. Percutaneous transhepatic stenting of portal cavernoma is sometimes possible in instances of chronic PVT, from either a transjugular or a transhepatic approach and should be attempted if angiography suggests that the cavernoma has one or several vessels greater than 2 mm in diameter. Splenectomy and derivative surgery are strongly discouraged in children and should never be attempted in patients who have not bled. The best operation is a portoportal interposition bypass graft shunt, connecting a potent mesenteric/splenic vein with the intrahepatic portal vein, which is usually not thrombosed. Distal splenorenal shunt (DSRS) is the second choice when the splenic vein is patent. Mesocaval graft shunts are sometimes possible. Other procedures, such as esophageal transection or splenectomy and ligation of the varices, are less useful because of the high frequency of gastric varices and the high index of late rebleeding secondary to recurrent varices.

Splenic vein thrombosis

The main causes of isolated splenic vein thrombosis are chronic pancreatitis and carcinoma of the pancreas (20). Occasionally, splenic vein thrombosis has been

described in association with retroperitoneal infection or retroperitoneal fibrosis.

Usually, splenic vein obstruction is diagnosed after an episode of bleeding related to gastric varices. Physical examination reveals an enlarged spleen; the results of biochemical determinations are usually normal, whereas hematologic parameters may indicate hypersplenism. Gastric varices are a prominent (if not the only) endoscopic finding in these patients. The diagnosis is established by ultrasonography and splenic artery angiography. It should be noted that nonvisualization of the splenic vein on splanchnic angiography is not unequivocal evidence of splenic vein thrombosis. False-positive results are frequent in patients with marked splenomegaly. In these cases, MRI can be helpful.

Unlike subjects with portal thrombosis, patients with isolated splenic vein obstruction should be treated surgically because splenectomy is a curative operation and not associated with high rates of morbidity and mortality. However, patients without previous bleeding must be informed in detail about the risks and the long-term care that they will require after splenectomy before they opt for surgery.

Congenital stenosis of the portal vein

It is important to consider congenital stenosis of the portal vein in children with prehepatic portal hypertension. The stenosis may be found at any point along the portal vein, but the hepatic hilus and the middle of the trajectory of the vein are particularly common locations. As in other patients with prehepatic portal

hypertension, the disease is usually diagnosed after an episode of gastrointestinal bleeding from ruptured gastroesophageal varices. The physical examination may show splenomegaly and subcutaneous collateral vessels. Parameters of liver function remain within the normal range, and ultrasonography shows patency of the portal vein, thereby suggesting a false diagnosis of intrahepatic portal hypertension. However, liver histology is normal, as are hepatic venous pressures. Careful ultrasonographic examination of the portal vein and analysis of the venous phase of splanchnic angiography may reveal the stenosis, which can then be confirmed by measuring the venous pressure along the portal vein and demonstrating a pressure gradient at the location of the stenosis. These children can be managed medically, by transluminal balloon angioplasty (with or without stenting), or surgically.

Extrinsic compression of the portal vein

Portal hypertension resulting from compression of the portal vein by a mass or a process located in the vicinity of its trajectory is an unusual condition. However, the splenic vein may be compressed by benign or malignant disease of the pancreas or by retroperitoneal fibrosis.

Partial nodular transformation of the liver is an infrequent disease of unknown origin characterized by the appearance of large nodules (up to 8 cm in diameter) in the hilar area of the liver. Serum liver chemistries are usually normal, and the condition is diagnosed either after an episode of bleeding from esophageal varices or during the diagnostic workup of an enlarged spleen. Pathologic examination shows the hilar nodules, which are composed of normal hepatocytes with minimal fibrosis, and a normal appearance of the surrounding liver. The nodules compress the portal vein, which on portography shows a characteristic smooth narrowing at the hepatic hilum.

Arteriovenous fistulae in the portal venous system

Arteriovenous fistulae in the spleen and splanchnic vascular bed may present with portal hypertension, ascites, and varices. Approximately one third of patients have abdominal pain, and in some of these cases, it is possible to hear an abdominal bruit. The location of arteriovenous fistulae may be intrahepatic or extrahepatic (e.g., in the

spleen or portal vein). They may be of congenital origin, associated with the Rendu-Osler-Weber syndrome, or caused by trauma. Intrahepatic arterioportal fistulae may be caused by liver biopsy or other invasive procedures. In other cases, fistulae are observed within a hepatocellular carcinoma. In patients with cirrhosis, the development of an intrahepatic arteriovenous fistula may markedly aggravate portal hypertension. In rare cases, an aneurysm of the hepatic artery may rupture into the portal vein and give rise to a fistula and portal hypertension. Aorta–portal fistulae or intrasplenic arteriovenous fistulae are infrequent complications of abdominal wounds.

Treatment of these patients by percutaneous arterial embolization is usually feasible. Otherwise, surgical ligation of the fistula may be required. These procedures are followed by total or partial normalization of the portal pressure. Arteriovenous fistulae increase the portal blood flow, and this may be the unique situation in which the portal pressure increases without an increased resistance to portal blood flow. However, evidence suggests that secondary "hepatoportal sclerosis," with fibrosis of portal radicles and thickening and sclerosis of the portal veins, may develop in response to an "arterialized" portal system. This is probably the reason why in some of these patients, portal hypertension is not entirely corrected despite surgical closure of the fistula (21).

Splenomegaly

Splenomegaly in the setting of hematologic or deposit diseases, such as leukemia, lymphoma, polycythemia vera, and myelophthisis with myeloid metaplasia, may be associated with complications of portal hypertension, including ascites and variceal hemorrhage, which were thought to be a consequence of an increase in portal blood flow (22). However, in most cases, the primary disease also infiltrates the liver, and portal hypertension is mostly caused by an increased resistance to portal blood flow.

Intrahepatic Causes of Portal Hypertension

Intrahepatic causes of portal hypertension have been classified according to the anatomic zone of obstruction to portal blood flow within the liver and according to the results of hepatic vein catheterization (see subsequent text). Hence, these syndromes are divided into presinusoidal (with normal "wedged" pressure), sinusoidal (with increased wedged pressure and normal "free" pressure), and postsinusoidal categories (with increases in both wedged hepatic venous pressure [WHVP] and free hepatic venous pressure [FHVP]). Some diseases cause lesions at several sites.

These liver diseases (Table 15.1) are fully discussed in other chapters. The specific aspects related to portal hypertension are briefly reviewed here.

Schistosomiasis

Portal hypertension is the consequence of a granulomatous reaction to the deposition of parasite eggs in the portal venules. The inflammatory response leads

to fibrosis and obliteration of the portal venules, with manifestations of portal hypertension in the absence of significant hepatocellular injury. As the disease progresses, fibrosis extends into the sinusoids, and the hemodynamic pattern and clinical course then resemble those of liver cirrhosis.

Sarcoidosis

Portal hypertension is an infrequent manifestation of hepatic sarcoidosis. Sarcoid granulomas frequently localize in the portal areas of liver lobules and injure portal venules. Early disease is predominantly presinusoidal, with normal sinusoidal pressure, whereas advanced disease leads to fibrosis and cirrhosis.

Myeloproliferative diseases

Myeloproliferative diseases may cause intrahepatic portal hypertension as malignant cells directly infiltrate the liver.

Nodular regenerative hyperplasia

Nodular regenerative hyperplasia is a nonspecific reaction to a variety of injuries (see Chapter 40). It is characterized by a nodular transformation of the hepatic parenchyma without fibrous tissue between the nodules. The cause of nodular regenerative hyperplasia seems to be heterogeneity of the blood supply. Whereas acini with normal or increased blood flow undergo hypertrophy, others, with decreased blood flow, undergo atrophy. This process may be the result of diseases that decrease the blood flow in the portal venules, in most cases as a result of portal thrombosis, and is probably the main mechanism leading to portal hypertension in this condition. Compression of the portal venous tract by the nodules may also play a role.

Primary biliary cirrhosis

The development of portal hypertension in the initial stages of primary biliary cirrhosis (before the development of cirrhosis) is thought to be caused by injury of portal venules at the portal tracts, which promotes a presinusoidal type of portal hypertension. Progression of the disease, with the development of fibrous tracts, adds a sinusoidal component. This is always present when the disease reaches stage IV.

Idiopathic portal hypertension

Idiopathic portal hypertension is known by different names, including *Banti's syndrome, noncirrhotic portal fibrosis*, and *hepatoportal sclerosis*. The syndrome is recognized predominantly in Japan and India. In India, up to 30% of patients with portal hypertension have this disease, with a male predominance noted.

Variceal bleeding is the main clinical manifestation of idiopathic portal hypertension; ascites, encephalopathy, and other signs of liver failure are encountered only in the late stages of the disease. Variceal hemorrhage is usually well tolerated, and endoscopic techniques or portacaval anastomosis is associated with low rates of rebleeding and death.

The etiology of idiopathic portal hypertension has not been explained satisfactorily. Exposure to toxins (arsenic and others) or infectious agents has been postulated, without confirmation. It has been suggested that idiopathic portal hypertension and idiopathic portal thrombosis may be part of the same spectrum, in which the lesion of the portal branches would affect the distal intrahepatic part of the portal tree in idiopathic portal hypertension and the more proximal branches in portal thrombosis.

In idiopathic portal hypertension, the liver surface may be pseudonodular. This fact should be taken into account so that the disease is not confused with liver cirrhosis. Patients with idiopathic portal hypertension must be distinguished by liver biopsy from patients with well-compensated cirrhosis.

Toxicity caused by vinyl chloride, arsenic, vitamin A, mercaptopurine, azathioprine, thioguanine, and other agents

A variety of drugs and chemicals have been associated with the development of portal hypertensive liver disease in the absence of cirrhosis. Among these, arsenic is a well-known cause of portal hypertension. Probably a consequence of vascular injury, a wide spectrum of arsenic-related lesions is recognized: Angiosarcoma, perisinusoidal fibrosis, peliosis hepatis in association with angiosarcoma, and veno-occlusive disease with centrilobular sinusoidal dilatation and perisinusoidal fibrosis. Other etiologic agents in addition to arsenic include vinyl chloride, vitamin A, busulfan, chlorambucil, mercaptopurine, and azathioprine. They all cause lesions with many similarities to

those of idiopathic portal hypertension.

Acute and fulminant viral hepatitis

Portal hypertension with all its complications has been described in severe acute hepatitis and fulminant hepatic failure of various causes. A significant correlation has been demonstrated between the severity of portal hypertension (assessed by hepatic vein catheterization) and the severity of hepatitis (indicated by encephalopathy, elevation of serum bilirubin and albumin levels, and coagulopathy). Histologically, portal hypertension seems to correlate with the degree of collapse of the sinusoids and reduction in the intrahepatic vascular space resulting from hepatic necrosis.

Acute fatty liver of pregnancy

A moderate degree of portal hypertension is frequently found in patients with acute fatty liver of pregnancy. It is thought to be caused by compression of the sinusoids by the microvesicular steatosis.

Posthepatic Portal Hypertension Syndromes

Posthepatic obstruction can take place in the IVC or at the level of superior vena cava or right atrium. It may occur in any disease in which right-sided heart pressures are increased.

Inferior vena cava obstruction

The causes of mechanical obstruction of the IVC include venous thrombosis, tumor, cysts, and abscesses. Membranous obstruction may be caused by a fibrous web located above the hepatic veins. The clinical presentations of these extrahepatic syndromes overlap with those of intrahepatic postsinusoidal syndromes, such as Budd-Chiari syndrome or veno-occlusive disease with congestive hepatomegaly, which may be painful and associated with ascites and variceal bleeding. The presence of venous collaterals on the abdominal wall and edema in the lower extremities may suggest the presence of IVC obstruction.

Membranous obstruction of the IVC is most commonly encountered in young adults in the Far East and Africa. Its course is subacute, in contrast to the usually acute presentation of thrombotic occlusion of the IVC.

Angiography demonstrates a filling defect in the IVC below the level of the diaphragm or a web with a collateral venous pattern. The hepatic veins are usually patent, with a high WHVP but a normal hepatic venous pressure gradient (HVPG) resulting from high IVC pressure. Patients with an IVC web may be cured by surgical excision or percutaneous angioplasty.

Heart disease

When pressure rises in the right chambers of the heart in constrictive pericarditis, valvular disease (e.g., mitral stenosis with tricuspid insufficiency), or cardiomyopathy of any cause, the pressure is transmitted backward through a valveless venous system from the IVC to the hepatic veins, hepatic sinusoids, and portal venous system. The consequence is a picture similar to that of hepatic vein occlusion, IVC web, or any syndrome of obstruction of the hepatic venous outflow. The symptoms of such patients—intractable ascites and hepatocellular dysfunction—may be difficult to distinguish from those associated with other causes of portal hypertension, even cirrhosis. Esophageal varices are usually not present because a gradient between the portal and azygos systems is lacking.

Pathophysiology of Portal Hypertension

PPG is the result of the interaction between the portal blood flow and the vascular resistance to the flow. This relationship is defined by Ohm's law in the following equation:

$\Delta P = Q \times R$

in which ΔP is the PPG (the difference between the portal pressure and the IVC pressure), Q is the blood flow within the entire portal venous system (which in portal hypertension includes the portal–systemic collaterals), and R is the vascular resistance of the entire portal venous system. It follows that portal pressure may be increased by an increase in portal blood flow, an increase in vascular resistance, or a combination of both (23). It is well established that in cirrhosis, the primary factor leading to portal hypertension is an increased resistance to portal blood flow. An increased portal venous inflow maintains and exacerbates portal hypertension. This component of increased blood flow becomes especially important in advanced stages (Fig. 15.1).

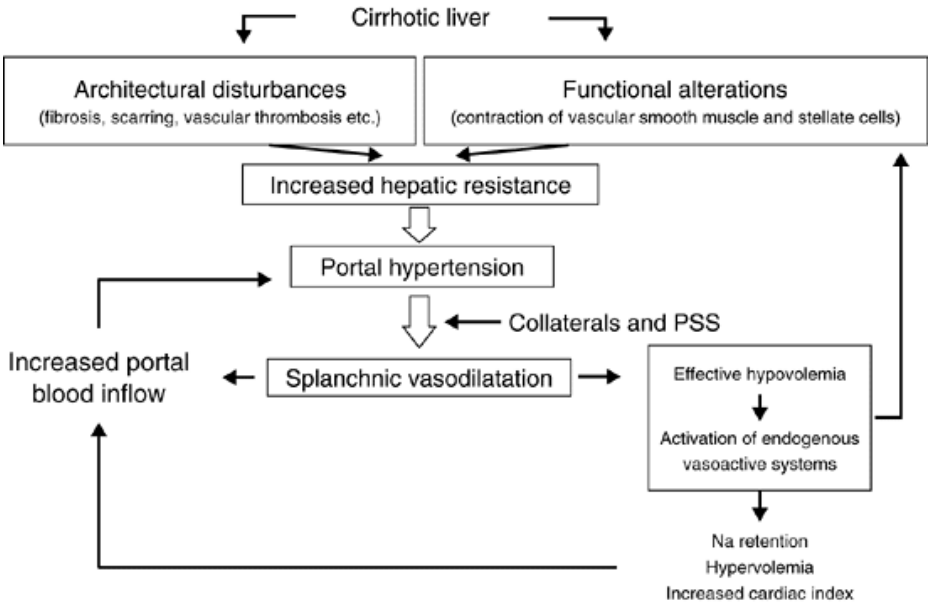
Increased Vascular Resistance to Portal Blood Flow

Increased resistance to portal blood flow is the primary factor in the pathophysiology of portal hypertension and may occur at any site within the portal venous system. In cirrhosis, increased intrahepatic vascular resistance is thought to be mainly in the hepatic sinusoids (5). For many years, the increased intrahepatic vascular resistance was thought to be a fixed, mechanical consequence of architectural distortion of the hepatic microcirculation by fibrosis, scarring, and nodules. In addition, careful pathologic studies have suggested that thrombosis of medium and large portal and hepatic veins is a frequent occurrence in cirrhosis and that these events may be important in causing a progression of cirrhosis and worsening of portal hypertension (24).

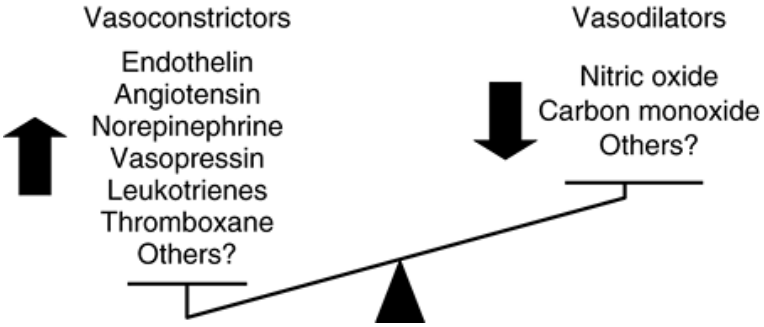
However, recent studies have demonstrated that in addition to the increased resistance caused by the morphologic changes of chronic liver diseases, a dynamic component of increased resistance is present that represents active contraction of the contractile elements in the liver. These elements constrict in a reversible and graded manner in response to several agonists, thereby further increasing the intrahepatic resistance (25). It has been claimed that this dynamic component may represent up to 40% of the increase in intrahepatic vascular resistance.

The contractile elements of the hepatic vascular bed are located at a sinusoidal level and at extrasinusoidal sites (26,27,28). They include smooth muscle cells of the intrahepatic vasculature (i.e., small portal venules in

portal areas) (26); activated hepatic stellate cells, which are located in the perisinusoidal space of Disse and have extensions that wrap around the sinusoids (27); and hepatic myofibroblasts, which are abundant in the fibrous tissue in and around cirrhotic nodules. Contraction of hepatic myofibroblasts may increase intrahepatic resistance by compressing venous shunts in the fibrous septa. It is now clear that vasoactive mediators, either vasoconstrictors or vasodilators, modulate intrahepatic vascular resistance in both the healthy and the cirrhotic liver. An increased production of vasoconstrictors and an exaggerated response of the hepatic vascular bed to these agents, as well as an insufficient release of vasodilators, together with an impaired vasodilatory response of the hepatic vascular bed, are the mechanisms that have been implicated in the pathogenesis of the dynamic component of the increased intrahepatic resistance of the cirrhotic liver (5) (Fig. 15.2).



▪ **Figure 15.1** Schematic representation of the pathophysiology of portal hypertension.



▪ **Figure 15.2** Factors modulating intrahepatic resistance in cirrhosis. A reduction in the release of endogenous vasodilators and an increase in vasoconstrictor activity contribute to the increased hepatic vascular resistance in cirrhosis.

Increased Production of Vasoconstrictors and Exaggerated Response of the Hepatic Vascular Bed

Endothelins (*ETs*) are a family of homologous 21 amino acid vasoactive peptides (ET-1, ET-2, and ET-3) that are thought to play a major role in modulating hepatic vascular tone in cirrhosis (29). The biologic properties of ETs are mediated essentially by two major ET receptors, ET-A and ET-B. The ET-A receptor shows a high affinity for ET-1, but not for ET-3, and mediates constriction; the ET-B receptor has equal affinity for ET-1 and ET-3. Activation of ET-B receptors located on the vascular smooth muscle cells promotes vasoconstriction, whereas activation of ET-B receptors located on

endothelial cells promotes vasodilatation, which is mediated by enhanced nitric oxide (NO) and prostacyclin production by the endothelial cell.

Patients with liver cirrhosis have increased circulating plasma levels of ET-1 and ET-3 (30). The increase is greater and more consistently found in patients with cirrhosis and ascites. A net release of ET-1 and ET-3 during splanchnic passage has been observed in patients with cirrhosis, but not in controls, a finding that suggests an increased production of ET-1 and ET-3 in the splanchnic territory. Immunostaining and in situ hybridization studies have detected an increased expression of ET-1 in human cirrhotic livers (31); endothelial cells, hepatic stellate cells (in their activated phenotype), and bile duct epithelial cells are the major intrahepatic sources of ET-1. A decreased clearance of ET-1 by the liver has also been demonstrated in cirrhotic rats.

