Key Concepts

- Autoimmune hepatitis (AIH) represents a chronic inflammatory disorder of the liver, involving loss of tolerance to hepatic tissue antigens.
- AIH is characterized by a predominantly periportal, lymphoplasmacytic infiltrate associated with hypergammaglobulinemia and circulating autoantibodies.
- Epidemiologically and clinically distinct subtypes are defined by different autoantibody patterns.
- AIH prevalence is highest among females, displaying an immunogenetic association with human leukocyte antigens (HLA)-A1-B8-DR3 or HLA-DR4 haplotypes.
- Extrahepatic immune-mediated syndromes are frequently found.
- The pathogenic mechanisms initiating chronic inflammation in AIH are incompletely understood. Genetic factors, molecular mimicry, dysregulated apoptosis, and immune response mechanisms have been implicated to play a role.
- AIH diagnosis is based on both the presence of characteristic laboratory features and histology, as well as the exclusion of other hepatobiliary diseases, facilitated by the revised AIH diagnostic score.
- In most cases AIH responds well to immunosuppressive therapy.
- Standard treatment consists of corticosteroids alone or in combination with azathioprine.
- If standard treatment fails, alternative drugs such as mycophenolate, cyclosporin A, tacrolimus, or cyclophosphamide may be considered.
- In refractory cases with chronic liver failure, liver transplantation remains the ultimate therapeutic option. However, AIH recurrence may complicate the course after liver transplantation.

History and Definition

First reports of severe icteric liver disease associated with hyperproteinemia were published in the 1930s and 1940s. In 1950 Waldenström described chronic hepatitis with hypergammaglobulinemia in young women, leading to jaundice and liver cirrhosis (1). This new entity of liver disease was confirmed by several authors

worldwide. Because of serologic similarities with systemic lupus erythematodes the term *lupoid hepatitis* was introduced in the mid-1950s.

Nowadays, autoimmune hepatitis (AIH) represents a chronic, mainly periportal hepatitis with lymphocytic infiltrates, plasma cells, and piecemeal necroses. It is characterized by a female predominance, hypergammaglobulinemia, circulating autoantibodies, and a good response to immunosuppressive treatment (2). Serologic detection of autoantibodies is one of the distinguishing features leading to the classification of AIH

into subgroups (Table 31.1). AIH type 1 represents the most common form of AIH and is characterized by the presence of antinuclear antibodies (ANAs) and/or anti–smooth muscle antibodies (SMAs). The target nuclear autoantigens of type 1 AIH are unknown and presumably heterogeneous. Characteristic antibodies of AIH type 2 are liver–kidney microsomal (LKM-1) antibodies directed against cytochrome P-450 CYP 2D6 and with lower frequency against uridine-5′-diphosphate-glucuronosyltransferase (UGT) (3,4). AIH type 3 is characterized by autoantibodies against soluble liver antigen and liver–pancreas antigens (SLA/LP), which are directed toward the UGA-suppressor transfer ribonucleic acid (tRNA)-associated protein (5,6). The clinical and epidemiologic features of AIH type 1 and 3 are similar. Therefore, some authors pool both subgroups under type 1 subgroup.

Table 31.1. Clinical Characteristics and Distinguishing Features of the Subclasses of Autoimmune Hepatitis

Clinical features	AIH type 1	AIH type 2	AIH type 3
Diagnostic autoantibodies	ANA/SMA	LKM-1	SLA/LP
Target antigen	Unknown	P-450 CYP 2D6 UGT	UGA-suppressor tRNA-associated protein
Percentage of prevalence of all AIH types (%)	80	20 in Europe 4 in the United States	<20
Main age of manifestation	Bimodal (16–30 y and >50 y)	Pediatric (2–14 y)	20–40 y
Extrahepatic associated diseases (%)	41	34	58
HLA association	B8, DR3, DR4	B14, DR3, C4AQO	Unknown

Progression to cirrhosis (%)	45	82	75

AIH, autoimmune hepatitis; ANA, antinuclear antibody, SMA, smooth muscle antibody, LKM, liver–kidney microsome; SLA/LP, soluble liver antigen and liver–pancreas antigens; UGT, uridine-5′-diphosphate-glucuronosyltransferase; tRNA, transfer ribonucleic acid; HLA, human leukocyte antigen.

Epidemiology

Originally described in white northern Europeans and North Americans, AIH has a worldwide distribution. The disease affects 100,000 to 200,000 persons in the United States (7) and accounts for 2.6% of transplant recipients in Europe (8) and 5.9% in the United States (9). In northern Europe the prevalence is estimated at 170 cases per million.

AIH type 1 (classical AIH) represents the most common form of AIH, whereas AIH type 2 and 3 are rare entities (10,11). AIH type 2 displays a regionally variable prevalence, with very low numbers (approximately 4%) in the United States but accounting for up to 20% of AIH cases in western Europe (10,12). In cases of ANA, SMA, and LKM negativity, which are present in 10% of AIH cases, measurement of SLA/LP autoantibodies is justified to recognize patients with AIH and to decrease the possibility of misdiagnosis (13).

Pathophysiology

Autoimmunity is characterized by T cell–dependent immunopathologic responses to auto-/neoantigens, leading to inflammatory tissue injury. An autoimmune response can be triggered by the human leukocyte antigen (HLA) class II–dependent presentation of specific antigenic peptides to T cells through antigen-presenting cells (APCs). As a response to cytokines, the exposed T cells become activated and differentiate into T_H1 or T_H2 cells. Proinflammatory cytokines are believed to play an important role in the initiation of the autoimmune response (14). Because of cytokine activation, autoimmune diseases are often observed in associated viral or bacterial infections.

Another mechanism is called *molecular mimicry*. For instance, the B-cell epitope of cytochrome P-450, which is targeted by LKM-1 autoantibodies in AIH type 2, shares sequence homology with the herpes simplex virus antigen IE 175 (3).

Under normal circumstances, the immune response is tightly regulated. T- and B-cell homeostasis, as well as the removal of autoreactive T cells, are regulated by apoptosis. The failure of control by apoptosis may therefore contribute to the initiation and perpetuation of AIH and autoimmune overlap syndromes (15). Deranged apoptosis may influence both the inability to kill autoreactive cells or the induction of autoimmunity against cellular constituents.

Genetic factors are implicated to play a role in the susceptibility to AIH. In particular, polymorphisms of the genes influencing lymphocyte homeostasis, such

as the tumor necrosis factor-α (TNF-α) promoter gene, the complement factor C4 gene, and the cytotoxic T-lymphocyte antigen-4 (CTLA-4) gene, contribute to increased susceptibility to AIH (16). One hypothesis suggests that inheritance of specific HLA class II alleles modified at critical sites provides one of the crucial

steps for the development of AIH. The relevance of genetic alterations for AIH is further underlined by the observation that chronic hepatitis occurs in 10% to 18% of patients with autoimmune polyendocrine syndrome type 1 (APS1), an autosomal recessive disorder that is caused by mutations in a single gene (AIRE) and is characterized by various autoimmune diseases mainly affecting the endocrine glands (17).

Clinical Presentation of Autoimmune Hepatitis

Patients with AIH type 1 clinically resemble those with AIH type 3 with respect to age and sex distribution, HLA antigen profile, inflammatory activity, and response to therapy (18). In contrast, the differences between AIH type 1/3 and AIH type 2 are more apparent. In AIH type 2, patients are younger and more frequently display an acute onset of hepatitis with a more severe course and more rapid progression than those with AIH type 1/3 (19).

Overall, approximately 25% of patients show an acute onset of AIH, and rare cases of fulminant progression of AIH leading to acute liver failure have also been reported (20). Commonly, the clinical presentation of AIH resembles that of other forms of chronic hepatitis. AIH is therefore characterized by unspecific features, such as fatigue, right upper quadrant pain, jaundice, mild pruritus, arthralgias, and, less frequently, spider nevi and palmar erythema. In later stages, signs of portal hypertension including ascites, bleeding esophageal varices, and encephalopathy dominate.

Patients with the initial presentation of acute onset, as well as that of chronic hepatitis, often show histologic evidence of cirrhosis at the onset of symptoms, thereby implicating that subclinical disease may precede the onset of symptoms by a substantial amount of time. Up to 25% of patients initially show signs of decompensated liver cirrhosis (21). AIH, especially type 2, is associated with a wide variety of other autoimmune disorders, in particular autoimmune thyroiditis, rheumatoid arthritis, and diabetes mellitus (Table 31.2).

Diagnosis

The diagnosis of AIH is based on both (a) clinical, serologic, and immunologic features and (b) the exclusion of other hepatobiliary diseases with and without autoimmune phenomena, such as chronic hepatitis C, drug- or alcohol-induced hepatitis, nonalcoholic steatohepatitis (NASH), Wilson disease, genetic hemochromatosis, and α_1 antitrypsin deficiency. Cryptogenic hepatitis, which is an etiologically undefined chronic hepatitis, should also be included in the differential diagnosis of AIH. Patients with cryptogenic hepatitis are negative for viral and autoantibody markers. It is unclear how many of these patients suffer from AIH without detectable autoantibodies. If cholestatic signs and immunoserologic markers of AIH are present, overlap syndromes between AIH and primary biliary cirrhosis or primary sclerosing cholangitis have to be included in the differential diagnostic considerations. Liver histology by itself is not sufficient to prove the diagnosis of AIH but has a role in grading and staging of the disease. The revised AIH diagnostic score contributes to the establishment of the diagnosis in difficult cases by calculating a probability expressed as a numeric score (Table 31.3) (2).

Natural Course and Prognosis

The natural history and prognosis of AIH are largely defined by the inflammatory activity present at the onset of disease and by the presence or development of liver cirrhosis. A 5- to 10-fold increase of the levels of aminotransferases and 2-fold elevation of levels of gammaglobulins are associated with a mortality of 90% without treatment (22,23). With the presence of cirrhosis, mortality is 58% in 5 years. However, the presence of cirrhosis does not influence the initial treatment response or short-term outcome (21). The course of AIH is also significantly influenced by the HLA antigen profile of

the affected individual. The presence of HLA B8 is associated with severe inflammation at presentation and a higher likelihood of relapse after treatment (24,25). Individuals with HLA DR3 have a lower probability of reaching remission, have more frequent relapses, and more frequently require liver transplantation. The HLA DR4–positive subgroup is characterized by a higher age of onset and a more benign outcome (26,27).

Table 31.3. Revised Scoring System for Diagnosis of Autoimmune Hepatitis of the International Autoimmune Hepatitis Group (2)

Category	Score
Sex	
Female	+2
Male	0
Ratio of alkaline phosphatase to aminotransferase	
>3.0	-2

1.5–3.0	0
<1.5	+2
Elevation in the levels of (times upper limit of normal) of serum globulin (total), γ-globulin, or IgG	
>2	+3
1.5–2.0	+2
1.0–1.5	+1
<1.0	0
Autoantibodies (adults) ANA, SMA, or LKM-1	
>1:80	+3
1:80	+2
1:40	+1
<1:40	0
Antimitochondrial antibodies	
Positive	-4
Negative	0
Hepatitis viral markers	
Positive	-3
Negative	+3
History of drug usage	

Yes	-4
No	+1
Alcohol (average of consumption)	
<25 g/d	+2
>60 g/d	-2
Histology	
Interface hepatitis	+3
Predominant lymphoplasmacytic infiltrate	+1
Rosetting of liver cells	+1
None of these	-5
Biliary changes	-3

Response to therapy	
Complete	+2

Relapse		+3

Interpretation of aggregate scores:		
Pretreatment	Definite AIH	>15
	Probable AIH	10–15
Posttreatment	Definite AIH	>17
	Probable AIH	12–17.

IgG, immunoglobulin G; ANA, antinuclear antibody, SMA, smooth muscle antibody, LKM, liver–kidney microsome; HLA, human leukocyte antigen; AIH, autoimmune hepatitis.

The presence of autoantibodies does not generally correlate with disease activity, disease progression, or treatment outcome. However, in some cases autoantibodies may be of prognostic value. In AIH type 1,

antibodies against actin identify a subgroup of anti-SMAs–positive patients with earlier onset of disease and a higher frequency of refractoriness to steroid treatment (28). The presence of anti–asialoglycoprotein receptor (anti-ASGPR) autoantibodies in patients with AIH type 1 is associated with increased laboratory and histologic disease activity and more frequent relapses after steroid withdrawal (29,30).

In case of AIH type 2, autoantibodies to liver cytosol type 1 (anti-LC1) appear to correlate with disease activity, whereas LKM autoantibodies do not (31).

Treatment Indications

AIH was the first chronic liver disease in which medical treatment was proved to prolong survival. A sustained serum aspartate aminotransferase (AST) abnormality of at least 10-fold of normal or a serum AST level of at least 5-fold of normal in combination with serum gammaglobulin level at least twice of normal represents an absolute treatment indication. Histologic evidence of bridging necrosis or multilobular necrosis, as well as severe hepatic and extrahepatic symptoms, also represents absolute treatment indications.

Mild clinical symptoms and less severe laboratory or histologic abnormalities are relative treatment indications. The benefit of immunosuppressive treatment of patients with mild symptoms remains unclear because further reduction of the already low incidence of cirrhosis and of long-term mortality may not occur at acceptable risk.

No treatment indications exist for patients with inactive cirrhosis, complications of portal hypertension in the absence of hepatitis, or mild interface hepatitis in the

absence of symptoms (32).

Induction of Remission

The standard initial treatment of AIH is either prednisone or prednisolone monotherapy (40 to 60 mg/day and tapering regimen) or combination therapy with prednisone (20 to 30 mg/day and tapering regimen) and azathioprine (1 to 2 mg/kg body weight per day) (33,34,35,36). Although steroid monotherapy is as effective as the combination therapy with azathioprine in inducing remission, azathioprine is ineffective in the induction of remission on its own, and this should not be attempted. Combination therapy is generally preferred because it allows for the reduction of the prednisone dose frequently to below 10 mg/day, thereby reducing the steroid-associated side effects. Conversely, candidates for the sole use of prednisone are patients with severe cytopenia or active malignancy or women who are pregnant or planning pregnancy, although the teratogenicity of azathioprine in humans remains a controversial issue.

Conventional treatment is continued until remission, treatment failure, drug toxicity, or incomplete response results. Remission is defined as a complete biochemical and histologic resolution of inflammation, as well as the disappearance of clinical symptoms. Histologic remission lags 6 to 12 months behind normalization of biochemical markers, and prompt discontinuation of medication without histologic documentation of resolution might result in an exacerbation of the disease. Therefore, biopsy-proved remission is the ultimate goal of all treatment regimens.

Maintenance of Remission

If histologic remission is achieved, the risk of relapse is only approximately 20% (35). In contrast, if biopsy specimens still show portal hepatitis, relapse occurs in 50% or more of patients within 6 months of the end of treatment. Relapse is characterized by deterioration of clinical signs and increase of serum aminotransferase levels after remission and drug withdrawal. Overall, a sustained response is achieved only in 17% of patients after withdrawal of immunosuppressive therapy. It has been demonstrated that azathioprine maintenance after prednisone withdrawal reduces the likelihood of relapse (37,38). Therefore, maintenance of immunosuppressive therapy with azathioprine (2 mg/kg body weight per day) alone or in combination with prednisone is generally recommended for at least 2 years. Prednisone withdrawal should proceed gradually over a period of 3 to 6 months.

Failure of Remission

Treatment failure is characterized by the deterioration of biochemical and clinical signs during therapy, whereas patients with an incomplete response show clinical, laboratory, and histologic improvement, but all manifestations of their disease are not resolved. One reason for treatment failure might be the intolerance to the administered drug in a certain proportion of patients. In these situations standard treatment schedules have to be altered or alternative drugs considered. In about 10% to 15% of patients the standard therapy failed, although it was well tolerated. Whether these patients show a different genetic background in regard to the pathogenesis of disease or drug metabolisms remains unclear. Nevertheless, an underlying overlap syndrome should be excluded.

Alternative Treatment Strategies

In addition to standard therapy, new approaches using various immunosuppressive agents have been tested (Table 31.4). These have emerged mainly from the field of transplantation and should be considered if standard treatment fails.

Cyclosporin A (3 to 5 mg/kg body weight per day) binds to cyclophilin and inhibits calcineurin action. This results in the downregulation of interleukin-2 (IL-2) and T-cell function. Several studies in a small number of patients demonstrated a benefit from cyclosporin A treatment in both AIH type 1 and type 2 (39,40,41,42). However, cyclosporin A has not been compared with standard treatment in a randomized manner. Its toxicity profile, particularly with long-term treatment, limits the widespread use of this drug. Among the most frequently observed side effects are renal failure and hypertension.

Tacrolimus (3 mg twice daily) binds to FK-binding protein 12 (FKBP12). The complex inhibits calcineurin, thereby inhibiting the synthesis of cytokines and the expression of the IL-2 receptor that suppresses T-cell function. Preliminary trials showed a significant biochemical improvement in patients treated with high-dose tacrolimus alone or with lower doses in combination with glucocorticoids (43,44). The side effects resemble those of cyclosporin A and may limit the long-term use of the drug.

Table 31.4. Current Options in the Treatment of Autoimmune Hepatitis

Drug	Dosage	Actions	Side effects
Prednisone	40–60 mg/d and tapering regimen	Inhibition of proinflammatory transcription factors/cytokines	Cushing's syndrome Osteopenia Diabetes mellitus Glaucoma Hypertension
Azathioprine	1–2 mg/kg BW per d	Inhibition of nucleic acid synthesis	Leukopenia/anemia Pancreatitis Nausea
Cyclosporin A	3–5 mg/kg BW per d	Downregulation of IL-2 and cytotoxic T-cell function	Hypertension Renal failure
Tacrolimus	3 mg twice daily	Inhibition of IL-2/IL-3/IFN-γ, of IL-2-receptor expression, and of cytotoxic T-cell function	Hypertension Renal failure Diabetes mellitus Pancytopenia
Mycophenolate	1,000	Inhibition of DNA	Nausea/diarrhea

mofetil	mg twice daily	synthesis and B-/T-cell proliferation	Leukopenia
Budesonide	3 mg thrice daily	Local inhibition of transcription factors/cytokines (high first-pass metabolism)	In the absence of cirrhosis or portosystemic shunts, side effects are rare and resemble those of systemic steroids
Deflazacort	7.5 mg daily	Inhibition of proinflammatory transcription factors/cytokines	Fewer side effects than other systemic steroids
Cyclophosphamide	1–1.5 mg/kg BW per d	Alkylating/DNA-damaging agent	Pancytopenia Cystitis

BW, body weight; IL, interleukin; IFN, interferon; DNA, deoxyribonucleic acid.

Mycophenolate mofetil (1 g twice daily) is an ester prodrug of mycophenolic acid that inhibits inosine monophosphate dehydrogenase, resulting in the depletion of guanine nucleotides and inhibiting deoxyribonucleic acid (DNA) synthesis. Preliminary data suggest that mycophenolate mofetil alone or together with prednisolone may represent an alternative treatment strategy in the induction or maintenance of remission, especially for those patients intolerant of or resistant to azathioprine therapy (45,46). Gastrointestinal discomfort is the main side effect. Myfortic, a novel immunosuppressive drug related to mycophenolate, may help overcome this problem.

Budesonide (3 mg three times daily) is a second-generation glucocorticoid with a high first-pass clearance by the liver. It is therefore characterized by reduced systemic side effects compared to conventional steroids. In a small study

including 13 patients, a beneficial effect of budesonide treatment over a period of 9 months could be demonstrated (47). Other investigators have questioned the benefit of budesonide (48). Remission can be achieved when budesonide is used instead of prednisolone (49). However, the main advantage of budesonide for the future treatment of AIH is to replace prednisolone in long-term maintenance therapy to reduce side effects of the steroid. Larger studies are under way to prove this potential benefit.

Deflazacort (7.5 mg daily) is an oxazolinic derivative of prednisolone with fewer

effects on bone and glucose metabolism than the parent molecule. In a small study including 15 patients, deflazacort was able to maintain remission. However, the efficacy and tolerance of deflazacort have not been tested in large cohorts of patients and long-term trials (50).

Cyclophosphamide (1 to 1.5 mg/kg body weight per day) is an alkylating chemotherapeutic drug that leads to DNA damage. In small case studies, cyclophosphamide in combination with corticosteroids was able to induce and maintain remission (51). However, because of its potentially severe hematologic side effects, continued application of cyclophosphamide remains a highly experimental treatment option.

Methotrexate (7.5 mg/week) is an antimetabolite with both immunosuppressant and antiproliferative effects. There is a single case report of successful induction and maintenance of remission of a patient with AIH type 1 refractory to standard therapy (52).

6-Mercaptopurine (1.5 mg/kg body weight per day) is an active metabolite of azathioprine. The purine analog inhibits T-cell proliferation by interfering with nucleic acid metabolism. 6-Mercaptopurine in combination with corticosteroids was demonstrated to be effective in the induction and maintenance of remission in three patients with AIH who either could not tolerate or failed to improve with azathioprine. 6-Mercaptopurine allows for the reduction of the prednisone dosage to or below 10 mg/day, thereby reducing the steroid-associated side effects (53).

Liver Transplantation

For patients refractory to medical treatment who progress to cirrhosis or do not reach remission within 4 years of continuous therapy, liver transplantation remains the treatment option of choice. Favorable 10-year survival rates of approximately 75% to 85% have been reported (54). However, recurrence of AIH is estimated to range between 11% and 41% (55,56,57,58,59,60). Persistence of autoantibodies does not indicate or predict recurrence of AIH (61). Moreover, patients undergoing transplantation for AIH might have a higher frequency of acute, chronic, and steroid-resistant rejection compared to those undergoing transplantation for other diseases (62,63). Careful monitoring of the patients with AIH who have undergone transplantation and individual adjustment of immunosuppressive therapy after transplantation are therefore necessary to prevent or control recurrence of AIH.

A distinct disease entity is de novo AIH after liver transplantation in patients undergoing the procedure for other causes of end-stage liver disease (64,65). The incidence of this type of AIH appears to be higher in children than in adults. A possible mechanism leading to de novo AIH after transplantation is a deranged elimination of autoreactive T-cell clones because of immunosuppression.

Further identification of the underlying molecular mechanisms of AIH recurrence, de novo AIH, and allograft rejection is necessary to clearly distinguish between these immunologically distinct conditions and to develop site-specific therapies.

Future Directions and Conclusions

Increasing insights into the molecular mechanisms of AIH will open new strategies for the development of novel immunosuppressive agents. Drugs have been established that disrupt the intracellular signaling pathways involved in AIH such as apoptosis or transcription of proinflammatory cytokines. In this respect, FTY-720, a novel immunosuppressive agent that exerts its effect through induction of lymphocyte apoptosis, may be a promising candidate immunosuppressant (66). Cytokine interactions can be manipulated by administering recombinant species or

be inhibited by the use of monoclonal antibodies. Human recombinant IL-10 and monoclonal antibody against TNF-α have each been tested in clinical trials (67,68,69,70,71,72). Targeting of various cytokines might therefore be effective in downregulating the immune response in AIH. T-cell vaccination that eliminates disease-specific T-cell clones might be another promising strategy because in an experimental AIH model it has been shown to not only prevent disease but also decrease disease activity as effectively as steroids (73). Similarly, antibodies against the protein product of the T-cell gene (TIRC7) that inhibits T-cell proliferation might be a future therapy (74). Agents that block transendothelial migration of effector T cells into target tissues are also feasible (75,76). Synthetic peptides that compete with self-antigen or foreign antigen that resembles self-antigen can inhibit the first costimulatory signal of immunocyte activation by occupying the binding grooves of the class II molecules of the major histocompatibility complex. Therapy with synthetic peptides is already being evaluated in rheumatoid arthritis (75,76). Soluble CTLA-4 that competes with CD4 helper T cells for interaction with APCs could also downregulate autoimmune response (77,78). Finally, gene therapy may represent a further strategy in the future that is capable of counterbalancing the overproduction of proinflammatory cytokines and the progression to fibrosis in addition to promoting liver regeneration in the course of AIH (79).

In summary, the therapeutic goal of the novel immunosuppressive agents includes the achievement of long-term remission in patients who do not respond to or do not tolerate standard therapy. However, long-term side effects of the novel immunosuppressants are a matter of concern. Larger studies are required to

provide more evidence for their risks and benefits that would justify their use as an alternative strategy to standard therapy.

Chapter 32

Alcoholic Liver Disease

Srinivasan Dasarathy
Arthur J. Mccullough

Key Concepts

- Although 90% to 100% of heavy drinkers show evidence of fatty livers, only 10% to 35% develop alcoholic hepatitis and 5% to 15% develop cirrhosis.
- The daily intake of alcohol that results in liver injury varies and depends on a number of modifiable and unmodifiable factors. Alcoholic liver disease (ALD) develops at much lower doses, especially in women, Hispanics, and patients with hepatitis C infection.
- Insights into the pathogenesis of alcohol-induced liver injury have improved significantly, but translation into clinical benefit has been slow. Interaction among the products of alcohol metabolism, hepatic parenchymal and nonparenchymal cells, and chemokine release all contribute to the injury and progression of the disease.
- The importance of continued abstinence and correction of nutritional deficiencies are major components in the long-term management of ALD.
- Alcoholic hepatitis has a variable mortality and the prognosis is determined most commonly by the modified discriminant function. Further studies are required to establish the prognostic accuracy of the Model for End-Stage Liver Disease (MELD) or the recently described Glasgow alcoholic hepatitis score (GAHS).
- Anti-inflammatory therapy with corticosteroids and anticytokine therapy with pentoxifylline are effective and are evidence-based therapy for patients with severe alcoholic hepatitis. It may be necessary to perform a liver biopsy in patients with ALD because the clinical diagnosis is not always accurate. This is of particular relevance when corticosteroids are being considered for treating alcoholic hepatitis.
- Patients with end-stage ALD should be considered for liver transplantation. Six months of abstinence is usually required before transplantation, but this length of time may be adjusted on an individual basis.
- Liver transplantation is being increasingly offered to patients with alcoholic cirrhosis and the results are similar to those in nonalcoholic patients. Post-transplantation alcohol abuse is a clinical issue that needs to be addressed throughout the pre- and post-transplantation setting. The role of liver transplantation, especially using living donors, for acute alcoholic hepatitis is a matter of debate.

Table 32.1. Characteristics of Alcoholism

Characteristic	Clinical feature
1. Tolerance	A state of adaptation in which increasing amounts of alcohol are needed to produce the desired effects
2. Physical dependence	A typical withdrawal syndrome appears on interruption of drinking, which is relieved by alcohol itself or other drugs in the alcohol/sedative group

3. Impaired control	Total alcohol intake cannot invariably be regulated once drinking has begun at any drinking occasion
4. Craving	A dysphoria of abstinence that leads to relapse
The Acronym TyPICal is suggested as an aid to clinicians to diagnose alcoholism.	

Worldwide, alcohol is the most frequently used and socially acceptable hepatotoxin (1). Geographic patterns of alcohol intake and the prevalence of alcoholic liver disease (ALD) are changing constantly with the rapid increase in per capita alcohol ingestion in eastern European countries and stabilized use in western European countries, Canada, and Australia (2). Approximately two thirds of the adult Americans drink some alcohol (3). Most drink light or moderate amounts and do so without problems (4,5,6,7); however, a subgroup of drinkers become dependent on alcohol and have the disease of alcoholism (8,9). Another group of drinkers are alcohol abusers (and problem drinkers) who experience negative consequences of drinking (e.g., unemployment, loss of family, or accidental injury or death). These patients are not considered to be alcohol dependent (7,10). Failure to recognize alcoholism remains a significant problem that impairs both the prevention and management of ALD (10,11). The clinical features of *t*olerance, *p*hysical dependence, *i*mpaired control, and *c*raving that define *al*coholism (shown in Table 32.1), as well as their acronym TyPICaL, are suggested as aids to the clinician for making the diagnosis. For more complete and formal diagnostic criteria of alcohol-use disorders, publications by various organizations including the American Psychiatric Association and the World Health Organization are recommended (12,13).

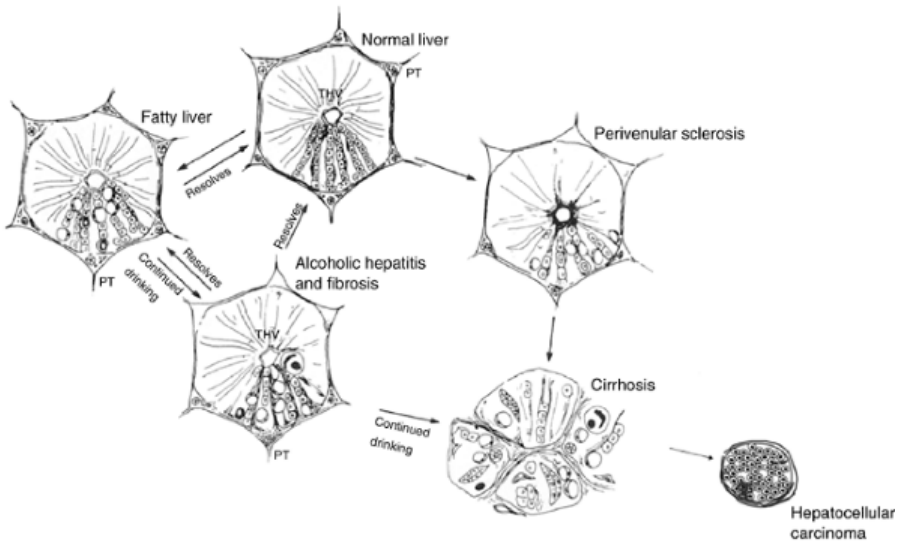
Disease Spectrum

Alcohol affects the liver depending on the dose and the duration of use or abuse (14,15,16). The spectrum of alcohol-related liver injury varies from asymptomatic hepatomegaly to profound hepatocellular failure and portal hypertension (17,18,19). Pathologically, this is translated into fatty infiltration of the hepatocytes at the stage of transition of asymptomatic hepatomegaly to frank cirrhosis, with decompensation at the end stage (17,20,21). There are at least five histologic manifestations of ALD, which include fatty liver or steatosis, acute alcoholic hepatitis, chronic hepatitis, hepatic fibrosis, and cirrhosis (22). Of these, chronic hepatitis is a stage that has been reported in ALD, but its diagnosis has been questioned. (23,24).

Figure 32.1 displays the different stages and evolution of ALD, and Table 32.2 lists the histologic characteristics and describes their prevalence in the different stages of ALD (22). Fatty liver develops in virtually every individual who drinks more than 60 g/day of alcohol and initially localizes to the perivenular or centrilobular region of the liver (25,26,27). Decreased energy stores due to hypoxia and a shift in lipid metabolism along with a shift in the redox reactions caused by the preferential oxidation of alcohol in zone 3 of the hepatic lobule are the reasons for this localization (Fig. 32.2) (27,28). Simple, uncomplicated fatty liver is usually asymptomatic and considered reversible (29,30). Once fatty infiltration becomes severe, particularly with a mixed (macro-/microvesicular) pattern and associated with giant mitochondria or perivenular fibrosis (26,31), progression to fibrosis and cirrhosis (8% to 20% of patients) can occur.

Progression of ALD culminates in scarring and development of cirrhosis (32). Although usually micronodular, it is occasionally mixed micro- and macronodular (19,33). Fibrogenesis is believed to start in the perivenular area and is influenced by the amount of alcohol ingested (26,34). Perivenular fibrosis and deposition of fibronectin occurs in 40% to 60% of patients who ingest more than 40 to 80 g daily for an average of 25 years. However, the thickness of the perivenular fibrosis does not correlate with the amount of alcohol ingested. It should also be noted that the occurrence of the fibrotic features was more than twice the frequency of cirrhosis. Although this may be partly related to sampling error, the disparity between the frequency of fibrosis and the development of cirrhosis suggests that factors other than fibrogenesis are involved in the progression of fibrosis to cirrhosis in patients with ALD (35).

Figure 32.3 shows the estimated prevalence of the different histologic forms of alcohol-mediated liver injury among heavy drinkers (22). This emphasizes the heterogeneity of the patient populations with regard to disease severity and individual susceptibility to alcohol. Among patients who are heavy drinkers, 90% to 100% will show histologic evidence of fatty liver but only 10% to 35% will develop alcoholic hepatitis and 8% to 20% will develop cirrhosis (36,37).



▪ **Figure 32.1** The schematic form of the progression and potential regression among the various histologic stages of alcoholic liver disease. *THV*, terminal hepatic venule; *PT*, portal tract.

P.883

Risk Factors

Only a minority of individuals who ingest significant amounts of alcohol progress beyond fatty liver and develop alcoholic hepatitis or cirrhosis. Therefore, other factors must play a role in placing these individuals at risk for developing these more severe forms of ALD (30,38). A number of risk factors have been proposed (Fig. 32.4), but none of them can either singly or in combination completely explain the reason why only a minority of individuals ingesting large amounts of alcohol develop ALD (39,40).

Ethnicity

Ethnic differences in the prevalence of alcohol-related liver disease and associated mortality have changed with time (2). In the first half of the 20th century, when reporting of mortality was done for whites and nonwhites (composed predominantly of African Americans), the mortality was significantly higher for the former. By the mid-1950s, this reversed and the mortality for nonwhites exceeded that for whites. Later, when data was published for different ethnic groups, a twofold increase in the level of transaminases was found to occur more frequently in Hispanics and Blacks than

P.884

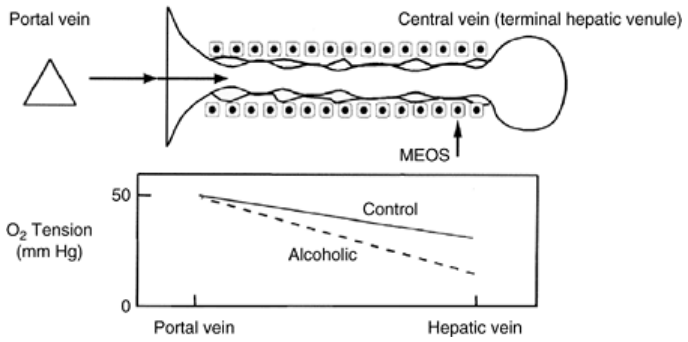
in whites (41). Recently, South Asian (Indian) non-Muslim men have been observed to have a higher rate of alcoholic cirrhosis at a younger age and after a shorter duration of alcohol abuse (42). It is not clear whether the ethnic differences are the result of genetic polymorphisms, or quantity or type of alcoholic beverages consumed (2).

Table 32.2. Histologic Characteristics of Alcoholic Liver Disease

	Fatty liver	Alcoholic	Cirrhosis	Cirrhosis–alcoholic

	(%)	hepatitis (%)	(%)	hepatitis (%)
Ballooning degeneration with PMNs	73	97	76	35
Mallory bodies	0	76	19	95
Megamitochondria	100	32	8	13
Sclerosing hyaline necrosis	4	68	3	44
Fibrosis	31	54	100	100
Fat (moderate to severe)	69	82	27	43
Perivenular fibrosis	4.9	19	—	—

PMN, polymorphonuclear cells.
These data were obtained and modified from MacSween RN, Burt AD. Histologic spectrum of alcoholic liver disease. *Semin Liver Dis* 1986;6(3):221–232.



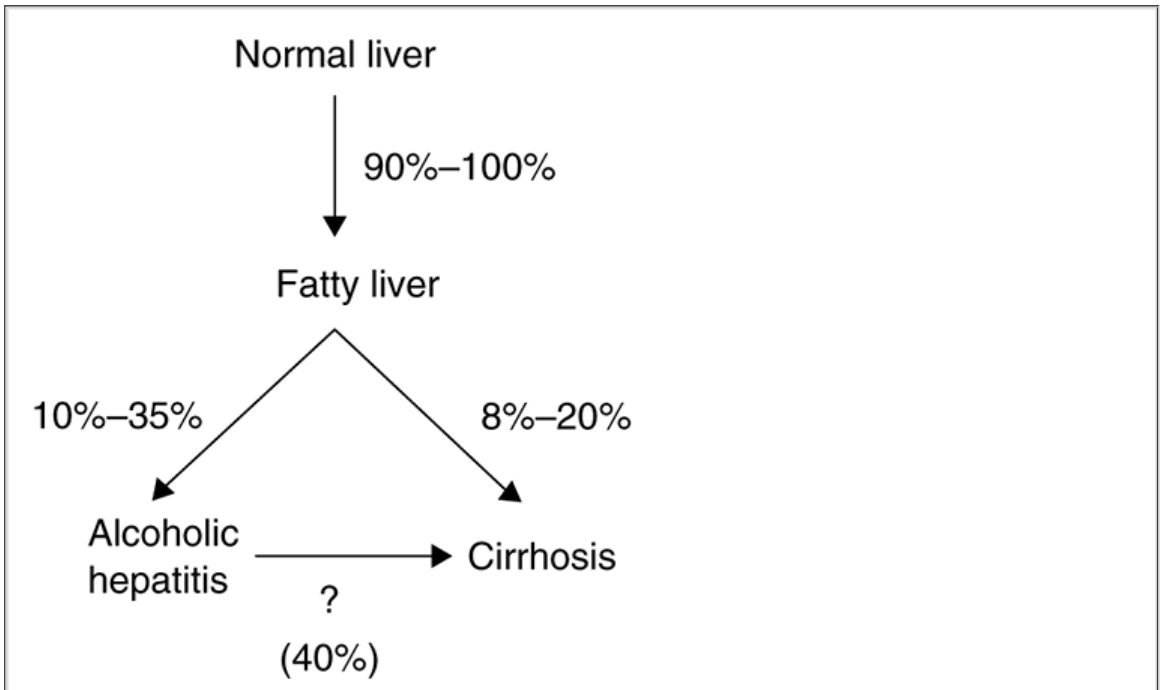
▪ **Figure 32.2** The oxygen gradient between the portal area (zone 1) and the pericentral area (zone 3) of the hepatic lobule. The metabolism of alcohol increases oxygen consumption and causes the largest gradient in zone 3. MEOS, microsomal ethanol-oxidizing system.

Alcohol

The quantity of alcohol ingested (independent from the form in which it is ingested) is an important risk factor for the development of ALD (43). A significant correlation exists between per capita consumption and the prevalence of cirrhosis. Epidemiologic evidence exists for a marked reduction in the prevalence of ALD, with diminished alcohol ingestion during war rationing, prohibition, and increased cost. (44,45).

Available evidence indicates that there is an increased risk of developing cirrhosis with the ingestion of more than 60 to 80 g/day of alcohol in men and more than 20 g/day in women, when consumed for 10 years or longer (2,16,46). Even in these groups, only 6% to 41% of those drinking at such levels develop cirrhosis (2,16,47). In the Dionysos study, even in patients with

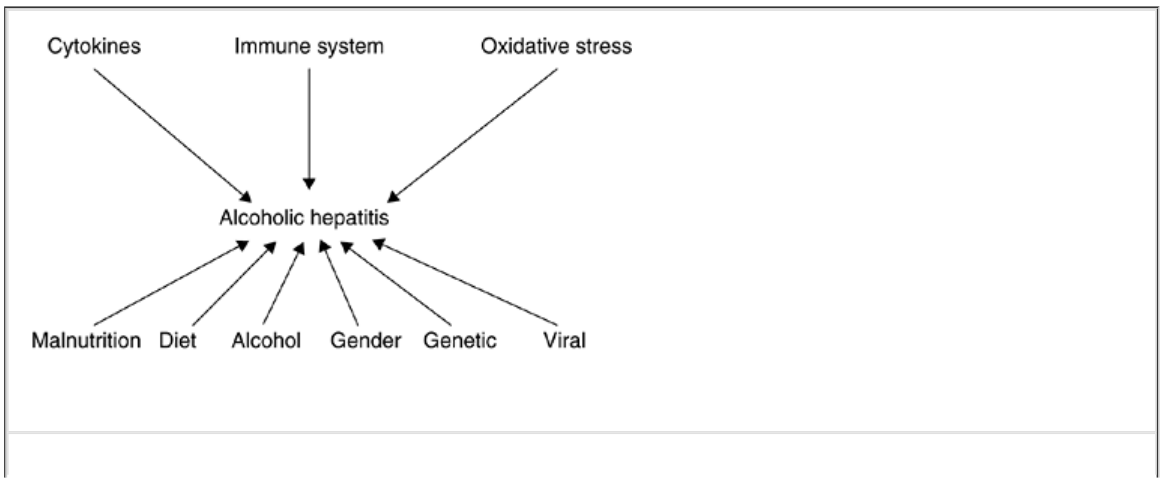
very high daily alcohol intake (>120 g/day) only 13.5% developed alcohol-induced liver damage (46,48). In addition, disagreement exists on whether the amount of alcohol consumption increases the risk of ALD proportionally. However, population-based data consistently confirm that the quantity of alcohol ingested is a risk factor for ALD (49). In the Dionysos study, the risk of cirrhosis or noncirrhotic chronic liver disease increased with a total lifetime alcohol intake of more than 100 kg or a daily intake of more than 30 g/day (46). The odds of developing cirrhosis or noncirrhotic liver disease with a daily alcohol intake of more than 30 g/day was 13.7 and 23.6, respectively, when compared with nondrinkers.



▪ **Figure 32.3** A schematic displaying the percentage of heavy drinkers who develop the different stages of alcoholic liver disease. ?, uncertainty regarding the precise percentage but may be as high as 40%.

There is now increasing evidence that the type of alcohol also determines the risk of development of liver disease (50). In a larger survey of over 30,000 persons in Denmark, beer or spirits were found more likely to be associated with liver disease. It was also observed that in persons who drank heavily, consumption of wine lowered the all-cause mortality (51,52). It is however

unclear whether wine drinking was itself protective or was a surrogate for other healthy behaviors such as consumption of fruits and vegetables (52). Alcoholic beverages that contain a higher content of short-chain aliphatic alcohols have been associated with a high prevalence of liver cirrhosis (53).



▪ **Figure 32.4** The risk factors, which may be cofactors required for the development of advanced alcoholic liver disease.

Another factor that has been identified is the contribution of the pattern of drinking to the development of liver injury. Drinking outside of mealtime has been reported to increase the risk of ALD by 2.7-fold compared to those who consumed alcohol only at mealtime (54). This was not, however, reproduced in a subsequent French study (55). Binge drinking, which may be considered to be a form of outside mealtime drinking, has also been shown to increase the risk of ALD and all-cause mortality (56). Binge drinking has also been shown to be associated with degradation of a large quantity of mitochondrial deoxyribonucleic acid (DNA) that contributes to steatohepatitis and reperfusion injury, both of which result in significant damage to the hepatocytes and potentially nonparenchymal hepatic cells (57).

Gender

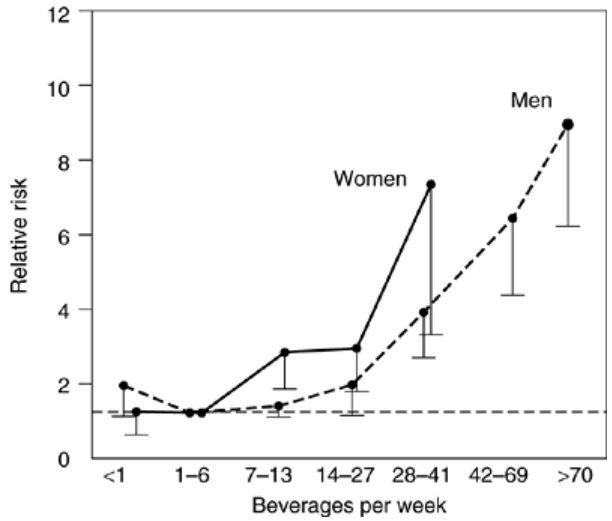
Women have been found to be twice as sensitive to alcohol and develop more severe ALD at lower doses and with shorter duration of alcohol consumption than men (27,58,59,60,61). As compared to men, in whom 80 g of daily alcohol consumption was considered to be a hazardous amount, early data suggested the hazardous level to be 60 g daily in women (62). Because most of those individuals developing ALD ingested more than 35 units/week, a "safe" limit of alcohol intake had been suggested to be 21 units/week in men and 14 units/week in women (62,63). However, more recent data from the Copenhagen City study suggest that a lower quantity, more than 7 units/week, may be toxic in women (49,64). The data in Table 32.3 and Figure 32.5 confirm the association between increased alcohol intake and ALD, the lower threshold toxic dose, and the increased female susceptibility for ALD. On a practical level 1 unit of alcohol (1 ounce of "spirits" [40% alcohol], one 12-ounce beer [5% alcohol], or one 4-ounce glass of wine [12.5% alcohol]) contains approximately 10 g of alcohol for wine and spirits and 14.4 g of alcohol for beer. This is based on a specific gravity of 0.8 for alcohol and the average alcohol content of beer. These amounts may vary depending on the actual alcohol content of beer, which varies significantly among commercial brands (Table 32.4), as well as the size of the pour for wine and spirits.

Table 32.3. Relative Risk of Alcoholic Liver Disease at Different Levels of Alcohol Intake

	Alcoholic cirrhosis		Alcoholic liver disease	
Weekly units of alcohol	**Men**	**Women**	**Men**	**Women**
<1	3.7	1.09	1.8	1.0
1–6	1.0	1.0	1.0	1.0
7–13	0.9	4.1[a]	1.1	2.9[a]
14–27	1.6	3.1[a]	1.4	2.9[a]
28–41	7.0[a]	16.8[a]	3.8[a]	7.3[a]
42–69	13.0[a]	NR	5.9[a]	NR
≥70	18.1[a]	NR	9.1	NR

These results were estimated from Figure 1 in reference 49.
[a]Represents a statistically significant increased relative risk of having alcoholic liver

disease.
NR, not reported.



▪ **Figure 32.5** Risk of alcoholic liver injury increases with increasing quantity of alcohol intake. This risk is higher in women at all doses of alcohol ingestion.

This increased female susceptibility has been related to gender-dependent differences in the hepatic metabolism of alcohol in the past (27,65). Alteration in gastric metabolism of alcohol is another explanation for the female susceptibility to develop ALD (58,65,66,67). First-pass gastric metabolism of alcohol does indeed exist in humans (65), but the gastric metabolism of alcohol may not be large (10% to 30% at most), decreases with gastric injury, may not occur during

most standard meals or realistic life conditions, and may vary among races because it has not been observed in Orientals (68,69). Furthermore, the lack of increased risk of ALD in postgastrectomy patients has also refuted this hypothesis (70). Experimental evidence exists for estrogen-induced endotoxemia and exaggerated hepatic inflammatory response to alcohol (71,72). The clinical significance of these proposed mechanisms is as yet unclear.

Table 32.4. Alcohol Content (%) of Commercial Beer

Brand	Light	Regular
Molson	2.41	3.88
Bud	3.88	4.82

Busch	4.12	5.19
Miller	4.40	4.80

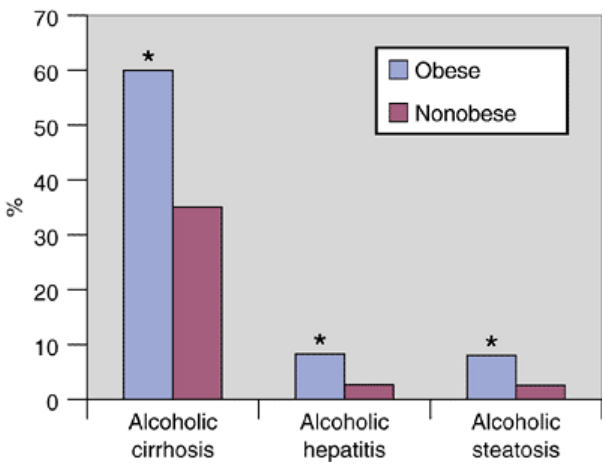
Michelob	4.52	4.99

Malnutrition and Diet

Dietary habits and nutritional status may also be important risk factors (16,18,73,74,75). Early studies conducted in hospitalized chronic alcoholic patients with liver disease led to the misconception that protein calorie malnutrition was a necessary risk factor for ALD (75,76). However, alcohol is directly hepatotoxic and does not require preexisting malnutrition to result in liver injury (77,78). In addition, although alcohol adversely affects energy and protein metabolism, the prevalence and extent of protein calorie malnutrition are similar in alcoholic and nonalcoholic cirrhosis (79).

Micronutrient abnormalities also potentially aggravate the liver disease. Hepatic vitamin A depletion activates the stellate cells and results in hepatic fibrosis with alcohol abuse. Vitamin E levels are depressed in alcoholic cirrhosis and may contribute to the enhanced membrane lipid peroxidation and hepatocyte damage (80).

Other nutritional disorders including obesity and dietary habits may be important risk factors (16,81,82). Data from France (Fig. 32.6) suggest that obesity may be an independent risk factor for developing ALD (82). In alcoholic patients from China, excess body weight was associated with a 5.6-fold increase in the risk for ALD (54). Increased tumor necrosis factor (TNF) activity and hepatic insulin resistance that are associated with obesity seem to contribute to the aggravation of ALD (83). Obesity also makes the liver susceptible to alcohol-mediated injury by metabolic activation of CYP 2E1, oxidant stress, and immune hyperreactivity in the liver (84). It is currently unclear whether the hepatotoxic consequences of obesity and ethanol ingestion are additive or synergistic. High-fat diets are also necessary to promote alcohol-induced liver disease in animals (Fig. 32.7) (85,86). In addition, the incidence of cirrhosis appears to be lower than that expected in countries with high intakes of saturated fat; an epidemiologic finding that is independent of other risk factors and supported by animal data (87,88).



▪ **Figure 32.6** A histogram showing the prevalence of obesity in different forms of alcoholic liver disease in obese patients. *, *P* <.05 between groups. (Extracted and modified from Naveau S, Giraud V, Borotto E, et al. Excess weight risk factor for alcoholic liver disease.

Hepatology 1997;25(1):108–111.)

Genetic

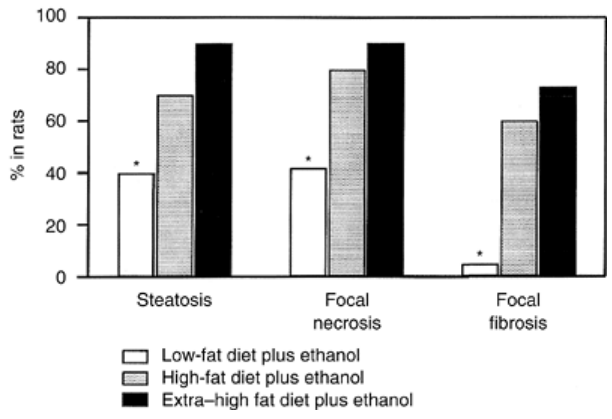
Environmental factors alone cannot explain variable susceptibility to alcohol, and genetic factors appear to provide a predisposition to both alcoholism and ALD (89,90,91,92). There has been growing interest in defining genetic factors that include functional polymorphisms in genes that may contribute to the pathophysiology of ALD (93,94,95).

Alcohol metabolism

Much of the initial work focused on the genes involved in the metabolism of alcohol: Alcohol dehydrogenase (ADH), acetaldehyde dehydrogenase (ALDH), and the cytochrome P-450 system (CYP 4502E1) (96,97,98,99). The most commonly reported abnormality is an increased frequency of ADH3-1 (gene that encodes for the γ-1ADH isoenzyme capable of faster metabolism of alcohol to acetaldehyde) that when combined with abnormalities in the ALDH2-2 allele (slow acetaldehyde metabolism) results in high acetaldehyde concentration (97,100,101). Such an abnormality may be responsible for some of the hepatotoxicity of alcohol and mediates the flushing and enhanced alcohol sensitivity commonly observed in Asians (102,103,104). Patients in Japan have a higher frequency of ADH2-1, and an increased frequency ALDH2-1 has been reported in patients who are alcoholics (with and without liver disease) than in controls (105). However, the data on a specific ADH/ALDH pattern in patients with ALD are conflicting.

The genetic pattern of P4502E1 (the microsomal enzyme primarily involved in alcohol metabolism) has been studied because it generates reactive oxygen species (ROS) when metabolizing alcohol (104,106). A specific polymorphism identified as the c2 allele has been shown to result in an increased expression of hepatic CYP 2E1 activity. An increased prevalence of the c2 allele has been reported in Japanese but not Chinese

alcoholic subjects with ALD (105,107,108). A higher prevalence of c2 in Mexican Americans than whites has also been reported (101). However, a meta-analysis of nine independent studies has shown that there was no relation between the c2 allele and the development of ALD among whites (99).



▪ **Figure 32.7** A histogram showing the effect of high-fat diet on the severity of liver disease along with alcohol feeding in experimental animals. *, *P* <.05 versus other two groups.

Mitochondrial dysfunction

Mitochondrial dysfunction has been identified in the liver in ALD, and a reduced activity of the mitochondrial form of superoxide dismutase 2 (SOD2) was expected to have a reduced activity. In French patients with ALD, a polymorphism in the gene with a valine to alanine mutation at position 1183 of the SOD2 gene was observed, but this resulted, unexpectedly, in an increase in SOD2 activity (109). In a subsequent study from England, no association was observed between SOD2

polymorphism and ALD (110).

Cytokines and the immune system

Data supporting a role for endotoxin-mediated release of cytokines in the pathogenesis of ALD have suggested a different set of candidate genes with a potential role in disease susceptibility (111,112,113). Small studies have reported an association between advanced ALD and promoter polymorphisms in the genes encoding the endotoxin receptor CD14 and interleukin-10 (IL-10), which need further confirmation (114,115,116,117).

These abnormalities suggested an upregulation of immune response in these patients (118,119). Reported targets of this immune response are autoantigens, which include ADH, cytochrome P-450 isoforms CYP 2E1/CYP 3AH, and endogenous protein adducts to ethanol metabolites or products of lipid peroxidation (120,121). Polymorphisms in TNF-α (associated with alcoholic hepatitis), type I collagen (associated with cirrhosis) genes, and the gene encoding cytotoxic T lymphocyte–associated antigen-4 (CTLA-4) that functions as a suppressor of T cell–mediated immune response in patients with ALD have been reported (119,122,123,124,125,126,127). Studies from England and Spain have reported polymorphisms in the gene encoding IL-10, a cytokine that downregulates inflammatory response, resulting in lower levels of IL-10 in patients with ALD (123,128).

An integrated view of genetic polymorphisms and the consequent immune-mediated liver injury has been suggested by the observations that CTLA-4 gene polymorphism and lower activity were associated with an increase in antibodies to the hydroxyethyl CYP 2E1 adducts and the development of liver disease (127,129). Despite interesting and valuable new information in this area, there is variability in the reported association between genetic and phenotypic abnormalities in different studies and racial populations. Specific genetic abnormalities for a susceptibility to alcohol abuse and the development of ALD have not yet been firmly established.

Viral Infection

There is a strong association between hepatitis C and ALD (130). Unlike hepatitis B, hepatitis C infection appears to be strongly involved in the development of advanced ALD (131). An increased prevalence of hepatitis C virus (HCV) has been reported in patients with

ALD (Fig. 32.8) (132,133). The combination of HCV and alcohol predisposes to more advanced liver injury than alcohol alone (134,135). Compared to patients with ALD without HCV infection, those with ALD and HCV infection have more severe histologic features, have decreased survival, and develop the disease at a younger age (31,136,137). The progression of fibrosis is most rapid in male patients who continue to abuse alcohol (131,138). Although a daily dose of more than 50 g of alcohol has been shown to be a risk factor for fibrosis in patients with HCV infection, even a moderate consumption of alcohol (<50 g/day) has been shown to result in a dose-dependent increase in liver disease (135,139). Despite these observations, the precise toxic threshold is not known and may be lower and nonuniform in patients at risk. The estimated rate of progression is represented in Figure 32.9 modified and adapted from published data (36,131,139,140,141,142). The prevalence of HCV also increases proportionally as the liver injury becomes more severe, with the relative risk for developing cirrhosis estimated at 8.7 in those patients with ALD and anti-HCV (143,144,145). A French study showed that both mortality and the length of hospital stay was longer in patients with alcohol abuse and hepatitis C (142). In addition, the presence of HCV is reported to be the major risk factor for the development of hepatocellular cancer (HCC) (146). In patients with alcoholic cirrhosis, the 10-year absolute cumulative occurrence risk of HCC has been reported to be as high as 81% in anti-HCV–positive patients with alcoholic cirrhosis as compared to 19% in anti-HCV–negative patients (135,147,148,149). Although one study has questioned this association between progression of HCV and alcohol consumption (150), patients with hepatitis C should be strongly urged to abstain from alcohol, even in moderate quantities, unless further evidence to the contrary becomes available.

Diagnosis

The diagnosis of ALD is often made in the context of a history of significant alcohol intake, physical signs of liver disease, and supporting laboratory data (18,151,152). However, denial of alcohol abuse is significant (153,154). Physicians usually identify less than 50% of their patients with drinking problems and institute specific recommendations even less frequently (155,156,157). Both the physical findings and laboratory evidence for ALD may be absent or nonspecific, especially in patients with mild ALD or early cirrhosis (19,158,159,160). Therefore, the clinician has to rely on indirect evidence of alcohol abuse, such as questionnaires, information from family members, or nonhepatic laboratory tests to suggest or strengthen a clinical suspicion of ALD (161,162).

General Screening

The historical features that suggest alcohol abuse or alcohol dependence include the amount of alcohol ingested, the social and psychological consequences of alcohol abuse, presence of other alcohol-related diseases, and past incidents of trauma (e.g., frequent falls, lacerations, burns, fractures, or emergency department visits) (155,163). The diagnosis of ALD consists of

documentation of alcohol abuse and evidence of liver disease (19,118). Both clinical and supporting laboratory data for liver disease and alcohol abuse are required for this. Furthermore, alcohol may be one of a number of factors causing the liver disease and the specific contributory role of alcohol alone may be difficult to assess

in a patient with multifactorial liver disease. Biochemical tests have been considered to be less sensitive than verbal tests in screening for alcohol abuse (164,165). Biochemical tests have, however, been considered useful in identifying relapse after abstinence (166,167).

A combination of patient self-reports with corroboration from family or close friends is considered essential in the diagnosis of alcohol abuse. Various questionnaires that have been used in the past for the detection of alcohol dependence and abuse include the CAGE (cut down, annoyed, guilty, and eye-opener) and the MAST (Michigan Alcoholism Screening Test) (164,168). The Alcohol Use Disorders Identification Test (AUDIT) is a ten-item questionnaire that has been discussed in detail in the previous editions of this book (Table 32.5) (169). The major perceived limitation of the full AUDIT questionnaire is the length of time required to administer it. A number of brief screening instruments have been developed, including CRAFFT (Car, Relax, Alone, Forget, Friends, Trouble), brief AUDIT, and RAPS4 (Rapid Alcohol Problems Screen 4) (170,171). The details of these instruments is beyond the scope of this review and have been discussed elsewhere (172). The brief screening questionnaire, RAPS4, has been compared to CAGE in patients from the National Alcohol Survey (173). The RAPS4 had a higher sensitivity (0.86) compared with CAGE (0.67). Both had similar specificity (0.95 vs. 0.98) across gender and ethnicity. Comparing brief versions of the AUDIT to the full AUDIT in the primary care setting showed variable sensitivity and specificity of the brief versions (171). The use of any of these brief instruments cannot be recommended to replace the full AUDIT at the present time. A quantity frequency (QF) score that included questions on drinking frequency was added to RAPS, and the combined instrument, RAPS-QF, outperformed CAGE. It appears that the QF will be a major component of brief questionnaires that are being developed to replace the full AUDIT. Clinical differentiation of the various stages of ALD is difficult at times, and there is no single marker that definitively establishes the etiology of liver disease to be alcohol and laboratory tests are often needed to confirm the diagnosis.

Physical Examination

On physical examination, patients with ALD may show a constellation of abnormalities, which are related to portal hypertension (e.g., ascites, splenomegaly, abdominal wall collaterals, and a venous hum), alcohol abuse and hepatic injury (e.g., cutaneous telangiectasia, palmar erythema, finger clubbing, Dupuytren's contractions, and peripheral neuropathy), and feminization (e.g., gynecomastia and hypogonadism). Detailed discussions of the physical signs have been published recently and are not discussed here (19,165,174).

Although some of the physical findings are more commonly observed in ALD (e.g., parotid enlargement, Dupuytren's contracture, and especially those associated with alcohol abuse and feminization) than in non-ALD, no single physical finding or constellation of findings is 100% specific or sensitive for ALD (175). Furthermore, there is significant interobserver variability for most of these physical findings, which is dependent on the experience of the examiner and the physical finding being sought (174,175). When present, certain findings on physical examination such as ascites, poor nutritional status, and cutaneous telangiectasia indicate significant liver injury and poor prognosis (176,177,178). However, even in the absence of significant liver injury, physical findings associated with alcohol abuse may be present and then subsequently ameliorate with abstinence. Physical examination of the liver, which may be normal in the presence of ALD, does not provide an accurate information about liver volume (179). Its major role is to define the characteristics of the consistency of the liver's lower edge rather than to delineate disease etiology or liver volume.

Other organ dysfunctions in ALD include cardiomyopathy, skeletal muscle wasting, pancreatic dysfunction, and alcoholic neurotoxicity that may coexist with ALD, and evidence of these must be sought during the clinical examination so that appropriate treatment may be provided (180,181,182).

Therefore, the physical examination is unable to either establish the diagnosis of ALD on its own or delineate ALD from non-ALDs and must be considered in the context of the patient's history and laboratory findings.

Laboratory Abnormalities

The various laboratory tests to diagnose ALD are shown in Table 32.6. Low sensitivity and

specificity limit the usefulness of γ-glutamyl transferase (GGT) to diagnose alcohol abuse (183,184,185). Serum transaminases have been used in the diagnosis of ALD. (186)Serum aspartate aminotransferase (AST) is raised only two to six times in severe acute alcoholic hepatitis. Levels of AST more than 500 IU/L or levels of alanine aminotransferase (ALT) more than 200 IU should suggest an etiology other than alcoholic hepatitis. In approximately 70% of patients, the AST/ALT ratio is higher than 2 but this is of greater value in noncirrhotic patients. Ratios greater than 3 are essentially diagnostic for ALD. Macrocytosis is seen in individuals abusing alcohol but lacks sensitivity. The specificity for the diagnosis of ALD is greater with increasing values of the ratio. A combination of raised GGT and mean corpuscular volume (MCV) has a sensitivity of 30% to 40% for diagnosing alcohol abuse. Serum carbohydrate-deficient transferrin (CDT) is a specific and sensitive

test for alcohol use independent of liver disease but is more accurate in men ingesting over 60 g of alcohol daily (187). Frequent determination of serum ethanol levels during the patient's office visits is another simple but often-ignored method of assessing for alcohol use. Other sensitive indices include fucosylated haptoglobin and serum secretory immunoglobulin A (IgA), which need prospective testing at multiple centers before their validity can be confirmed (188,189,190). A direct comparison of four markers of alcohol consumption showed that the overall accuracy of GGT and CDT was highest to detect alcohol drinking while sialic acid and *N*-terminal peptide of type III procollagen (PIIINP) were of value in differentiating liver disease from alcohol abuse (191). Serum hyaluronic acid has been used alone (192) and in combination with other tests (193) to detect the stage of liver disease in ALD. These and other promising biomarkers require additional studies in this area (31).

Table 32.5. Alcohol-Use Disorders Identification Test (AUDIT) Questionnaire Consisting of Ten Questions with Scores Assigned to the Answers

1. How often do you have a drink containing alcohol?
   0—Never
   1—Monthly or less
   2—Two to four times a month
   3—Two to three times a week
   4—Four or more times a week
2. How many drinks containing alcohol do you have on a typical day when you are drinking?
   0—One or two
   1—Three or four
   2—Five or six
   3—Seven to nine
   4—Ten or more
3. How often do you have six or more drinks on one occasion?
   0—Never
   1—Less than monthly
   2—Monthly
   3—Weekly
   4—Daily or almost daily
4. How often during the last year have you found that you were not able to stop drinking once you had started?
   0—Never
   1—Less than monthly
   2—Monthly
   3—Weekly
   4—Daily or almost daily
5. How often during the last year have you failed to do what was normally expected from you because of drinking?
   0—Never
   1—Less than monthly
   2—Monthly
   3—Weekly

4—Daily or almost daily

6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?
   0—Never
   1—Less than monthly
   2—Monthly
   3—Weekly
   4—Daily or almost daily
7. How often during the last year have you had a feeling of guilt or remorse after drinking?
   0—Never
   1—Less than monthly
   2—Monthly
   3—Weekly
   4—Daily or almost daily
8. How often during the last year have you been unable to remember what happened the night before because you had been drinking?
   0—Never
   1—Less than monthly
   2—Monthly
   3—Weekly
   4—Daily or almost daily
9. Have you or someone else been injured as a result of your drinking?
   0—No
   2—Yes, but not in the last year
   4—Yes, during the last year
10. Has a relative, friend, doctor, or other health worker been concerned about your drinking or suggested that you should cut down ?
    0—No
    2—Yes, but not in the last year
    4—Yes, during the last year

Table 32.6. Typical Laboratory Abnormalities in Alcoholic Liver Disease

1. Serum enzymes
   - AST>>ALT
     AST usually <500 IU and ALT <200 IU
   - Alkaline phosphatase and γ-glutamyl transpeptidase
     Levels of both usually elevated to a variable degree
2. Igs
   - Levels of both IgG and IgA are elevated
3. Metabolic alterations
   - Hyperglycemia
   - Hypertriglyceridemia
   - Hyperuricemia
   - Electrolyte abnormalities
     Low levels of potassium, magnesium and phosphorus
4. Tests of liver function
   - Serum albumin, prothrombin time, and serum bilirubin usually normal until significant liver injury is present
5. Hematologic abnormalities
   - Mild anemia common (usually macrocytic)
   - Platelets (normal to markedly decreased)
   - Elevated white blood cell count
     Leukemoid reactions associated with alcoholic hepatitis

AST, aspartate aminotransferase; ALT, alanine aminotransferase; Ig, immunoglobulin.

In symptomatic patients, nonspecific findings include elevated levels of uric acid, lactate, and triglycerides and a decrease in the concentration of magnesium, glucose, phosphate, and potassium. Polyclonal hyperglobulinemia and increase in circulating IgA level also occurs with ALD (194). It must be reiterated that no specific laboratory test exists that is specific for ALD.

Nonalcoholic steatohepatitis (NASH) is a distinct clinical entity with histologic features suggestive of alcohol abuse with little or no alcohol ingestion (195). This is seen in association with other features of the metabolic syndrome (196). There are many similarities in the pathogenesis of NASH and alcoholic steatohepatitis, but the critical component of the injury in ALD is consumption of significant amounts of alcohol. There are no laboratory tests or histologic patterns that reliably differentiate NASH from alcoholic steatohepatitis.

Liver Biopsy in Alcoholic Liver Disease

A liver biopsy is useful but not essential in the management of ALD (197). The role of liver biopsy in ALD is shown in Table 32.7. A liver biopsy is helpful in establishing the diagnosis because as many as 20% of patients with alcohol abuse have non-ALD or a coexisting etiology for liver disease (198). Clinical and biochemical indicators are poor markers of the severity of liver disease, and a biopsy is needed to establish the stage and severity of liver disease (197,199). A biopsy assumes greater importance in patients who continue to have abnormal liver test results after a period of abstinence of approximately 3 to 4 months. Liver biopsy is usually safe, with a low morbidity and mortality, but precautions taken should be the same as that for any other patient undergoing a liver biopsy. In patients with a diagnosis of acute alcoholic hepatitis with a coagulation profile precluding a percutaneous liver biopsy, consideration should be given to the transjugular biopsy.

The histologic features of alcohol-induced hepatic injury include steatosis (fatty change), lobular hepatitis, periportal fibrosis, Mallory bodies, nuclear vacuolation, bile ductal proliferation, and fibrosis or cirrhosis (17). Development of large-droplet (macrovesicular) steatosis (fatty liver) is the earliest and most common manifestation of ALD. It is often clinically asymptomatic and completely reversible on abstinence (200). It is most prominent in the centrilobular regions but in severe cases may involve the entire lobule (201). It

is most commonly diagnosed on ultrasound, demonstrating fatty change with increased echogenicity of the liver parenchyma (202).

Table 32.7. Role of Liver Biopsy in Alcoholic Liver Disease

Diagnosis

- Confirm diagnosis
- Exclude other causes of liver disease (primary or concomitant)
- Assess extent of liver damage

Prognosis (adverse)

- Neutrophilic infiltration
- Stenosis of central veins

- Number of hepatic stellate cells, giant stellate cells, and lipid vesicles in stellate cells
- Number of Kupffer cells
- Degree of liver cell necrosis
- Perivenous fibrosis

Therapeutic decision

- Before corticosteroid therapy

Alcoholic hepatitis is characterized by liver cell damage, neutrophilic infiltration of the lobules, and fibrosis (22,178). Steatosis and hepatitis may exist independent of each other and do not imply a continuum of changes. The liver cell damage in alcoholic hepatitis includes hepatocyte necrosis, ballooning degeneration, and lobular inflammation that affect the perivenular regions in the earliest stages (34). Ballooning is secondary to the accumulation of protein and water. Mallory bodies are irregular refractile eosinophilic cytoplasmic structures with a beaded structure and stain positive for ubiquitin (203). They have been shown to be aggregated cytokeratin intermediate filaments and other proteins. Mallory bodies, giant mitochondria, neutrophilic infiltration, and fibrosis may also be seen in conditions other than ALD (204). In contrast to their presence in simple fatty liver, megamitochondria in alcoholic hepatitis have been reported to be associated with a milder form of alcoholic hepatitis, a lower incidence of cirrhosis, and fewer complications with a good long-term survival (205). Alcoholic hepatitis is associated with perivenular and pericellular fibrosis as a consequence of stellate cell activation. Compared to patients who consume alcohol and have normal hepatic histology, inactive cirrhosis, or active alcoholic cirrhosis, those with acute alcoholic hepatitis without cirrhosis have a 2- to 5-fold increase in the number of hepatic stellate cells (HSCs) and a 7- to 15-fold increase in number of giant HSCs. There is also a marked increase (15- to 20-fold) in the number of lipid vesicles in giant HSCs (206). These changes are associated with an increase in the extent of perisinusoidal collagenization. Perivenular fibrosis is considered to be a harbinger of future cirrhosis, especially in patients who continue to abuse alcohol or those who are coinfected with HCV (26,145). Sclerosing hyaline necrosis is a more extensive degree of alcoholic hepatitis and is associated with extensive fibrosis (207). The number of Kupffer cells and serum levels of TNF-α, IL-6, and IL-12 were significantly higher in patients with ALD than in controls (208). In patients with severe steatohepatitis, stenosis of the central veins and the degree of stenosis correlate with the amount of ascites, hyperbilirubinemia, and peripheral leukocyte counts (209). Histologically, the Mallory bodies appear to increase in size significantly as veno-occlusive lesions become more severe, but these lesions do not correlate with the degree of sinusoidal neutrophilic infiltration.

There are a number of nonalcoholic hepatic disorders and conditions (e.g., NASH, total parenteral nutrition, and certain drugs—corticosteroids, amiodarone, and synthetic estrogens) that may mimic ALD histologically and these have been reviewed extensively elsewhere (210,211). In particular, it may be necessary to perform a liver biopsy to identify other diseases that may mimic ALD clinically. Histologic differentiation between these diseases may be difficult. Perivenular fibrosis, which is similar but not identical to that often described in association with ALD, has been described in hepatitis C infection (143,212,213). This emphasizes the need for a detailed evaluation of the histology of and appropriate clinical correlation in these diseases. Excessive iron accumulation with siderosis of both the hepatocytes and the Kupffer cells occur in up to two thirds of patients with ALD (214). This is secondary to increased intestinal absorption, prior transfusion, or rarely spur cell anemia (215). A liver biopsy should be performed in patients who have biochemical findings suggestive of iron overload (total iron-binding capacity [TIBC] saturation >45%) to rule out hereditary hemochromatosis by calculating the hepatic iron index because both HCV infection and ALD can each individually cause biochemical abnormalities suggestive of hereditary hemochromatosis (216,217). In the alcoholic patient without cirrhosis, the presence of moderate periportal hemosiderosis should warrant testing for HFE (the abnormal gene in most patients with hemochromatosis) in addition to biochemical tests of iron overload (i.e., serum iron, TIBC, and ferritin)(217).

Imaging Studies in Alcoholic Liver Disease

Imaging studies have been used to diagnose the presence of liver disease but may not have a specific role in establishing alcohol as the etiology of liver disease. The diagnosis of fatty change, established cirrhosis, and hepatocellular carcinoma is suggested by ultrasound or computed tomography (CT) scan and confirmed by other laboratory investigations (197,218). Altered echogenicity of the liver has been considered to be moderately sensitive but not specific for the diagnosis of the fatty change associated with alcoholic liver injury. Established cirrhosis can be suspected on CT scan or magnetic resonance imaging on the basis of the findings of a lobular surface of the liver with altered density of the liver, but the etiology cannot be established with certainty. Enlargement of the caudate lobe and right posterior notch has been suggested to identify alcohol as the etiology of liver disease (219). Evidence of portal collaterals and dilated portal–splenic axis suggests the presence of associated portal hypertension (220). The major value of imaging studies is to exclude other causes of abnormal liver function test results in a patient who abuses alcohol such as obstructive biliary pathology, and infiltrative and neoplastic diseases of the liver (221). Another tool for the diagnosis of ALD is hepatic phosphorus 31 magnetic resonance spectroscopy (222). This is used to calculate hepatic energy metabolism and phospholipid membrane metabolism.

Lower phosphodiesterase to adenosine triphosphate (ATP) ratios have been reported in patients with alcoholic cirrhosis.

Endoscopy in Alcoholic Liver Disease

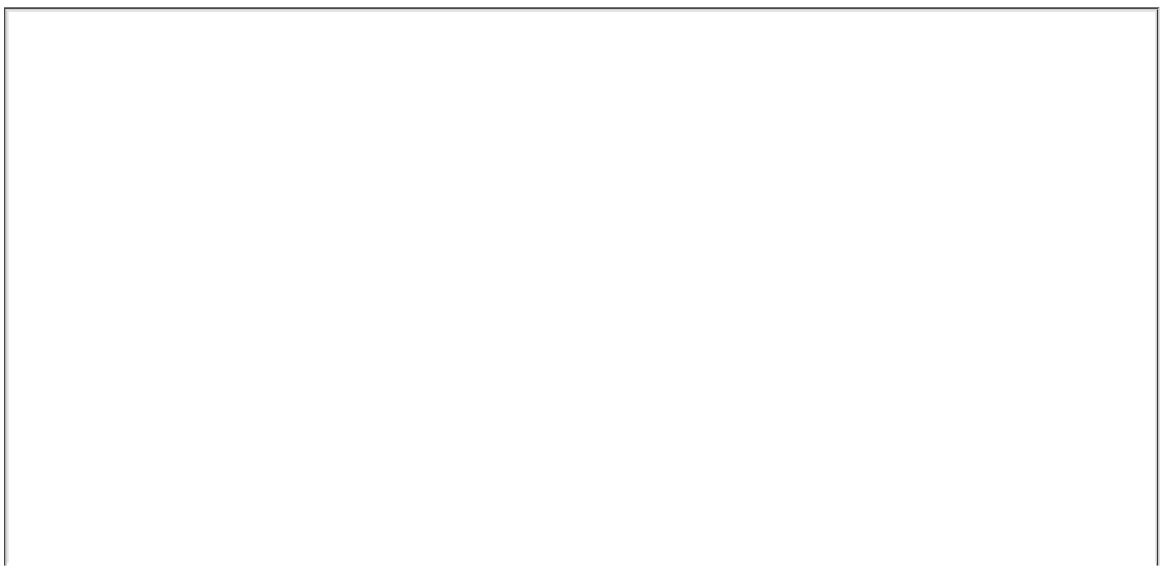
An upper gastrointestinal endoscopy in patients with ALD is used electively to establish the presence of esophagogastric varices and emergently to identify the source of gastrointestinal bleeding. In the clinical situation of alcohol abuse, upper gastrointestinal bleeding may be secondary to a variety of causes that include Mallory-Weiss tear, peptic ulcer disease, direct alcohol-induced gastric mucosal erosions and injury, portal hypertensive bleeding from varices, or congestive gastropathy secondary to cirrhosis (223,224). Endoscopy has both diagnostic and therapeutic value in an alcoholic patient with active upper gastrointestinal bleeding.

Pathogenesis

An in-depth discussion of the pathophysiology of alcohol-induced liver disease is beyond the scope of this chapter and recent major reviews are recommended (18,47,201,225). However, a general understanding of the mechanisms of alcohol-mediated liver damage is essential because it forms the basis of current therapeutic strategies.

In the past, it has been considered that whole liver tissue analysis would provide an understanding of the pathogenesis of ALD. However, the liver consists of both hepatic parenchymal cells (65%) and nonparenchymal cells (e.g., endothelial cells, Kupffer cells/hepatic macrophages, HSC, bile duct epithelial cells, and pit cells/liver natural killer cells)(226,227,228,229). All these cellular components are involved in the pathogenesis of ALD (Table 32.8). Although the nonparenchymal cells constitute less than a third of the liver volume, they have distinct functions and are

involved in cellular homeostasis, hepatocyte support, chemokine release and hepatocyte injury, fibrosis, and cell death (206,208,227,230,231).



Target	Mediator	Consequence
HEPATOCYTES		
Cytochrome P450IIE1	Reactive oxygen species	Lipid peroxidation
Abnormal methionine metabolism		
SAMe, *S*-Adenosyl Homocysteine	Transmethylation reaction	Nucleic acid, protein, phospholipids
Mitochondria	GSH depletion	Reactive oxygen species
	Membrane fluid abnormality	Megamitochondria
	Electron transport chain	Defective ATP depletion
	Mitochondrial DNA breaks	Apoptosis induction
Hepatocyte growth	Impaired protein synthesis, Inhibits calcium mobilization, Decreased DNA synthesis	Impaired regeneration
Increased expression of proto-oncogenes	Increased regenerative proliferation	Hepatocellular carcinoma
Matrix remodeling and deposition	Hepatocyte communication	Impaired apoptosis, regeneration
KUPFFER CELL/MACROPHAGES		
Alcohol-induced damage	Cytokine release	Increased TNF-α expression
	Defective IL-10 release	Increased apoptosis
	Defective regulation of local inflammation	Hepatocyte inflammatory cell infiltration
Iron overload (increased absorption)	Impaired function	Endotoxemia
SINUSOIDAL ENDOTHELIAL CELLS		
Inflammatory cell, Migration	ICAM expression increased	Hepatocyte injury
Hypoxemia	Microvascular circulation abnormalities	
HEPATIC T LYMPHOCYTES		
Increased activation	TNF-α release	Hepatocyte apoptosis
HEPATIC STELLATE CELLS		
Oxidative stress, Endotoxemia, Differential MAT expression	Activation	Lobular fibrosis

SAMe, *S*-adenosyl methionine; GSH, glutathione; ATP, adenosine triphosphate; DNA, deoxyribonucleic acid; TNF, tumor necrosis factor; IL, interleukin; ICAM, intercellular adhesion molecule; MAT, methionine adenosyl transferase.

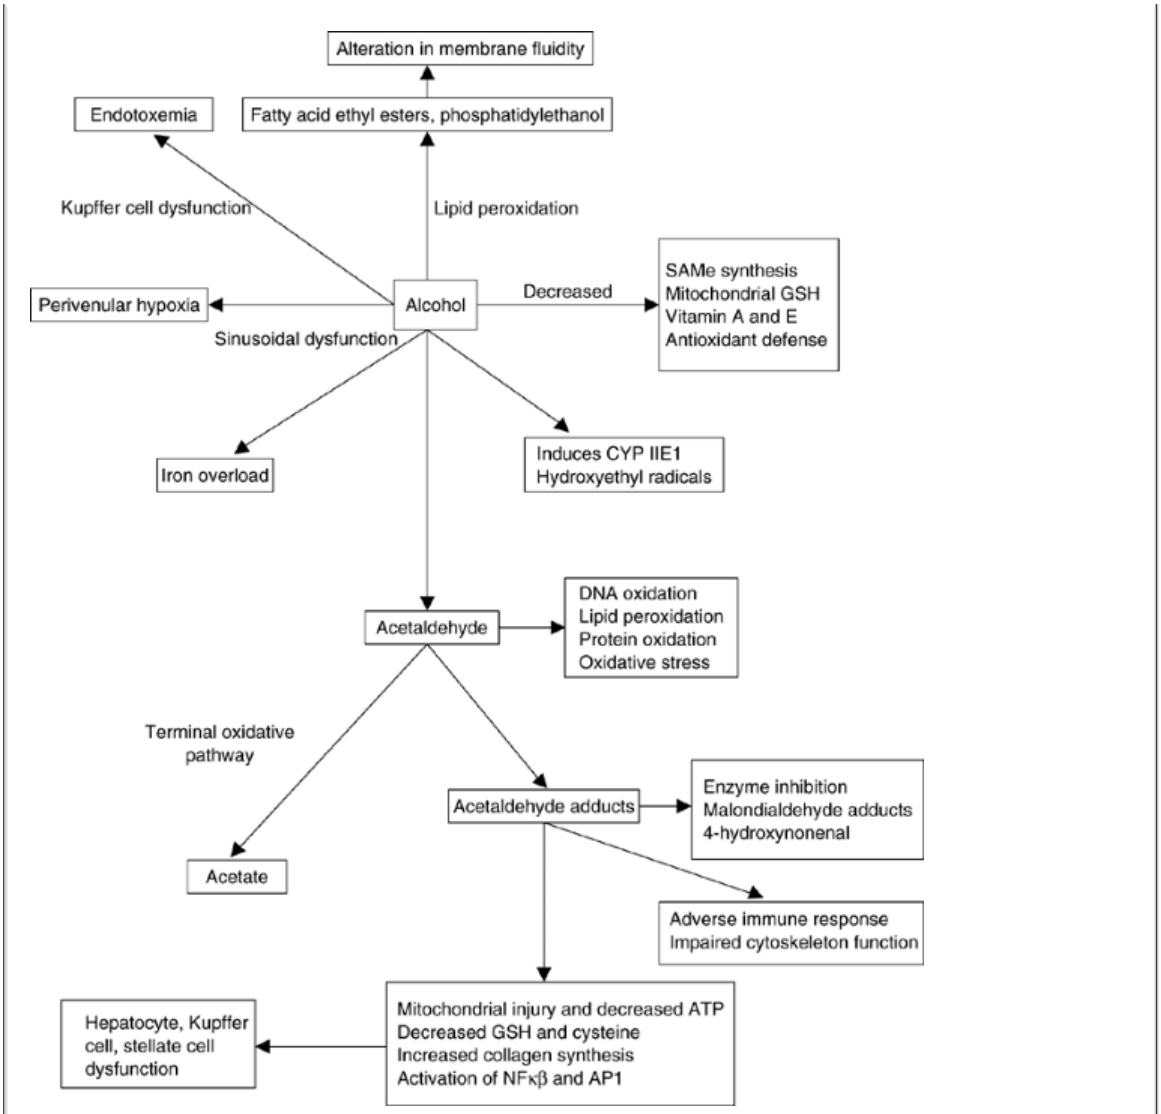
Table 32.8. Role of Cellular and Subcellular Organelles in the Pathophysiology of Alcoholic Liver Disease

Alcohol-induced liver injury is the result of a complex interaction between alcohol metabolism, and inflammatory and immune responses that result in cellular injury. These include oxidative stress and the consequent inflammatory cellular response that cause direct injury to hepatocytes in addition to activation of hepatic nonparenchymatous cells (Fig. 32.10). Additionally, indirect damage to the liver occurs because of endotoxin/cytokine activation, immune-mediated mechanisms, and induction of fibrogenesis (232). Superimposed on these hepatotoxic mechanisms is the impairment of hepatic regeneration with alcohol use, although studies on rats have questioned this (233,234,235).

Direct Hepatocyte Injury

Hepatocytes are the primary site of alcohol oxidation, and there are two major oxidative pathways

involved: The alcohol and aldehyde dehydrogenase pathway and the microsomal ethanol-oxidizing system (MEOS), the major component of which is CYP 2E1 (Fig. 32.10) (225,236). Therefore, ethanol oxidation generates reactive free radicals, leading to oxidative stress that is reinforced by the depletion of glutathione (GSH) and vitamin E (antioxidants) (237,238). Oxidative stress induces the transcription of several cytokines and release of growth factors from the different cells in the liver that interact with the immune cells mediating hepatocyte injury (228,232).



▪ **Figure 32.10** Schematic of the role of the hepatocyte and alcohol oxidative pathways in the pathogenesis of alcoholic liver disease. SAMe, *S*-adenosyl methionine; GSH, glutathione; DNA, deoxyribonucleic acid; ATP, adenosine triphosphate; NF, nuclear factor; AP, activator protein.

Alcohol dehydrogenase pathway

ADH is an enzyme that produces acetaldehyde, which causes direct hepatocyte damage and immune-mediated damage by the formation of acetaldehyde adducts that are potent immunogens (121,239). In addition to acetaldehyde, other aldehydes produced as a result of free radical generation include malondialdehyde (MDA) that has been shown to combine with the cytochrome *c* oxidase subunits IV and V of mitochondria (121). Anti–acetaldehyde adduct IgA and IgG, as well as anti-MDA adduct antibodies, were found in a significantly higher number of patients with severe alcoholic hepatitis and cirrhosis (194). Additionally, acetaldehyde and MDA can form hybrid adducts with proteins (mercaptoacetic acid adducts) that are also highly immunogenic (240). These suggest that the ADH pathway provides a strong immunologic mechanism in the pathogenesis of ALD. Acetaldehyde also significantly enhances the DNA binding of two major transcription factors: Nuclear factor κβ (NFκβ) and activator protein-1 (AP-1) and increases their transactivating activities (241). These observations suggest that acetaldehyde plays a major role in regulating the expression of proinflammatory cytokines by activating NFκβ and AP-1 (242).

Cytochrome P4502E1 pathway

Cytochrome P4502E1 (CYP 2E1) is a component of the MEOS enzyme pathway that plays a major role in inducing oxidative stress and alcohol-induced hepatocellular damage (243). After chronic

ethanol ingestion, a 5- to 10-fold induction of CYP 2E1 occurs that not only metabolizes ethanol but is also responsible for the activation of xenobiotics to toxic metabolites (104,106,243). This increases the vulnerability of patients who abuse alcohol to solvents, xenobiotic compounds used in industry, and therapy, as well as vitamin A precursors (i.e., β-carotene and retinol) (244,245,246). In contrast to the ADH pathway that is not inducible in humans, CYP 2E1 is induced in humans by ethanol ingestion; it increases the production of ROS and the consequent membrane peroxidation that results in cell damage (236,247). There is increased generation of superoxide radical and free radical production including the 1-hydroxyethyl free radical intermediates (129,248). Normally, cellular protective mechanisms against oxidative stress prevent the adverse effects of these ROS (249). In the presence of liver disease and malnutrition, with the maximal activation of the system, the detrimental responses predominate and result in tissue injury (250). Other cytochromes such as the P-450 1A2 and 3A4 are also induced and may contribute to the cell injury and ROS generation associated with ethanol ingestion (104).

The CYP 2E1 system may not be as essential as other cytochrome enzymes in the pathogenesis of ALD (251). CYP 2E1 knockout mice have been shown to be as susceptible to the hepatoinjurious effects of ethanol (252). Induction of other cytochrome enzymes (i.e., CYP 1A, CYP 2A, CYP 2B, and CYP 3A) also occur with ethanol and may contribute to the oxidative damage associated with ethanol ingestion. Dissociation of CYP 2E1 and ALD is also suggested by the prevention of experimental ALD with gadolinium chloride despite the induction of CYP 2E1 (253). Nonetheless, most data suggest that CYP 2E1 is involved in the pathogenesis of ALD (226). Furthermore, studies that have attempted to question the role of CYP 2E1 have examined the early stages of ALD, whereas CYP 2E1 plays a role later in the progression of ALD. Finally, CYP 2E1 is much lower in mice than rats or humans and caution must be exercised before extrapolating the findings in mice to humans (226).

Abnormal methionine metabolism

The liver plays a central role in methionine metabolism with the formation of *S*-adenosyl methionine (SAMe) in the presence of the enzyme methionine adenosyl transferase (MAT) (254). An inactivation of hepatic MAT occurs in ALD with the depletion of hepatic SAMe and GSH and decreased transmethylation reactions. These result in impaired antioxidant defense, altered phospholipid composition and membrane fluidity, and possibly altered DNA stability (47). Finally, the homocysteine released as a consequence of altered MAT activity may stimulate HSCs and promote hepatic fibrosis (255,256).

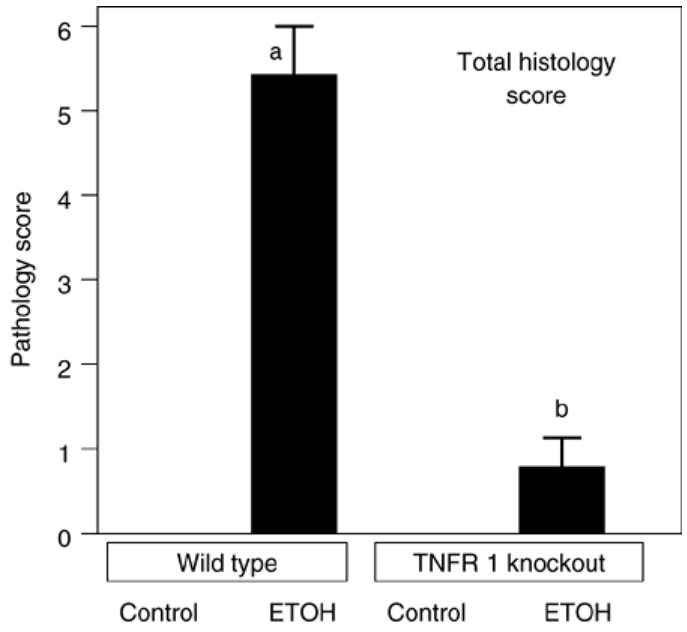
Role of hepatic mitochondria

Mitochondrial dysfunction has been observed in the alcohol-fed animal models (257). Increased synthesis of ROS, decreases in mitochondrial membrane potentials, increased oxidative modification, and single-strand breaks in mitochondrial DNA have been reported (257,258). These may be inducers of apoptosis and result in hepatocyte death in ALD. Dysregulated apoptosis has been suggested as a key pathogenic

event in ALD, with activation of effector caspaces (228,259,260,261).

Indirect Hepatocyte Injury

Hepatic macrophages (Kupffer cells) generate cytokines (such as TNF-α and transforming growth factor-β) that may accentuate or promote liver cell injury (27,228,262). The role of TNF-α in alcoholic hepatitis is not clear (263). Elevated serum levels of TNF-α in alcoholic hepatitis has been correlated with disease severity and mortality (122). TNF-α receptor 1 knockout mice are resistant to alcohol-induced liver damage, as shown in Figure 32.11 (264). These studies suggest a role for TNF-α in the pathogenesis of liver injury in ALD. The contribution of Kupffer cells is supported by an attenuated alcohol-mediated hepatic injury by blocking Kupffer cell function (265). Furthermore, MAT is expressed in both Kupffer cells and sinusoidal endothelial cells, and an alteration in the expression of this enzyme system in the three groups of cells (i.e., hepatocytes, macrophages, and endothelial cells) could contribute to the pathogenesis of injury in ALD (226). Liver-associated T lymphocytes mediate injury and these may be responsible for both immune-mediated and non–immune mediated (through release of cytokines) hepatic injury (266). HSCs may be responsible for both matrix remodeling and regulation of local inflammation (206). Alteration in stellate cell activation may result in fibrosis and cell death in ALD (267,268). Products of lipid peroxidation have the ability to activate the HSC and stimulate fibrogenesis (269). The contribution of nonhepatic cellular components to hepatic injury is not entirely understood and warrants further studies to examine the role of these cell types.



▪ **Figure 32.11** TNF receptor 1 (TNFR 1) knockout mice are less prone to alcohol-mediated hepatic injury compared to wild-type control mice. ETOH, ethanol. *a*, *P* <.001 versus control; *b*, *P* <.01 versus control.

Prognostic Factors

Alcoholic cirrhosis has a worse prognosis than other forms of cirrhosis, as shown in Table 32.9 (270). A number of adverse prognostic factors for the long-term outcome in ALD have been suggested, and these include the development of cirrhosis, ascites, portal hypertension (especially with evidence of encephalopathy), spontaneous bacterial peritonitis, hepatic encephalopathy, hepatorenal syndrome, coagulopathy, severe hyperbilirubinemia, hypoalbuminemia, severe malnutrition, decreased galactose elimination capacity, evaluation of α-fetoprotein, increasing age, histological evidence of hepatic inflammation, continued alcohol abuse, and coinfection with other hepatotropic virus infection (18,271,272,273,274). Iron overload and bacterial infections also predict poor outcome in ALD (275,276).

Scoring System for Disease Severity

Clinical progress in the therapy for ALD has been limited in part by the lack of accurate predictors of prognosis. This has also resulted in difficulty in comparing outcomes and results of different treatments because of the nonhomogeneity in the predictors used. Accurate prediction of the prognosis of the most severe form of ALD, alcoholic hepatitis, is necessary to develop reliable treatment strategies for this disease. The modified Maddrey discriminant function (DF) that includes prothrombin time and bilirubin levels is the most widely used predictor of severity of alcoholic hepatitis (277). Values of 32 and more are associated with a mortality

of 35% to 40% and are used to identify patients who will benefit from corticosteroid therapy. Patients with a DF less than 32 had a survival of 83% to 90% and they do not benefit from corticosteroids (278). Presence of encephalopathy has been included by some workers to predict outcome and the decision to start corticosteroids (279). The Model for End-Stage Liver Disease (MELD) and the Glasgow alcoholic hepatitis score (GAHS) have been used more recently to predict the outcome in patients with acute alcoholic hepatitis (279,280,281). A MELD score of 21 or higher had the best sensitivity and specificity in predicting 90-day mortality (282). Other authors have also used MELD, and a score of 11 has also been used as a cutoff to predict the outcome (283). These studies have compared MELD with Maddrey DF and either found them to be equally sensitive and specific or found MELD to be superior to Maddrey DF in predicting the outcome in acute alcoholic hepatitis (279). The limitations of MELD include the difficulty in its calculation at the bedside, the variation of the predictive value among studies, and the inclusion of serum creatinine that limits its usefulness in the presence of hyperbilirubinemia, which reduces the accuracy of

creatinine measurement (284). The GAHS has been validated in a large population of patients studied up to day 84, allowing the assessment of not only the short-term outcome on days 28 to 30 but also the clinical course of the disease (281). The key components of GAHS include age, white blood cell count, blood urea, prothrombin time, and serum bilirubin (280,281). It is still unclear whether GAHS will be universally applied, and both MELD and GAHS need to be extensively studied by different groups before they are accepted as predictors of outcome and replace the widely used Maddrey DF.

Table 32.9. Survival of Different Types of Cirrhosis

Etiology	*N*	5 year (%)	10 year (%)
Alcohol	82	23[a]	7[a]
Cryptogenic	13	33	20
HCV	62	38	24
HBV	42	48	20
Hemochromatosis	20	41	22
Autoimmune	16	46	23
PBC	36	56	39

[a]*P* <0.05 versus other forms of cirrhosis.
HCV, hepatitis C virus; HBV, hepatitis B virus; PBC, primary biliary cirrhosis.
Adapted from Pessione F, Ramond MJ, Peters L, et al. Five-year survival predictive factors in patients with excessive alcohol intake and cirrhosis. Effect of alcoholic hepatitis, smoking and abstinence. *Liver Int* 2003;23(1):45–53.

Abstinence

Abstinence is a major goal of therapy and remains a fundamental factor in the management of ALD (270,285). It is perhaps the most important but difficult therapeutic intervention for ALD (225,286). Abstinence has been shown to improve the outcome and histologic features of hepatic injury, reduce portal pressure, and decrease progression to cirrhosis (Table 32.10), but this may be lower in female patients (58,209,272,287,288,289,290,291). This improvement can be relatively acute, and in 66% of patients abstaining from alcohol, significant improvement was observed in 3 months (292). Continued alcohol ingestion results in increased portal hypertensive bleeding, especially in patients who have bled in the past, and worsens both short- and long-term survival (224). The deleterious effect of continued alcohol ingestion on the outcome compared to the abstinent population is shown in Figure 32.12. Furthermore, a survival analysis of abstinent alcoholic patients with cirrhosis who are infected with HCV compared to those with HCV cirrhosis who had never consumed alcohol showed no difference (293).

Table 32.10. Five-Year Survival in Alcoholic Liver Disease (the Effect of Abstinence)

			Survival (%)	
Authors	Time (y)	Number	Stopped drinking	Continued drinking

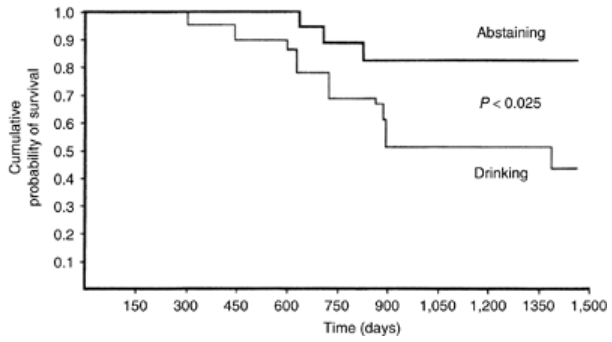
Pessione et al. (270)	5	122	57[a]	27
Merkel et al. (272)	4	45	87	55
Borowsky et al.[b] (287)	3	54	45[a]	20
Brunt et al. (288)	7	258	77[a]	48
Juhl and Tygstrup (290)	8	168	70[a]	44
Powell and Klatskin (291)	12	278	63[a]	40

Figures in parentheses are the reference number in bibliography.
[a]$P < 0.05$ versus continued drinking, as stated in the text or estimated from Life Table Analysis.
[b]Data in Borowsky's study was for 2-year survival for heavy drinking versus total abstinence.

Recidivism is the major risk in all patients at any time after abstinence (294,295). No controlled trials exist on the benefits of alcohol abstinence and the effects of recurrent drinking on ALD. Cohort studies, however, have consistently demonstrated that abstinence does improve survival at all stages of the disease (270,287). Several drugs have been tried to help sustain abstinence. Naltrexone, a pure opioid antagonist controls the craving for alcohol. A Cochrane systematic review of the use of naltrexone and nalmefene in 29 randomized controlled trials concluded that short-term treatment with naltrexone lowers the risk of relapse of alcohol abuse (296). Acamprosate (acetylhomotaurine) is a novel drug with structural similarities to excitatory amino acids and γ-aminobutyric acid and is associated with reduction in withdrawal symptoms (297). In 15 controlled trials, the efficacy of acamprosate has been demonstrated in reducing withdrawal symptoms but the effects on survival are not yet available (298).

Exercise has been shown to ameliorate the alcohol-induced hepatic injury in rats (299). It is possible that a healthy behavior pattern in humans would reinforce abstinence in addition to its beneficial effect on ALD (52). Human studies should be encouraged given the multiple beneficial effects of exercise. Caution must, however, be exercised before recommending exercise

in patients with ALD because of the possible underlying cardiomyopathy in these patients.



▪ **Figure 32.12** Effect of abstinence on long-term survival (Kaplan-Meier survival curve).

Hepatic Inflammation

The presence of hepatic inflammation appears to be the single most important prognostic histologic factor in patients with ALD (18,300,301). In a study of 217 patients (140 with cirrhosis and 77 without cirrhosis) with biopsy-proved ALD, the presence of hepatitis indicated a poor prognosis (300). Patients with cirrhosis and hepatitis had increased the 1- and 5-year mortality rates to 27% and 47%. This contrasts with the survival rates in patients with cirrhosis without hepatitis are similar to those with no cirrhosis or hepatitis. These data have been indirectly confirmed in cases in which the presence of polymorphonuclear cells on liver biopsy was found to be a prognostic factor for early and late survival (273).

Hepatitis C

As discussed previously, the presence of HCV is another factor that causes inflammation in these patients (302,303). The decision to use antiviral therapy in patients with ALD and HCV infection should be determined on an individual basis. Because the data available indicate that active drinking will reduce the efficacy of interferon therapy for HCV infection, the potential use of interferon or other antiviral agents must be decided on an individual basis (304,305,306). However, the potential efficacy of antiviral therapy may be improved by abstinence, and therefore, the potential for HCV therapy may be a motivational factor (305).

Interaction with other drugs

The activation of the microsomal oxidative enzyme pathways also enhances the hepatotoxicity of other drugs, especially acetaminophen. A combination of enhanced cytochrome P-450 system and decreased hepatic GSH results in severe toxicity. A significant proportion (64%) of patients who developed acetaminophen toxicity have been reported to be alcohol abusers (307,308). Furthermore, most patients reported taking doses that were well below the accepted toxic range (309). Awareness and suspicion of the diagnosis are the most important factors in the management of these patients. Diagnostic clues include very high aspartate transaminase levels (>1,000 IU/L) and a prolonged prothrombin time. Early and accurate diagnosis is essential because of the high mortality and need for early therapy (310).

Therefore, continued alcohol abuse, evidence of hepatic inflammation with hyperbilirubinemia, elevated transaminase levels, prolonged prothrombin time, and hypoalbuminemia seem to correlate with the worst prognosis.

Therapy

Therapy is based on the stage of the disease at which therapy is started and the pathogenetic event being targeted (Table 32.11) (225,311). The primary treatment modalities that have been evaluated in the acute phase of alcoholic hepatitis include agents that suppress inflammation (e.g., corticosteroids) and anticytokine therapy (e.g., pentoxifylline, infliximab, and etanercept), nutritional improvement (e.g., enteral and parenteral supplements including amino acids and anabolic steroids), modifiers of metabolism (e.g.,

propylthiouracil [PTU]), and inhibitors of hepatic fibrosis (e.g., colchicine) (47). Once cirrhosis is established, complications of cirrhosis that include evidence of chronic hepatic failure (e.g., encephalopathy, ascites), as well as those of portal hypertension (e.g., variceal bleeding), are treated along similar lines as those in patients with non-ALD, with additional attention given to other organ dysfunctions associated specifically with alcohol (311,312).

Direct injury		Indirect injury	
Proposed treatment	**Mechanism**	**Mechanism**	**Proposed treatment**
PUL	Membrane damage	Intestinal function	Antibiotics, nutrition
		Cytokines	Anti-TNF-α Pentoxifylline[a], steroids γ-interferon

	Hypermetabolism	Fibrogenesis	
	Regenerative capacity Nutrition[c], oxandrolone[c], hepatotropic agents		

Table 32.11. Pathophysiology and Potential Therapies

Treatment of Alcoholic Hepatitis

Therapy for acute alcoholic hepatitis is determined partly on factors that estimate mortality. These indices are calculated on the basis of laboratory tests, and the most commonly used index is the Maddrey DF ([prothrombin time prolongation over controls in seconds × 4.6] + serum bilirubin in mg/dL) (278). A number of previously used predictors including the Child-Turcotte-Pugh score and the combined clinical and laboratory index have fallen out of favor because of low diagnostic accuracy (300,313). Recently, the MELD and GAHS have been gaining interest as accurate predictors of outcome (281).

The accuracy of five extracellular matrix serum markers (e.g., laminin, PIIINP, and type I, type III, and type IV collagens) has been assessed to diagnose the severity of alcoholic hepatitis (314). On the basis of a histologic scoring system, serum laminin and type IV collagen levels were the most accurate in identifying severe alcoholic hepatitis. The sensitivity of serum laminin was 90% and its specificity was 77%, while those of serum collagen type IV were 80% and 77%, respectively. The major role for these markers may be to identify patients with severe alcoholic hepatitis who are being considered for corticosteroid therapy so that a liver biopsy can be avoided. Studies are needed to combine one of the predictors with other tests such as serum matrix markers that may improve the diagnostic accuracy of the severity of alcoholic hepatitis.

Corticosteroids

Rationale

Corticosteroids have been used to suppress inflammatory and immune response directed against the neoantigens induced by acetaldehyde adducts that include liver-specific lipoprotein, liver membrane antigen, Mallory bodies, and epitopes of protein–aldehyde adducts in the liver (315). Specific immune targets that have been considered targets of corticosteroids include MDA and acetaldehyde adducts, autoantibodies to P4502E1 and P4503A4, and antibodies to the liver membrane antigen (316). There is enhanced cytotoxicity of lymphocytes toward hepatocytes in patients with alcoholic hepatitis (228,317) Steroids also exert a direct antifibrotic effect by suppressing the expression of extracellular matrix proteins in the liver (113). Finally, inhibition of cytokine synthesis by glucocorticoids in response to gut-derived endotoxins also contributes to their beneficial effects in ALD.

Clinical trials

Corticosteroids have been the most extensively used mode of treatment of alcoholic hepatitis, but their efficacy still remains controversial. Of a total of 13 randomized controlled trials, 5 showed that corticosteroids

reduce mortality compared with placebo, while 8 others found no difference in outcomes (Table 32.12) (318,319,319,320,321,322,323,324,325,326,327,328,329,330). Although the results are not consistent, differences in study design may explain the different outcomes. These include variability in dose and duration of therapy, selection of patients (e.g., varying time intervals before randomization or inconsistent use of disease severity scoring), possible misclassification (a consequence of inclusion without liver biopsy), and severity of illness, concomitant medical problems, or medications, as well as undiagnosed chronic viral hepatitis infections. Despite these variations, three separate meta-analyses (331,332,333) have found a benefit in the use of steroids and one meta-aggregate (330) suggested no improvement after attempting to control for potential confounders. The results of the combined data from these meta-analyses suggested that corticosteroids should be targeted to the subset of patients with severe disease. In one meta-analysis, steroid treatment provided a protective efficacy in 27% of patients with hepatic encephalopathy, which increased to 40% among higher-quality trials and in 51% of patients without gastrointestinal bleeding (Table 32.13) (332). In patients without hepatic encephalopathy, corticosteroids had no protective efficacy.

Summarized from O'Shea RS, McCullough AJ. Treatment of alcoholic hepatitis. *Clin Liver Dis* 2005;9(1):103–134.

The major limitation of these meta-analyses was that they were not designed to analyze the individual patient data. A reanalysis of the pooled raw data from the three recent placebo-controlled randomized trials, restricted to patients with a DF of 32 or more, concluded that patients treated with corticosteroids had a significantly higher survival at 28 days than those given

placebo—84.6% versus 65% (Fig. 32.13) (277,278). Therapy with corticosteroids, age, and serum

creatinine were the independent predictors of outcome of these patients. On the basis of these data, the number needed to treat was calculated to be five (i.e., five patients treated to prevent one death).

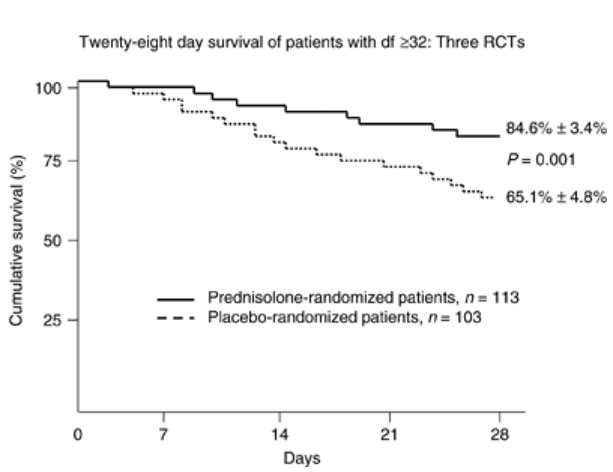
Table 32.13. Corticosteroids in Alcoholic Hepatitis—A Meta-Analysis

Trial characteristic	*N*	Risk ratio RR (95% CI)[a]	Protective efficacy (1–RR) (%)
PATIENTS WITH HEPATIC ENCEPHALOPATHY			
All trials	11	0.73 (0.58–0.92)	27
GI bleeding excluded	7	0.49 (0.33–0.72)	51
GI bleeding not excluded	4	1.06 (0.76–1.48)	NS
Quality score ≥4	7	0.56 (0.38–0.83)	44
Quality score <4	3	1.05 (0.75–1.47)	NS
"Best Estimate"[b]	5	0.64 (0.42–0.97)	36
PATIENTS WITHOUT HEPATIC ENCEPHALOPATHY			
All trials	9	1.07 (0.68–1.71)	NS
GI bleeding excluded	5	1.01 (0.36–2.81)	NS
GI bleeding not excluded	4	1.21 (0.72–2.04)	NS
Quality score ≥4	6	1.02 (0.47–2.26)	NS
Quality score <4	3	1.18 (0.65–2.13)	NS
"Best Estimate"[b]	4	1.01 (0.35–2.91)	NS

[a]If the 95% confidence interval includes unity then there is no significant therapeutic benefit (or protective efficacy) of corticosteroids for that subgroup.
[b]Best estimate = Those trials with:

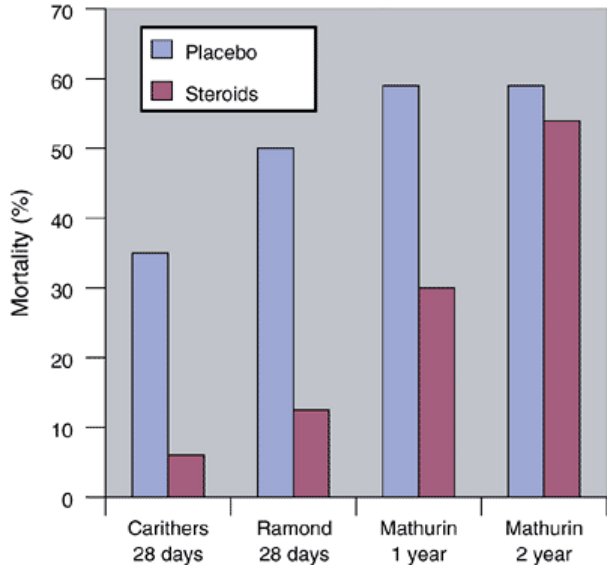
1. Quality score 4
2. Baseline equivalence between groups
3. An exclusion of active gastrointestinal bleeding.

RR, relative risk; CI, confidence interval; GI, gastrointestinal; NS, not significant; N, number of trials.



▪ **Figure 32.13** Effect of corticosteroids on the mortality of patients with alcoholic hepatitis for 28-day treatment with both prednisolone and placebo. DF, discriminant function; RCTs, randomized controlled trials.

In addition to these observations of the short-term benefits of corticosteroids in acute alcoholic hepatitis, a follow-up study showed that steroids improved the survival at 1 year but not 2 years in these patients (Fig. 32.14) (273). The long-term benefit of corticosteroids in acute alcoholic hepatitis is uncertain. A number of factors may contribute to these results and include recidivism, comorbidities, and progression of disease.



▪ **Figure 32.14** Corticosteroids showing benefit for 1-year but not for 2-year mortality in alcoholic hepatitis.

These observations provide a number of suggestions for the management of alcoholic hepatitis (330). Approximately five to seven patients need to be treated to avoid one death. This necessitates careful selection of patients to avoid the side effects of corticosteroids in the other four to six patients who will derive no clinical benefits or may suffer the adverse effects of corticosteroids. This means excluding patients with active infection and being certain of the diagnosis (liver biopsy may be necessary) because histologically confirmed alcoholic hepatitis correlates poorly with the clinical impression of alcoholic hepatitis (273). As many as 28% of patients with a clinical picture of alcoholic hepatitis do not have the histologic features of alcoholic hepatitis on liver biopsy. Only patients with severe disease (as defined by the presence of hepatic

encephalopathy, the Maddrey DF and MELD score, or the GAHS) should be treated with corticosteroids. Another recently identified marker is the early change in bilirubin content at 7 days that has been shown to accurately identify patients who are not likely to respond to corticosteroids (334). This needs to be validated before firm recommendations can be made. Finally, on the basis of pharmacologic considerations (prednisone is converted to active form—prednisolone—in the liver) rather than published data, prednisolone (40 mg daily × 4 weeks followed by a taper) should be used in favor of prednisone. One may conclude from these observations that corticosteroids reduce mortality by up to 25% in alcoholic hepatitis, but the

mortality still remains high (44%) in patients treated with corticosteroids. Therefore, other therapies or combination of therapies need to be considered (277).

Anticytokine therapy

Rationale

Cytokines are essential to the processes of hepatocyte inflammation, cell death, and regeneration. Serum levels of TNF, as well as IL-1, IL-6, and IL-8, are elevated in alcoholic hepatitis (232,335,336). Human studies have shown that the levels of soluble TNF receptor correlate linearly with an increased risk of mortality and that serum levels of TNF are high on admission and correlate with mortality (337). In addition, monocytes from patients with alcoholic hepatitis produce TNF-α at higher levels than do controls in response to endotoxin. On the basis of these observations, clinical trials have been performed using therapy targeted toward blocking TNF-α.

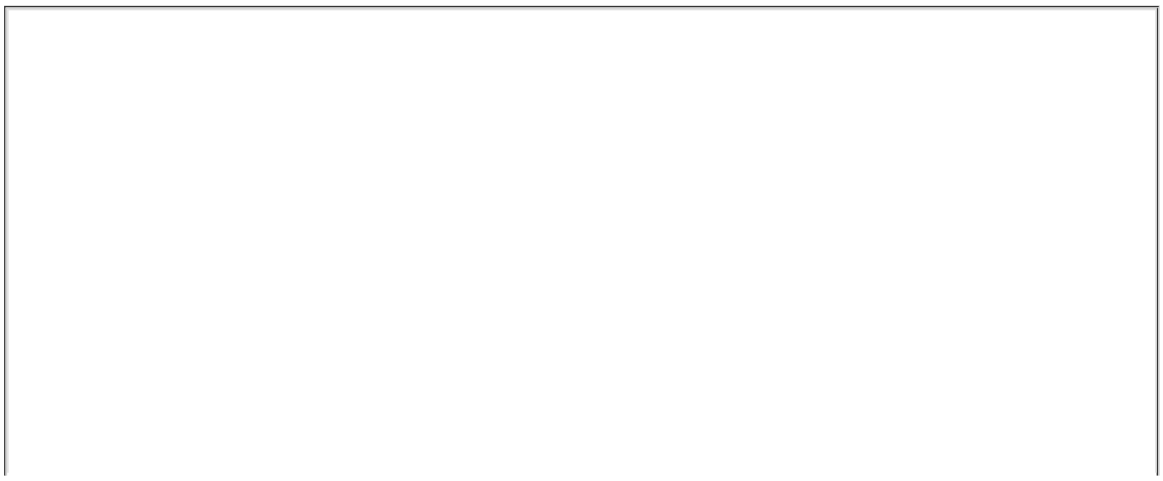
Pentoxifylline

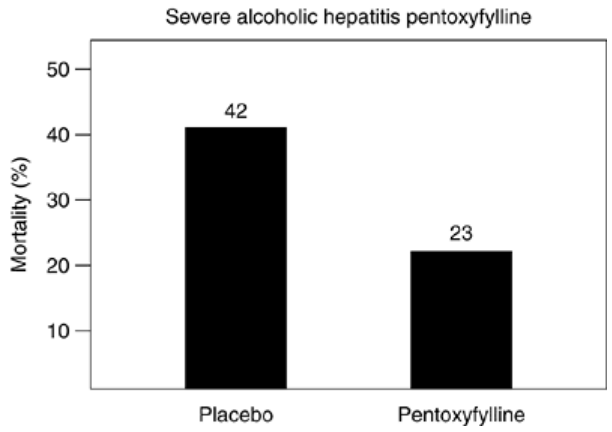
Rationale

Pentoxifylline is a phosphodiesterase inhibitor used in the treatment of peripheral vascular disease on the basis of its ability to increase erythrocyte flexibility, reduce blood viscosity, and inhibit platelet aggregation (338). Pentoxifylline also reduces the production of TNF-α, IL-5, IL-10, and IL-12 (339). It has also been shown to decrease the transcription of IL-2 and TNF-α promoters in transiently transfected normal T cells, to inhibit the activation of NFκβ and nuclear factor of activated T cells, and stimulate activation of protein-1 and cyclic adenosine monophosphate (cAMP) response of element-binding proteins. In an animal model it has been shown to reduce portal pressure in patients with cirrhosis (340).

Clinical trials

A 4-week double-blind prospective randomized trial in 101 hospitalized patients with severe alcoholic hepatitis (Maddrey score ≥32) treated with either pentoxifylline (400 mg three times a day) or placebo showed a significantly decreased mortality with pentoxifylline therapy (24% with pentoxifylline and 46% with placebo) (Fig. 32.15) (338). Hepatorenal syndrome was the major cause of death in both the groups but significantly more frequent in the placebo group. The difference in mortality between the two groups suggests a number needed to treat of 4.7, which is almost identical to the number arrived by Mathurin et al. who compared the use of steroids to placebo (273). The mechanism by which pentoxifylline decreased the development of hepatorenal syndrome is unclear but could be related to either direct effects on the liver (through any of the possible mechanisms discussed in the preceding text) or, alternatively, by a direct renal effect.





▪ **Figure 32.15** Pentoxifylline lowers mortality in acute alcoholic hepatitis compared to placebo.

Infliximab

Therapy designated to specifically target TNF-α have been used in alcoholic hepatitis.

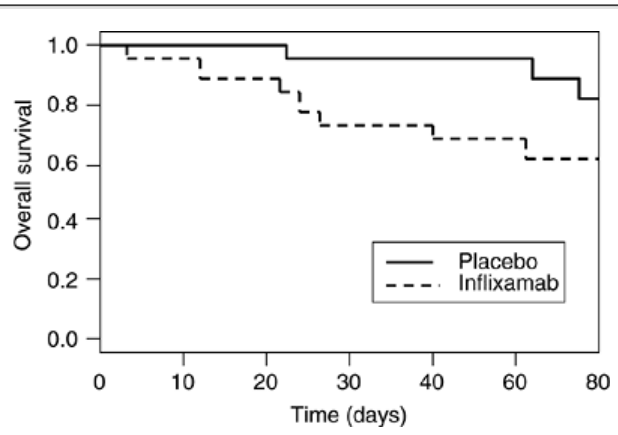
Clinical trials

Two small uncontrolled pilot studies using infliximab (IgG-1 monoclonal antibody to TNF) suggested a benefit in alcoholic hepatitis (341,342). A subsequent randomized controlled trial using infliximab (10 mg/kg) in combination with prednisolone (40 mg/day) versus prednisolone alone was begun in a total of 36 patients (343). The trial was terminated prematurely because of the significantly higher mortality related to infection in the infliximab group compared to the controls (39% vs. 11%) (Fig. 32.16). This study has been criticized on the basis of the specifics of the study design, as well as the premise for the use of such therapy (344).

Etanercept

Etanercept, a P75-soluble TNF receptor:Fc fusion protein, neutralizes soluble TNF and excludes an effect on

membrane-bound TNF. It has been used in rheumatoid and psoriatic arthritis, as well as ankylosing spondylitis (345). A single study involving 13 patients with moderate or severe alcoholic hepatitis for a 2-week duration showed that the 30-day survival rate for patients receiving etanercept was 92% (346). Adverse events (including an infection, hepatorenal decompensation, and gastrointestinal bleeding) necessitated premature discontinuation of etanercept in 23% of patients. A larger multicenter clinical trial is currently ongoing and the results of this are awaited.



▪ **Figure 32.16** Kaplan-Meier survival curve demonstrating lower survival with infliximab

compared to placebo when administered to patients with acute alcoholic hepatitis.

Finally, aggressive new therapy to remove cytokines through leukocytapheresis or other extracorporeal recirculating systems deserve further evaluation (347,348).

In summary, the results of measures directed against TNF-α appear controversial. Lack of a control arm, inclusion of patients with moderate disease (making interpretation of survival statistics uncertain), and the high dropout rate dampen the enthusiasm for the use of etanercept. On the basis of data from the studies using infliximab in alcoholic hepatitis, the extent to which complete TNF inhibition (through antibody or receptor blockade) is useful, or how best to measure it, is unclear. Further clinical trials are needed to address these issues. In addition, questions have been raised about the extent to which TNF inhibition is of benefit in this disease because TNF has been shown to be important in hepatic regeneration (233).

Antioxidants

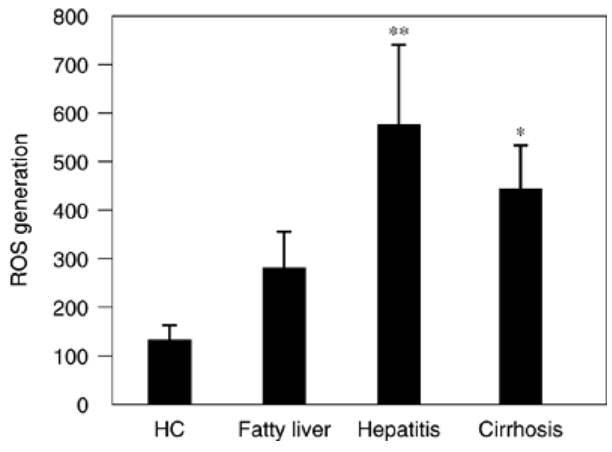
Rationale

A major mechanism of alcohol-related liver injury is mediated by the generation of superoxides, the induction of cytochrome P4502E1 activity, and the product of inducible nitric oxide synthetase–related oxidative stress (Fig. 32.17) (349,350).

In vitro studies indicate that oxidative stress sensitizes lymphocytes to TNF-α–mediated cytotoxicity that is mediated through the cellular death domain pathways (351). In addition, blood vitamin E levels and mitochondrial GSH levels are decreased by ethanol (352,353). These lead to an imbalance between alcohol-induced oxidative stress and the endogenous components of cellular defense against oxidative stress. Antioxidants also attenuate NFκβ activation and TNF-α production in monocytes of patients with alcoholic hepatitis and rat Kupffer cells in vitro (335).

Clinical trials

Vitamin E when used alone was not shown to be significantly beneficial in either alcoholic hepatitis or alcoholic cirrhosis (354,355). However, neither of these studies were optimally designed and there are data suggesting that vitamin E when combined with other antioxidants may improve outcome in alcoholic hepatitis (356).



▪ **Figure 32.17** Nonstimulated neutrophils releasing greater quantities of reactive oxygen species (ROS) in patients with alcohol-induced liver injury compared to placebo. The release of ROS is greater with increasing severity of liver injury. ** and * indicates significant difference from HC and fatty liver groups.

Nutritional supplementation

Rationale

Nutritional therapy for ALD is based on the observations of a high prevalence of protein calorie malnutrition in ALD (77,80,357). The metabolic abnormalities in ALD that contribute to nutritional deficiencies are shown in Table 32.14. Aggressive nutritional therapy should supply optimal nutritional replacement to correct preexisting malnutrition and provide sufficient amino acids to encourage hepatic regeneration without precipitating encephalopathy. The nutritional requirements in ALD are shown in Table 32.15.

Clinical trials

In a large trial of over 200 patients with ALD, 100% prevalence of nutritional deficiency was reported (358). Furthermore, protein calorie malnutrition correlated with short- and long-term mortality and the degree of liver dysfunction in patients with ALD and improved nutritional status correlated with increased survival (358). On the basis of these observations, amino acid infusions have been used in the therapy for alcoholic hepatitis (359). A total of eight randomized controlled trials have been published in 309 patients with alcoholic hepatitis, with six studies showing beneficial results and two showing negative results (360,361). The beneficial results were related to improved histology and/or liver function test results. Improved survival was only reported in a single study (362). Overall mortality in all studies combined was 17% in the treated

group and 9.6% in the control group ($P > 0.05$). In the two studies reporting a negative result, there was a large proportion of patients with inactive cirrhosis rather than active hepatitis (363,364). As is true with all artificial feedings, the enteral route is preferred over the parenteral route, if possible. On the basis of these results, one may conclude that routine protein restriction is not needed in patients with alcoholic hepatitis with or without cirrhosis even if encephalopathy is present, provided oral feeds can be tolerated. However, if encephalopathy worsens with protein-based diets, special amino acid formulations enriched in branched-chain amino acids (BCAAs) must be considered (365). A number of trials have examined various nutritional therapies for patients with alcoholic liver disease (Table 32.16). These trials demonstrate that both short-term (366,367,368,369) and long-term nutritional intervention provides therapeutic benefit for a number of important clinical outcomes (370,371,372). Nutritional therapies have also been used successfully in patients with cirrhosis undergoing liver transplantation and those with cirrhosis and HCC (374). These trials have been reviewed elsewhere (360,361). Some practical guidelines for daily dietary feeding in ALD are shown in Table 32.17.

Table 32.14. Nutritional Deficiency, Poor Intake, and Consequent Metabolic Derangements in Alcoholic Liver Disease

RELATED TO HEPATIC DYSFUNCTION
Poor intake: Anorexia, change in mental status, abdominal distension (ascites)
Malabsorption: Portal hypertensive enteropathy, bile salt deficiency
Metabolic derangement: Decreased respiratory quotient and protein synthesis; increased amino acid oxidation, resting energy expenditure
ALCOHOL-RELATED ALTERED
Energy metabolism: Anorexia, inhibition of ATP production
Protein synthesis: Increased protein breakdown and decreased synthesis
Cytokine mediated: TNF-induced apoptosis, decreased DNA synthesis, Increased energy expenditure
Micronutrient imbalances: Low thiamine, folic acid, pyridoxine, vitamin A, vitamin C, and vitamin K; hypocalcemia; hypomagnesemia; low selenium and zinc; and low choline and lecithin

ATP adenosine triphosphate; DNA, deoxyribonucleic acid.

Other agents evaluated

A number of other agents have been evaluated and these include PTU, colchicine, and anabolic steroids.

Propylthiouracil

Rationale

Alcoholic hepatitis is associated with a hypermetabolic state, with increased energy expenditure and oxygen consumption by the hepatocytes (375). This could be blocked by PTU.

Clinical trials

There have been two controlled trials of the use of short-term PTU in alcoholic hepatitis (376,377). No difference in mortality was reported in either of these studies. A recent Cochrane meta-analysis of six randomized controlled clinical trials of PTU in patients with ALD (includes steatosis, fibrosis, hepatitis, and/or cirrhosis) found no significant difference between placebo and PTU in the all-cause or liver-related mortality, complications of liver disease, or liver histology (378).

Colchicine

Rationale

Colchicine inhibits collagen production, increases hepatic collagenase activity, mobilizes ferritin deposits, and inhibits cytokine production.

Clinical trials

There have been two studies reported on the use of colchicine in the treatment of alcoholic hepatitis with no therapeutic benefit (379,380). A Cochrane review concluded that

colchicine has no role in alcoholic hepatitis outside ofcontrolled clinical trials (381).

Table 32.15. Nutritional Requirements in Alcoholic Liver Disease

Condition	Protein (g/kg/d)	Energy (Kcal/kg/d)	Energy substrate	
			%CHO	%Fat
Alcoholic hepatitis	1.0–1.5	30–40	67–80	20–33
Cirrhosis (uncomplicated)	1.0–1.5	30–40	67–80	20–33
Cirrhosis (complicated)				
Malnutrition	1.0–1.8	40–50	72	28
Cholestatis	1.0–1.5	30–40	73–80	20–27
Encephalopathy				
Grade 1 or 2	0.5–1.2	25–40	75	25
Grade 3 or 4	0.5	25–40	75	25
Liver Transplant				
Peritransplant	1.2–1.75	30–50	70–80	20–30

Post-transplant	1.0	30–35	>70	≤30

Table 32.16. Nutritional Therapy in Alcoholic Liver Disease

Studies	*N*	Patient profile	Therapy	Benefit
SHORT TERM				
Kearns et al. (367)	31	Decompensated alcoholic liver disease	Hospitalized enteral feeding (isocal 1.5 g protein/kg)	Encephalopathy, serum bilirubin, antipyrine clearance
Campillo et al. (368)	26	Malnourished cirrhosis	Standard oral diet (30–35 kcal/kg daily)	Improved nutritional status and nitrogen balance
Cabré et al. (373)	35	Severely malnourished patients with cirrhosis	Hospitalized enteral feeding (2,115 kcal)	Child-Pugh score mortality (P = 0.065)
LONG TERM				
Cabré et al. (366)	71	Alcoholic cirrhosis and hepatitis	Enteral tube feeding (2,000 kcal/d) or steroids	Higher mortality due to steroids related to infection
Marchesini et al. (369)	174	Advanced cirrhosis	BCAA vs. lactalbumin/maltodextrin 14.4 g/d	Improved Child-Pugh score Trend to improved survival
Marchesini et al. (370)	64	Chronic encephalopathy	BCAA vs. casein supplements(0.24 g/kg)	Encephalopathy Nitrogen balance Bilirubin
Yoshida et	32	Symptomatic	BCAA supplements (16 g)	Delayed death

al. (371)		cirrhosis BCAA/AAA <1.0	Enteral supplements (1,000 kcal)	Less frequent hospitalization for sepsis
Hirsch et al. (372)	51 31	Decompensated Alcoholic cirrhosis Child-Pugh B and C	Oral supplements(1,000 kcal + 34 g protein) Nutritional supplement (Ensure) (1,000 kcal + 35 g protein)	Less frequent hospitalizations for infections Improved nutrition and cell-mediated immunity

Figures in parentheses are the reference number in bibliography.
BCAA, branched-chain amino acid, AAA, aromatic amino acid.

Anabolic steroids

Rationale

Anabolic steroids, testosterone, and oxandrolone have been shown to improve the hepatic histology in fatty liver and improve the synthetic functions (330). In contrast to testosterone, oxandrolone has higher nitrogen-retaining and myotrophic properties. Cotreatment with nutritional supplementation may result in further improved results.

Clinical Trials

A multicenter trial of oxandrolone in alcoholic hepatitis showed no difference in 30-day hospital mortality compared to placebo (323).

However, patients with moderate but not severe disease had improved 6-month survival. The Cochrane systematic meta-analysis of anabolic steroids in alcoholic hepatitis did not show a benefit in mortality, complications, or other outcome measures (382).

Table 32.17. Guidelines for Daily Dietary Feeding in Alcoholic Liver Disease

- Protein = 1.0–1.5 g/kg BW
- Total calories = 1.2–1.4 × REE, with a minimum of 30 kcal/kg BW
  50%–55% as carbohydrate (preferably as complex carbohydrates)
  30%–35% as fat; preferably high in unsaturated fat and with adequate essential fatty acids
- Nutrition should be given enterally by voluntary oral intake and/or by small-bore feeding tube; PPN is second choice; TPN is last choice
- Salt and water intake should be adjusted for patient's fluid volume and electrolyte status
- Liberal multivitamins and minerals
- Specialized BCAA-enriched supplements not usually necessary
  Most patients tolerate standard AA supplements
  Reserve BCAA formulations for patients who cannot tolerate the necessary amount of standard AA (which maintain nitrogen balance) without precipitating encephalopathy
  Avoid supplements providing only BCAA; they do not maintain nitrogen balance
  Conditionally essential AA and all essential AA are needed
  (Conditionally essential AA are those that can normally be synthesized from other precursors, but cannot be synthesized in patients with cirrhosis; these include choline, cystine, taurine, and tyrosine)
- Nighttime snack consisting of 500–700 cal should be given

BW, body weight; REE, resting energy expenditure; PPN peripheral parenteral nutrition; TPN, total parenteral nutrition; BCAA, branched-chain amino acids; AA, amino acids. Modified from McCullough AJ, O'Connor JF. Alcoholic liver disease: proposed recommendations for the American college of Gastroenterology. *Am J Gastroenterol* 1998;93(11):2022–2036.

We conclude that these agents have a secondary role as an experimental option in alcoholic hepatitis.

Long-Term Management of Alcoholic Liver Disease

Although less acute than alcoholic hepatitis, continuous long-term management is an important component of the treatment of patients with ALD.

Nutritional therapy

Protein calorie malnutrition that is widely prevalent in ALD (358) is associated with major complications observed in cirrhosis (e.g., infection, encephalopathy, and ascites) and indicates a poor prognosis. Consequently, the importance of the clinician recognizing and understanding the significance of malnutrition in these patients has been emphasized.

Enteral feeding for 3 to 4 weeks in hospitalized, severely malnourished or decompensated patients with cirrhosis improved survival ($P < 0.065$), hepatic encephalopathy, liver function, and Child-Pugh score, as compared with controls receiving a standard oral diet (374). In longer-term studies, Marchesini et al. compared equinitrogenous amounts of dietary BCAA versus casein supplements for 3 to 6 months in patients with chronic hepatic encephalopathy (370). BCAA significantly improved response to encephalopathy, nitrogen balance, and serum bilirubin compared with casein. Hirsch et al. supplemented 34 g of protein and 1,000 kcal to a regular diet in decompensated alcoholic patients with cirrhosis and it reduced hospitalizations for infections over a 1-year period (372). These studies are important because they emphasize the concept that patient selection and long-term therapy may be important factors for employing and demonstrating the benefits of nutritional therapy. Because standard nutritional supplements are effective and the cost of BCAA is high, the use of BCAA-enriched formulations should be restricted to patients who cannot tolerate nutritionally required amounts of standard formulations.

Changes in the dietary feeding patterns may also be beneficial. After an overnight fast, patients with cirrhosis obtain more than 70% of nonprotein calories from fat as compared with 40% in normal volunteers (383). Therefore, patients with alcoholic cirrhosis have early recruitment of alternative fuels and have metabolic profiles similar to those observed with prolonged fasting. Consequently, it has been demonstrated that patients with cirrhosis should not be allowed to starve for extended periods and deserve frequent interval feedings, emphasizing a nighttime snack and morning feeding that improve nitrogen balance (384,385,386).