ET-1 increases portal perfusion pressure by increasing intrahepatic resistance in isolated, perfused normal livers and carbon tetrachloride–induced cirrhotic livers. Although some experimental studies reported a slight reduction of portal pressure in cirrhotic animals after the administration of ET antagonists (32,33), this was not confirmed by other studies (34). Therefore, the role of ETs in increasing the vascular tone in cirrhosis remains unsettled.

Other vasoconstrictive factors are involved in the regulation of hepatic vascular tone. Studies in perfused cirrhotic livers have shown that *norepinephrine, angiotensin II*, and *vasopressin*, three circulating vasoactive factors whose levels are usually elevated in cirrhosis, increase intrahepatic vascular resistance (35,36). The increased resistance promoted by norepinephrine is completely blunted by the administration of α-adrenergic antagonists, such as prazosin. These agents by themselves markedly reduce hepatic resistance and portal pressure in patients with cirrhosis. On the other hand, the administration of α-adrenergic agonists, such as isoproterenol, reduces intrahepatic vascular resistance in perfused cirrhotic liver. These data suggest that adrenergic receptors may be involved in the regulation of intrahepatic resistance in cirrhosis and that α-adrenergic receptor blockers may decrease portal pressure in cirrhosis. In addition, the hepatic vascular bed of cirrhotic livers exhibits an exaggerated response to the α-adrenergic agonist methoxamine. This hyper-response is associated with the overproduction of thromboxane A_2 (TXA_2) by cyclo-oxygenase (COX-1) isoenzyme and is completely corrected by pretreating the livers with nonselective COX blockers, COX-1–selective blockers, or TXA_2 antagonists. Therefore, an increased production of TXA_2 markedly enhances the vasoconstrictive response of the cirrhotic hepatic vascular bed to methoxamine (37). Whether this effect is also shared by other vasoconstrictors has not been investigated so far. However, it is known that the coupling of different agonists to the membrane G-coupled receptors promotes the release of arachidonic acid from the plasma membrane, facilitating its metabolization to different prostanoids (38,39).

Angiotensin II is a powerful vasoconstrictor that may increase hepatic resistance. Strategies based on direct angiotensin II blockade by specific A-II antagonists, inhibitors of the converting enzyme, or A-II receptors blockers may reduce portal pressure but cause systemic hypotension.

Cysteinyl leukotrienes are a group of highly potent vasoactive substances derived from the oxygenation and dehydration of arachidonic acid by 5-lipoxygenase. These substances have been shown to increase intrahepatic vascular resistance in normal and carbon tetrachloride–induced cirrhotic rat livers. The response is significantly greater in cirrhotic livers, which exhibit increased production of cysteinyl leukotriene and expression of 5-lipoxygenase messenger ribonucleic acid (mRNA). In addition, inhibition of 5-lipoxygenase produces a significant and marked reduction in portal pressure in cirrhotic livers, which suggests that 5-lipoxygenase–derived eicosanoids contribute to the increased hepatic vascular resistance in cirrhosis.

Endothelial Dysfunction of Cirrhotic Livers

In normal conditions, the endothelium is able to generate vasodilator stimuli in response to increases in blood volume, blood pressure, or vasoconstrictor agents in an attempt to prevent or attenuate the concomitant increase in pressure. In several pathologic conditions there is an impairment in this endothelium-dependent vasodilatation, called *endothelial dysfunction* (40,41). Endothelial dysfunction is considered one of the main pathologic mechanisms involved in the increased vascular tone observed in several vascular disorders, such as arterial hypertension, diabetes, and atherosclerosis, and has been attributed to a diminished NO bioavailability (40,41) or to an increased production of endothelial-derived contracting factors, such as prostaglandin H_2 (PGH_2)/TXA_2 (42), ET (43), or anion superoxide (44).

The hepatic vascular bed of cirrhotic livers also exhibits endothelial dysfunction (45). Indeed, studies performed both in patients with cirrhosis and in experimental models have shown that, contrary to what happens in normal livers, the cirrhotic liver cannot accommodate the increased portal blood flow caused by the postprandial hyperemia, which determines an abrupt postprandial increase in portal pressure (46). This is important because such repeated brisk increases in portal pressure and portal–collateral blood flow in response to meals and other physiologic stimuli are thought to be a major determinant of the progressive dilatation of the varices in patients with cirrhosis (5). In addition, endothelial dysfunction has been further characterized in experimental models of cirrhosis by showing that the cirrhotic liver exhibits an impaired response to the endothelium-dependent vasodilator acetylcholine (45,47). This impaired response to acetylcholine was shown to be associated with an increased production of TXA_2 and completely prevented by selective COX-1 blockers and TXA_2 antagonists. These results suggest that an increased production of a COX-1–derived vasoconstrictor prostanoids, probably TXA_2, is, at least in part, responsible for endothelial dysfunction (47). Acetylcholine coupling to the endothelial muscarinic M3 receptor has been shown to promote the stimulation of NO synthase and COX-1, with the subsequent release of NO and vasoconstrictor endoperoxides, respectively (48). In physiologic states,

a vasodilating response is the final balance between the interactions of these endothelial vasoactive mediators. However, in cirrhosis, as in other conditions such as hypertension, diabetes, and arteriosclerosis, there is a perturbation of this balance, resulting in endothelial dysfunction with the consequent impaired response to acetylcholine. All these findings suggest that in cirrhotic livers there is an overactivation of the COX-1 pathway with an increased production of the vasoconstrictor-derived compounds.

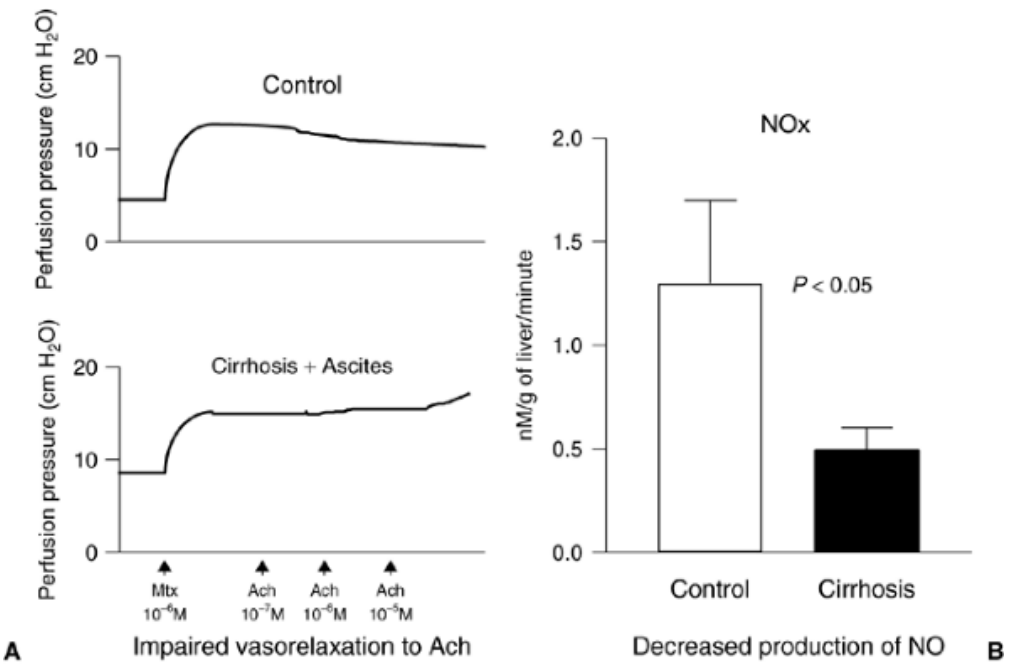
Insufficient Release of Hepatic Vasodilators

Nitric oxide

The role of NO in modulating intrahepatic vascular resistance is a subject of considerable interest. NO is a powerful endogenous vasodilator generated in several tissues by NO synthases from the amino acid L-arginine. It is the natural ligand for soluble guanylate cyclase and is responsible for an increase in the levels of cyclic guanosine monophosphate, the final agent responsible for the relaxation of the vascular wall through the extrusion of cytosolic Ca^{2+}.

NO blockade has been shown to increase portal perfusion pressure in isolated perfused rat livers. In addition, the hepatic response to norepinephrine is markedly enhanced after NO inhibition, a finding that further suggests a role for NO in modulating hepatic vascular tone in normal conditions (49). In the cirrhotic liver, the synthesis of NO is insufficient to compensate for the activation of vasoconstrictor systems frequently associated with cirrhosis (Fig. 15.3). This occurs despite a normal expression of

endothelial nitric oxide synthase (eNOS) mRNA and normal levels of eNOS protein (45,50). The decreased activity of hepatic eNOS in cirrhosis is due in part to increased expression of caveolin (51). This insufficient hepatic NO generation plays a major role in increasing intrahepatic vascular resistance in cirrhosis, thereby worsening portal hypertension. In accordance with this concept, the infusion of L-arginine, the precursor of NO biosynthesis, and the administration of nitrates (exogenous donors of NO) have been shown to decrease portal pressure. In addition, enhancement of the expression of NO synthase in liver cells, through the portal injection of adenovirus coupled with the gene encoding NO synthase, significantly reduces portal pressure (52). More recently, strategies aimed at increasing NO release by enhancing intrahepatic eNOS activity, on the basis of constitutively active *Akt* gene transfer (53), or by simvastatin administration (54) have opened new perspectives with potential therapeutic implications.



▪ **Figure 15.3** Cirrhotic rat livers exhibit endothelial dysfunction, characterized by an impaired vascular relaxation in response to acetylcholine (Ach) **(A)** and a decreased production of nitric oxide (NO) **(B)**. NOx, nitrite/nitrate; Mtx, methotrexate. (From Gupta TK, Tourner M, Chung MK, et al. Endothelial dysfunction and decreased production of nitric oxide in the intrahepatic microcirculation of cirrhotic rats. *Hepatology* 1998;28:926–931, with permission.)

Carbon monoxide

A role for carbon monoxide (CO), a by-product of heme group oxidation by heme oxygenases (HOs), as an important modulator of intrahepatic vascular tone has been suggested. CO, although less potent than NO, also activates guanylate cyclase and thereby

promotes smooth muscle relaxation. The inhibition of CO production increases portal resistance in normal livers (55).

Heme oxidation is catalyzed by two different enzymes, HO-1 and HO-2. In normal conditions, CO is produced in the liver by the constitutive isoform (or HO-2). However,

in several stress conditions, such as endotoxemia and hemorrhagic shock, the inducible isoform (or HO-1) is formed. In this situation, the inhibition of HOs with specific agents leads to a much greater increase in portal–hepatic resistance than is seen in normal, unstimulated livers (56).

HO-1 expression is increased in the liver in experimental models of cirrhosis (57). In addition, there is a complex interaction between the NO and CO systems. NO has been shown to induce HO-1 expression and, therefore, CO synthesis. On the other hand, CO may inhibit the NO-mediated production of cyclic guanylate cyclase monophosphate. Therefore, an increased expression of HO-1 in cirrhosis suggests that CO may play a role in the hepatic circulatory disturbances found in liver cirrhosis.

Splanchnic Vasodilatation

An increased portal venous inflow is characteristically observed in advanced stages of portal hypertension and is the result of marked arteriolar dilatation in the splanchnic organs draining into the portal vein. The increased blood flow contributes to the portal hypertensive syndrome (5) (Fig. 15.1).

Different mechanisms have been suggested to explain the observed hemodynamic abnormality, which likely represents a multifactorial phenomenon involving neurogenic, humoral, and local mechanisms. Initial studies focused on the potential role of increased levels of circulating vasodilators. Many candidate substances were proposed, most of them being vasodilators of splanchnic origin that undergo hepatic metabolism and accumulate in the systemic circulation when hepatic uptake is reduced in liver disease or during portosystemic shunting.

Glucagon

Glucagon is probably the humoral vasodilator for which most evidence has been accumulated to indicate a significant role for it in splanchnic hyperemia and portal hypertension.

Many studies have demonstrated that plasma glucagon levels are elevated in patients with cirrhosis and experimental models of portal hypertension. Hyperglucagonemia results, in part, from a decreased hepatic clearance of glucagon, but more importantly from an increased secretion of glucagon by pancreatic α cells (58). The support for a role of glucagon in modulating splanchnic blood flow comes from physiologic studies showing that in rats with experimental portal hypertension, normalizing circulating glucagon levels by administering glucagon antibodies or infusing somatostatin partially reverses the increase in splanchnic blood flow, a response that can be specifically blocked by the concomitant infusion of glucagon (59,60). Conversely, other studies have shown that increasing circulating glucagon levels in normal rats to values similar to those observed in portal hypertension causes a significant increase in splanchnic blood flow. On the basis of these studies, it has been suggested that hyperglucagonemia may account for approximately 30% to 40% of the splanchnic vasodilatation of chronic portal hypertension. Glucagon may promote vasodilatation by a dual mechanism: Relaxing the vascular smooth muscle and decreasing its sensitivity to endogenous vasoconstrictors, such as norepinephrine, angiotensin II, and vasopressin (61,62). The role of glucagon in the splanchnic hyperemia of portal hypertension provides a rationale for the use of somatostatin and its synthetic analogs to treat portal hypertension (63).

Endocannabinoids

Recent data suggest a role for endocannabinoids in the hyperdynamic circulation of portal hypertension (64,65). Increased levels of the endogenous cannabinoid anandamide have been found in the monocyte fraction of blood from cirrhotic humans and rats, and an increased expression of the cannabinoid CB1 receptors was found in

hepatic human endothelial cells (64). In addition, CB1 receptor blockade has been found to reduce portal blood flow and pressure and increase arterial pressure in cirrhotic rats (64,65). The mechanism of action is not well understood. It has been suggested that it could be due, at least in part, to an increased NO production, mediated by the activation of endothelial CB1 receptors (64). However, the data are not conclusive (65).

Several other circulating vasodilators have been implicated in splanchnic vasodilatation. *Bile acids* are increased in portal hypertension and have vasodilator properties. However, the data in the literature are controversial, and the role of bile acids in the hyperdynamic circulation is not well defined. Likewise, the role of the *capsaicin–calcitonin gene-related peptide* vasodilator pathway in the systemic and splanchnic vasodilatation of portal hypertension is controversial. Other candidates, including neuropeptides, adenosine, endotoxin, and a variety of vasodilator gastrointestinal hormones, have also been studied. However, supporting evidence is scarce for most of them.

Nitric oxide

Experimental studies of specific NO inhibitors have shown that NO is involved in the regulation of

splanchnic and systemic hemodynamics in portal hypertensive and control animals. The splanchnic vasoconstrictive effect caused by NO inhibitors is significantly greater in portal hypertensive than in control animals, which suggests that an excessive production of NO may be responsible, at least in part, for the vasodilatation observed in portal hypertension (66,67). In addition, NO inhibition has been shown to reverse the vascular hyporesponsiveness to vasoconstrictors that is characteristic of portal hypertension and is thought to contribute to systemic and splanchnic vasodilatation (68). In addition, an overproduction of NO has been clearly demonstrated in vitro in perfused mesenteric artery preparations from portal hypertensive rats (69). The finding in patients with cirrhosis of increased serum and urinary concentrations of nitrite and nitrate, which are products of NO oxidation, also supports a role for NO in the genesis of the circulatory disturbances of portal hypertension (70).

The increased production of NO is due both to an increased expression and an increased activity of eNOS (71,72). Factors likely to activate the constitutive NO synthase include shear stress, circulating vasoactive factors (e.g., ET, angiotensin II, vasopressin, and norepinephrine) and overexpression of the angiogenic factor vascular endothelial cell growth factor (VEGF) (73,74). In portal hypertensive animals, NO overproduction by eNOS in the splanchnic circulation precedes the development of hyperdynamic circulation (75) and is mostly due to an upregulation of eNOS catalytic activity, rather than eNOS overexpression (76). Indeed, eNOS phosphorylation by Akt seems to be the mechanism of the initial upregulation of eNOS activity and NO-mediated hyporesponsiveness to vasoconstrictors (76). Later on, other mechanisms become important, including an enhanced signaling of the molecular chaperone heat shock protein 90 (Hsp90) (77,78). In addition, in cirrhotic rats with ascites, it was shown that bacterial translocation further increased eNOS expression in the mesenteric artery, probably in response to increased levels of tumor necrosis factor α (TNF-α). TNF-α production was associated with elevated levels of tetrahydrobiopterin, a TNF-α–stimulated cofactor and enhancer of eNOS-derived NO biosynthesis and NO synthase activity (72).

Prostaglandins

Several studies support a role for prostaglandins in the hyperdynamic circulation in portal hypertension (79,80,81). Prostacyclin is an endogenous vasodilator produced by vascular endothelial cells. It causes vascular smooth muscle relaxation by activating

adenylate cyclase and augmenting the intracellular level of cyclic adenosine monophosphate. Two different isoforms of COX are involved in the biosynthesis of prostacyclin. The constitutive isoform (COX-1) may be stimulated by factors similar to those that stimulate the constitutive isoform of NO synthase (eNOS). In addition, the inducible isoform (COX-2), like inducible nitric oxide synthase, can be expressed on stimulation with proinflammatory agents. Animal studies have shown a partial reversal of splanchnic vasodilatation after COX blockade. This effect is independent of that of NO. They have further shown that systemic levels of prostacyclin may be increased in patients with cirrhosis. In addition, the inhibition of prostaglandin biosynthesis by indomethacin reduces the hyperdynamic circulation and portal pressure in patients with cirrhosis and portal hypertension. Recent studies suggest that both isoenzymes COX-1 and COX-2 are involved in the increased prostacyclin production by the mesenteric vascular bed of portal vein–ligated rats (82). The selective inhibition of COX-2, and to a lesser extent of COX-1, improved the endothelial-dependent vasodilatation in response to acetylcholine (82).

Carbon monoxide

Recent studies have shown an increased expression and activity of the inducible form, or HO-1, in splanchnic tissues from animals with portal hypertension (57,83). In addition, the simultaneous inhibition of NO and HO has been shown to completely reverse the reduced vasoconstrictor response to potassium chloride in the mesenteric vascular bed (83).

Altogether, these data suggest that the splanchnic vasodilatation present in portal hypertension is likely to be multifactorial in origin, being promoted in part by an excessive release of NO, CO, and other vasoactive mediators. In addition, experimental studies suggest that when one of the vasoactive mediators is chronically inhibited, the enhancement of other vasoactive pathways may prevent the correction of splanchnic vasodilatation (84). Coupling of several vasoactive systems may cause the splanchnic vasodilatation seen in portal hypertensive states.

Portosystemic Collateral Circulation

The development of portal–collateral circulation is one of the main complications of portal hypertension. Formation of collaterals is a complex process involving the opening, dilatation, and hypertrophy of preexisting vascular channels (4). Collaterals develop in response to the increased portal pressure. A minimum HVPG threshold of 10 mm Hg should be reached for the development of portosystemic collaterals and esophageal varices (2,85). In addition to the increased portal pressure, recent studies have shown that formation

of portosystemic collateral vessels in portal hypertension is influenced by a VEGF-dependent angiogenic process and can be markedly attenuated by interfering with the VEGF/VEGF receptor-2 signaling pathway (73,74). These studies have opened a new perspective in the understanding of the pathophysiology of portal hypertension, with potential clinical relevance, because these studies indicate that manipulation of the VEGF may be of therapeutic value.