It now seems clear that long-term aggressive nutritional therapy is necessary and reasonable for these patients. General goals and practical points for nutritional therapy in chronic liver disease (Tables 32.15 and 32.17) have been suggested, but three additional points need to be emphasized (361,387). First, nutritional assessment should be an ongoing process. Second, multiple feedings emphasizing breakfast and a nighttime snack with a regular oral diet at higher than usual dietary intakes (1.2 to 1.5 g/kg for protein and 35 to 40 kcal/kg for energy) seem to be indicated (384,385,386). Third, during intermittent acute illness or exacerbations of the underlying chronic liver disease, a higher than normal protein intake (1.5 to 2.0 g/kg body weight and 40 to 45 kcal/kg energy) improves protein calorie malnutrition (361,383,387).

Propylthiouracil

The hypermetabolic state induced by alcohol ingestion can be ameliorated by PTU (375). Direct vasodilator effects of PTU and its antioxidant potential have been suggested to be of value in

alcoholic cirrhosis.

Clinical trials

In a large prospective study, involving 310 patients, therapy with PTU for up to 2 years showed improved survival in the PTU-treated group compared to placebo (388). A Cochrane review of PTU in ALD reviewed six randomized controlled trials in a total of 710 patients administered PTU or placebo. There was no significant benefit of PTU compared to placebo on the total or liver-related mortality, complications of liver disease, or liver histology. There was an increase in nonserious adverse effects that was not significant (378).

S-Adenosyl L-Methionine

Rationale

SAMe is produced from methionine and ATP in the presence of the enzyme SAMe synthetase also known as *MAT* (389). SAMe is the principal biologic methyl donor involved in transmethylation, trans-sulfuration, and aminopropylation. The trans-sulfuration pathway is responsible for GSH synthesis—the main cellular antioxidant. Impaired MAT activity occurs in cirrhosis, resulting in impaired methionine metabolism with increased levels of methionine and homocysteine (255). Deficient MAT results in low SAMe levels and hence low GSH levels. Exogenous GSH is not useful therapeutically because it does not penetrate the hepatocytes. Cysteine is the precursor of GSH and

methionine is the precursor of cysteine. Cysteine and methionine administration have been unsuccessful in correcting the deficiency of GSH. Oral administration of SAMe bypasses the deficit in SAMe synthesis from methionine.

Clinical trials

Oral SAMe administration has been shown to be effective in humans studies in ALD after a few initial disappointing results (389,390). SAMe supplementation improved survival in patients with alcoholic cirrhosis who were Child-Pugh class A and B (390). In contrast, the Cochrane database, based on eight randomized controlled trials with 330 patients in different stages of ALD, did not demonstrate any significant effect of SAMe on mortality, liver-related mortality, complications, or liver transplantation in patients with ALD (391). It was concluded that SAMe should not be used for ALD outside randomized clinical trials.

Colchicine

Colchicine has been used in alcoholic cirrhosis, with beneficial results reported, but few hepatologists prescribe this agent. This may be related to doubts cast on the results of the biggest study reported on the use of colchicine in cirrhosis (392), its potential toxicity, and the need for long-term use before any potential benefits can be observed. A systematic meta-analysis by the Cochrane group showed that a total of 14 randomized trials with 1,150 patients have been studied (patients with alcoholic fibrosis, alcoholic hepatitis, and/or alcoholic cirrhosis, as well as patients with viral-induced or cryptogenic fibrosis and/or cirrhosis) (381). The results showed that there was no benefit on overall mortality, liver-related mortality, liver function tests, or histology, with an increased risk of adverse effects related to colchicine therapy. On the basis of the currently available evidence, colchicine cannot be recommended for the treatment of established alcoholic cirrhosis.

Antiviral therapy

Alcohol use even in moderate quantities has been suggested to worsen the course of hepatitis C (135,303). Additionally, it has been shown that the response rates to interferon-based treatment protocols are less effective in the presence of active alcohol use (393). It is therefore recommended that therapy for hepatitis C be started only in patients who become abstinent. If hepatitis C can be eradicated, the long-term prognosis of ALD should improve.

Liver transplantation for alcoholic liver disease

ALD is the second most common indication for orthotopic liver transplantation (OLT) for chronic liver disease in the Western world (394). In the United States, although specific candidate selection criteria vary from center to center, patients with ALD undergo transplantation in virtually all centers (395). There is resistance to performing transplantation in patients with ALD because of

the pretransplantation socioethical issues of donating organs to patients who have self-inflicted liver disease while others who did not pursue such an active self-injurious course wait and potentially die (396,397). Other concerns include questions about the patient's ability to comply with the complex clinical protocols and immunosuppressive regimens after the transplantation, the rate of recidivism to a behavior of alcohol abuse, and recurrence of injury to the transplanted liver (294). As the number of OLT in ALD increases, it is becoming acceptable to perform transplantation in these patients because their outcome after OLT is similar to that in nonalcoholic patients (397,398).

A 6-month period of abstinence has been recommended as a minimal listing criterion, allowing chemical dependency issues to be resolved during this period. Adherence to the 6-month abstinence could result in a resolution of the anti-inflammatory effects of recent alcohol consumption and, therefore, may make OLT unnecessary in a subset of these patients. The requirement for a fixed abstinence period, the so-called 6-month rule, as a predictor of future abstinence is arbitrary but used most often. However, many abstinence experts are skeptical about this rule because it ignores the complex nature of addictive behavior and does not accurately predict future drinking by alcoholic candidates for liver transplantation (398).

An evaluation of the peritransplantation period in ALD showed that patients were more ill at the time of OLT and likely to have prolonged intensive care unit stays and increased blood product requirements (399). Decreased acute and chronic rejection after OLT have been reported in patients with ALD compared to nonalcoholic subjects and is probably related to the depression in cellular immunity from the alcohol abuse before OLT (400,401,402). There have been a total of 22 published reports on the outcome of liver transplantation in alcoholic patients in over 1,200 patients followed up over 11 years (Table 32.18) (294,394,399,403,404,405,406,407,408,409,410,411,412,413,414,415,416,417,418,419,420,421).

One third to one half of the transplant recipients with ALD will report some use of alcohol in the first 5 years after transplantation (397). It has been suggested that the consequences for alcohol is minimal for many recipients because the amount consumed is small and occurs infrequently, but there is little reliable data to support this contention. Rates of recidivism at 3 to 5 years after OLT have been reported between 11% and 49% (286,294,408,409,415,421,422). It should be emphasized that the rate of recidivism depends on the method used to assess alcohol use and abuse. Higher rates have been reported with objective criteria such as urine and blood alcohol levels, CDT, or a detailed structured

interview rather than unstructured questioning of the patient (423,424). However, recipients who relapse into alcohol use after OLT have similar or potentially lower graft failure rates compared to non-ALD patients. Poor follow-up attendance and noncompliance with therapy is observed in only a minority of patients; graft rejection rates are similar for patients with ALD (41% acute rejection and 5.6% chronic rejection) compared to the non-ALD patients (43.7% acute rejection and 6.2% chronic rejection) (394,397,425). Therefore, OLT should be offered to appropriately selected patients with ALD.

Table 32.18. Results of Liver Transplantation for Alcoholic Liver Disease

Author	Number of patients	1-year survival	5-year survival	Recidivism (%)
Mackie et al. (294)	64	49 (2 y)	—	45

Figures in parentheses under the column “authors” are the corresponding reference numbers in the reference section.

One of the issues that is still unresolved is the role of OLT in acute alcoholic hepatitis. It was observed in a previous study using retrospective histologic analysis of the explanted liver that superimposed alcoholic hepatitis did not worsen the outcome after OLT. However, all patients in this study had been abstinent for at least 3 months, had a DF less than 32, and had variable clinical and biologic features of alcoholic hepatitis at the time of OLT. Therefore, the role of OLT in acute alcoholic hepatitis is unresolved at this time (284). With the availability of living donor transplantation and extended criteria donor, this is likely to further the debate on this issue.

Potential New Treatment Options

Various nonconventional treatment options have been considered promising in the therapy of ALD. Recently, advances in the understanding of the pathogenesis of ALD have suggested new targets for more successful intervention. Some of the nontraditional treatment options include the following.

Silymarin: Silymarin (milk thistle) is a mixture of flavinolignans (i.e., silibinin, silidianin, silichristin, and silybin), of which silybin is the most active (426). The exact mechanism of action of silymarin is not yet clear but is most likely related to its antioxidant properties.

There have been six published trials of silymarin in patients with ALD in doses ranging from 80 to 420 mg/day for periods of 4 weeks to 6 years, with a total of 302 patients treated with silymarin and 305 patients with placebo (426). Normalization of liver function tests, improvement in liver histology, and possibly survival was observed in a significantly higher proportion of patients treated with silymarin compared to placebo. No adverse effects were reported. A Cochrane systematic review and meta-analysis of the 13 published studies of silymarin in ALD and hepatitis B- or C-related liver diseases showed that the overall methodologic quality of the studies was low and based on high-quality trials and that milk thistle does not significantly influence the course of patients with alcoholic and/or hepatitis B or C liver diseases (427).

Other agents: Thalidomide, misoprostol, adiponectin, and probiotics have been shown in preliminary reports to have anticytokine properties (344,428,429,430). However, it must be emphasized that in the past many promising treatments have not passed the test of time as treatment for ALD and alcoholic hepatitis. Emerging data suggest a role for TNF-α–mediated apoptosis in

alcoholic hepatitis, and therapy targeting this cytokine to inhibit apoptosis may be effective (431).

Future Directions

In light of a still incomplete understanding of the involved pathophysiologic mechanisms and conflicting data about the efficacy of specific interventional therapies of ALD, a conservative approach seems justified. These include general supportive care, aggressive nutritional interventions, and the judicious use of corticosteroids and pentoxifylline in select patients with severe alcoholic hepatitis. In addition, abstinence from alcohol, treating the comorbidities of obesity and hepatitis C, and continuous nutritional monitoring are prudent on a long-term basis, with liver transplantation offered for select patients with progressive disease. Algorithms have been proposed for both short-term and long-term management of ALD (Tables 32.19 and 32.20). Although these algorithms are by necessity incomplete, they are provided to stimulate different approaches to this disease and to emphasize several of the following important issues:

1. Abstinence and dietary manipulation should be emphasized in the long-term management of these patients. The issue of abstinence from alcohol will play an important role in determining medical treatment, as well as candidacy for liver transplantation.
2. The high prevalence of hepatitis C must be considered with respect to its potential influence on prognosis and therapeutic strategies.
3. Future therapeutic directions should aim at specific pathophysiologic mechanisms of alcohol-induced hepatocellular damage, as well as the regulation of hepatic regeneration in this disease. Combination therapy targeting both direct and indirect mechanisms of alcohol-induced hepatocellular damage, as well as the regenerative capacity of the injured liver, may prove to be necessary after assessment of disease

severity and prognosis. Clinical trials of combined therapy are needed and include the following:

   a. A mechanism to reduce hypermetabolism and centrilobular hypoxia/ischemia
   b. A means to maintain or enhance gut integrity; the role of nutrition needs to be investigated; furthermore, more objective and systemic ways to assess the function and integrity of the intestinal mucosa are required
   c. The role of bowel sterilization with antibiotics to decrease bacterial translocation and endotoxin- and cytokine-mediated liver damage

d. Modification of immunologic mechanisms

e. Alteration of cytokine-mediated inflammation and fibrosis; potential therapeutic interventions include antibodies or antagonists to specific cytokines of pathogenetic importance and drugs that modulate the actions of these cytokines; therapies directed against anti-TNF may be particularly helpful

f. Inhibition of fibrogenesis by blocking factors that promote fibrogenesis and by stimulating collagen degradation or suppressing collagen gene expression

g. Hepatotropic agents to maximize the capacity of cell repair

h. Exploration of new strategies to decrease lipid peroxidation and its sequelae; SAMe may be particularly relevant in this area

i. Orthotopic and living donor liver transplantation, which are a realistic option for alcoholic cirrhosis; their role in alcoholic hepatitis remains a matter of debate

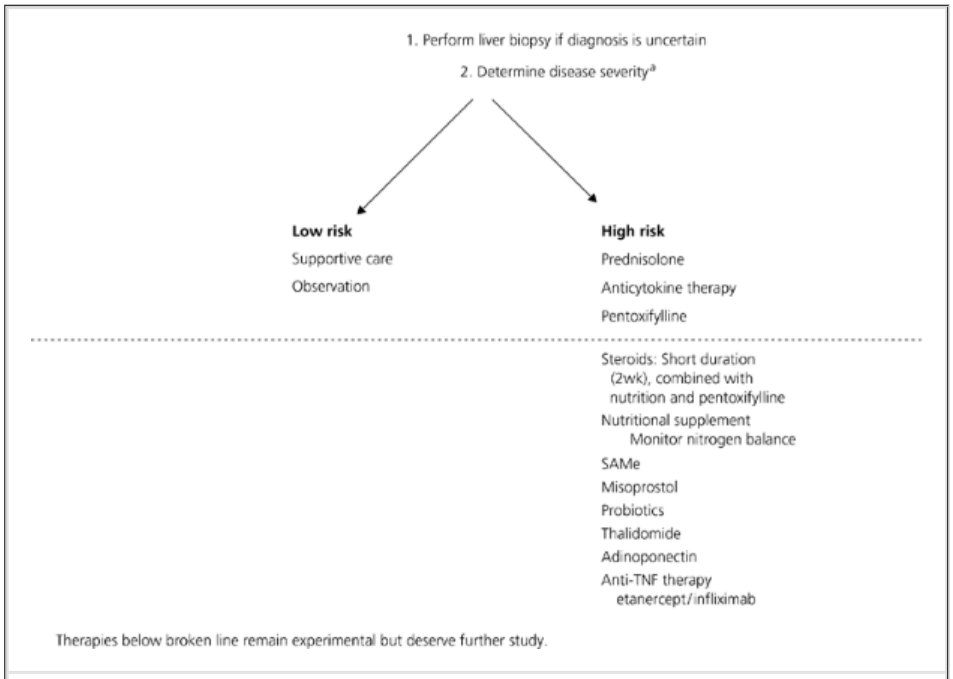

Table 32.19. A Proposed Therapeutic Algorithm for Alcoholic Hepatitis

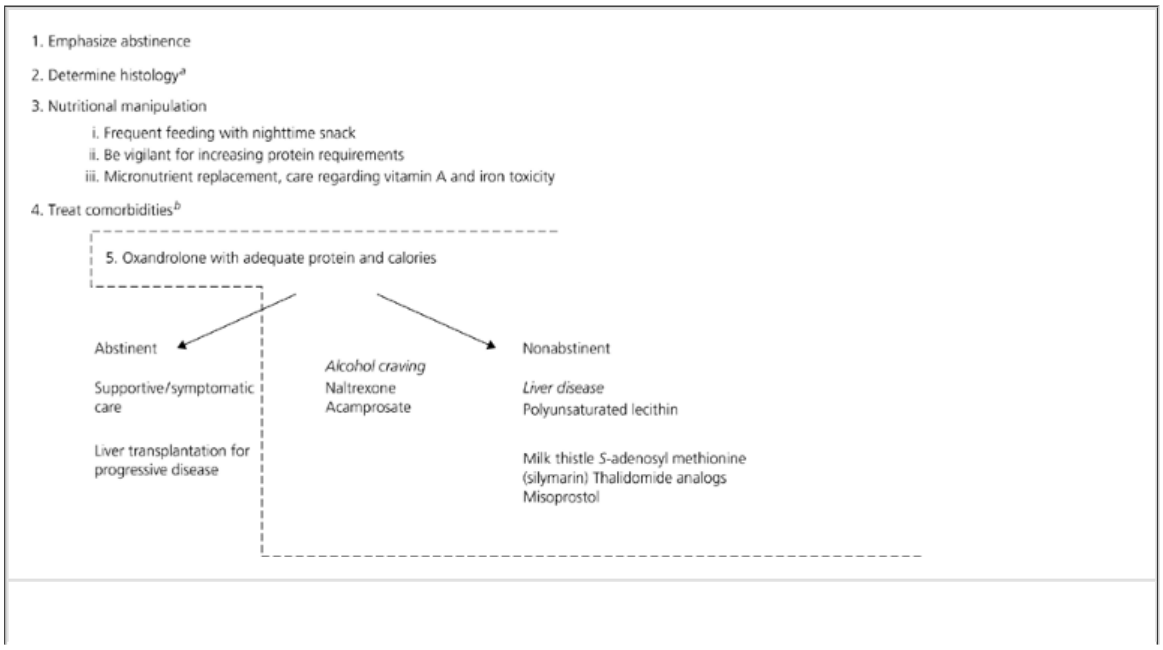

Table 32.20. Proposed Therapeutic Algorithm for the Long-Term Management of Alcoholic Liver Disease

Summary and Conclusions

ALD is a common illness, which develops in only a subgroup of people who chronically use or abuse alcohol. The hepatotoxic dose of alcohol is nonuniform and dependent on incompletely understood risk factors, which include gender, ethnicity, hepatitis C, nutritional status (particularly obesity), and possibly genetic factors. These factors, in addition to a variable natural history and vaguely defined epidemiology and pathophysiology, can make ALD difficult to diagnose and frustrating to manage.

The management of the complications of chronic liver disease (e.g., ascites, portal hypertension associated bleeding, encephalopathy, and hepatocellular carcinoma) is similar in alcoholic and non-ALD patients. Abstinence remains the cornerstone of therapy for ALD. There is also consensus for the use of corticosteroids and pentoxifylline in severe alcoholic hepatitis for maintaining good nutritional status, for treating comorbidities in all forms of ALD, and for liver transplantation in carefully selected patients with end-stage ALD. No other therapies can be recommended at the present time, although nascent data suggest that a number of newer therapies may be effective, as discussed in the preceding text.

Building on our increased knowledge of the molecular basis of ALD, a greater understanding of the pathophysiology of ALD and the interactive role of other cofactors in causing hepatotoxicity needs to remain a major focus of alcohol research.

Zetterman RK. Liver transplantation for alcoholic liver disease. *Clin Liver Dis* 2005;9(1):171–181.

These may be considered to be the most comprehensive reviews on liver transplantation in ALD. The current beliefs, myths, and facts are discussed. The evolution of the current status of transplantation for ALD is discussed, emphasizing as a conclusion that abstinent alcoholic cirrhosis is considered an appropriate indication for liver transplantation.

Chapter 33
Drug-Induced Liver Disease

Shivakumar Chitturi
Geoffrey C. Farrell

Key Concepts

- Over 300 drugs in current use have been implicated in causing liver injury, but there is strong evidence for causality with fewer than 20 of these agents.
- Most implicated drugs cause liver disease in fewer than 1 in 10,000 persons who are exposed, but the frequency of hepatotoxicity is influenced by genetic factors, age, gender, intake of other drugs or alcohol, nutritional status, and preexisting liver disease.
- Interactions between drugs and disease-related factors include highly active anti-retroviral treatment (HAART) and hepatitis C virus (HCV) infection, tamoxifen and nonalcoholic fatty liver disease (NAFLD), methotrexate with diabetes and hepatic fibrosis, and antituberculosis drugs with chronic hepatitis B and hepatitis C.
- The clinicopathologic spectrum of drug-induced liver disease ranges from nonspecific injury to acute and chronic hepatitis, granulomatous hepatitis, cholestatic reactions, vascular lesions, and hepatic tumors.
- Although characteristic "signature" patterns are observed with some drugs, others are associated with diverse clinical syndromes.
- Although the liver biochemistry profile may aid initial evaluation, liver biopsy remains the gold standard for defining the type and extent of drug-induced liver disease.
- Pathogenic mechanisms underlying hepatotoxicity include dose-dependent injury, metabolic idiosyncrasy, and immunoallergic reactions. The latter may be part of the reactive metabolite syndrome, a multisystem disorder with hallmarks of hypersensitivity.
- Supportive measures remain the cornerstone in managing patients with drug-induced liver disease. Early recognition of drug toxicity and immediate withdrawal of the offending drug are critical. With the exception of *N*-acetylcysteine, there are no specific antidotes. Corticosteroids are not routinely recommended but may be valuable in select cases showing pronounced hypersensitivity characteristics (e.g., allopurinol). Anecdotal evidence favors the use of ursodeoxycholic acid in the setting of protracted cholestasis. Early consultation with a liver transplantation center is mandatory for individuals developing progressive impairment of liver function.
- Serial liver test profiles are often recommended to facilitate early detection of liver injury. However, with few exceptions, the sensitivity and cost-effectiveness of this approach remains untested.

- Clinical evaluation of symptoms that could be drug related is critical in facilitating early detection, and subsequent drug discontinuation is the key to preventing adverse outcomes.
- Herbal hepatotoxicity and use of recreational drugs (of abuse) should now be considered in the differential diagnosis of all liver disorders.

Introduction

Terminology and Definitions

Hepatotoxicity is liver injury caused by foreign compounds (*xenobiotics*). These include prescribed and nonprescribed therapeutic agents (*drugs*), including herbal medicines, and a vast array of other organic and inorganic substances that may be ingested deliberately or accidentally and that may contaminate the environment, workplace, or home. Therefore, xenobiotics include pesticides, herbicides, plant, fungal, and microbial products, each of which may have toxic and/or carcinogenic properties. The present chapter concentrates on *drug-induced liver injury*, in which hepatotoxicity is caused by drugs used either in medical practice or those used by individuals for therapeutic, nutritional, or recreational purposes; the latter including drugs of abuse. Although passing reference is made to other hepatotoxins, the interested reader is referred to more detailed texts for a comprehensive coverage of environmental and industrial hepatotoxicity (1,2).

Injury to the liver is largely defined by increased blood levels of proteins that are liberated from damaged hepatocytes; a typical example is alanine aminotransferase (ALT). To implicate a drug as the cause of ALT level elevation we need to know that (a) there is no other hepatic process that could account for the test abnormality (e.g., steatosis), (b) the logistics (particularly the temporal relationships) relating drug intake

and liver test abnormality are consistent and compelling, and (c) elevation of ALT level really means that the liver is injured. There is often a considerable amount of uncertainty in each of these three areas; some practical implications will be dealt with in "Hepatic Adaptation" (physiologic responses by the liver when exposed to drugs) and "Diagnosis".

We have avoided the term *hepatic dysfunction* in this text because of its confusion between injury, adaptation, and indices that truly reflect the functions of the liver. Likewise, the pathologically meaningless term *transaminitis* (an ALT level elevation without histologic evidence of liver inflammation or cell damage) is not used. When the presence of a major (fivefold or greater) elevation in the level of ALT clearly indicates liver injury, or when one or more of the *functions of the liver* are abnormal (e.g., low levels of plasma proteins such as albumin and clotting factors synthesized by the liver or clinicopathologic evidence of impaired bile flow [*cholestasis*]), it is *highly probable* that a drug to which the person has been exposed is the cause of liver disease. Ideally, however, definition of *drug-induced liver disease* requires histopathologic characterization rather than syndromic recognition of liver test abnormalities. Although the distinction between injury and disease is sometimes artificial because they clearly overlap, it is maintained, wherever possible, in this chapter so as to provide insights into the clinical significance of hepatic adverse drug reactions.

As new drugs emerge, the evidence that they induce liver injury is often weak and circumstantial; it is sometimes hotly debated because of the implications for further use and marketing of valuable therapeutic agents or for medicolegal implications (3). To partly meet the challenge of possible newer types of drug-induced liver disease that are not yet well defined as reproducible entities, we have included a section "Emerging Drugs" at the end of this chapter. Another definitional challenge is that drugs may sometimes alter physiologic parameters that have an impact on hepatic viability. In particular, some drugs can profoundly reduce hepatic blood flow and oxygen delivery, induce hyperthermia, or modify arterial supply to major bile ducts, each of which can result in liver injury that may be minor or profound. Cocaine, general anesthetic agents, alcohol, intra-arterial floxuridine, and "ecstasy" are agents that most likely produce liver injury by such indirect mechanisms rather than by direct hepatotoxicity or *adverse drug reactions*.

Another challenge in defining drug-induced liver disease is the increasing number of circumstances in which drug ingestion appears to contribute to chronic liver disease or hepatic tumors, as discussed in later sections. The lead time ("latent period") to onset or diagnosis of such associations is many months or years. As a result, repeated observations and case–control studies are essential to ensure that they are not chance associations, while experimental evidence from laboratory or animal studies are desirable to invoke biologically plausible mechanistic explanations for this type of effect of the drug on the liver.

Therefore, there is no "gold standard" by which drugs can be proved to have a unique etiologic role in liver disease, particularly because some of the disorders with which they are associated appear very similar or identical to syndromes associated with other causes.

Further, it is increasingly apparent that drugs may interact with each other or with other hepatotoxins (particularly alcohol) as part of *interactive hepatotoxicity*, as well as with viruses (human immunodeficiency virus [HIV] and hepatitis B and C viruses), immune mechanisms (HIV/acquired immunodeficiency syndrome [AIDS] and bone marrow transplantation), and metabolic factors (nonalcoholic steatohepatitis [NASH]), to accentuate or cause liver injury. Such interactions may be exceedingly difficult to recognize or prove, and nearly impossible to quantify as "relative risk" by conventional epidemiologic techniques. The evidence implicating involvement of drugs in liver injury associated with more complex medical settings is discussed in a later section.

Dose-Dependent Hepatotoxicity and Hepatic Drug Reactions

Some agents possess a high degree of *intrinsic hepatotoxic potential*; they cause *dose-dependent liver injury* in humans and usually many other species. The history of industrial hepatotoxicity is replete with such examples, among which dimethylnitrosamine, carbon tetrachloride, tetrachloroethane, trinitrotoluene, phosphorus, tannic acid, and vinyl chloride are well known. Some early therapeutic drugs and anesthetic agents (arsenicals, chloroform) have also been assigned to this category, although older studies are inadequate in ascertaining causal mechanisms because viral hepatitis, hepatic perfusion, and tissue oxygenation could not be assessed by contemporary criteria. Among today's drugs, very few are *dose-dependent hepatotoxins* (Table 33.1). For those that are, as illustrated by acetaminophen, it is not the chemical structure of the parent drug that is responsible for liver injury but rather the production of chemically reactive metabolites that interfere with the integrity of the liver. It follows that for most dose-dependent hepatotoxins, a range of host factors predicate the amount of reactive (toxic) metabolites that accumulate, thereby determining the risk of liver injury for a given dose of the toxicant.

The vast majority (>95%) of drugs implicated as causing drug-induced liver disease are clearly *not* dose-dependent human hepatotoxins, although some of them (usually at high, *nonpharmacologic* doses) produce experimental liver injury. This relative "intrinsic hepatotoxic potential" tends to be roughly proportional to the risk of liver injury in humans (2); for a few agents there is also evidence that liver injury is partially dose dependent (e.g., perhexiline maleate, herbal medicines, tacrine, dantrolene, cyclophosphamide, sex steroids, and cyclosporine). However, the frequency with which such agents cause liver injury among those exposed is either low or extremely small, ranging from 0.5% to 2% with chlorpromazine and isoniazid (INH), through more typical rates of 1 to 10 cases per 100,000 persons exposed, to even lower rates (e.g., 1 case per 1,000,000 persons exposed) with minocycline, and some of the oxypenicillins and nonsteroidal anti-

inflammatory drugs (NSAIDs) (Table 33.2).

Table 33.1. Examples of Dose-Dependent Hepatotoxins

- Acetaminophen (paracetamol)
- Drugs used in cancer chemotherapy (especially those used with radiotherapy); cyclophosphamide, busulphan, bis-chlorethyl-nitrosourea
- Amodiaquine
- Hycanthone
- Carbon tetrachloride, dimethylnitrosamine, methylenedianiline
- Plant and fungal toxins: Pyrrolizidine alkaloids, aflatoxin
- Ethanol
- Metals: Copper, iron, mercury
- Bile salts

It is clear that for these rare, dose-independent, unpredictable, or *idiosyncratic drug reactions* to occur, it is the host response to the drug that often determines liver injury, not the dose or chemical structures of the agent and its metabolites. Idiosyncratic hepatotoxicity is difficult to reproduce in other species, and it is therefore hard to ascertain the pathogenetic mechanisms involved. Clinical recognition will always remain a challenge because most doctors will never encounter individual reactions or observe them more often than once or twice in a professional lifetime.

Two broad types of pathogenic mechanisms could account for idiosyncratic hepatic drug reactions. The first is "metabolic idiosyncrasy," in which pathways of drug metabolism or disposition favor drug accumulation or formation of toxic metabolites. The underlying determinants include pharmacogenetic variability of drug metabolism and expression of "antistress" and antioxidant cell defense pathways. The metabolic

idiosyncrasy concept now needs to be extended to consider ways in which the liver, a highly adaptable organ, normally counters the "stress" of potentially damaging chemicals. Therefore, using experimental toxicants, it has become evident that foreign compounds, drug metabolites, and resultant oxidative stress can stimulate or interrupt intracellular signaling pathways that converge on the target genes involved in stress responses, cell death, or cell cycle regulation. Alternatively, they may directly activate transcriptional regulators to the same effect or more indirectly interfere with cell integrity and cell death pathways by their interactions with mitochondrial function and integrity; the latter includes the unique "guardian role" of mitochondria for cell survival, as well as in energy generation. As discussed in Chapter 8, drugs can alter the regulation of adenosine triphosphate (ATP)-dependent transporters that actively pump drug metabolites out of liver cells, particularly through canalicular pathways that are physiologically engaged in the generation of bile. Finally, drugs, reactive metabolites, and oxidative stress can interact with the cytoskeletal determinants of cellular transport, receptor signaling, and cell–cell communication (discussed further in Chapter 34).

Table 33.2. Frequencies of Some Types of Idiosyncratic Drug-Induced Liver Diseases

Frequency[a]	Drugs
5–20/1,000 exposed	Isoniazid, chlorpromazine, dantrolene
1–2.5/10,000 exposed	Estrogen-induced cholestasis
0.5–20/10,000 exposed	Ketoconazole
1–10/100,000 exposed	Diclofenac, sulindac, phenytoin, flucloxacillin
0.5–3/100,000 exposed	Amoxicillin–clavulanate, nitrofurantoin, terbinafine, dicloxacillin
≤1–10/1,000,000 exposed	Minocycline

[a]Based on published data referred to in the text.

The alternative pathogenic mechanism underlying idiosyncratic hepatic drug reactions is an "immunoallergic" response. This refers to classical "hypersensitivity" in the sense that repeated exposure results in an

exaggerated and unhelpful tissue-based or systemic injurious inflammatory response. Immunoallergic reactions are even less well understood than metabolic idiosyncrasy for their role in drug-induced liver disease. The possible immunologic mechanisms are reviewed elsewhere (4,5). Some may be examples of drug-induced autoimmunity in which the liver is the principal organ involved, implying that the drug (or its metabolites) induces immune dysregulation (6). Syndromes of chronic hepatitis with hyperglobulinemia and autoantibodies (e.g., with nitrofurantoin, minocycline or diclofenac) are examples of such an immune-based mechanism. There is increasing evidence that, for a subset of reactions, reactive metabolites are involved in recruiting inflammatory mechanisms, either as haptens or with molecular mimicry (7). Regulation of hepatic cytokines may also be important, as shown by studies of drug hepatotoxicity in mice with targeted disruptions of interleukin (IL)-4, IL-10, or cyclo-oxygenase 2 (COX-2) mediators that help prevent allergic hepatitis (5). Recruitment of eosinophils to the liver in the later stages of idiosyncratic drug reactions may depend on the expression of the chemokine, eotaxin (8).

It is often not possible to clearly distinguish between these apparently diametrically different causative mechanisms. They may often overlap, particularly because hepatic inflammatory reactions appear to evoke the liver's own innate immunity, as seen by the presence of liver lymphocytes and activated Kupffer cells (resident macrophages). Ultimately, it is most likely that the principal factors predicating idiosyncratic drug reactions are *genetically determined* (4,9,10,11,12,13); this provides a challenge for future studies directed at prevention and for timely interventions to avoid the adverse clinical outcomes that are unacceptably common for some agents and reactions (see "Improving Outcomes").

The Importance of Drug-Induced Liver Disease

The importance of drug-induced liver disease is summarized in Table 33.3. The pertinent factors are the disproportionate importance and potential preventability of serious hepatic adverse drug reactions in older

people. Some newer aspects include the potential of drugs to produce synergistic hepatotoxicity in persons with, for example, viral hepatitis, HIV/AIDS, and NASH; this is discussed later in relation to interactive hepatotoxicity and interactions with alcohol. The low frequency of reactions for a host of commonly used drugs can delay recognition of drug-induced liver disease; the resultant continued ingestion of the causative agent is the single most important determinant of adverse outcome. In addition to the key responsibility of physicians to make an early diagnosis and stop patients' exposure to potentially implicated agents, they have moral, ethical, and medicolegal responsibilities to prevent, mitigate, and report iatrogenic disease.

Table 33.3. Factors that Contribute to the Importance of Drug-Induced Liver Disease

- Approximately 6% of all adverse drug reactions
- Higher frequency among severe adverse drug reactions
- Most frequent cause for postmarketing withdrawal of medications
- Preventable or correctable cause of acute and chronic liver disease
- Approximately 5% of cases of jaundice or acute hepatitis in the community
- Higher proportion (10%–40% depending on age) of cases of hepatitis admitted to hospital
- Important cause of acute liver failure (>50% of cases in the United States; 36% from acetaminophen, 16% idiosyncratic hepatic drug reactions)
- Common cause of undiagnosed liver injury, particularly among persons aged >50 years.
- More than 300 currently used drugs cited in literature as potential causes
- Low frequency of liver injury leads to cases often being overlooked and difficulty in attributing causality
- One agent may cause more than one pattern of drug-induced liver disease
- Critical importance of early diagnosis and stopping drug exposure to avoid progression and poor outcomes
- Poor understanding of pathogenic mechanisms makes reactions difficult to predict and prevent
- Role of drugs in synergistic hepatotoxicity with viral hepatitis, nonalcoholic steatohepatitis, human immunodeficiency virus/acquired immunodeficiency syndrome, and bone marrow or organ transplantation
- Moral/ethical responsibility to prevent or minimize iatrogenic disease
- Medicolegal implications of this responsibility (informed consent, practice standards, due diligence, etc.)

The increasing number of pharmacologic agents for which adverse hepatic drug reactions have been described is a major challenge for clinicians (2,9,14,15,16,17,18,19,20). In addition to case recognition, this invokes consideration of what level of patient information should be regarded as appropriate at the time of prescribing drugs, and how this information should be imparted to the consumer.

Diversity of Clinical Expression

Drugs have become the greater mimickers of "natural" liver diseases. Therefore, hepatic drug reactions range from nonspecific abnormalities of liver tests (which may represent minor degrees of liver injury or hepatic adaptation), through clinicopathologic features of cholestasis, acute hepatitis, and acute liver failure, to more

exotic syndromes such as hepatic sinusoidal or venous outflow obstruction syndromes, nodular regenerative hyperplasia (NRH), chronic hepatitis resembling autoimmune hepatitis (AIH), hepatic fibrosis, NASH, cirrhosis, and benign or malignant liver tumors. It therefore remains crucial that physicians should always consider a possible drug etiology or some other type of hepatotoxicity, irrespective of the pattern of liver injury. A common pitfall is to impute causality to known causes of liver disease that happen to be present (hepatitis C virus [HCV], alcohol, and gallstones are common "confounders") in what are actually cases of drug-induced liver disease. Another challenge is the propensity of some drugs to cause more than one clinicopathologic syndrome of liver injury; examples such as oral contraceptive steroids (OCSs), diclofenac, and nitrofurantoin are discussed later.

Epidemiology and Risk Factors

Epidemiology

In discussing how commonly a drug causes liver injury, it is important to note that the term "incidence" (the number of new cases in a period of time) is not particularly helpful because the onset of adverse drug reactions is nonlinear with time; they tend to occur within the first few weeks or months of treatment. A better descriptor is the proportion of persons exposed to the agent who develop the reaction. This proportion is best described by the *frequency of the reaction* within the affected group; the latter is expressed ideally as the number of persons exposed, but surrogate estimates are often used, such as the number of prescriptions written or the number of person-years of drug ingestion. Other estimates of the frequency of adverse drug reactions or risk of hepatotoxicity come from prescription event monitoring or record linkage conducted prospectively by health maintenance groups and from case–control studies. More commonly used methods include voluntary (or mandated) reporting of reactions to agencies that monitor adverse drug reactions or drug manufacturers. However, this approach is weakened by the inherent inaccuracies of case definition and the vagaries of case documentation, factors that depend on the skill and motivation of observers.

Drugs that carry a high frequency of liver injury are usually recognized as hepatotoxic during phase III trials, which typically involve hundreds or a few thousand persons, or during the first 2 years of postmarketing surveillance (which may involve hundreds of thousands or millions of subjects) (3). Fialuridine, bromfenac, and troglitazone are recent examples of agents withdrawn because of a high frequency of severe liver injury. More often, the recognition of drug-induced liver disease comes several years after the release of a new agent, often with a flurry of case reports, small series, and analyses of larger repositories of information held by drug-monitoring authorities or pharmaceutical companies. More recent examples include amoxicillin–clavulanate, oxypenicillins, diclofenac, sulindac, and troglitazone (21,22,23). Such "miniepidemics" serve principally to highlight how often early reactions to the implicated agents may have been overlooked, or they evolve from massive prescribing of the vigorously marketed new drugs; the latter phenomenon is illustrated by hepatic reactions to flucloxacillin in Australia, where the number of prescriptions written per million people greatly exceeded that of any other country (24).

Reliable information about the risk of liver injury is available for less than 20 of the 300 or so currently used drugs that have been implicated as possible or likely causes of drug-induced liver disease. Some of these data are summarized in Table 33.2. It is reiterated here that a significant issue confounding the epidemiology of this type of disorder is the lack of diagnostic accuracy in defining cases of drug-induced liver disease. As discussed in the next section, this depends entirely on probabilistic evidence surrounding the onset of the

reaction and its resolution or recurrence in relation to drug exposure, the elimination of other known causes of similar hepatobiliary disease, and occasionally on ancillary evidence of an adverse drug reaction.

When drugs contribute to but are not the unique cause of liver disease, it may be possible to assign a relative risk for this complication. This has been attempted in the case of OCS and liver tumors (25,26), OCS and hepatic venous outflow obstruction (27) (see Chapter 40), aspirin and Reye's syndrome (28), and methotrexate and hepatic fibrosis among those who drink appreciable quantities of alcohol (29). Future attempts at providing similar semiquantitation of the risks of drug-induced hepatotoxicity within "high-risk" scenarios should be directed at the use of antiretroviral agents for HIV/AIDS, and tuberculosis or cancer chemotherapy among persons with chronic hepatitis B or C infection.

Risk Factors for Incidence and Severity

The factors that increase the risk of drug-induced liver injury may include dose, duration of treatment, blood levels, age, gender, coincidental metabolic disorders or genetic predisposition to hypersensitivity reactions, concomitant exposure to other drugs or environmental agents, and underlying liver disease. Some examples are summarized in Table 33.4, while further details are given in later sections concerned with individual drugs. A recurring theme is the relationship between failure to recognize a given drug as the possible cause of the patient's symptoms, the resultant failure to discontinue exposure to that drug, and subsequent development of severe hepatotoxicity, often with liver failure and lethal consequences.

Table 33.4. Risk Factors for the Incidence and Severity of Drug-Induced Liver Diseases

Risk factor	Representative agents	Importance

Age	Isoniazid, nitrofurantoin, halothane, troglitazone	Age >60 y increases frequency and severity
	Valproic acid, salicylates	More common in children
Gender	Halothane, minocycline, nitrofurantoin, dextropropoxyphene	More common in women, especially chronic hepatitis
	Amoxicillin–clavulanate, azathioprine	More common in men
Dose	Acetaminophen; some herbal medicines	Risk of hepatotoxicity depends on blood levels
	Anticancer drugs; perhexiline, tacrine, oxypenicillins, dantrolene	Partial relationship to dose
	Methotrexate, vitamin A	Total dose, dose frequency, and duration of exposure influence risk of hepatic fibrosis
Genetic factors	Halothane, phenytoin, sulfonamides	Multiple cases in families, in vitro test results
	Amoxicillin–clavulanate	Strong human leukocyte antigen association
	Valproic acid	Familial cases, association with mitochondrial enzyme deficiencies
Other drug reactions	Isoflurane, halothane, enflurane	Cross-sensitivity reported between these classes of drugs
	Erythromycin, other macrolide antibiotics Diclofenac, ibuprofen Sulfonamides, cyclo-oxygenase 2 inhibitors	
Concomitant drugs	Acetaminophen	Isoniazid, zidovudine, and phenytoin lower hepatotoxic dose threshold and increase severity
	Valproic acid	Other anticonvulsants increase risk
Excessive alcohol use	Acetaminophen hepatotoxicity	Lowers dose threshold, worsens outcome
	Isoniazid, methotrexate	Increases risk of liver injury, hepatic fibrosis
Nutritional status		

Obesity	Halothane, tamoxifen, methotrexate	Increases risk of liver injury, nonalcoholic steatohepatitis, or hepatic fibrosis
Fasting	Acetaminophen	Increases risk of hepatotoxicity
Liver disease	Hycanthone, pemoline Antituberculosis chemotherapy, ibuprofen	Increases risk of liver injury Increases risk of liver injury with chronic hepatitis B and C
Other diseases		
Diabetes mellitus	Methotrexate	Increases risk of hepatic fibrosis
Human immunodeficiency virus/acquired immunodeficiency syndrome	Sulfonamides (cotrimoxazole)	Increases risk of hypersensitivity
Renal failure	Tetracycline, methotrexate	Increases risk of liver injury, hepatic fibrosis
Organ transplantation	Azathioprine, thioguanine, busulfan	Increases risk of vascular toxicity

Genetic factors

It seems likely that host predisposition to idiosyncratic hepatic drug reactions is genetically determined (10,11,12,13). The relatively small number of instances in which familial clustering has been documented may reflect the dual requirements for altered expression of relevant genes and for exposure to particular drugs; halothane, OCS cholestasis, valproic acid (VPA), and phenytoin reactions are those for which more than one case has occured in the same family (14). Phenytoin is an example of the reactive metabolite syndrome (RMS) pattern of severe skin reactions often associated with systemic involvement, among which drug-induced liver disease is common (30). Some of the causative agents, risk factors, and clinical features are summarized in Table 33.5. Individuals have a 25% likelihood of developing adverse drug toxicity if a first-degree relative has experienced a similar reaction; the chances are even higher with other risk factors such as HIV/AIDS, systemic lupus erythematosus (SLE), and antecedent intake of VPA or corticosteroids (Table 33.5).

In addition to determining the expression and inducibility of CYP pathways of drug oxidation, conjugation reactions, and antioxidant enzymes (see Chapter 34), genetic factors encode ATP-dependent pathways of drug elimination from hepatocytes, through the canalicular membrane into bile or through the basolateral membrane into sinusoidal blood (31,32). Regulation of the immune response (presumably including hepatic innate immunity) is also genetically determined, and other critical genes encode the structure of the cytoskeleton, heat shock proteins, and cellular resistance against activated cell death pathways. These are all variables in the pathogenesis of drug-induced liver injury (see Chapter 34). Characterization of the genes that are involved in hepatic reactions to clinically relevant agents provides an outstanding challenge in the field of drug-induced liver disease, as reviewed elsewhere (5). The likelihood that more than one "abnormality" (e.g., genetic polymorphisms, extreme variation) is required before tissue-destructive responses occur would explain the rarity of most reactions. It is already known that inherited defects of mitochondrial metabolism clearly predispose to valproate hepatotoxicity (33) (See "Valproic acid (sodium valproate)"), and there are strong associations between human leukocyte antigens (HLAs) and cholestatic drug reactions to amoxicillin–clavulanate and tiopronin (34,35,36). Weaker associations between HLA molecules and particular types of drug hepatitis have also been reported (37).

Age and sex

The frequency and severity of hepatic drug reactions both increase with age (Table 33.4). The explanations are likely to be multifactorial and include increased exposure; higher probability of multiple drug therapy; biologic effects of aging on drug disposition, especially altered hepatic uptake as the result of decreases in blood flow; and/or diffusion of drugs across the hepatic microvasculature into hepatocytes (38). Some of the many examples of drug reactions that are more common in older people are listed in Table 33.4. Conversely, a small number of drug-induced liver diseases

are more common in children, particularly those that involve mitochondrial injury, such as VPA hepatotoxicity and Reye's syndrome.

Table 33.5. The Reactive Metabolite Syndrome and Hepatic Drug Reactions

Drugs implicated	Risk factors	Clinical and laboratory features
• Sulfonamides • Clozapine • Anticonvulsants (e.g., phenytoin, lamotrigine, phenobarbital, carbamaze pine) • Some nonsteroidal anti-inflammatory drugs • Aminopenicillins • Chinese herbal medicines • Quinolones • Protease inhibitors (e.g., nevirapine, abacavir) • Allopurinol • Minocycline	• First-degree relative with serious rash to same drug (one in four risk), or metabolically cross-reacting drug • Human immunodeficiency virus/acquired immunodeficiency syndrome (100-fold increased risk) • Systemic lupus erythematosus (10-fold increased risk) • Corticosteroids at time of starting drug (4.4-fold increased risk) • Valproic acid at time of starting new anticonvulsant (4- to 10-fold increased risk)	• Onset: 1–6 wk (up to 12 wk) • Sentinel symptoms: Fever, pharyngitis, malaise, headache, periorbital edema, otalgia/ headache, mouth ulcers, rhinorrhea • Serious rash: Erythematous, Stevens-Johnson syndrome, toxic epidermal necrolysis, erythema multiforme • Lymphadenopathy (16%), splenomegaly • Hepatic reactions: Cholestasis, hepatitis, granulomas (13%) • Nephritis (9%) • Pneumonitis (6%) • Hematologic (neutropenia, thrombocytopenia) (5%) • Encephalitis/meningitis (5%) • Myositis (4%) • Colitis (2%) • Arthritis, transient hypothyroidism • Blood tests: Neutrophilia (shift to left); atypical lymphocytes, acute-phase reactants (early); eosinophilia (often late)

Women are more likely than men to develop drug-induced hepatitis after exposure to nitrofurantoin, sulfonamides, diclofenac, minocycline, troglitazone, and halothane. Chronic hepatitis caused by the first four of these agents (and historically with methyldopa and oxyphenisatin) has an even higher (80% to 90%) female predominance. Some cholestatic reactions are more common in men (Table 33.4); these include amoxicillin–clavulanate- and azathioprine-induced vascular injury in transplant recipients. The reasons for sex differences in some hepatic drug reactions remain unclear.

Exposure to other drugs and toxins

Patients taking more than one agent have an increased risk of adverse drug reactions, including drug-induced liver disease (14,39,40,41,42,43). Particularly relevant examples include acetaminophen, INH, VPA, and anticancer drugs (44). A possible relationship between agents that alter canalicular bile pathways has also been indicated, including interactive hepatotoxicity between OCS and other drugs to produce prolonged cholestatic reactions (45).

Chronic excessive intake of ethanol is a risk factor for hepatotoxicity with acetaminophen, INH, nicotinamide, and methotrexate.

Nutritional status

Fasting predisposes to acetaminophen hepatotoxicity because of its effects on drug conjugation and oxidation pathways, as well as on hepatic glutathione (GSH) levels. It has also been proposed that malnutrition increases the risk and severity of hepatotoxicity from drugs used to treat tuberculosis (46), but controlled studies are lacking. Overnutrition (obesity) increases the risk of halothane hepatitis. The increased risk of NASH and hepatic fibrosis among those taking methotrexate, estrogens, tamoxifen, or corticosteroids (Table 33.4) is discussed later.

Past history and other medical disorders

Instances of cross-reactivity to similar agents are reported with haloalkane anesthetics (e.g., halothane, enflurane, isoflurane), INH and pyrazinamide, sulfonamides and some COX-2 inhibitors, some NSAIDs, and macrolide antibiotics. Such cross-reactivity is surprisingly uncommon, but a history of any previous adverse drug reaction increases the risk of drug-induced liver injury to other agents. It is again emphasized that *a previous reaction to the same drug* is the single most important factor predisposing to unusual severity of

drug-induced hepatitis (e.g., acute liver failure, chronic liver disease).

Renal failure predisposes to methotrexate-induced hepatic fibrosis and tetracycline-induced fatty liver, while renal and other solid organ transplantation is a risk factor for hepatic vascular injury with azathioprine. Likewise, disorders associated with hepatic venous outflow obstruction, such as veno-occlusive disease (VOD) (now termed the *sinusoidal obstruction syndrome* [SOS]; the terms *VOD* and *SOS* are used interchangeably in this chapter), are attributed to cancer chemotherapeutic agents prescribed during bone marrow transplantation (as well as with radiotherapy) (47). Rheumatoid arthritis, and possibly SLE, appears to increase the risk of salicylate hepatotoxicity and sulfasalazine-induced hepatitis. The risk of drug reactions (including hepatitis) to both sulfonamides and sulfones is greatly increased among persons with HIV/AIDS and also in SLE (Table 33.5), while diabetes (as well as obesity, alcohol, renal failure, and preexisting liver disease—see subsequent text) predisposes individuals to hepatic fibrosis during methotrexate therapy.

Preexisting liver disease

Early studies of chlorpromazine, halothane, and methyldopa reactions clearly demonstrated that other liver disorders, including alcoholic cirrhosis and cholestatic liver diseases, did not predispose to these archetypical examples of idiosyncratic drug hepatitis. On the other hand, for a few agents in which partial dose dependency or metabolic mechanisms appear likely, preexisting liver disease may be a risk factor for incidence and severity of drug-induced liver disease (Table 33.4). These drugs include nicotinamide (niacin), hycanthone, pemoline, and some anticancer drugs (48,49,50,51). The risk of methotrexate-induced hepatic fibrosis is also increased in the presence of other forms of liver disease (52). More recently, interactions between inflammatory forms of liver disease, particularly chronic viral hepatitis, and accentuation of liver injury have been described, including an apparently heightened risk of reactions to antituberculosis chemotherapy, ibuprofen, flutamide, cyproterone acetate, and highly active anti-retroviral treatment (HAART) (53,54,55,56,57,58,59).

Toward Better Outcomes

Prevention

Given the central role of the liver in drug metabolism and disposition, and the rarity of most types of liver injury with what are otherwise valuable therapeutic agents, it is impossible to completely prevent all cases of drug-induced liver disease. General approaches to

primary prevention include appropriate use of drugs (nonpharmacologic approaches whenever possible, optimal choice of agents based on efficacy and safety, case selection, avoiding polypharmacy where possible, avoiding excessive dosage), restricted availability and blister packaging of over-the-counter medication (See "Acetaminophen") (60), physician and public education about possible drug side effects and about how to recognize and what to do about them, and monitoring for adverse drug reactions. Conveying appropriate recommendations about dose limitations for agents such as acetaminophen, nicotinamide, and complementary and alternative medicines (CAMs) would prevent many instances of liver injury.

Careful adherence to dosage guidelines (or use of blood levels) has virtually abolished methotrexate-induced hepatic fibrosis (See "Methotrexate"), tetracycline-induced mitochondrial injury, and aspirin hepatitis. Avoiding repeated halothane administration within 28 days or in people with suspected previous halothane sensitivity would prevent many cases of this serious form of drug-induced hepatitis.

For select agents with known hepatotoxicity, and particularly when treatment is likely to extend for longer than 2 to 4 weeks, it may be appropriate to first establish that the liver test results are normal before starting treatment and then estimate liver tests (liver function test [LFT]) or conduct other safety monitoring during therapy. However, although such "LFT monitoring" is often suggested as one approach to prevent serious outcomes of drug-induced liver disease (particularly by authors of single case reports and by manufacturers who share liability in litigation cases), there is little evidence to support this as a general policy (61,62). Therefore, the high costs and inconvenience of such screening, the need to determine appropriate testing intervals (4 weeks is usually too long for agents that can cause acute liver failure), the weak specificity of abnormal results for identifying serious hepatotoxic potential, and the difficulty of defining a threshold at which the drug should be discontinued all thwart the logistics of monitoring drug treatment with liver tests. It particularly needs to be appreciated that 7.5% of subjects receiving placebo in clinical trials have persistently raised ALT levels (63). In the absence of symptoms, it is difficult to specify a level of ALT abnormality at which treatment should be discontinued. It is generally recommended that the drug should be stopped if ALT exceeds five times the upper limit of normal (ULN) (approximately 250 U/L), but any abnormality of serum bilirubin or albumin concentration or prothrombin time and the presence of any symptoms are clear indications to stop therapy.

In practice, there are few agents for which liver test monitoring is strongly endorsed (see also later sections); these include methotrexate, INH, etretinate and other synthetic retinoids, ketoconazole, anticancer drugs, and prolonged therapy with minocycline. Conversely, the "statins" (β-hydroxy-β-methylglutaryl-coenzyme A reductase inhibitors) are a group of commonly used drugs that rarely cause significant liver injury (62,64), and for which the recommendation (by the manufacturers) for LFT monitoring is now being seriously questioned.

Management

The most important aspect is early recognition and discontinuation of the putative causative agent. At each visit, patients should be warned to report any untoward new symptoms, and particularly fever, systemic symptoms (malaise—"I don't feel these tablets agree with me, doctor"; see also the sentinel symptoms listed in Table 33.5), anorexia, nausea, and vomiting. If patients present after jaundice has developed, it is often too late to avoid a severe reaction because of the potential for developing liver failure or prolonged cholestasis. When patients report symptoms of a possible drug reaction, physicians should immediately check liver test results to establish whether there has been a change from baseline; in cases of doubt, the agent should be discontinued.

After drug discontinuation, most adverse drug reactions will resolve spontaneously, rapidly, and completely, but this is not always the case. Drugs with a prolonged half-life are particularly associated with protracted hepatic drug reactions. Amiodarone, etretinate, ketoconazole, and hypervitaminosis A are examples, but delayed resolution of liver injury can occur with several other drugs on some occasions. In case of severe reactions, hospitalization is advisable, and further evaluation is carried out if the diagnosis is unclear. Otherwise, relief of symptoms is all that is required. As for any type of hepatic injury, older age carries an increased risk of severe liver injury. Repeated vomiting, deepening jaundice, and development of even subtle laboratory or clinical features of liver failure are indications for admission. Transfer to a liver failure unit should be considered and/or discussions with a liver transplant team should be initiated before the patients decline into hepatic coma, or have bleeding from coagulation disorder, sepsis, and hepatorenal failure.

In cases of dose-dependent hepatotoxicity, approaches to management include testing for drug levels and monitoring the clinical condition of the poisoned person. Attempts to remove unabsorbed drug by aspiration of stomach contents should be considered for agents such as acetaminophen, metals, and toxic mushrooms; other approaches (administration of charcoal or other resins or osmotic cathartics) are generally unlikely to be effective, although they have been advocated

for poisoning with toxic mushrooms (65). Likewise, approaches to remove residual drug from the body, such as using chelating resins for drugs with an enterohepatic circulation (66) or by hemodialysis, passage of blood through charcoal columns, or forced diuresis are not effective for most hepatotoxins.

Acetaminophen hepatotoxicity is the only drug-induced liver disorder for which a specific antidote (*N*-acetylcysteine [NAC]) is available (67). Two agents that have been proposed to control protracted hepatic drug reactions are corticosteroids and ursodeoxycholic acid. There are few clear guidelines for their use, and the evidence of efficacy is confined to uncontrolled reports among individual cases or in small series. Older studies with corticosteroids found limited or no efficacy among cases of severe drug hepatitis for methyldopa, iproniazid, INH, chlorpromazine, halothane, phenytoin, and oxyphenisatin (14). More recent observations indicate occasional responses, particularly when drug-induced liver injury is associated with vasculitis (e.g., allopurinol, sulfonamides) and in some (but not all) cases of drug-induced chronic hepatitis (14). A pragmatic approach is to observe the course for 3 to 6 weeks after stopping the drug (unless there is evidence of further deterioration), reserving corticosteroids for cases in which there is failure to show clinical or biochemical improvement or in which the differential diagnosis between AIH and drug-induced chronic hepatitis remains in doubt.

Some experienced clinicians still favor a short course of corticosteroids ("steroid whitewash") to hasten recovery in persons with prolonged drug-induced cholestasis. If the mechanistic basis for such efficacy can be established (stimulating reexpression of the canalicular transporters responsible for bile flow would be a possible example), a firmer conceptual basis or more appropriate pharmacologic agents to stimulate a clinical resolution may become possible. Meanwhile, corticosteroids have a range of unpleasant or severe side effects, and our preference would be to use ursodeoxycholic acid (15 mg/kg body weight) in such cases. There is a reasonable body of uncontrolled data to indicate that approximately two thirds of such cases will respond with reduction of pruritus and other symptoms and acceleration of biochemical improvement. Ursodeoxycholic acid is safe, well tolerated, and has been used with occasional success in patients presenting with cholestatic liver injury attributed to amoxicillin–clavulanate, flucloxacillin, and flutamide (68,69,70,71), as well as cyclosporine (which is not a form of cholestasis) (72). Other approaches to treating pruritus are discussed (73) in Chapter 24. During prolonged cholestatic reactions, fat-soluble vitamin deficiency should be corrected.

Diagnosis of Drug-Induced Liver Disease

Diagnosis of drug-induced liver disease is always presumptive because it is based on a logistic approach rather than on absolute criteria and specific diagnostic tests. As a result, there will be varying degrees of certainty about the diagnosis, depending on the strength of supporting evidence. In estimating the likelihood of diagnosis ("causality assessment") (74,75), evidence is sought by first determining whether the link between drug ingestion and liver injury is plausible, then by excluding other disorders and seeking the presence of any positive features of adverse drug reactions, and finally by assessing features indicative of the liver histology. Attempts have been made to compile these lines of evidence into diagnostic "scales" that give weight to various features (76,77). Regrettably, these fall down in relation to less common or atypical types of drug-induced liver disease, which are those most difficult to diagnose. They have particular limitations for cases with a long delay between the start of drug ingestion and recognition of liver injury (74,77).

Clinical Suspicion

Some situations in which drug-induced liver disease may be particularly likely are summarized in Table 33.6. In such cases, meticulous attention should be paid to the drug history, returning to it as a special investigation, with consideration of nonprescribed medications, CAM, and environmental toxins. It may be pertinent to direct inquiry to other members of the household and primary care providers and to examine all medications being taken or even the contents of drug cupboards, bedside tables and lockers, and so on.

Time of Onset in Relation to Drug Ingestion

Dose-dependent hepatotoxins usually produce overt evidence of liver injury within hours or a few days (See "Acetaminophen"). For adverse hepatic drug reactions, there is a *latent period* between commencing the drug and the development of symptoms and/or abnormal liver test results. With immunoallergic types of drug hepatitis, granulomatous hepatitis, and drug-induced cholestasis, this is within 4 months (most typically 2 to 10 weeks) in more than three quarters of cases. Occasionally, liver injury becomes evident only after the drug is stopped; for amoxicillin–clavulanate this may be up to 6 weeks after discontinuation. With other types of drug hepatitis (presumed to be instances of metabolic idiosyncrasy), the latent period to onset tends to be a little longer, often between 6 and 26 weeks, and with drug-induced chronic liver disease (e.g., chronic hepatitis, steatohepatitis, and syndromes related to

vascular injury), drug exposure may be for 6 months or longer than 1 year before clinical onset is apparent.

Table 33.6. Some Situations in which Drugs are a Particularly Likely Cause of Liver Disease

- The person has started new treatment (including CAM) in last 3 to 6 m
- Presence of extrahepatic manifestations, especially rash, lymphadenopathy, eosinophilia (see also Table 33.5)
- Acute hepatitis not readily accounted for by hepatitis viruses, other infections, or metabolic or immunologic disorders
- There are atypical features of liver disease—mixed "hepatocellular and cholestatic" reactions, hepatitis with microvesicular steatosis
- Cholestasis with normal bile duct caliber on hepatobiliary imaging
- Cholestasis after common causes have been excluded, particularly in the elderly
- Histologic features suggest drug-induced liver disease (see text) in cases of cholestasis or acute hepatitis, and hepatitis with hepatic granulomas
- Chronic hepatitis without autoantibodies or hyperglobulinemia
- Abnormal liver tests in complex medical situations
- Obscure or poorly explained liver disease among those taking sex steroids, immunosuppressive agents, or other drugs (including CAM) for years

CAM, complementary and alternative medicine.

Exploring the *chronologic relationships* between drug ingestion and the onset and resolution of liver injury is the most important consideration in the diagnosis of drug-induced liver disease, as discussed elsewhere (74,75,78).

Repeated Drug Ingestion

Some drugs almost never cause liver injury after first exposure, but the risk of hepatotoxicity increases with each subsequent treatment course. Halothane, dacarbazine, and nitrofurantoin are recognized examples. For a much broader range of compounds, a personal history of previous reaction to the drug (*inadvertent rechallenge*) is common among those with severe or prolonged liver injury; INH, NSAIDs, Chinese herbal medicines, germander, and chaparral are typical examples.

To provide stronger evidence of causality, *deliberate rechallenge* has been used in the past, employing a single and smaller than usual dose of the suspected hepatotoxin; it has proved particularly valuable to incriminate agents not previously known to be associated with liver injury and to identify which agent is responsible when the person has been taking more than one potentially hepatotoxic drug. A positive response (connoted by a recurrence of fever or other symptoms and/or a twofold increase of ALT or serum alkaline phosphatase [SAP] levels) (78) strongly implicates the drug in causing liver injury. However, the practical application of rechallenge is greatly limited by safety considerations; it should never be conducted without the fullest consideration by both the persons involved and their family, and should be done with reference to an Institutional Human Ethics Review Board. Particularly, it should be noted that deliberate rechallenge is potentially dangerous and should never be attempted for the types of reactions listed in Table 33.5.

Response to Discontinuation of the Drug

Dechallenge should be followed by improvement in liver test results within days or weeks of stopping the drug; some guidelines have been provided (78). As for time to onset, there are clear exceptions to this generality. Therefore, in cases of liver disease caused by agents such as ketoconazole, troglitazone, coumarol,

etretinate, amiodarone, and minocycline, severe reactions may resolve slowly (months), or incompletely, with further decline of hepatic function (e.g., troglitazone). Although some instances of drug-induced cholestasis can also be prolonged, failure of jaundice to resolve in case of suspected hepatic drug reactions more often indicates that an alternative diagnosis (e.g., malignant biliary obstruction) has been missed.

Clinical Features

Although the clinicopathologic syndrome associated with exposure to a particular drug may be a useful aid to diagnosis, the diversity of reactions to individual drugs is such that absence of the "drug signature" (or "syndromic recognition") test should *not* be used to exonerate a given drug as the cause of liver injury. In most respects, the clinical features of drug hepatitis or drug-induced cholestasis are not dissimilar from those found with other causes of these disorders. However, identifying specific risk factors for hepatotoxicity (e.g., prolonged fasting or chronic excessive alcohol intake by a person regularly taking acetaminophen) or the presence of extrahepatic features of drug hypersensitivity (Table 33.5) may suggest the correct diagnosis.

Exclusion of Other Disorders

It is critical to exclude other liver diseases before attributing liver injury to drugs (Table 33.7). In an earlier work (79), approximately two thirds of reactions reported as drug-induced chronic hepatitis were subsequently ascribed to chronic hepatitis C. Contemporary

serologic, viral, immunologic, and imaging tests have facilitated the early diagnosis of most acute viral, vascular, and metabolic liver disorders. Likewise, the cause of cholestasis, and particularly mechanical obstruction of the biliary tract, is usually easy to identify with modern imaging (see Chapter 8). Approaches to make the correct diagnosis of a drug reaction when the clinical and laboratory features resemble AIH include the course of the disease after discontinuation of the drug and the patient's response to a short course (4 to 6 weeks) of corticosteroids if there is not rapid improvement after stopping the drug. If there is impressive response to the patient's condition with corticosteroids, followed by relapse after reducing the dose, it allows the physician to assume that the case is actually one of AIH.

Table 33.7. Drug-Induced Liver Disease is a Diagnosis of Exclusion: Consider the Following

- Hepatitis viruses: Serology and molecular virology (especially hepatitis C virus ribonucleic acid)
- Other infectious agents: Epstein-Barr virus, cytomegalovirus, human immunodeficiency virus, herpes simplex virus, *Coxiella burnetii*
- Autoimmune hepatitis: Antinuclear antibodies, smooth muscle antibodies, liver/kidney microsomal antibodies, immunoglobulin G levels
- Acute biliary obstruction, exclude cholangitis
- Metabolic disorders—Wilson disease, α_1-antitrypsin deficiency, risk factors for nonalcoholic fatty liver disease/nonalcoholic steatohepatitis (serum lipids, fasting blood glucose or abnormal glucose tolerance test, insulin, C peptide, family history of diabetes, features of the insulin resistance [metabolic] syndrome)
- Vascular disorders of liver; risk factors, imaging with vascular phase (see Chapter 8)
- Alcohol
- Bacterial infection
- Hepatic metastases
- Systemic malignancy or lymphoma

Liver Biopsy

Liver biopsy plays a special role in excluding other hepatobiliary disorders, but it may also provide positive evidence to corroborate drug-induced liver injury. Biopsy is most strongly indicated when the cause of liver disease remains in doubt; for example, there may be ambiguous evidence of autoimmunity or the pattern of reaction may be very unusual or not previously reported for the drug in question. Details such as whether continued treatment with this medication is highly desirable and whether there is rapid improvement after stopping the drug may influence the decision of performing liver biopsy. As for any indication, the justification for liver biopsy must satisfy the question "Does the likelihood that this procedure will make a difference to the management of the person justify the inconvenience, discomfort, and risks of the procedure?" Informed consent is clearly mandatory, and it may be valuable to document in the medical record (or on a signed consent form) why the biopsy is considered valuable in this particular case.

Table 33.8. Histologic Changes that may Indicate Drug-Induced Liver Disease

- Zonal lesions, including necrosis and/or steatosis
- Microvesicular steatosis (often results from mitochondrial injury)

- Necrotic lesions of disproportionate severity of the clinical picture
- Mixed hepatitis and cholestasis
- Destructive bile duct lesions
- Prominent neutrophils and (in later stages) eosinophils (>25%)
- Granulomas
- Vascularity of hepatic tumors—sinusoidal dilatation, peliosis
- Vascular lesions
- Florid steatohepatitis—resembles alcohol-related steatohepatitis more than typical "primary" nonalcoholic steatohepatitis

There are no histologic features that are pathognomonic for drug-induced liver disease, and indeed some, such as the presence of occasional eosinophils, are often overinterpreted. Nonetheless, some patterns of hepatic lesions may suggest, to an experienced liver pathologist, that a drug or toxin could be implicated (Table 33.8). The reader is referred to the excellent detailed illustrations found in texts such as Hall (80) and Zimmerman (2), as well as earlier editions of this book.

Specific Diagnostic Tests

As reviewed elsewhere (5,9), there are no completely validated specific tests for any type of drug-induced liver disease. Interesting data have been presented about the relative specificity of some drug-induced autoantibodies, including anti-M6 (antimitochondrial antibodies [AMAs]) with iproniazid, anti-LKM-2 (against CYP 2C9) with tienilic acid, anti-CYP 1A2 with dihydralazine, and anti-CYP 2E1 with halothane. A test that detects antibodies against trifluoroacetylated (TFA) proteins has been advocated for halothane and other haloalkane-related hepatotoxicity (see later section). However, all such tests have minimal applicability in clinical practice because of their unavailability and lack of standardization, including agreement on what comprises a significant titer of antibodies.

Identifying One Causative Agent Among Many

Having established with near certainty that one or more drugs are responsible for an individual case of liver disease, an additional challenge may be to identify which among several is the guilty party. In general, the drug started most recently before the onset of liver injury is the one most likely to be responsible; new and nonproprietary medicines should also heighten suspicion. Otherwise, the drug with the most hepatotoxic track record becomes the prime contender. Whenever possible, all therapeutic agents, or all potential hepatotoxins, should be discontinued. If the patient's condition and laboratory test results improve, the drug(s) that seem(s) unlikely to be responsible can be carefully reintroduced.

Clinicopathologic Syndromes of Drug-Induced Liver Disease

The initial "labeling" of cases with apparent drug-induced liver injury has relied heavily on the profile of liver test abnormalities (Table 33.9) and not histopathology, which provides a more definitive classification. It is noted here that the clinical and laboratory features are not always congruent with the liver pathology, and there is much overlap between categories. Therefore, although the histologic changes usually mirror the biochemical abnormalities, certain caveats should be borne in mind. *First*, alteration of liver enzymes is not synonymous with liver injury and can represent hepatocyte adaptation (see subsequent text). *Second*, liver tests may underestimate the severity of liver disease, as with the fairly modest changes in levels of aminotransferases (ATs) that may accompany acute liver failure from drug-induced microvesicular steatosis. Conversely, drugs such as estrogens can sometimes be associated with a major increase in ATs despite bland cholestasis on biopsy, while other agents (e.g., methotrexate, vinyl chloride, arsenic) can cause cirrhosis with minimal or no change in biochemical tests of liver disease. *Third*, the pattern of liver tests is most often mixed or relatively nonspecific, and this occurs with granulomatous hepatitis, steatohepatitis, cholestatic hepatitis, chronic hepatitis, and minor nonspecific patterns of liver injury.

A relatively simple approach to clinicopathologic classification of drug-induced liver disease is outlined in Table 33.10.

Hepatic Adaptation

Many drugs induce abnormal liver test results without causing symptoms or biochemical evidence of *significant* liver disease. Minor elevations in the levels of ALT may be transient. In reality, these may indicate minor degrees of nonprogressive injury to key organelles such as mitochondria or cell membranes, without causing cell death and without recruiting an inflammatory response. The nonprogression (and often resolution) of these changes may result from induction of protective processes, such as antioxidant and antiapoptotic pathways; in this sense, minor forms of chemical liver injury are probably often followed by adaptation of the liver to withstand continuing or more substantial insults. Experimental work has demonstrated the hepatoprotective effects of a small dose of carbon tetrachloride against subsequent massive poisoning and the

phenomenon of ischemic preconditioning that substantially abrogates subsequent ischemic or reperfusion injury; the mechanisms of these adaptive processes are of potential importance in the understanding of drug-induced liver disease.

Other forms of "hepatic adaptation" include drug-induced hyperbilirubinemia, as observed with agents such as rifampicin, flavaspidic acid, and cyclosporine, and "induction of hepatic enzymes." Drug-induced hyperbilirubinemia is best understood as a direct interference with pathways of bilirubin uptake, conjugation, and canalicular excretion into bile. Sustained elevation of levels of enzymes such as γ-glutamyl transpeptidase

(GGTP) and SAP is seen with phenytoin and other anticonvulsants, rifampicin, alcohol, and warfarin. Because such agents induce hepatic CYP enzymes, this phenomenon is often referred to as *microsomal enzyme induction*; the actual relationships between the activity of drug oxidases and the increased plasma levels of these nonmicrosomal enzymes are less clear. Potential explanations are that the indirect effects of increased CYP enzyme activity on bile acid metabolism produce more "detergent" metabolites that liberate these enzymes from the hepatocyte plasma membranes or stimulate increased synthesis of alkaline phosphatase and GGTP; there is some evidence that both these mechanisms may apply. The important clinical point is to clearly recognize the difference between these biochemical changes and cholestasis; for example, serum bile acid levels increase with cholestasis or liver injury but not with hepatic adaptation.

Table 33.9. Definition of Patterns of Liver Injury

Liver injury	Hepatocellular	Cholestatic	Mixed
ALT >2–3 × ULN	ALT >2–3 × ULN and normal SAP	SAP >2 × ULN	ALT >2–3 × ULN and SAP >2 × ULN
or	*or*	*or*	*or*
>2 × ULN conjugated bilirubin *or* elevated aspartate aminotransferase, SAP, and total bilirubin (one of these must be >2 × ULN) levels	ALT/SAP ratio ≥5[a]	ALT/SAP ratio ≤2[a]	ALT/SAP ratio[a] between 2 and 5
Note that these patterns are a relatively poor guide to the histologic nature of liver disease (see text). [a]The ALT and SAP values are expressed as multiples of the upper limit of normal. ALT, alanine aminotransferase; SAP, serum alkaline phosphatase; ULN, upper limit of normal.			

Table 33.10. Clinicopathologic Classification of Drug-Induced Liver Disease

Category	Description	Examples
Hepatic adaptation	No symptoms; raised GGTP and SAP (occasionally ALT) levels	Phenytoin, warfarin, rifampin
	Hyperbilirubinemia	Rifampin
Dose-dependent hepatotoxicity	Very short interval to onset; symptoms of hepatitis; zonal, bridging, and massive necrosis; ALT >5 × ULN, often >2,000 U/L	Acetaminophen, nicotinic acid, amodiaquine
Other cytopathic liver injury;		
Acute steatosis	Microvesicular steatosis, diffuse or zonal; partially dose dependent; severe liver injury; features of mitochondrial toxicity (lactic acidosis, pancreatitis)	Valproic acid, didanosine, highly active anti-retroviral treatment, fialuridine, L-asparaginase, some herbal medicines, ecstasy

Acute hepatitis	Onset within 1–20 wk; sentinel symptoms of hepatitis; focal, bridging, and massive necrosis; ALT >5 × ULN; extrahepatic features of drug allergy in some cases (Table 33.5)	Isoniazid, dantrolene, nitrofurantoin, halothane, sulfonamides, phenytoin, disulfiram, etretinate, ketoconazole, terbinafine, troglitazone
Chronic hepatitis	Duration >3 m; interface hepatitis, bridging necrosis, fibrosis, cirrhosis; clinical/laboratory features of chronic liver disease; autoantibodies in some cases	Nitrofurantoin, etretinate, diclofenac, minocycline, mesalamine
Granulomatous hepatitis	Hepatic granulomas with varying hepatitis and cholestasis; raised ALT, SAP, GGTP levels	Allopurinol, carbamazepine, hydralazine, quinidine, quinine
Steatohepatitis	Onset delayed (6–18 m); steatosis, focal necrosis, Mallory's hyaline, pericellular fibrosis, cirrhosis; chronic liver disease, portal hypertension	Perhexiline, amiodarone, tamoxifen, toremifene; rarely nifedipine, diltiazem
Cholestasis without hepatitis	Cholestasis, no inflammation; SAP >2 × ULN	Oral contraceptives, androgens, cyclosporin A
Cholestatic hepatitis	Cholestasis with inflammation; symptoms of hepatitis; raised ALT and SAP levels	Chlorpromazine, tricyclic antidepressants, erythromycins, amoxicillin/clavulanate, angiotensinogen-converting enzyme inhibitors
Cholestasis with bile duct injury	Bile duct lesions and cholestatic hepatitis; clinical features of cholangitis	Chlorpromazine, flucloxacillin, dextropropoxyphene, carmustine, paraquat
Chronic cholestasis Vanishing bile duct syndrome Sclerosing cholangitis	Cholestasis present >3 m Ductopenia; resembles primary biliary cirrhosis but antimitochondrial antibodies absent Strictures of large bile ducts	Chlorpromazine, flucloxacillin, trimethoprim- sulfamethoxazole (Table 33.14) Intra-arterial floxuridine, intralesional scolicidals
Vascular disorders	Sinusoidal dilatation, peliosis, noncirrhotic portal hypertension, nodular regenerative hyperplasia, sinusoidal obstruction syndrome (veno-occlusive disease)	Anabolic steroids, oral contraceptives, vinyl chloride, Thorotrast (Table 33.14)
Liver tumors	Focal nodular hyperplasia, hepatic adenoma, hepatocellular carcinoma, angiosarcoma	Anabolic steroids, oral contraceptives, vinyl chloride, Thorotrast (Table 33.14)

ALT, alanine aminotransferase; GGTP, γ-glutamyl transpeptidase; SAP, serum alkaline phosphatase; ULN, upper limit of normal.

A morphologic or ultrastructural consequence of microsomal enzyme induction by drugs is the presence of ground glass cytoplasm in hepatocytes, as seen by light microscopy. This results from hypertrophy of the endoplasmic reticulum, which can be confirmed by electron microscopy.

Drug-Induced Acute Hepatitis

Many drugs are associated with acute hepatocellular injury (Table 33.11). There is a latent period between starting treatment and onset of symptoms or liver test

abnormalities; this tends to be shorter (2 to 6 weeks) for agents clearly associated with immunoallergic mechanisms (see Table 33.5) and more variable and longer for those presumed to be due to metabolic idiosyncrasy. Onset is often with prodromal features of fever, malaise, and other "sentinel symptoms" (Table 33.5), followed by rash, lymphadenopathy, or other systemic features of drug hypersensitivity. Clinical features that resemble acute viral hepatitis soon follow, or they may be the presenting symptoms; anorexia, nausea, vomiting, and lassitude are prominent among these. Jaundice is present in severe cases. AT levels are raised (Table 33.9) proportionately more than those of SAP. Serum bilirubin concentration and indices of hepatic synthetic function such as prothrombin time and serum albumin concentration are variably altered depending on the severity and duration of liver injury.

Table 33.11. Drugs Associated with Acute Liver Failure

ANALGESICS/NONSTEROIDAL ANTI-INFLAMMATORY DRUGS Acetaminophen[a] Bromfenac[b] Diclofenac Etodolac Ibuprofen Leflunomide Nimesulide Oxaprozin Piroxicam Tienilic acid	**CARDIOVASCULAR DRUGS** Amiodarone Captopril Ecarazine Enalapril Lisinopril Labetalol **ENDOCRINE DRUGS** Carbimazole Propylthiouracil Troglitazone[b]	**NEUROPSYCHIATRIC DRUGS** Carbamazepine Chlormethiazole Felbamate Lamotrigine Nefazodone Pemoline Phenytoin Tacrine Tetrabamate Tolcapone Topiramate Valproic acid
ANTIMICROBIAL DRUGS Amoxicillin–clavulanate Ciprofloxacin, ofloxacin, trovofloxacin Cotrimoxazole Dapsone Fialuridine[b] Flucloxacillin Highly active antiretroviral treatment Isoniazid, rifampin, pyrazinamide Ketoconazole, itraconazole Lamotrigine Minocycline Sulfonamides (many) Terbinafine Tetracycline (intravenous)	**ENVIRONMENTAL AGENTS** Carbon tetrachloride[a] Mushroom poisoning[a] **GASTROINTESTINAL DRUGS** Ebrotidine Omeprazole Ranitidine **GENERAL ANESTHETICS** Halothane Enflurane Isoflurane	**ONCOTHERAPEUTIC DRUGS** Carboplatin Chlorambucil Cyproterone acetate Flutamide Gemcitabine Imatinib mesylate **MISCELLANEOUS DRUGS, INCLUDING HERBAL MEDICINES AND SELF-ADMINISTERED AGENTS** Allopurinol Chaparral[a] Cocaine[a] Disulfiram Germander Herbal slimming aids Hydrazine sulfate Interferon-α, interferon-β[a] Kava 3,4-Methylenedioxymethamphetamine ("ecstasy") Nicotinic acid[a] Zafirlukast

[a]Dose-dependent hepatotoxicity.
[b]Withdrawn.

The histologic lesions consist mainly of focal hepatic necrosis, with apoptotic (acidophil) bodies and a mixed inflammatory infiltrate. Bridging necrosis is present in severe cases and may lead to chronic hepatitis if the causative agent is not withdrawn.

Zonal necrosis is a typical feature of more severe forms of liver injury caused by drugs and other chemical or plant toxins. *Zone 3 lesions* (centrilobular or perivenular) are seen with acetaminophen and carbon tetrachloride toxicity but can also occur in acute SOS (or VOD). The overrepresentation of zone 3 lesions in

cases of drug-induced liver injury is related to the high metabolic activity of this zone, which generates reactive metabolites. By comparison, isolated *zone 1* (phosphorus or iron poisoning) and *zone 2 lesions* (cocaine toxicity) are extremely rare.

Severe acute hepatitis may culminate in *acute liver failure*; massive or submassive hepatic necrosis is often present. Acetaminophen (See "Acetaminophen") is the leading cause of drug-induced acute liver failure worldwide, but regional differences exist. Other drugs that have been associated with acute liver failure are listed in Table 33.11.

Mitochondrial Injury

Fatty liver (*steatosis*) can be seen in the vicinity of zonal necrotic lesions but may also be the predominant manifestation. Microvesicular steatosis is a severe form of hepatotoxicity that results from mitochondrial injury; decreased numbers of mitochondria are often found. There is often evidence of other organ involvement, particularly pancreatitis, nephrotoxicity, encephalopathy, and metabolic acidosis. The clinical syndrome resembles acute fatty liver of pregnancy (see Chapter 46). Patients present with nausea, vomiting, abdominal pain, and rapidly evolving encephalopathy. Liver biopsy specimens show accumulation of small fat droplets (microvesicular steatosis) in hepatocytes in a zonal or diffuse distribution. Biochemical features include profound hepatocellular dysfunction with hypoglycemia, coagulopathy, hyperammonemia, and lactic acidemia. There may be a rise in serum bilirubin and AT levels, but these are less pronounced than in other forms of acute hepatotoxicity or hepatitis. Historically, this syndrome was associated with the use of tetracycline in pregnant women, Reye's syndrome (see Chapter 46) caused by the use of aspirin in febrile young children with influenza B and some other viral infections, and with sodium valproate in very young children with predisposing factors (see later section). Currently, the most important cause is HAART, and particularly the nucleoside inhibitors, but amphetamine analogs used recreationally, especially ecstasy, and buprenorphine misuse can produce similar lesions (81). The drugs associated with microvesicular steatosis are listed in Table 33.12.

Unlike acute microvesicular steatosis, drug-induced *steatohepatitis* is a type of hepatocellular injury associated with chronic liver disease. Hepatic decompensation can occur, and some drugs associated with steatohepatitis have also been implicated as causing acute liver failure. In general, however, progression to cirrhosis or liver complications is slower. Drugs associated with steatohepatitis are listed in Table 33.13. The histologic features are indistinguishable from those of alcoholic steatohepatitis, with varying degrees of steatosis, focal lobular inflammation with polymorphonuclear cells, hepatocellular necrosis, and Mallory bodies. Excluding ethanol abuse is critical, but the changes also resemble those found in NASH (see Chapter 39). Therefore, some associations between the drugs used for complications of the metabolic syndrome (e.g., diabetes, high arterial blood pressure, cardiac failure) and steatohepatitis may be fortuitous, while other agents (e.g., corticosteroids, estrogens, tamoxifen) may exacerbate NASH because of effects on insulin resistance and lipid turnover. Drug-induced steatohepatitis often causes hepatic fibrosis in the pericentral (perivenular or acinar zone 3) and pericellular distribution; this distribution is typical for all other causes of steatohepatitis. Cirrhosis can develop and eventually lead to hepatic decompensation.

Table 33.12. Drugs Associated with Microvesicular Steatosis

Aspirin (Reye's syndrome in febrile children)[a]
Fialuridine[b]
Highly active antiretroviral treatment
Industrial toxins—dimethylformamide, selenium
Nonsteroidal anti-inflammatory drugs—ibuprofen, piroxicam, pirprofen, tolmetin[b]
Riluzole
Tetracycline (historical)
Tetrabamate (Atrium)
Ticlopidine
Valproic acid
Vitamin A

[a]Declining incidence since health warnings have been issued on the use of aspirin in young children.

[b]More likely to be a fortuitous association resulting from association with risk factors for "primary" nonalcoholic steatohepatitis (see text).

Cholestasis

There are several different syndromes of drug-induced cholestasis (Table 33.14) (82,83). *Bland cholestasis* occurs without symptoms of hepatitis. Liver biopsies show intrahepatic cholestasis without significant hepatic inflammation. This syndrome is associated with oral contraceptive use and occurs more often in women with a family or personal history of cholestasis of pregnancy (see Chapter 46). Pruritus is often troublesome, but jaundice is less common. Recovery is the rule, but complete resolution can be protracted in some cases.

In *cholestatic hepatitis*, liver histology shows lobular and portal tract inflammation, as well as cholestasis. As with other forms of drug hepatitis, clinical onset is with flu-like symptoms, but this is soon followed by features

of hepatitis, such as anorexia, vomiting, jaundice, and right hypochondrial pain. The latter can be severe and misinterpreted as acute cholecystitis. Drugs that cause cholestatic hepatitis can also cause *bile duct injury*; dextropropoxyphene (84) and methylenedianiline (an epoxy resin hardener associated with cases of liver injury or jaundice after industrial exposure or food contamination, the latter called most infamously as *the Epping jaundice*) cause a striking syndrome of cholangitis (85). Cholangiolytic (interlobular bile duct) injury is prominent in many cases of drug-induced cholestatic hepatitis, and when lesions are severe enough this can lead to ductopenia or the *vanishing bile duct syndrome* (VBDS).

Table 33.14. Clinicopathological Syndromes of Drug-Induced Cholestasis

Type	Clinical and laboratory features	Examples
ACUTE FORMS		
Cholestasis without hepatitis ("bland" cholestasis)	Prodromal symptoms, then intense pruritus; SAP >3 × ULN; AT rise is often transient (rarely >3–5 × ULN); bilirubin <12 mg/dL	Estrogens, anabolic steroids, tamoxifen, azathioprine
Cholestasis with hepatitis[a]	Right upper quadrant or generalized abdominal pain, jaundice often present; can simulate acute cholangitis; pruritus less impressive; SAP >3 × ULN in 70%, AT >2–5 × ULN	Chlorpromazine, other phenothiazines, macrolide antibiotics, oxypenicillins, tricyclic antidepressants, amoxicillin-clavulanate, ketoconazole, nonsteroidal anti-inflammatory drugs (sulindac, piroxicam), captopril, enalapril, azathioprine
Cholestasis with bile duct injury[a] (cholangiolytic)	Resembles acute cholangitis (often with cholestatic hepatitis)	Dextropropoxyphene, flucloxacillin, paraquat, methylenedianiline
CHRONIC FORMS		

Vanishing bile duct syndrome (Table 33.15)	Chronic cholestasis, resembles primary biliary cirrhosis but antimitochondrial antibodies absent	Chlorpromazine, flucloxacillin, and other oxypenicillins
Large bile duct strictures (similar to sclerosing cholangitis)	Chronic cholestasis, resembles sclerosing cholangitis (but strictures at junction of right and left hepatic ducts)	Floxuridine, intralesional scolicides (2% formaldehyde, hypertonic saline, iodine solution, absolute alcohol, silver nitrate)

[a]Several drugs implicated in causing cholestatic hepatitis may also produce bile duct injury.
AT, aminotransferase; SAP, serum alkaline phosphatase; ULN, upper limit of normal.

Table 33.15. Drugs Associated with the Vanishing Bile Duct Syndrome

Amoxicillin–clavulanic acid[a]	Flucloxacillin[a], dicloxacillin
Ampicillin	Glycyrrhizin (a component of Chinese herbal medicines)
Amitriptyline, imipramine	Gold
Azathioprine	Haloperidol
Barbiturates	Ibuprofen
Carbamazepine[a]	Itraconazole
Chlorothiazide	D-Penicillamine
Cotrimoxazole[a]	Phenytoin[a]
Clindamycin	Prochloperazine[a]
Chlorpromazine[a]	Tetracycline[a]
Cimetidine	Terbinafine
Cyproheptadine	Thiabendazole
Erythromycin esters[a]	Tiopronin
Estradiol, norandrostenolone, methyltestosterone[a]	Tolbutamide

Original references can be obtained from refs 2,14,67,83,86.
[a]More than one reported case.

The VBDS is characterized by progressive destruction of segments of the biliary tree (82). Over 30 drugs have been implicated (82,86,87,88,89,90,91) but those with highest risk of this outcome after drug-induced cholestatic hepatitis are chlorpromazine (7% of cases), oxypenicillins (particularly flucloxacillin [10% to 30% of cases]), and erythromycins (5% of cases) (92) (Table 33.15). The main predictor of VBDS after cholestatic hepatitis may be the initial severity of bile duct damage (87). The clinical features resemble those of primary biliary cirrhosis (PBC) with jaundice, with liver test results indicating cholestasis, hypercholesterolemia, xanthomas, and other manifestations of chronic cholestasis. However, unlike PBC, AMAs are usually absent. Hepatic fibrosis is not usually prominent, but biliary cirrhosis can sometimes develop. Resolution may take up to 2 years and is sometimes incomplete.

Large duct bile duct lesions ("sclerosing cholangitis") are an uncommon type of drug-induced injury. Well-characterized historical examples include intra-arterial floxuridine infusions (which cause an ischemic cholangiopathy) and intracavitary instillation of scolicidal agents (82,93). Current practices of targeted chemotherapy for hepatic malignancy and ultrasound-guided scolicidal therapy have a low risk of drug-induced biliary injury.

Granulomatous Hepatitis

Hepatic granulomas are associated with numerous infective, inflammatory, vasculitic, and neoplastic disorders (94) (see Chapter 52). Older studies found that approximately one third of cases of hepatic granulomas were attributable to drugs (95), and it seems likely that drugs remain an important cause of "granulomatous hepatitis." In drug reactions, granulomatous hepatitis may be the sole manifestation of liver injury, but more commonly granulomas accompany other histologic features and represent one of several patterns of hepatic response to injury. Therefore, granulomas have been described with many drugs that are better known for other types of pathology, especially acute hepatitis (e.g., nitrofurantoin, methyldopa, halothane), but also cholestatic hepatitis (chlorpromazine, phenylbutazone, carbamazepine) and steatohepatitis (e.g., amiodarone, calcium channel blockers) (Table 33.16).

The clinical presentation is indistinguishable from other causes or idiopathic granulomatous hepatitis (see Chapter 52). Therefore, profound lethargy, fever, night sweats, rigors, myalgia, and weight loss are prominent. There is tender hepatomegaly and the spleen is enlarged in 25% of cases. Other extrahepatic manifestations include rashes, particularly a form typifying small vessel vasculitis, lymphadenopathy, and bone marrow granulomas (14). Serum ALT level is often raised, but typically less than that of SAP and GGTP. Jaundice is much less common than that with other types of drug-induced acute hepatitis but has been observed when cases overlap with cholestatic hepatitis; carbamazepine and hydralazine are examples. Withdrawal of the offending drug leads to rapid resolution in most cases. A short course of corticosteroids may hasten recovery in special circumstances, particularly in cases associated with vasculitis or other extrahepatic complications such as interstitial nephritis; allopurinol and sulfonamides are examples.

Drug-Induced Chronic Hepatitis

Chronic hepatitis is defined by persistence of symptoms and biochemical or histologic abnormalities for longer than 3 months (14). All drugs implicated as causing chronic hepatitis have also been associated with acute reactions. Continued ingestion of the drug beyond the phase of acute hepatitis is one of the key factors leading to the development of chronic hepatitis, cirrhosis, and liver failure. Early recognition and timely withdrawal of the offending drug are therefore crucial.

A distinctive type of drug-induced chronic hepatitis resembling AIH is described. This probably occurs through the process of drug-induced immune dysregulation. The relatively few agents that cause this type of liver disease include nitrofurantoin, diclofenac, methyldopa, and minocycline. More than 80% of reported cases occur in women. Characteristic features include fever and arthralgia in addition to symptoms of chronic hepatitis and signs of chronic liver disease, hypergammaglobulinemia, and antinuclear and/or smooth muscle antibodies (SMAs). A second pattern of drug-induced chronic hepatitis is characterized by autoantibodies directed against specific hepatic microsomal proteins (e.g., tienilic acid, halothane). However, yet other agents (e.g., etretinate and germander) can be associated with chronic hepatic inflammation and liver cell injury (hepatitis) in the absence of autoantibodies or other features of autoimmunity. Finally, a picture of classical AIH may emerge after an episode of drug-induced acute hepatitis. It is unclear whether the emergence of AIH is related to unmasking of latent AIH or whether the drug may directly induce AIH in susceptible persons.

Table 33.16. Drugs Associated with Hepatic Granulomas

ANTIMICROBIALS	**ANALGESICS/NONSTEROIDAL ANTI-INFLAMMATORY DRUGS**	**ANTIEPILEPTICS**	**MISCELLANEOUS, INCLUDING HERBAL MEDICINES**
Amoxicillin–clavulanate	Aspirin	Carbamazepine[a]	Allopurinol[a]
Cephalexin	Acetaminophen	Chlorpromazine	Chaparral
Dapsone	Clometacin	Phenytoin[a]	Gold
Dicloxacillin, oxacillin	Phenylbutazone[a]	**ENDOCRINE DRUGS**	Glibenclamide
Isoniazid	**CARDIOVASCULAR DRUGS**	Chlorpropamide	Halothane
Mebendazole	Amiodarone	Methimazole	Interferon-α
Nitrofurantoin	Diltiazem	Glibenclamide	Mesalamine
Norfloxacin	Disopyramide	Tolbutamide	Methotrexate
Penicillin G, penicillin V	Hydralazine[a]		Rosiglitazone
Pyrazinamide	Methyldopa		Tacrine
Quinine[a]	Procainamide[a]		Tetrabamate
Sulfonamides (many)[a]	Quinidine[a]		Ticlopidine

[a]Well-characterized examples with causality proved. Note that the high frequency with which hepatic granulomas are found in liver biopsies is such that other associations may be fortuitous.

Hepatic Fibrosis

Hepatic fibrosis may be the end result of chronic hepatitis, chronic hepatotoxicity, steatohepatitis, or chronic cholestasis with bile duct injury. However, some drugs and chemicals such as methotrexate, vitamin A, and arsenic can provoke an intense fibrotic reaction *without* a prominent inflammatory response. With these agents, other profibrogenic risk factors, especially ethanol but possibly also obesity, diabetes, insulin resistance, and iron overload, can accelerate the rate of fibrogenesis (discussed later in relation to vitamin A and methotrexate).

Vascular Lesions

Drugs and chemicals are the most important cause of vascular lesions of the liver. The latter include histologic

curiosities, such as sinusoidal dilatation, to clinically important disorders, such as peliosis hepatis, SOS (VOD), the Budd-Chiari syndrome, NRH, and other causes of noncirrhotic portal hypertension (Table 33.17).

Causative drugs include sex steroids, alkylating chemotherapeutic agents (such as cyclophosphamide, busulfan, melphalan, dactinomycin), and immunosuppressive agents (azathioprine). In current practice, *SOS* (or *VOD*) most often occurs in the setting of bone marrow transplantation, but in the past it was synonymous with pyrrolizidine alkaloid hepatotoxicity resulting from ingestion of brewed herbal tea mixtures ("Jamaican morning sickness") (96) or from plant alkaloid contamination of herbal medicines such as comfrey (97). Epidemics of VOD have also been reported in areas where pyrrolizidine alkaloid–contaminated wheat flour had been consumed, particularly in south Asia and the Middle East. Hepatic vein and portal vein thrombosis can occur in OCS users, although latent or overt myeloproliferative disorders or inherited procoagulants states (such as factor V Leiden) (98) are usually also found in cases of venous thrombosis at these sites (see Chapter 40).

Hepatic Neoplasms

Drugs and toxins are a rare cause of liver tumors (see Chapters 42 and 43), but some associations exist, as exemplified by OCS and *hepatic adenomas*. OCS use is recorded in over 80% of patients with these adenomas, and there is a strong relationship between adenomas and the dose and duration of estrogen therapy (25,99,100). In addition, evidence of estrogen dependence of these tumors is evident; regression occurs in a significant proportion of patients after discontinuing OCS (101). As discussed later, surgery is still required in most cases.

The relationship between estrogens and *focal nodular hyperplasia* (FNH) is more complex and less clear etiologically (See "Oral contraceptive steroids"). As for cavernous hemangiomas, sex steroids, and particularly estrogens, may have trophic effects on these two benign hepatic neoplasms, and particularly on their vascularity, although this remains controversial (102); estrogens cannot, therefore, be regarded as the primary causative factor.

Malignant tumors such as *hepatocellular carcinoma* (HCC) are caused by chronic viral hepatitis in more than 80% of cases (see Chapter 43), but in parts of Africa and Asia ingestion of aflatoxin-contaminated or other fungal toxin–contaminated food may play a synergistic role in carcinogenesis. Estrogens increase the risk of HCC in long-term OCS users, but this effect is weak and is overwhelmed in importance by chronic hepatitis B virus (HBV) and HCV infection in regions endemic for these viruses (26).

Angiosarcoma is an uncommon liver tumor that was classically associated with the radiocontrast agent Thorotrast (see Chapter 43), vinyl chloride monomer, arsenic, and rarely, androgen use.

Table 33.17. Drug-Induced Vascular Disorders and Tumors

	Examples
VASCULAR DISORDERS	
Peliosis hepatis	Anabolic steroids, azathioprine, oral contraceptives, 6-thioguanine, Thorotrast
Hepatic sinusoidal obstruction syndrome (venous outflow obstruction, including veno-occlusive disease)	Oral contraceptives, pyrrolizidine alkaloids, 6-thioguanine, dacarbazine, gemcitabine
Noncirrhotic portal hypertension	Vitamin A, methotrexate, arsenic, vinyl chloride, azathioprine
Nodular regenerative hyperplasia	Azathioprine, 6-thioguanine, busulfan
TUMORS	
Hemangioma	Oral contraceptives (trophic effect on preexisting lesions only)
Focal nodular hyperplasia	?Oral contraceptives (see text)
Hepatic adenoma	Oral contraceptives, anabolic steroids

Hepatocellular carcinoma	Anabolic steroids, danazol, oral contraceptives, Thorotrast, vinyl chloride
Angiosarcoma	Vinyl chloride, thorium dioxide, arsenic
?, recent data refute existing views of a possible association with oral contraceptives.	

Role of Drugs in Multifactorial Liver Disease

Viral Hepatitis

Patients with chronic hepatitis B or C may be at increased risk of liver injury during chemotherapy for tuberculosis, with cancer chemotherapy, and after intake of ibuprofen and possibly other NSAIDs (56,57,58).

A common problem involves the patient who regularly attends the liver clinic with mild-to-moderate ALT level elevation associated with chronic viral hepatitis, who then presents with an ALT level greater than 300 U/L. Particularly for chronic hepatitis C, changes due to hepatotoxic drugs (56) are more likely than spontaneous fluctuations of disease severity; drugs are almost always the cause with ALT values that greatly exceed 1,000 U/L. A common culprit is acetaminophen taken in moderate daily dosage over a period when there are factors such as concomitant medication, prolonged fasting, or chronic alcohol excess (see later section). Another frequent scenario is the patient who has tried Chinese herbal medicines or some other form of CAM.

Highly Active Antiretroviral Treatment

Abnormal liver test results and clinical evidence of liver disease are common in patients with HIV/AIDS. Contributory factors include chronic hepatitis B or C, hepatobiliary infections and infestations, lymphoma and other tumors, and possibly direct effects of HIV infection (see Chapter 51). However, the most common cause of liver injury is hepatotoxicity from drugs used to treat HIV/AIDS. When monotherapy was used against HIV, individual nucleoside analogs were associated with uncommon episodes of severe cytopathic liver injury, as illustrated later for didanosine. In clinical studies, zidovudine and didanosine have been most often implicated in hepatotoxicity, but no particular nucleoside or nucleotide analog appears more hepatotoxic. As discussed later, it seems likely that drug combinations that include protease inhibitors and nucleoside/nucleotide analogs are more toxic than individual agents.

Bone Marrow Transplantation

As discussed in Chapter 60, hepatobiliary complications of hematopoietic cell transplantation are common, are often serious, and may be multifactorial in origin. Bone marrow transplantation particularly increases the risk of vascular complications, such as VOD and NRH. Therefore, although SOS (or VOD) causes complications in at least 1% of cases during the use of anticancer drugs, the risk of developing this complication can be as high as 54% after bone marrow transplantation, depending on the regimen used (103,104,105). Of 103 patients undergoing bone marrow transplantation in one series, NRH was present in 23% and SOS (VOD) in 9% (106).

The clinical features are similar to those of portal hypertension, often complicated by bleeding esophageal varices and ascites. Hepatic encephalopathy can occur after an episode of severe upper gastrointestinal hemorrhage. Liver test results may be normal or show minor nonspecific changes. The diagnosis is made histologically, although a wedge biopsy may be necessary. In general, the prognosis for NRH is good; complete reversibility may occur in some drug-induced cases (106).

Metabolic Syndrome and Nonalcoholic Steatohepatitis

Steatohepatitis is a form of chronic liver disease in which fatty change is associated with focal liver cell injury, Mallory's hyaline, inflammation with mixed cellularity including polymorphonuclear cells, and progressive hepatic fibrosis in a pericentral and pericellular distribution (see Chapter 39). While alcohol is a common etiology, NASH can be associated with diabetes, obesity, and several drugs (e.g., perhexiline maleate [107] and amiodarone [108]).

Among drugs associated with steatohepatitis during the 1990s and the 21st century, causality is harder to prove because NASH is such a common disorder among patients with insulin resistance or metabolic syndrome (see Chapter 39). Therefore, calcium channel blockers used for arterial hypertension have been associated with steatohepatitis (109,110), and methyldopa has been reported to cause cirrhosis in obese middle-aged women (111); these associations may be fortuitous. Other drugs, including estrogens (112), tamoxifen, and glucocorticosteroids, may precipitate NASH because of their effects on the metabolic risk factors: Insulin

resistance, type 2 diabetes, obesity, and hypertriglyceridemia.

Postoperative Jaundice

Drug-induced liver disease is a common cause of postoperative liver disease. The differential diagnosis of cases with jaundice is considered in Chapter 25. It is usually easy to distinguish underlying hepatobiliary disorders and bilirubin transport abnormalities resulting from tissue hypoxia or systemic infection ("benign postoperative cholestasis" or "jaundice in sick patients") resulting from drug reactions. Halothane-induced liver injury is one of the classic types of hepatic drug reactions but has become much less common now that halothane has been almost completely

replaced (in some countries) with equally acceptable and less hepatotoxic agents. Other than halothane, which causes a typical "signature syndrome," few anesthetics cause significant liver injury. Some cases have been attributed to isoflurane; the evidence and practical implications are discussed in a later section. Postoperative liver injury is also observed with antibiotics (especially amoxicillin–clavulanate, less commonly synthetic penicillins or cephalosporin derivatives), analgesics (particularly acetaminophen given alone or in drug combinations), dextropropoxyphene, tranquilizers, antidepressants, and (undisclosed) use of herbal medicines.

Liver Disease Associated with Particular Classes of Drugs

Antimicrobial Agents

Penicillins

Hepatic injury associated with natural penicillins (e.g., penicillin G, penicillin V) is poorly documented (14). It is usually recorded in the setting of anaphylaxis, suggesting a possible ischemic basis for liver injury rather than direct toxicity (113). In contrast, the semisynthetic penicillins have been implicated in many hepatic drug reactions, including hepatocellular injury, bland cholestasis, and cholestatic hepatitis that may lead to VBDS (114,115,116) (Table 33.18).

Oxacillin

There are many reports of abnormal liver test results, mainly raised AT levels (117,118), with oxacillin. Isolated instances of cholestatic hepatitis or acute hepatitis have also been reported. Onset is within 2 to 24 days. Although eosinophilia has been described, features of hypersensitivity are not conspicuous. The liver test abnormalities usually normalize when the drug is withdrawn.

Flucloxacillin

Over 600 cases of cholestatic hepatitis have been reported, mainly from Europe, Scandinavia, and Australia (119,120,121,122,123). The frequency of liver injury is between 1 and 10 cases per 100,000 persons exposed (120,122). Risk factors for flucloxacillin-induced liver injury are high daily doses, prolonged courses (>2 weeks), and age over 55 years (120). Symptoms usually begin after 1 to 9 weeks but can be delayed for up to 6 weeks after the antibiotic course is completed. Nausea, anorexia, and vomiting herald the onset of hepatitis

and are followed by jaundice and pruritus. Constitutional symptoms and weight loss are often striking. Blood tests reflect severe hepatitis with high AT, SAP, and GGTP values. Bilirubin levels can be markedly raised (122). Liver histology shows cholestatic hepatitis with bile duct injury and ductopenia (121). This is a very severe form of drug-induced liver disease, and the reported mortality is up to 5% (20). Although most patients recover after drug withdrawal, prolonged cholestasis is observed in 10% to 30%, and in some cases this can lead to cirrhosis. Management is supportive in the acute phases, but with continued cholestasis ursodeoxycholic acid appears to benefit approximately two thirds of cases (69). The postulation of an idiosyncratic basis for flucloxacillin liver toxicity is supported by the identification of reactive metabolites capable of inducing cytotoxicity in biliary epithelial cells (124).

Table 33.18. Hepatic Injury Associated with Antimicrobial Agents

Drug	Pattern of liver injury	Comments
Penicillin G Penicillin V	Acute hepatitis, granulomatous hepatitis	Very rare; hypersensitivity features often present
Ampicillin	Acute hepatitis, mixed hepatocellular–cholestatic injury, granulomatous hepatitis	Rarely, vanishing bile duct syndrome; cross-hepatotoxicity with cefuroxime
Ampicillin–sulbactam	Cholestatic hepatitis	Single case

Amoxicillin, carbenicillin	Minor, nonspecific increase in aminotransferases	—
Amoxicillin–clavulanate	Cholestatic hepatitis with bile duct injury; acute hepatitis (15% of cases)	Associated with vanishing bile duct syndrome; granuloma; cirrhosis (single case)
Flucloxacillin	Cholestasis with bile duct injury; vanishing bile duct syndrome	Similar toxicity with oxacillin, cloxacillin, and dicloxacillin, but possibly less frequent, less severe
Cephalosporins	Minor liver injury, acute hepatitis, cholestatic hepatitis	Rare; mild, reversible; granulomas (cephalexin); biliary sludge (ceftriaxone)
Chloramphenicol	Hepatocellular, cholestasis	Hepatic injury rare
Cotrimoxazole	Acute hepatitis, cholestatic hepatitis, granulomatous hepatitis, vanishing bile duct syndrome	Cholestasis recorded with trimethoprim alone; increased risk with human immunodeficiency virus/acquired immunodeficiency syndrome
Erythromycin	Cholestatic hepatitis	Also with azithromycin, clarithromycin, roxithromycin
Minocycline	Acute and chronic hepatitis	Autoimmune hepatitis–type features (see text)
Nitrofurantoin	Acute and chronic hepatitis, granulomatous hepatitis, cirrhosis	Declining incidence; was common in long-term users (>6 m)
Quinolones	Mainly cholestasis; rarely hepatitis, fulminant hepatic failure;	Overall low incidence; granulomas (norfloxacin)
Sulfonamides	Acute hepatitis, cholestatic hepatitis, granulomatous hepatitis, vanishing bile duct syndrome	Similar toxicity with sulfones, sulfasalazine, pyrimethamine–sulfadoxine
Tetracycline	Microvesicular steatosis	Rarely, vanishing bile duct syndrome
Trovafloxacin	Fulminant hepatic failure	Now withdrawn

Cloxacillin and dicloxacillin

Some data indicate that cholestatic hepatitis may be less common and possibly less severe with cloxacillin and dicloxacillin, compared with flucloxacillin (123), but this remains unproved and controversial. In other respects, the liver injury and clinical course resemble the flucloxacillin reaction described earlier (122).

Amoxicillin–clavulanate (Augmentin)

At least 150 cases of cholestatic liver injury have been attributed to amoxicillin–clavulanate (34,35,125,126). The clavulanate component has been implicated because such toxicity is rare with amoxicillin, whereas other clavulanate–penicillin compounds such as ticarcillin–clavulanate (Timentin) can cause cholestasis (127,128). The frequency of liver injury has been estimated at 1.1 to 2.7 cases per 100,000 persons exposed (22). Male gender, age over 60 years, and prolonged courses of treatment are risk factors for hepatic injury. Although there is a strong association with DRB1 *1501-DRB5*0101-DQB1*062 (34,35), this haplotype does not appear to influence the clinical expression and outcomes of amoxicillin–clavulanate hepatitis.

Onset is within 6 weeks (mean 18 days) of beginning therapy; rarely, the onset of symptoms may be up to 8 weeks after completion of treatment (129). Hypersensitivity features such as fever, rash, and eosinophilia are seen in 30% to 60% of patients (113). Bland cholestasis or cholestatic hepatitis is observed in biopsied cases (125). Bile duct injury and perivenular bilirubinostasis with ceroid pigment deposits are often present. Other histologic features include hepatic granulomas, biliary ductopenia (34,129,130,131,132), and rarely, cirrhosis (133). Most patients recover but this can take up to 4 months. Fatalities are rare (134).

Quinolones

Transient increases in AT levels are recorded in 2% to 3% of fluoroquinolone recipients. Serious liver injury is infrequent, with the exception of *trovafloxacin*, which was withdrawn because of severe hepatotoxicity (135). Among the reported cases, cholestatic liver injury predominates, usually occurring within 2 to 21 days (82,136,137,138). *Ciprofloxacin* (137), *norfloxacin* (138), *ofloxacin* (139), *gatifloxacin* (140), and *moxifloxacin* (141) have all been implicated. Instances of hepatocellular injury have also been recorded, including acute liver failure with ciprofloxacin (82,142) and ofloxacin (139). Acute cholestatic hepatitis followed by prolonged cholestasis and biliary ductopenia were observed with gatifloxacin (140). Two elderly subjects with renal impairment developed acute hepatocellular injury with *levofloxacin*, presumably a consequence of altered pharmacokinetics because levofloxacin undergoes renal elimination (143).

Tetracycline

Tetracycline hepatotoxicity was characterized by microvesicular steatosis, resulting in acute liver failure. Risk factors included the administration of high intravenous dosages (usually >2 g/day) of tetracycline to women during pregnancy (15,144) or to men while taking estrogens. The other important risk factor was renal failure, which reduces tetracycline clearance. The clinical features resembled those now seen in some cases of severe liver injury associated with HAART (see later section). Tetracycline hepatotoxicity is attributed to impaired hepatic lipid transport and inhibition of mitochondrial β-oxidation of fatty acids (2). It is no longer observed, now that tetracycline is contraindicated in pregnancy. Oral tetracycline has been associated with two cases of prolonged cholestasis with bile duct injury; bilirubin levels remained elevated for approximately 3 years in one of these patients (90).

Minocycline

Minocycline, a semisynthetic tetracycline used in treating acne, is an important cause of drug-induced liver disease (145,146,147). A systematic review identified 65 published cases, while 493 (6%) of the over 8,000 adverse drug reactions attributed to minocycline reported to an international pharmacovigilance center were liver related (148). Two modes of presentation are described. Those presenting with "early onset" hepatitis (within 5 weeks) exhibit prominent hypersensitivity features such as exfoliative dermatitis, lymphadenopathy, and eosinophilia; this is typical of the RMS (Table 33.5). Among such cases, 6 of 16 were in patients of African Caribbean ethnicity, suggesting possible racial susceptibility. By contrast, long-term minocycline

recipients (>12 months) present with a clinical and histologic picture simulating AIH, with fever, arthralgia (>70%), antinuclear antibodies (ANAs) and/or SMAs (>90%), and raised level of globulins (149). Other features of drug-induced SLE may be present, including arthritis and nephritis (145). The absence of tissue eosinophilia in some cases may divert attention from a drug etiology. Approximately half (48%) of those affected have been women, most (94%) younger than 40 years. This reflects, in part, the age of those exposed to prolonged minocycline for the treatment of acne.

Most patients recover completely after minocycline is discontinued. However, both acute and chronic hepatitis can be severe, with a few patients needing liver transplantation or dying from liver failure (150,151). Occasionally, patients seemed to benefit from a short course of immunosuppressive therapy, but it is unclear whether spontaneous resolution would have occurred. Among fatal cases, additional factors such as myocarditis or concurrent viral infections may have contributed to the mortality (148).

It is unclear how minocycline induces AIH. The sera of one affected patient contained antibodies that reacted with 50- and 90-kDa proteins expressed by human HCC cell lines and with rat CYP proteins (152); this raises the possibility of molecular mimicry between drug-induced autoantibodies and host proteins. The suggestion that minocycline could have triggered latent AIH seems less plausible because most affected patients recover without immunosuppression, and hepatitis occurs in those who do not exhibit the usual HLA haplotypes (HLA-DR3 and HLA-DR4) associated with AIH (153).

Sulfonamides

Sulfonamides have long been implicated as causing acute and chronic hepatitis; cholestatic, granulomatous, or mixed reactions; and rarely fulminant hepatic failure (113,154,155). Persons with HIV/AIDS (156) are particularly susceptible, implicating immune dysregulation in the pathogenesis of the hepatic injury. On the other hand, 90% of patients with sulfonamide hypersensitivity in one series were identified as slow acetylators (157,158); reduced activity of the acetylation pathway may contribute to defective detoxification of a sulfonamide metabolite or facilitate the CYP-mediated production of a nitroso metabolite (14,159). How this triggers an apparent immune liver injury is unclear.

Sulfonamide-induced liver injury usually occurs in the setting of systemic drug hypersensitivity (Table 33.5). Symptoms begin early (within 2 weeks of starting therapy). Associated features include a rash (occasionally

with the Stevens-Johnson syndrome), vasculitis, lymphadenopathy, pancreatitis, neuropathy (113), pancytopenia, and renal failure (158).

Sulfonamide combinations: Cotrimoxazole, sulfasalazine, sulfadoxine, and pyrimethamine (Fansidar)

In addition to other types of sulfonamide-induced liver injury, prolonged cholestasis with biliary ductopenia has been attributed to cotrimoxazole (160,161). Significant liver injury has occurred in recipients of sulfasalazine (see subsequent text) and pyrimethamine–sulfadoxine (Fansidar) (162).

Sulfasalazine and mesalamine

Sulfasalazine has been associated with several reports of acute hepatitis (163,164,165,166,167). Sulfasalazine-associated hepatic injury was observed more often in patients with rheumatoid arthritis than in those with inflammatory bowel disease (168). Reactions are often severe, and at least ten deaths have been recorded. Fever, rash, and arthralgia usually develop within 1 to 4 weeks. Liver injury was originally ascribed to the sulfonamide component (sulfapyridine). However, other 5-aminosalicylic acid (5-ASA) compounds, including *mesalamine* (*mesalazine*) and *olsalazine*, can also cause acute hepatitis, implicating the 5-ASA moiety in at least some cases (169,170). Sulfasalazine- and mesalamine-related hepatic drug reactions occur with similar frequency (168). Mesalazine has also been associated with cholestasis (170a) and rarely chronic hepatitis (one report) with hypergammaglobulinemia, ANAs, and SMAs (169).

Dapsone (4,4-diaminodiphenylsulfone)

Indications for dapsone include leprosy, dermatitis herpetiformis, and increasingly, treatment of *Pneumocystis carinii* infection in HIV-positive individuals. Liver involvement as part of a severe hypersensitivity syndrome ("sulfone syndrome") is well described with dapsone. This reaction, another example of the RMS (see preceding text), is reported in up to 1.3% of dapsone recipients (171). Most cases occurred within 6 weeks. Liver histology shows acute hepatitis or cholestatic hepatitis. Hepatic granulomas or acute cholangitis are also described (172). Resolution occurs within 4 weeks of stopping dapsone. Acute liver failure and death are uncommon but can occur in severe cases. Corticosteroids have been used with success in some reports. However, untreated patients have also recovered, while fatalities are recorded despite corticosteroid use (171,172).

Nitrofurantoin

Cases of significant hepatotoxicity still occur with this formerly prescribed urinary tract antiseptic; in a recent survey from Michigan, nitrofurantoin accounted for 3 of 32 (10%) cases of drug-induced hepatitis (173).

Acute and chronic hepatitis are the most characteristic hepatic syndromes, but varying degrees of cholestasis can occur, as do granulomas in rare cases.

Nitrofurantoin-induced chronic hepatitis simulates AIH. It is seen only in individuals using nitrofurantoin for more than 6 months; in some cases, exposure is intermittent and to very small doses of nitrofurantoin, such as those found in cow's milk (174). Positive rechallenge is well documented and may occur even after 17 years (175). The clinical features are those of chronic hepatitis with fatigue, malaise, nausea, abnormal liver test results with raised level of ALT, hypoalbuminemia, and hyperglobulinemia. ANAs (80%) and SMAs (70%) are often present. Cirrhosis is present in up to 20% of patients with nitrofurantoin-induced chronic hepatitis. Nitrofurantoin is also an important cause of pulmonary fibrosis, and concurrent liver and lung injury are observed in approximately 20% of persons developing nitrofurantoin hepatitis (176).

Clinical recovery follows nitrofurantoin withdrawal, but the course may be prolonged and sometimes recovery is incomplete (2). Corticosteroids are not routinely used but patients taking these medications seem to have accelerated recovery in occasional cases (177). Monitoring liver tests is not likely to be clinically useful or cost-effective.

Erythromycins and other macrolide antibiotics

Erythromycin estolate was recognized as a paradigm of cholestatic hepatitis in the early 1970s, but similar toxicity, although far less common, has been reported with all the erythromycin esters (rarely with erythromycin base) and other macrolides, such as clarithromycin (14). The presence of fever, serum, and tissue eosinophilia, along with the accelerated response to rechallenge, is consistent with immunoallergic idiosyncrasy, although intrinsic toxicity may also contribute (178).

Symptoms begin 2 to 25 days after commencing treatment (114). Nausea, anorexia, vomiting, and abdominal pain are common; the abdominal pain may be quite severe and it mimics acute cholecystitis. Before this syndrome was appreciated, inappropriate cholecystectomy was often performed. Dark urine (bilirubinuria), jaundice, and itch may also occur. The biochemical profile shows raised AT and alkaline phosphatase levels, with hyperbilirubinemia in severe cases. Peripheral eosinophilia can occur. Liver biopsies show intrahepatic cholestasis and portal inflammation, often accompanied by numerous eosinophils. Rare cases have been associated with chronic cholestasis, with biliary ductopenia on histologic sections.

Most recover after the drug is withdrawn, although liver test abnormalities may take up to 4 months to subside (87). Cross-sensitivity between erythromycin preparations has been reported (113). Intravenous

erythromycin lactobionate (179) has been implicated in a case of fulminant hepatitis.

Clarithromycin (180,181), *azithromycin* (182,183), and *roxithromycin* (184) have also been associated with cholestasis or mixed hepatocellular–cholestatic injury. Two reports of fulminant hepatic failure have accrued for clarithromycin; one of these patients was also receiving disulfiram (see "Disulfiram") (185,186).

Antituberculous Drugs

Of the current antituberculous drugs, hepatotoxicity is an important complication of INH, rifampin, and pyrazinamide, particularly when used in combination. Risk factors for liver injury are shown in Table 33.19. Except for a single report of cholestasis (187), *ethambutol* appears to be devoid of hepatic adverse effects. Among drugs used in the past, severe hepatocellular injury and cholestasis were recorded with *p-aminosalicylic acid*, often as part of a multisystem syndrome with hypersensitivity features (2); *prothionamide* (hepatocellular injury); and *ethionamide* (2). Ethionamide is still used rarely as a second-line antituberculous drug. Rifabutin causes liver enzyme changes, but these are usually part of hepatic adaptation; hepatitis has not been a problem.

Isoniazid

Frequency and risk factors

The hepatotoxic potential of INH was established by landmark studies in the late 1960s and early 1970s (188,189,190,191). Minor (less than threefold) elevations in the level of serum AT occur in 10% to 20% of subjects during the first 3 months of treatment. However, these AT abnormalities often settle with continued treatment and a progressive rise is uncommon. Jaundice occurs in approximately 1% of recipients of INH but in more than 2% of those aged 50 years or older. Conversely, liver injury is rare in persons younger than 20. Women, especially of African American and Hispanic ethnicity, and

persons with a history of excessive alcohol use are also at increased risk of toxicity (190,192). The presence of hepatitis B, hepatitis C, or HIV has been suggested as a risk factor (54,193). The relative risk of developing hepatotoxicity if the person was hepatitis C or HIV positive was 5-fold and 4-fold, respectively, and 14-fold in case of HIV/HCV coinfection. Antituberculous therapy could be reinstituted after successful antiviral therapy against HCV. In another study, persons who were hepatitis B surface antigen (HBsAg) positive were more likely to sustain liver injury than HBsAg-negative individuals (9). Further, those with positive replication status (i.e., HBeAg positive) had a higher likelihood of developing hepatotoxicity with INH than those with "inactive" hepatitis B (7.7-fold increased risk). Discontinuation rates were also higher in the former group. Opposing views were expressed in a case–control study (194) in which malnutrition was the only determinant of hepatotoxicity.

Table 33.19. Risk Factors for Antituberculosis Treatment–Related Hepatotoxicity

Age over 60 y
Serum albumin <35 g/L
Female gender
Increased serum bilirubin, preexisting chronic liver disease
Hepatitis B surface antigen positivity
Genetic factors: Human leukocyte antigen haplotype associations, glutathione-*S*-transferase mutations
Multidrug regimens, particularly those containing pyrazinamide
Excess alcohol consumption
CYP 2E1 status

Evidence regarding the influence of the acetylator phenotype has been conflicting. Initial studies conveyed the impression that fast acetylators are at increased risk, but other reports have suggested either that the acetylator status is not a predictor of toxicity (195,196) or that slow acetylators are more susceptible (197,198).

Metabolic idiosyncrasy is postulated as the basis for INH toxicity. Therefore, a CYP-generated toxic metabolite of INH induces oxidative stress–mediated injury to mitochondria or other key organelles. This could explain why the risk of severe liver injury is enhanced by concomitant intake of rifampicin (197) and why pyrazinamide (which is structurally similar to both INH and nicotinamide, a dose-dependent hepatotoxin discussed later) is also associated with an increased risk of more severe hepatotoxicity. Persons carrying certain genetic polymorphisms in key enzymes (e.g., CYP 2E1) that enhance reactive metabolite formation or that are involved in detoxification processes (e.g., glutathione-*S*-transferase) (199) may be predisposed to INH-induced liver injury. An association with certain HLA haplotypes (absence of HLA-DQA1*0102 antigen and the presence of HLA-DQB1*0201 antigen) was observed in North Indian patients (200) (Table 33.19).

Clinical features, outcome, and management

Prodromal features are those of nonspecific drug reactions or resemble those of viral hepatitis. Because of the often vague nature of these symptoms, patients taking INH should be warned (repeatedly) about the potential significance of malaise, fatigue, anorexia, nausea, vomiting, and dark urine. Jaundice is the presenting symptom in 10% of patients. Fever, rash, eosinophilia, or other manifestations of drug hypersensitivity are rare. Patients present within 4 weeks of starting INH in 15% of cases; half of them present within 2 months, but the onset may be delayed from 3 to 12 months in the remainder. A marked rise of AT levels is common, with peak values as high as 4,000 IU/L. Liver biopsy shows lobular hepatitis, often with marked hydropic changes of hepatocytes, and bridging (submassive) or massive (panlobular) hepatic necrosis in fatal cases. Cases associated with apparent chronic hepatitis (without autoimmune features) and cirrhosis have been described rarely, mostly before HCV testing was introduced. These seem to be cases of chronic hepatotoxicity not chronic hepatitis, and patients generally recover after discontinuation of the drug.

Rapid resolution of symptoms and liver test abnormalities occurs when INH is stopped before the onset of liver failure. The almost universal feature of cases leading to liver transplantation or fatal liver failure, from the early 1970s until the present time (190,201) is continued ingestion of INH after commencement of symptoms. The case fatality of patients with jaundice exceeds 10%. Management of liver failure is supportive; corticosteroids are of no benefit. Liver transplantation has been performed successfully (201).

Prevention

In the United States, a 9-month course of INH is recommended for tuberculin-positive family members of patients with tuberculosis. Monitoring of ALT, aspartate aminotransferase (AST), and bilirubin level is recommended at baseline in high-risk groups (e.g., HIV-positive individuals, those with a history of alcoholism, individuals with previous liver disease, pregnant women, and those presenting in the postpartum period) and during treatment (if baseline values are abnormal and in high-risk groups) (202). It is now generally agreed that patients taking INH (or other forms of antituberculosis chemotherapy) should be advised to seek medical attention as soon as new symptoms develop, even if these seem nonspecific and relatively minor. Biochemical monitoring does not effectively substitute for clinical monitoring (203). Therefore, one study found that no more than 0.15% of over 11,000 clinically monitored patients receiving INH developed significant hepatotoxicity (202). In contrast, the most noteworthy aspect of US case reports of liver failure attributable to antituberculosis chemotherapy that resulted in death or liver transplantation has been the failure of patients to report early symptoms and/or failure of health care workers to recognize the significance of these symptoms, thereby allowing continued intake of INH (190,201).

Rifampin

A meta-analysis showed that regimens combining INH and rifampin were associated with a higher incidence of hepatotoxicity (2.5%) than did regimens without this

combination (1.1%) (204). Rifampin probably increases both the risk and severity of INH-associated liver disease (197). The potent CYP-inducing properties of rifampin could facilitate the production of reactive INH metabolites.

On some occasions, rifampin may itself be hepatotoxic, as shown by cases with positive rechallenge and in situations where it is used alone (e.g., to relieve pruritus) (205). In the latter setting (typically in persons with PBC), the frequency of rifampin hepatitis (7.3% to 12.5%) may be higher than what is generally recognized (206). Liver test result changes usually occur within 2 months, rarely as late as 14 months; they mostly conform to a mild hepatocellular pattern (207). The clinical features resemble viral hepatitis. Histologic features include focal hepatocellular necrosis and apoptosis (acidophilic bodies), especially in zone 3; portal inflammation; and cholestasis. Patients recover when rifampin is stopped. However, continued use of rifampin has been associated with jaundice and impaired hepatic synthetic function; histology showed severe interface and intra-acinar hepatitis together with bridging and confluent necrosis. Therefore, new recipients of rifampin (monotherapy) should be prescribed in lower dosages (150 mg/day) initially and the dosage titrated to the clinical response. Rifampin can also be associated with hyperbilirubinemia, possibly because of impairment of canalicular drug transporters (208). This transport defect is unrelated to hepatocellular injury or cholestasis and resembles reactions to cyclosporine.

Interstitial nephritis, described with intermittent use of rifampin, can accompany liver injury. Conversely, in one series of 60 patients with rifampin nephrotoxicity, concurrent hepatotoxicity was present in 25% (209).

Increased liver enzymes were reported in 12% of recipients treated with high-dose *rifabutin*, a rifamycin antibiotic. Serious liver injury has not been reported (185).

Pyrazinamide

Pyrazinamide causes dose-dependent liver injury. High-dose pyrazinamide (40 to 50 mg/kg) was associated with a greater frequency of hepatotoxicity than the doses used in current regimes (25 to 35 mg/kg). The concurrent administration of pyrazinamide with INH–rifampin increases the risk of hepatotoxicity compared to dual therapy (210). A recently approved 2-month protocol of rifampin and pyrazinamide for treating latent tuberculosis infection (LTBI) was associated with significant liver injury. Twenty-three cases of acute hepatitis were reported (211), all developing in the second month of treatment. There were seven deaths and the case-fatality rate was estimated to be 0.9 per 1,000 treatment initiations. In some cases, patients continued taking their medications after the onset of symptoms. On the other hand, one patient developed symptoms 6 weeks

after the drugs were stopped and eventually needed a liver transplantation 1 month later. Many restrictions have been placed in using this drug combination for LTBI; frequent liver test monitoring, absence of alcohol abuse or history of isoniazid toxicity, and need for monitoring by experienced physicians have been recommended (211). An alternative combination of pyrazinamide with levofloxacin for treating LTBI has also fallen out of favor because of the increased frequency of side effects, including hepatocellular injury (212).

Perceptions of the excellent safety of antitubercular drugs in children have been challenged by a Japanese report of hepatotoxicity in children younger than 5 years (213). Ohkawa et al. studied 117 pediatric recipients of antituberculosis treatment. Of these, 8% developed hepatotoxicity, all eight being younger than 5 years; four were receiving pyrazinamide. The probability of developing liver injury with a pyrazinamide-based regime was estimated as 0.95, 0.72, and 0.16 at 1, 5, and 10 years of age, respectively. On the basis of this observation, the authors have suggested careful monitoring of children younger than 5 years receiving pyrazinamide-based antituberculosis drug treatment (213).

Antifungal Drugs

Liver injury with the oral "azole" antifungal agents is best documented for *ketoconazole* (Table 33.20), but *itraconazole* and *fluconazole* have been implicated in a few reports (214,215,216,217,218,219,220,221). *Itraconazole* is largely perceived as being nonhepatotoxic. However, among more than 69,000 patients who received an oral antifungal agent, ketoconazole and itraconazole were most often associated with liver injury; the relative risks were 228 and 17.7 respectively, compared to nonusers (222). Further, a U.S. Food and Drug Administration (FDA) public health advisory has been issued after receiving 40 reports of acute liver failure in association with itraconazole; there were 22 deaths and two patients needed liver transplantation. In view of the serious nature of possible (although rare) liver injury, a diagnosis of onychomycosis should be clearly established before starting antifungal treatment.

Ketoconazole

Between 5% and 17% of recipients of ketoconazole develop abnormal liver test results. Previous estimates of symptomatic hepatitis have varied between 0.7 and 5 per 10,000 persons exposed (214,223). More recent studies cite figures of almost 20 per 10,000 persons exposed (222,224). Biochemical tests most often reflect a hepatocellular pattern, but cholestatic or mixed hepatocellular–cholestatic reactions are also common.

Women (female-to-male ratio 2:1) and persons older than 40 years are particularly susceptible (214,224) to ketoconazole-induced liver injury.

Table 33.20. Liver Injury Associated with Antifungal Drugs

Drug	Pattern of liver injury	Comments
Amphotericin	Hepatocellular	Rare
Griseofulvin	Cholestasis	Mallory bodies in mice; liver toxicity in humans is rare
Ketoconazole	Hepatitis, cholestasis, fulminant liver failure, cirrhosis (single case)	Frequency of liver injury is approximately 20 per 10,000 persons exposed
Itraconazole	Acute hepatitis, prolonged cholestasis (two cases) with biliary ductopenia (vanishing bile duct syndrome); acute liver failure	Pulse therapy appears safer than continuous dose regimes
Fluconazole	Raised alanine aminotransferase level in 25% of recipients, rarely hepatitis, fatal hepatic necrosis	Patients with human immunodeficiency virus/acquired immunodeficiency syndrome may be particularly susceptible
Terbinafine	Cholestasis, vanishing bile duct syndrome, acute liver failure	Frequency of liver injury approximately 1 per million persons exposed
Flucytosine	Transient rise in aminotransferase levels (10%); hepatic necrosis	Dose-dependent liver injury

Symptoms develop within 6 weeks in 60% of patients but can also be delayed (up to 6 months) (214,225). Jaundice occurs in 50% of those developing acute hepatitis, but up to one third may present with nonspecific symptoms, such as nausea, anorexia, and vomiting. Fever, rash, eosinophilia, and other immunoallergic characteristics are uncommon; liver injury is therefore hypothesized as a sequel of metabolic idiosyncrasy (226). Unintentional positive rechallenge has been described 30 months after the first reaction (227). Fulminant hepatic failure requiring liver transplantation has been reported (228). Fatal liver failure also follows the use of ketoconazole to reduce hypercortisolism in Cushing's syndrome (229).

The common histologic change is diffuse hepatocellular necrosis, particularly evident in zone 3, but cholestasis can be prominent (214). Recovery is usual after discontinuation of the drug, but progressive liver disease can occur if the drug is continued after the onset of symptoms. Several instances of protracted jaundice have been described. In one case ascites, pedal edema, and progressive hypoalbuminemia were observed after an initial episode of acute hepatitis; liver histology obtained after 6 months showed cirrhosis (230).

Terbinafine

Terbinafine is an allylamine derivative used to treat superficial onychomycosis. Elevation of AT level (>2 × ULN) is observed in 3.3% of those treated, but the frequency of symptomatic hepatitis is substantially lower (approximately 2 per 10,000 persons exposed) (231).

Hepatocellular mixed or bland cholestatic reactions have been reported. Most patients were older than 50. No clear gender differences were observed (232). Onset is within 3 to 8 weeks of beginning treatment. Symptoms may appear as long as 2 months after the drug has been discontinued; liver biopsies show hepatocyte degeneration and canalicular cholestasis with variable portal tract inflammation (82). Prolonged cholestasis with progressive biliary ductopenia and portal fibrosis (233,234) can occur. Terbinafine hepatotoxicity mimicking acute rejection has been reported in a liver transplant recipient (235). Although a rare association, the FDA has received at least 16 reports of fulminant liver failure possibly linked to terbinafine (236). Such an outcome has been estimated at 1 per million persons exposed (231). Recovery is usual with drug discontinuation. There have been anecdotal reports of ursodeoxycholic acid hastening recovery in a few protracted cases (237). Terbinafine-associated liver injury is probably idiosyncratic because hypersensitivity features are unusual. The recent identification of a hepatotoxic metabolite of terbinafine is consistent with this hypothesis (238). Liver injury associated with other antifungal drugs is summarized in Table 33.20.

Agents Used to Treat Parasitic Infestations

Pyrimethamine–sulfadoxine (Fansidar) has been linked with several instances of severe hepatocellular injury, including fatalities from hepatic necrosis. The frequency of liver toxicity is approximately 1 per 100,000 prescriptions (239). Because liver injury has been attributed to pyrimethamine and sulfonamides (see preceding text), it is not clear which component is responsible or whether interaction between the two components is important (240). The hepatotoxicity of other antimalarial and antiparasitic agents is summarized in Table 33.21.