The collateral circulation may carry as much as 90% of the blood entering the portal system. In this circumstance, the vascular resistance of these vessels becomes a major component of the overall resistance to portal blood flow and, therefore, may be important in determining portal pressure. In addition, although it was traditionally thought that the hyperdynamic splanchnic circulatory state associated with portal hypertension was the consequence of active splanchnic vasodilatation, recent data suggests that the increased neovascularization in splanchnic organs plays an important role in allowing the increase in splanchnic blood inflow (74).

The elements that modulate collateral resistance are not well known. Studies

performed in perfused portosystemic collateral beds suggest that NO may play a role in the control of portal collateral vascular resistance (86). This may be the mechanism by which isosorbide-5-mononitrate (IMN) and nitroglycerin (NTG) reduce collateral resistance in patients with cirrhosis. These vessels are also probably hypersensitive to serotonin (5-HT), which markedly increases their vascular tone. In portal hypertensive animals, the administration of selective 5-HT2 receptor blockers decreases portal pressure.

Vasoconstrictive agents (including vasopressin and nonselective β-blockers) may significantly increase the collateral resistance. The increase in portal collateral resistance brought about by these agents attenuates the reduction in portal pressure achieved by reducing the splanchnic blood flow (87). Another circumstance in which active changes in portal collateral resistance appear to modulate changes in portal pressure is the restitution of blood volume after hemorrhage, during which a paradoxical increase in portal pressure occurs in portal hypertensive animals.

Increased Plasma Volume and Hyperkinetic Circulation

Splanchnic vasodilatation is typically associated with peripheral vasodilatation and a systemic hyperkinetic syndrome, which is characterized by reduced arterial pressure and peripheral resistance, and increased plasma volume and cardiac output. The pathophysiologic mechanisms involved in peripheral vasodilatation are similar to those previously described for splanchnic vasodilatation (5). Peripheral vasodilatation plays a major role in the activation of endogenous neurohumoral systems that cause sodium retention and expansion of the plasma volume, followed by an increase in the cardiac index (88). The relevance of these abnormalities to the pathophysiology of ascites and the hepatorenal syndrome is discussed in detail in Chapters 7 and 9.

Expansion of plasma volume is a necessary step to maintain an increased cardiac index, which in turn aggravates portal hypertension (88). This provides the rationale for using a low-sodium diet and diuretics in the treatment of portal hypertension.

Pathophysiology of Variceal Hemorrhage

Two theories have been proposed to explain variceal bleeding (Fig. 15.4). The *erosion theory* suggested that varices bleed when external trauma to their thin and fragile walls is caused by the deglutition of solid food or by gastroesophageal reflux. This theory has been abandoned because of a lack of objective evidence. No relationship between eating and bleeding has been proved, nor is the incidence of reflux and esophagitis greater in patients with bleeding varices than in those without bleeding (5,89).

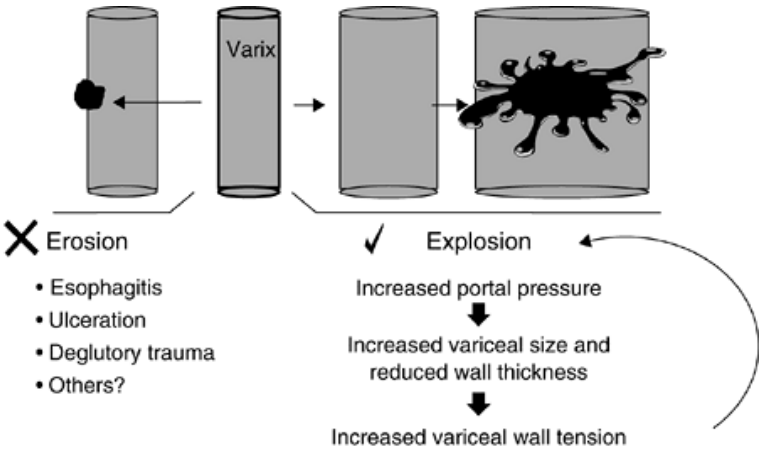
On the contrary, the so-called explosion hypothesis suggests that the main cause of bleeding is excessive hydrostatic pressure inside the varices, which is a consequence of increased portal pressure (Fig. 15.4). In support of this hypothesis, many studies have shown that variceal bleeding does not occur before the HVPG reaches a threshold value of 12 mm Hg (1,3,4) (Fig. 15.5). In addition, since the introduction of endoscopic techniques to measure variceal pressure (see subsequent text), new observations have been made to support the role of increased intravariceal pressure in variceal rupture. Therefore, variceal pressure is higher in patients with previous bleeding than in nonbleeders, and longitudinal studies have shown that variceal pressure is a good prognostic indicator of the risk for bleeding and of the response to pharmacologic therapy.

Variceal pressure, size, and wall thickness can be integrated in the concept of *wall tension*, the inwardly directed force exerted by the variceal wall to oppose an outwardly directed force that causes further distention (Fig. 15.6). Variceal bleeding occurs when the tension exerted by the thin wall of a varix is beyond a critical value, as determined by the elastic limit of the vessel. At this point, the variceal wall cannot

resist further dilatation, and variceal rupture occurs. According to Frank's modification of Laplace's law, variceal wall tension (*WT*) can be defined by the following equation:

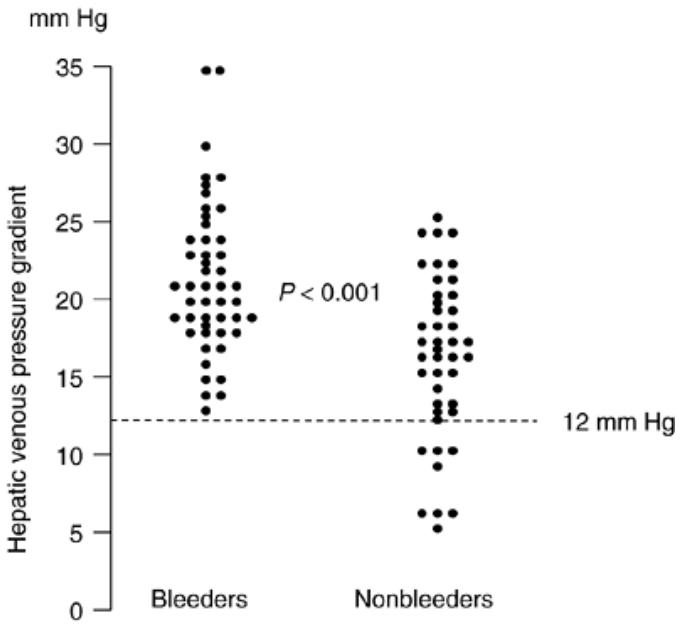
$WT = (P_i - P_e) \times r/w$

in which P_i is the intravariceal pressure, P_e the pressure in the esophageal lumen, *r* the radius of the varix, and *w* the thickness of its wall (5,89).



▪ **Figure 15.4** Proposed theories of the mechanism of variceal hemorrhage. Variceal bleeding occurs when the thin wall of a varix leaks. The erosion theory proposes that leaks are caused by external injury. On the contrary, today's accepted "explosion" theory proposes that variceal rupture is mainly a consequence of increased hydrostatic pressure inside a varix, which causes an increase in the tension of the variceal wall to above its elastic limit.

This equation indicates that a large variceal size exaggerates the deleterious effects of a high intravariceal pressure, so that the tension exerted on the wall of the varix is increased; at a much lower variceal pressure the wall tension (and risk for bleeding) of a big varix with thin walls will be higher than that of a small varix with thick walls. This may explain why large gastric fundal varices bleed at relatively low portal pressures. Similarly, the equation explains the prognostic value of the red color signs (which indicate areas where the wall of a varix is especially thin) (90,91).



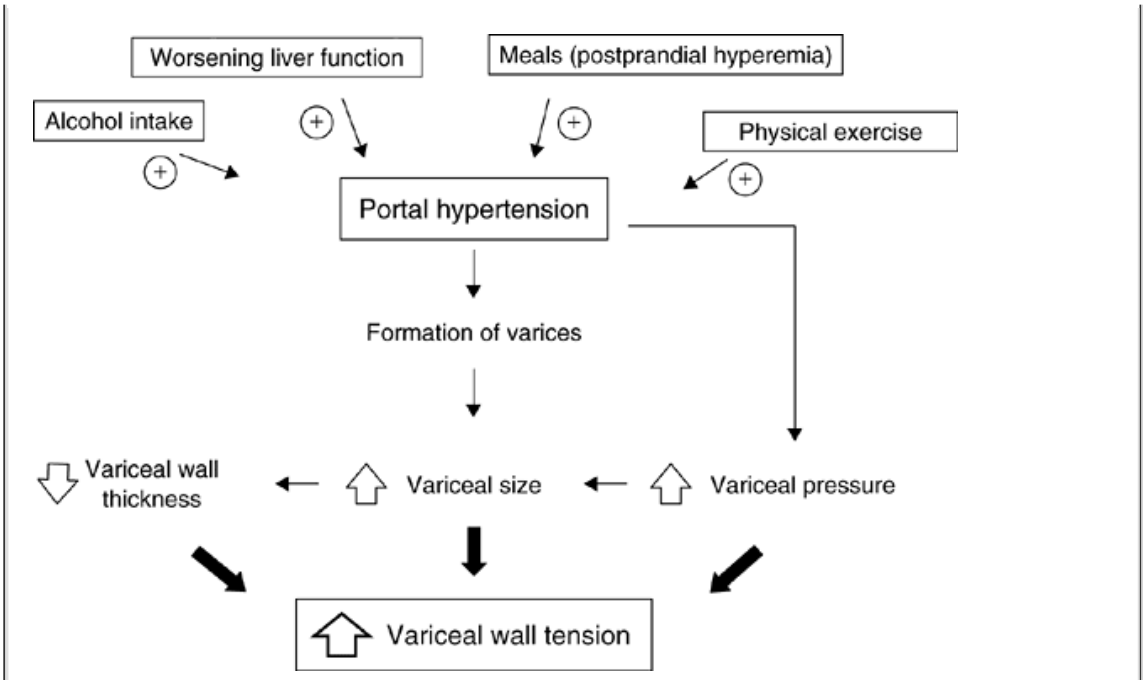
▪ **Figure 15.5** Variceal bleeding occurs only in patients with a hepatic venous pressure gradient above 12 mm Hg (the threshold value for variceal bleeding). (From Garcia-Tsao G, Groszmann RJ, Fisher RL, et al. Portal pressure, presence of gastroesophageal varices and variceal bleeding. *Hepatology* 1985;5:419–424, with permission.)

The concept of variceal wall tension explains why esophageal varices are more likely to bleed than other collaterals, in the thorax (e.g., the periesophageal veins), gut, or other abdominal organs (ectopic varices). The transmural pressure is higher in esophageal varices than in varices at other locations because negative esophageal luminal pressure occurs during inspiration. Furthermore, the lack of external tissue support of esophageal varices decreases their elastic limit. The factors determining variceal wall tension are interrelated. Increased variceal pressure increases wall tension directly; it also increases the size (radius) of a varix and, by the same mechanism, decreases wall thickness (Fig. 15.6).

Accordingly, the natural history of portal hypertension can be described as a function of variceal wall tension. Once wall tension increases to values exceeding the elastic limit of a varix, the patient experiences a first episode of bleeding. After this, the patient remains at a high risk for rebleeding unless wall tension is decreased. Similarly, primary prophylaxis protects the patient from bleeding by preventing or delaying variceal wall tension from reaching the rupture point, which is achieved by decreasing portal pressure and portal–collateral blood flow.

The sequence of events leading to variceal hemorrhage is therefore initiated by a high portal pressure, which promotes the formation of collaterals and varices. An increase in intravascular pressure, together

with a high rate of collateral blood flow, causes varices to dilate, and as they dilate, their walls become thinner (Fig. 15.6). At this point, any further increase in variceal pressure or size or any defect in the variceal wall causes rupture and clinical hemorrhage.



▪ **Figure 15.6** The factors determining variceal wall tension are interrelated. An increase in variceal pressure increases wall tension directly; it also increases the size (radius) of the varix and decreases the thickness of its wall. As indicated, repeated increases in portal pressure caused by several factors contribute to accelerate this process.

In this regard, it should be remembered that portal pressure and blood flow are not static parameters; on the contrary, they vary markedly in response to physiologic stimuli. It is well known that portal pressure increases transiently after a meal in relation to the postprandial hyperemic response. Alcohol intake, physical exercise, and conditions that increase intra-abdominal pressure can increase portal pressure abruptly (Fig. 15.6). In all these circumstances, repeated abrupt increases in portal pressure cause a progressive dilatation of varices and, therefore, increase the risk for variceal bleeding. These observations are relevant because they suggest important new therapeutic targets to reduce the risk for variceal hemorrhage. Moreover, circadian variations have been observed in portal pressure—pressure increases during the night and decreases during the afternoon and evening. These physiologic variations in portal pressure may affect the onset of bleeding in patients at risk (those with a high variceal tension in resting conditions); a circadian pattern has been observed in variceal hemorrhage, which is more frequent at midnight, when portal pressure generally is increasing. In patients with cirrhosis, portal pressure is also increased by circumstances that worsen liver failure, such as alcoholic hepatitis, severe infections, and acute or chronic liver failure.

Assessment of Hepatic Hemodynamics in Patients with Cirrhosis

The evaluation of patients with portal hypertension is based on the visualization of varices at endoscopy, definition of the portal collateral anatomy by ultrasonography or angiography, and the measurement of portal pressure. There are also techniques to assess changes in pressure and blood flow in the collateral circulation. These have allowed a better understanding of the hemodynamic changes associated with portal hypertension, the mechanism of bleeding, and the effects of new forms of

pharmacologic therapy.

Imaging Techniques: Portal Venography, Ultrasonography, Pulsed Doppler Ultrasonography, Computed Tomography, and Magnetic Resonance Imaging

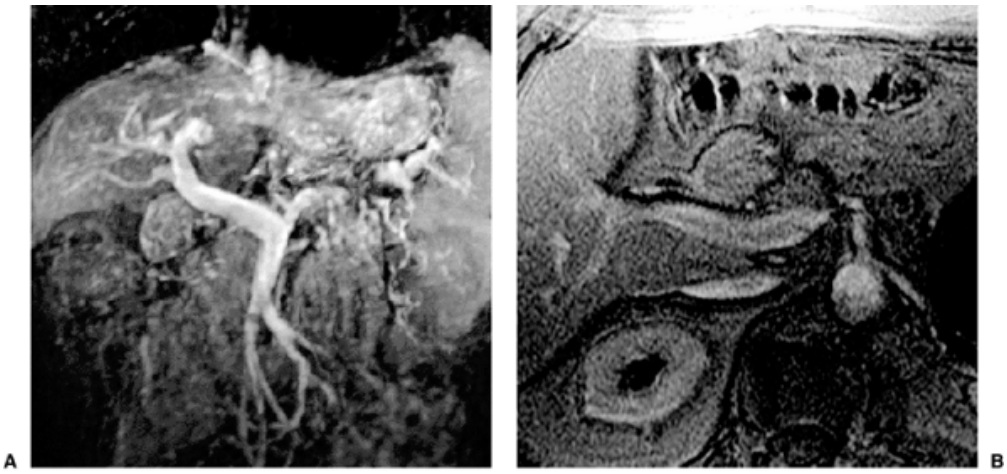
Imaging techniques are useful in the initial evaluation of the patient with portal hypertension. Frequently, portal hypertension is first diagnosed when a dilated portal vein, portosystemic collaterals, ascites, or splenomegaly is detected.

The patency of the portal vein or the presence of PVT should be investigated in every patient with portal hypertension. Portal venography obtained at the venous phase of splenic and mesenteric angiography is being

replaced by noninvasive methods, such as Doppler ultrasonography with echo enhancement, helical CT scan, and MRI. Retrograde wedged hepatic venography, performed with the use of carbon dioxide as a contrast medium during hepatic vein catheterization, is a safe technique that allows an adequate visualization of the portal vein in more than 70% of patients with cirrhosis (92) (Fig. 15.7).

▪ **Figure 15.7** Wedged retrograde portography with the use of carbon dioxide as a contrast agent shows patent portal, mesenteric, and splenic veins and extensive collateralization in a patient with hepatitis C–related cirrhosis.

Ultrasonography, CT scan, and MRI are as accurate as angiography in detecting PVT (Fig. 15.8). Ultrasonography is the preferred initial investigation because of its low cost and high accuracy (93,94,95). The use of pulsed Doppler (the so-called duplex technique) allows the determination of the presence, direction, and velocity of portal blood flow. Multiplying the portal flow velocity by the cross-sectional area of the portal vein provides an estimate of the portal blood flow. However, these estimates are subject to many errors and should be used with caution. Ultrasonography and pulsed Doppler flow measurements are also useful in the assessment of the patency of transjugular intrahepatic or surgical portacaval shunts and in the evaluation of the patency of arterial and venous anastomoses after orthotopic liver transplantation.



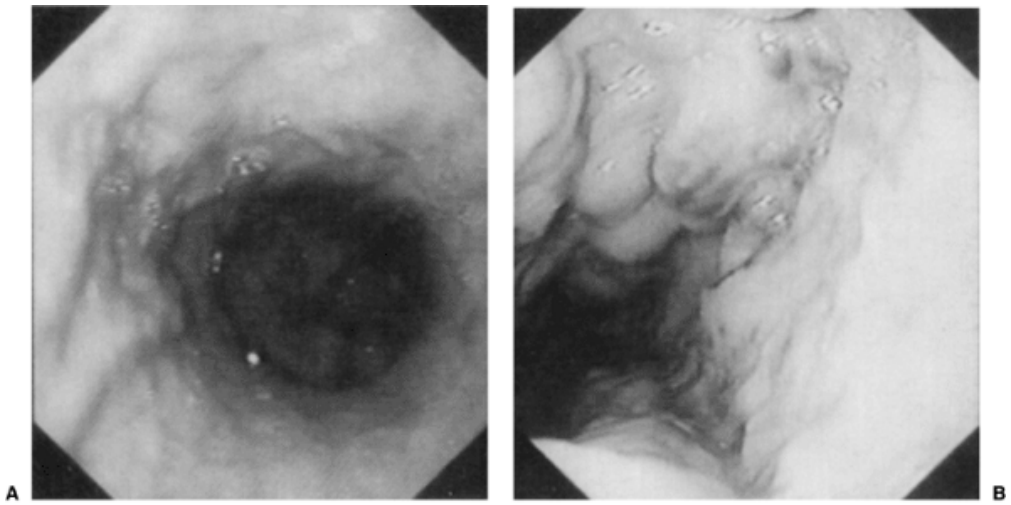
▪ **Figure 15.8** Magnetic resonance image shows a patent portal vein (sagittal and coaxial sections). This technique also allows an estimation of portal blood flow. (Courtesy of Dr. J. R. Ayuso.)

Promising results have been obtained by measuring portal blood flow with phase-contrast magnetic resonance angiography, although the clinical applications of this method are still under study.