Table 33.21. Liver Injury Associated with Antiparasitic Agents

Drug	Pattern of liver injury	References
Albendazole	Raised aminotransferase levels (20%), jaundice (5%)	(241)
Amodiaquine	Severe hepatitis (1 in 15,000 exposed); dose dependent	(239)
Antimonials	Steatosis	(2)
Artemisinin	Raised aminotransferase levels (0.9%)	(242)
Atovaquone-proguanil	Transient alterations in aminotransferase levels	(243)
Chlorguanide	Acute hepatitis (single case)	(244)
Mebendazole	Acute hepatitis; granulomatous hepatitis	(245)
Mefloquine	Transient rise in aminotransferase levels, fatty liver (one case)	(246,247)
Metronidazole	Hepatocellular carcinoma; cholestasis (few cases)	(248,249)

Ornidazole	Acute hepatitis, acute cholestatic hepatitis, chronic hepatitis	(250)
Thiabendazole	Cholestasis, vanishing bile duct syndrome; cirrhosis, occasionally associated with sicca syndrome	(251,252)
Quinine	Granulomatous hepatitis (usual presentation); mixed hepatocellular–cholestatic reactions	(253,254)
Quinacrine	Acute hepatitis, cholangitis	(255)

P.950

Antiretroviral Therapy (Highly Active Antiretroviral Treatment)

The frequency of hepatic injury with HAART (which often includes three to four agents) is at least 10%. The agents used can be broadly categorized as nucleoside (or nucleotide) reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors, and protease inhibitors.

Nucleoside (or nucleotide) reverse transcriptase inhibitors

Mitochondrial toxicity is a group-specific feature of the NRTIs used to treat HIV (256,257) and HBV infections. The first-generation NRTIs, zidovudine, didanosine, and stavudine, have most often been implicated in causing liver injury (258,259,260,261,262,263,264,265). These agents inhibit mitochondrial deoxyribonucleic acid (DNA) polymerase-γ, a key enzyme involved in mitochondrial DNA replication. Additional mechanism of hepatotoxicity may involve oxidative stress, the consequences of impaired oxidative phosphorylation and fatty acyl β-oxidation, and insulin resistance. Reported risk factors for mitochondrial drug toxicity among people with HIV infection include obesity, female gender, and absence of AIDS-defining illness (256); one study was unable to confirm the gender predisposition or the influence of HIV status (256). Mitochondrial toxicity is unusual with second-generation NRTIs such as lamivudine, tenofovir, and abacavir.

The hallmarks of mitochondrial hepatotoxicity are extensive microvesicular and/or macrovesicular steatosis, lactic acidosis (sometimes with a shock-like state), and liver test abnormalities, progressing to acute liver failure. Asymptomatic hyperlactatemia is common (especially with stavudine) among those treated with HAART (266), but life-threatening lactic acidosis/hepatic steatosis is rare; the estimated risk is 1 to 15 per 1,000 person-years of antiretroviral use (259,267). Onset is usually within 6 months (range, 3 to 17 months) of starting treatment. The presenting symptoms are nonspecific: Nausea, vomiting, diarrhea, dyspnea, lethargy, and abdominal pain. In many cases there are extrahepatic manifestations, such as myopathy or peripheral neuropathy, and in severe cases pancreatitis and renal failure may follow the onset of the lactic acidosis and liver injury. Discontinuation of drugs is mandatory, but despite this deaths still occur (259).

Non-nucleoside reverse transcriptase inhibitors

Persons receiving nevirapine or *abacavir* (an NRTI) can develop an early (within 6 weeks) severe hypersensitivity reaction manifested by fever, rash, and eosinophilia. In such individuals, further use of these agents is contraindicated (Table 33.5). *Nevirapine* has also been implicated in causing severe hepatotoxicity (268,269). Examples include health care workers developing liver injury after receiving nevirapine as part of postexposure prophylaxis (270). The FDA received 12 reports of such hepatotoxic reactions during 1997 through 2000; seven recipients developed acute hepatitis, four had asymptomatic increases in serum AT levels, and one person developed acute liver failure. It is noteworthy that in some cases there was no adherence to the recommended 2-week dose escalation regime (271).

Nevirapine is no longer recommended for postexposure prophylaxis and should be used with caution in individuals with liver disease (272). Sequential toxicity with nevirapine followed by *efavirenz* has been reported in an HIV–HCV coinfected person (273). Although one study reported a lower frequency of liver toxicity with efavirenz (8%) as compared to nevirapine (15%), there are other reports that did not

P.951

show significant differences in hepatotoxicity (267). A combination of genetic and immune factors has been identified that could predict some nevirapine reactions. In one predominantly white cohort, HIV-positive individuals with a CD4 percentage over 25% who also carried the HLA-DRB1*0101 haplotype were at risk of developing liver toxicity with rash and/or fever. The authors calculated that screening for this HLA haplotype could prevent 1 in 14 potentially fatal reactions (274) among whites with a CD4 percentage over 25%. Pregnant women should also use nevirapine with great caution. Likewise, the same group also found that the presence of HLA-B*5701, HLA-DR7, and HLA-DQ3 had a positive predictive value of 100% in predicting abacavir hypersensitivity (275).

Protease inhibitors

Elevated liver enzyme levels are common with this class of drugs, but clinical hepatitis is infrequent (276).

The agents most often implicated in liver injury are *ritonavir* and *indinavir*. *Indinavir* and *atazanavir* may also be associated with unconjugated hyperbilirubinemia in 6% to 40% of treated persons, resulting from inhibition of uridine diphosphate–glucuronosyl transferase, a finding that is of no clinical consequence (277). Severe acute hepatitis can rarely occur with indinavir and atazanavir (278,279). The association with peripheral and/or tissue eosinophilia in some biopsied cases involving indinavir suggests an immunoallergic liver injury (279).

Acute hepatitis has also been reported in 3% to 30% of those prescribed ritonavir (280). The course of the illness is generally mild, and the liver injury responds favorably to drug withdrawal. Rarely, acute liver failure may develop; in these cases, liver histology shows severe microvesicular steatosis, cholestasis, and extensive fibrosis (280). By contrast, the combination of low-dose ritonavir (200 mg/day) with other protease inhibitors is not associated with an increased frequency of severe liver injury when compared with protease inhibitors such as nelfinavir or efavirenz (281).

Two studies have addressed the potential impact of underlying chronic viral hepatitis on the toxicity of protease inhibitors. Although hepatotoxicity was more frequent, the liver injury was rapidly reversible in most cases; this suggests that there is no overall detrimental effect of protease inhibitors when used in HIV/HCV or HIV/HBV coinfected persons (282). Further, the immune reconstitution that can follow successful HAART may cause a flare-up of previously quiescent chronic hepatitis B (283).

Monitoring for hepatotoxicity

The concept of monitoring for hepatotoxicity is beyond the scope of this chapter (see also HIV and the liver) but a few general rules have emerged. Baseline and serial monitoring of liver tests should be routine in HAART recipients. Grade 4 hepatotoxicity (AT × 10 × ULN or bilirubin × 5 × ULN) warrants immediate discontinuation and use of an alternative drug combination. For lesser changes in liver test results, frequent monitoring (1 to 2 weeks) is suggested, with treatment being continued only if there are no signs and symptoms of hyperlactatemia, hepatitis, or hypersensitivity (267).

Cardiovascular Drugs

Angiotensin-converting enzyme inhibitors

Drug-induced liver disease is a rare but important complication of this widely prescribed class of drugs. Onset of liver injury has varied from 2 weeks to 4 years after starting treatment (284). Cholestatic liver toxicity predominates. Recovery is usual but may be protracted (up to 6 months). Fatalities or advanced liver injury (e.g., ductopenia, cirrhosis) are infrequent (285).

Captopril is the oldest and possibly most hepatotoxic representative. Reactions to it and to *enalapril* usually manifest as cholestatic hepatitis, but hepatocellular or mixed hepatocellular reactions can occur both in adults and rarely in children (284). Enalapril-related cholestatic hepatitis can culminate in biliary ductopenia. However, the short-term outcome seems favorable after drug withdrawal (286). Hypersensitivity features such as fever, skin rashes, and eosinophilia can accompany captopril hepatotoxicity (287). Fulminant hepatic failure has been attributed to *lisinopril* (288), while *fosinopril* has been associated with bland cholestasis (289). Three instances of cholestatic liver injury have been recorded with *ramipril*; liver histology showed cholestasis, bile duct necrosis, bile extravasation, and ductular proliferation. Prolonged cholestasis was observed in one case (14 months); liver biopsy showed biliary cirrhosis (285).

Methyldopa

Methyldopa is much less prescribed now, but it retains a place in the management of obstetric hypertension. The history of methyldopa-induced liver injury remains relevant because of the range of hepatic disorders it can produce. These encompass a spectrum of toxicity including asymptomatic elevation of AT levels, acute hepatitis, chronic hepatitis, cirrhosis, bland cholestasis, cholestatic hepatitis, steatosis, and hepatic granulomas (14,290,291). Between 10% and 30% of recipients have abnormal liver test results without overt liver disease, and these changes often resolve despite continuation of the drug (2). Acute hepatitis occurs in less than 0.1% of recipients, usually within 3 months of starting methyldopa treatment; up to 50% present within 2 to 4 weeks.

The clinical presentation resembles that of acute viral hepatitis, with anorexia, nausea, and vomiting,

followed by jaundice. Serum AT levels are elevated (5 to 30 × ULN), with moderately raised SAP level. Liver biopsy specimens show focal or confluent hepatocellular necrosis, acidophilic bodies, and mixed portal/periportal inflammatory infiltrates. Bridging hepatic necrosis and massive hepatic necrosis can occur. Tissue or peripheral eosinophilia is rare. Most patients recover after withdrawal of the drug. However, mortality among patients presenting with jaundice has been reported to be 10% or higher (290).

Chronic hepatitis or cirrhosis has been reported as the first clinical manifestation of liver injury (290). In such cases, liver histology shows confluent areas of lobular collapse, periportal necrosis, and inflammation; the latter includes plasma cells and occasional eosinophils (290). Fibrous septa and established cirrhosis may also be present. Older reports of middle-aged women with steatosis and cirrhosis attributed to long-term methyldopa therapy may have confused drug reactions with NASH (108).

The pathogenesis of methyldopa-induced liver injury has been attributed to either immunologic or metabolic

idiosyncrasy; this dramatically illustrates the uncertainty of the indirect criteria used to assign etiopathogenic mechanisms of drug-induced liver disease. Female preponderance, positive rechallenge, presence of autoantibodies (ANAs, less commonly SMAs), hypergammaglobulinemia, and a positive Coombs' test have been cited in favor of an immune basis, but many of these features occur in those taking methyldopa without developing liver injury. Conversely, there is some evidence that methyldopa can be metabolized to a reactive intermediate (semiquinone or quinone) (2), and this could cause membrane injury or generate a neoantigen target for an immune-mediated hepatodestructive response.

β-Blockers

The hepatotoxic potential of β-blockers is very low, but reactions to *acebutolol*, *propranolol* (2), *metoprolol* (292) (both hepatocellular), *atenolol* (cholestasis), *carvedilol* (mixed hepatocellular–cholestatic) (293,294,295), and *labetalol* (296) have been described. *Labetalol* has been implicated in over 11 reports of acute hepatitis, including three fatal cases (296); histology showed massive, submassive hepatic necrosis or chronic hepatitis.

Calcium channel blockers

Liver injury associated with the calcium channel antagonists (e.g., *verapamil*, *nifedipine*, *diltiazem*) is infrequent. Most reported cases were hepatocellular in nature (297), but other presentations include cholestasis, granulomatous hepatitis (e.g., diltiazem) (298), and steatohepatitis (e.g., nifedipine and diltiazem) (299). As discussed earlier, the association of calcium channel blockers with steatohepatitis may be fortuitous because hypertension is a component of the metabolic syndrome, which predisposes to NASH.

Diuretics

Of the currently used thiazide derivatives, *chlorothiazide* (14), *chlorthalidone*, and *hydrochlorothiazide* (2) have been linked with rare instances of cholestasis. *Ticrynafen* (tienilic acid), a uricosuric diuretic, was associated with acute and chronic hepatocellular injury. The case-fatality rate was 10% (300), as a result of which this agent was withdrawn. Experimental studies of tienilic acid toxicity have been of interest because they provide an illustration of drug-induced AIH. Circulating antibodies directed against hepatic CYP 2C9 (which catalyzes the oxidation of tienilic acid) were often present in the sera of affected patients (301). There are a few anecdotal reports of acute hepatitis with *spironolactone* (14,302).

Hydralazine

Acute hepatitis with bridging necrosis is an occasional complication of hydralazine treatment. Granulomas (303) and cholestasis have also been described (304).

Other antihypertensive agents

Angiotensin II receptor antagonists

Although their overall hepatotoxic potential appears low, cases of liver injury have accrued with all drugs within this group. Most cases have occurred within 5 months of commencement. *Tasosartan* was withdrawn at the preregistration stage because of hepatotoxicity (305). *Losartan*, *valsartan*, and *candesartan* have been implicated in causing acute hepatitis or cholestatic hepatitis (306,307). Early resolution has been the rule after stopping these agents. Exceptions include two reports of prolonged cholestasis (1 year) after *irbesartan*-associated cholestatic hepatitis and biliary ductopenia accompanied by portal–portal fibrosis with candesartan (306). Irbesartan has also been implicated in triggering acute hepatitis with histologic features of AIH. Although autoantibodies were absent, the subsequent course, including steroid responsiveness and relapse with steroid withdrawal, was indistinguishable from AIH (308).

Antiarrhythmic Drugs

Amiodarone

Amiodarone is widely used in treating refractory ventricular and supraventricular tachyarrhythmias. Raised AT levels (one- to fivefold) are observed in up to 25%, but clinically significant liver disease occurs in 0.6%

of amiodarone recipients (309). The typical histologic lesion is a form of steatohepatitis that is indistinguishable from alcoholic liver disease (309,310), with microvesicular and macrovesicular steatosis, hydropic change, Mallory bodies, neutrophilic infiltrates, and pericellular and perivenular fibrosis. Micronodular cirrhosis is present in 15% to 50% (311) of cases. Other manifestations include granulomas, cholangitis (312), and acute liver failure; the latter may result from severe acute hepatitis or a Reye's syndrome–like illness (313), which has been reported within a few days of starting treatment with amiodarone. Amiodarone can also cause acute hepatic injury (314) within hours to days of an intravenous loading dose. Rapid resolution follows drug withdrawal, although a single loading dose can be fatal. In a few cases, positive rechallenge has been observed. The vehicle, polysorbate 80, rather than amiodarone itself may be responsible for the hepatotoxicity associated with parenteral preparations of the drug; the successful reintroduction of oral amiodarone in such cases supports this hypothesis (315,316).

The onset of amiodarone-induced chronic liver disease is delayed and insidious; most patients have received

treatment for at least a year (median, 21 months) (14). Symptoms include fatigue, weight loss, nausea, vomiting, and abdominal swelling due to ascites. Hepatomegaly, jaundice, and other features of chronic liver disease are evident. Liver test abnormalities are often seemingly minor, even in cases with hepatic decompensation. AT values are increased at least fivefold above normal, with the AST:ALT ratio close to unity; this differs from those with alcoholic hepatitis. There is a minor increase in SAP level. In more severe cases there may be jaundice, hypoalbuminemia, and prolongation of prothrombin time. Chronic liver injury from amiodarone is associated with prolonged storage of the drug in the liver, which therefore appears radio-opaque on computed tomographic (CT) examination because of the iodine content of this iodinated benzofuran derivative (317). Electron microscopy shows lysosomal inclusions (representing phospholipidosis) in hepatocytes and other liver cells (318). The presence of hepatocytes with the granular cytoplasm has been suggested as an early marker of amiodarone toxicity (319).

In less severe cases, biochemical resolution occurs between 2 weeks and 4 months after stopping amiodarone. However, in advanced cases the mortality is high, with a progressive decline in liver function despite discontinuing treatment. A likely explanation is that tissue levels of the drug remain high for some time because of the prolonged retention of amiodarone and its principal metabolite *N*-desethylamiodarone in hepatic lysosomes.

Prevention of amiodarone toxicity by baseline and serial monitoring of liver tests has been suggested (320). In many cases, this is impractical because of the high frequency of abnormal liver test results in patients treated with amiodarone because of factors such as cardiac failure, other drugs, or NASH. Furthermore, the development of abnormal liver test results during amiodarone therapy represents a conundrum because in one uncontrolled study the cardiac mortality after stopping amiodarone exceeded the total mortality among those who continued the drug despite suspected adverse reactions (311). Another recommendation is the measurement of serum amiodarone levels in long-term amiodarone recipients; ALT level elevations were minimal in those with serum amiodarone concentration of less than 1.5 mg/L (320).

The pathogenesis of phospholipidosis from amiodarone is unclear but may be related to inhibition of the lysosomal phospholipase, A_1 and A (321). Phospholipidosis is a constant association with steatohepatitis but appeared not to be related to it pathogenetically in animal studies. A series of elegant studies from Hospital Beaujon in Paris has shown that amiodarone, an amphiphilic cationic compound, accumulates in the anionic milieu of the mitochondrial matrix, and this leads to the disruption of mitochondrial electron transport and impairment of β-oxidation of fatty acids, resulting in microvesicular steatosis, generation of oxidative stress, and lipid peroxidation (322,323,324).

Other antiarrhythmic drugs

Quinidine is an infrequent cause of hepatocellular injury. Fever and elevated AT levels occur 1 to 24 weeks after commencing therapy (325). Liver histology shows hepatic necrosis and granulomas (326). Recovery usually occurs after stopping the drug. *Procainamide* has been associated with hepatic granulomas, hepatocellular injury, and intrahepatic cholestasis (14,327). *Propafenone* has been implicated in at least nine cases of predominantly cholestatic jaundice (328). Most reported cases occurred within 2 to 6 weeks (range, 2 to 28 weeks). Liver biopsy specimens showed portal tract inflammation with prominent cholangiolitis. No fatalities were recorded. Resolution occurred several months after drug cessation (328).

Anticoagulants

Unfractionated heparin and *low-molecular-weight heparins* can both cause elevation of serum AT levels (329). At least four cases of cholestasis have accrued with unfractionated heparin (329). Of the currently used oral anticoagulants, the *coumarin* derivatives (e.g., warfarin, phenprocoumon, dicoumarol, acenocoumarol) have been associated with transient increases in liver enzyme levels, which usually settle without changing therapy. Occasionally, they may cause hepatocellular or mixed hepatocellular–cholestatic injury and bland cholestasis (329). Several instances of acute

hepatitis including subacute liver failure requiring liver transplantation have been reported from Germany, where *phenprocoumon* is used extensively (330,331). An alternative coumarin or reintroduction of phenprocoumon can be considered in mild cases. However, reintroduction may be unsuccessful and further cross-reactivity with other coumarins can also occur. In such cases, long-term anticoagulation is achieved with low-molecular-weight heparin. *Phenindione* has now been withdrawn; it was associated with severe hypersensitivity reactions and liver injury in up to 10% of recipients (14).

Lipid-Lowering Drugs

Hydroxymethylglutaryl-coenzyme A reductase inhibitors (the "statins")

Overall, the statins are not strongly associated with significant hepatic injury, although there appears to be discordance between literature reports and data contributed to drug safety surveillance authorities. The frequency of hepatotoxicity is estimated at approximately 1 per 100,000 patient-years of exposure; comparative figures for NSAID liver injury are between 2.2 and 50 per 100,000 patient-years of exposure (332). Between 1% and 3% of people who receive statins develop a dose-related increase in ATs (332). These abnormalities settle rapidly with discontinuation of treatment and often also if therapy is not interrupted (332). Further, a recent study did not find significant differences in the frequency of severe hepatoxicity (serum bilirubin >3 mg/dL or AT × 10 times ULN or baseline values) between a cohort with and without

baseline elevation of liver test results (0.6%, 0.2%, respectively) (333).

Lovastatin (334), *pravastatin* (335), *atorvastatin* (336), and *simvastatin* (337) have been implicated in a few cases of cholestatic hepatitis. Acute liver failure has also been attributed to lovastatin. This is an extremely rare event (<1 per million patient-treatment years) and its frequency is similar to the background rates for idiosyncratic acute liver failure in the community. AIH has been associated with atorvastatin; the drug appears to have unmasked preexisting AIH rather than induce immune liver injury by itself (338).

Although monitoring liver enzyme levels is often recommended, this is neither likely to predict toxicity (331,339) nor likely to be cost-effective. In the Air Force/Texas Coronary Atherosclerosis Prevention (AFCAPS/TEXCAPS) study, only 18 of 100,000 AT estimations performed were raised more than three times the ULN; in none of these instances did the affected person develop hepatitis (339). Like amiodarone, the benefits of continued treatment may outweigh the potential (but low) risks of liver injury.

Other lipid-lowering drugs

Rare cases of acute hepatitis and cholestatic hepatitis have been attributed to the *fibrates*. A few cases of chronic hepatitis with portal or bridging fibrosis have also been described in persons receiving statins (340). Serologic and histologic features resembling AIH were observed but these resolved after the drugs were discontinued. Other than one report of hepatocellular injury with *colestipol*, bile acid sequestrants have not been implicated in causing liver injury (341).

Nicotinic acid (niacin)

The hepatotoxic potential of nicotinic acid has been recognized for more than 60 years; it is a dose-dependent hepatotoxin. Liver injury usually occurs at dosages that exceed 2 g/day, but rare examples of low-dosage (500 mg/day) sustained release (SR) niacin have been implicated in fulminant hepatic failure (342). Patients taking sulfonylurea drugs and those with preexisting liver disease, particularly alcoholic hepatitis, are at increased risk of nicotinamide hepatotoxicity (343,344).

Both the crystalline unmodified immediate-release (IR) and SR preparations have been associated with liver injury (345,346,347). SR preparations have improved bioavailability and are therefore more potent (about twice) than equivalent IR preparations; a dose reduction of 50% to 70% has been recommended (347). Hepatotoxicity has often occurred when the formulation of nicotinamide was changed without appropriate dose modification.

The symptoms of nicotinamide hepatotoxicity begin as early as 1 week to as long as 4 years after initiating therapy. Fatigue, malaise, anorexia, and jaundice are typical features, usually resolving completely when the drug is stopped. Liver biopsy specimens show hepatic necrosis and centrilobular cholestasis. Well-documented cases of fulminant hepatitis have also been attributed to nicotinamide, some necessitating liver transplantation (346).

Niaspan is an extended-release preparation of nicotinamide with IR characteristics. Its hepatotoxic potential appears to be minimal. Less than 3% of recipients developed elevated AT levels greater than two times the ULN; most were also receiving statins. Liver test results normalized with dose reduction (348).

Drugs Used in the Treatment of Endocrine Disorders

Oral contraceptive and anabolic steroids

Both OCSs and the 17-alkylated anabolic steroids are associated with cholestasis, vascular lesions, and hepatic neoplasms. However, the strength of these associations with individual lesions varies. Benign hepatic neoplasms are clearly associated with OCS, whereas

their association with HCC is controversial. By contrast, HCC is well documented in users of anabolic steroids. Likewise, hepatic and portal vein thrombosis is an established adverse effect of OCS, but not with anabolic steroids. Other vascular lesions, such as peliosis hepatis, are more often observed with anabolic steroids than with OCS.

Oral contraceptive steroids

Cholestasis

The frequency of cholestasis with OCS is 2.5 per 10,000 women exposed. Genetic factors influence the frequency of this complication, with a particularly high incidence among women in Chile and Scandinavia. Individuals with a previous history of cholestasis of pregnancy are also at risk (50%). Mild prodromal symptoms such as anorexia and nausea, followed by pruritus, develop 2 to 3 months after starting OCS (rarely as late as 9 months). SAP level is moderately elevated, and this is accompanied by a transient increase in ATs, occasionally exceeding 10 × ULN; GGTP levels are often normal. Development of chronic cholestasis is an extremely rare occurrence (82) and, in general, recovery is invariable within days to weeks of drug cessation. Hormonal replacement therapy (HRT) is safe in patients with liver disease, but jaundiced patients may experience an increase in bilirubin levels and should be monitored with liver tests (82).

Benign neoplasms

OCSs can induce enlargement of preexisting *hemangiomas* through their trophic effects on the vascular endothelium (349). Recurrences of hemangiomas have also been described in patients with a history of previously resected lesions (350). A role for estrogens in the pathogenesis of FNH is plausible because these lesions occur principally in young women (up to 86%) (351). However, unlike liver adenomas, an increased incidence of FNH has not been observed commensurate with the increasing use of OCS. Further, FNH can occur in persons not using OCSs (352). A study of over 200 patients with FNH failed to show a relationship between OCS and the size or number of FNH lesions (352). Discontinuation of OCS did not generally influence the size of FNH, and estrogen-dependent tumors were rare. The authors suggested that hepatic adenomas misclassified as FNH, could account for the apparent growth of FNH reported previously with OCS.

The association between OCS and *hepatic adenomas* was described approximately 30 years ago. The increasing frequency of this neoplasm has paralleled the rising use of OCS. In the 1970s and 1980s, the annual risk was approximately 3 to 4 per 100,000 exposed persons (25,100), but this risk is now probably lower with the lower-dose preparations currently used. There is also a relationship with the duration of OCS use, so that the risk (compared to nonusers) for long-term OCS users (>10 years) is increased 100-fold. Patients with liver adenomas usually present with a painless or tender right upper quadrant mass or occasionally with hemoperitoneum secondary to hepatic rupture. Adenomas usually regress after OCSs are withdrawn (101), but surgery is required for larger lesions to avert possible rupture (353) or because of the small but definite risk of malignant transformation. To prevent hepatic adenomas, OCSs with lower estrogenic potency are preferred. Long uninterrupted periods of OCS use should be avoided.

Hepatocellular carcinoma

The relative risk for HCC is increased twofold among women who have ever taken OCS, and it is increased sevenfold in long-term users (>8 years) compared with age-matched controls (26,353,354). However, it must be emphasized that estrogen-related HCC is rare, accounting for less than 2% of primary liver cancer in western countries. In countries with a high prevalence of HCC, OCS is not an independent risk factor because of the far greater importance of chronic viral hepatitis and aflatoxin (26). Median age at presentation is 30 years, and HCC occurs at least 5 years after starting combination OCSs. The tumors are well differentiated and have a better short-term outcome than HCC because of other causes (14).

Anabolic steroids

Cholestasis

At high doses, anabolic steroids often produce reversible bland cholestasis, usually within 1 to 6 months of beginning treatment. Prolonged jaundice with ductopenia is a rare complication (355). Acute hepatitis is also an unusual sequel after self-ingestion of high-dose anabolic steroids (356).

Benign neoplasms

The association with hepatic adenomas is less robust. Many reports were from patients with Fanconi's anemia (357), a disorder caused by genomic instability and a resultant high background incidence of neoplasms. However, reports of adenomas among female body builders and in persons taking anabolic steroids for other indications (354,358) indicate a probable etiologic association. Oral and parenteral androgens are both implicated (354).

Hepatic adenomas were identified in 3 of 11 long-term users of *danazol* (359), all patients with hereditary angioneurotic edema. Danazol-associated hepatic adenomas have also been observed in other disorders such as SLE and endometriosis. For this reason, surveillance ultrasonography is suggested in long-term recipients of danazol (359) and also for former users of other anabolic steroids; liver tumors have been described up to 24 years after steroid discontinuation (354). These tumors can regress with androgen withdrawal (360), but this is not always the case and surgical resection may be required.

Hepatocellular carcinoma

Several cases of HCC have been documented (361,362), but confounding

factors such as viral hepatitis were not clearly excluded in earlier cases. Because some of these tumors metastasize late and sometimes regress (363), doubts have been expressed about the true nature of these tumors; it is sometimes difficult to distinguish well-differentiated HCC from adenomas (364). Furthermore, hepatic adenoma and HCC can coexist (365). Four reports of HCC have been attributed to long-term *danazol* use (366,367); the underlying diseases were hereditary angioneurotic edema, SLE, and chronic idiopathic thrombocytopenic purpura. These liver tumors were large, well-differentiated carcinomas that did not show regression with drug withdrawal. Serum α-fetoprotein levels were normal in three of the four cases; therefore, α-fetoprotein cannot be used as the sole tumor marker for diagnosis in these patients.

Estrogen-receptor antagonists

The range of *tamoxifen* hepatotoxicity includes hepatic steatosis, NASH, and rare instances of submassive hepatic necrosis and even cirrhosis. Of these, the association with hepatic steatosis and NASH is most striking. In one series of 66 women with breast cancer who had received tamoxifen for 3 to 5 years, 24 showed radiologic evidence of hepatic steatosis (368). In another study, liver biopsy specimens were obtained from 15

women with moderate-to-severe hepatic steatosis (as designated by liver/spleen CT scan ratio of <0.5); 14 showed NASH (369). The metabolic profile of these women resembled that of most patients with NASH; half were obese and hepatic steatosis correlated with increases in body mass index (370). Tamoxifen can also induce hypertriglyceridemia, a risk factor for NASH. It therefore seems possible that tamoxifen may play a synergistic role with other factors such as hyperlipidemia, obesity, and insulin resistance to cause NASH. A more direct role for tamoxifen has been postulated recently on the basis of results of a study showing inhibition of intrahepatic fatty acid synthesis, which contributes to steatosis (371).

Physicians should be aware of the high frequency of hepatic steatosis (approximately 30%), as determined by hepatic imaging, or NASH in women treated with tamoxifen. Monitoring patients for this adverse effect should include physical examination for hepatomegaly and liver tests. Some authors have also recommended that hepatic imaging (ultrasonography or CT) be performed annually (372). Liver biopsy is required to establish the severity of the disorder, particularly if liver test abnormalities fail to resolve after stopping tamoxifen, and also to exclude metastatic breast cancer in difficult cases. Many cases improve after stopping tamoxifen, but this is a valuable agent for the treatment of breast cancer, and it is not yet clear whether treatment should always be withdrawn permanently. Preliminary experience with bezafibrate appears promising; improvement in liver imaging characteristics and AT level was demonstrated in a small series (369). An alternate strategy is to attempt optimization of the metabolic milieu, especially in patients with preexisting hepatic steatosis; 43% of this group developed increases in AT levels with tamoxifen and were approximately three times more likely to have abnormal glucose tolerance as compared to those who did not (69% and 24%, respectively) (370). Similar conclusions were also reached in a recent Italian study, which found that obese and overweight women with features of the metabolic syndrome were at an increased risk of developing NASH with tamoxifen (373).

Toremifene, a tamoxifen analog, is also implicated in causing steatosis or steatohepatitis, but with a lower frequency (<10%) (372).

Antithyroid Drugs

The estimated frequency of hepatotoxicity from antithyroid drugs is less than 0.5% (374). *Methimazole* and *carbimazole* have rarely been incriminated in reports of cholestasis or cholestatic hepatitis (375,376). By contrast, *propylthiouracil* reactions usually result in acute hepatitis (374,377), which can be severe. Hypersensitivity features are frequently present. Histologic appearances range from portal inflammation and cholestasis in milder forms of hepatitis to submassive or massive hepatic necrosis in severe cases (378). Chronic hepatitis is a rare complication. A review of 36 published cases of liver toxicity associated with propylthiouracil identified seven deaths from acute liver failure (339,343). Three more fatal cases, including 1 in pregnancy, have been recently added to this list (379). Most patients recover, but continued ingestion of the drug after symptoms develop can lead to a poor outcome.

Anesthetic Agents

Halothane

In the first years after the introduction of halothane in the mid-1950s, most cases of postoperative massive liver necrosis were readily attributable to nonanesthetic causes, such as shock and hypoxia. However, cases of *unexplained massive hepatic necrosis after anesthesia* appeared to be more common after halothane than after the use of other agents (380). The clinical syndrome was characteristic, and the temporal relationships between exposure to halothane and the development of liver injury were convincing. This evidence, together with the observations of recurrence after deliberate or inadvertent rechallenge eventually led to the acceptance of *halothane hepatitis* as a real

entity. Rare cases of halothane-induced liver injury have also occurred after workplace exposure among anesthetists, surgeons, nurses, and laboratory staff, and after halothane sniffing for "recreational" use. Despite its rarity, the severity of cases of halothane hepatitis and the greater availability of equally acceptable agents have contributed to the virtual abandonment of halothane.

Two types of postoperative liver injury occur after the use of halothane. Minor elevations of the levels of ALT occur between the first and tenth postoperative day in 10% to 20% of patients, all of whom remain asymptomatic; the risk of hepatic enzyme abnormalities is higher after a second halothane anesthetic than for agents such as enflurane, isoflurane, and desflurane (14,381). This change in liver test results is rapidly reversible. Its relationship with the more severe lesions of halothane hepatitis is unclear; potentially the changes could be explained by minor nonspecific toxic injury or by ischemia-reperfusion consequent to the profound reduction of hepatic blood flow that can be ascribed to halothane anesthesia. Halothane hepatitis is a rare, dose-independent hepatic drug reaction. After one halothane anesthetic, the frequency of this reaction is very low (approximately 1 per 10,000 persons), but after two or more halothane exposures within a 28-day period, this increases to 15 per 10,000 exposed persons (14).

The reaction is unrelated to the type of surgery, duration of anesthesia, or to the presence of underlying liver disease. Halothane hepatitis is extremely rare in children, and more severe in those older than 40 years. Two thirds of cases are in women. A key feature is repeated exposure to halothane within a relatively short period; this is observed in 80% of cases. Further, many patients give a history of previous unexplained, delayed-onset fever, nausea, or jaundice in the postoperative period. Onset of liver injury is earlier after a repeat administration of halothane and typically increases in severity with each exposure. Obesity is another risk factor, possibly related to increased storage of halothane or induction of hepatic CYP 2E1, an enzyme involved

in halothane metabolism. The induction of CYP enzymes has been implicated experimentally in the pathogenesis of halothane-induced liver injury, and one study indicated that the coadministration of antiepileptic drugs predisposed patients to halothane hepatitis (382). A genetic predisposition to halothane-induced liver injury is evident in guinea pigs, and there are data in humans to invoke familial predisposition, such as instances of several closely related family members experiencing halothane hepatitis (10) Likewise, with the use of an in vitro test that detected injury to peripheral blood mononuclear cells after exposure to phenytoin epoxide, increased susceptibility was noted among the relatives of patients with halothane hepatitis, as well as in the patients themselves (383).

Fever is common in the first 48 hours after any major surgery, but fever associated with an adverse reaction to halothane is typically delayed until 3 to 14 days; occasionally, a rash is noted. Jaundice occurs within 21 days of halothane exposure; the median time to onset is 9 days after a single anesthetic and 5 days after multiple exposures. Jaundice is usually preceded or accompanied by symptoms of hepatitis. The liver may be swollen and tender, but in severe cases it decreases in size as a result of extensive hepatic necrosis. Liver failure ensues, with bruising, bleeding, clouding of consciousness and onset of hepatic coma, or hepatorenal failure. Renal failure may develop as part of the hepatorenal syndrome, but acute tubular necrosis could result from a nephrotoxic effect of halothane, as has been better documented for methoxyflurane. Liver histology may show zonal, bridging, or panlobular necrosis.

In milder cases, symptoms may not be attributed to a halothane reaction. It is therefore crucial to take a full history of earlier anesthetic exposures to prevent fatal cases of halothane-induced liver injury. In more severe cases, hepatic failure may follow a fulminant course. Apart from acetaminophen hepatotoxicity, halothane was the leading cause of drug-induced liver failure until the mid-1980s. The reported mortality is 10% to 80%, but the higher rates reflect referral to specialized centers (12,384,385,386). In most cases, however, symptoms resolve within 5 to 14 days and recovery is complete. Rare cases have been reported in which halothane was implicated as the cause of chronic liver disease (6,13,387).

Although an immunologic mechanism has been invoked as part of the causative mechanism (5,6), immunosuppressive agents do not alter the clinical outcome. Management centers on intensive medical support. Liver transplantation must be considered in cases with a poor prognosis, as presaged by previous episodes, early onset, serum bilirubin level of more than 200 µmol/L (10 mg/dL), and prolongation of prothrombin time. In adults, halothane-induced liver disease can be prevented in 90% of reported cases by paying attention to the previous history and adhering to safety guidelines. As many as two thirds of cases occur in individuals with a history of previous reactions to halothane, and most cases are associated with repeated use of halothane within 28 days, especially in obese middle-aged women.

Because halothane may leach out of the tubing of anesthetic devices, prevention of recurrence in sensitized patients requires that the equipment used for anesthesia should never have been exposed to halothane. Cross-sensitivity between halothane and other haloalkane anesthetics is best documented for

methoxyflurane, an agent that is no longer used because of nephrotoxicity. Cross-sensitivity is likely with enflurane and is possible for isoflurane, as described later, but it has not been reported for desflurane and sevoflurane.

There is no readily available diagnostic test for halothane hepatitis. Some interest has surrounded use of an antibody test claimed to be 80% sensitive (7), but independent validation is lacking and the test is not widely applicable. Diagnosis therefore requires careful consideration of the present and past relationships of liver injury to halothane exposure and rests also on the exclusion of other causes of liver disease in the postoperative period (see Chapter 25).

Other agents

General anesthetic agents in current use other than halothane have rarely been associated with postoperative liver failure and massive hepatic necrosis. However, the evidence that such agents cause idiosyncratic hepatic drug reactions is strong only for enflurane (14,388,389). The likelihood that individual haloalkane anesthetics can cause liver injury appears to be related to the extent to which they are metabolized by hepatic CYP enzymes, which is 20% for halothane, 2% for enflurane, 1% for sevoflurane, and 0.2% or less for isoflurane and desflurane. Accordingly, the estimated frequency of enflurane-related hepatitis is much less than that for halothane. The clinical syndrome is similar, with onset of fever within 3 days and jaundice in 3 to 19 days. At least one case was proved by positive rechallenge (388). Two thirds of patients had been previously exposed to either enflurane or halothane.

The possibility that *isoflurane* could be responsible for drug-induced liver injury is more contentious. More than 50 suspected cases were reported to the FDA by 1986, but in two thirds of these another potential cause of liver injury seemed more likely (389), and in the remainder isoflurane was only one of several possible factors that could cause hepatic damage. There have been a small number of more recent case reports in which isoflurane seemed to be the likely cause of fatal hepatotoxicity, either because of repeated exposure to isoflurane in the absence of other potential causes of liver injury (390,391,392) or because isoflurane had been administered after possible previous sensitization to halothane (393) or enflurane (394). Isoflurane should be regarded as a possible but very rare cause of hepatotoxicity; the pathogenic mechanism remains unclear.

The newer haloalkane anesthetics, *sevoflurane* and *desflurane*, appear essentially free from adverse hepatic events, although rare isolated reports have noted an association between liver injury and desflurane

anesthesia; none of these was proved by rechallenge (395).

Drugs Used in the Management of Diabetes Mellitus

Thiazolidinediones

Troglitazone

Troglitazone is a peroxisome proliferator activator receptor-γ agonist that was associated with elevated AT levels in 0.5% to 1.9% of recipients in a clinical trial (396). Reports of acute liver failure emerged early in the postmarketing phase (397,398,399). Troglitazone was implicated in over 75 instances of fatal hepatotoxicity or liver failure requiring hepatic transplantation (400) before it was withdrawn in 1999. The frequency of acute liver failure was estimated at 240 per million person-years of troglitazone exposure (3,400,401).

Troglitazone is metabolized by the CYPs 3A4 and 2C8. Unlike the newer thiazolidinediones, it has a unique α-tocopherol side chain that is metabolized to a quinone. This raises the possibility of quinone-related liver injury, similar to that of acetaminophen or methyldopa hepatotoxicity. However, the quinone metabolite is less toxic than the parent compound, and an alternative hypotheses implicating (402) mitochondrial injury leading to cell death (through necrosis or apoptosis) is currently favored (402,403). A potentially aggravating factor is bile salt–induced apoptosis resulting from inhibition of the bile salt export pump (Bsep) by troglitazone or by coadministration of cholestasis-inducing drugs such as glibenclamide (402,404). Abrogation of inherent cytoprotective mechanisms (e.g., reduction in heat shock protein 70 levels) may also contribute (405). Finally, features of drug allergy are unusual (396). Taken together, the existing data are consistent with an idiosyncratic metabolic form of liver injury. However, the evidence for any of these pathways is weak and/or indirect and speculative, as reviewed elsewhere (401,402).

Risk factors for troglitazone hepatotoxicity have not been clearly defined. The reported cases were generally in older women and obese persons, but this represents the common phenotype of those with type 2 diabetes; detailed epidemiologic studies have not been performed (377). In Japan, persons carrying mutations of CYP 2C19 were over-represented (50%) in a small series of eight patients with troglitazone-induced hepatocellular injury as compared to those without liver injury (13%) (406). Likewise, Japanese subjects carrying the combined glutathione-*S*-transferase GSTT1-GSTM1 null phenotype were three times more likely to develop liver injury. However, this phenotype was present in only approximately 21% to 59% of those developing liver toxicity, suggesting that other factors may be important (407). There is no evidence that preexisting liver disease or other drugs predispose to troglitazone hepatotoxicity, although a progressive

course reported in one patient was attributed to concurrent simvastatin and troglitazone (408). Interaction with NASH, which occurs in at least 20% of obese individuals with type 2 diabetes, has not been explored thoroughly (401). However, many patients affected by troglitazone-induced liver injury had normal liver test results before starting troglitazone treatment.

The onset of troglitazone hepatotoxicity was often as long as 9 months, and sometimes more than 12 months after starting treatment (409,410); rare cases have had a much earlier onset (3 days) (411). Patients presented with nausea, fatigue, jaundice, vomiting, and symptoms of liver failure. Progression from jaundice to encephalopathy, liver failure, or death was often rapid (average 24 days) (411), even after detection of biochemical abnormalities before the development of symptoms, and in some cases deterioration continued despite cessation of troglitazone intake (398). Only 13% of the patients survived without receiving a liver transplantation (411). Histology from biopsy specimens, explants, or autopsies showed submassive or massive hepatic necrosis, with postcollapse scarring, bile duct proliferation, and some eosinophils (412). Severe cholestasis has also been reported (413), but this is sometimes observed in other cases of fulminant hepatic failure (e.g., valproate) and does not necessarily imply any different pathogenic mechanism.

Rosiglitazone and pioglitazone

By comparison with troglitazone, serious liver injury is infrequent with these second-generation thiazolidinediones. In clinical trials, an elevation in the level of ALT (>3 × ULN) was reported in 0.25% and 0.26% of patients treated with rosiglitazone and pioglitazone, respectively (414). Rosiglitazone has been associated with six reports of hepatotoxicity (415,416,417). The onset was earlier (1 to 3 weeks) than that for most cases reported with troglitazone. Rarely, liver injury can occur beyond 1 year of use (418,419,420). Liver histology from two patients showed cholestatic hepatitis (420) or granulomatous hepatitis (418). Resolution occurred within 3 months in all but one fatal case. The validity of the diagnosis has been questioned in three of these cases (416,417,419). In one case, an alternative diagnosis of ischemic hepatitis was proposed because of the exceptionally high levels of ALT (11,000 U/L) and rapid resolution (within 9 days). In the other two reports, potential confounding factors were present such as alcohol ingestion or coprescription of known hepatotoxic agents such as acetaminophen, zafirlukast, and testosterone.

Pioglitazone has been implicated in five reports of acute hepatocellular injury (414,421). In most cases, liver injury occurred within 1 to 7 months of starting the drug and resolved within 3 months of discontinuing pioglitazone (414). Liver histology from two biopsied cases showed cholestatic hepatitis with bile duct injury (422). Other presentations of pioglitazone hepatotoxicity include one report of fulminant hepatic failure (421). Another instance of isolated, reversible increase in alkaline phosphatase likely represents adaptation (423).

The FDA recommends liver tests before beginning treatment with pioglitazone or rosiglitazone; pretreatment

ALT level should be less than 2.5 × ULN. Further evaluation every 2 months during the first year of therapy is recommended, and periodically thereafter. If ALT levels remain persistently elevated (>3 × ULN), the drug should be discontinued. As with INH, symptoms suggestive of hepatitis should be assessed immediately. Individuals who developed jaundice with troglitazone should not receive these thiazolidinediones, although cross-toxicity was not a problem in one reported case (420).

It must be noted that however intuitive such biochemical screening may seem, this protocol has not been validated. Even if adhered to strictly, it could not have prevented some cases of fatal hepatotoxicity in which transition from normal AT to liver failure occurred within 1 or 2 weeks (411). In this situation, the probability of detecting new cases by monthly monitoring is extremely low (estimated at 0.000065) (424). Further, the troglitazone episode has highlighted the low compliance with monitoring recommendations; less than 5% of patients taking troglitazone were monitored per protocol. Finally, the positive predictive value of abnormal liver tests is likely to be suboptimal in patients with type 2 diabetes (425) because of confounding factors such as nonalcoholic fatty liver disease (NAFLD)/NASH (see Chapter 39), chronic hepatitis C, or concomitant drug therapy.

Oral hypoglycemic drugs

Liver injury (typically hepatocellular) was common with older sulfonylureas, such as *carbutamide*, *metahexamide*, and *chlorpropamide* (2,14). Of the currently used agents, *tolbutamide*, *tolazamide*, *glibenclamide*, and *glimepiride* have rarely been associated with cholestasis or cholestatic hepatitis (2,426,427,428). Considering the structural relationship of sulfonylureas with sulfonamides, it is perhaps not surprising that hypersensitivity phenomena (fever, skin rash, eosinophilia) were present in some (but not all) cases (429). Most cases resolved after drug withdrawal, but chronic cholestasis progressing to VBDS has been described with tolbutamide and tolazamide (14). Death from liver failure has been reported in two patients, one of whom had cirrhosis (429). There are three reports of acute hepatitis induced by *gliclazide*; hypersensitivity features were present in one case (429a). *Glibenclamide* has also been

associated with hepatocellular liver injury and hepatic granulomas (426).

Table 33.22. Liver Injury Associated with Drugs Used in Diabetes Mellitus

Drug	Pattern of liver injury	Comments
Acarbose (glucosidase inhibitor)	Acute hepatitis; most reported cases from Spain (to date) Cholestasis with voglibose (another glucosidase inhibitor)	Positive rechallenge
Metformin (biguanide)	Cholestatic hepatitis; cholestasis; acute hepatitis	Very rare
Human insulin	Mixed liver injury; all reports from Japan; resolved when changed to porcine insulin	Positive rechallenge
Sulfonylureas	Acute hepatitis, cholestasis, cholestatic hepatitis, vanishing bile duct syndrome, granulomatous hepatitis	Usually reversible but fatalities reported
Repaglinide	Acute hepatocellular injury	Single report
Thiazolidinediones		
Troglitazone	Submassive or massive hepatic necrosis; cholestasis	Many fatal cases. Withdrawn from use
Rosiglitazone	Acute cholestatic hepatitis, granulomatous hepatitis	Few reports, fatalities rare
Pioglitazone	Acute hepatocellular injury; cholestatic hepatitis (one case), fulminant hepatic failure (one case)	Few reports, fatalities rare

Other antidiabetic agents that have been rarely associated with liver injury include *metformin*, *repaglinide*,

acarbose, and *human insulin* (430,431,432,433) (Table 33.22).

Analgesics and Drugs Used to Treat Rheumatologic Diseases

Acetaminophen

Acetaminophen (paracetamol) hepatotoxicity is an important cause of drug-induced liver injury in most countries (434,435); currently it accounts for approximately 50% of cases of acute liver failure in the United States (436). When used in recommended doses (1 to 4 g/day), acetaminophen is extremely safe (437), but single doses exceeding 15 to 25 g may cause severe liver injury that is fatal in up to a quarter of cases. Acetaminophen hepatotoxicity usually follows deliberate self-poisoning in an attempted suicidal or parasuicidal gesture. However, up to 30% of cases of acetaminophen hepatotoxicity admitted to hospital now result from "therapeutic misadventure," in which the daily dose has not greatly exceeded the recommended safe limits but in which specific risk factors were present (438,439) (see subsequent text); daily doses of 2 to 6 g have been associated with fatal hepatotoxicity. Cases associated with actual therapeutic doses are much rarer and may represent inadequate/unreliable disclosure and documentation.

Risk factors

Acetaminophen causes dose-dependent liver injury but individual susceptibility is also important. Therefore, death has occurred after ingestion of single doses of 7.5 g in adults or 150 mg/kg in children, whereas survival has been recorded with massive overdoses (50 g or more) (440). Age alters individual susceptibility; liver injury has been described even in neonates, but children are considered to be relatively resistant to acetaminophen poisoning (441). This has been attributed to differences in disposition and metabolism of the drug, but relatively larger liver and kidney sizes (as a proportion of total body weight) is an alternative explanation (442). However, there is increasing recognition that both intentional and unintentional acetaminophen toxicity can occur in children. Common prescribing errors involved in these cases include use of adult doses, wrong dosing intervals, concomitant use of other acetaminophen-containing or hepatotoxic products, and host factors—particularly undernutrition, fasting, and drug–drug interactions. Rectal preparations of acetaminophen were implicated in a few cases. The bioavailability of acetaminophen in this formulation can vary (up to ninefold). Furthermore, the slower onset of action encourages repetitive use and consequent cumulative toxicity (443). Although acetaminophen self-poisoning is more common in women, fatal acetaminophen hepatotoxicity occurs more frequently in men; this is largely due to alcoholism and late presentation (20).

Clinical features

The clinical evolution of liver injury follows three phases. In the first, anorexia, nausea, and vomiting are prominent, and this may last from 12 to 24 hours. These symptoms often subside so that the person often feels well during the second phase, which lasts another 24 hours. Signs of hepatic failure, often with renal insufficiency, appear 48 to 72 hours after ingestion of acetaminophen (phase 3). Pain over the liver may be pronounced. It is accompanied by jaundice, hypoglycemia, coagulopathy, renal failure, acidosis, and encephalopathy. Myocardial injury has also been described (440). Renal failure can occur with or without significant liver injury. In untreated subjects, death

occurs between 4 and 18 days after drug ingestion, usually from cerebral edema, and/or sepsis from multiorgan failure.

ALT levels are markedly elevated (2,000 to 10,000 IU/L); indeed, when the cause of acute liver injury is unclear (e.g., in an unconscious individual or someone known to have chronic hepatitis C), such high AT levels should arouse suspicion of acetaminophen toxicity. These high ALT values are unusual in viral hepatitis but may occur with ischemic hepatitis and with other forms of drug-induced liver injury, including herbal toxicity (see later section). The following clinical and laboratory indices predicate a poor outcome of acetaminophen hepatotoxicity: Prothrombin time greater than 100 seconds, serum creatinine greater than 300 μmol/L, the single finding of a pH of less than 7.3 after adequate fluid replacement, or grade 3 or 4 encephalopathy in patients with a normal pH (434,444). Other prognostic indices proposed include the Acute Physiology and Chronic Health Evaluation (APACHE) II score, and blood lactate, phosphate, and α-fetoprotein levels (445). None of these indices has been widely adopted, and they await independent validation.

Histology

The histologic features are zone 3 necrosis, with submassive (bridging) or panacinar (massive) necrosis in severe cases (14). Inflammatory activity is inconspicuous, and resolution occurs without fibrosis. Chronic liver injury has been described in patients consuming moderate doses of acetaminophen for many months (2 to 6 g each day). Preexisting liver disease or concurrent alcohol intake were not always excluded in such individuals (14), and the rapid resolution after discontinuing acetaminophen abuse implies a form of chronic hepatotoxicity rather than a syndrome of drug-induced chronic hepatitis.

Acetaminophen toxicity with therapeutic doses (therapeutic misadventure)

Enhanced susceptibility to acetaminophen toxicity is now well recognized both in alcoholic and nonalcoholic individuals. At least 200 instances of inadvertent hepatotoxicity have been recorded in heavy drinkers; they

have followed acetaminophen intake for 1 day to several weeks. In one series, 40% of individuals had taken acetaminophen in excess of 6 g/day (438), but 35% had taken doses below 4 g/day; in other reports, hepatotoxicity has occurred after as little as 1.5 to 2 g of acetaminophen intake a day. Data from the US Acute Liver Failure group revealed that 60% of persons who had taken an unintentional overdose were using an acetaminophen–narcotic combination. It has been suggested that addiction (and later, tolerance) to the narcotic component induces repetitive use that may not always be recalled or disclosed by the patient (436). Alcohol enhances CYP 2E1 activity, and accompanying malnutrition may contribute to GSH depletion. As in acute self-poisoning cases, AST and ALT levels are often 40- to 1,000-fold elevated above the ULN; this allows ready distinction of cases of acetaminophen hepatotoxicity from alcoholic hepatitis.

The importance of chronic excessive alcohol intake as a potentiator for susceptibility to acetaminophen hepatotoxicity has recently been challenged because in many case reports invoking such an interaction the person had clearly taken a hepatotoxic dose of acetaminophen (412). Nonetheless, the authors' experience is that therapeutic misadventures with acetaminophen are a common and clinically important type of drug-induced liver injury (434,446). A recent study of alcohol–acetaminophen interaction was conducted in an alcohol detoxification unit, with all trial participants receiving acetaminophen 1 g q.i.d. for 2 days or placebo (447). No differences in hepatotoxicity were observed between the two groups. However, the investigators' assertion that acetaminophen can be safely used in patients with chronic alcohol abuse has been criticized on several grounds, including the selection of only those persons with serum AT levels less than 120 U/L, which could have excluded a subset with significant underlying liver disease (448). The FDA recommends that persons taking more than three drinks of alcohol daily should not receive acetaminophen.

In nonalcoholic patients, fasting (449) has emerged as one of the most important risk factors, particularly after near complete deprivation of carbohydrate intake for at least 48 hours; this is a particularly important risk factor for acetaminophen hepatotoxicity in young children. Fasting decreases the activity of hepatic conjugation pathways for acetaminophen elimination, increases CYP 2E1 activity, and depletes hepatic GSH levels. However, others have contended that fasting has been overstated as a risk factor for acetaminophen hepatotoxicity (450). They contend that earlier studies were flawed because CYP 2E1 and GSH measurements had not been carried out simultaneously; depletion of GSH level is also accompanied by a decrease in CYP 2E1 activity (450).

Concurrent medication (e.g., INH, zidovudine, phenytoin, and other anticonvulsants) are also important. These agents compete for the "safe" conjugation pathways and may also induce CYP 3A4 (phenytoin) or 2E1 (INH), the net effect of which is to promote CYP-mediated oxidation of acetaminophen to its reactive intermediate, *N*-acetyl-*p*-quinone imine (NAPQI). However, human studies do not appear to support a phenytoin–acetaminophen adverse interaction. It is contended that phenytoin induces only CYP 3A4, a relatively minor metabolic pathway; further, it enhances

glucuronidation, a key detoxification step (450). Severe cardiopulmonary disease and renal failure have also been described as settings for acetaminophen hepatotoxicity (451), although the importance of metabolic factors or impaired (fluctuating) hepatic blood flow was not clarified in these studies.

Mechanism of liver injury and basis for antidote therapy

Acetaminophen undergoes metabolism to glucuronide and sulfate conjugates, which are excreted in the urine. Normally, only a small proportion (approximately 5%) of acetaminophen is oxidized to NAPQI; this reaction is catalyzed by CYP 2E1 (which increases with fasting, and INH and chronic alcohol intake) and, to a lesser extent, by CYP 3A4 (induced by anticonvulsants, several other drugs, and possibly alcohol). The small amounts of NAPQI formed with pharmacologic doses of acetaminophen are readily detoxified by hepatic GSH; hepatorenal injury occurs only when GSH reserves are depleted. This is the basis for the therapeutic rationale of administering thiol donors such as NAC and methionine, which replenish intracellular GSH stores (440). NAPQI binds cellular proteins, inducing oxidation of thiol groups in mitochondria, leading to mitochondrial permeability transition (452). The ensuing mitochondrial dysfunction generates profound oxidative stress and also facilitates peroxynitrate formation; the latter can also undergo covalent binding with key proteins and also further aggravate mitochondrial dysfunction. These events culminate in oncotic necrosis (oncosis) of hepatocytes and sinusoidal endothelial cells. Although apoptosis does occur, oncosis is considered the principal mode of cell death (453).

Depletion of natural killer (NK) cells and NK cell with T-cell (NKT cell) receptors appears to protect against acetaminophen liver toxicity in mice (454). The reduction in liver injury was accompanied by decreased expression of proinflammatory cytokines such as interferon-γ, key chemokines, and neutrophil recruitment. On this basis, it has been suggested that these cells, which are part of the hepatic innate immune system, may contribute to the progression of acetaminophen-induced liver injury (454).

Prevention

Adherence to the recommended therapeutic dose should be stressed. However, both prescribers and consumers should be made aware of the increased risk of acetaminophen toxicity in those who consume excess alcohol and in the setting of prolonged fasting, cardiorespiratory disease, and where other drugs are also being used. Recently, doubts have been expressed about the safety of acetaminophen in patients with underlying liver disease. Although acetaminophen is not contraindicated in such persons, the finding of detectable serum levels of acetaminophen in 20% of those with acute viral hepatitis–related acute liver failure has raised questions on the safety of acetaminophen in both acute and chronic liver disease (455). There is a

public health need to revise downward and promulgate altered dosage guidelines for acetaminophen when used in regular daily doses under any of the high-risk circumstances mentioned earlier. To reduce the impact of impulsive self-poisoning, attempts have been made to restrict pack sizes and change the packing (to bubble packs) of acetaminophen by legislation in the United Kingdom. This has been associated with a reduced number of liver transplantations for acetaminophen overdose (by approximately 66%), as well as a reduction in mortality (by 21%) (455). However, the impact has not been uniform, with only a transient decline in Scotland, and it remains unclear whether the decline in adverse outcomes is attributable to this measure alone (456).

Management

Gastric lavage with a wide-bore tube is performed in all patients presenting within 4 hours of acetaminophen overdose. Activated charcoal and osmotic cathartics are of no benefit. Serum levels of acetaminophen are often determined at baseline, but a 4-hour postingestion level is a more reliable predictor of the risk of liver injury (457). The need for antidote treatment is assessed using blood acetaminophen levels with reference to well-established nomograms (458,459). The 4-hour serum acetaminophen concentration may be misleading in overdoses with extended-release acetaminophen preparations (460); blood acetaminophen levels should be estimated after a further 4 to 6 hours (460). In persons presenting after nonaccidental or staggered ingestion of acetaminophen, the total dose ingested and time from ingestion to presentation are important determinants of liver injury. In these cases, hepatotoxicity is likely if the interval exceeds 24 hours or if the total acetaminophen dose exceeds 150 mg/kg (75 mg/kg in high-risk individuals); NAC therapy is initiated beyond these thresholds (461).

NAC is the principal antidote. By functioning as a thiol donor, NAC replenishes intracellular GSH stores. Significant hepatotoxicity is rare when NAC is administered within 16 hours of drug ingestion. Beyond 16 hours, oxidation of acetaminophen to NAPQI is complete and thiol donation is unlikely to prevent hepatocyte or renal tubular cell death. Nevertheless, the benefits of NAC have been shown extend to patients presenting up to 24 hours and even in those with acute liver failure (462). The beneficial effects of NAC in acute liver failure were attributed to improved tissue

oxygen delivery (462), although this has been disputed (463).

NAC is administered intravenously in Europe and Australia, and by mouth in the United States (459,464). The intravenous regime is now approved by the FDA for persons who cannot or will not use oral NAC.

Treatment protocol

An oral loading dose of 140 mg/kg is followed by 4-hour administration of half this dose up to 72 hours. Intravenous administration involves a loading dose (150 mg/kg) of NAC given slowly over 15 minutes, followed by a 4-hour infusion (50 mg/kg) and a 100-mg/kg infusion over 16 hours. A third intravenous (48-hour) protocol has also been evaluated (465). It has been suggested that the incidence of hepatotoxicity is lower with the oral and 48-hour intravenous regimes when compared to the 20-hour intravenous infusion among high-risk patients (460), but direct comparisons have not been performed. Only the 20-hour intravenous protocol has been approved by the FDA.

Anaphylactoid reactions to intravenous NAC are relatively common (6% to 15%). They are generally mild and rarely lead to treatment discontinuation, but severe reactions can occur. Guidelines to deal with such reactions (466) include observation during drug administration (with appropriate antidotes readily available), discontinuing the infusion with the onset of angioedema or respiratory symptoms, administration of antihistaminics, and resumption of the infusion after 1 hour if there are no persistent symptoms. For minor reactions, such as flushing, the infusion can be slowed or continued uninterrupted (466).

Other thiol donors such as methionine may be effective but must be administered within 10 hours. Methionine solutions should be freshly prepared, else they often cause troublesome vomiting; their use is restricted to patients with hypersensitivity to NAC. Managing acetaminophen overdoses in pregnant women and in children is along usual lines (460); in one small study, NAC did not have any major adverse effects on the fetus (467).

Treatment of acute liver failure is along usual lines (see Chapter 21). Assessment for liver transplantation requires consideration of the psychosocial factors underlying self-poisoning and the likelihood of survival without transplantation. When liver transplantation has been performed, survival rates exceed 70% (434) and long-term outcomes appear reasonable. However, deaths have occurred in survivors from repeat overdoses, stressing the need for detailed psychiatric evaluation and support before and after transplantation (468).

Dextropropoxyphene

Dextropropoxyphene is an opioid that is commonly used in compound analgesics, as well as on its own. Adverse drug reactions are rare but important, particularly because liver injury may occur in the postoperative period or in other medically complex situations. At least 25 cases of cholestasis with bile duct injury have been reported (39,84), some proved by inadvertent rechallenge. Most of those affected are women. Abdominal pain is the most impressive symptom. It is often severe and resembles pain from other causes of cholangitis with which it is often confused, particularly because jaundice is usually present. However, the large bile ducts appear normal at cholangiography. Liver histology shows portal tract edema, irregularity and necrosis of the biliary epithelium, bile ductular proliferation, and a peribiliary infiltrate of neutrophils and eosinophils.

Cholestasis is usually evident. Recovery occurs within 1 to 3 months of stopping dextropropoxyphene.

Nonsteroidal anti-inflammatory drugs

NSAIDs are among the most commonly used prescription and nonprescription drugs, with up to 15% of the population using them in any 1 year. AT abnormalities are observed in up to 15% of patients taking NSAIDs, but overt hepatotoxicity is much less common with currently used agents. There are distinct differences in the frequency of hepatic injury associated with individual NSAIDs (469,470), with some agents being virtually free from reported hepatotoxicity and others such as *bromfenac*, *benoxaprofen*, and *ibufenac* having been withdrawn because of fatal liver injury (471) (Table 33.23). Several pharmacoepidemiologic studies have attempted to categorize risk factors associated with NSAID-associated liver injury and to also ascertain the hepatotoxic potential of individual NSAIDs. The results of these studies have been conflicting, which could be attributed to methodologic differences, including study settings (hospital vs. ambulatory care) and study definitions. Focusing on studies with significant clinical events (i.e., hospitalization and death), Rubenstein and Laine conducted a systematic review and found a slight (but not significant) increase in the risk of liver injury for current as compared to former NSAID users (odds ratio 1.2 to 1.7, *P* = not significant) (472). Contrary to general belief, women and the elderly were not found to be at greater risk. However, in another study carried out in an ambulatory care setting in France, gender differences were striking; after adjustment for confounding factors, there was a significant association between liver injury and NSAID use in women (odds ratio = 6.49 [1.67 to 25.2]) (473). Other risk factors identified in the Rubenstein review were rheumatoid

arthritis (as compared with osteoarthritis) and use of nimesulide or sulindac.

Table 33.23. Liver Injury Associated with Salicylates and Nonsteroidal Anti-Inflammatory Drugs

Drug	Pattern of liver injury	Comments
Aspirin and other salicylates	Dose-dependent hepatocellular injury; Reye's syndrome (febrile children)	Similar toxicity with sodium salicylate, mesalamine; diflunisal causes cholestasis
Bromfenac	Acute hepatitis; fulminant hepatic failure	Withdrawn from clinical use
Cyclo-oxygenase 2 inhibitors	Cholestatic hepatitis (few reports) with celecoxib, rofecoxib	Overall incidence low
Clometacin	Acute or chronic hepatitis, cholestatic hepatitis, cirrhosis, granulomatous hepatitis	Fatalities recorded; female predominance (chronic hepatitis); some reported cases were later found to have hepatitis C virus infection
Diclofenac	Acute hepatitis; chronic hepatitis	Women, older patients with osteoarthritis
Ibuprofen	Acute hepatitis; rarely vanishing bile duct syndrome; hepatotoxic potential is low	Hepatocellular injury with pirprofen, fenoprofen, flurbiprofen, ketoprofen; cholestasis (tiaprofenic acid)
Indomethacin	Acute hepatitis, cholestasis; massive hepatic necrosis (rare)	Low incidence of toxicity
Naproxen	Mixed liver injury	Low incidence of toxicity
Nimesulide	Acute hepatitis; acute liver failure; cholestasis	Female predominance (with acute hepatitis)
Phenylbutazone	Acute hepatitis, cholestasis, granulomatous hepatitis	Similar toxicity as oxyphenbutazone
Piroxicam	Hepatocellular, cholestasis,	Low incidence; isoxicam, droxicam cause

	massive/submassive hepatic necrosis (at least six reports)	acute cholestatic hepatitis
Oxaprozin	Hepatocellular; fulminant hepatitis	—
Sulindac	Cholestatic hepatitis (predominant), acute hepatitis	Hypersensitivity features common

NSAID-associated hepatic disease encompasses a clinicopathologic spectrum from acute self-limited hepatitis, cholestasis, cholestatic hepatitis, and hepatic granulomas to fulminant hepatic failure, chronic hepatitis, and chronic cholestasis with ductopenia (471) (Table 33.23). Consistent with the diverse chemical structures of NSAIDs, both immunologic and metabolic idiosyncratic mechanisms have been invoked.

Sulindac

Sulindac is structurally related to indomethacin but has been implicated more often in liver injury. Cholestatic reactions predominate, although appreciable hepatic inflammation was noted in 25% of cases (473a). Sulindac has also been associated with acute pancreatitis, and this may cause extrahepatic biliary obstruction. Women appear more susceptible to liver injury (female-to-male ratio 3.5:1). Approximately 70% of affected individuals are older than 50 years (473a). Hypersensitivity features are common, as evidenced by the presence of fever, eosinophilia, and cutaneous reactions, including the Stevens-Johnson syndrome; this indicates operation of the RMS. Resolution often follows drug cessation but protracted cholestasis can occur. The overall case-fatality rate is approximately 5%, attributable both to sequelae of systemic hypersensitivity reactions (such as Stevens-Johnson, nephrotoxicity) and liver injury.

Ibuprofen

Ibuprofen rarely causes significant hepatic injury. In the few reported cases, the reactions have been hepatocellular or mixed hepatocellular–cholestatic (14). There are three case reports of VBDS, including two pediatric cases with associated Stevens-Johnson syndrome; two of these were referred for liver transplantation and the other had prolonged cholestasis (474,475). The presence of rash, fever, and eosinophilia suggests an immunoallergic basis. Rare cases of subacute liver failure have followed both overdose and therapeutic doses of ibuprofen. Explant histology showed submassive necrosis (474) or microvesicular steatosis (476). Recent reports of acute hepatitis induced by ibuprofen ingestion among HCV-positive patients are of interest but need to be confirmed by larger prospective studies (56).