Endoscopy

As discussed later in this chapter (see "Natural History and Clinical Manifestations of Portal Hypertension"), upper gastrointestinal endoscopy is mandatory in patients with cirrhosis or in those in whom portal hypertension is suspected. At endoscopy, it is important to semiquantitatively assess the number, appearance, and size of any esophageal varix and to note the presence of red color signs (Fig. 15.9). Endoscopy should include a careful evaluation for the presence of gastric varices (Fig. 15.10), which in some cases may require endosonography, and the presence, extent, and severity of PHG (Fig. 15.11). It can be useful to standardize the moment at which the varices are observed (i.e., at full inflation, before removal of the endoscope) and obtain digital images for later review, especially given the fact that these patients require follow-up endoscopy. It is

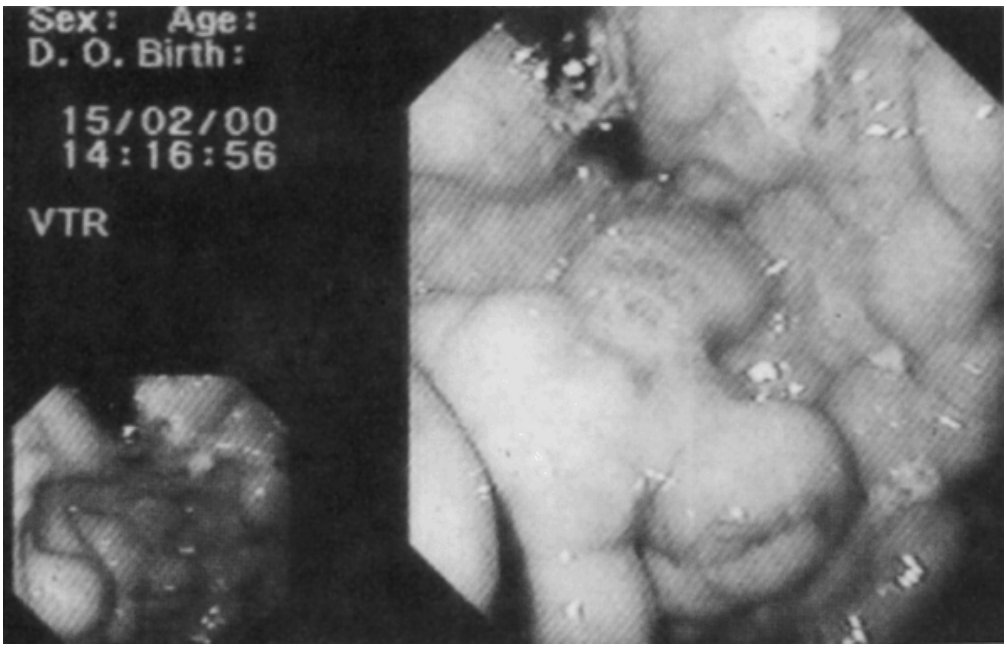
also important to provide conscious sedation because it markedly increases the acceptability of the procedure. Capsule endoscopy is now available for the examination of the upper gastrointestinal tract; initial studies suggest a high sensitivity in the detection of esophageal varices.



▪ **Figure 15.9** Esophageal varices. Small varices **(A)** and large esophageal varices with red color signs **(B)**. (Courtesy of Drs. J. M. Bordas and J. Llach.)

Measurement of Portal Pressure

Measurement of portal pressure is still the single most important hemodynamic measurement in portal hypertension. Other methods provide additional information but do not substitute for the measurement of portal pressure. Portal pressure should be expressed in terms of the pressure gradient between the porta and the IVC, which represents the perfusion pressure within the portal and hepatic circulation. Normal values of PPG are up to 5 mm Hg. Portal pressure expressed as PPG is not affected by changes in the intra-abdominal pressure caused by tense ascites and total volume paracentesis. An increase in intra-abdominal pressure increases both the portal pressure and the IVC pressure but does not significantly affect the PPG (except in the case of marked changes in the intra-abdominal pressure that are associated with changes in splanchnic and systemic hemodynamics).



▪ **Figure 15.10** Isolated fundal gastric varices (IGV-1) in a patient with cirrhosis. (Courtesy of Drs. J. M. Bordas and J. Llach.)

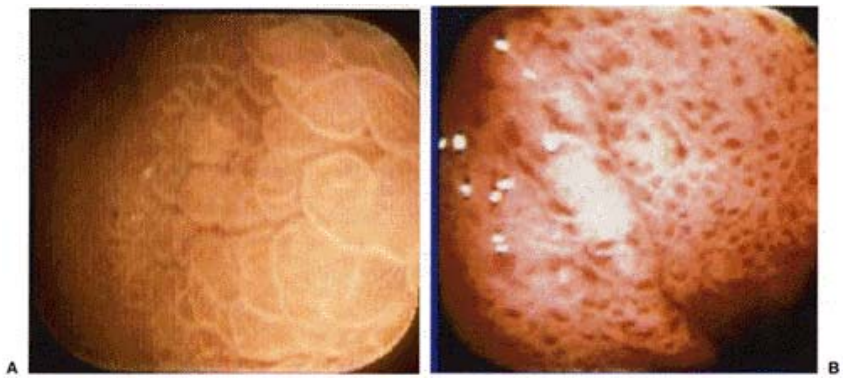
An important concept that has been strongly substantiated in recent years is that the major factor in determining the development of complications and the clinical significance of portal hypertension is an increase in the PPG above a critical threshold value. The threshold value of the PPG for the formation of varices is 10 mm Hg and that for the appearance of other complications, such as variceal bleeding, ascites, and PHG, is 12 mm Hg (1,2,3,4).

Portal pressure can be assessed by direct or indirect methods.

Direct measurement

Direct measurements of portal pressure are invasive investigations based on the surgical, percutaneous transhepatic, or transvenous (transjugular) catheterization of the portal vein. In these techniques, except for the transjugular approach, measurement of the IVC pressure requires the additional and simultaneous puncture of a hepatic vein to determine the PPG. Because of this inconvenience and the associated

surgical or hemorrhagic risk, direct measurements of portal pressure are rarely used. When required, the percutaneous transhepatic approach is the preferred technique (96). Transjugular catheterization of the portal vein is the first step during a transjugular intrahepatic portosystemic shunting (TIPS) procedure. The safety of percutaneous transhepatic or transjugular catheterization of the portal vein can be increased by performing the procedure under ultrasonographic guidance. The hemorrhagic risk is greater in the percutaneous procedure. The risk can be reduced by using a thin needle. This allows one to measure the portal pressure, but not to perform portal venography during the procedure.



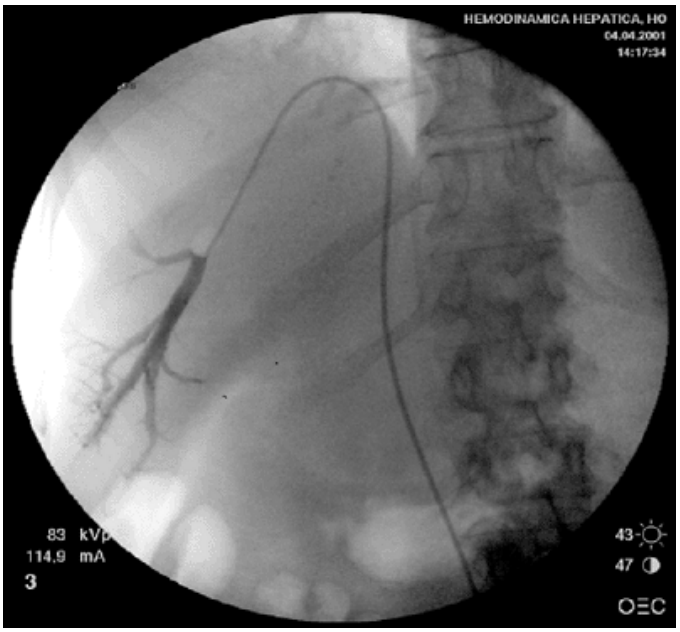
▪ **Figure 15.11** Portal hypertensive gastropathy (PHG). Mild PHG (*left*) is characterized by the mosaic pattern, and severe PHG (*right*) by multiple red spots. (Courtesy of Dr. R. de Franchis and the New Italian Endoscopic Club.)

Indirect measurement

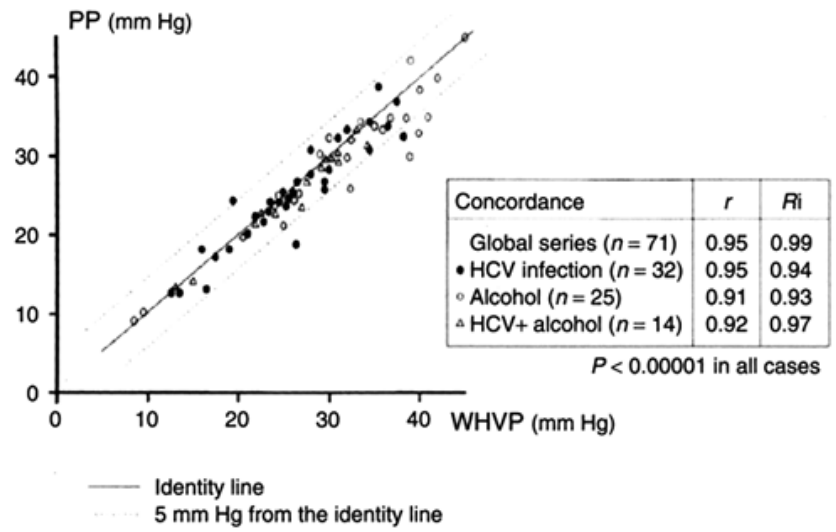
The indirect and safe approach of hepatic vein catheterization, with measurements of the WHVP and FHVP, is the preferred technique to estimate portal pressure (97,98,99).

The FHVP, measured when the tip of the catheter is maintained "free" in the hepatic vein, is close to the IVC pressure (maximal difference of 2 mm Hg). The WHVP is measured by occluding the hepatic vein, either by inflating a balloon at the tip of the catheter (Fig. 15.12) or by advancing the catheter until it becomes "wedged" into a small branch of a hepatic vein. The balloon occlusion technique is preferred because it reflects the pressure of a greater hepatic area than does the "manual occlusion" technique. When blood flow in a hepatic vein is stopped by a "wedged" catheter or a balloon catheter, the static column of blood transmits the pressure to the preceding communicating vascular territory (the hepatic sinusoids). Therefore, the WHVP is a measurement of the hepatic sinusoidal pressure, not of the portal pressure itself. However, it is important to note that the WHVP adequately reflects the portal pressure in diseases causing "sinusoidal" portal hypertension, such as alcoholic liver diseases, nonalcoholic steatohepatitis, and cirrhosis due to hepatitis C virus or hepatitis B virus (Fig. 15.13). These entities are the most frequent forms

of chronic liver disease in developed countries. On hepatic vein catheterization, the PPG is expressed as the HVPG (the gradient between the WHVP and FHVP). The HVPG is the parameter most commonly used to report portal pressure in the medical literature. In the older literature, the HVPG was frequently referred to as *corrected* WHVP or *corrected* sinusoidal pressure.



· **Figure 15.12** Occlusion balloon catheter located in the main right hepatic vein. The wedged hepatic vein pressure (WHVP) is measured after the hepatic vein has been occluded by inflating a balloon at the tip of the catheter. When blood flow is stopped by the balloon, the static column of blood transmits the pressure to the preceding communicating vascular territory (the hepatic sinusoids). Therefore, the WHVP is a measurement of the hepatic sinusoidal pressure, not of the portal pressure itself. The free hepatic vein pressure is measured after the balloon has been released and should be similar to the inferior vena cava pressure.



▪ **Figure 15.13** The wedged hepatic vein pressure (WHVP) accurately reflects the portal pressure (PP) in patients with alcoholic or hepatitis C–related cirrhosis of the liver. (From Perello A, Escorsell A, Bru C, et al. Wedged hepatic venous pressure adequately reflects portal pressure in hepatitis C virus–related cirrhosis. *Hepatology* 1999;30:1393–1397, with permission.)

A limitation of the HVPG is that it does not reflect the PPG in diseases in which the increased resistance is located at presinusoidal sites, such as PVT and some liver diseases predominantly affecting the portal tracts, including schistosomiasis, the initial stages of primary biliary cirrhosis, and idiopathic portal hypertension. In these cases, a direct measurement of the portal pressure may be indicated.

On hepatic vein catheterization, in addition to measuring the HVPG, it is possible to obtain a wedged hepatic retrograde portography using carbon dioxide as a contrast agent. This demonstrates the portal vein in most instances to the point that a failure to demonstrate the portal vein on carbon dioxide retrograde portography strongly suggests the presence of presinusoidal portal hypertension (92).

An additional advantage of this technique is that during hepatic vein catheterization (through a jugular vein), it is possible to obtain a liver biopsy specimen, which adds very little time, discomfort, and risk to the procedure and can be accomplished during a 1-day hospital stay. Furthermore, during hepatic vein catheterization, it is possible to measure the hepatic blood flow with indocyanine green; the intrinsic clearance of indocyanine green is a quantitative test of liver function that assesses overall hepatic metabolic activity (100).

Diseases causing a hepatic outflow block, classified as "postsinusoidal" or "posthepatic" portal hypertension, show abnormal increases in both the WHVP and FHVP, with a normal HVPG.

The main applications of HVPG measurements include evaluation of portal hypertension, assessment of the response to pharmacologic therapy, preoperative evaluation of the risk of resection in patients with small hepatocellular carcinoma (101), prognostic evaluation during variceal bleeding and acute liver failure, and evaluation of the progression of chronic liver disease, especially severe chronic hepatitis C and alcoholic hepatitis, in which the HVPG may be a good index of the response to therapy (102,103).

The main advantages of the hepatic vein catheterization technique are its simplicity, reproducibility, and safety. There was no fatality in more than 10,000 studies. Major complications have been limited to local injury to the femoral or jugular vein (e.g., arteriovenous fistulae, leakage, or rupture of venous introducers). The procedure causes very little discomfort, and if performed under slight conscious sedation, its acceptability is comparable to that of upper gastrointestinal endoscopy. Because of its many clinical applications, hepatic vein catheterization is becoming a routine test in many hospitals. Although it is easy and simple to perform, accurate measurements require specific training because the procedure differs from that used in cardiac catheterization laboratories and intensive care units. It would be desirable if fellowship programs in hepatology included training in this specific technique. The following are a few useful tips to ensure adequate measurements:

1. Use an appropriate scale so that small changes can be detected. The scales used for arterial pressure measurements are not adequate. The scale should be set, at least, so that 1 mm Hg equals 1 mm of paper.

2. Stabilization of venous pressures should be evaluated over a period of at least 1 minute for the WHVP and 15 seconds for the FHVP (some patients may require longer). A slow paper speed should be used in the recorder. A speed of less than 5 mm/second is appropriate.
3. Never rely on digital readings on the screen. These are instantaneous readings and may not be representative of the correct measurement.
4. Calibrate transducers by obtaining tracings of known external pressures at least once a day (e.g., 13.6 cm H_2O should read as 10 mm Hg and 27.2 cm H_2O should read as 20 mm Hg). Discard transducers that do not calibrate exactly.
5. Place the transducer at the level of the right atrium (midaxillary line).
6. Check that the "zero" pressure (with the transducer open to air) corresponds exactly with the "zero" line in the pressure tracing.
7. The FHVP should be measured with the catheter tip inserted less than 5 cm in the hepatic vein. The FHVP should not differ by more than 2 mm Hg from the IVC pressure measured at the level of the hepatic veins.
8. Check that inflating the distal balloon totally occludes the hepatic vein before the WHVP is measured. A slow injection of 5 mL of contrast dye should show the typical "wedged" pattern, without washout through communication with other hepatic veins. Rinse the catheter with a solution of 5% dextrose before the pressures are measured.
9. For each measurement, also obtain a "mean" pressure by "filtering" the waves or by selecting this option in the recorder.
10. Take note of whatever happens. A cough or other movement may cause artifacts that will lead to an incorrect interpretation.

Hepatic Blood Flow

Under normal circumstances, the total hepatic blood flow represents approximately 25% of the cardiac output. One third of this flow is contributed by the hepatic artery and the remainder by the portal vein.

Regulation of hepatic arterial flow

Flow in the hepatic artery is autoregulated. A reduction in portal flow results in an

increase in hepatic arterial flow. Flow in the hepatic artery may increase up to 100% in response to a decrease in portal flow. The mechanism of this "hepatic artery buffer response" is not well known. It has been suggested that it may be mediated in part by adenosine release and washout in the vicinity of the portal tracts (104). The "buffer response" is important when portal blood flow decreases dramatically, as in PVT and portacaval shunting. It has been suggested that after portacaval anastomosis, the prognosis correlates with the increase in arterial flow that follows the diversion of the portal blood flow.

Arterial flow to the liver is not determined by oxygen demand. Under conditions of increased oxygen demand, oxygen extraction rather than arterial flow is augmented in the liver.

Portal vein flow

The portal system is thought to be a passive vascular bed. The portal blood flow is composed of venous blood draining the stomach, intestines, pancreas, spleen, and omentum. Therefore, the factors that govern portal venous flow are predominantly those that control the supply of blood to these organs, such as the ingestion of a meal.

Contrary to the buffer response of the hepatic artery to decreases in portal blood flow, portal venous hyperemia does not occur in response to a decrease in hepatic arterial flow.

Measurement of hepatic blood flow

Clearance techniques

Clearance techniques require the injection of dyes or particles labeled with radioactive isotopes that are avidly extracted by the liver. If a substance is totally extracted by the liver in a single pass, its plasma clearance will be equal to the total hepatic blood flow. However, no substance possesses this property. For this reason, it is necessary to measure the hepatic extraction of the test compound (the fractional uptake in a single passage through the liver) directly. This measurement requires the simultaneous sampling of blood flow in a hepatic vein and a peripheral artery, particularly in the setting of clinical liver disease, in which extraction of the indicator is frequently diminished (100). This represents another application of hepatic vein catheterization. The most commonly used indicator is the albumin-bound dye indocyanine green (105). Bromsulfophthalein and bile salts labeled with radioactive isotopes have also been used. The *extrarenal sorbitol clearance* has been reported to be a safe, noninvasive, and reliable means of measuring "parenchymal" or "effective" hepatic blood flow in patients with a normal or diseased liver (106).

Indicator dilution technique

The indicator dilution technique is an invasive method that requires catheterization of the hepatic artery, portal vein, superior mesenteric artery, or splenic artery (any one of these vessels is sufficient if the splanchnic circulation is normal) and the hepatic vein (107). Its only advantage over clearance techniques is that it does not depend on liver function.

Inert gas washout

The administration of inert gases such as krypton and xenon by intraparenchymal, intrasplenic, or portal vein injection has been used to assess hepatic blood flow. Less invasive methods, such as inhalation and administration through the lumen of the gastrointestinal tract, have also been reported but are not very accurate because it is difficult to assess the exact amount of administered inert gas, which is instantaneously

absorbed. This technique can be adapted to estimate portosystemic shunting.

Measurement of Azygos Blood Flow

This technique is based on the well-known fact that most gastroesophageal collaterals (including esophageal varices) drain into the azygos venous system; therefore, an increased azygos blood flow in patients with portal hypertension reflects the emptying of the collateral blood into the azygos vein (108,109). Obviously, the technique does not allow one to determine the extent of the increase in azygos blood flow that is contributed by esophageal varices and that contributed by periesophageal collaterals, which also drain into the azygos vein. In addition, in 25% of cases, the gastroesophageal collaterals drain into other thoracic veins (i.e., subclavian, innominate, and pulmonary). Therefore, a normal azygos blood flow does not necessarily indicate an absence of esophageal varices. Drainage into other thoracic veins may also be the reason why the azygos blood flow is not significantly correlated with the size of esophageal varices and the risk for bleeding (110).

The direct measurement of azygos blood flow requires retrograde catheterization of the azygos vein with a continuous thermal dilution catheter. This is a simple procedure performed in the course of routine hemodynamic investigations. Fick's principle is applied to measure blood flow by the thermodilution technique. The whole procedure, including repeated measurements of blood flow, takes less than 15 minutes and has been shown to be accurate and reproducible, with less than 10% variability in repeated measurements. Azygos blood flow is usually markedly increased in portal hypertension. Values in healthy subjects range between 0.10 and 0.25 L/minute, whereas in patients with cirrhosis and portal hypertension, these are increased on average to 0.65 L/minute. The azygos blood flow is also increased in patients with noncirrhotic portal hypertension. Azygos blood flow is markedly reduced after surgical portacaval shunting, esophageal tamponade, and orthotopic liver transplantation.