Other propionic acid derivatives

Bromfenac was implicated in several cases of acute liver failure resulting in death or necessitating liver transplantation (477). In most cases, treatment had been provided for more than 90 days before the patients developed malaise and fatigue, followed by symptoms of severe hepatitis that progressed to liver failure over 5 to 37 days. There were no extrahepatic features of drug allergy. The liver pathology showed confluent or zonal necrosis and a predominantly lymphocyte infiltrate. Other propionic acid derivatives associated with

liver injury include *fenoprofen*, *ketoprofen*,*pirprofen*, and *tiaprofenic acid* (114) (Table 33.23).

Diclofenac

Diclofenac has been implicated in more than 200 published cases of hepatic injury (478,479,480), some severe and with occasional fatalities. In several cases, causality has been proved by inadvertent rechallenge. Significant hepatotoxicity occurs in approximately 1 to 5 per 100,000 persons exposed (23). Acute hepatitis or mixed hepatocellular–cholestatic injury is characteristic, but chronic hepatitis resembling AIH has been reported (481). Women, the elderly, and patients with osteoarthritis appear to be susceptible to diclofenac-induced liver injury. A comparative study of diclofenac with nabumetone found a better safety profile for the latter in elderly patients, with no patient developing ALT level elevation greater than 2 × ULN as compared to 4% in the diclofenac group (482). However, the relevance of ALT level elevation to cases of overt liver disease is unclear.

A prodromal illness or symptoms of hepatitis herald the onset of liver injury, most often within 3 months (range, 1 to 11 months) of starting diclofenac treatment. This is followed by jaundice and liver failure in severe cases. Fever and rash occur in 25% of cases. Liver tests usually reflect acute hepatitis, but some features of cholestasis may be present; jaundice occurs in 50% of reported cases (480). In some cases, the clinicopathologic features of ascites, hypoalbuminemia, and hyperglobulinemia indicate chronic liver disease. Liver biopsy specimens usually show acute lobular hepatitis, but confluent necrosis may be seen in severe cases; in chronic cases, periportal inflammation (interface hepatitis) and fibrous expansion of portal tracts are

noteworthy.

Resolution usually follows cessation of diclofenac, although fatalities have been recorded, particularly in elderly subjects. Corticosteroids were used successfully in a few cases of chronic diclofenac-induced hepatitis when no clinical improvement had been evident 3 months after drug discontinuation (479). Cross-sensitivity between NSAIDs is rare but has been reported with ibuprofen in a person with a history of diclofenac hepatitis; another had an adverse reaction to tiaprofenic acid (481).

Pathogenic mechanisms involved in diclofenac toxicity include oxidative stress alone or in combination with mitochondrial injury (482,483). In certain cases, immune mechanisms may be relevant, especially in those presenting with chronic hepatitis. The presence of diclofenac metabolite–protein adducts in liver tissue raises the possibility of liver injury resulting from direct disruption of critical cellular functions or from elicitation of an immune response to these neoantigens (484). Supporting this hypothesis is the finding that certain polymorphisms favoring a T helper 2 (T_H2)-mediated antibody response were found more often among patients with diclofenac hepatotoxicity than in healthy controls and persons receiving diclofenac without hepatotoxicity (485).

Piroxicam

The frequency of hepatic injury with this oxicam derivative is low (14). Acute hepatitis and cholestasis have been described, and there have been at least six cases of massive or submassive hepatic necrosis (14). The reaction appears to be dose independent, and immunoallergic features have not been conspicuous. Other oxicam derivatives implicated occasionally in cases of acute cholestatic hepatitis include *isoxicam* and *droxicam* (114).

Salicylates

Aspirin causes dose-dependent hepatic injury, usually with increased AT levels. Overt jaundice is uncommon, occurring in less than 5% of those affected (14). Patients with hypoalbuminemia, juvenile rheumatoid arthritis, and SLE are especially susceptible to salicylate-induced liver injury (14). Hepatitis resolves rapidly after drug withdrawal and usually does not recur after reintroduction of salicylates at a lower dose. Blood levels of salicylate should not exceed 24 mg/L (14). Only one fatality has been recorded (486). Focal necrosis and lobular inflammation are usual. Other salicylates can cause similar injury (487). Epidemiologic studies have linked the use of aspirin in febrile children with Reye's syndrome but concerted public health campaigns have led to a major decline (near abolition) in the incidence of this disorder (see Chapter 56).

Ticlopidine is not an NSAID but is discussed here with aspirin because it also inhibits platelet aggregation and is often used for similar indications. Unlike aspirin, ticlopidine-induced hepatotoxicity is dose independent and associated predominantly with cholestasis. More than 30 cases have been reported (82,488). Most cases have been found in individuals older than 55 years, reflecting the main use of ticlopidine as secondary prophylaxis against cerebrovascular and coronary artery disease. Onset of symptoms can be as early as 2 weeks, and in most cases is within 12 weeks of commencement. Rarely, symptoms may commence 1 month after the drug is withdrawn (489). Histology shows bland cholestasis, but cholestatic hepatitis with bile duct injury has been described. Recovery is usual within 3 to 6 months of stopping ticlopidine but occasionally may take longer than a year (490). Eosinophilia in some cases and a positive in vitro T-cell stimulation study to ticlopidine have been cited as favoring an immune basis for liver injury (491). Although corticosteroids

appear to have aided recovery in one patient (492), their routine use cannot be justified in this older group of patients (mean age, 67 years); one report of cytomegalovirus-associated acute hepatitis after corticosteroid therapy in this setting is a timely reminder of the risks associated with steroid use in this older group of patients (mean age, 67 years) (493). *Clopidogrel* has been successfully substituted for ticlopidine in a patient with cholestasis. However, clopidogrel can itself rarely cause hepatocellular or hepatocellular-cholestatic injury (494).

Cyclo-oxygenase 2 inhibitors

Celecoxib—in clinical trials, the frequency of hepatic dysfunction (0.8%) with this COX-2 inhibitor was not significantly different from that with placebo-treated (0.9%) subjects (495). However, celecoxib has been now incriminated in four reports of severe acute cholestatic hepatitis (114,496,497). Interestingly, two of these patients were allergic to sulfonamides; a history of sulfonamide allergy is considered by some to be an absolute contraindication to the use of celecoxib because there are structural similarities that predispose to hypersensitivity reactions. However, the implications of preexisting sulfonamide allergy are disputed by others (498), who contend that although celecoxib contains a sulfonamide moiety, it lacks the critical determinants that are implicated in sulfonamide allergy. One of the affected patients had alcoholic cirrhosis. This raises questions of celecoxib safety in persons with reduced hepatic reserve (497).

Symptoms suggestive of liver injury develop 4 days to up to 3 weeks after commencing celecoxib. Pruritus, jaundice, and malaise are accompanied by a mixed hepatocellular–cholestatic biochemical profile. Peripheral eosinophilia has been observed in some cases, suggesting a possible immunoallergic mechanism. Resolution occurs within 4 months of discontinuing the COX-2 inhibitor.

Rofecoxib, now withdrawn because of cardiovascular toxicity, was associated with a few reports of cholestatic hepatitis (114,499,500). Although the clinical features of liver injury resolved rapidly with drug withdrawal,

complete biochemical recovery could be delayed for as long as 2 years.

Nimesulide, another NSAID with preferential COX-2 selectivity, has also been associated with several instances of hepatocellular injury and cholestasis, and occasional cases of fulminant hepatic failure (501).

Allopurinol

Granulomatous hepatitis is a typical feature of liver injury with allopurinol (502). Other manifestations include increased AT levels in asymptomatic persons, cholestasis, and hepatocellular injury, which can be occasionally severe enough to progress to fulminant hepatic failure. Severe centrilobular hemorrhagic necrosis resembling Budd-Chiari syndrome has also been described (503). Exfoliative dermatitis, fever, eosinophilia, interstitial nephritis, and microangiopathic vasculitis may be present in these cases. In a few severe cases, corticosteroids have been used with apparent benefit (504). *Benzbromarone*, a uricosuric agent, has been implicated in causing chronic hepatitis, cirrhosis, and fulminant hepatic failure (505).

Gold

Hepatic toxicity of gold (gold sodium thiomalate) is usually characterized by mild cholestatic hepatitis. Onset is within 1 to 4 weeks of starting treatment. Fever, rash, and eosinophilia are often present. Liver biopsy specimens show canalicular cholestasis with minimal hepatocellular degeneration or portal tract inflammation. Resolution is the rule; fatalities are extremely rare (506). Rarely, prolonged cholestasis with ductopenia and other accompanying features of the VBDS (e.g., sialadenitis, sicca syndrome) can occur (507). Hypersensitivity features such as skin rash and peripheral and tissue eosinophilia were present in this case.

Hepatocellular injury is less common but can be severe, resulting in death (508,509). This severe reaction to gold appears to be dose dependent and is more likely the consequence of metabolic toxicity than in cases presenting with cholestatic hepatitis. Submassive or massive hepatic necrosis with a mixed inflammatory infiltrate is observed on liver biopsies. Resolution can be slow (510). Gold accumulates in the lysosomes ("aurosomes") in persons undergoing long-term crysotherapy. It has been proposed that liver injury occurs when the lysosomal storage capacity for gold is exceeded (510). Other gold compounds containing the same *aurothio* side group as gold sodium thiomalate (e.g., gold thiosulfate, aurothioglucose) are also associated with similar liver injury. Recently, acute cholestatic hepatitis has been reported after an overdose of *gold potassium cyanide*, a nonaurothio gold compound used in electroplating (511).

Penicillamine

Used in the treatment of Wilson disease and as a disease-modifying agent in rheumatoid arthritis, D-penicillamine has been associated with a range of side effects from nephrotoxicity to provoking autoimmune phenomena. Liver injury is less frequent. Most reports are of cholestatic hepatitis in association with hypersensitivity features (512). These occur within 2 weeks of commencing treatment. The prognosis is good, with resolution occurring within few weeks of cessation of penicillamine; fatalities are rare (513).

Leflunomide

Leflunomide is a disease-modifying antirheumatic drug. Its principal metabolite, A771726, is highly metabolized and eliminated through the liver. CYP 2C9 is probably involved in its metabolism. In clinical trials, 5% of recipients showed mild, reversible changes in AT. Concerns about significant liver toxicity were first highlighted by the European Medicines Evaluation Agency, which had received 296 reports of hepatic adverse effects, including 15 cases of liver failure; 9 of these cases had a fatal outcome. However, assigning a cause–effect relationship has proved problematic because many (78%) were receiving potential hepatotoxic drugs, including NSAIDs and methotrexate. Furthermore, other confounding factors were present such as alcohol use, abnormal baseline liver test results, congestive heart failure, and failure to comply with recommended doses. The low hepatotoxic potential of leflunomide compared with methotrexate was confirmed in two large cohorts involving over 40,000 patients (514). A special committee of the FDA concluded that the risk of hepatotoxicity was small with leflunomide, thereby permitting its continued usage (515).

Special caution is advised when leflunomide is used with methotrexate. AT level increase is seen more often in persons receiving this combination (22%) as compared to recipients of methotrexate plus placebo (5%). However, normalization of AT levels was achieved without dose change (59%) or a single dose decrease (29%) (516). Nevertheless, continued vigilance is necessary because early changes of cirrhosis were observed in a patient taking both these drugs (516a). It has also been suggested that persons carrying a low–metabolizing activity polymorphism (e.g., CYP 2C9*3) may be at an increased risk of liver injury (517).

The manufacturer recommends baseline and monthly monitoring of liver test results for the first 6 months, and every 2 months thereafter. Minor ALT level changes (<2 × ULN) should prompt retesting in 2 to 4 weeks. Dose reduction (from 20 to 10 mg) is suggested if the ALT level increases above 2 × ULN. Increases of ALT levels greater than 3 × ULN or persistent ALT abnormalities should prompt drug withdrawal, together with the use of cholestyramine to facilitate the elimination of leflunomide.

Oncotherapeutic and Immunosuppressive Drugs

Systemic malignancy is commonly associated with abnormal liver test results (14). In addition to the direct and indirect effects of neoplastic cells, radiotherapy, sepsis, concurrent medication, viral hepatitis, parenteral

nutrition, and hypoxemia may contribute to hepatic liver test result abnormalities; this makes it difficult to interpret changes or assign liver toxicity to individual drugs. An emerging problem is the reactivation of quiescent chronic hepatitis B after withdrawal from the immunosuppressive effects of chemotherapy; this can be prevented by preemptive lamivudine therapy (see Chapter 29). Interactive toxicity between individual oncotherapeutic drugs also merits special consideration. This is exemplified by the development of hepatic SOS with combination chemotherapy and the potentiation of doxorubicin hepatotoxicity by 6-mercaptopurine.

Antimetabolites and antibiotics are more often linked to significant liver injury than are alkylating agents. Hepatocellular injury is characteristic, but a wide range of histologic lesions may be encountered (14,518). Steatosis is often present, especially with dactinomycin, L-asparaginase, and methotrexate. Cholestasis is typically associated with the hormonal agents but can be a feature of liver injury with azathioprine and IL-2. A range of vascular lesions, including peliosis hepatis, SOS (VOD) and NRH, has been observed, usually in the setting of bone marrow or renal transplantation. Chronic hepatitis can rarely occur with doxorubicin and azathioprine, but cirrhosis is distinctly uncommon, except with methotrexate (discussed subsequently). The hepatotoxicity of commonly used oncotherapeutic agents is summarized in Table 33.24. More in-depth discussions of the subject can be obtained from recent reviews and texts (2,14,518).

Methotrexate

The hepatotoxic potential of methotrexate was recognized soon after it was introduced in the 1950s for the treatment of acute childhood leukemia; significant hepatic fibrosis and cirrhosis were reported in up to 25% of patients (14). Methotrexate is now used more often in a low-dose weekly regime for treating rheumatoid arthritis, psoriasis, and other immunologic conditions, including inflammatory bowel disease. The hepatoxicity of low-dose regimens is much lower but is still debated (29,519,520); although ultrastructural changes can occur, clinically significant liver disease is now rarely, if ever, encountered.

The development of hepatic fibrosis during methotrexate therapy is greatly influenced by the factors listed in Table 33.25. Pretreatment variables, such as older age, renal failure, preexisting liver disease, and risk factors for NASH (e.g., diabetes, obesity) should be carefully considered before commencing treatment with methotrexate (519). Alcohol intake, preexisting liver disease, and the total and incremental dose are the most important of these risk factors. In earlier studies, a cumulative methotrexate dose of 3 g was associated with histologic progression in 20% of cases, but only 3% had advanced fibrotic changes (29). In a

meta-analysis of 15 studies, moderate or heavy drinkers (>100 g/week) were more likely to have advanced histologic changes (18%) and show histologic progression (73%) (29). Compared to those with rheumatoid arthritis, patients with psoriasis were also more likely to have advanced changes (7.7% vs. 2.7%) and histologic progression (33% vs. 24%). Finally, it is noteworthy that preexisting liver test result abnormalities are observed in 25% to 50% of patients with psoriasis and rheumatoid arthritis.

Table 33.24. Liver Injury Associated with Oncotherapeutic Drugs

Drug	Pattern of liver injury
ANTIMETABOLITES	
Azathioprine	Cholestasis; vascular injury–peliosis hepatis, SOS (VOD)
Cytosine arabinoside	Raised AT level (with low dose), cholestasis or hepatocellular injury (high doses)
5-Fluorouracil	Rare liver injury with intravenous and intra-arterial route (particularly when associated with levamisole); floxuridine causes primary sclerosing cholangitis–like lesions
Gemcitabine	Transient AT level changes; cholestatic hepatitis leading to acute liver failure; SOS
6-Mercaptopurine	Bland cholestasis, hepatocellular or mixed injury; rarely fatal hepatic necrosis
Methotrexate	Steatosis, hepatic fibrosis, cirrhosis
6-Thioguanine	VOD (in combination); peliosis; hepatocellular injury or cholestasis (rare)

ANTIBIOTICS	
Bleomycin	Low incidence of liver toxicity
Cyclosporine	Mild cholestasis (more accurately—impaired bilirubin transport), usually reversible with dose modification
Doxorubicin	Rarely acute or chronic hepatitis; hepatotoxicity enhanced by 6-mercaptopurine
Dactinomycin	Hepatopathy–thrombocytopenia syndrome (with vincristine); clinically resembles SOS (VOD)
Daunorubicin	SOS (when used in combination treatment)
Mithramycin (plicamycin)	Raised AT level (in up to 100%); occasionally centrilobular necrosis, steatosis
Mitomycin C	SOS, steatosis
Mitoxantrone	Minor increase in AT level
SPINDLE INHIBITORS	
Vincristine	Transient liver enzyme changes; synergistic with irradiation in producing liver injury
Paclitaxel, docetaxel	Minor increase in AT level
PLATINUM	Cisplatin
Liver injury rare	Raised AT level (high doses); steatosis, cholestasis, minor hepatic necrosis
Carboplatin	Acute liver failure (one case), SOS (with etoposide)
TOPOISOMERASE INHIBITORS	
Etoposide Irinotecan, topotecan	Frequent liver test abnormalities (high dose); occasionally severe hepatitis (standard dose) Abnormal liver tests
ALKYLATING AGENTS	Low incidence of liver injury with this group
Busulfan	Cholestasis, porphyria cutanea tarda, nodular regenerative hyperplasia, SOS (in combination)
Capecitabine	Hepatocellular
Chlorambucil	Hepatocellular, cholestatic hepatitis, acute liver failure
Cyclophosphamide	Hepatocellular, SOS (in combination), steatosis

Ifosfamide	Liver injury rare; cholestasis (two cases)
Melphalan	Minor increase in AT levels
Thiotepa	Severe hepatotoxicity resembling phosphorus poisoning (rare)
NITROSOUREAS	
BCNU, CCNU, streptozotocin	Minor increase in AT level; rare fatalities from liver injury (BCNU, CCNU)
HORMONAL AGENTS	
Aminoglutethamide	Cholestasis
Flutamide	Cholestatic hepatitis, fulminant hepatic failure; megestrol acetate associated with cholestasis
Tamoxifen	Steatosis, nonalcoholic steatohepatitis, rarely submassive hepatic necrosis, and cirrhosis
MISCELLANEOUS DRUGS	
Amsacrine	Hepatocellular injury, cholestasis, rarely fatal hepatic necrosis
L-Asparaginase	Microvesicular steatosis, hepatic necrosis, coagulopathy (also with pegasparaginase)
Dacarbazine	SOS (VOD)
Procarbazine, hydroxyurea	Hepatocellular injury

SOS, sinusoidal obstruction syndrome; VOD, veno-occlusive disease; AT, aminotransferases; BCNU, carmustine; CCNU, lomustine.
Original references can be obtained from refs. 2, 14, and 518.

Table 33.25. Risk Factors for Methotrexate Liver Toxicity

Risk factor	Importance	Implications for prevention
Age >60	Increased risk (reduced renal clearance may contribute)	Greater care in use of methotrexate for older people
Dose	Incremental dose Dose frequency Duration of therapy Cumulative (total) dose	5–15 mg/wk very safe Weekly bolus (pulse) safer than daily schedules Consider review of hepatic status every 2 to 3 y Review hepatic status after every 2 g methotrexate
Alcohol	Increased risk with daily levels	Avoid methotrexate use if intake not curbed

consumption	of >15 g (one to two standard drinks)	Consider pretreatment liver biopsy
Obesity, diabetes, metabolic syndrome	Increased risk	Consider pretreatment and progress liver biopsies
Preexisting liver disease	Greatly increased risk Particularly related to alcohol, obesity, and diabetes (nonalcoholic steatohepatitis)	Pretreatment liver biopsy mandatory Avoid methotrexate, or schedule progress biopsies according to severity of hepatic fibrosis, total dose, and duration of methotrexate therapy Monitor liver test results during therapy (see text)
Folate supplements	Increased risk of liver injury in persons not receiving folic acid	Concurrent folate therapy recommended
Systemic disease	Risk greater with psoriasis than rheumatoid arthritis	None
Impaired renal function	Reduced systemic clearance of methotrexate	Reduce dose; greater caution with use

Clinical features and laboratory data

Minor increases in ALT levels are seen 1 to 2 days after starting methotrexate treatment. These changes bear little relevance to the development of hepatic fibrosis, which can only be assessed by liver biopsy. Clinical features are absent or nonspecific for liver disease until complications of portal hypertension and liver failure develop. In these now rare advanced cases, hepatosplenomegaly, ascites, muscle wasting, thrombocytopenia, and hypoalbuminemia can be noted, but jaundice, hyperbilirubinemia, and coagulation disturbances are distinctly uncommon.

Histology

The specific scoring system, devised by Roenigk et al. is widely used for grading liver histology in methotrexate users (521). In this system, grades I and II indicate a variable amount of steatosis, nuclear pleomorphism, and necroinflammatory activity but fibrosis is absent. Higher grades reflect increasing degrees of fibrosis, as follows: Grade IIIA (few septa), grade IIIB (bridging fibrosis), and grade IV (cirrhosis). The pattern of hepatic fibrosis includes striking pericellular fibrosis, a feature of both alcoholic steatohepatitis and NASH; the possibility that methotrexate itself causes steatohepatitis or accentuates fibrogenesis among persons with underlying “primary NASH” has been suggested (52). However, cases have been reported in which hepatic fibrosis appeared in livers with a relative paucity (or complete absence) of portal and lobular inflammation. Because the extent of hepatic fibrosis is the only important abnormality in those taking methotrexate, Richards et al. have proposed a new semiquantitative method for the evaluation of liver biopsy specimens in patients with rheumatoid arthritis (522). The objective is to provide greater sensitivity for detecting early hepatic fibrosis than the Roenigk system, and further validation will be of interest.

Prevention of methotrexate fibrosis

Coprescription of folic acid is associated with a lower risk of liver injury (odds ratio [confidence interval (CI)] 0.10 [0.04 to 0.21]) (523) without sacrificing efficacy. However, its impact on preventing hepatic fibrosis is unknown (524). Guidelines have been published for monitoring methotrexate therapy (519,525,526,527) in patients with rheumatoid arthritis and psoriasis (summarized in Table 33.26). Less stringent guidelines for monitoring have been suggested. Yazici et al. have proposed less frequent liver tests (every 3 to 4 months), without additional risks but with reduced costs to the patient (528). However, the generalizability of these suggestions has been questioned because they have been based on a study population that was younger than that reported in other series and the patients were receiving lower doses of methotrexate (529).

A revised threshold for liver biopsy has also been proposed (530). In this British retrospective study, advanced liver fibrosis was found in 2.6% and 8.2% of patients with psoriasis who had received a cumulative dose of 4 and 5 g, respectively. On this basis, liver biopsy was recommended after a cumulative methotrexate dose of 5 g (530). The value of liver biopsies, to

assess methotrexate hepatotoxicity in diseases other than psoriasis and rheumatoid arthritis, has not been established. In a study of 32 patients with inflammatory bowel disease receiving long-term methotrexate (mean dose 2.6 g; follow-up 131 weeks), histologic changes were common but minor, and significant hepatic fibrosis was rare (531). Similar considerations apply to methotrexate use in sarcoidosis; hepatic reactions were common, but it proved difficult to separate drug toxicity from sarcoidosis-related liver features (532).

Table 33.26. Guidelines for Monitoring Hepatotoxicity in Patients with Rheumatoid Arthritis and Psoriasis During Methotrexate Treatment

Approach	Psoriasis (Said 1997, Roenigk 1998)	Rheumatoid arthritis (Kremer 1994)
Pretreatment (laboratory tests)	Routine liver tests, full blood count, urinalysis, blood urea, creatinine, creatinine clearance, hepatitis B/C serology	Same as psoriasis
Pretreatment (liver biopsy)	Not mandatory	
	Early treatment biopsy (2 to 4 m) in patients with risk factors for liver disease (past/current ethanol intake greater than one to two drinks/d, abnormal liver test results, familial liver disease, diabetes, obesity, exposure to hepatotoxic drugs)	Recommended in patients with history of excessive ethanol intake, abnormal baseline AST values, chronic hepatitis B or C virus infection[a]
During treatment (laboratory tests)	Liver tests 4 to 8 wk (1 wk after last dose). Frequent monitoring during initial treatment, dose escalation during episodes in which blood MTX levels could be elevated (dehydration, impaired renal function, nonsteroidal anti-inflammatory drug use)	Recommended in patients with history of excessive ethanol intake, abnormal baseline AST, chronic hepatitis B or C virus infection
	With significant and persistent abnormalities, withhold MTX 1 to 2 wk and repeat tests If abnormalities persist, consider liver biopsy	
During treatment (liver biopsy)	This is with no risk factors for liver disease, and normal physical examination and liver tests: Liver biopsy recommended after cumulative MTX dose 1.5 g[b]; if biopsy is normal, repeat at subsequent 1 to 1.5 g cumulative dose[c]	Liver biopsy recommended if five of nine AST determinations within 12 m (6 of 12 if tests performed monthly) are above upper limit of normal or serum albumin level falls (less than normal) in controlled rheumatoid arthritis

[a]The authors agree that this should now be 2 to 4 g.
[b]Additional 2 g cumulative dose (modified by earlier biopsy findings).
[c]Current understanding would add "risk factors for nonalcoholic fatty acid liver disease/nonalcoholic steatohepatitis, especially metabolic syndrome."
MTX, methotrexate; AST, aspartate aminotransferase.

Noninvasive methods of assessing hepatic fibrosis have been proposed for use during methotrexate therapy but have yet to be fully validated and adopted. These include measurement of serum procollagen-III peptide (PIIIP) levels (533) and dynamic hepatic scintigraphy. Doubts have been expressed about the reliability of PIIIP measurements in individual patients (534). Further, serial measurements are necessary to assess a dynamic process such as fibrogenesis (533). Dynamic hepatic scintigraphy evaluates the contribution of portal blood flow to the hepatic blood supply. Its application is based on the premise that changes in portal blood flow would be sensitive to structural alterations (534); a portal blood flow contribution of greater than 52% correlated with a 95% likelihood of normal liver histology.

Azathioprine

Azathioprine, the prodrug of 6-mercaptopurine, is used as an immunosuppressive agent or as a steroid-sparing agent in autoimmune diseases (see Chapter 31). Hepatic complications of azathioprine are rare but severe, diverse, and often of very late onset; all these factors provide a challenge for appropriate diagnosis and management. Disorders associated with azathioprine include bland cholestasis, cholestatic hepatitis with bile duct injury (535), zonal necrosis, and vascular toxicity (536,537). The latter encompasses diverse syndromes of SOS (VOD), peliosis hepatis, NRH, and noncirrhotic portal hypertension (537). HCC has also been recorded in a long-term recipient (538). Indirect hepatic effects of azathioprine such as opportunistic infections (e.g., cytomegalovirus) or, rarely, liver infiltration from lymphoma should always be considered.

6-Mercaptopurine causes dose-dependent hepatocellular necrosis, which can be fatal. Rarely, it is associated with cholestasis (14,539). Measuring 6-mercaptopurine metabolite levels (6-methylmercaptopurine) may be useful in making a diagnosis of drug hepatotoxicity in complex settings such as post–liver transplantation (539).

6-Thioguanine

Vascular toxicity, particularly hepatic SOS (VOD), is a characteristic feature of 6-thioguanine (6-TG) hepatotoxicity (Table 33.24) in the context of hematologic malignancies. Less well recognized is the development of NRH in persons with inflammatory bowel disease. In one study conducted in Los Angeles, 111 patients with inflammatory bowel disease receiving 6-TG were examined for potential hepatotoxic effects. Increase in liver enzyme levels and reduced platelet counts were found in 26% (540). These were seen more often in men and in those with preferential 6-methylmercaptopurine production during treatment with 6-mercaptopurine or azathioprine. Liver histology was available in 38 cases. Reticulin-stained sections showed NRH in 20 (53%); conventional hematoxylin–eosin sections identified NRH in only 4 of these cases. Ultrastructural studies demonstrated sinusoidal collagen deposition in 60% (14 of 23), a figure significantly higher than that observed with conventional trichrome stains (34%). SOS (VOD) was observed in one case (541). NRH was present more often (76%) in patients with abnormal laboratory tests than among those without such abnormalities (33%).

Cyclosporin A

Between 6% and 86% of organ transplant recipients receiving cyclosporine develop abnormal liver test results (14,542). However, these changes are mild and self-limiting, consisting of transient increase in SAP level, accompanied by a slight elevation in bilirubin and AT levels. Most patients do not develop symptoms of cholestasis or hepatitis. The biochemical changes are most evident in the first month after transplantation. However, up to 32% of cases may be associated with prolonged liver test abnormalities (542). Long-term recipients of cyclosporine are also at risk of developing biliary calculi (543), the consequence of altered bile flow and biliary lipid composition. Cyclosporine-induced liver test result abnormalities usually settle with dose reduction or discontinuation of treatment. There is anecdotal evidence that ursodeoxycholic acid may be beneficial in this setting (72).

In experimental models, cyclosporine induces cholestasis by inhibiting Bsep-mediated taurocholate transport, culminating in decreased bile flow (544). It also disturbs bile salt kinetics by inhibiting bile salt synthesis, reducing the size of the bile salt pool, and increases cholesterol saturation in bile by reducing phospholipid secretion (see Chapter on cholestasis for details).

Sirolimus

Increases in AT levels have been observed in liver and renal transplant recipients on sirolimus (545). Such cases were initially misdiagnosed as representing allograft rejection and were managed (unsuccessfully) with dose escalation. Resolution occurred only when sirolimus was withdrawn. Liver biopsy specimens show sinusoidal congestion or mild hepatitis.

Anticonvulsants

Phenytoin

Raised GGTP and SAP levels are very often observed in the absence of hepatic injury among people taking phenytoin; this usually reflects enhanced hepatic enzyme synthesis (a form of hepatic adaptation), but in those without adequate sunlight exposure, it is important to exclude vitamin D deficiency arising from enhanced hepatic metabolism of this vitamin. Acute hepatitis, including severe cholestatic hepatitis leading to VBDS, is a very rare but important side effect of phenytoin (2,546,547), usually as part of the RMS (Table 33.5). There may be an increased rate of hepatic reactions among African Americans compared with whites (546). Onset is usually within 6 weeks. Biochemical features reflect hepatocellular necrosis with high AT levels, but mixed patterns may occur. In phenytoin hepatitis, liver biopsy specimens show diffuse hepatocellular degeneration and multiple acidophilic (apoptotic) bodies, bridging necrosis, and a prominent lymphocytic or mixed cell inflammatory infiltrate containing neutrophils and eosinophils. Hepatic granulomas may also be present. The combined appearances of lymphocyte beading, mitotic hepatocytes, and granulomas resemble those observed in infectious mononucleosis (2).

Phenytoin was one of the first drugs associated with hypersensitivity features now regarded as characteristic of the RMS (anticonvulsant hypersensitivity syndrome or "pseudomononucleosis" syndrome) (30). Fever, severe forms of rash, lymphadenopathy, leukocytosis, and Stevens-Johnson syndrome are frequent, and the key link is with visceral involvement including the liver, kidney, bone marrow, and lung (Table 33.5). Resolution occurs with phenytoin withdrawal, but the case-fatality rate of patients developing liver injury is up to 20%. Continued ingestion of phenytoin after the onset of symptoms is associated with a poor outcome. Treatment consists of supportive measures. Corticosteroids have not proved beneficial.

Although the presence of hypersensitivity features suggests immunologic idiosyncrasy, it now seems likely that the primary abnormality is related to the generation of a highly reactive arene oxide metabolite. If detoxification of this metabolite by epoxide hydrolase is inadequate, it binds to cellular macromolecules

or initiates oxidative stress, causing cell injury with apoptosis or necrosis. The way in which this reactive metabolite incites profound drug hypersensitivity is less clear, but neoantigenic determinants of immune reactivity, cytokine mobilization, and defects in cell defenses against oxidative stress and proinflammatory stressors are potential candidates. A genetic deficiency of this enzyme has been identified in patients and their family members (548). CYP 2C9 is a key enzyme in phenytoin metabolism. Phenytoin-associated VBDS has been described in a patient heterozygous for CYP 2C9*3 (an allele conferring low enzyme activity); this supports a pharmacogenetic basis for this adverse drug reaction (549).

Carbamazepine

Liver disorders comprise approximately 10% of adverse drug reactions with carbamazepine (14). The frequency of liver injury is estimated at 16 cases per 100,000 treatment-years (14). Granulomatous hepatitis with varying degrees of hepatocellular injury and cholestasis have been reported (550,551,552,553,554). Children may also be affected, including neonates of women receiving carbamazepine during pregnancy (555). Onset is within 6 to 8 weeks. The hallmarks of hypersensitivity (e.g., fever, rash, angioedema, eosinophilia, and raised immunoglobulin E [IgE] levels) are often observed, linking this reaction as part of the RMS observed with other aromatic anticonvulsants (e.g., phenytoin, phenobarbitone) metabolized through arene oxides.

Submassive or massive hepatic necrosis has been noted in a few patients. Multiple hepatocellular adenomas were described in a man receiving carbamazepine for 17 years (556), but there is no evident biologic basis for an etiopathogenic role of the drug in this syndrome.

The case-fatality rate of carbamazepine hepatitis is 10% among those with hepatocellular reactions. Some reported cases of fulminant liver failure were also associated with concurrent acetaminophen intake or antituberculous therapy (557); the role of interactive hepatotoxicity needs to be considered in such severe cases. Patients presenting with granulomatous and/or cholestatic reactions usually survive, although bile duct injury and VBDS may rarely occur (88).

Lamotrigine

Indications for lamotrigine include partial and generalized seizures and as adjunctive therapy in children with refractory epilepsy. Early reports of liver test abnormalities were wrongly attributed to status epilepticus. Subsequently, a small but definite risk of hepatotoxicity was documented (558). However, attributing causality can be difficult because other potentially hepatotoxic antiepileptic drugs are often coprescribed.

Acute hepatitis was reported in ten persons, including two instances of fulminant hepatic failure. Symptoms developed within 2 to 3 weeks (range, 6 to 39 days). Extrahepatic features such as rash, disseminated intravascular coagulopathy, and rhabdomyolysis were sometimes present. Liver biopsy specimens showed acute hepatic necrosis or focal hepatitis with mild portal inflammation (558). Progressive hepatic necrosis culminating in fatal acute liver failure has been documented. In most other reported reactions, liver injury settled within a few weeks of stopping lamotrigine. Lamotrigine is structurally different from the aromatic anticonvulsants (e.g., phenytoin, phenobarbital, carbamazepine). Although in vitro cross-reactivity has been reported in patients with a history of reactions to the older antiepileptic drugs (559), there is no documented clinical cross-reactivity between lamotrigine and these agents.

Valproic acid (sodium valproate)

Risk factors

Up to 40% of recipients of VPA develop reversible increases in AT levels. These changes are frequently observed within in the first 2 months of treatment and are unrelated to the rare severe form of liver injury. VPA-associated hepatic injury is independent of dose and duration of treatment. It occurs predominantly in children, particularly those younger than 3 years. Among 37 fatal cases noted in a retrospective analysis of 400,000 persons taking VPA between 1978 and 1984, children younger than 10 years represented 73% (27 of 37 affected) (560). Risk factors include a family history of mitochondrial enzyme deficiencies (including urea cycle, long-chain fatty acid metabolism defects), Friedreich's ataxia, Reye's syndrome, having a sibling affected by VPA hepatotoxicity, and multiple drug therapy. There are 26 published cases of VPA liver toxicity in adults (561). The overall risk of liver injury among persons taking VPA is between 1 per 500 persons exposed among high-risk groups and less than 1 in 37,000 in low-risk groups (562).

Onset, clinical features, and laboratory findings

Symptoms begin 4 to 12 weeks after starting VPA and are often nonspecific; lethargy, malaise, poor feeding, somnolence, worsening seizures, muscle weakness, and facial swelling are important new symptoms among children prescribed VPA. They may be followed by features more readily attributable to hepatotoxicity, including anorexia, nausea, vomiting, weight loss, right upper quadrant discomfort, or abdominal pain. Jaundice, hypoglycemia, ascites, coagulation disorders, and encephalopathy indicate liver failure with imminent

coma and death. Another presentation is associated with fever and tender hepatomegaly suggestive of Reye's syndrome. The prognosis is better in such cases. Yet others exhibit prominent neurologic features, such as ataxia and confusion with little evidence of hepatic involvement. Additional extrahepatic features observed among patients with VPA hepatotoxicity include thrombocytopenia, pancreatitis, and alopecia. The biochemical features resemble those described earlier for other mitochondrial hepatotoxins; a modest rise in bilirubin and ALT level is accompanied by hypoalbuminemia, hyperammonemia, and profound impairment in serum levels of clotting factors synthesized by the liver.

Pathology

Histologic appearances include submassive or massive hepatic necrosis in two thirds of cases (562) and zonal or diffuse microvesicular steatosis in the others; steatosis may also accompany hepatic necrosis. Bile duct injury has been observed in a few cases, but as part of massive or submassive necrosis in which any additional significance is questionable.

Management, outcome, prevention

Management, outcome, and prevention include supportive measures for underlying metabolic defects and managing acute liver failure. In one retrospective study, L-carnitine supplementation reduced mortality (563); 20 (48%) of 42 patients treated with L-carnitine survived, as against only 5 (10%) of 50 patients managed by aggressive supportive care alone. The place of liver transplantation is unclear; it has been performed successfully in some cases (564), but in others it led to worsening of neurologic disease (565).

At least 60 deaths from VPA hepatotoxicity are recorded and the mortality remains high. Prevention is possible by adherence to prescribing guidelines; these include avoiding VPA in combination with other drugs in the first 3 years of life and in children with mitochondrial enzyme defects. Monitoring liver tests is unhelpful because of the high frequency of nonspecific liver test abnormalities. Children and their parents should be urged to report any new symptoms developing within the first 6 months of VPA therapy.

Mechanism of liver injury

Unlike the aromatic anticonvulsants, VPA hepatotoxicity is rarely accompanied by manifestations of the RMS (566). Metabolic idiosyncrasy is probably the principal mechanism of VPA toxicity. Glucuronidation and β-oxidation are the principal pathways of VPA metabolism, but VPA may be metabolized by CYP enzymes to 4-en-VPA, a pathway that is accentuated in persons taking concurrent medications (particularly other anticonvulsants) that induce CYPs. Some VPA oxy-metabolites, and notably 4-en-VPA, inhibit mitochondrial fatty acid β-oxidation. Other metabolic effects of VPA therapy include secondary carnitine deficiency, therapeutic correction of which may be valuable (see preceding text).

Topiramate

A woman receiving topiramate and carbamazepine developed acute liver failure. The explanted liver showed centrilobular necrosis (567). Another person prescribed topiramate for a bipolar affective disorder developed raised ALT level (>700 U/L), hypoalbuminemia, and mild hyperammonemia. Resolution occurred after topiramate was discontinued. Other medications including VPA could be resumed without ill effects (568). By contrast, topiramate used as an add-on anticonvulsant induced acute liver failure (569), which resolved only after VPA was withdrawn.

Felbamate

Cases of acute hepatitis and fatal fulminant hepatic failure have been attributed to felbamate (570). Most affected individuals were women. The overall frequency of liver injury and liver-related death was estimated at 1 per 7,000 and 1 per 125,000 persons exposed, respectively. Half the reported cases occurred between 3 and 6 months (range 2 weeks to 8 months). Generation of atropaldehyde, a reactive metabolite, could be critical to felbamate toxicity (571). Felbamate should be reserved for treating refractory epilepsy, especially the Lennox-Gastaut syndrome.

Gabapentin

Gabapentin has been implicated in causing cholestatic hepatitis (572). Another report of liver injury attributed to gabapentin has been disputed because other potentially hepatotoxic medicines had been coprescribed (573). The Committee on Safety of Medicines, the United Kingdom, has received reports of four other unpublished cases of jaundice, including one other cholestatic drug reaction. Overall, this drug has low hepatotoxic potential.

Antipsychotic Agents, Sedative-Hypnotics, and Antidepressant Drugs

Chlorpromazine

Chlorpromazine is historically one of the most important causes of drug-induced liver disease, both because of the relatively high frequency of idiosyncratic reactions and because it is the archetypical example of a drug causing cholestatic hepatitis; VBDS and other

complications, such as massive hepatic necrosis, also occur occasionally. Full descriptions of chlorpromazine hepatitis may be found elsewhere (2,14,574), but the essential features are recapitulated here because of what chlorpromazine has taught us about hepatic drug reactions and because the agent is still used occasionally.

Chlorpromazine is associated with cholestatic hepatitis in 0.2% to 2% of recipients; the risk increases with age and is higher in women. The onset of prodromal symptoms occurs within 1 to 6 weeks (574). Fever and nonspecific systemic complaints are present in over half the patients, but rash is uncommon. Jaundice, pruritus, and generalized or right upper quadrant pain occur later. SAP level is elevated more than threefold, along with a moderate rise in the AT level and variable increase in serum bilirubin level, depending on severity. Peripheral blood eosinophilia is present in 10% to 40% of those affected. Liver histology is characterized by centrilobular cholestasis, portal inflammation, mild parenchymal injury, and occasionally bile duct damage (574). Resolution occurs within 12 weeks in most cases, but approximately 7% develop VBDS.

The brisk response to rechallenge suggests immunoallergic idiosyncrasy but there is evidence of a toxic component to liver injury. Chlorpromazine and, particularly, its hydroxylated metabolites inhibit plasma membrane Na^+/K^+-ATPase, alter membrane fluidity, and polymerize actin. Genetically determined defects in sulfoxidation of chlorpromazine (the sulfoxide metabolite is inert) have been postulated but are unproved (575).

A similar pattern of cholestatic liver injury has been described less frequently with *prochlorperazine* (576) and other neuroleptics such as *haloperidol* (577), *pimozide*, and *sulpiride*, including rare cases of VBDS (82).

Sedative-hypnotics

Liver injury is extremely rare with the benzodiazepines and other minor tranquilizers, anxiolytics, or hypnotics. Both hepatocellular and cholestatic reactions are described, but often from times preceding the accurate diagnosis of all forms of viral hepatitis (14).

Antidepressants

Monoamine oxidase inhibitors

Iproniazid was one of the first drugs associated with acute hepatitis (2). These reactions occurred in 1% of recipients and were often severe, including instances of fatal fulminant liver failure. The hydrazine substituent (which iproniazid partly shares with INH, ethionamide, pyrazinamide, and nicotinamide) was probably the hepatotoxic moiety (578). Hydrazine sulfate can cause severe hepatorenal toxicity (578). *Phenelzine* and *isocarboxazid* have also been associated with occasional instances of hepatocellular injury, but monoamine oxidase inhibitors (MAOIs) are now rarely prescribed.

Tricyclic antidepressants

Tricyclic antidepressants bear structural resemblance to the phenothiazines and are an occasional cause of cholestatic or, less commonly, hepatocellular injury. Recovery after drug cessation is usual, but prolonged cholestasis has been observed with amitriptyline (579) and imipramine (580).

Selective serotonin reuptake inhibitors and other modern antidepressants

Liver enzyme level alterations in asymptomatic persons have been observed with *fluoxetine* and *paroxetine* (581). A few reports of acute and chronic hepatitis have been attributed to the use of selective serotonin reuptake inhibitors (SSRIs) (581) (Table 33.27). In all reported cases, the liver injury subsided with drug discontinuation. *Nefazodone* has been withdrawn after being implicated in the induction of acute and subacute liver failure (582). A Spanish pharmacovigilance study examining antidepressant hepatotoxicity found that nefazodone had the highest frequency of liver injury among these drugs (28.96 per 100,000 patient-years); the comparative figures for fluoxetine, paroxetine, sertraline, and citalopram were less than 2 per 100,000 patient-years (583). Of 32 cases of liver injury analyzed by the Canadian adverse drug-monitoring program, 26 (81%) were classified as severe. About half the patients recovered after drug withdrawal but three patients progressed to acute liver failure (584), necessitating liver transplantation. Centrilobular, massive or submassive hepatic necrosis was observed on histology. Two thirds of affected persons were women aged between 30 and 70 years. Although most had been taking the drug for 3 to 6 months, early liver injury (within 4 weeks) has also been reported (585). Bioactivation of nefazodone to a reactive quinone–imine species metabolite may underlie its hepatotoxicity (586).

Trazodone has been implicated in cases of acute and chronic hepatocellular injury (587). The onset is usually within 6 months (range, 4 days to 18 months) (588). Positive rechallenge within 2 days of reinstituting the drug has been described (589). Recovery is complete within 2 months of discontinuing trazodone. Occasional

reports note the occurrence of severe hepatotoxicity with combinations of antidepressants (590) or antidepressants with other neuroleptics (43).

The liver toxicity associated with other antidepressants is summarized in Table 33.27 (591).

Table 33.27. Liver Injury Associated with Antipsychotic, Sedative-Hypnotic and Antidepressant Drugs

Drug	Nature of liver injury
ANTIPSYCHOTIC DRUGS	
Chlorpromazine	Cholestasis; vanishing bile duct syndrome
Haloperidol	Cholestasis; vanishing bile duct syndrome
Clozapine	Hepatocellular, acute liver failure
Quetiapine	Acute liver failure (single case)
Risperidone	Raised aminotransferase levels, cholestatic hepatitis
SEDATIVE-HYPNOTICS	
Barbiturates	Cholestatic or hepatocellular injury
Benzodiazepine	Hepatocellular, chronic hepatitis (bentazepam)
Chlormezanone	Cholestasis, hepatocellular, acute liver failure
ANTIDEPRESSANTS	
Monoamine oxidase inhibitors	Acute hepatitis
Tricyclic antidepressants	Hepatocellular or cholestatic; vanishing bile duct syndrome (amitriptyline, imipramine)
Tetracyclic antidepressants	Cholestasis with mianserin, maprotiline
SELECTIVE SEROTONIN REUPTAKE INHIBITORS	
Fluoxetine	Acute hepatitis, chronic hepatitis
Paroxetine	Raised aminotransferase levels, chronic hepatitis (one case)
Sertraline	Acute hepatitis when used alone and also combination with other drugs, cholestatic hepatitis
Citalopram	Cholestasis
OTHER ANTIDEPRESSANTS	
Bupropion	Raised aminotransferase levels in trials; acute hepatitis (one case),

	cholestatic hepatitis
Fluvoxamine	Acute hepatitis
Nefazodone	Raised aminotransferases, occasionally subacute liver failure
Trazodone	Acute and chronic hepatitis, cholestasis, fatal hepatic necrosis
Venlafaxine	Acute hepatitis with zone 3 necrosis, mixed liver injury; low-dose venlafaxine associated with hepatocellular injury in a patient with chronic hepatitis B

Cognition Modifiers

Tacrine (1,2,3,4-tetrahydro-9-acridinamine)

Tacrine is a reversible cholinesterase inhibitor that was formerly used in treating Alzheimer's disease. Following initial concerns about possible hepatotoxicity, a seminal observational study was conducted (592). ALT values greater than the ULN were recorded on more than one occasion in 49% of recipients; 25% had values that were more than threefold elevated, and in 2% ALT level was more than 20-fold increased (values usually >1,000 IU/L). Among patients in whom treatment was discontinued because of abnormal liver enzyme changes, biochemical resolution invariably occurred, and 88% were able to resume long-term therapy (usually at lower dose); there were no fatalities (592). Only few cases of overt hepatic disease have been reported. Histologic appearances include mild lobular hepatitis, centrilobular hepatic necrosis, steatosis, and granulomatous hepatitis (593).

The mechanism of tacrine-induced liver injury remains unclear. Hypersensitivity features were observed only infrequently and rechallenge also did not produce an exaggerated rise in ALT level. The frequency of combined glutathione-*S*-transferase genetic polymorphisms (M1 and T1) is increased in patients with tacrine-related liver injury (594), suggesting possible individual susceptibility to tacrine hepatotoxicity.

Donepezil

Donepezil hydrochloride is a specific, reversible inhibitor of centrally active acetylcholinesterase. Although postmarketing surveillance has not yet revealed significant hepatotoxicity when used alone, fulminant hepatic failure has been reported in a patient taking both donepezil and sertraline (595).

Methylphenidate

Methylphenidate is a sympathomimetic amine prescribed for attention-deficit disorders (ADDs) in children and narcolepsy and is also self-administered by intravenous injection for "recreational" use. Hepatocellular injury is documented with therapeutic (oral) and intravenous use (596,597). The latter reactions are more severe and have been associated with multiorgan

failure involving the liver, kidney, pancreas, lung, and central nervous system (597).

Pemoline

Pemoline is a psychostimulant previously prescribed for children with ADD. Clinical trials revealed mild, reversible liver injury in approximately 2% of recipients. However, instances of serious liver toxicity have since been reported to the FDA. Of 13 cases presenting with fulminant hepatic failure, 11 died or required liver transplantation (598). Symptoms were usually reported within 4 weeks but could be delayed for up to 1 year after starting therapy. Liver histology showed focal necrosis, mild steatosis, or portal inflammation (45).

Rash, fever, or eosinophilia was infrequent (599). Moreover, the observation of a similar rise in serum AT level in twins with ADD supports a hypothesis of genetically determined individual susceptibility (51). On the other hand, the existence of distinctive cases of steroid-responsive chronic liver disease resembling AIH indicates that immunoallergic mechanisms could also be involved (600). Zimmerman suggested that persons prescribed pemoline should be monitored for serum AT changes, but it is noted that the onset of acute liver failure can be extremely rapid (599). This drug is no longer considered as first-line therapy for ADD and has been withdrawn in many countries.

Other Drugs Used in the Treatment of Neurologic Diseases

Riluzole

Riluzole is a glutamate antagonist approved for the treatment of amyotrophic lateral sclerosis. Increased ALT level was observed in 1.3% to 10% of clinical trial recipients. Two cases of acute hepatitis with microvesicular steatosis have since been reported, with onset at 4 and 8 weeks after starting treatment (601). Rarely, hepatocellular injury may be delayed for as long as 6 months (602). Liver test abnormalities settle shortly after riluzole is stopped.

Dantrolene

Dantrolene is a skeletal muscle relaxant used against spasticity. The frequency of liver injury is approximately 1%. A feature has been the severity (the case fatality is approximately 28%) (603) of liver injury, which in some cases progressed even after stopping dantrolene. Most cases have been in people older than 30 years. Up to one third of affected persons had been asymptomatic, while others developed symptoms of hepatitis and jaundice. Hepatocellular necrosis, often submassive or massive, was the usual histologic characteristic (14,603). Chronic hepatitis and cirrhosis have also been observed (604). Liver tests should be performed every 2 weeks for the first 6 weeks of dantrolene therapy. The drug should be stopped if there is no clinical benefit.

Other drugs with muscle relaxant properties, which have been rarely associated with liver injury include phenyramidol (hepatocellular injury), chlormezanone (cholestasis, hepatocellular injury, and acute liver failure), and baclofen (serum AT changes) (605,606).

Tolcapone

Tolcapone is a catechol-*o*-methyl transferase (COMT) inhibitor used in the treatment of Parkinson's disease. In preclinical trials, significant ALT level elevations (>3 × ULN) were present in 1% to 3% of recipients. Tolcapone has now been implicated in at least four cases of acute liver failure (607), all in women older than 70 years. They presented with jaundice and high ALT levels. Centrilobular necrosis was observed at autopsy in one case. Ultrastructural changes included mitochondrial swelling with disruption of cristae and reduced matrix density. Patients developing severe hepatotoxicity had not been monitored as recommended, and it is noteworthy that significant liver injury has not been reported in correctly monitored recipients (608). In the United States, stringent monitoring guidelines consist of ALT testing every 2 weeks during the first year, and every 2 months thereafter. Drug withdrawal is suggested if the ALT levels exceeded the ULN. Because most cases of liver injury occur within the first 6 months, a panel of experts have suggested that less rigorous testing may be reasonable beyond this period and also that ALT levels up to two to three times ULN could be permissible (607,608).

The mechanism of tolcapone hepatotoxicity could be related to uncoupling of mitochondrial oxidative phosphorylation (609). It is relevant that *entacapone*, another COMT inhibitor does not exhibit similar toxicity at comparable concentrations (609). As compared to tolcapone, entacapone has a greater binding affinity with glucuronidation enzymes but a lower capacity for penetrating the mitochondrial outer membrane (609). Of the three recent cases of hepatic injury attributed to entacapone, there were confounding factors in two cases such as underlying alcoholic cirrhosis and use of concurrent hepatotoxic drugs. The remaining case was of mixed hepatocellular–cholestatic injury, which could possibly be linked to this drug (610). Overall, the experience with entacapone (over 300,000 patient-years) has confirmed its generally safe track record. Manufacturers advise caution in persons with impaired liver function, but routine liver test monitoring is not mandatory (611).

Drugs of Abuse

3,4-Methylenedioxymethamphetamine ("ecstasy")

Ecstasy is a widely used recreational agent that has been associated with more than 30 cases of acute liver injury, including several deaths from acute liver failure (612,613). In some European countries, 3,4-methylenedioxymethamphetamine (MDMA) is recognized as an important cause of unexplained acute liver failure in young adults, accounting for up to 25% of such cases in Spain (614). Cases may go unrecognized in Asian countries where ecstasy use is a more recent phenomenon and viral hepatitis remains very common. Liver injury was initially described as part of a hyperthermic syndrome with rhabdomyolysis, acute renal failure, and coagulopathy; this was precipitated by vigorous muscle exercise, dehydration, and increased ambient temperatures, particularly during all-night "rage" dancing (613). However, it is now clear that acute hepatitis may be the sole manifestation of MDMA toxicity; it can occur following ingestion of even a single tablet, although many of the reported cases have involved consumption of MDMA for longer periods.

MDMA is demethylated in the liver by the CYP 2D6 pathway. One initial suggestion was that persons with low-level expression of CYP 2D6 (the debrisoquine slow-metabolizer phenotype) may be susceptible to MDMA-induced hepatitis, but this has been challenged (615). Liver biopsy specimens may show acute lobular hepatitis, or zone 3 or massive hepatic necrosis, but others have observed chronic cases with hepatic fibrosis (616).

Methylene dianiline (MDA) may be confused with MDMA (617) if used in similar settings. This is illustrated by a report of cholestasis in participants of a "technoparty" who had their alcoholic beverage spiked with MDA. Unlike MDMA, which primarily causes hepatocellular injury, MDA toxicity manifests as cholestasis, as exemplified by the 1965 outbreak of jaundice in Epping, England, where bread flour had been contaminated

with MDA (618). Acute right upper quadrant abdominal pain (similar to erythromycin hepatitis) is a major feature.

Phencyclidine

Severe phencyclidine (angel dust) overdose can lead to submassive hepatic necrosis (619) accompanied by hyperthermia, rhabdomyolysis, respiratory, and renal failure (14).

Cocaine

Cocaine is a dose-dependent hepatotoxin in mice (45). Massive doses self-administered to humans cause liver injury in association with shock and other toxic phenomena (620,621). Rarely, cocaine can cause acute hepatitis without altered systemic hemodynamics and after intranasal (as opposed to parenteral) use (622). In rodents, the histologic lesions include extensive centrilobular, midzonal, or panlobular necrosis, together with microvesicular steatosis (14); gender and genetic differences, as well as the activity of CYP enzymes determine this varied histologic spectrum.

Clinical presentation of cocaine hepatotoxicity is with raised serum AT level (>10-fold in 40% of cases), nearly always accompanied by hypotension, hyperpyrexia, renal failure, myoglobulinuria, and disseminated intravascular coagulation (623). The high mortality is illustrated by one series of 39 patients among whom more than 40% died (623). Thrombotic microangiopathy is a rare complication; early recognition and institution of plasma exchange can be lifesaving for this hematologic disorder (624). The mechanism of liver injury may vary between species; in rodents it involves drug metabolism to toxic, oxy- or nitrometabolites and factors pertaining to host defenses (2). In humans, systemic hypotension and hypoxia (and possibly hyperthermia) are more likely to contribute to liver injury (623) than the direct effects of cocaine on the liver. Induction of hepatic CYP 2E1 by alcohol can potentiate the hepatotoxic effects of cocaine experimentally (625).

Drugs Used in Aversion Therapy and Treatment of Alcohol Withdrawal

Tetrabamate (Atrium)

Tetrabamate is a drug combination (i.e., febarbamate, difebarbamate, and phenobarbital) that has been used in France and Spain to treat alcohol withdrawal, tremor, and depression. *Phenobarbital* is an extremely rare cause of liver injury (cases are similar to phenytoin hepatitis) (626), while difebarbamate and febarbamate have not been previously implicated in hepatotoxicity. However, use of the combined preparation (tetrabamate) has been implicated in causing acute hepatitis (626). Onset of symptoms was between 15 days and 2 years after commencement of drug ingestion (627). Complete recovery was observed in most patients after drug cessation, but two deaths from liver failure were recorded; both fatalities were in persons who continued taking tetrabamate after the onset of symptoms. Histology shows acute hepatocellular necrosis. Other lesions described include cholestasis, microvesicular steatosis, and granulomatous hepatitis.

Hypersensitivity features were prominent in some individuals, including the presence of ANAs and/or SMAs. Therefore, immunologic idiosyncrasy may contribute to liver injury, but genetic differences in drug

metabolism could have also been responsible (628). Phenobarbital, a potent CYP enzyme inducer, could also have potentially enhanced the production of toxic metabolites from the other constituents (as in the case of VPA and the anticonvulsant hypersensitivity syndrome [RMS]) when used in drug combinations.

Disulfiram

Disulfiram has been incriminated in at least 30 instances of acute hepatocellular injury. Recovery usually occurs within 2 weeks, but liver test results can take up to 3 months to normalize. The high AT readings distinguish these reactions from alcoholic hepatitis. Rarely, acute liver failure may develop (629,630). The frequency of fatal liver injury is estimated at 1 per 30,000 treated persons per year. Three liver transplantations have been performed for disulfiram-induced acute liver failure, the youngest patient being only 16 years old (631). Baseline and serial liver test monitoring is recommended for persons receiving disulfiram therapy. *Cyanamide* produces a characteristic ground glass appearance of hepatocytes, which resembles Lafora bodies (632). This is a form of hepatic adaptation rather than liver injury. The intense immunohistochemical staining of these cytoplasmic inclusions with a polyglucosan-reactive monoclonal antibody suggests that they are derived from altered glucose metabolism (633). However, cyanamide can rarely cause acute hepatitis, and serial liver biopsy specimens from alcohol-abstinent recipients of cyanamide showed portal–portal and portal–central fibrosis (634).

Chlormethiazole

Used for years to treat alcohol withdrawal symptoms, chlormethiazole had been previously associated with only one report of acute cholestatic hepatitis. However, a recent case series suggests that chlormethiazole is associated with greater hepatotoxic potential than previously appreciated (635). All three affected persons were older than 70 years and had been taking the drug for less than 2 months for indications other than alcohol withdrawal (e.g., insomnia, depression). The biochemical profile reflected hepatocellular or mixed liver injury. One developed fatal acute liver failure; histology showed submassive necrosis. The other two patients recovered within 2 months. The authors speculated that chlormethiazole hepatotoxicity may be underreported

in the context of alcohol withdrawal because of difficulties in separating drug toxicity from the underlying alcoholic liver disease (635).

Antihistamines: H_1 Receptor Antagonists

Cetirizine

Cetrizine is a nonsedating H_1 receptor antagonist associated with transient liver enzyme abnormalities in less than 2% of recipients. Cetirizine has been implicated in four reports of liver toxicity; three were hepatocellular reactions and in the other the patient developed cholestasis (54,636). Appearance of a rash (637), eosinophilia, and presence of anti–liver/kidney microsomal antibodies in two cases (637,638) is suggestive of drug hypersensitivity. Positive rechallenge (inadvertent) has been reported (638). Other H_1 receptor blockers that have been associated with cholestatic drug reactions include *terfenadine*,*cinnarizine*, *chlorpheniramine*, and *pizotyline* (82). Temporal relationship of loratadine to two hepatocellular reactions has been described. One of these cases developed subfulminant hepatic failure and needed liver transplantation. Liver histology showed massive hepatic necrosis (639).

Gastric Acid–Lowering Agents

H_2 receptor antagonists

Rare episodes of liver injury have been reported with most H_2 receptor antagonists (640). Cross-reactivity between famotidine and cimetidine has been described (641), but there is no overall evidence of a class effect on hepatotoxicity among these structurally variable drugs. Although these agents have a good safety profile, serious hepatotoxicity has led to the withdrawal of *oxmetidine*, *ebrotidine*, and *niperotidine*.

Compared to nonusers, the relative risk for liver injury was 5.5 for cimetidine and 1.7 for ranitidine (and 2.1 for omeprazole) (642). The frequency of hepatotoxicity with cimetidine and ranitidine has been estimated at 3 to 6 per 100,000 and 1 per 100,000 prescriptions, respectively (643). The risk of liver injury with cimetidine is highest with doses exceeding 800 mg/day and at the onset of treatment. Cimetidine, ranitidine, and famotidine usually cause acute hepatitis or cholestatic hepatitis (643). Of 170 cases of H_2 receptor antagonist toxicity reported to the Australian Adverse Drug Reaction Advisory Committee, hepatotoxicity constituted 4% to 8% of reactions. Most of the affected individuals were older than 50 years (643). Hepatic reactions were more frequently reported with ranitidine than with cimetidine or famotidine. Supportive evidence of hypersensitivity features was recorded in a few patients. Others have reported Stevens-Johnson syndrome in association with ranitidine in two patients with preexisting severe liver disease; it was suggested that altered hepatic metabolism may have contributed

to the syndrome, but no data were presented to support this (644). However, others point out that markers of hypersensitivity and positive rechallenge have not been consistently demonstrated, leading them to propose an alternative hypothesis for liver injury (645). In a rat model, they showed that significant hepatocellular injury could be elicited in the presence of lipopolysaccharide-induced liver inflammation. On this basis, they suggest that similar mechanisms may underlie human ranitidine hepatotoxicity because these cases are preceded by a cluster of symptoms (e.g., fever, diarrhea, abdominal pain) that could be explained by endotoxemia. In turn, the ensuing endotoxemia-related hepatic inflammation could render the hepatocytes susceptible to ranitidine-related liver injury. Interestingly, in the same rat model, coadministration of lipopolysaccharide with famotidine, a less frequent cause of hepatotoxicity, did not elicit significant liver injury.

Proton pump inhibitors

A few reports of acute hepatitis or mixed hepatocellular–cholestatic liver injury (646) have been ascribed to the proton pump inhibitors (PPIs). Although *omeprazole* was implicated in one case of fulminant hepatic failure, concurrent acetaminophen use was not clearly excluded (see earlier) (646). Fulminant hepatic failure has also been attributed to *rabeprazole* (647). However, the role of rabeprazole in causing fulminant hepatitis appears equally less conclusive because terbinafine had also been prescribed. The authors' assertion that terbinafine hepatotoxicity is usually mild is not consistent with other data presented to the FDA (see earlier section).

Antispasmodic Drugs

Alverine

Alverine is a smooth muscle relaxant used to treat patients with irritable bowel syndrome. Two cases of acute hepatocellular injury have been reported. In the first report, the accompanying peripheral and tissue eosinophilia along with ANAs directed against a component of the nuclear envelope (lamin A and C) suggested immune-mediated liver injury. These features were absent in the second case. Both patients recovered after alverine was discontinued (648,649).

Emerging Drugs

A clinical challenge with drug-induced liver disease is provided by instances of hepatotoxicity attributable to recently introduced drugs (Table 33.28). The frequency of liver injury with these drugs will not be known until

larger studies are conducted.

Alfuzosin

Two reports of liver injury (i.e., hepatocellular and mixed hepatocellular-cholestatic) have been recorded with alfuzosin, a α_1-adrenoceptor antagonist used in treating benign prostatic hyperplasia (650,651). One of these patients had underlying chronic liver disease (651). Because alfuzosin is extensively metabolized in the liver, it is possible that the ensuing hepatotoxicity in this case was a consequence of increased drug levels. Normalization of liver test results was complete within 6 months of stopping the drug (650,651).

Bosentan

Bosentan is an endothelin antagonist prescribed for primary pulmonary hypertension, chronic heart failure, and hypertension. Dose-dependent, reversible AT level increases (up to 3 × ULN) were observed with 10% of clinical trial recipients. In a pivotal trial of patients with primary pulmonary hypertension, AT level increases of eight times ULN were observed in 3% and 7% of those assigned to the 125 mg b.i.d. and 250 mg b.i.d. arms, respectively (652). The pharmacokinetics of bosentan is unaltered by mild hepatic

function impairment (Child-Pugh A) (653) but the drug is contraindicated if more severe liver disease is present. However, an area of study is the use of bosentan in controlling portopulmonary hypertension (654,655).

Table 33.28. Liver Injury Associated with Emerging Drugs

Drug	Nature of liver injury
Alfuzosin	Hepatocellular or mixed hepatocellular–cholestatic injury
β-Interferon	Raised AT level common; clinically significant liver injury rare; can trigger autoimmune hepatitis
Bosentan	Raised AT level in at least 10% but clinically significant liver injury not described; raised AT level also observed with sitaxsentan
Orlistat	Cholestatic hepatitis, subacute liver failure (single cases only)
Imatinib mesylate	Raised AT level in 35%; acute hepatitis; massive or submassive hepatic necrosis (rare)
Infliximab	Bland cholestasis, cholestatic hepatitis with bile duct injury; acute liver failure (rare); reactivation of chronic hepatitis B
Leukotriene antagonists	
Zafirlukast	Submassive or massive hepatic necrosis
Montelukast	Acute hepatitis, cholestatic hepatitis
Ximelagatran	Raised AT in 6%; acute liver failure (relationship with drug not definitely established)

AT, aminotransferase.

In a rat model, bosentan inhibited canalicular Bsep (656). Further, coadministration of cholestasis-inducing agents such as glibenclamide (glyburide) is associated with an increased frequency of AT level elevations (29%). Bosentan-treated patients with chronic heart failure also appear to be at an increased risk of liver injury, with up to 18% showing AT level elevations in one study.

Dose-dependent AT increases were also reported with *sitaxsentan*, a selective endothelin (ET_A) receptor antagonist. The cumulative risk of developing raised AT level (up to 3 × ULN) with the 100 and 300 mg daily dose after 9 months was estimated at 8% and 32%, respectively (657).

Orlistat

This gastrointestinal lipase inhibitor was not associated with hepatic side effects in clinical trials. Abnormal AT levels were noted on routine evaluation in an obese young woman 3 weeks after beginning orlistat. She developed subacute liver failure 2 weeks later and required liver transplantation (658). Explant histology showed massive hepatic necrosis. Other reports of liver injury include an instance of fatal massive hepatic necrosis and a case of acute cholestatic hepatitis (659). Other than these three reports, orlistat has not been implicated in causing significant liver injury. Further, it has been studied as a potential therapeutic agent in patients with NAFLD.

Interferons

Interferon-α has been associated with acute "flares" in patients with hepatitis C, sometimes resulting in viral clearance (see Chapter 26). It may also rarely activate latent AIH (660). This may occur if the autoimmune etiology of chronic hepatitis has been not correctly appreciated at diagnosis, or it may represent a direct immune-mediated complication of interferon.