The main application of measurements of azygos blood flow is to monitor the effects of pharmacologic therapy in portal hypertension. The ability of the technique to detect changes in portal–collateral blood flow has increased the understanding of the beneficial effects of the vasoactive drugs currently used in the treatment of portal hypertension. It has been demonstrated that some splanchnic vasoconstrictors, such as propranolol, cause greater decreases in azygos blood flow than in portal pressure. On the other hand, equal falls in portal pressure can be associated with different effects on azygos blood flow. Obviously, a decrease in the HVPG and azygos blood flow, as obtained with propranolol, reflects a greater beneficial effect than a decrease only in the HVPG (as usually happens with vasodilator drugs).

Azygos blood flow can also be measured noninvasively with phase-contrast magnetic resonance angiography (111). Endosonographic pulsed Doppler estimates of azygos blood flow are likely to be much less reliable.

Measurement of Variceal Pressure

The pressure in esophageal varices can be measured using endoscopy by *direct puncture of the varices*, with *endoscopic pressure-sensitive gauges*, or with an *inflating–deflating balloon* attached to the tip of the endoscope (Fig. 15.14). The two latter techniques measure variceal pressure noninvasively, so that the risk for precipitating variceal hemorrhage is eliminated. Variceal puncture is justified only by endoscopic injection sclerotherapy.

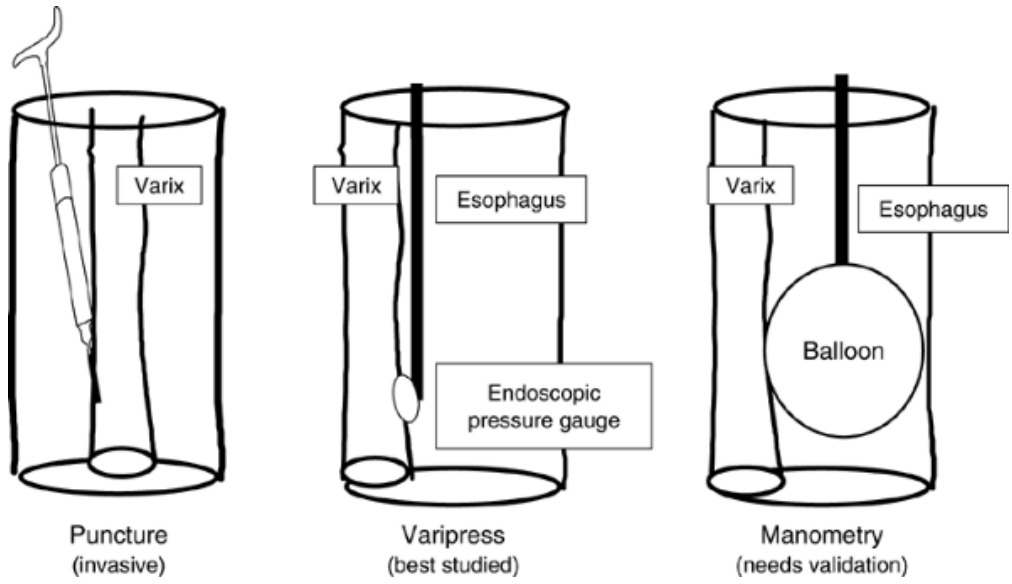
Noninvasive techniques are based on the assumption that because of their thin walls and lack of external tissue support, varices behave as elastic structures; therefore, the pressure needed to compress a varix (which can be sensed by a pressure gauge or directly visualized using a clear balloon) equals the pressure inside the varix. Several studies have shown a good correlation between these techniques and the more

aggressive variceal puncture technique (2,112).

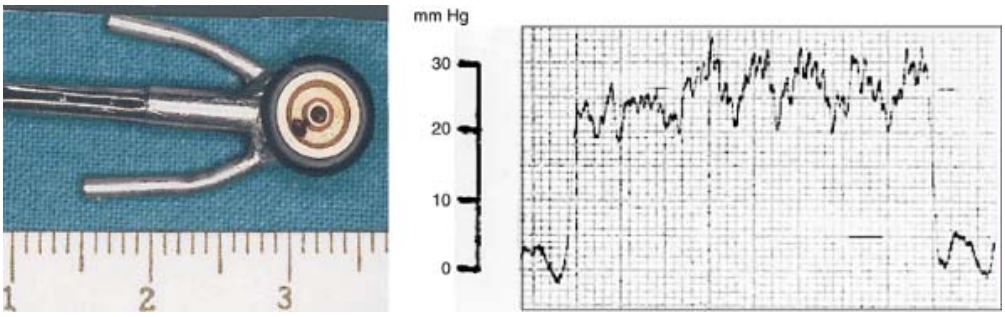
The endoscopic pressure gauge is the method used most commonly in prospective studies. A pressure-sensitive capsule, attached to the tip of an endoscope, consists of a small chamber covered by a thin latex membrane that is continuously perfused with nitrogen. The perfusion pressure is continuously recorded by means of an electromagnetic pressure transducer. It is assumed that when the gauge is applied over a varix, the increase in pressure required to perfuse the gauge equals the pressure inside the varix. The difference between the pressure measured when the gauge is applied over a varix and when the gauge is free in the esophageal lumen equals the transmural variceal pressure, which is the value used to express results (113).

Endoscopic pressure measurements can be difficult, especially in small varices. However, these techniques are reproducible when strict criteria are used to define satisfactory measurements, such as the following:

(a) Stable intraesophageal pressure, (b) absence of artifacts caused by esophageal peristalsis, and (c) correct placement of the capsule over the varix, demonstrated by fine fluctuations of the pressure tracing according to the cardiac cycle or respiration, for at least 10 seconds or three respiratory cycles, respectively (114,115) (Fig. 15.15). These conditions are easily met when the procedure is performed by a skilled endoscopist in a cooperative patient. The administration of 20 mg of butyl scopolamine intravenously diminishes the artifacts caused by esophageal peristalsis without affecting variceal pressure measurements (116). Nonetheless, approximately 25% of patients initially scheduled for variceal pressure measurements must be excluded because of technical difficulties that preclude obtaining correct measurements. Of these, two thirds are patients with small varices.



▪ **Figure 15.14** The pressure of esophageal varices can be measured at endoscopy by direct puncture (*left*), with an endoscopic pressure gauge (*center*), or with an inflating–deflating balloon attached to the tip of the endoscope (*right*).



▪ **Figure 15.15** Endoscopic pressure gauge (Varipress, Labotron, Barcelona, Spain) and a typical recording of variceal pressure showing the fine fluctuations of the tracing according to the cardiac cycle or respiration.

Studies in which variceal pressure was measured in patients with cirrhosis have provided important information. It has been shown that variceal pressure is significantly lower than portal pressure (2,112). This difference is thought to be a consequence of resistance to portal–collateral blood flow in the collaterals feeding the varices and indicates that measurements of variceal pressure cannot be used to estimate portal pressure. It has also been shown that variceal pressure is greater in patients whose varices have bled than in those whose varices have not bled, a finding that supports the concept that increased variceal pressure plays a key role in the mechanism of bleeding and suggests that measurements of variceal pressure may be of prognostic value in assessing the risk for bleeding. Repeated measurements of variceal pressure can detect acute and long-term changes in variceal pressure produced by the administration of pharmacologic agents.

It has been demonstrated that drugs that decrease portal pressure cause equal or even greater falls in variceal pressure. A reduction of variceal pressure, after pharmacologic therapy, of at least 20% from baseline has been associated with a low actuarial probability of variceal bleeding on follow-up (7% at 3 years vs. 46% in patients without this reduction) (117).

Endosonography

Endosonography (or endoscopic ultrasonography) allows the visualization of esophageal and gastric varices, periesophageal and perigastric collateral veins, the portal venous system, and the azygos vein. Endosonography, however, does not seem to add further important prognostic information about the risk for the complications of portal hypertension in comparison with conventional endoscopy (which also identifies red color signs in the variceal wall) (118,119).

The clinical use of endosonography is restricted to two main applications: The diagnosis of gastric fundal varices when the results of endoscopy are doubtful and assessment of the risk for recurrence after varices have been eradicated by endoscopic sclerotherapy or banding ligation. In the latter situation, the finding of grossly dilated periesophageal veins or patent perforating veins below the gastroesophageal junction carries a high risk for the recurrence of varices.

The combined use of endosonography for an objective measurement of variceal diameter and endoscopy for the measurement of transmural variceal pressure allows a

quantitative estimation of variceal wall tension, which is the relevant parameter in regard to risk for variceal bleeding. This technique has proved useful in pathophysiologic and pharmacologic research in patients with portal hypertension.

Clinical Consequences of Portal Hypertension

The portal hypertensive syndrome portal hypertensive gastropathy is responsible for many of the manifestations of advanced, decompensated liver disease. Some of these complications are a direct consequence of portal hypertension: Gastrointestinal bleeding resulting from ruptured gastroesophageal varices, portal hypertensive gastropathy, and colopathy; hyperkinetic syndrome; hypersplenism; and an increased systemic availability of drugs and endogenous compounds with rapid hepatic uptake (5). In other complications, portal hypertension plays a key role, although it is not the only pathophysiologic factor involved in their development. These include ascites, abnormalities of renal function, hepatorenal syndrome, spontaneous bacterial peritonitis, hepatopulmonary syndrome, and hepatic encephalopathy. This chapter focuses on gastrointestinal bleeding; the other complications are dealt with elsewhere in this book.

Collateral Circulation

The most important clinical consequences of portal hypertension are related to the formation of portosystemic collaterals; these include gastroesophageal varices, which are responsible for the main complication of portal hypertension, massive upper gastrointestinal bleeding (120).

Collaterals develop in areas where anatomic connections exist between the portal venous and systemic circulation. The portal system and the systemic venous circulation are connected at several locations (120). Gastroesophageal collaterals develop from connections between the short gastric and coronary veins and the esophageal, azygos, and intercostal veins; the result is the formation of esophageal and gastric varices. Other collaterals may also develop: Between the superior hemorrhoidal vein and the middle and inferior hemorrhoidal veins, giving rise to anorectal varices; between the portal and epigastric veins through the reopening of remnants of the umbilical or paraumbilical veins, forming a vascular net that is at times apparent on the abdominal wall as a caput medusae and causing a murmur over the umbilicus (the Cruveilhier-Baumgarten syndrome); between the portal system and the posterior abdominal wall through the liver capsule and diaphragm; and between the portal system and the left renal vein, forming spontaneous splenorenal shunts. In instances of PVT, "hepatopetal" collaterals develop between the splenic and the coronary veins through the short gastric veins, giving rise to gastric varices, and between the mesenteric or portal vein and the intrahepatic vena porta through the veins of Sappey, causing pseudocavernomas of the portal vein (120). Ectopic varices may develop at other locations, depending on local anatomic factors. Most ectopic varices develop in the duodenum (primarily associated with extrahepatic portal hypertension) and in the colon and small intestine (more frequent in patients who have previously undergone abdominal surgery). Overall, these ectopic varices account for between 1% and 5% of all episodes of variceal bleeding (121,122).

Lymph flow is also increased in portal hypertension. Enlargement of the hilar lymphatics and lymph nodes has been demonstrated. Increased hepatic lymph flow contributes to the formation of ascites (123).

Natural History and Clinical Manifestations of Portal Hypertension

The information provided here on the natural history and clinical manifestations of portal hypertension is

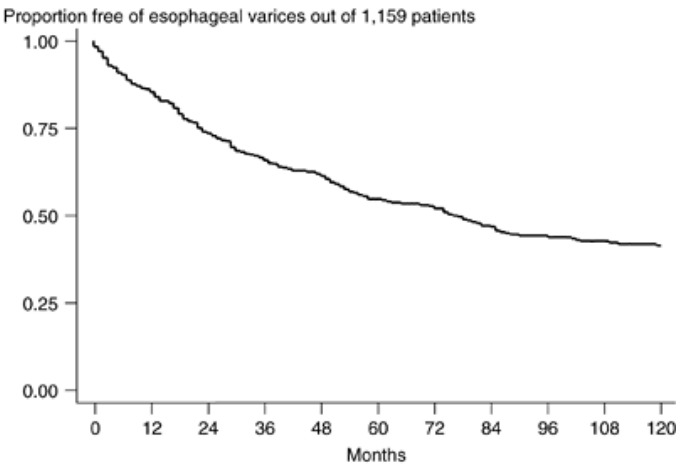
drawn from liver cirrhosis, the best studied disease causing portal hypertension. It is generally accepted that this information is applicable to most of the other causes of portal hypertension, although some differences may be identified in specific disease. These are outlined wherever needed.

Development of esophageal varices

Portal hypertension is an almost unavoidable complication of cirrhosis. Prevalence of varices at the time of the diagnosis of cirrhosis is widely variable across published studies and ranges from 0% to 80% in 93 prognostic studies published from 1980 to 2003. Overall, the median prevalence of esophageal varices in these studies is 55%; in studies including mostly compensated patients it is 48% and in those including mostly decompensated patients it is 61% (124,125).

Recent prospective cohort studies showed that the incidence of esophageal varices in patients with newly diagnosed cirrhosis is nearly 5% per year (85,126,127). A similar finding was recently also reported in a large consensus conference after a thorough review of available studies (128). Therefore, assuming that approximately 40% of patients already have varices when first seen, the estimated risk of varices is of approximately 65% at 5 years after the diagnosis of cirrhosis (Fig. 15.16).

Cross-sectional studies have shown that esophageal varices do not develop below the threshold HVPG value of 10 mm Hg (4). However, not all patients with an HVPG above this threshold have esophageal varices and the relationship between the incidence of varices and HVPG above this level is poorly understood. Worsening of liver function and continuing exposure to alcohol are clinical factors associated with an increasing risk of developing varices. The HVPG frequently increases with worsening liver function and continued alcohol abuse and may decrease when liver function improves and alcohol is discontinued (129). A baseline HVPG greater than 10 mm Hg (clinically significant portal hypertension) is independently associated with an increased risk of developing varices (85,128). Because of this, an increased HVPG is presently considered the most important risk factor for the development of esophageal varices.



▪ **Figure 15.16** The incidence of esophageal varices among 1,159 patients with cirrhosis and without varices at diagnosis. Cumulative data from two studies on the natural history of cirrhosis.

Progression of esophageal varices from small to large

Once developed, varices increase in size from small to large before they eventually

rupture and bleed. Prospective studies have reported progression rates ranging from 0.05 to 0.20 per year (median 0.12) (126,127,130). This variability probably reflects different patient selection across studies with inclusion of patients with different degrees of progression of the underlying cirrhosis. In this respect it may be worth noting that the only study that included only those patients with newly diagnosed cirrhosis reported a variceal progression rate of 0.05 per year.

Improvement in liver function and abstinence from alcohol may result in decrease or even disappearance of varices (129). As already stated, this may be related to a decrease in HVPG. It has been shown that changes in HVPG (either "spontaneous" or caused by drug therapy or TIPS) are usually accompanied by parallel variations in the size of the esophageal varices, which is significantly reduced when HVPG decreases below 12 mm Hg (131) or when it decreases more

than 15% from baseline value. Therefore, the increased HVPG plays a key role both in the development and progression of the varices. It will probably become a main target in monitoring treatment to prevent variceal bleeding or rebleeding.

A striking association has been noted between an increased size of esophageal varices and a poor prognosis of cirrhosis in terms of risk of bleeding, of developing ascites, and mortality (Fig. 15.17).

Incidence of first bleeding from esophageal varices and indicators of risk

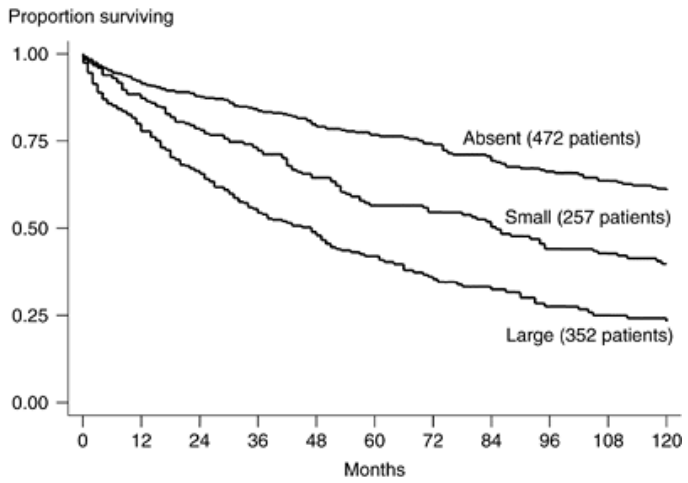
The probability of bleeding from esophageal varices is variable and depends on cirrhosis status. In patients with no varices at endoscopy, the risk of bleeding is as low as 1% to 2% per year (85,125,127) and increases to approximately 5% to 6% per year in those with small varices (Fig. 15.18) and to 15% per year in those with medium or large varices at diagnosis (125) (Fig. 15.18).

The importance of the size of the varices in determining the bleeding risk is further discussed in the subsequent text.

Clinical and endoscopic risk indicators:

Among patients with esophageal varices the bleeding incidence is significantly lower in Child-Pugh class A patients than in class B or C patients, and in patients without ascites versus those with ascites, independent of variceal size (125).

The risk of variceal bleeding is significantly associated with variceal size, severity of liver dysfunction expressed by the Child-Pugh classification, and red weal marks. These risk indicators have been combined in the North Italian Endoscopic Club (NIEC) index (90,91), which allows the classification of patients into different classes, with predicted 1-year bleeding risk ranging from 6% to 76%. Although this index has been validated (91), its predictive accuracy is far from satisfactory. In fact, the best operative characteristics of the NIEC index in the prediction of the bleeding risk are 74% sensitivity and 64% specificity. Another endoscopic index combining variceal size, the presence of PHG, and the presence of gastric varices has similar unsatisfactory operative characteristics for the prediction of bleeding risk. Whether these indexes can be improved by incorporating additional parameters related to portal hypertension (i.e., spleen size, platelet count) remains to be determined.



▪ **Figure 15.17** Survival of patients with cirrhosis according to the presence and size of esophageal varices at diagnosis. Cumulative data from two studies of the natural history of cirrhosis. *Absent*, no esophageal varices at diagnosis; *small*, small esophageal varices at diagnosis; *large*, medium or large varices at diagnosis.

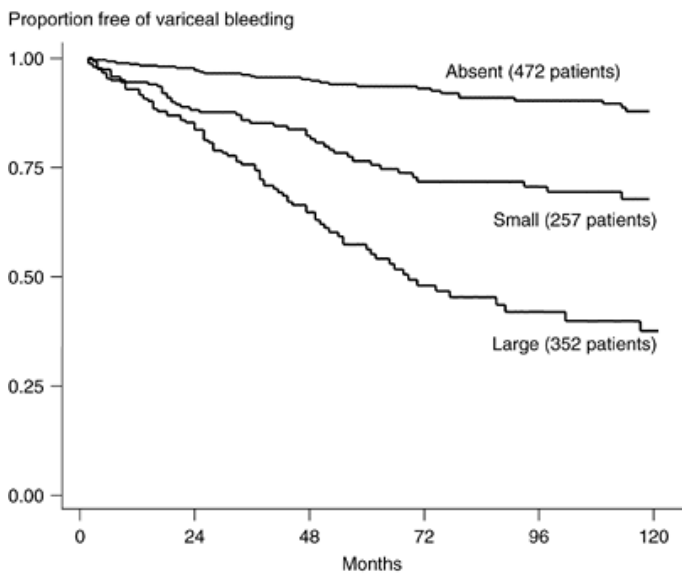
Hemodynamic risk indicators:

Cross-sectional and prospective studies have shown that esophageal varices do not bleed below the threshold HVPG level of 12 mm Hg (128). Importantly, it has also been demonstrated that variceal hemorrhage does not occur if HVPG is reduced, either spontaneously or pharmacologically, to levels below 12 mm Hg (128) or more than 20% from baseline. The reduction in risk of bleeding occurs in spite of varices continuing to be demonstrated in most patients, but variceal size is significantly decreased when HVPG is reduced below threshold values (1,85).

Variceal pressure is significantly related to the risk of bleeding and death (113).

The relationship between variceal pressure and the risk for bleeding reflects the increase in variceal wall tension associated with increasing

variceal pressure and size (2,132). Variceal wall tension cannot be measured accurately because the endoscopic evaluation of variceal diameter is only approximate, and it is not possible to measure variceal wall thickness with sufficient accuracy. However, it has been suggested that endosonography or high-resolution endoluminal probe sonography allow a more precise and reliable measure of variceal diameter than endoscopy (133,134) and may allow the estimation of wall thickness. This may contribute to further improvement in the assessment of the risk of variceal bleeding (117).



▪ **Figure 15.18** Incidence of variceal bleeding in patients with cirrhosis according to the presence and size of esophageal varices at diagnosis. Cumulative data from two studies of the natural history of cirrhosis. *Absent*, no esophageal varices at diagnosis; *small*, small esophageal varices at diagnosis; *large*, medium or large varices at diagnosis.

Ultrasonographic risk indicators:

Although great efforts have been made, no ultrasonographic or Doppler flowmetry parameters have been identified as reliable indicators of the risk of variceal bleeding (128).

Assessment of the risk of first bleeding from esophageal varices in clinical practice

The size of varices, as estimated at endoscopy, is the most widely used risk indicator of first variceal bleeding. Patients with medium- to large-sized varices are considered to be at considerable risk of bleeding and should receive therapy to prevent variceal bleeding (128,135). Patients with small varices but with advanced liver failure (Child-Pugh C) have a similar bleeding risk (90,91).

Screening for esophageal varices:

In a recent large consensus conference it was agreed that all patients with cirrhosis should be screened for the presence of esophageal varices at the time of initial diagnosis (8).

Although several studies indicate that noninvasive tests (particularly, platelet count and data obtained from abdominal ultrasonography) may have a potential use in selecting patients at high risk for varices, so far none of these have been proved to be accurate enough that endoscopy can be safely omitted in patients with negative noninvasive indicators (132).

Timing for subsequent evaluations:

In patients without varices on initial endoscopy, a second (follow-up) evaluation should be performed to detect the development of varices before they bleed.

Because the expected incidence of newly developed varices is approximately 5% per year, the general consensus (125,126,127,128) is that endoscopy should be repeated after 2 to 3 years in patients without varices on the first endoscopy. In patients with small varices on initial endoscopy the aim of subsequent evaluations is to detect the progression of small to large varices because of its important prognostic implications. On the basis of an expected 10% to 15% per year rate of progression of variceal size, endoscopy should be repeated every 1 to 2 years in patients with small varices (125,126,127,128).

Acute bleeding from esophageal varices: Definitions and intervals

Ruptured esophageal varices cause 60% to 70% of all upper gastrointestinal bleeding episodes in patients with portal hypertension (136). Variceal bleeding is diagnosed on emergency endoscopy. Diagnosis is based on observing: (a) Blood spurting from a varix (near 20% of patients), (b) white nipple or clot adherent on a varix, and (c) varices without other potential sources of bleeding. Because variceal bleeding is frequently intermittent, it is difficult to assess when the bleeding stops and when a new hematemesis or melena should be considered a rebleeding episode. Several consensus conferences have addressed this issue and set definitions for events and timing of events related to the variceal bleeding episode (8,137). The time frame for the events related to the acute bleeding episode is 5 days (8). The index bleeding episode is separated from the first episode of rebleeding by at least a 24-hour bleeding-free period, during which there is no new hematemesis and/or melena with stable hemoglobin level (137). Using these criteria the median duration of the acute variceal bleeding episode is approximately 18 hours (136). Data from placebo-controlled clinical trials have shown that variceal bleeding ceases spontaneously in 40% to 50% of patients. Active treatment achieves control of bleeding within 24 hours of admission in nearly 80% of episodes (138). Active bleeding on endoscopy (138), bacterial infection (139), HVPG greater than 20 mm Hg, hematocrit, aspartate aminotransferase, Child-Pugh class, and PVT (128,136) are significant prognostic indicators of failure to control bleeding. Immediate mortality from uncontrolled bleeding is in the order of 5% (136).

Early rebleeding is significantly associated with the risk of death within 6 weeks, suggesting that its prevention should be a primary objective in the therapeutic approach to variceal bleeding. The incidence of early rebleeding ranges between 30% and 40% in the first 6 weeks. The risk peaks in the first 5 days, with 40% of all rebleeding episodes occurring in this very early period, remains high during the first 2 weeks and then declines slowly in the next 4 weeks. After 6 weeks the risk of further bleeding becomes virtually equal to that before bleeding (140).

Active bleeding in emergency endoscopy, gastric varices, low albumin and/or high blood urea nitrogen (BUN) levels, and HVPG greater than 20 mm Hg have been reported as significant indicators of early rebleeding risk (141).

Six-week mortality— because it may be difficult to assess the true cause of death (i.e., bleeding vs. liver failure or other adverse events), the general consensus is that any death occurring within 6 weeks from hospital admission for variceal bleeding should be considered a bleeding-related death. Six-week mortality after variceal bleeding is approximately 20%. Almost 40% of deaths are caused by uncontrolled bleeding, either during the initial episode or after early rebleeding (136). Like rebleeding, mortality peaks in the first few days after bleeding, slowly declines thereafter, and after 6 weeks becomes constant and similar to that before bleeding (136,140).

Accurate indicators of early death risk could allow selection of patients for emergency shunt or TIPS before their conditions deteriorate, hampering further therapy.

Unfortunately, the risk indicators so far identified are mainly indicators of poor liver and/or renal function, which are also associated with high operative risk and are consequently of limited clinical value. On hospital admission, the most consistently reported death risk indicators are Child-Pugh classification or its components, BUN or creatininemia, age, active alcohol abuse, active bleeding on endoscopy, bacterial infection, HVPG greater than 20 mm Hg, hepatocellular carcinoma, and the total number of blood units transfused (136).

Long-term recurrent bleeding from esophageal varices and mortality

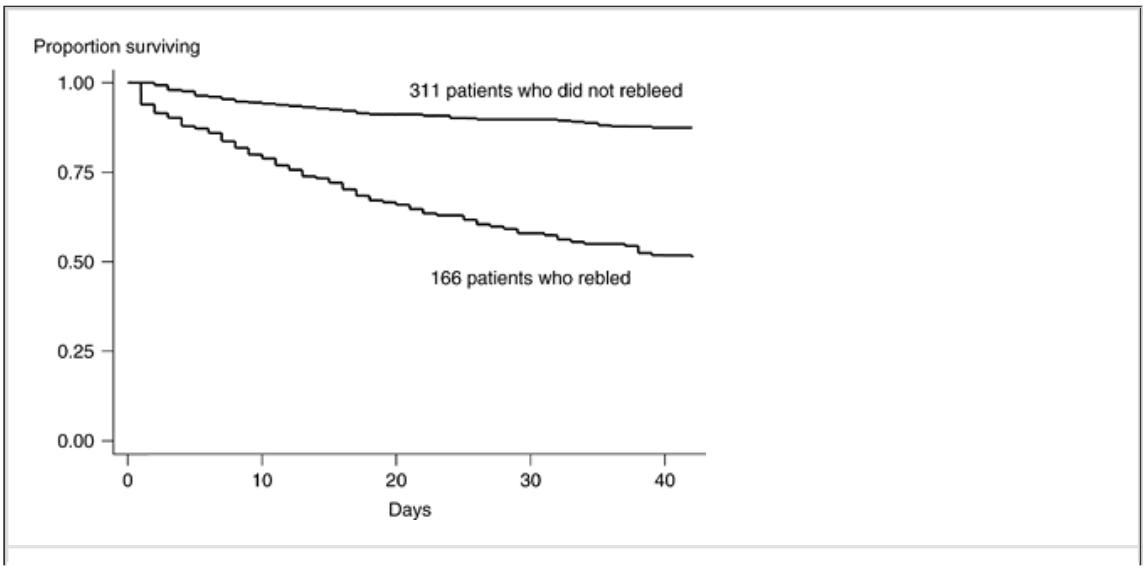
Patients surviving a first episode of variceal bleeding have a very high risk of rebleeding and death. In untreated controls in randomized clinical trials (RCTs), reported after 1981, of nonsurgical treatment for prevention of recurrent bleeding, the median rebleeding incidence within 1 to 2 years of the study, was 63% (141). The corresponding mortality figure was 33% (Fig. 15.19). Because of these high risks, all patients surviving a variceal bleeding should be treated for prevention of rebleeding independent of other risk indicators (142).

RCTs for prevention of rebleeding suggest that the risk indicators of rebleeding and death are variceal size, Child-Pugh class, continued alcohol abuse and hepatocellular carcinoma. HVPG greater than 20 mm Hg is significantly associated with a higher risk of 1-year mortality. Reduction of HVPG to below 12 mm Hg totally prevents recurrent bleeding (143). A reduction in HVPG by more than 20% of baseline values is associated with reduced risk of rebleeding, ascites, spontaneous bacterial peritonitis, and death (144).

Gastric varices

The natural history of gastric varices is far less known than that of esophageal varices. According to the most widely used classification (145,146) gastric varices may be found as a continuation of esophageal varices along the lesser curve of the stomach (gastroesophageal

varices type 1 [GOV1]) or in the fundus (GOV2); more rarely *isolated gastric varices* (i.e., not connected with esophageal varices) may be found in the fundus (isolated gastric varices type 1 [IGV1]) or in the rest of the stomach (IGV2). These are more frequent in patients with prehepatic portal hypertension. Overall, the prevalence of gastric varices in patients with portal hypertension is approximately 20% (14% GOV1, 4% GOV2, 2% IGV1 or 2) (146,147). Sometimes it may be difficult to differentiate gastric varices from plicae; endoscopic ultrasonography may be helpful in these cases.



▪ **Figure 15.19** Survival after an episode of variceal bleeding according to early rebleeding. Cumulative proportion of survivors among a cohort of 477 patients with esophageal variceal bleeding observed consecutively at the Medical Department of V. Cervello Hospital, Palermo, Italy, between 1984 and 1992. The survival of patients who experienced early rebleeding was significantly worse.

Gastric varices are commonly fed through the short and/or posterior gastric veins and are frequently associated with lower portal pressure than are esophageal varices. Moreover, spontaneous shunts may develop between the splenic vein (i.e., splenorenal shunt or gastric varices) and the left renal vein through the inferior phrenic or suprarenal vein, respectively. Such shunts are termed *gastrorenal shunts* and may be found in 60% to 85% of cases (146). For these reasons, the risk of bleeding of gastric varices is generally lower than that of esophageal varices, but it is associated with a higher incidence of portosystemic encephalopathy.

Gastric varices are the source of 5% to 10% of all upper digestive bleeding episodes in patients with cirrhosis (136). The 2-year risk of bleeding has been reported to be markedly lower from gastric nonfundal varices than from fundal varices: 10% for GOV1 or IGV2, 78% for IGV1, and 55% for GOV2 (136,145). As for esophageal varices, the risk of bleeding is significantly related with the variceal size, Child class, and the presence of red color signs on the varices.

The effect of sclerotherapy or banding ligation of esophageal varices on gastric varices is still unsettled: Regression, no change, and de novo appearance of gastric varices have all been reported.

Bleeding-related mortality after a first gastric variceal bleeding episode is approximately 20%, and long-term recurrent bleeding and mortality are in the same order as those for esophageal varices.

Portal hypertensive gastropathy

Gastric mucosal changes associated with portal hypertension (148,149,150) are termed *PHG*. The most frequently observed elementary lesions of PHG are the "mosaic pattern" and the "cherry red spots." The mosaic pattern consists of multiple erythematous areas outlined by a white reticular network and is generally considered as "mild" PHG. Cherry red spots are round, red lesions, slightly raised over the surrounding hyperemic mucosa. These carry a higher bleeding risk and are considered to reflect "severe" PHG (118). Reliability and clinical relevance of this classification as mild or severe PHG (147) have been recently validated (151). The term *PHG* has been used after its relationship with portal hypertension was definitively recognized. The gastric mucosal changes of PHG are associated with increased gastric mucosal and submucosal perfusion and, therefore, are hyperemic—not "congestive"—changes. The term *congestive gastropathy* is therefore inadequate and should not be used (149,152). Histologically, these lesions are characterized by dilatation of the capillaries and venules of the gastric mucosa, whereas mucosal inflammation and *Helicobacter pylori* infection are infrequent (153).

Data on prevalence, incidence, and natural history of PHG differ widely across studies (154), mostly because patients were included at different stages of progression of cirrhosis.

During the diagnosis of cirrhosis, the prevalence of PHG is approximately 30% and its incidence is approximately 12% per year (155). However, in patients with advanced cirrhosis these figures may be as high as 70% and 30%, respectively (147). Patients

with severe liver dysfunction and large esophageal varices are at higher risk of developing PHG, whereas large fundal varices may have a protective role, particularly when they are associated with spontaneous gastrorenal shunt. Endoscopic variceal sclerotherapy or banding has been reported as a risk factor for PHG (154). Overall, during the course of cirrhosis, mild PHG may be observed in up to 50% to 70% of patients and severe PHG in 20% to 40% (155). Progression of severity, and also disappearance of PHG, have both been reported (147,156).

The clinical course of PHG is characterized by overt or chronic gastric mucosal bleeding. The incidence of overt bleeding from any source in patients with mild PHG is approximately 5% per year, as compared to 15% for severe PHG. The source of bleeding is the gastric mucosa in most of these bleeding episodes. Overt bleeding from PHG is usually manifested by melena and has a far better prognosis than variceal bleeding, with less than 5% mortality per episode. Mortality is higher in patients with severe PHG, but this has been found to be dependent on the severity of liver dysfunction (155).

The incidence of minor mucosal blood loss, without overt bleeding, is approximately 8% per year in patients with mild PHG and up to 25% in those with severe PHG, in whom severe chronic iron deficiency anemia may result, requiring frequent hospital admissions and blood transfusions. It appears that the wide use of β-blockers in patients with cirrhosis is reducing both chronic and overt bleeding from PHG because it has been proved that β-blockers significantly reduce the rebleeding risk in patients who have bleeding from PHG (157,158).

PHG should be distinguished from gastric antral vascular ectasia (GAVE). This is a distinct entity that may be found in association with conditions different from cirrhosis, such as scleroderma or chronic gastritis. GAVE is characterized by aggregates of red spots, usually with radial distribution from the pylorus in the antrum of the stomach (for this pattern it is also called *watermelon stomach*). Histology of GAVE is characterized by marked dilatation of capillaries and collecting venules in the gastric mucosa and submucosa, with areas of intimal thickening in fibromuscular hyperplasia, fibrohyalinosis, and thrombi (154). From a clinical point of view, GAVE behaves as severe PHG, but it may be less responsive to β-blocker treatment.

Portal hypertensive lesions in the gut

Mucosal lesions similar to those of PHG have been described in the duodenum, jejunum, and colon. Similar to PHG, these lesions tend to cause overt or chronic occult mucosal bleeding. Their incidence and clinical course have not been adequately studied. These lesions are managed similarly as PHG.

Pathophysiologic Basis of Therapy

Clinical–Hemodynamic Correlations in Portal Hypertension

Several studies have demonstrated that in patients with cirrhosis who receive either placebo or long-term pharmacologic therapy for portal hypertension, the occurrence of clinical events is related to the hemodynamic changes observed during treatment. Therefore, changes in the HVPG before and during maintenance therapy (or no treatment) are closely correlated with the occurrence of first variceal bleeding or rebleeding. These studies have demonstrated that the HVPG response to treatment can be considered "good" when the HVPG decreases by at least 20% of the baseline value. This response is associated with a very low risk for rebleeding (<10% at 2 years) (Fig. 15.20). The HVPG response is "optimal" when the HVPG decreases to 12 mm Hg or below, in which case the risk for variceal bleeding is negligible (131,143). An optimal response is also associated with a significant reduction in the size of varices and a significantly longer actuarial survival (131). Therefore, these studies show that

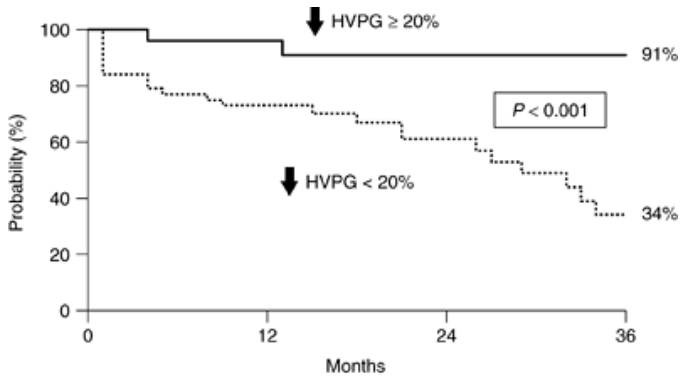
decreasing the portal pressure below the critical threshold values for clinically significant portal hypertension is associated with a reversal of the natural history of the portal hypertensive syndrome and an improved prognosis. These findings represent the rational basis for the medical treatment of portal hypertension.

Therefore, the goal of long-term pharmacologic therapy in patients with portal hypertension should be to decrease the HVPG by at least 20% from baseline values, and preferably to below the threshold of 12 mm Hg. The rational treatment of portal hypertension requires that the underlying alteration—the increase in HVPG—be modified. Such modification should be based on an understanding of the mechanisms that lead to increased portal pressure in liver disease.

Pharmacologic Manipulation of the Intrahepatic Circulation

Studies have shown that a relative deficit of NO and an exaggerated response to endogenous vasoconstrictors

(e.g., norepinephrine, ET, angiotensin II) are responsible for approximately 30% to 40% of the increased intrahepatic vascular resistance of cirrhosis; therefore, some pharmacologic approaches aim at decreasing intrahepatic resistance (Fig. 15.21).