β-*Interferon* is increasingly used as a first-line agent in relapsing–remitting multiple sclerosis, as well as for hepatitis C in Asian countries. Analysis of pooled data from six randomized controlled trials involving over 2,800 subjects has shown that AT level increases are frequent (67% of subjects by 24 months) (661); most (75%) of these increases occur within 6 months. AT level changes settled spontaneously or after dose reduction (in 5%), and only a minority (0.4%) had their medication withdrawn. A retrospective chart review of 844 patients in British Columbia compared three different preparations of interferon-β-1b with respect to their hepatotoxic potential (662). AT level increases of up to 2.5 × ULN, 5 × ULN, and greater than 5 × ULN were found in 23% to 39%, 1.9% to 7.8%, and 0% to 1.9% of patients, respectively; the lowest figures were recorded with the intramuscular preparation of interferon-β-1b. Despite the high frequency of AT level changes observed with the β-interferons, clinically significant toxicity is rare. Of the two reported patients developing fulminant hepatic failure (622), one was also receiving nefazodone. Unmasking of AIH has also been observed with β-interferon (663,664). Baseline and periodic liver test monitoring is recommended by the manufacturers (665).

Pegylated interferon-α has a higher rate of AT abnormalities than conventional recombinant interferon-α but clinically significant hepatotoxicity has not been reported.

Imatinib mesylate

Imatinib mesylate is a tyrosine receptor kinase inhibitor that has been approved for treating chronic myeloid leukemia and advanced gastrointestinal stromal tumors. Nonhematologic adverse effects include sodium retention (resulting in pleuropericardial effusions, pulmonary edema, and ascites) and abnormal liver test results. Raised AT and/or serum bilirubin levels were observed in up to 3.5% of individuals treated. Median time to onset of raised AT and/or bilirubin levels was 100 days (666). These abnormalities usually settled with dose reduction; the drug needed to be discontinued on account of hepatotoxicity in only 0.5% of recipients. Few reports of acute hepatitis have accrued (666,667), including three cases of acute liver failure (668,669); concurrent acetaminophen intake was recorded in one of these cases. Positive rechallenge was observed in two patients with chronic myeloid leukemia (666). Histologic appearances showed acute hepatitis with extensive lobular and portal inflammation (670) or focal hepatic necrosis in less severe cases and submassive hepatic necrosis in those presenting with acute liver failure (669).

Leukotriene Antagonists

Leukotriene antagonists are a group of drugs used to treat asthma and include zileuton, zafirlukast, and montelukast. As a group, reversible increases in AT levels (>2 × ULN) were recorded in up to 3% of leukotriene antagonist (LTA) recipients in preclinical trials. Zileuton, the first member of this drug class, was implicated in a single case of acute hepatocellular injury. It has been superseded by zafirlukast and montelukast (671).

Zafirlukast

Collated global surveillance data published by the manufacturers on-line indicate over 100 cases of disturbed liver function in zafirlukast users. These include 46 reports of hepatitis and 14 of acute liver failure. The risk of developing acute liver failure was estimated at less than 1 per 100,000 patient-years. Assigning causality is difficult because details of concomitant drug intake or preexisting liver disease were not provided. Nevertheless, detailed descriptions of clinically significant hepatic injury have been published elsewhere (672,673). In these two case series, jaundice was observed in seven of nine cases. Two patients progressed to acute liver failure and needed liver transplantation. Symptoms were delayed until 6 months (range, 1.5 to 13 months) after starting zafirlukast. Inadvertent rechallenge reproduced liver injury in one case. Submassive or massive hepatic necrosis was observed in the hepatic explants. It is important to note that in persons developing acute liver failure preceding signs and symptoms of hepatitis were not always present. The apparent response to corticosteroids in four patients, three of whom had hypersensitivity features such as skin rash, and peripheral and tissue eosinophilia suggestive of immune-mediated liver injury. However, in another report the absence of hypersensitivity features and the long latent period (13 months) are more consistent with idiosyncratic liver injury (674). Cross-reactivity with montelukast has not been described (673). Periodic

monitoring of liver tests is suggested (671). However, the long latent period to liver injury in some cases, lack of preceding symptoms, and also the progression of liver injury even after drug withdrawal cast doubts on the validity of routine surveillance (671).

Montelukast

Three reports of acute hepatitis have been documented with montelukast. Time to onset of liver injury has been variable (1 month to 2 years) (675,676,677). Recovery was complete in all cases. Biochemical resolution can be slow and AT level (>2 × ULN) remained elevated for more than 1 year after drug withdrawal. Liver histology showed acute hepatitis or cholestatic hepatitis (676,677). A lymphocyte transformation test was reported as positive in one case, supporting a cause–effect relationship (676).

Infliximab

Infliximab is an anti–tumor necrosis factor monoclonal antibody used in refractory rheumatoid arthritis and Crohn's disease. Transient AT level elevations were recorded in combination with methotrexate but no major hepatic adverse effects were noted in clinical trials. Two reports of liver injury have since emerged in the early postmarketing phase. Bland reversible cholestasis was noted in one case and acute hepatitis with bile duct injury, interface hepatitis, and antibodies to double-stranded DNA in another (678,679). Smooth muscle and anti–liver/kidney microsomal antibodies were not present. Whether infliximab is directly hepatotoxic or whether it triggers autoimmune hepatocellular and bile duct damage is not clear. Two further reports of infliximab hepatotoxicity have since accrued. Fulminant hepatic failure developed in a 28-year-old woman with adult-onset Still's disease, 10 days after the second infliximab infusion. She was hepatitis B surface antigen positive, although there was no evidence of liver disease or viral replication (680). However, other potential factors to be considered in this case are the use of concurrent hepatotoxic drugs (cotrimoxazole) and also the risk of hepatic failure with Still's disease (681). There are now two well-documented cases of chronic hepatitis B reactivation after infliximab treatment in patients with Crohn's disease; a third patient with chronic hepatitis B who was receiving lamivudine was unaffected, suggesting that serologic screening and antiviral prophylaxis are appropriate for persons with chronic hepatitis B who commence infliximab treatment (682).

Ximelagatran

Ximelagatran is a thrombin inhibitor associated with increased AT levels (>3 × ULN) in 7.9% of long-term recipients, occurring most often within 6 months of commencement. Most (96%) of these biochemical changes declined slightly to less than twofold above ULN irrespective of whether the drug was continued or withdrawn. Symptomatic cases have been rare (683). Three cases of acute liver failure have been attributed to this drug but a definitive relationship has not been clearly established. At the present time, FDA approval has been withheld because of concerns about hepatotoxicity.

Hepatotoxicity of Herbal Medicines

The potential therapeutic benefits of herbal medicines in liver disease have yet to be fully defined, as reviewed elsewhere (683,684). However, the growing popularity of CAM in industrialized societies has brought about an increasing number of cases of herbal hepatotoxicity (685). Many of the herbal products have been used for centuries, in part because of their excellent safety record, so that recognition of hepatotoxicity has seemed surprising. Explanations include nonadherence to recommended doses and concurrent intake of other agents, including conventional medicines (such as acetaminophen). Toxicity may also result from the

use of newer more biologically active formulations. For instance, a 78-year-old woman developed acute hepatitis soon after using a readymade powder formulation of a fungal extract Linghzi (*Ganoderma lucidum*) despite having used this herbal compound previously for a year without toxicity (686). The only difference was that earlier treatment had been home prepared and presumably was not as concentrated as the marketed product that caused the adverse reaction. Individual susceptibility may also be an important determinant of herbal toxicity. Kava, a reasonably safe and widely used anxiolytic agent with rare hepatotoxicity, appears more likely to cause acute hepatitis (687) in whites with the slow debrisoquine phenotype (low expression of CYP 2D6) (also see "Kava"). The same phenotype has also been implicated in facilitating senna-associated hepatocellular injury; altered pharmacokinetics with prolongation of serum half-life and high metabolite levels were demonstrated (688). In comparison with these agents, others such as the pyrrolizidine alkaloids have substantial hepatotoxic potential.

Some herbal preparations (e.g., Jin Bu Huan) could incite an immunoallergic mechanism of liver injury. Others could aggravate preexisting liver disease, as noted with Ma huang, which can exacerbate AIH (689). Rarely, herbal medicines may trigger latent AIH (e.g., Dai-saiko-to, Black cohosh) (690,691,692). Such interactions between herbal medicines and preexisting liver disease are poorly understood. This is an important aspect because many patients with viral hepatitis use herbal remedies, and disclosure is not always forthcoming.

Recurring themes among reports of herbal hepatotoxicity are delayed diagnosis, product contamination, or botanical misidentification (685). The latter two issues can be rectified by exclusive use of agents prepared according to codes of good manufacturing practice; relevant legislation governing the sale of herbal products is in place in some countries, but the international availability of herbal medicines by mail and Internet ordering partly abrogates such improvements. Greater awareness of possible herbal hepatotoxicity is required on the part of physicians and the public so as to avoid the problem of delayed diagnosis; the implications of continued intake of hepatotoxic chemicals after the onset of liver injury is identical whether it is a

conventional medicinal agent or a herbal product. Natural products, often equated with "safety," may be easily overlooked by patient and doctor. Items not readily identified include skin creams, "natural" sedatives, herbal tea infusions, health tonics, and so-called energy vitalizers.

Some herbal products can complicate the management of patients with chronic liver disease by exacerbating a bleeding tendency (e.g., ginkgo) or by antagonizing the antimineralocorticoid action of spironolactone (e.g., glycyrrhizin, licorice) (685). Agents with immunostimulant actions, such as *Echinacea* and *St. John's wort*, can interfere with immunosuppressive therapy and provoke allograft rejection (693).

Herbal hepatoxicity encompasses a range of hepatic pathology from acute hepatitis, steatosis, and fibrosis, through to SOS and submassive or massive hepatic necrosis. Table 33.29 provides an updated account of contemporary agents implicated in significant liver injury, and some well-characterized and illustrative examples are briefly outlined in the subsequent text. More detailed accounts are available in recent reviews (685,693).

Chaparral

Chaparral (*Larrea tridentata*) is marketed as tablets, capsules, or herbal tea infusions. It is used as a dietary "energy" supplement and as a cure for numerous ailments ranging from chicken pox to cancer. Cholestatic hepatitis is the predominant mode of presentation, but chaparral has been associated with acute hepatitis, subacute hepatic necrosis, and acute liver failure (694). Hepatotoxicity is at least partly dose dependent; dosage recommendations were exceeded in some severe cases (694). At least three patients have developed end-stage liver disease requiring hepatic transplantation.

Germander

Used as a traditional remedy for many centuries, germander became popular as a slimming aid in the 1980s, particularly in France and Italy. More than 30 cases of liver injury were recorded, mostly in middle-aged women. Acute hepatitis developed 8 weeks after ingestion of germander capsules or herbal teas (695). Presence of ANAs, SMAs, and, transiently, antimitochondrial M2 antibodies have been recorded occasionally (696). Although most patients recovered, several fatalities from liver failure have been recorded. In some individuals, chronic hepatitis or cirrhosis was evident at presentation. Other case studies suggest that unfavorable outcomes are related more often to continued or repeated drug ingestion after the onset of liver injury. Early recrudescence of liver test abnormalities after rechallenge is suggestive of immunologic idiosyncrasy. The identification of a microsomal target for germander-induced autoantibodies is consistent with this proposal (697). On the other hand, the demonstration that the constitutive neoclerodane diterpenoids in germander are metabolized by CYP 3A enzymes to epoxides that can deplete GSH and incite oxidative stress–dependent apoptosis favors a reactive metabolite mechanism of liver injury (698).

Herbal products derived from closely allied medicinal plants *Teucrium polium L.* and *Teucrium capitatum L.*

P.983

P.984

have also been associated with acute liver failure and acute hepatitis with bridging necrosis, respectively (699,700).

Table 33.29. Herbal Remedies and Dietary Supplements Implicated as Causing Toxic Liver Injury

Herbal remedy	Indications	Toxic constituent	Pattern of liver injury
Atractylis gummifera	Purgative, emetic, diuretic	Potassium atractylate and gummiferin	Acute liver failure
Black cohosh	Menopausal symptoms	Not known; contains diterpenoids	Acute liver failure; can trigger autoimmune hepatitis
Chaparral leaf	Multiple uses	*Larrea tridentate*	Zone 3 necrosis; massive hepatic necrosis chronic hepatitis; cholestasis
Chaso	Slimming aid	*N*-Nitrosofenfluramine	Submassive or massive hepatic necrosis, acute hepatitis
Chinese herbal medicines (see text)	Multiple indications; skin diseases; health	Many; *Dictamnus dasycarpus* present in six cases (in	Liver injury (no histology); acute hepatitis; SOS;

	tonic; viral hepatitis	combination)	vanishing bile duct syndrome
Comfrey; gordolobo yerba tea; maté tea; Chinese herbal tea	Health tonic	Pyrrolizidine alkaloids; compositae	SOS (veno-occlusive disease)
Camphor	Rubefacient	Cyclic terpenes	Abnormal liver tests, encephalopathy
Carp capsules (raw carp gallbladder)	Rheumatism, visual acuity	Cyprinol	Liver enzyme changes (no biopsy) with acute renal failure; hepatic necrosis (rats)
Cascara sagrada	Laxative	Many constituents, possibly anthraquinones	Cholestatic hepatitis, portal hypertension
Dai-saiko-to (TJ-9)[a]	Liver disease, especially chronic viral hepatitis	Scutellaria; glycyrrhizin	Acute and chronic hepatitis
Greater celandine	Gallstones	*Chelidonium majus*	Acute hepatitis; cholestatic hepatitis; fibrosis
"Green juice"	Dietary supplement	Contains vegetable extracts, micronutrients	Granulomatous hepatitis
Germander (tea, capsules)	Weight reduction; health tonic	Neoclerodane diterpenes (*Teucrium chamaedrys L.*)	Acute and chronic hepatitis; zone 3 necrosis; fibrosis, cirrhosis
Isabgol	Laxative	Not identified	Giant cell hepatitis (one report)
Jin Bu Huan Anodyne tablets	Sedation; analgesic	*Lycopodium serratum*	Acute and chronic hepatitis; steatosis; fibrosis
Kava	Anxiety disorders	Kava-lactone	Diffuse hepatocellular necrosis; cholestatic hepatitis; isolated γ-glutamyl transpeptidase increase
Kombucha "mushroom"	Health tonic	Yeast–bacteria aggregate (see text)	Liver injury (no histologic studies)
Linghzi	Multiple indications	*Ganoderma lucidum*	Acute cholestatic hepatitis
LipoKinetix	Slimming aid	? Ephedra, ? Usnic acid	Acute hepatitis, acute liver failure
Ma huang	Slimming aid	Ephedrine	Acute hepatitis;

			exacerbates autoimmune hepatitis
Margosa oil	Health tonic	*Azadirachta indica*	Reye's syndrome
Mediterranean remedy	Anti-inflammatory agent	*Teucrium polium*	Zone 3 necrosis; acute liver failure; fibrosis
Mixed preparations: Mistletoe, skullcap, valerian	Herbal tonics	Not identified; ? Scutellaria Skullcap has diterpenoids (see "Germander")	Liver injury (no histologic studies)
"Natural laxatives"	Cathartic	Senna, podophyllin, aloin	Liver injury (no histologic studies)
Oil of cloves	Dental pain	Eugenol	Dose-dependent hepatotoxin; zonal necrosis
Pennyroyal oil (squawmint)	Abortifacient; herbal drug	Pulegone metabolites	Confluent hepatocellular necrosis
Prostata	Prostatism	Saw palmetto	Hepatitis; fibrosis
Shark cartilage	Food supplement	Not identified	Abnormal liver tests (no histology)
Shou-wu-pian	Dizziness, premature graying of hair, liver disease	*Polygonum multiflorum* (?anthraquinones)	Acute hepatitis
Sho-saiko-to (TJ-9) [a]	Health tonic; viral hepatitis	Scutellaria; glycyrrhizin; others	Zonal/bridging necrosis; fibrosis; microvesicular steatosis
Usnic acid	Slimming aid	Usnic acid	Acute liver failure
Zulu remedy	Health tonic	*Callilepis laureola*	Hepatic necrosis

[a]TJ-9 is used in Japan and China; there are several alternative spellings, including Sho-saiko-to and Dai-saiko-to.
SOS, sinusoidal obstruction syndrome.

Jin Bu Huan

Jin Bu Huan has been implicated in several cases of acute hepatitis (701). Onset of symptoms occurred after a mean of 20 weeks (range, 7 to 52). Focal hepatic necrosis with numerous eosinophils, minor lobular hepatitis with microvesicular steatosis, and bridging fibrosis have been described. Resolution occurred within 8 weeks of discontinuation, but chronic hepatitis has been reported with long-term use (702). Levo-tetrohydropalmatine, the active ingredient, is structurally similar to the hepatotoxic pyrrolizidine alkaloids (see subsequent text). Despite being banned in the United States and Canada since 1994, new cases of Jin Bu Huan toxicity continue to accrue, stressing the need for continued vigilance.

Kava

Extracts of *Piper methysticum* have been used as a traditional ceremonial beverage (*Kava*, *Kava Kava*) in

South Pacific countries. Elsewhere, they are dispensed by alternative medical practitioners as anxiolytics or sedatives. Over 60 cases of hepatotoxicity have been reported worldwide (703,704,705). Most reported cases have occurred in users of alcohol or acetone extracts of the herb but traditional preparations of kava, which are aqua based, have also been rarely implicated in causing liver injury (705). The frequency of Kava-associated liver injury has been estimated at 0.24 to 0.26 per million daily doses. Many of the affected individuals are women (female-to-male ratio, 3:1). These included 11 patients with acute liver failure who required liver transplantation (704); the explants showed panacinar necrosis. In less severe cases, cholestatic or lobular hepatitis was noted. Symptoms of liver injury were reported to begin 3 to 16 weeks after starting ingestion (range, 2 weeks to 2 years; median 4.5 months). Reversible increase in GGTP level has also been recorded in Kava users (705), but this appears unrelated to the marked rise in AT level seen in patients developing liver injury and could instead reflect adaptation (microsomal enzyme induction).

The hepatotoxic potential of Kava has been disputed by phytomedicine practitioners, who cite its safe track record, and also by the presence of alcohol or concurrent hepatotoxic medications in some reports. However, there are well-documented cases occurring in the absence of such confounding factors. Moreover, positive rechallenge has been documented in at least two cases (703).

The active ingredients in kava are collectively termed *kava pyrones* (or *kavalactones*). The mechanism of liver injury is unclear but the following have been suggested: Inhibition of CYP enzymes, inhibition of cyclo-oxygenases COX-1 and COX-2, or depletion of hepatic GSH (706). An immunoallergic basis has been postulated because of the lack of dose dependency; it is further supported by the presence of autoantibodies, eosinophilia, positive lymphocyte transformation test, and also the successful use of corticosteroids in some cases. However, metabolic idiosyncrasy appears more plausible as the above "immune" phenomena are lacking in most cases (703). As noted above, the debrisoquine slow-metabolizer phenotype may predispose to Kava hepatitis in whites. However, studies involving affected Pacific islanders have not confirmed such a relationship (705), which is not surprising given the low prevalence (approximately 1%) of CYP 2D6 deficiency in these ethnic groups (706).

Pyrrolizidine alkaloids

Ingestion of these plant alkaloids is endemic in Africa (707) and Jamaica, usually as herbal tea mixtures, decoctions, or even as an enema (692). Such preparations have been associated with hepatic VOD (SOS), fibrosis, and cirrhosis. Pyrrolizidine alkaloid contamination has also been found in cases of SOS associated

with consumption of Chinese herbal teas and comfrey (97,693). In India and Afghanistan, epidemics of SOS have occurred after the contamination of wheat flour with pyrrolizidine alkaloids (708). In the acute form of SOS, the typical manifestations are abdominal pain, ascites, hepatomegaly, and raised AT levels. Liver failure can occur, even during the acute phase, but recovery is also possible. On the other hand, the prognosis is poor for individuals presenting with the chronic form of this disease; death occurs from liver failure.

Herbal slimming aids

Several cases of acute liver injury have been reported in association with herbal weight reduction remedies (709,710,711,712,713). In Japan, 12 women presented with jaundice, fatigue, diarrhea, and a biochemical picture of hepatocellular injury, 5 to 45 days after commencing *Chaso* or *Onshido* (709). Of these, two developed acute liver failure; one survived after a liver transplantation and the other died 6 weeks after admission. Pathologic findings were of massive or submassive hepatic necrosis or acute hepatitis. Over 400 cases of hepatotoxicity associated with herbal weight-loss aids were reported to the Japanese Health Ministry in 2002; Chaso and Onshido use were recorded in 21 and 135 cases, respectively. *N*-Nitrosofenfluramine has been identified as a potential hepatotoxin with these two products; it is a recognized hepatocarcinogen. Other *N*-nitrosofenfluramine–containing compounds associated with liver toxicity include *Sennomotokounou* and *LipoKinetix* (710) (see subsequent text). Over 100 cases, including 2 deaths from Sennomotokounou liver toxicity were reported to the Japanese Ministry of Health, Labour, and Welfare (713). Individual susceptibility may be important because the frequency of liver injury appears to be low; the CYP 2C19 poor-metabolizer phenotype was present in one of two patients with acute hepatitis. An immunoallergic basis was postulated for the other patient, who lacked this phenotype, but developed peripheral and tissue (liver) eosinophilia.

LipoKinetix, a dietary supplement, has been implicated in seven cases of acute hepatocellular injury in Los Angeles (710). Five of these were Japanese nationals. Onset of liver injury was within 3 months of ingestion (many within 1 month). Three patients developed acute liver failure but eventually recovered. Recovery was complete within 3 months. Liver histology was not available. The toxic ingredient was not identified in this multicomponent herbal product; potential candidates include ephedra alkaloids or usnic acid. The latter, marketed as a "fat burner," works by uncoupling oxidative phosphorylation. It has been implicated in causing acute liver failure in a 35-year-old woman (712). The disruption in mitochondrial bioenergetics and generation of oxidative stress could be central to usnic acid hepatotoxicity. Interestingly, usnic acid is also present in Kombucha "mushroom," a multipurpose tonic previously implicated in cases of hepatocellular injury (685). It has also been suggested that usnic acid could be the primary hepatotoxin in LipoKinetix-related liver toxicity. However, the absence of lactic acidosis argues against the involvement of usnic acid, a primary mitochondrial toxin (710).

Natural and Synthetic Retinoids

Hypervitaminosis A

Risk factors

Vitamin A is a dose-dependent hepatotoxin. Historically, cases of acute hypervitaminosis A with liver injury occurred among Arctic travelers who were forced to consume large quantities of polar bear liver. Today, liver injury more often follows self-medication with vitamin A preparations, although rare instances of hypervitaminosis A occur after consumption of large amounts of raw liver alone or in combination with β-carotene–rich vitamins (714,715).

Hepatic injury occurs both with acute ingestion of massive doses (>600,000 IU) and with prolonged ingestion of smaller doses (716). The mean daily dose of vitamin A in reported cases has been 96,000 IU, and the average duration of ingestion has been 7.2 years (range 11 days to 30 years), representing a mean cumulative dose of 229 million units (717). Cirrhosis has occurred in persons with a daily intake of 25,000 IU for 6 years or longer (717). It is therefore noted that up to 3% of vitamin supplements in the United States that are recommended for daily use contain 25,000 IU or more of vitamin A (716). In patients with renal failure, vitamin A dosages as low as 4,000 IU/day can lead to hepatotoxicity (718).

Diagnosis: Presentation, clinical features, and laboratory findings

In a Belgian series, only about a third of 41 cases were correctly identified at presentation; the average delay in diagnosis was 18 months (719). Hypervitaminosis A is associated with hepatotoxicity in approximately 50% of cases; other features of hypervitaminosis are usually present, such as fatigue, myalgia, bone pain, dry skin, alopecia, gingivitis, xanthosis, headache, neuropsychiatric disturbances, hypercalcemia, and growth retardation (663). The liver is often enlarged. Splenomegaly, ascites, and signs of portal hypertension are present in severe cases, but jaundice is not usually found (717).

The clinicopathologic spectrum of hypervitaminosis A–related liver disease includes minor alteration of liver enzymes, peliosis hepatis (720), noncirrhotic portal hypertension with perisinusoidal fibrosis, sclerosis of central veins, and cirrhosis. Decompensated chronic

liver disease can occur in the absence of cirrhosis and may be irreversible. Liver enzyme changes are nonspecific. Hypoalbuminemia, prolongation of prothrombin time, and hyperglobulinemia (with predominant IgM) are seen in advanced cases (717). Increased plasma level of retinyl esters (>10%) as a proportion of total serum vitamin A level (normal <8%) has been suggested as a marker of hypervitaminosis A (721), but this is not supported by the National Health and Nutrition Examination Survey (NHANES) III survey, which showed no correlation between retinyl esters and liver test abnormalities (722). Further, plasma vitamin A levels may also be normal in patients with hepatic fibrosis (717). Demonstration of increased hepatic vitamin A stores and the characteristic histologic appearances are a more reliable guide to diagnosis.

Liver pathology

Stellate cells store vitamin A in the liver. As expected, liver biopsy specimens of people with hypervitaminosis A show stellate cell hypertrophy and hyperplasia. This can give rise to sinusoidal compression and a typical honeycombed ("Swiss Cheese") appearance. Perisinusoidal fibrosis is often striking, whereas hepatocellular injury is usually minimal. Microvesicular steatosis and focal degeneration have also been reported (723). Vitamin A deposition is readily detected on fresh liver sections by the characteristic greenish autofluorescence after irradiation with ultraviolet light.

Course and management

Gradual improvement usually occurs after vitamin A is discontinued, but progression from noncirrhotic portal hypertension to cirrhosis may continue (717,724). Features of liver failure with established cirrhosis at diagnosis indicate a poor prognosis; most patients die or require hepatic transplantation (717,725). This is because turnover of vitamin A stores is very slow (half-life 58 to 286 days) (726) Abstinence from alcohol is advised because ethanol can potentiate vitamin A hepatotoxicity (716).

Synthetic retinoids

Etretinate is an aromatic synthetic retinoid (structurally unrelated to vitamin A) used in the management of psoriasis and other dyskeratotic skin disorders. Abnormal liver test results are found in up to 20% of recipients of etretinate but overt liver injury is less common (<1%). Acute and chronic hepatitis, mild cholestasis, and cirrhosis have all been reported (727,728,729). Features of drug allergy are usually not present, although eosinophilia was reported in one case (730). Recovery can be delayed because of the long tissue half-life of etretinate (120 days). Corticosteroids appeared to induce a clinical response in one report of etretinate-induced chronic hepatitis (727). It is recommended that patients taking etretinate be monitored with regular liver tests. If the liver enzyme levels are raised (>3 × ULN), the options are to either perform a liver biopsy to assess the significance of liver injury or discontinue etretinate (14).

Acitretin, the major metabolite of etretinate, has a shorter half-life (50 hours). A large study evaluating the effect of sequential liver biopsies on recipients of acitretin did not show significant histologic progression (731). However, acitretin has also been associated with a few reports of acute hepatitis, including one instance of acute cholestatic hepatitis with bile duct injury accompanied by marked hyperbilirubinemia (70

mg/dL) (732,733). Progressive fibrosis and cirrhosis can occur despite stopping acitretin (732,733). Periodic monitoring of LFTs is recommended.

Chapter 34

Mechanisms of Drug-Induced Liver Injury

Paul B. Watkins

Key Concepts

- Most drug-induced liver injury appears to be caused by the formation of reactive metabolites from the parent drug.
- The initiating event in liver injury is often the accumulation of a reactive metabolite over a "threshold," which occurs when the rate at which the reactive metabolite is produced exceeds the rate at which it can be safely eliminated.
- Reactive metabolites can injure cells in many ways, including creating "oxidative stress" and "covalent binding," which may inhibit functioning of critical proteins or create neoantigens, stimulating an immune attack on the liver.
- The innate immune system is involved in events that kill drug-injured hepatocytes that would otherwise survive; whether a drug-injured hepatocyte dies or recovers is largely based on a balance of multiple factors that favor cell killing or cell survival.
- The liver can often adapt to low levels of liver toxicity through mechanisms that involve altered regulation of glutathione, enzymes, and transporters.
- The mechanisms common to both predictable and idiosyncratic toxicity are generally not known and can probably only be identified by studying patients who actually experienced idiosyncratic toxicity.

Drug-induced liver injury has been traditionally divided into two categories: Predictable and unpredictable (or "idiosyncratic"). Predictable liver toxins produce dose-dependent injury; essentially all patients will develop liver injury if they receive a sufficiently high dose. Drugs that are predictable toxins are generally identified in preclinical (animal) studies or during the early clinical trials specifically designed to look for dose-related toxicity. If liver toxicity occurs at doses likely to be near those required for significant therapeutic benefit, the drug is generally abandoned from further development. As a result, there are few predictable hepatotoxins in

therapeutic use today. One example of a drug that is a predictable hepatotoxin is acetaminophen. As with all predictable toxins, subtoxic exposures can generally be safely tolerated because "the dose makes the poison."

In contrast to predictable toxicity, idiosyncratic toxicity is not clearly dose related. With a true idiosyncratic toxin, only a very small fraction of the patients are susceptible to liver injury, even when receiving high doses (i.e., it is the *host* that makes the poison). Animal models, although having value in identifying predictable liver toxins in man, are generally of little help in identifying drugs capable of causing idiosyncratic toxicity. If the toxicity occurs in less than 1 in 1,000 patients receiving the drug, it might not be recognized during preapproval clinical trials and become evident only after regulatory approval and widespread usage. Recognition that an otherwise good drug can cause idiosyncratic hepatotoxicity often leads to regulatory

actions that limit access of patients to that drug, even when most patients are at no risk for toxicity. Idiosyncratic hepatotoxicity has been the major reason for regulatory actions concerning drugs, including failure to approve, marketing restrictions, and withdrawal from the market place (1).

Idiosyncratic hepatotoxicity, therefore, poses a great problem for physicians, patients, and the pharmaceutical industry. Until the mechanisms underlying idiosyncratic hepatotoxicity are identified, it is unlikely that the industry will be able to design this liability out of new drugs. The vast majority of research on the mechanisms underlying drug-induced liver injury has involved predictable hepatotoxins, particularly acetaminophen. Furthermore, it is generally assumed that the mechanisms underlying predictable toxicity are relevant to idiosyncratic toxicity, but that the latter occurs because of genetic or nongenetic factors that are present only in the susceptible patients.

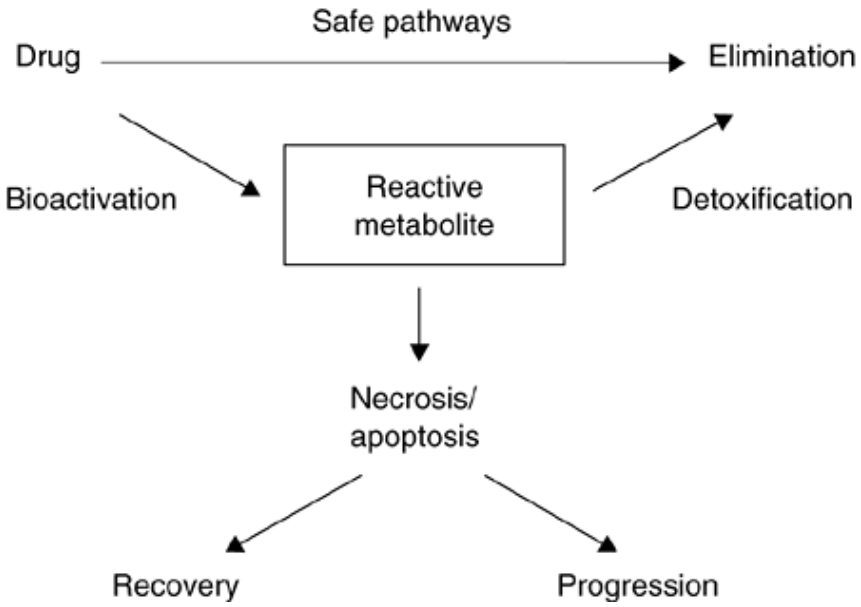
Mechanisms of Predictable Hepatotoxicity

Most predictable hepatotoxins, including environmental compounds such as aflatoxin B1, bromobenzene, and carbon tetrachloride, are relatively harmless to the liver. Predictable toxicity generally results from reactive, or toxic, metabolites generated from the parent (or "protoxin") in the liver (2,3,4,5). Formation of the reactive metabolite is generally thought of as an essential step in the cascade of events leading to hepatocyte injury. A general scheme for hepatotoxicity mechanisms involving reactive metabolites is shown in Figure 34.1. The liver is particularly susceptible to generating reactive metabolites because it is the major organ responsible for drug metabolism and elimination. Furthermore, many of the same enzymes involved in the safe elimination of drugs (nontoxic pathways) have also been implicated in creating reactive and potentially toxic metabolites.

When a reactive metabolite is involved in toxicity, it usually represents only a small fraction of the total metabolism of the drug. Hepatocytes are generally capable of efficiently detoxifying and eliminating reactive

metabolites once they are formed, thereby preventing toxicity. A generally held concept is that the initiating event is the accumulation of the reactive metabolite above some threshold. Accumulation occurs when the relative rates of production of the reactive metabolite exceeds its rate of safe removal.

The rate of production of a reactive metabolite in the hepatocyte reflects the intrinsic activity of the enzyme responsible for this conversion (termed *bioactivation* in Fig. 34.1) and the concentration of parent molecule surrounding the enzyme within the hepatocyte. The concentration of the parent molecule at the enzyme chiefly reflects (i) the competing rates of uptake into, and efflux out of, the hepatocyte and (ii) the rate of conversion of the parent molecule to safe and readily excreted metabolites (the competing *safe pathways* are shown in Fig. 34.1).



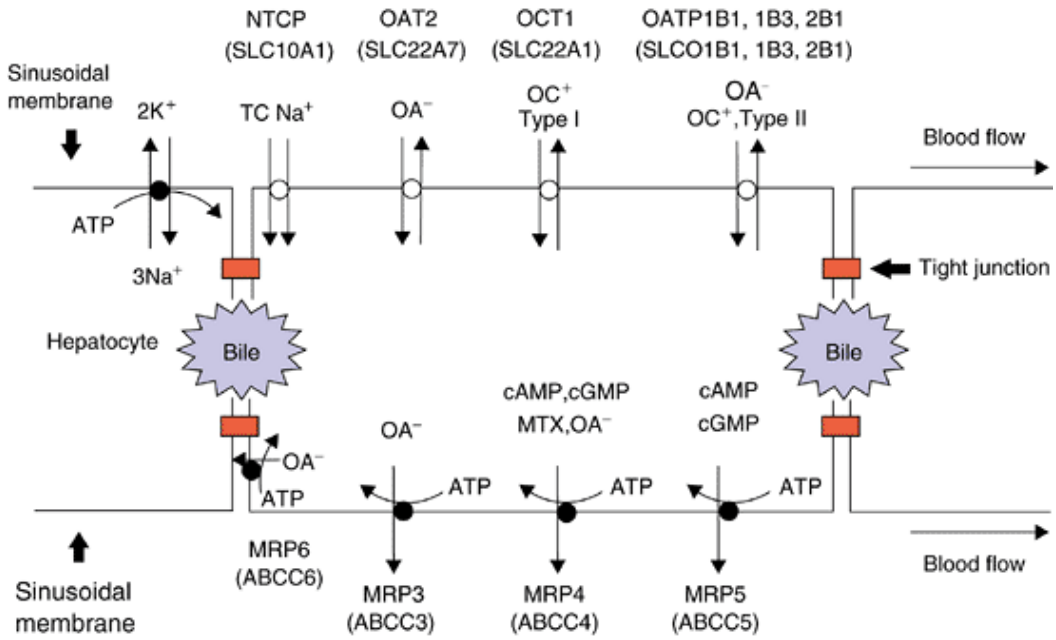
▪ **Figure 34.1** Central role of reactive metabolites in drug-induced liver injury. For most drugs, the major routes of elimination involve production of metabolites that are safely excreted and represent no threat to the liver cell because they are readily and safely excreted. Drugs that produce liver injury generally appear to do so through "bioactivation" to form reactive or toxic metabolites, which often result from relatively minor metabolic pathways. Fortunately, the liver generally has adequate ability to detoxify these metabolites, allowing their safe elimination. However, under certain circumstances, the reactive metabolite can accumulate in the hepatocyte above a threshold level for toxicity, resulting in hepatocyte damage through a variety of mechanisms discussed in the text. For a given level of hepatocyte injury, the outcome may be complete recovery or progression to death, depending on the response of the innate immune system.

Safe Pathways of Drug Metabolism and Transport

The rates of uptake and efflux of drugs (and metabolites) probably reflect largely the activities of specific transport proteins and not passive diffusion, as previously thought. There has been great progress in the identification and characterization of these transporters (Figs. 34.2 and 34.3). Uptake transporters are present on the basolateral membrane of the hepatocyte and efflux transporters are present on both the basolateral and canalicular membranes (6,7,8,9). Once inside the hepatocyte, the rate of conversion of the parent molecule to nontoxic metabolites reflects the activities of a variety of enzymes traditionally divided into two categories: Phase 1 or Phase 2. Phase 1 reactions result in a direct modification of the

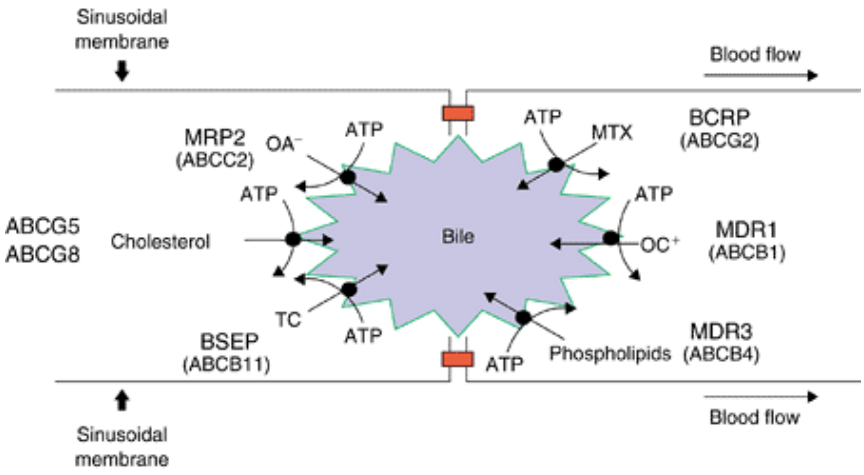
primary structure of the drug, usually resulting in insertion of an oxygen atom in the form of a hydroxyl (–OH) group. Phase 2 reactions involve covalent binding (conjugation) of the drug to polar ligands, usually glucuronic acid or sulfate, often to the hydroxyl group resulting from Phase 1

metabolism. The terms *Phase 1* and *Phase 2* refer to the fact that often, but not always, drugs must first be subjected to Phase 1 metabolism before they can be conjugated. Metabolites generated by Phase 1 and Phase 2 enzymes are generally secreted actively into bile or back into systemic circulation for elimination in the urine by the kidneys. In most instances, this appears to reflect active transport by at least many of the same proteins involved in the efflux of parent drugs (Figs. 34.2 and 34.3). Active efflux of metabolites from the hepatocyte is sometimes termed *Phase 3*.



▪ **Figure 34.2** Basolateral uptake and efflux transporters in the hepatocyte. Uptake of serum bile acids results from the action of sodium taurocholate cotransporting polypeptide (NTCP) and, to a lesser extent, organic anion transporting polypeptides (OATPs), which are also involved in uptake of many drugs. Multidrug resistance proteins (MRPs) are chiefly involved in the efflux of drugs and their metabolites, particularly glucuronide and sulfate conjugates. During the recovery phase of hepatotoxicity, due to acetaminophen or carbon tetrachloride, there is downregulation of NTCP and several OATPs, and upregulation of several MRPs, including MRP3 and MRP4. The aggregate effect of these changes, which would reduce the hepatocyte content of potentially injurious bile acids and xenobiotics, likely account in part for the adaptation to hepatotoxicity with recurrent dosing. OAT, organic anion transporter; OCT, organic cation transporter; OATP,

organic anion transporting polypeptide; TC, taurocholate; OA^-, organic anion; OC^+, organic cation; ATP, adenosine-5'-triphosphate; cAMP, cyclic adenosine-3',5'-monophosphate; cGMP, cyclic guanosine-3',5'-monophosphate; MTX, methotrexate. (Adapted from Chandra P, Brouwer KL. The complexities of hepatic drug transport: current knowledge and emerging concepts. *Pharm Res* 2004;21(5):719–735.)



▪ **Figure 34.3** Canalicular efflux transporters in the hepatocyte. Bile salt excretory protein (BSEP) is the major bile acid efflux pump. Multidrug resistance-1 (MDR1) and multidrug resistance protein-2 (MRP2) are responsible for biliary excretion of most xenobiotics and their metabolites. During the recovery phase of hepatotoxicity, due to acetaminophen or carbon tetrachloride, there is upregulation of MRP2 and probably MDR1 and bile salt export pump (BSEP). These changes complement the altered regulation in basolateral transporters (Fig. 34.2) and further reduce hepatocyte content of potentially injurious bile acids and xenobiotics, thereby contributing to adaptation with recurrent dosing. OA^-, organic anion; ATP, adenosine-5'-triphosphate; MTX, methotrexate; BCRP, breast cancer resistance protein; OC^+, organic cation; TC, taurocholate. (Adapted from Chandra P, Brouwer KL. The complexities of hepatic drug transport: current knowledge and emerging concepts. *Pharm Res* 2004;21(5):719–735.)

Phase 1

It is now appreciated that most (but not all) of what was described as Phase 1 drug metabolism is the result of the activity of a large family of enzymes termed *cytochromes P-450*, now termed simply *P-450s* or *CYPs* (pronounced "sips"). Liver P-450s metabolize most drugs in use today; in many and perhaps most instances, metabolism by a P-450 is the rate-

limiting step in the elimination of the parent drug. There are relatively few P-450s important for drug metabolism (10,11), and these derive from three gene families, now termed *CYP1*, *CYP2*, and *CYP3* (12). Within each P-450 family, there are subfamilies designated by capital letters. Each subfamily generally contains multiple members, designated by Arabic numbers usually reflecting the order in which they were discovered.

Table 34.1. Characteristics Of Major Human Liver P-450S

P-450	Substrates	Inhibitors	Inducers
CYP 1A2	Tacrine Theophylline Tolcapone[a] (13) Dihydralazine[a] (14)	Fluvoxamine Cimetidine Ciprofloxacin	Cigarette smoke Charcoal-broiled foods Omeprazole
CYP 2A6	Acetaminophen[a] (15) Halothane[a] (16) Nicotine	8-Methoxypsoralen	None known
CYP 2B6	Bupropion Carbamazepine[a] (17)	None known	Rif, phen, carb, pheno, SJW
CYP 2C8	Paclitaxel Rosiglitazone	None known	Rif, phen, carb, pheno, SJW
CYP 2C9	Diclofenac[a] (18) Warfarin Tienilic acid[a] (19) Phenytoin	Fluvoxamine	Rif, phen, carb, pheno, SJW
CYP 2C19	Omeprazole Mephenytoin Diazepam Phenytoin[a] (20)	Sulfinpyrazone Ticlopidine Fluvoxamine	None identified
CYP 2D6	Debrisoquine Dextromethorphan	Fluoxetine and other selective	None identified

	Metoprolol and other β-blockers Perhexiline Amitriptyline and other neuroleptics Encainide Codeine	serotonin reuptake inhibitors Quinidine	
CYP 2E1	Acetaminophen[a] Ethanol Tolcapone[a] (13) Isoniazid[a] (21) Halothane (16)	Disulfiram Ethanol	Ethanol Isoniazid
CYP 3A4	Erythromycin Cyclosporin A Carbamazepine[a] (17) Midazolam/triazolam Lovastatin and other statins Saquinavir and other protease inhibitors Trazodone[a] (22) Nefazodone[a] (23) Troglitazone[a] (24)	Ketoconazole and other azoles Troleandomycin Ritonavir	Rif, phen, carb, pheno, SJW

[a]Drugs are metabolized to the reactive metabolites implicated in hepatotoxicity.
Rif, rifampin; phen, phenytoin, carb, carbamazepine; phenol, phenobarbital; SJW, Saint John's Wort.

A list of the major P-450s involved in human drug metabolism is shown in Table 34.1. In many instances, a single P-450 represents the major pathway of

metabolism of a drug. Many pharmaceutical companies now use high-throughput technology to identify the P-450s that metabolize compounds in development and use this information to select lead candidates for further development (25,26,27).

Phase 2

The best-studied Phase 2 enzymes involved in the elimination of nontoxic metabolites are uridine-5′-diphosphate (UDP) glucuronyltransferases and

sulfotransferases, which catalyze conjugation to glucuronic acid and sulfate, respectively. Conjugation generally results in enhanced water solubility and elimination in urine and stool. As with the P-450s, the UDP glucuronyltransferases (UGTs) and sulfotransferases arise from multigene families (28–30). The sulfotransferases are divided into five gene families, whereas the UGTs are divided into two gene families termed *UGT1* and *UGT2*. The UGT1 family contains eight enzymes (designated by Arabic numerals) and the UGT2 family contains seven enzymes. There appears to be considerable catalytic specificity of UGTs toward drugs, although such characterization is progressing relatively slowly. One problem has been that unlike P-450s, it has proved challenging to reconstitute the activity of UGTs in robust, in vitro systems.

Enzymes Involved in Generating Reactive Metabolites

It appears that the initiating step in drug-induced liver injury often involves creation of a reactive metabolite from the parent molecule in the liver (Fig. 34.1). Reactive metabolites are generally minor products of drug metabolism, and their reactivity can make them very short lived and difficult to detect in biologic systems. For this reason, identifying the precise structure of a reactive metabolite can be challenging.

P-450s are the major enzymes capable of generating reactive and potentially toxic metabolites. The identical enzymes involved in the safe metabolism of drugs are those that have been most implicated in the production of hepatotoxic metabolites (see Table 34.1 for examples). In general, P-450s are expressed in highest concentration in zone 3 hepatocytes, and this in part accounts for the predominance of pericentral (zone 3) necrosis in some forms of drug-induced liver injury (such as that due to acetaminophen) (31). Interspecies differences in P-450 catalytic activity and regulation probably contribute to the imperfect ability of preclinical animal studies to identify human hepatotoxins (32).

Several methods have been used to determine the P-450s responsible for the production of toxic metabolites. For example, if an antibody or chemical that specifically inhibits a certain P-450 causes significant reduction in the production of the reactive metabolite in liver extracts, it is assumed that this P-450 is involved (33). In some instances, it is possible to use selective P-450 inhibitors to identify the responsible P-450s in clinical studies. This strategy is suggested by the listing of specific inhibitors in Table 34.1. For example, acetaminophen is believed to cause toxicity in the liver because of the production of the metabolite *N*-acetyl-*p*-benzoquinone imine (NAPQI). The total production of NAPQI from an oral dose of acetaminophen can be estimated from the production of thiol metabolites, which are eliminated in urine. When healthy volunteers were given a dose of acetaminophen together with a CYP 2E1 selective inhibitor (disulfiram), the urinary production of NAPQI derivatives fell to an average of 69% (15), indicating a major role for CYP 2E1 in the production of this metabolite. In contrast, treatment with rifampin, which would induce multiple other P-450s (Table 34.1), did not increase urinary elimination of the thiol

metabolites (15).

Similar clinical research has been done with halothane. Severe halothane liver toxicity is thought to result from a trifluoroacetyl intermediate, which in turn leads to measurable levels of trifluoroacetyl acid (TFA) in plasma and urine (34). Plasma and urine levels of TFA fell 70% when patients receiving halothane anesthesia were pretreated with the CYP 2E1 inhibitor disulfiram (35). A small reduction in TFA production was also observed when these patients were pretreated with the CYP 2A6 inhibitor 8-methoxsalen, but no change was observed after treatment with triacetyloleandomycin (TAO), a potent inhibitor of CYP 3A4 (16). These studies indicate that the major enzyme involved in the production of the trifluoroacetyl intermediate from halothane in vivo is CYP 2E1, with a minor contribution from CYP 2A6 and no contribution from CYP 3A4.

Not all reactive metabolites are produced by P-450s. Some reactive metabolites, such as acylglucuronides (36), are products of Phase 2 metabolism. For example, glucuronide metabolites of diclofenac and valproic acid have been shown to covalently bind multiple proteins in the hepatocyte, and this covalent binding may contribute to the hepatoxicity rarely associated with these drugs (37,38).

Enzymes Involved in the Safe Elimination of Reactive Metabolites

Minor reactive metabolites are probably produced commonly during the metabolism of drugs. Fortunately, the liver generally has the ability to dispose of these

metabolites before they can cause injury. The major safe elimination pathway for reactive metabolites involves conjugation to glutathione (GSH). Although GSH is synthesized in every cell in the body, the liver is the major site of its synthesis. Under usual conditions, the hepatocyte cytosolic concentration of GSH is quite high (approximately 10 mM). GSH may conjugate to reactive metabolites spontaneously, but this reaction is usually catalyzed by the glutathione-*S*-transferases (GSTs) (39). The resultant conjugates are generally nonreactive and readily excreted into bile or urine. GSH conjugates are pumped from the liver cell into bile by transporters, particularly multidrug resistance protein-2 (MRP2) (Fig. 34.3).

There are three families of GSTs: Cytosolic, mitochondrial, and microsomal. The cytosolic GSTs are those most involved in drug metabolism and are divided into seven classes, designated α, μ, π, σ, θ, ω, and ζ (40). Each family has several members designated by Arabic numbers. For example, GSTM1 is the first of the five members of the μ gene family.

The important role of GSH conjugation has led some industry scientists to develop sophisticated methods to detect GSH conjugates in liver microsomes and whole animals (41) as an initial means of detecting reactive metabolites. However, GSH conjugates can enter bile and not be detected in whole animal studies. In addition, not all reactive metabolites depend on GSH for safe elimination. One important class of reactive

metabolites is epoxides, which can be safely eliminated through the action of microsomal epoxide hydrolase (42). There appears to be just one gene encoding this enzyme in humans.

How the Reactive Metabolites Cause Hepatotoxicity

There appear to be many potential ways by which toxic metabolites can injure the liver cells, but the most common mechanisms appear to involve covalent binding and oxidative stress. A critical target to reactive metabolites appears to be mitochondria.

Covalent Binding

A variety of experimental evidence supports the view that covalent binding of reactive metabolites to proteins can alter their function, contributing to, or causing, hepatotoxicity (5,43,44). For example, the location of covalently bound protein adducts within the acinus correlates well with the location of hepatocyte damage due to acetaminophen (45) and cocaine (46). In addition, experimental manipulations that increase or decrease the rate of covalent binding (e.g., treatment with inducers or inhibitors of specific P-450s) proportionately increase or decrease the sensitivity of the liver to toxicity (46,47,48). However, the simple magnitude of covalent binding produced by a drug does not accurately predict hepatotoxicity (37,44). For example, there exist structural analogs of acetaminophen that have relatively little hepatotoxic potential but nonetheless covalently bind to hepatic proteins at rates comparable to, or actually higher than, that observed with acetaminophen (49). In addition, under certain experimental conditions, hepatocyte injury produced by cocaine can be prevented without influencing the extent of covalent binding to hepatocyte proteins (50). It has, therefore, become clear that covalent binding to protein does not always result in toxicity. Indeed, covalent binding may in some instances represent an adaptive mechanism for the cell. For example, it has been speculated that certain cytosolic proteins identified as targets for acetaminophen covalent binding may function to protect the cell by inactivating reactive metabolites (51).

In view of the discrepancies between total covalent binding and toxicity, the idea that toxicity is caused by covalent binding to specific proteins critical to cell viability has emerged. During acetaminophen hepatotoxicity, multiple enzymes important to the hepatocyte undergo covalent modification that results in loss of catalytic activity (5). The identity of specific proteins targeted by a given metabolite probably reflects several factors. First, if the metabolite is extremely reactive, it is likely to be short lived; hence, binding can only occur to proteins that are located in close proximity to the enzyme that produced the metabolite. The closest protein to the metabolite when it is created is the enzyme that produced it; hence, when a specific P-450 is identified as the target for covalent binding, it is likely that this is the enzyme responsible for the generation of the reactive metabolite (52). If the implicated metabolite is less reactive and longer lived, it may diffuse from the site where it was formed to bind to more

distant proteins. Which specific proteins are affected also reflects the chemical nature of the metabolite and target protein. Acetaminophen and the structurally similar but not hepatotoxic compound *N*-acetyl-*m*-aminophenol (AMAP) produce comparable amounts of total covalent binding in the liver (49). However, covalent binding with acetaminophen occurs largely in mitochondria, whereas AMAP forms adducts predominantly in other cellular compartments (53). Specific binding to critical mitochondrial proteins may therefore account for the differences in hepatotoxic potential of acetaminophen and AMAP.

Oxidative Stress

The liver is the largest solid organ in the body, and its numerous metabolic functions require substantial

energy. Energy is largely provided by adenosine-5′-triphosphate (ATP), which is derived from the reduction of molecular oxygen to water. This process, termed *oxidative phosphorylation*, occurs in mitochondria. In the process of generating ATP and water, up to 5% of oxygen is converted to superoxide anion (O_2^-) and its metabolites, which are collectively termed *reactive oxygen species* (*ROS*). ROS can also be produced outside of the mitochondria as a by-product of oxidative metabolism by cytochromes P-450, particularly CYP 2E1 (54) and CYP 3A4 (55). ROS can be harmful to cells because they can react with proteins, deoxyribonucleic acid (DNA), or lipids, causing cell damage or death (56,57). For example, ROS can initiate lipid peroxidation. This is a self-propagating chain reaction in which unsaturated fatty acids of the membranes are broken down to volatile small molecules (e.g., F2-isoprostanes) that can be measured in the breath (58).

ROS usually do not accumulate in hepatocytes because there exist multiple mechanisms for their deactivation to less harmful species. Moreover, when ROS begin to accumulate, the cell mounts a coordinated "antioxidant response." This involves activation of NFR2 that mediates transcriptional activation of a cassette of genes that include those coding for glutathione synthesis and glutathione transferases, as well as certain UGTs. (59). The term *oxidative stress* has been used for the situation in which production of ROS exceeds the capabilities of antioxidant defenses, resulting in accumulation of ROS and oxidative damage to the cell (56). Oxidative stress can result in programmed cell death (apoptosis) in addition to necrosis (60).

The Role of Mitochondria as a Target for Reactive Metabolites

The mitochondria are the cell's major source of energy (ATP). With complete loss of functioning of mitochondria, the ATP-dependent Na^+/K^+ ion pumps at the plasma membrane cease to function, and the hepatocyte swells and ruptures in a process known as *necrosis*. Programmed cell death, or apoptosis, requires energy, and therefore, some mitochondrial function is required.

Loss of mitochondrial function could theoretically result from covalent binding of a reactive metabolite to key proteins involved in the maintenance of the mitochondria or from damage to mitochondrial DNA (61). Most mitochondrial proteins are encoded by genes present in the cell nucleus; however, some vital mitochondrial proteins involved in the oxidative phosphorylation are the products of mitochondrial genes. Mitochondria are relatively deficient in DNA repair enzymes, and hence DNA mutations caused by reactive metabolites (or resulting from oxidative stress) can have a greater effect on mitochondria than on other cellular organelles. For example, some antiviral drugs (e.g., fialuridine [FIAU] and azidothymidine [AZT]) are believed to have caused liver failure because of drug-induced mutations in mitochondrial genes (62,63).

Mitochondrial dysfunction can also occur as a consequence of depletion of mitochondrial GSH (64). Mitochondria are particularly susceptible to GSH depletion because they do not synthesize GSH and it must be imported from the cytosol. Mitochondria also lack catalase, and therefore rely more on glutathione peroxidase to handle ROS. The activity of glutathione peroxidase is critically dependent on the concentration of GSH within the mitochondria, with a rapid fall in activity as GSH concentrations (usually 10 to 15 mmol) fall below 2 to 3 mmol. More than 90% depletion of mitochondrial GSH therefore significantly impairs the mitochondria's ability to safely dispose of ROS. Because ROS are constantly produced in mitochondria, even in totally healthy hepatocytes, depletion of mitochondrial GSH by reactive metabolites may be sufficient to cause oxidative stress. Because the mitochondria are the preferred targets for NAPQI, which readily binds GSH, depletion of mitochondrial GSH is believed to be a mechanism for acetaminophen hepatotoxicity.

Mitochondria play a central role in apoptosis. This may reflect the notion that mitochondria evolved from a primitive bacterium that, when an oxygen atmosphere began to emerge, entered and became part of early eukaryotic cells (65). The bacterium's rudimentary machinery for oxidative phosphorylation provided the eukaryote with a means for survival in what would have otherwise been a toxic environment. The bacterium also probably benefited in most instances from the controlled environment afforded by the host cell. It has been theorized that the bacterium retained or developed the ability to kill the cell and thereby "go it alone" (66). According to this theory, as the bacteria evolved to become permanent residents in cells (i.e., mitochondria), the death mechanisms remained.

The mechanisms by which mitochondria initiate apoptosis have been largely clarified. The critical event appears to be depolarization of the inner membrane of the mitochondria, termed *mitochondrial permeability transition* (*MTP*), which results from opening of pores (67). MTP results in loss of the proton gradient required for generation of ATP. If all mitochondria are affected, necrosis will result. However, an immediate effect of MTP pore opening is the swelling of mitochondria and eventual rupture of the outer mitochondrial membrane. When mitochondria rupture, cytochrome *c* is released, and this causes activation of cytosolic caspases that initiate apoptosis. Evidence suggests that MTP may be a common

pathway for hepatocyte apoptosis resulting from diverse signals that may be involved in some forms of hepatotoxicity, including ligand binding to

plasma membrane death receptors (Fas and tumor necrosis factor receptor [TNFR]), release of calcium from the endoplasmic reticulum, and release of lysosomal enzymes (68). Apoptosis requires ATP; hence the energy status of the hepatotomy (i.e., how many mitochondria remain functional) appears to determine whether death will be by apoptosis or necrosis. Features of both necrosis and apoptosis can be present in a dying hepatocyte, termed *necrapoptosis* (69).

Progression versus Recovery

Once liver injury has begun, it can either progress to liver failure or can subside with recovery (Fig. 34.1). It was originally assumed that the critical variable here was how much damage was done by the reactive metabolite, such as the extent of critical covalent binding or extent of oxidative stress. Although this is an important variable, it has recently become clear that there are many factors that can influence the outcome that are "downstream" of the events discussed so far. These factors speed the death of injured or dying cells. Many of these factors are components of the "innate immune system" (70). The innate immune response, unlike the acquired immune response, is not antigen specific, has no memory, and can be immediately activated to attack pathogens. It is the coordinated and rapid release of certain cytokines and other biologic mediators that neutralize pathogens and, together with natural killer T cells and tissue macrophages, kill infected cells.

The innate immune response is beneficial if it limits the spread of infection. The drug-injured hepatocyte may appear as an infected cell to the innate immune system. In this case, however, the innate immune system may not be beneficial because hepatocytes that would otherwise recover are killed. This has been most clearly shown with acetaminophen in which elimination of various components of the innate immune system reduce susceptibility to acetaminophen hepatotoxicity in rodents (71). Examples of factors that increase susceptibility to acetaminophen hepatotoxicity include interferon-γ (72), macrophage inhibitory factor (MIF) (73), and TNF (74).

Factors that counteract the innate immune response are also prominent in the liver (71,75). This may reflect the fact that the liver's drug metabolizing machinery probably evolved to handle natural substances, such as natural insecticides made by edible plants or fungal products of food spoilage. Reactive metabolites are generated in the liver by many of these natural "xenobiotics," and this can result in liver injury. In this situation, as with drugs, it is probably not desirable to kill the otherwise viable hepatocytes. A reasonable hypothesis is that factors counteracting the innate immune response evolved in the liver to limit needless hepatocyte killing. Data suggest that Kupffer cells may be important in reducing response to liver toxicity (75). Cytokines that reduce susceptibility to acetaminophen hepatotoxicity include interleukin-10 (IL-10) (76) and IL-

6 (77).

Other issues that may determine whether liver injury progresses or regresses have been identified. Soluble factors released from dying hepatocytes (e.g., calpain) (78) may kill adjacent healthy hepatocytes. In addition, it has been shown that liver injury caused by one predictable toxin can be "amplified" by pretreatments that hinder the liver's ability to regenerate (79).

Although most studies of acetaminophen hepatotoxicity involve single toxic doses, recurrent dosing has been shown in rodents to greatly reduce susceptibility to subsequent otherwise toxic doses. In addition, mice treated with certain halogenated hydrocarbons develop hepatic necrosis after 1 week of treatment, but the liver injury largely resolves with continued exposure (80). This indicates that the liver can adapt in the face of true hepatotoxicity, with resolution of the injury despite continued exposure to the offending agent. This is reminiscent of transient elevations in the level of alanine aminotransferase (ALT) that reverse with continued exposure to drugs that can cause progressive liver injury (e.g., isoniazid) (1). In addition, this adaptation phenomenon may account for rare reports of narcotic/acetaminophen abusers consuming up to 65 g of acetaminophen daily without evidence of significant liver injury (81).

Adaptation to hepatotoxicity appears to involve altered regulation of the genes involved in determining reactive metabolite accumulation. For example, there is downregulation of the P-450s involved in producing NAPQI and increase in the hepatocyte content of GSH when rodents are exposed to increasing doses of acetaminophen (81). In addition, it has been shown that during the recovery phase of the acute exposure to acetaminophen or carbon tetrachloride, there is downregulation of certain basolateral uptake transporters (sodium taurocholate cotransporting polypeptide [NTCP] and several organic anion transporting polypeptides [OATPs]) and upregulation of basolateral and canalicular efflux transporters (including MRP3, MRP4, and MRP2) (82,83,84). This appears to protect the cell by preventing uptake and accelerating removal of xenobiotics and potentially toxic bile acids. These effects could result from a combination of the antioxidant response and the acute phase reaction chiefly mediated by Nrf-2 activation and IL-6, respectively (85,86). In addition, regenerating hepatocytes have reduced P-450 activity and increased GSH levels (87). A human study suggested upregulation of the several transporters, including multidrug resistance-1

(MDR1), in hepatocytes remaining after subfulminant liver injury (88).

Variation in Susceptibility to Drug-Induced Liver Injury

Increased susceptibility to hepatotoxicity could occur from any of the conditions outlined in Table 34.2. To date, most studies of susceptibility to predictable toxins have focused on the drug metabolizing enzymes and transporters implicated in the accumulation of the reactive metabolite

(89,90). For example, patients who are genetically deficient in the activities of both GSTM1 and GSTT1 appear to have increased incidence of liver injury from tacrine and valproic acid (91,92). However, significant correlation between toxicity and genetic variation, when found, appears to account for only a small fraction of susceptibility. This undoubtedly reflects the fact that accumulation of the reactive metabolite is only the initial step in the cascade of events culminating in liver injury, and each of these steps is loci for variation (Table 34.2).

Another reason for the relative lack of success in linking genetic polymorphisms to susceptibility is the prominent role played by nongenetic factors. For example, some drugs or other xenobiotics either inhibit or increase (induce) the activity of certain drug metabolizing enzymes (Table 34.1) and transporters. If safe pathways are induced or bioactivation pathways are inhibited, there should be less toxicity at a given dose of predictable toxin. Alternatively, if safe pathways are inhibited and bioactivation pathways are induced, susceptibility to toxicity should increase. This could account for the enhanced hepatoxicity of certain drug combinations, such as rifampin and pyrazinamide (93). However, because induction of metabolic pathways usually involves activation of transcription factors that result in the transcription of multiple genes (94), the effects of inducers of bioactivation pathways may be offset by simultaneous induction of safe elimination pathways (32).

An example where variation in susceptibility to toxicity can result from nongenetic factors is the enhanced susceptibility to acetaminophen toxicity observed in alcoholics. As previously discussed, the reactive metabolite mediating liver toxicity is NAPQI, which is produced predominantly by CYP 2E1 and is normally safely eliminated through conjugation with GSH.

Ethanol and Acetaminophen

Chronic consumption of ethanol appears to increase susceptibility to acetaminophen hepatotoxicity (95). Chronic ethanol consumption can increase CYP 2E1 activity (Table 34.1), and this provides an attractive explanation for incremental risks in ethanol consumers. However, early animal (96,97) and human (98) studies did not show increases in NAPQI formation when acetaminophen was given during or immediately after ingestion of ethanol. Indeed, these studies suggested that ethanol consumption actually reduces the rate of production of NAPQI, protecting the liver from toxicity. This is explained by the observation that induction of CYP 2E1 largely involves stabilization of

the enzyme (reduced degradation) and that this occurs when ethanol is bound to the enzyme as a substrate (99,100). Prolonged intoxication, therefore, results in an accumulation of CYP 2E1, but the enzyme activity is reduced because the induced CYP 2E1 is inhibited by ethanol (Fig. 34.4). When ingestion is stopped and ethanol is cleared from the liver, the accumulated CYP 2E1 is no longer inhibited and the aggregate CYP 2E1 activity is increased above baseline levels (100). However, the stabilization against degradation is also reversed, resulting in a relatively rapid fall in

enzyme activity to the preethanol exposure level. This results in a narrow window of susceptibility that probably last less than 24 hours (100). This effect of inhibition followed by transient induction is also mimicked by some other substrates of CYP 2E1, including isoniazid (101). This may account for reports of enhanced susceptibility to acetaminophen toxicity in patients treated with isoniazid (102,103).

Table 34.2. Some Potential Reasons for Increased Susceptibility to Predictable Hepatotoxicity

1. Decreased activity of safe elimination pathways
   Genetic—polymorphisms in Phase 1 and 2 enzymes, transporters
   Nongenetic—drug interactions involving enzyme/transporter inhibition, nutrition, inflammation
2. Increased activity of enzymes producing the reactive metabolite
   Genetic—gene duplication (CYP 2D6)
   Nongenetic—induction of P-450s
3. Reduced elimination of the reactive metabolite
   Genetic—polymorphisms in elimination enzymes (e.g., GSTs, EH) or transporters (e.g., MRP2)
   Nongenetic—drug interactions involving enzyme/transporter inhibition, nutrition, inflammation, cofactor depletion (GSH)
4. Variation in proteins and pathways targeted by reactive pathways
   Genetic—polymorphisms in the proteins involved in target pathways (e.g., inherited defects in oxidative phosphorylation proteins)
   Nongenetic—drug effects (e.g., aspirin inhibition of oxidative phosphorylation), nutrition, concomitant disease
5. Variation in the innate immune response
   Genetic—polymorphisms in cytokines and proteins involved in Kupffer cell and lymphocyte function
   Nongenetic—inflammation, nutrition
6. Variation in the ability to regenerate hepatocytes
   Genetic—polymorphisms in genes that are important in regeneration
   Nongenetic—effects of other drugs/xenobiotics, age, nutrition, inflammation
7. Variation in the ability to adapt to toxicity
   Genetic—polymorphisms in enzymes, transporters, and proteins involved in their regulation
   Nongenetic—effects of other drugs/xenobiotics, age, nutrition, inflammation

GST, glutathione-*S*-transferase; EH, epoxide hydrolase; MRP, multidrug resistance protein; GSH, glutathione.