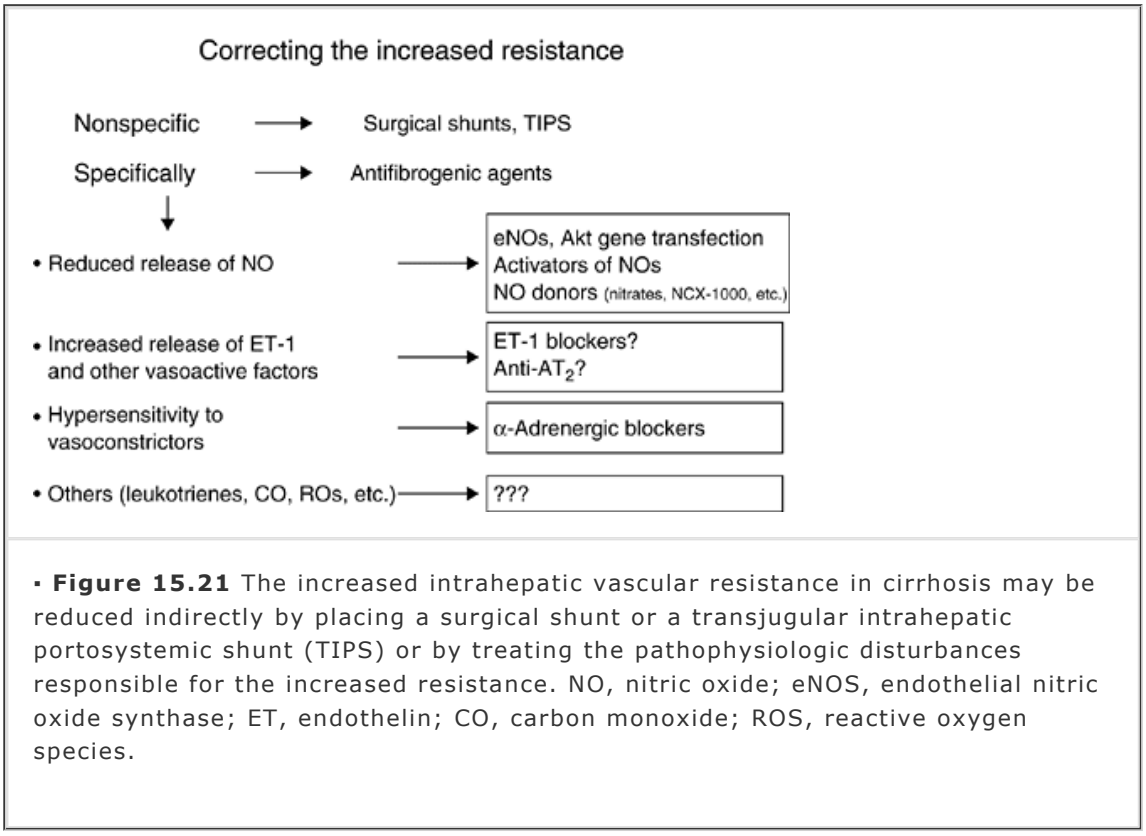
▪ **Figure 15.20** Actuarial probability of remaining free of variceal rebleeding according to the hemodynamic response of the hepatic vein pressure gradient (HVPG) to pharmacologic treatment. A reduction in the HVPG of at least 20% of the baseline values is associated with a very low risk for rebleeding (<10% at 3 years). When the portal pressure gradient decreases to 12 mm Hg or below, the risk for variceal bleeding is negligible. (From Feu F, Garcia-Pagan JC, Bosch J, et al. Relation between portal pressure response to pharmacotherapy and risk of recurrent variceal hemorrhage in patients with cirrhosis. *Lancet* 1995;346:1056–1059, with permission.)

Increasing intrahepatic delivery of nitric oxide

Nitrovasodilators such as NTG, isosorbide dinitrate (ISDN), and IMN, through their capacity to release NO, may compensate for the NO deficit within the cirrhotic liver and thereby reduce the intrahepatic vascular resistance. IMN, the most extensively studied nitrate, has been shown to reduce HVPG in patients with cirrhosis without reducing the hepatic blood flow; its effect reflects a reduction in the hepatic vascular resistance (159). Although it is possible to determine the effect of pharmacologic agents on the individual factors that determine portal pressure (i.e., resistance and flow) in the

experimental setting, it is not easy to do so in clinical studies. A further complication is the fact that the vasodilator action of these drugs is not limited to the hepatic and portal circulation but extends to the systemic circulation, where they cause arterial hypotension; this in turn may elicit reflex splanchnic vasoconstriction, with an ensuing reduction in portal blood flow (160). Vasodilators usually also decrease the cardiac preload and hence the cardiac output, which may further decrease the splanchnic

blood flow. Moreover, many vasodilators reduce the vascular resistance in the portal–collateral circulation. This represents another mechanism by which a vasodilator may reduce the PPG, but at the expense of increased blood flow in the portosystemic collaterals and esophageal varices (134). In some instances, the beneficial effect of decreasing intrahepatic resistance by means of a vasodilator, in terms of a reduction in portal pressure, is offset by the splanchnic vasodilator effect of the drug, which increase the portal–collateral blood flow and prevent any decrease in portal pressure (161).



▪ **Figure 15.21** The increased intrahepatic vascular resistance in cirrhosis may be reduced indirectly by placing a surgical shunt or a transjugular intrahepatic portosystemic shunt (TIPS) or by treating the pathophysiologic disturbances responsible for the increased resistance. NO, nitric oxide; eNOS, endothelial nitric oxide synthase; ET, endothelin; CO, carbon monoxide; ROS, reactive oxygen species.

Another important limitation of vasodilators is that they may be dangerous in patients with advanced cirrhosis. These drugs, by enhancing preexisting peripheral vasodilatation, further decrease the arterial blood pressure and activate endogenous vasoactive systems, which may worsen sodium retention and ascites. However, recent studies have shown that in patients with compensated cirrhosis, long-term treatment with IMN is safe when combined with β-blockade (162). Combined treatment, unlike treatment with IMN alone, does not cause adverse effects on renal function, sodium handling, or endogenous vasoactive systems because the mild systemic vasoconstriction and suppression of renin release resulting from β-blockade oppose the adverse systemic and renal effects of IMN.

Another method to increase the intrahepatic production of NO is to administer agents that act preferentially in the liver, such as the "liver-selective" NO donor NCX-1000 (163,164,165,166). Interest in this method has increased because of recent studies showing that in experimental models of cirrhosis the expression of NO synthase in liver cells can be enhanced by the portal injection of adenovirus transfected with the gene

encoding neural NOS or eNOS and that such treatment may significantly reduce portal pressure for some weeks (52,164,165). Similarly, transfer of the constitutively active Akt results in enhanced eNOS activity and reduces portal pressure in carbon tetrachloride–induced cirrhotic rats (53). More recently, it has been shown that hepatic eNOS activity may be enhanced in patients with cirrhosis by the administration of simvastatin (54,166), findings that may be of therapeutic relevance.

α-Adrenergic antagonists

Prazosin is an α_1-adrenergic antagonist that markedly reduces the HVPG in patients with cirrhosis. This reduction is associated with an increase in hepatic blood flow, which suggests a reduction in the hepatic vascular resistance (163,167). However, long-term prazosin administration is associated with a significant reduction in arterial pressure and systemic vascular resistance and an activation of endogenous vasoactive systems that lead to plasma volume expansion, sodium retention, and, in some cases, ascites. Recent data suggest that the adverse effects of prazosin on the systemic circulation and renal function may be attenuated by the combined administration of prazosin and propranolol. In a randomized controlled investigation, the combination of propranolol and prazosin was significantly more effective, in terms of reducing the HVPG, than the combination of propranolol and IMN, although it was less well tolerated (168). However, this drug combination has not been assessed in long-term RCTs of the prevention of variceal hemorrhage.

Clonidine is a centrally acting α_2-adrenergic agonist that reduces peripheral adrenergic output. Its hemodynamic effects are therefore similar to those of both β- and α-adrenergic blockers. In the systemic circulation, clonidine reduces the heart rate, cardiac index, and arterial blood pressure, whereas in the splanchnic circulation, it reduces the HVPG by decreasing portal and hepatic resistance and splanchnic inflow (169). Despite the marked fall in arterial pressure after clonidine administration, hepatic blood flow and liver and renal function are maintained. The fall in the HVPG is slightly greater than that achieved with propranolol.

Carvedilol is a nonselective β-adrenergic blocker with intrinsic anti–α-adrenergic activity, which indicates that its effects are similar to those of clonidine without some of its inconveniences (rebound adrenergic hyperactivity) (170).

Blockade of the renin–angiotensin system

Activation of the renin–angiotensin system is a frequent finding in patients with cirrhosis, especially those with more advanced disease. This is thought to represent a homeostatic response to counterbalance the systemic and splanchnic vasodilatation and arterial hypotension observed in portal hypertension. A direct relation between HVPG and plasma renin activity has been observed in patients with cirrhosis (171), and several studies have demonstrated that the infusion of angiotensin II increases portal pressure by increasing the hepatic vascular resistance. These observations provided the rationale of renin–angiotensin blockade in portal hypertension. Initial studies with the intravenous administration of *saralasin*, a peptide-competitive antagonist of angiotensin II, showed a reduction in the HVPG but also a marked reduction in arterial pressure (172). Angiotensin-converting enzyme inhibitors have also been tested. Although no effect on HVPG was observed with *captopril*, a significant reduction was observed with *enalapril* in two studies performed in a small group of patients. However, a reduction in arterial pressure was frequently noted in these studies. More recently, in a nonrandomized study of patients with portal hypertension, *losartan*, a nonpeptide antagonist of angiotensin

receptor type I, was reported to markedly reduce portal pressure (173). However, these results were not reproduced in subsequent studies, in which significant reduction in arterial pressure and almost negligible effects on HVPG were observed (174).

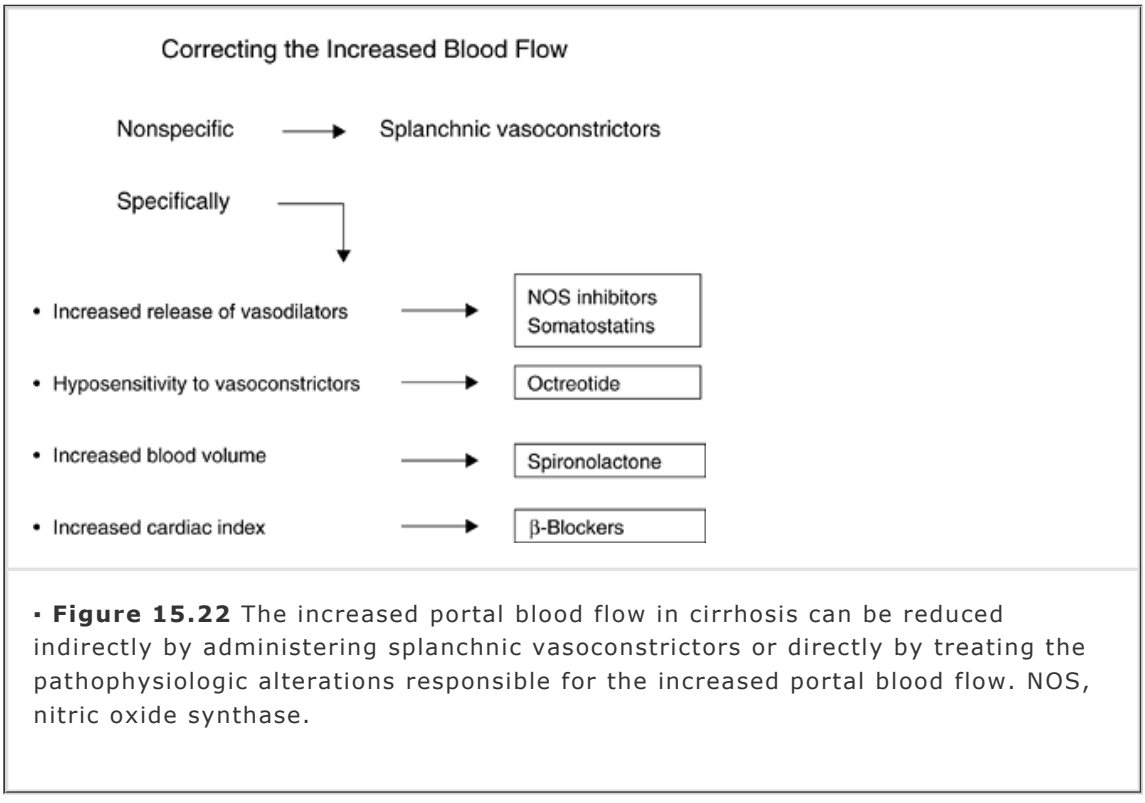
However, these agents may still have a role in preventing the progression of hepatic fibrosis in early stages of the disease, as suggested by studies in cirrhotic rat models (175).

Blockade of endothelin

Conflicting results have been obtained with ET blockers in experimental models of portal hypertension. Acute administration of the mixed ET-A and ET-B receptor blocker bosentan decreased portal pressure (32), whereas long-term administration of Ro 48-5695, a second-generation mixed ET receptor blocker, did not modify portal pressure and even increased liver fibrosis (34). Long-term selective blockade of ET-A receptor with LU 135252 dramatically decreased collagen accumulation in a model of secondary biliary cirrhosis (176), whereas the acute administration of another ET-A blocker (FR 139317) to cirrhotic rats did not lower portal pressure (177). It seems obvious that the pathophysiologic role of ET must be further clarified.

Calcium channel blockers

Experimental studies in isolated perfused liver suggest that calcium channel blockers may decrease portal pressure in cirrhosis by reducing the hepatic vascular resistance. However, several studies in patients with cirrhosis in which verapamil, nifedipine, and nicardipine were tested failed to show any reduction in HVPG. Nicardipine improved hepatic perfusion without modifying HVPG but increased the portal–collateral blood flow, an effect that might be dangerous in patients with esophageal varices. Overall, these data indicate that calcium channel blockers have no role in the treatment of portal hypertension (5).



▪ **Figure 15.22** The increased portal blood flow in cirrhosis can be reduced indirectly by administering splanchnic vasoconstrictors or directly by treating the pathophysiologic alterations responsible for the increased portal blood flow. NOS, nitric oxide synthase.

Pharmacologic Agents that Decrease Splanchnic Blood Flow

Most pharmacologic treatments of portal hypertension have attempted to correct the increase in portal blood inflow with splanchnic vasoconstrictors (Fig. 15.22). Some of these drugs, such as nonselective β-blockers, can be given orally and are therefore

appropriate for the long-term treatment of portal hypertension, whereas others, such as somatostatin or terlipressin, require parenteral administration and are used only on a short-term basis, as in the treatment of acute variceal hemorrhage.

Nonselective β-blockers

The reduction in portal venous inflow by nonselective β-blockers such as propranolol, nadolol, and timolol is the consequence of a decrease in cardiac output caused by blockade of cardiac β_1-adrenoceptors and of splanchnic vasoconstriction caused by blockade of vasodilating β_2-adrenoceptors in the splanchnic vasculature (178,179,180). This dual effect explains why cardioselective β_1-blockers reduce the portal pressure less effectively than nonselective β-blockers. The reduction in portal pressure averages approximately 14% and is accompanied by a significant reduction in esophageal variceal pressure and azygos blood flow, which is an index of blood flow through the gastroesophageal collaterals and esophageal varices. The

mean reduction in azygos blood flow with propranolol is approximately 35% (109). The significant effect of propranolol on portal pressure and the pronounced reduction in collateral blood flow explain why this drug reduces both variceal pressure (which decreases in parallel with portal pressure) *and* the volume/radius of the varices (which are reduced in the same proportion as azygos blood flow). Because of these two effects, propranolol causes a greater decrease in variceal wall tension than in variceal pressure (134).

β-Blockers are contraindicated in approximately 15% of patients who are considered for this treatment. Side effects are reported in approximately 15% to 20%, but severe events are rare. The most frequent complaints are fatigue, shortness of breath (often associated with marked bradycardia), and sleep disorders. Some of these side effects disappear with time or after the dose has been reduced. Although the complications of propranolol therapy in cirrhosis have never been lethal, side effects are important because they discourage compliance.

Nadolol is easier to administer because it has a longer half-life (allowing once-a-day administration) and is eliminated by the kidneys. Also, it has been suggested that, because it does not cross the blood–brain barrier, it is less likely to cause central effects. Frequently, side effects become less severe after propranolol is exchanged for nadolol, or vice versa.

A more important limitation of nonselective β-blockers is that they achieve the targeted reduction in HVPG in only about one third of patients with advanced cirrhosis (143). This limitation is, at least in part, a consequence of the fact that these drugs increase the portal collateral resistance, which attenuates the fall in portal pressure that should be expected from the reduction in portal–collateral blood flow. This explains why patients with advanced portal hypertension, who have already bled from varices, do not respond as well as compensated patients or patients without varices (178,181).

Vasopressin and analogs

Vasopressin is thought to be the most powerful vasoconstrictor; however, its clinical efficacy is still controversial. At pharmacologic doses, it reduces the blood flow to all splanchnic organs and thereby decreases portal blood flow and portal pressure. Vasopressin is also effective in reducing collateral blood flow and variceal pressure. Adverse hemodynamic effects of vasopressin are systemic vasoconstriction with increased peripheral vascular resistance and reduced cardiac output, heart rate, and coronary blood flow. These effects may result in serious complications, such as myocardial ischemia or infarction, arrhythmias, mesenteric ischemia, limb ischemia, and cerebrovascular accidents. In 25% of cases, vasopressin therapy must be

withdrawn because of such complications (182).

The *combination of NTG and vasopressin* enhances the reduction in portal pressure and attenuates the systemic side effects of vasopressin. NTG, which acts by delivering NO, reduces the vascular resistance in the liver microcirculation and portal venous system and improves myocardial performance (183). Several RCTs and meta-analyses have shown that this drug combination is more effective and safer than vasopressin alone in controlling bleeding from ruptured esophageal varices. Therefore, if vasopressin is used, it should always be combined with NTG. However, better pharmacologic alternatives are now available, such as terlipressin and somatostatin.

Terlipressin is a synthetic analog of vasopressin (triglycyl-lysine vasopressin). After intravenous injection, it is slowly converted into vasopressin through enzymatic cleavage of the triglycyl residues by tissue peptidases; therefore, tissue levels are high and circulating levels low. Terlipressin, unlike vasopressin, does not enhance fibrinolysis and its biologic activity lasts longer, so that continuous intravenous infusion is unnecessary. The preferred schedule of administration is intravenous injection of 2 mg every 4 to 6 hours (184). Terlipressin is not readily available in the United States.

Somatostatin and analogs

Somatostatin was introduced for the treatment of variceal hemorrhage because it decreases portal pressure without the adverse effects caused by vasopressin on the systemic circulation. Somatostatin causes splanchnic vasoconstriction and thereby decreases portal and collateral blood flow and portal pressure (185). Somatostatin probably inhibits the release of splanchnic vasodilator peptides, such as glucagon, and enhances the effects of endogenous vasoconstrictor systems. In addition, somatostatin blocks postprandial increases in portal blood flow and portal pressure. Bolus injections of somatostatin cause marked vasoconstriction in humans, characterized by rapid and intense, but transient, falls in portal pressure and azygos blood flow; the effects of bolus injections are much more pronounced than those of continuous infusions (186). Usually, somatostatin is administered as an intravenous bolus injection of 250 µg, which is followed by continuous infusion at a rate of 250 µg/hour for 2 to 5 days. However, the dosage used for continuous infusions is largely empiric because hemodynamic studies have shown that to achieve a consistent effect, with a reduction of both HVPG and azygos blood flow, a dosage of 500 µg/hour is required (186). Actually, better clinical results are achieved by the 500 µg/hour infusion dosage (187).

Octreotide, vapreotide, and *lanreotide* are cyclic octapeptide analogs of somatostatin that have a longer biologic half-life. Somatostatin analogs have been shown to reduce portal pressure in animals; however, their hemodynamic effects in patients with cirrhosis are controversial (185). Octreotide injection is followed by rapid desensitization and a loss of its effects in decreasing HVPG and azygos blood flow and suppressing circulating glucagon levels. However, the effects of octreotide in attenuating postprandial splanchnic hyperemia may be maintained (188).

Nitric oxide synthase inhibitors

Blocking NO synthesis in animals with experimental cirrhosis has been shown to correct the hyperdynamic circulation (66,67). In a recent report, the systemic administration of the NO synthase inhibitor *N*(G)-monomethyl-L-arginine to patients with compensated cirrhosis and portal hypertension decreased the hyperkinetic systemic circulation and enhanced renal function and sodium excretion (189). However, the study did not assess its effects on the HVPG. In experimental models, the reduction of portal blood flow by NO blockade was not paralleled by a decrease in portal pressure because of a concomitant increase in hepatic and collateral resistance. Therefore, there is no place

for the use of NO blockers in reducing splanchnic blood flow and portal pressure.

Other Drugs and Drug Combinations

It is unlikely that any single agent can decrease the portal pressure sufficiently to provide complete protection from the risk of variceal bleeding or rebleeding in most patients. Prevention is probably more easily achieved by using combinations of drugs that act through different mechanisms. The strategy for the treatment of portal hypertension may profit from the experience gained in the treatment of systemic hypertension.

Drug combinations

The first drug combination used in patients with portal hypertension was *vasopressin and NTG* to treat acute variceal bleeding. The same concept (combination of a vasoconstrictor and a nitrovasodilator) was thereafter applied by administering *propranolol and IMN* (190). This drug combination has been repeatedly shown to cause a greater reduction in portal pressure than either drug alone, so that "good" or "optimal" responses (decreases in HVPG of at least 20% of baseline values or to below 12 mm Hg) are achieved in a greater number of patients. Part of the reason for the efficacy of this combination is that IMN prevents the increase in portal resistance caused by propranolol. It is important to emphasize that unlike the acute administration of IMN, long-term treatment with the combination of propranolol (or nadolol) and IMN does not cause deleterious effects on renal function or sodium handling in patients with cirrhosis (162). This result is different from what occurs when propranolol and ISDN are combined. Adding IMN achieves the target decrease in HVPG in one third of propranolol nonresponders (a la carte treatment) (191).

Other drug combinations have been shown to enhance the portal pressure–reducing effect of propranolol, either in experimental models of portal hypertension or in patients with liver cirrhosis. These include propranolol and serotonin antagonists, propranolol and spironolactone, propranolol and clonidine, and *propranolol and prazosin*. This last combination is the most interesting one because its portal pressure–reducing effect is significantly greater than that of propranolol plus IMN (168). It should be emphasized that long-term combination therapy enhances the fall in portal pressure only in those patients who fail to exhibit an adequate response to propranolol or nadolol alone. In other words, patients who "respond" to β-blockers do not benefit from the addition of a vasodilator.

Drugs with combined actions

Nipradilol combines in one molecule the action of a nonselective β-blocker and a nitrate-like vasodilator activity. Studies in experimental models suggest that nipradilol may achieve a greater reduction in portal pressure than propranolol (192). However, this finding has not been confirmed in patients with liver cirrhosis (193).

Carvedilol, a nonselective β-blocker with intrinsic α_1-adrenergic antagonist activity, has been used to treat arterial hypertension, ischemic heart disease, and heart failure. Its effects in HVPG are greater than those of propranolol (see preceding text) (170).

Other Pharmacologic Approaches

Manipulation of splanchnic blood volume

Peripheral vasodilatation in cirrhosis plays a major role in the activation of endogenous neurohumoral systems, which in turn leads to sodium retention and expansion of the plasma volume. Expansion of the plasma volume is thought to worsen portal hypertension by increasing the cardiac index. Indeed, the administration of *spironolactone* and a low-sodium diet have both been shown to reduce portal pressure

in patients with cirrhosis. Reduction of the plasma volume may trigger vasoactive mechanisms that further decrease the splanchnic blood flow and portal pressure (194). Clearly, the concomitant use of diuretics by patients with portal hypertensive cirrhosis may be an important factor affecting portal

pressure that has not been taken into account sufficiently in the past and that may explain in part some conflicting results of previous clinical trials.

Drugs that increase pressure in the lower esophageal sphincter

It has been suggested that metoclopramide, domperidone, and other drugs that increase pressure in the lower esophageal sphincter be used as ancillary therapy in the management of variceal bleeding, on the basis of the finding that they reduce the inflow of blood into varices in portographic studies and significantly decrease azygos blood flow and variceal pressure. However, their value in the management of variceal bleeding is uncertain.

Noninvasive Evaluation of Response to Drug Therapy

The wide variations in HVPG response of individual patients to pharmacologic treatment suggests that it would be desirable to schedule follow-up measurements of the HVPG during long-term pharmacologic therapy, to determine whether the treatment is likely to offer adequate protection from the risk for bleeding. Although measurement of the HVPG is a simple and safe technique, it is an invasive investigation. For this reason, substantial interest has been shown in developing noninvasive methods to monitor the hemodynamic response to pharmacologic therapy. These methods are summarized in the subsequent text.

Duplex Doppler ultrasonography

Initial studies evaluated the use of Doppler ultrasonography to measure changes in the femoral blood flow, after the acute administration of propranolol, in the hope that these would correlate with the splanchnic hemodynamic effects. However, the test identified only a fraction of patients with a poor HVPG response to propranolol and none of those with a good response. Therefore, when a reduction in femoral blood flow was absent or minimal, HVPG response was usually poor, but only about half the patients with a marked reduction in femoral blood flow had a clinically significant reduction in portal pressure (50% positive predictive value) (195). Similar results were found when changes in forearm blood flow were measured by strain gauge plethysmography (196).

The duplex Doppler technique has been used to assess changes in portal blood flow and blood flow velocity and changes in the superior mesenteric artery blood flow velocity and pulsatility index after β-blockade. Although it has been suggested that the overall predictive accuracy of duplex Doppler in identifying "good" and "bad" responders to nonselective β-blockers may be high, these results have not been confirmed, probably because the intraobserver and interobserver variability of duplex Doppler measurements is relatively high (197,198). On the other hand, most studies evaluating duplex Doppler for predicting the HVPG response have used β-blockers. However, this technique is not adequate to assess changes in portal pressure caused by drugs or drug combinations that modify vascular resistance.

Measurements of variceal pressure

Several studies have shown that the noninvasive measurement of variceal pressure with a pressure-sensitive endoscopic gauge may be of value in assessing the hemodynamic response to β-blockers and the risk for variceal bleeding during follow-up. In a longitudinal, prospective study, a fall in variceal pressure by more than 20%

of baseline values was associated with a very low risk for variceal bleeding on follow-up (5% probability of variceal bleeding on long-term follow-up vs. 41% in patients failing to achieve such a marked response), which suggests that variceal pressure measurements may provide useful prognostic information (117) (Fig. 15.23). However, the measurement of variceal pressure is of limited applicability, mainly because measurements are frequently not possible in small varices, and artifacts caused by esophageal peristalsis may prevent satisfactory measurements. However, measurements of variceal pressure have the potential advantage of being applicable in patients with esophageal varices of any cause, including prehepatic portal hypertension, in which measurement of the HVPG is not adequate to assess the portal pressure.

Interventional Treatment of Acute Bleeding Related to Portal Hypertension

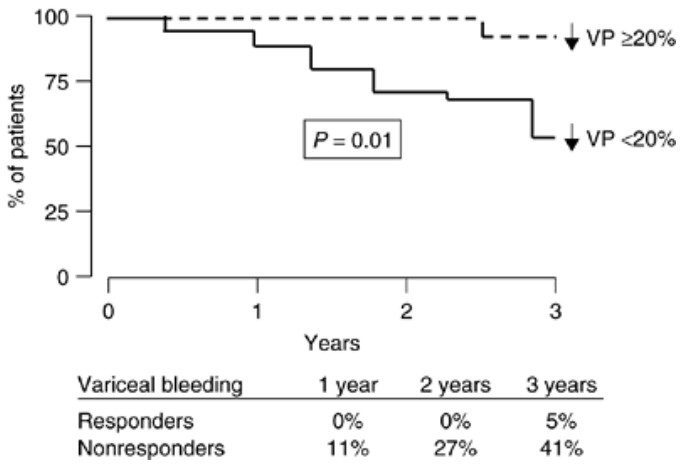
Endoscopic therapy

The endoscopic procedures for managing bleeding esophageal varices are described later in this chapter.

Balloon tamponade

The Sengstaken-Blakemore tube is a triple-lumen tube with gastric and esophageal balloons and a tube for aspirating the stomach. The Minnesota tube has a larger gastric balloon and a lumen for aspirating the esophagus. The Linton-Nachlas tube, which is used for gastric varices, has a large gastric balloon and two lumina for aspirating the stomach and esophagus. Balloon tamponade may temporarily control bleeding in 60% to 90% of patients. On deflation of the balloons, bleeding recurs in approximately 50% of cases (199). Balloon tamponade is used only for 12 to

24 hours in emergency situations as a bridge to definitive therapy if drugs and endoscopy fail to control variceal bleeding. Complications occur in 10% to 15% of patients and mainly involve aspiration pneumonia and, rarely, esophageal rupture. Complication-related mortality ranges between 2% and 5%. Only well-trained personnel should attempt tamponade (199).



Variceal bleeding	1 year	2 years	3 years
Responders	0%	0%	5%
Nonresponders	11%	27%	41%

▪ **Figure 15.23** Prognostic value of repeated measurements of variceal pressure (VP) with an endoscopic pressure gauge (Varipress) in patients on pharmacologic therapy. A fall in VP of more than 20% of the baseline values is associated with a much higher actuarial probability of the patient remaining free of bleeding at follow-up (5% probability of variceal bleeding vs. 41% in patients failing to

achieve such a marked response, *P* = 0.01). (From Escorsell A, Bordas JM, Castaneda B, et al. Predictive value of the variceal pressure response to continued pharmacological therapy in patients with cirrhosis and portal hypertension. *Hepatology* 2000;31:1061–1067, with permission.)

Percutaneous transhepatic embolization of gastroesophageal varices

Percutaneous transhepatic embolization of gastroesophageal varices, first proposed in the early 1970s, was practically abandoned after it was shown to be less effective than sclerotherapy (200). It is performed by catheterizing the gastric collaterals that supply blood to varices through the transhepatic route. Percutaneous transhepatic embolization is used nowadays only as a complement to TIPS in patients with severe acute bleeding, especially in patients with gastric varices.

Portosystemic shunts

Transjugular intrahepatic portosystemic shunt

TIPS is an intrahepatic calibrated portosystemic shunt performed between an intrahepatic branch of the portal vein (usually the right) and one hepatic vein (usually the right) using vascular intervention radiologic techniques (Fig. 15.24). Immediately after TIPS placement, there is a marked reduction in the PPG. This is due both to a marked decrease in absolute portal pressure and a slight increase in the IVC pressure. Reduction in the PPG after TIPS is also associated with a marked reduction in portal–collateral blood flow. TIPS is very effective in variceal bleeding refractory to medical and endoscopic treatments. Indeed, complete protection from variceal bleeding is achieved when PPG decreases below 12 mm Hg (1). Therefore, the goal of TIPS is to reduce the PPG below the threshold gradient of 12 mm Hg. Despite the marked reduction in PPG observed after TIPS, PPG tends to increase again during follow-up because of the development of stenosis or occlusion of the shunt in the stent, at the portal vein opening, or, more frequently, at the hepatic vein. Progression of the stenosis will again promote the increases in PPG above the 12 mm Hg threshold (TIPS dysfunction) and patients reenter the bleeding risk zone. The actuarial probability of TIPS dysfunction with the use of bare stents is greater than 75% after 1 year of follow-up. The introduction of the expanded

polytetrafluoroethylene (ePTFE)-covered stents has completely changed this scenario, with a reported 1-year actual rate of dysfunction as low as 10% (201).

Surgical procedures are discussed in Chapter 16.

Prevention of the First Bleed from Esophageal Varices

Pharmacologic treatment

Pharmacologic prophylaxis is aimed at preventing the first bleeding episode and at improving survival by reducing bleeding-related deaths. More recently the hypothesis that drug therapy may prevent development or progression of varices has been tested (*preprimary prophylaxis*) (202). Nonselective β-blockers, nitrates, and spironolactone are the only drugs assessed for primary prophylaxis of variceal bleeding. Although several risk factors for variceal bleeding have been identified, clinical trials assessing pharmacologic treatments for prophylaxis of first bleeding included patients mainly on the basis of variceal size.

Nonselective β-blockers

As discussed in a preceding section in this chapter, nonselective β-blockers reduce portal pressure through a reduction in portal and collateral blood flow.

Three RCTs assessed nonselective β-blockers for preprimary prophylaxis with discordant results (85,203,204). Two of these studies included patients with small varices (although 79/206 patients had no varices in one study) (204). In one study (204) an unfavorable effect of propranolol was found, while in the other (203) nadolol effectively reduced the progression of varices and the bleeding risk. The discordant results may be explained, at least in part, by the high proportion of dropouts (almost one third) in the first study (203). The third, the only study that was double blind, aimed at assessing whether timolol prevents the development of varices in patients with HVPG greater than 6 mm Hg but failed to show a beneficial treatment effect, although it was confirmed that patients in whom HVPG was below 10 mm Hg or in whom HVPG decreased by greater than 10% had a significantly lower risk of developing varices. Therefore, at present, the conclusion for preprimary prophylaxis is that there is no indication to treat patients without varices for the prevention of the formation of varices; patients with small varices could be treated with a nonselective β-blocker, but

further studies are required before a formal recommendation may be made (8).

The efficacy of the nonselective β-blockers propranolol and nadolol for the prophylaxis of the first variceal bleeding has been compared with that of placebo or nonactive treatment in 13 RCTs (141,205), including mainly patients with medium or large esophageal varices. Several meta-analyses of these studies consistently showed a significant reduction in the risk for bleeding, from 25% with nonactive treatment to 15% with β-blockers (135) over a median follow-up of nearly 2 years (135,141,205,206). According to this bleeding risk reduction, one bleeding episode will be prevented in every 10 treated patients. Mortality was only slightly reduced from 27% to 23%—this effect barely approached the level of statistical significance. The lack of a significant reduction of mortality with β-blockers is probably due to inadequate power of the reported studies and to their relatively short follow-up.

Overall, available data, including subgroup analyses (85,135,141,203,204,205,206), shows that nonselective β-blockers are more beneficial in patients with medium or large varices without ascites than in those with ascites. The effect is small and nonsignificant in patients with small varices.

Several contraindications remarkably reduce the number of patients suitable for β-blocker therapy. The most frequent are active pulmonary obstructive disease, aortic valve disease and other heart diseases that may be worsened by β-blockers, atrioventricular heart block, and peripheral arterial insufficiency. Sinus bradycardia and insulin-dependent diabetes are relative contraindications. Because of these contraindications, approximately 15% of patients are excluded from therapy with β-blockers in clinical practice (207). The incidence of side effects among treated patients is approximately 15%. The most frequent are fatigue, dyspnea, bronchospasm, and reduction of sexual activity. Five percent of side effects require treatment discontinuation. Renal function is not affected. Hepatic encephalopathy has been attributed to β-blockers in rare patients with severe liver disease. However, in patients without severe hepatocellular dysfunction or history of encephalopathy, propranolol does not impair cerebral blood flow, arterial ammonia, or neuropsychologic functions.

Propranolol should be initially dosed at 20 mg b.i.d. and titrated on a biweekly basis, up to a maximum of 160 mg b.i.d. In most clinical trials the dosage has been titrated empirically to decrease the resting heart rate by 25% of baseline value. However, this target is not related to the hemodynamic effect of the drug. A reduction of HVPG to levels less than 12 mm Hg was found to abolish the risk of variceal bleeding (131,208). However, the efficiency of such a hemodynamic target in clinical practice is still uncertain in patients treated for prevention of first bleeding who have a relatively low bleeding risk. Therefore, in clinical practice propranolol is empirically dosed up to the maximum tolerated dose, within the limit of 160 mg b.i.d. This results in a median dose of near 80 mg b.i.d. Similar concepts apply to nadolol, which should be dosed at 20 mg a day in a single daily dose and titrated every 2 to 3 days up to a

maximum of 160 mg; the median maximum tolerated daily dose is 80 mg. When propranolol is withdrawn, the risk of variceal hemorrhage returns to what would be expected in an untreated population, and the risk of mortality is higher than that observed in an untreated population. These observations support the current practice of indefinite prophylactic therapy (209).

After cessation of propranolol therapy bleeding may occur in some patients; therefore, patients should be instructed not to discontinue treatment, and if needed, to be under direct monitoring by a physician.

Organic nitrates

Administration of short-acting (e.g., NTG) or long-acting (e.g., ISDN or IMN) nitrates decreases portal pressure mainly through a reduction in intrahepatic and portal–

collateral resistance (5). As discussed in another section of this chapter, vasodilators may adversely affect renal function and are not used as single agents for the treatment of portal hypertension (5,210). However, the combination of a vasodilator (e.g., IMN) with a vasoconstrictor (e.g., propranolol or nadolol) enhances the fall in portal pressure achieved by either drug alone while preventing its systemic side effects (162,167,168,190). These combinations achieve a greater reduction of portal pressure and also allow a significant additional portal pressure reduction in some of the patients who are *nonresponders* to propranolol.

Among long-acting nitrates, only IMN has been evaluated in clinical trials for the prevention of variceal bleeding. It has been compared with propranolol in three studies including 276 patients overall. Pooled results from these three RCTs showed a nonsignificant increase in bleeding rate and mortality with IMN (141). One study of IMN versus β-blockers reported an increased mortality with IMN among patients older than 50 (141). Although this may reflect an improved prognosis in the group on β-blockers, it suggests that IMN should not be used as single agent. Moreover, a recent double-blind study of IMN versus placebo in patients with contraindications or intolerance to β-blockers failed to show any benefit from IMN in the prevention of first bleeding (207).

The combination of IMN and β-blockers has been compared with β-blockers alone in three RCTs (211,212,213). Two studies used nadolol and one propranolol. The first one, an open study, showed a significant bleeding risk reduction with combination therapy, without significant effects on mortality (211). The other two studies were double blind and placebo controlled. One was a small single-center study including 57 patients with large varices and red color sign and failed to show any significant advantage with the combination therapy, although it was clearly underpowered (212). The last one, a multicenter study, included 349 patients (199 with large varices) and found no differences between the two treatment groups in bleeding or mortality rates, even when only patients with large varices were considered (213). Overall, 552 patients were included in the three studies. Bleeding rate was 15% in the β-blocker–treated patients and 10% in the combination therapy patients; the 5% bleeding risk reduction with the combination therapy was not significant (95% CI -16% to 6%). Mortality rate was 10% with both treatments, and side effects were significantly more frequent with combination therapy. No evidence of impairment of renal function or of worsening or increased incidence of ascites was found with nitrates in any of these studies (141). These results do not support the use of combination therapy for the prevention of first variceal bleeding.

Major side effects of nitrates are headache (which occurs in nearly 20% of patients but rarely requires treatment discontinuation) and hypotension (63,207). When nitrates are given in combination with β-blockers, side effects occur in 30% to 50% of patients and leads to discontinuation of nitrates in 10% to 40% of patients. The probability of side effects with nitrates is dose dependent. If the choice to give nitrates to a patient is made, then IMN should be started at a dosage of 10 mg b.i.d. and titrated every other day up to 40 mg b.i.d. A dosage of 10 to 20 mg b.i.d. may be better tolerated and cause less systemic side effects, while being able to cause intrahepatic and collateral vasodilatation (46).

Diuretics

Spironolactone, by counteracting the increase in plasma volume that sustains the hyperdynamic circulation in portal hypertension, lowers HVPG in patients with cirrhosis (194). Its combination with nadolol has been compared with nadolol alone for the prevention of first variceal bleeding and ascites in compensated patients with cirrhosis in an RCT including 100 patients (214); similar HVPG reductions (-16% ± 12% vs. -11% ± 14%), bleeding rates (17% vs. 14%), and 2-year mortality rates (2% vs. 6%) were achieved in both groups.

Monitoring pharmacologic treatment response

In prospective cohort studies and clinical trials it has been shown that the risk of bleeding is virtually abolished when HVPG or the variceal pressure is reduced by as much as or more than 20% of baseline values or HVPG is reduced below 12 mm Hg (117,131,143,215,216,217). Overall, the proportion of patients in whom HVPG was reduced to 12 mm Hg or less was 21%; in these patients the odds ratio for bleeding compared to those who did not reach this hemodynamic target was 0.21 (95% CI 0.05 to

0.80). The proportion of patients with HVPG reduction by as much as or more than 20% of baseline values or to 12 mm Hg or less was 31%, and the odds ratio for bleeding in these patients compared to those not reaching this target was 0.14 (95% CI 0.05 to 0.42). However, failure to reach a treatment response according to these hemodynamic targets does not mean that the patient will bleed. In fact, approximately 60% of patients who do not achieve these targets after being treated prophylactically with β-blockers will not bleed. Because of this relatively low bleeding risk, there is consensus that hemodynamic monitoring of pharmacologic treatment response is not a definite indication during the prophylaxis of the first variceal bleeding (8).