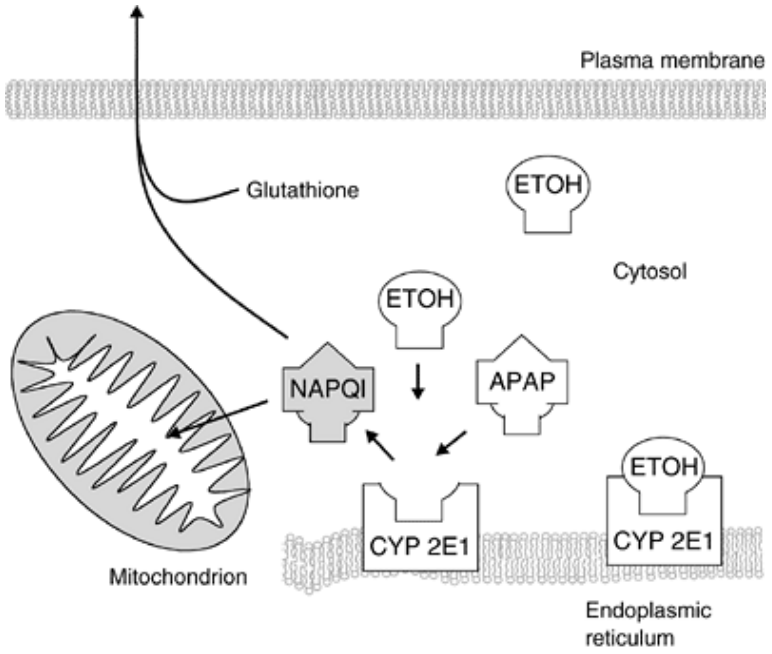
Chronic alcoholics are also likely to have reduced hepatocyte concentrations of GSH, particularly mitochondrial GSH (104), limiting the ability to safely eliminate the NAPQI once formed.

Another clinical situation that appears to increase susceptibility to acetaminophen toxicity is fasting (105). This should result in reduced GSH levels but should also cause depletion of the UGT cofactor glucuronic acid, reducing the ability to eliminate acetaminophen by nontoxic pathways. It has also been suggested that liver hypoxia due to cardiopulmonary insufficiency can increase susceptibility to acetaminophen toxicity because of reduced glucuronidation capacity (106).

Relevance of Predictable Toxicity to Idiosyncratic Toxicity

Understanding the processes involved in the production of liver toxicity from reactive metabolites has greatly improved the understanding of variation in susceptibility to predictable liver toxins, particularly acetaminophen. However, the toxicity observed still has the characteristics of a predictable toxin, such as early onset and dose dependence, within the individual. In addition, the injury to the liver remains pericentral (zone 3) necrosis, a characteristic of many direct hepatotoxins. In contrast, idiosyncratic toxicity generally begins after weeks or months of treatment and

typically involves a panacinar injury (1). These findings suggest fundamental differences between idiosyncratic and predictable hepatotoxicity. One fundamental difference may be the involvement of the acquired immune system.



▪ **Figure 34.4** Effect of ethanol on acetaminophen (APAP) toxicity. Acetaminophen is converted by CYP 2E1 to the reactive metabolite *N*-acetyl-*p*-benzoquinoneimine (NAPQI), which is then conjugated to glutathione and safely excreted. If production of NAPQI is rapid enough to deplete available cytosolic glutathione stores, NAPQI travels to mitochondria where it covalently binds to critical proteins and depletes mitochondrial glutathione, resulting in oxidative stress. Ethanol (ETOH) binds tightly to the substrate-binding site of CYP 2E1, preventing APAP from being metabolized to NAPQI. This accounts for the observation that acutely intoxicated rodents produce less NAPQI and are resistant to APAP toxicity. However, the intracellular half-life of CYP 2E1 is prolonged when bound to ETOH, so the enzyme accumulates in an inactive form during intoxication. When ETOH consumption is ceased and ETOH removed from the liver, the accumulated CYP 2E1 becomes fully active and the rate of NAPQI formation would be increased until the CYP 2E1 levels return to baseline (probably not more than 24 hours). This effect is modest in social drinkers but can become significant when very large amounts of ethanol are consumed for prolonged periods (100).

Immunologic Mechanisms of Hepatocyte Injury

It is generally accepted that immunological mechanisms underlie the liver injury produced by some drugs (107). For example, liver injury due to halothane, phenytoin, and sulfonamides characteristically present with fever, rash, and eosinophilia, the classic clinical hallmarks of hypersensitivity (108). This type of liver injury characteristically occurs within the first month of starting therapy with the drug, similar to the time

required to become fully immunized to a vaccine. Reexposure after an episode of toxicity generally results in more rapid onset of the toxicity and greater severity of the injury, as would be expected with a hypersensitivity reaction.

There is evidence that acquired immune mechanisms may be involved in idiosyncratic hepatotoxicity even in the absence of clinical signs of hypersensitivity. For example, methyldopa-induced liver injury is not usually associated with peripheral eosinophilia, fever, or rash but recurs promptly and may be more severe on rechallenge, consistent with an immune mechanism (109). Tacrine-induced liver disease (110) also recurs promptly on rechallenge, consistent with an immunologic mechanism. However, the injury observed on rechallenge is characteristically much less severe than the original insult. The idea that the acquired immune system is involved in many forms of hepatotoxicity is also supported by lymphocyte proliferation studies. These studies are performed by isolating peripheral blood lymphocytes of patients experiencing hepatotoxicity and determining whether a subpopulation of the cells proliferate on exposure to the implicated drugs. A proliferative response implies drug stimulation of cell-mediated immunity, although it is possible that this is a consequence rather than a cause of the injury. In one study (111), 56% of 95 patients with liver injury to diverse drugs demonstrated lymphocyte proliferation in response to exposure to the implicated drug. In contrast, proliferation was not observed in any of the 35 controls who had been exposed to the same drugs without evidence of liver toxicity. In 70% of the patients with a positive test result, there were no clinical signs suggestive of hypersensitivity.

Antigens stimulating the acquired immune system

Patients with liver injury associated with several drugs characteristically have circulating antibodies to liver and kidney endoplasmic reticulum, termed *anti–liver/kidney microsomal* (*LKM*) *antibodies* (112,113). It is assumed that an acquired immune response is to a new antigen created by covalent binding between the reactive metabolite and a hepatocyte protein. Anti-LKM antibodies frequently react with P-450s (114,115,116). The current concept is that if a P-450 produces a highly reactive metabolite, the metabolite can covalently bind to, or otherwise damage, the P-450. Antibodies are formed if this altered P-450 is antigenic and gets outside the hepatocyte, from where it can be picked up by antigen-presenting cells. However, cell lysis may not be necessary for antigen recognition because P-450s appear to be present in low abundance outside the liver plasma membrane (114). It should also be noted that most proteins destined for the plasma membrane are synthesized in the endoplasmic reticulum, where most reactive metabolites are produced. Covalent modification of proteins can occur in the endoplasmic reticulum before transport to the plasma membrane (117).

There remains controversy over whether anti–P-450 antibodies actually mediate an immune attack on the liver because no one has yet convincingly shown that these antibodies can cause liver injury in a living animal model.

It remains possible that the antibodies are an epiphenomenon, appearing only after the antigens are released into circulation as hepatocytes are lysed by other mechanisms. For example, it has been noted that anesthesiologists commonly have circulating antibodies to CYP 2E1 but have no evidence of liver injury (118). However, the immune system generally will not attack healthy cells just because they contain novel antigens on their surface; it has been postulated that a second "danger signal" is required (119). The nature of this signal is not known, but it is speculated that it is present in injured cells. This is consistent with the observation that vaccines only work when given with adjuvants that cause tissue injury at the site of injection. If this theory is correct, reactive metabolites may stimulate immune attack on the liver only if they cause hepatocyte injury in addition to creating neoantigens.

Regardless of whether they mediate drug-induced liver injury, anti–P-450 antibodies can be employed in immunochemical techniques to identify the specific human P-450s that are involved in generating the reactive metabolite, even if the structure of the reactive metabolite is unknown.

It should be noted that when the lymphocyte proliferation test result is positive, the proliferation is generally most pronounced in response to the parent drug and not to its metabolites (120). This has led to the pharmacological interaction (PI) hypothesis, which states that parent drugs can initiate an immunological reaction that leads to adverse drug reactions, including hepatotoxicity (121).

Hepatotoxicity Not Related to Reactive Metabolites

Although it is generally believed that reactive metabolites are the initiating events in most forms of drug-induced liver disease, this is not always the case. For example, drugs may directly interfere with crucial hepatocyte functions, resulting in toxicity. One example of this is the interference with the homeostasis of bile acids, which can be toxic to cells, particularly to mitochondria (122). The concentration of bile acids within the hepatocyte is governed by the rates of synthesis, uptake, and efflux of bile acid, which are usually tightly regulated. If a drug interferes with this homeostasis, toxicity could result. For example, it has been demonstrated that troglitazone and bosentan inhibit the bile salt excretory protein (BSEP) (Fig. 34.2) and this may contribute to the hepatoxicity observed with these drugs (123,124,125).

The Pharmaceutical Industry and Preclinical Drug Testing

Idiosyncratic hepatotoxicity is the major single reason for regulatory actions concerning drugs. Pharmaceutical companies are currently spending many millions of dollars to improve the ways by which drug candidates are screened for hepatotoxic potential. No consensus has yet been reached and practices vary.

One approach has been to try to "humanize" preclinical testing by using cultured human hepatocytes (126) or mice that express human genes relevant to toxicity (such as human P-450s) (127). The value to these approaches is questionable because many important genes stop being expressed in cultured hepatocytes (128), it is generally not possible to maintain hepatocytes in culture for the weeks or months it characteristically takes to develop idiosyncratic toxicity, and it is statistically unlikely that the hepatocytes would have been obtained from one of the rare people actually susceptible to the toxicity. A problem with humanized mice is that we do not yet know which are the relevant genes to target.

Another approach taken is to screen compounds for the ability to form reactive metabolites. The rationale is that if formation of reactive metabolites is an essential step in idiosyncratic hepatotoxicity (Fig. 34.1), understanding the many potential processes that culminate in liver injury are irrelevant if no reactive metabolite is produced (41,129,130). The simplest way to screen compounds for the potential to produce reactive metabolites is to look for a time-dependent fall in the activity of P-450s as they metabolize the drug in in vitro systems. Such a fall may indicate the formation of a reactive metabolite that is damaging the enzyme. Another more expensive approach is to use mass spectral techniques to detect GSH adducts in liver extract incubations. A more informative (but also the most expensive) method for detecting reactive metabolite formation is to radiolabel the drug and thereby track exactly what happens to it in liver extracts or whole rats (129). Covalent binding can be easily demonstrated, and identification of the reactive metabolite is also facilitated. Once identified, chemists can attempt to modify the molecule to preserve its therapeutic effect, while reducing the ability to form the reactive metabolites.

One problem with attempting to screen reactive metabolite formation is that most drugs generate them to some degree, and some drugs will be discarded unnecessarily. This is a problem because reactive metabolite screening generally occurs relatively late in compound selection when there are only a few molecules from which to choose a "lead compound." This is because methods to screen for reactive metabolites are not high throughput, although this may soon change (131). Furthermore, some mechanisms of toxicity, such as BSEP inhibition, would not be detected by this approach.

Finally, there has been the broad application of current genomic technology to traditional preclinical toxicity testing (132). This technology allows simultaneous quantitation of thousands of messenger ribonucleic acids (mRNAs) (the "transcriptome"), proteins (the "proteome"), and endogenous metabolites (the "metabolome"). At least some companies have treated rats with known hepatotoxic and nontoxic drugs and examined time-dependent changes in the liver transcriptome, liver and serum proteome, and liver, serum, and urine metabolome. The goal is to find specific patterns that predict hepatotoxicity potential. Proteome and metabolome analyses have yet to become a standard part of preclinical testing. However, at least

several companies have selected a set of mRNA transcripts that appear to correlate with certain forms of hepatotoxicity and are routinely measuring them, along with traditional serologic markers (like ALT) and pathological evaluation, in the lead candidate selection process. This technology is also being applied to cultured hepatocytes. In one study involving cultured human hepatocytes, trovafloxacin (a fluoroquinolone antibiotic whose use was restricted because of idiosyncratic hepatotoxicity) produced transcriptome changes that were distinct from those produced by other fluoroquinolones that rarely, if ever, produce hepatotoxicity (133).

It remains to be determined whether the application of genomics technology to animal models or to cultured human hepatocytes will reduce the risk of idiosyncratic hepatotoxicity for new drugs currently in the

development pipeline. However, these techniques may speed preclinical testing by providing earlier signals of toxicity and may lead to the discovery of the new biomarkers of liver injury that can be used in the clinic.

Summary and Future Directions

The understanding of mechanisms underlying predictable liver toxicity, particularly acetaminophen-induced liver injury, has improved substantially in recent years. There has been identification of many new proteins involved in determining the extent of initial liver injury and those involved in the balance between recovery and progression. It seems logical that variation in these proteins will in part underlie susceptibility to idiosyncratic hepatotoxicity. However, testing this hypothesis will probably require studying people who have actually experienced idiosyncratic hepatotoxicity. The Drug-Induced Liver Injury Network (134) has been recently established to create a registry of such individuals and to collect serum and genomic DNA. Some susceptibility factors are likely to be highly drug specific, and meaningful study may therefore require collection of many patients with liver injury due to the same drug. However, it also seems likely that key components of susceptibility lie in the "downstream" events that may not be molecule specific and can therefore be identified by pooling subjects with toxicity to different drugs. Time will tell.

Chapter 35
Wilson Disease

Michael L. Schilsky
Anthony S. Tavill

Key Concepts

- Wilson disease is a genetic disorder in which copper accumulates in the liver and brain in excess of normal metabolic needs. The accumulation is based on an inherited defect in the hepatic biliary excretion of copper.
- The inheritance pattern is autosomal recessive. Homozygotes for this disorder, numbering about 1 in 30,000 of the population, inherit disease-specific mutations of both alleles of the gene for Wilson disease, *ATP7B*, on chromosome 13. The disease does not develop in heterozygotes with a mutation of a single *ATP7B* allele, and they do not require treatment.
- The diagnosis of Wilson disease is established by a combination of clinical and biochemical findings, most notably a decrease in levels of circulating ceruloplasmin, the presence of corneal Kayser-Fleischer (K-F) rings, and a hepatic copper concentration above 250 mg/g dry weight of liver.
- Molecular genetic studies demonstrating two disease-specific mutations of *ATP7B* may be used to establish a diagnosis of Wilson disease, but clinical and biochemical evaluation are needed to demonstrate phenotypic expression and to stage the disease.
- In most symptomatic patients, treatment with metal chelating agents is effective in stabilizing or reversing the disease. Asymptomatic patients may be treated with metal chelating agents or zinc salts. In all circumstances, lifelong pharmacologic treatment is required and results in excellent patient survival.
- Fulminant hepatic failure in Wilson disease or hepatic insufficiency unresponsive to medical therapy is best treated with orthotopic liver transplantation (OLT), which, by providing the liver with a normal physiologic capacity for copper excretion, is curative.

History

In 1912, while serving as a senior resident at the National Hospital for Nervous Diseases in London, Kinnier Wilson published his work *Progressive Lenticular Degeneration: a Familial Nervous Disease Associated with Cirrhosis of the Liver* as part of his dissertation for the MD degree (1). Correctly, he speculated that the brain disease, characterized by extrapyramidal features, was caused by the liver disease. However, his concept of a “morbid toxin” produced by the cirrhotic

liver, although strictly correct, could not have anticipated the much later insights into the role of the liver in copper metabolism and the vulnerability of certain areas of the brain to the toxic effects of excessive copper deposition. It was not until 33 years later that Glazebrook (2) detected a marked excess of copper in the basal ganglia of a patient dying of Wilson disease and surmised from the recognized accumulation of copper in the liver that

the inability of the liver to excrete copper was the dysfunction responsible for the lenticular degeneration, a pathogenetic association later confirmed by other workers (3,4).

In 1902 and 1903 the first descriptions of corneal pigmented rings, now recognized eponymously as Kayser-Fleischer (K-F) rings, were based on observations in patients with neurologic disease (5,6). Fleischer (7) was the first to associate three seminal features of Wilson disease—namely, corneal pigmentation, neuropsychiatric disease, and hepatic cirrhosis—and another 10 years passed before the first hypothesis that the corneal pigmentation is caused by the pathologic deposition of copper was proposed (8,9). Recognition of the value of a low serum ceruloplasmin concentration in the diagnosis of Wilson disease came from the observations of Scheinberg and Gitlin (10), who first reported this phenomenon in 96% of Wilson disease homozygotes. However, Sternlieb and Scheinberg (11) subsequently recognized that up to 20% of heterozygotes also have low ceruloplasmin concentrations without any other clinical manifestations of Wilson disease. This observation and the presence of a normal ceruloplasmin in a small minority of Wilson disease homozygotes argued against a direct pathogenetic role for ceruloplasmin in the accumulation of copper in tissues in case of Wilson disease.

With the understanding that the clinical features of Wilson disease are the result of copper toxicity in the various affected tissues of the body, the rationale for chelation therapy became apparent. The first chelation agent used for the treatment of Wilson disease, in 1951, was British anti-Lewisite (BAL), or dimercaptopropanol (12,13). This drug, which is lipophilic and therefore administered intramuscularly, enhances cupriuresis and provided the first effective therapy for a previously untreatable disorder. John Walshe of Cambridge University, while working at the Boston City Hospital, introduced the first effective oral chelation therapy in the form of penicillamine and demonstrated its cupriuretic action and role in the symptomatic improvement of patients with life-threatening features of Wilson disease (14). Sternlieb and Scheinberg (11) subsequently expanded the use of this drug to include the treatment of asymptomatic (or presymptomatic) patients with Wilson disease by showing its effectiveness in preventing disease progression. Walshe (15) proceeded to develop another, safer chelating agent, triethylene tetramine (trientine), which proved a valuable alternative agent in the treatment of those patients intolerant of the toxic effects of penicillamine. Walshe (16) was also instrumental in the initial human use of tetrathiomolybdate, currently an investigational drug in the United States.

ATPase, adenosine triphosphatase.

The possibility of preventing the toxic accumulation of copper in Wilson disease by blocking the absorption of copper with oral zinc therapy was first considered by Schouwink (17). Although oral zinc therapy would not be regarded as appropriate for the management of newly diagnosed, symptomatic Wilson disease, subsequent studies have shown it to be an effective alternative to chelation agents for long-term maintenance therapy (18,19).

A development that revolutionized the treatment of a subset of patients with Wilson disease presenting with acute liver failure was orthotopic liver transplantation (OLT), which effectively cures the disease (20). The phenotypic reversion from a diseased to a normal state in transplant recipients demonstrates the central role of the liver in Wilson disease and copper metabolism.

The recognition of Wilson disease as an inherited disorder, defined by a complex of signs and symptoms, has evolved in less than a century to the point at which we are now able to define the molecular basis for the pathophysiology of this disorder. Milestones in this process, which culminated in the identification of the gene for Wilson disease, designated *ATP7B*, and the recognition of disease-specific mutations, are reviewed in subsequent text and outlined in Table 35.1.

Genetics

Although Wilson correctly recorded the familial nature of the disease, it was Hall (21) in 1920 who demonstrated its inheritance, later shown to be autosomal recessive (22). Subsequently, the linkage of Wilson disease to the locus of the red cell *esterase-D* gene

placed the gene for Wilson disease on the long arm of chromosome 13 (23), and additional studies further delineated its chromosomal localization (24,25).

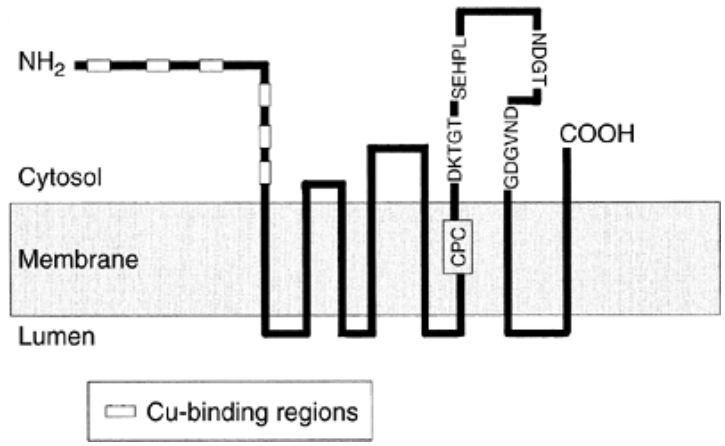
A breakthrough in the understanding of the molecular basis of the defect of copper metabolism in Wilson disease was the discovery of the gene for Menkes disease, another rare inherited disease of copper metabolism, and the identification of its gene product, ATP7A, a cation-transporting P-type adenosine triphosphatase (ATPase) involved in copper transport in many tissues (26,27,28). The extrapolation of the copper-transporting P-type ATPase to the Wilson disease model led to the hypothesis that a mutation in the gene for a liver-specific copper transporter might be responsible for the association between the defective incorporation of copper into ceruloplasmin, failure of biliary secretion of copper, and accumulation of copper in the liver.

The isolation and identification of the gene for Wilson disease, designated *ATP7B*, followed closely the discovery of the gene for Menkes disease. The identification of the specific gene was accomplished almost simultaneously by three independent laboratories (29,30,31,32). The detection of specific mutations unique to individuals with clinical and biochemically proven disease confirmed the identity of the responsible gene (29,30).

The *ATP7B* gene is contained within an approximately 80-kb region of DNA containing 22 exons (exon 22 being contained in a rare transcript); these encode an approximately 7.8-kb messenger ribonucleic acid that is highly expressed in the liver (33). Analysis of the gene sequence indicates that *ATP7B* belongs to a family of ATP-dependent metal transporters that are highly conserved through evolution (34). A schema of the *ATP7B* gene showing specific regions of known homology to ATPases and metal transporters is shown in Figure 35.1.

Screening for mutations of *ATP7B* has led to the identification of a large number (>200) of disease-specific mutations and polymorphisms of the gene (30,31,34,35,36). Most of the mutations thus far identified are point mutations that result in amino acid substitutions. However, deletions, insertions, missense, and splice site mutations have also been reported. A summary of the mutations and polymorphisms of the gene can be found in the following Web site: http://www.medicalgenetics.med.ualberta.ca/wilson/index.php. However, when particular mutations are found frequently among members of a specific population or ethnic group, direct mutational analysis is particularly useful. Haplotype analysis (polymorphism analysis of the region surrounding *ATP7B*) has proved useful for genetic screening of siblings of probands (see subsequent text). The most frequently observed point mutation, which results in a change from histidine to glutamine (H1069Q), is present in nearly 30% of patients of European descent (30,36). In only a single population in Austria has the frequency of this mutation been reported to be higher (up to 65%) (37). Most mutations are clustered about several transmembrane regions of the protein and in another region predicted to be involved in ATP binding. Some evidence indicates that mutations that result in loss of the expression of the ATP7B protein may cause more severe phenotypic expression; however, not all studies support

this conclusion. Another study suggests that expression of another gene, *APOE*, may modify the phenotype of Wilson disease. Polymorphisms in other genes involved in copper metabolism may also modify the disease phenotype, as suggested by studies of *MURR1* (38), the gene responsible for copper toxicosis in Bedlington terriers but whose function is not yet certain. Further investigations are ongoing that aim to correlate specific phenotypic presentations or manifestations of Wilson disease with *ATP7B* genotype and the expression of other potential modifying genes.

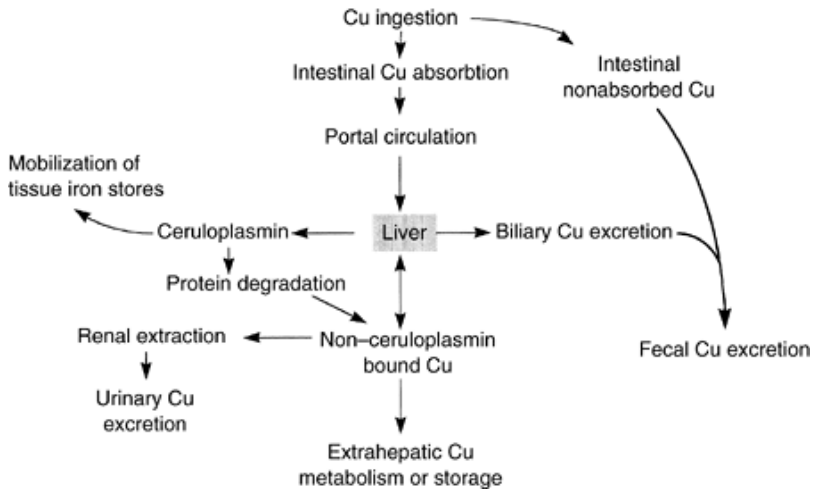


▪ **Figure 35.1** Predicted major structural features of the Wilson disease gene product (ATP7B). ATP7B, as a member of a class of heavy metal–transporting adenosine triphosphatases (ATPases), is predicted to contain the following structural features: Cysteine-rich metal-binding regions near the amino terminus, a transduction and phosphatase domain, multiple transmembrane regions with one containing the amino acids cysteine-proline-cysteine (CPC), a phosphorylation domain (DKTGT), an ATP-binding region (NDGT), a hinge region (GDGVND), and a conserved domain for metal-transforming ATPase, critical for copper transfer (SEHPL). (Adapted from Petrukhin K, Fischer SG, Pirastu M, et al. Mapping, cloning and genetic characterization of the region containing the Wilson disease gene. *Nat Genet* 1993;5:338–343, and Cox DW. Molecular advances in Wilson disease. In: Boyer JL, Ockner RK, eds. *Progress in liver disease*. Philadelphia, PA: WB Saunders, 1996:245–264, with permission.)

Pathophysiology

Copper is an essential cofactor for many enzymes and proteins and is important for the mobilization of tissue iron stores. The normal pathways for copper metabolism are outlined in Figure 35.2. Ingested copper

is extracted from the portal circulation by hepatocytes, possibly by the newly discovered cell surface human copper transporter (hCTR1) (39). Intracellular copper then interacts with low-molecular-weight ligands such as glutathione (40), metallothionein (41), and HAH1 (42), which serve as transfer or storage agents, and is subsequently used for cellular metabolic needs, incorporated into the secretory glycoprotein ceruloplasmin, or excreted into bile.



▪ **Figure 35.2** Copper metabolism and pathophysiology of Wilson disease. Dietary copper is absorbed in the proximal small intestine, whereas nonabsorbed copper or copper bound within shed enterocytes passes into the feces. Absorbed copper is bound mainly to albumin in the portal circulation, from which it is avidly extracted by hepatocytes. Hepatocellular copper is bound to ligands and used for metabolic needs, transferred to endogenous chelators, incorporated into ceruloplasmin, or excreted into bile. Biliary copper does not undergo enterohepatic recycling and is therefore excreted in the feces. In Wilson disease, biliary copper excretion is reduced, and copper accumulates within hepatocytes. The incorporation of copper into ceruloplasmin is also impaired in Wilson disease; as a result, circulating levels of this protein are decreased in most patients. When cellular stores are overloaded or after a hepatocellular injury, the amount of copper released into the circulation is increased. Extraction of the excess of non–ceruloplasmin-bound copper by the kidneys leads to an increase in urinary copper excretion and extrahepatic deposition of this metal. The dietary intake of copper is approximately 2 mg/24 hours, with intestinal absorption varying between 25% and 60% of intake. Fecal excretion is between 1 and 2 mg/24 hours, and urinary copper excretion and renal excretion do not usually exceed 50 mg/24 hours. In Wilson disease, non–ceruloplasmin-bound copper is the precursor of the excessive copper deposited in the tissues.

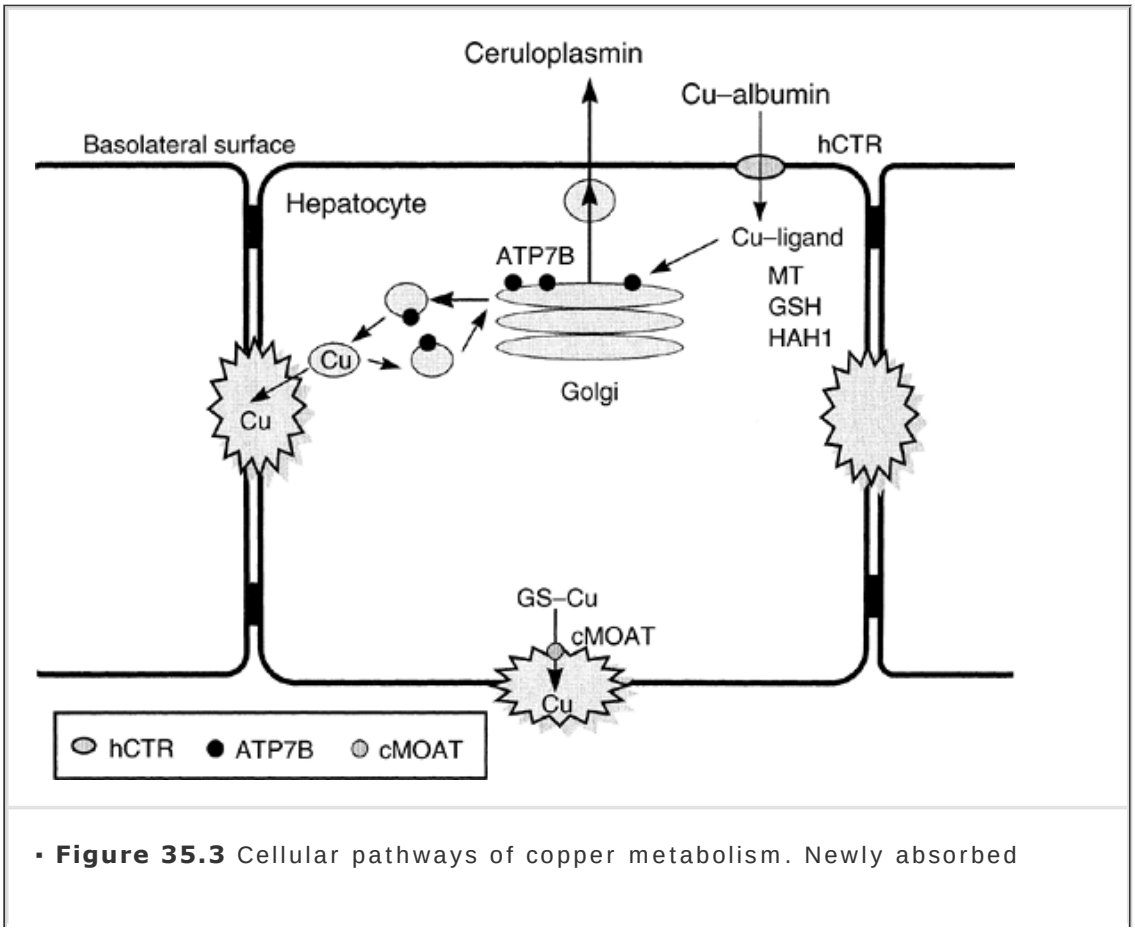
The passage of copper from hepatocytes to bile is critical for homeostasis of this metal because copper excreted into bile undergoes minimal enterohepatic recirculation (43). The transport of hepatocellular copper to bile is thought to involve a vesicular pathway that is dependent on the function of ATP7B. This protein appears to be present mainly in the *trans*-Golgi network of liver cells under basal conditions (44) (Fig. 35.3). Interestingly, in recent studies of the homologous Menkes disease protein, ATP7A, this protein was observed to alter its intracellular localization in response to increases in the level of copper (45). Although studies of ATP7B protein suggest that it also redistributes to a vesicular compartment in response to copper loading (44), how the redistribution affects the function of the protein remains to be determined. It is presumed that the vesicular pathway is critical for biliary copper excretion. However, other investigators suggest that ATP7B protein resides in a pericanalicular region and

relocates directly to the canalicular membrane in response to increased cellular copper (46). If the ATP7B protein is present at this site, it would be involved in the direct transfer of copper to bile. Whether the ATP7B protein resides in the canalicular membrane or whether copper is delivered through this site by vesicular transport, the absence or diminished function of ATP7B results in a decrease in biliary copper excretion, which is responsible for the hepatic accumulation of this metal in Wilson disease (4,47,48,49).

Ceruloplasmin is a serum glycoprotein that contains six copper atoms per molecule. It is synthesized predominantly in the liver. Copper is thought to be incorporated into apoprotein ceruloplasmin in the Golgi apparatus (50) and the copper-containing holoprotein secreted from the hepatocyte. Newly transported copper, which is used for ceruloplasmin biosynthesis, must also cross organelle membranes to enter into the protein biosynthetic pathway, a process that is dependent on ATP7B and is absent or diminished in most patients with Wilson disease. A reduction of the incorporation of copper into ceruloplasmin is believed to lead to a reduced circulating level of this protein in most patients with Wilson disease because the non–copper-containing apoprotein is less stable.

When copper accumulates beyond the cellular capacity for its safe storage, hepatocellular injury may result. Toxic effects of excess copper include the

generation of free radicals, lipid peroxidation of membranes and DNA, inhibition of protein synthesis, and alterations in the levels of cellular antioxidants (51). Recent data suggest that both hepatocellular necrosis and apoptosis may be triggered by copper-induced cell damage (52,53). When copper-induced injury occurs, the functional status of the liver is determined by the delicate balance between injury, cell death, and the regenerative capacity of liver cells.



▪ **Figure 35.3** Cellular pathways of copper metabolism. Newly absorbed

copper, loosely bound to albumin, is transported across the plasma membrane of the hepatocyte, where it is transported by a variety of ligands to the Golgi apparatus. There, the ATP7B protein serves to transport it across the Golgi into ceruloplasmin for secretion into the circulation. Excretion into bile may occur by vesicular secretion, by transcanalicular association with glutathione (GSH) through the canalicular organic anion transporter (cMOAT), or by copper-transporting adenosine triphosphatase in the canalicular membrane. hCTR, human copper transporter; MT, metallothionein;

When the capacity of the liver to store copper is exceeded, or when hepatocellular damage results in the release of cellular copper into the circulation, levels of non–ceruloplasmin-bound copper in the circulation become elevated. It is from this pool that the extrahepatic deposition of copper is thought to occur. The brain is the most critical extrahepatic site of copper accumulation, and copper-induced neuronal injury is responsible for the neurologic and psychiatric manifestations of Wilson disease and the characteristic changes on radiologic imaging studies of the brain.

Pathology

The evolution of pathologic changes in the tissues of patients with Wilson disease (see ref. 51 for review) follows the relative rates of accumulation of copper in the various body organs. Because the primary genetic defect resides in the liver and because the liver is the predominant storage organ for copper, it is not surprising that the earliest pathologic manifestations are hepatic in nature. As copper "spills" over to other organs from the liver, pathologic manifestations become evident in the brain, kidneys, eyes, and joints.

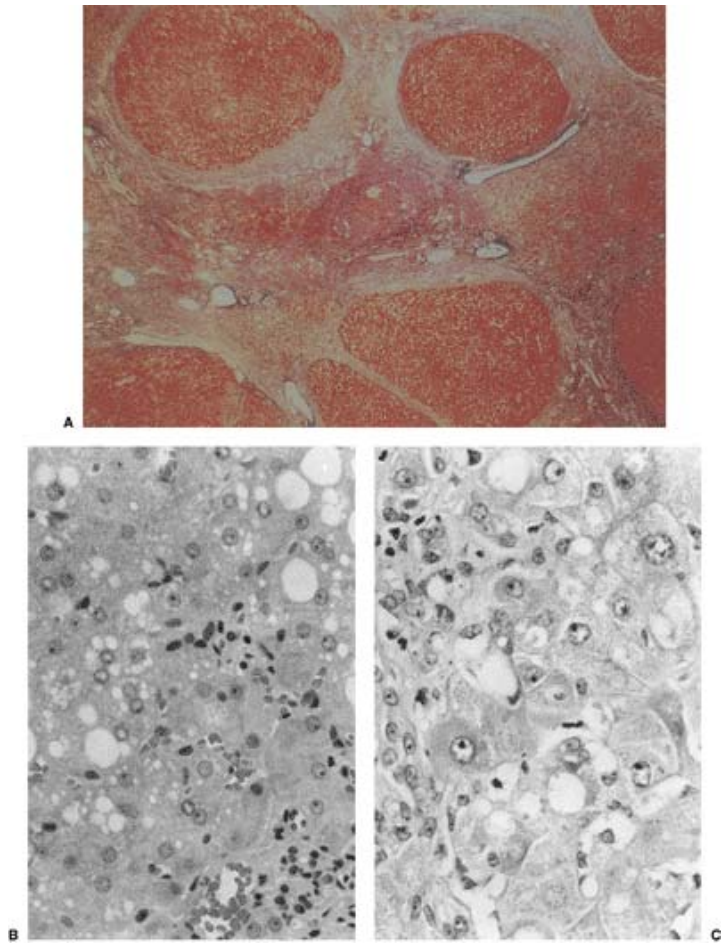
Hepatic Pathology

Macroscopically, the liver may be only mildly enlarged in the early stages of life. Later, without treatment, the liver pathology progresses in most patients to fibrosis and cirrhosis. The nodular transformation of cirrhosis is a mixed macronodular–micronodular pattern, in which the nodules may vary in color depending on the degree of copper accumulation (Fig. 35.4A). The rate of pathologic change varies greatly between patients, and in some cases steatosis and fibrosis without cirrhosis may persist for decades (54).

At a microscopic level, the evidence of copper accumulation in early infancy may be subtle and nonspecific. Diffuse cytoplasmic copper accumulation may not be visible by immunohistochemical methods for detecting copper (e.g., rhodanine, rubeanic acid). This early stage of copper accumulation is associated with macrosteatosis, microsteatosis, and glycogenated nuclei, features that may be seen in a variety of other conditions (55) (Fig. 35.4B). Sternlieb (56) emphasized the almost ubiquitous presence of distinctive mitochondrial changes at this early stage of the disease. The

ultrastructural abnormalities range from enlargement and separation of the inner and outer membranes, with widening of the intercristal spaces, to increases in the density and granularity of the matrix or replacement by large vacuoles.

Pleomorphic changes may also be seen in distorted peroxisomes and endoplasmic reticulum, with nuclei showing glycogen inclusions. With progression of the disease, copper–protein is sequestered in lysosomes, appearing as electron-dense pericanalicular structures visible on light microscopy as granules detectable by copper immunohistochemistry (Fig. 35.5).



▪ **Figure 35.4** Light microscopic findings in liver in Wilson disease. **A:** Masson trichrome stain of liver from a patient with established cirrhosis reveals broad bands of fibrosis intersecting variably sized nodules with varied staining characteristics (×80). **B:** Prominent microvesicular and macrovesicular steatosis and some inflammatory cells in a specimen from an asymptomatic patient with Wilson disease (×250). **C:** Hepatocellular ballooning and degeneration in a biopsy specimen from a patient with fulminant Wilsonian hepatitis (×250).

If the condition is untreated or unrecognized, the initial stages of Wilson disease progress to an intermediate hepatic stage; this is characterized by periportal inflammation with mononuclear cellular infiltrates, erosion of the limiting lobular plates, lobular necrosis, and bridging fibrosis, features indistinguishable from those of chronic active hepatitis of many other causes (55). Cirrhosis is virtually invariable at this stage of disease, with either a micronodular or a mixed macronodular-micronodular histologic pattern. Mallory bodies may be visible in

up to 50% of biopsy specimens.

In patients presenting with fulminant hepatic failure, parenchymal necrosis with ballooning of hepatocytes, apoptotic bodies and cholestasis, and collapse may predominate (Fig. 35.4C). In some of these individuals with fulminant failure, the liver has significant collapse and bridging fibrosis but cirrhosis may not be present (M. Schilsky, J. Lefkowitch, personal observations, 2005).

A histochemical confirmation of copper deposition may be helpful; however, a negative result does not exclude copper overload. Rhodanine and rubeanic acid may show dense granular lysosomal copper deposition in hepatocytes at the stage of cirrhotic nodular regeneration. Staining at this stage often shows marked variability from nodule to nodule (Fig. 35.6). Paradoxically, the results of immunohistochemical staining for copper are usually negative in the earlier stages of the disease, when the hepatocyte copper is diffusely distributed in the cytoplasm (57). A more sensitive stain, Timms sulfide, is more effective in detecting cytoplasmic copper-binding proteins; however, it is not routinely utilized.

Neuropathology

Macroscopically, most of the overt neuropathologic changes in advanced Wilson disease are concentrated in the lenticular nuclei. These show atrophy and discoloration, with cystic degeneration, pitting, and fissuring of the cut surfaces. Similar changes have been described in the thalamus, subthalamic region, and even the cerebral white matter (58).

Microscopically, the major pathologic changes occur in those parts of the central nervous system with the highest copper levels. Scheinberg and Sternlieb (58) calculated that the concentrations are highest in the thalamus, followed by the putamen and cerebral cortex. Neuroglial changes are the most distinctive in Wilson disease, with an increase in the number of astrocytes in the gray matter of the lenticular nuclei. Swollen glia may undergo cavitation and liquefaction, which create small cavities with an overall appearance of spongiform degeneration. Neuronal loss is accompanied by gliosis and astrocytosis and the production of glial fibrillary protein. The characteristic astrocytes seen within areas of lenticular degeneration are Alzheimer type I and II cells and, distinctively for Wilson disease, Opalski cells (59), which are large cells, up to 35 µm in diameter, with fine granular cytoplasm and slightly eccentric nuclei (single or multiple) that Scheinberg and Sternlieb (58) suggested originate from degenerating astrocytes. It is unclear at the present time whether the glial changes are secondary to the stimulation of metallothionein protein synthesis by copper in selective areas of the brain populated by protoplasmic astrocytes or whether the selective targeting of glial cells is related to other, as yet unidentified, factors.

Miscellaneous Pathologic Changes

Functional changes in the kidneys are often disproportionate to any observable changes on light microscopy. Proximal or distal tubular dysfunction leading to tubular proteinuria, bicarbonate loss, aminoaciduria, glycosuria, hyperphosphaturia, uricosuria, and hypercalciuria is common. Glomerular abnormalities, in the form of hypercellularity, basement membrane thickening, hyalinization, and fibrosis, have been described (58). Penicillamine-induced immune complex nephropathy has been described. Bone pathology and

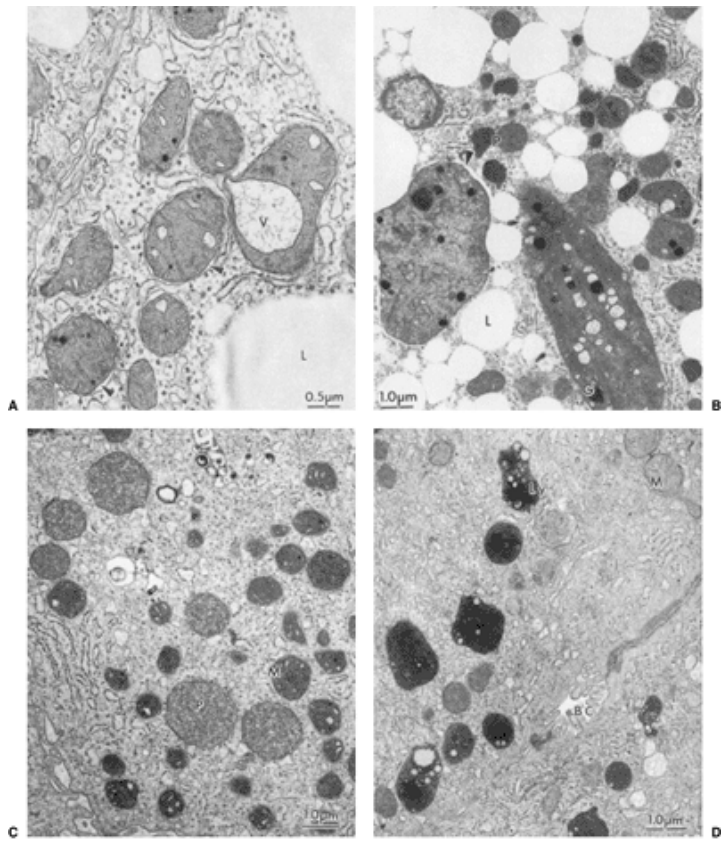
periarticular abnormalities have been observed, accounting for osteoporosis, osteomalacia, spontaneous fractures, adult rickets, osteoarthritis, osteochondritis dissecans, chondrocalcinosis, and subchondral cyst formation (58). Involvement of the spine and knee joints is the most common distribution of skeletal and articular abnormalities.

Ophthalmologic findings include K-F rings and sunflower cataracts. The K-F rings, most marked at the upper and lower poles of the cornea, are caused by the granular deposition of elemental copper on the inner surface of the cornea in the Descemet membrane (Fig. 35.7). The rings have a golden brown or green appearance on slit-lamp examination. The sunflower cataracts, with radiating centrifugal extensions, are associated with the granular deposition of copper in the anterior and posterior lens capsule. Both the K-F rings and sunflower cataracts are reversible with effective

P.1030

P.1031

therapy for Wilson disease. Classic K-F rings are caused exclusively by the presence of excess copper in the Descemet membrane; however, rings indistinguishable from K-F rings have been seen in other forms of chronic liver disease, particularly those characterized by prolonged cholestasis (60). On slit-lamp examination, they resemble K-F rings, but chemical analysis has not confirmed that they are caused by copper deposition, although it has been hypothesized that such patients may show excessive copper retention.



▪ **Figure 35.5** Electron micrographs of fine sections of liver biopsy specimens obtained from untreated patients with Wilson disease, showing portions of hepatocytes. **A:** Ten-year-old asymptomatic girl with normal

physical findings: Aspartate aminotransferase, 76 IU/L; alanine aminotransferase, 55 IU/L; serum ceruloplasmin, 21.4 mg/dL; hepatic copper, 1,258 mg/g of dry tissue. Some of the mitochondria display vacuoles (*V*) with granular material. Note separation of inner from outer membrane (*arrowheads*), with creation of an enlarged intermembranous space. *L*, lipid droplet. **B:** Nineteen-year-old woman with a history of progressive fatigue, found to have Kayser-Fleischer rings 2 months after an episode of hemolytic anemia with jaundice: Serum ceruloplasmin, 12.7 mg/dL; hepatic copper, 591 mg/g of dry tissue. The mitochondria are markedly pleomorphic, some displaying multiple, pathognomonic abnormalities: Gigantism, increased matrical density, separation of inner from outer membrane (*arrowhead*), vacuoles, dilated cristae, crystals, and enlarged dense granules (*G*). *P*, peroxisomes. **C:** Ten-year-old asymptomatic girl with serum ceruloplasmin level below 1 mg/dL and a hepatic copper concentration of 1,029 mg/g of dry tissue. Mitochondria (*M*) display dilated cristae; the markedly enlarged peroxisomes (*P*) with grainy matrices are strikingly abnormal. **D:** In a 20-year-old woman with severe neurologic Wilson disease, the hepatocellular cytoplasm appears virtually normal except for the abundance of electron-dense, peribiliary, lysosomal granules (*Ly*). *BC*, bile canaliculus; *M*, mitochondria.

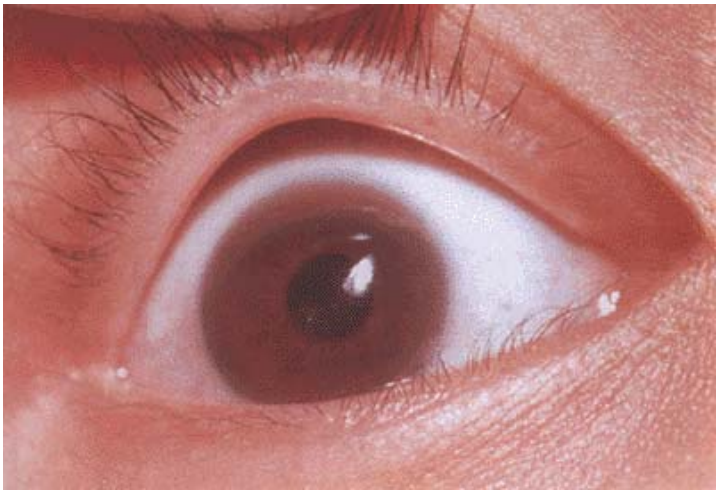
Diagnosis

The diagnosis of Wilson disease should be considered in any person aged between 3 and 40 years with unexplained hepatic, neurologic, or psychiatric disease, although rare cases have been diagnosed in persons in the sixth, seventh, and even eighth decades of life (54). In particular, this diagnosis must be excluded unequivocally in children or young adults who present with unusual extrapyramidal or cerebellar motor disorders, atypical psychiatric disease,

unexplained hemolysis, or elevated liver enzyme levels or other manifestations of liver disease, with or without a family history of liver or neurologic disease. The failure to do so will lead to unnecessary and preventable demise. In most cases, the diagnosis can be made by a combination of clinical and biochemical testing. In practice, three levels of tests may be undertaken to confirm the diagnosis of Wilson disease (Table 35.2). The presence of K-F rings and a reduced serum concentration of ceruloplasmin are sufficient to establish the diagnosis. However, in the absence of K-F rings, it is necessary to proceed to a liver biopsy for a quantitative copper determination to confirm the diagnosis.



▪ **Figure 35.7** Kayser-Fleischer ring in a 17-year-old patient with neurologic symptoms of Wilson disease.

Molecular testing is currently available for Wilson disease. There are two types of testing that may be employed. Haplotype analysis that looks for familial inheritance of polymorphisms around the *ATP7B* gene should be considered for use in screening the siblings of affected persons. Direct mutational analysis is now available for de novo diagnosis of Wilson disease. Newer methodology has made the molecular screening of the entire coding region of *ATP7B* less cumbersome and time consuming, although some targeting of specific exons with higher frequencies of mutations may make sense while testing in individual populations in which specific mutations are present at higher frequency. There is a need to identify disease-specific mutations of the gene to firmly establish the diagnosis without biochemical testing. Although molecular studies may detect the disease, it may still be useful to fully characterize patients with the disorder who are detected by standard testing to better understand the degree of disease involvement, as well as to provide confirmation of the diagnosis. Given the current relative high cost and complexity of this testing, molecular testing will not readily be used as a screening test for Wilson disease. However, for patients in whom there is

difficulty in determining the diagnosis by clinical and biochemical testing, molecular testing should prove extremely useful.

Table 35.2. Diagnostic Tests in Wilson Disease

Level 1	Level 2	Level 3
Low serum ceruloplasmin (a)	Liver copper concentration (c)	Incorporation of radiocopper into ceruloplasmin
Slit-lamp examination for K-F rings	—	Ultrastructural studies of hepatocytes
Raised serum-free copper level (b)	24-h urine copper (d)	Molecular genetic studies for Wilson disease

Normal values: (a) 20–50 mg/dL; (b) <10 mg/dL; (c) <250 mg/dL; (d) <50 µg/24 hours.
Wilson disease: (a) <20 mg/dL; (b) >25 mg/dL; (c) >250 µg/g dry weight; (d) >100 µg/24 hours.
K-F, Kayser-Fleischer.

Concentration of Ceruloplasmin

A test to determine the serum concentration of ceruloplasmin is routinely available in all clinical laboratories. It is most useful, when measured by means of enzymatic methods, to determine oxidase activity because this best reflects the copper content of the protein, although immunologic assays are frequently utilized. The normal range is 20 to 50 mg/dL. About 95% of homozygotes with Wilson disease have values of less than 20 mg/dL. Up to 5% of all homozygotes and up to 15% to 50% of persons with liver disease may have normal levels, which is defined as concentrations above 20 mg/dL (58,61). In some cases, normal levels are present in patients with active liver disease, presumptively as a consequence of acute-phase responses in the liver or estrogen supplementation. Homozygotes rarely have serum concentrations exceeding 30 mg/dL. Low serum concentrations of ceruloplasmin may also be observed in hypoproteinemic states, such as protein-calorie malnutrition, nephrotic syndrome, protein-losing enteropathy, and other forms of severe decompensated liver disease, and in up to 20% of asymptomatic heterozygous carriers of the gene for Wilson disease. Rarer causes of serum ceruloplasmin deficiency include hereditary aceruloplasminemia and Menkes disease.

Concentration of Circulating Copper not Bound to Ceruloplasmin

The total concentration of copper in plasma or serum represents ceruloplasmin-bound copper plus non–ceruloplasmin-bound (“free”) copper, which is bound mainly to albumin, peptides, or amino acids. Because the former is reduced in proportion to the degree of hypoceruloplasminemia, the total copper may be low in the face of a typically raised free copper concentration. To calculate the latter, the ceruloplasmin copper content (approximately the ceruloplasmin level in

milligrams per deciliter multiplied by 3) is subtracted from the total copper content (in micrograms per deciliter). The value for total plasma copper ranges from 80 to 120 mg/dL and the value for non–ceruloplasmin-bound copper is usually 10% of the total value (8 to 12 mg/dL). In Wilson disease, levels of non–ceruloplasmin-bound copper are typically above 25 mg/dL in symptomatic patients before treatment.

Slit-Lamp Detection of Kayser-Fleischer Rings

It is essential that all patients in whom Wilson disease is suspected undergo a slit-lamp examination, performed by an experienced ophthalmologist, for the detection of K-F rings. These rings are present in patients with neurologic disease, with only rare exceptions, but they may be absent particularly in younger patients with only hepatic manifestations (Fig. 35.7). Another finding that may suggest Wilson disease is the presence of sunflower cataracts, also best observed by slit-lamp examination.

Concentration of Copper in the Liver

Normal concentrations of copper in the liver rarely exceed 50 µg/g dry weight of liver. Most patients homozygous for Wilson disease have levels above 250 µg/g, whereas the concentration of copper in the liver of heterozygotes, although commonly elevated above normal, typically does not exceed 250 µg/g (58). The hepatic copper concentrations may also be elevated in other liver diseases, particularly chronic cholestatic diseases such as primary biliary cirrhosis and primary sclerosing cholangitis. However, these disorders are usually readily distinguishable from Wilson disease on the basis of serologic and histologic criteria.

A recent study by Ferenci et al. (62) suggested that in some individuals confirmed to have Wilson disease by molecular studies, hepatic copper content does not reach 250 µg/g dry weight liver. On the basis of these results, these investigators proposed a lower threshold for considering Wilson disease—70 µg copper/g dry weight liver. However, no data are presented in this study on heterozygotes in whom hepatic copper may easily exceed this threshold. Therefore, the previous cutoff of 250 µg copper/g dry weight liver may better

differentiate heterozygotes and homozygotes with Wilson disease, but this must not be the sole criterion for excluding the diagnosis if there is appropriate histology or clinical signs of disease. In patients for whom the diagnosis remains uncertain despite extensive clinical and biochemical evaluation, molecular studies will help in confirming or refuting the diagnosis of Wilson disease.

Biopsy specimens for a quantitative copper determination should be obtained with a (Tru-Cut or Jamshidi) needle and placed dry in a copper-free vessel. About 1 cm of a 1.6-mm-diameter core of liver should be dried overnight at 56°C in a vacuum oven or, alternatively, frozen immediately before being shipped to a laboratory specializing in microchemical analysis for copper. The remainder of the specimen can be fixed in the usual manner for histopathologic examination, with the option to perform immunohistochemical staining for copper. In asymptomatic patients, the hepatic copper level is higher than that in patients with established cirrhosis. Specimens with extensive fibrosis and fewer parenchymal cells may yield copper concentrations that are nondiagnostic, and therefore the result of hepatic copper quantification should be correlated with the histologic, clinical,

and biochemical data.

Urinary Excretion of Copper

The copper excreted in urine is derived from the free copper circulating in plasma, which represents filterable, non–ceruloplasmin-bound copper. The rate of excretion may exceed 100 µg/24 hours in symptomatic patients. In patients presenting with chronic liver disease, the urinary copper level is elevated above normal levels but may not reach diagnostic levels of more than 100 µg/24 hours. False-positive increases in urinary copper level may be seen in the face of significant proteinuria and urinary loss of ceruloplasmin, and rarely in other liver diseases in which copper storage is increased or in fulminant liver failure. A provocative test for urinary copper excretion with the use of the chelating agent penicillamine has been studied in children but has not been standardized in adults (63). When urinary excretion of copper is tested, it is crucial that a metal-free container be used and that the adequacy of the collection be monitored by correlation with creatinine excretion.

Incorporation of Radioactive Copper into Ceruloplasmin

In patients with Wilson disease and a normal serum level of ceruloplasmin, the incorporation of radioactive copper into ceruloplasmin is significantly reduced in comparison with that in healthy persons or heterozygotes. The failure to incorporate copper into ceruloplasmin within the hepatocyte is seen in all homozygotes with the disease (64). This test has been used to validate the diagnosis of Wilson disease in patients with normal levels of ceruloplasmin. When the test is performed in persons with abnormal levels of ceruloplasmin, as may occur, for example, in generalized hypoproteinemia, the results should be interpreted with caution. This test is now rarely performed because the development of the transjugular liver biopsy technique, as well as the advent of de novo molecular screening, has made it possible to obtain specimens from patients in whom liver biopsy was previously contraindicated. An experimental alternative to radioactive copper is a nonradioactive isotope of copper, ^{65}Cu, which can be detected by mass spectrometric methods (65); however, the utility of this test to distinguish between patients and heterozygous carriers is uncertain.

Molecular Genetic Studies

The identification of the gene for Wilson disease has enabled the molecular genetic diagnosis of this disorder. There are now numerous disease-specific mutations of the gene described; however, the most common mutation is present in only 15% to 30% of most populations (36,37). This makes most patients compound heterozygotes, possessing different mutations on each allele of ATP7B. Direct de novo analysis for the presence of disease-specific mutations is now possible, given the advances in DNA sequencing and screening technology. The ability to establish the diagnosis by this methodology depends on distinguishing disease-specific mutations from polymorphisms of the gene and is further limited by the fact that some of the noncoding regions of the gene, which may also affect gene expression, are not analyzed. It is also possible to screen family members of an affected person by haplotype analysis. This process involves inspecting the patterns of polymorphisms of the DNA in the region surrounding the Wilson disease gene to determine whether mutant regions present in the affected person

have been inherited by family members (30). Future developments in DNA analysis should make it possible to screen for disease-specific mutations in a cost-effective manner, so that de novo population screening will one day prove practical. At present, genetic testing should be used for screening families and used in concert with standard clinical and biochemical testing.

Ultrastructural Studies

In cases in which indeterminate hepatic copper concentrations make it difficult to distinguish between heterozygotes and homozygotes, ultrastructural analysis

for the pathognomonic mitochondrial abnormalities described by Sternlieb (56) may be helpful. The performance of these studies requires proper specimen handling and the assistance of pathologists skilled in electron microscopy, obviously with forethought to process the specimen prospectively for such analysis.

Clinical Manifestations

Patients with symptomatic Wilson disease most frequently present with liver disease or neurologic/psychiatric symptoms. Affected persons detected by family screening are often asymptomatic (also termed *presymptomatic*). The failure to initiate specific treatment for Wilson disease or the disruption of ongoing treatment results in progression to hepatic insufficiency, neuropsychiatric disease, and ultimately hepatic failure and death.

The clinical spectrum of liver diseases associated with Wilson disease is broad (Table 35.3). Younger patients identified by family screening or serial evaluations of isolated biochemical abnormalities are most often asymptomatic. Some patients present with chronic liver disease indistinguishable from other forms of chronic active hepatitis, with or without specific symptoms. In patients with cirrhosis and hepatic insufficiency, ascites, edema, or other stigmata of chronic liver disease, including hepatic encephalopathy, may be observed. When untreated, the liver disease progresses to cirrhosis with hepatic insufficiency, liver failure, and death. Some patients, most often in their second decade of life, present with fulminant hepatitis and an associated nonimmunopathic hemolytic anemia, which without the life-saving intervention of OLT is frequently fatal (see subsequent text). Among patients presenting with Wilsonian fulminant hepatitis, the female-to-male ratio is almost 2:1 (66).

Table 35.3. Clinical Presentations of Wilson Disease

Asymptomatic (presymptomatic)
Hepatic disease
Asymptomatic with only biochemical abnormalities
Chronic active hepatitis
Cirrhosis with hepatic insufficiency and associated signs and symptoms
Fulminant hepatitis with or without hemolytic anemia
Neurologic signs and symptoms
Dystonia with rigidity and contractures
Tremors
Dysarthria and dysphonia

- Gait disturbance
- Choreiform movements

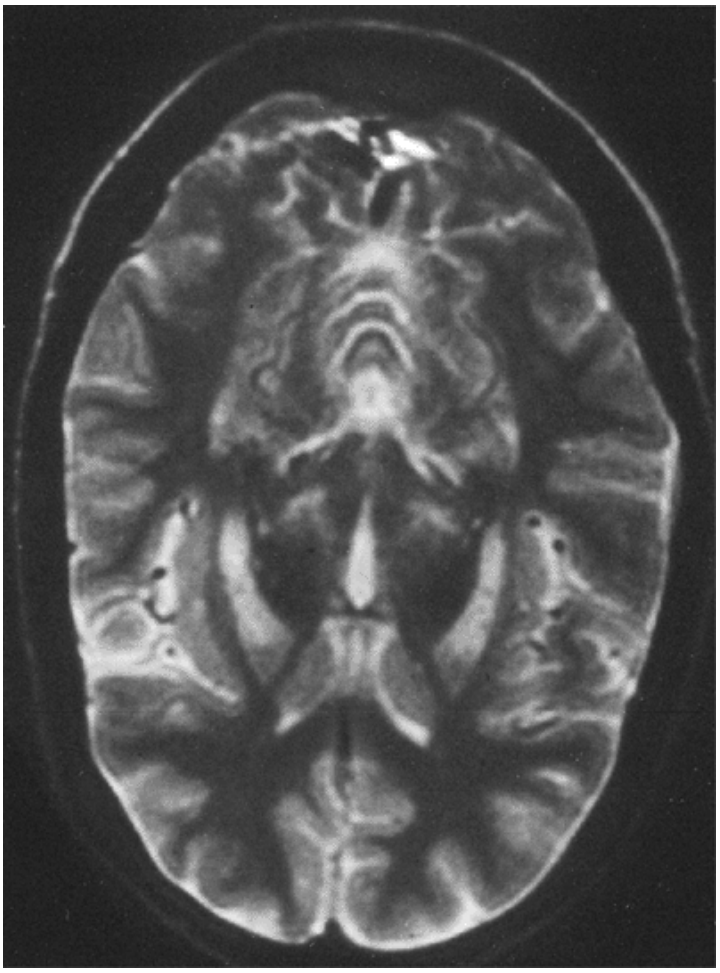
Psychiatric symptoms
- Range from neuroses to psychoses

Renal disease
- Aminoaciduria
- Nephrocalcinosis

The patients in whom the first presenting symptoms of Wilson disease are either neurologic or psychiatric are frequently older than those who present with hepatic symptoms. Most patients with central nervous system involvement are believed to have significant liver disease at the time of presentation; however, hepatic histology is not generally available for these patients because the diagnosis is often established on the basis of a decreased ceruloplasmin level and the presence of K-F rings. Neurologic disease may be manifested as motor abnormalities with parkinsonian characteristics of dystonia, hypertonia and rigidity, chorea or athetosis, tremors, and dysarthria (67). Disabling muscle spasms can lead to contractures, dysarthria and dysphonia, and dysphagia. At this stage of disease, magnetic resonance imaging or computed tomography of the brain may be useful in delineating changes in the basal ganglia (Fig. 35.8).

Wilson disease infrequently presents with abnormalities of other organ systems. Changes induced by copper toxicity in the kidneys include nephrocalcinosis,

hematuria, and aminoaciduria (58) and those in the skeletal system include arthritis, arthralgias, and premature osteoarthrosis (58). Myocardial copper accumulation can cause cardiomyopathy and arrhythmias (68,69), although these are rarely manifested clinically. A more indolent form of hemolytic anemia unassociated with fulminant hepatitis may occasionally be seen (70).



▪ **Figure 35.8** Magnetic resonance image of the brain of a 21-year-old woman with dysarthria, dysphagia, slurred speech, and tremors caused by Wilson disease. Note hyperintensity in the region of the basal ganglia.

Table 35.4. Treatment and Follow-Up Management

Medical therapy for Wilson disease Treatment	Chemical form	Route of administration
British anti-Lewisite	Dimercaptopropanol	Intramuscular
Penicillamine	Dimethylcysteine	Oral
Trientine	Trientine dihydrochloride	Oral

Zinc salts	Zinc sulfate, zinc gluconate, zinc acetate	Oral
Tetrathiomolybdate (experimental)	—	Oral

Maintenance therapy for Wilson disease

Agent	Oral maintenance dose (adult)	Comments	Monitoring of efficacy and compliance
Penicillamine	750–1,000 mg in three to four divided doses	Monitor for lupus-like reactions, marrow suppression; requires supplemental pyridoxine, dose reduction for surgery and pregnancy	Nonceruloplasmin Cu <10 µg/dL Urine Cu >250 µg/24 h
Trientine	750–1,000 mg in three to four divided doses	Monitor for sideroblastic anemia, dose reduction for surgery and pregnancy	Nonceruloplasmin Cu <10 µg/dL Urine Cu >250 µg/24 h
Zinc salts	150 mg in three divided doses	Occasional gastric intolerance	Nonceruloplasmin Cu <10 µg/dL Urine zinc >1,000 µg/24 h Urine Cu <150 µg/24 h

The diagnosis of Wilson disease in the setting of acute fulminant hepatitis deserves special mention because of several unique features. In this setting, fulminant hepatitis is associated with a nonimmunopathic hemolytic anemia and markedly elevated serum and urinary levels of copper. Most of these patients are in the second decade of life, and K-F rings may not yet be apparent. Paradoxically, levels of serum alkaline phosphatase are frequently depressed

(71,72,73), and this feature led to the observation that a ratio of alkaline phosphatase to bilirubin of less than 2 might be diagnostic of Wilsonian fulminant hepatitis (73,74). We and others have observed some patients with Wilsonian fulminant hepatitis in whom this ratio was above 2 (66).

Treatment

The therapeutic options in Wilson disease include pharmacologic treatment and OLT. The aim of medical therapy is to abolish symptoms, if present, and prevent the worsening or progression of disease. Successful therapy may be gauged by clinical improvement or stabilization and by the normalization of biochemical parameters of liver function and copper metabolism. Serial liver biopsies have no role in the management of Wilson disease. Repeated liver biopsies should be performed only to exclude concurrent illness or as part of an experimental treatment protocol. Liver transplantation should be reserved for patients with severe hepatic insufficiency or liver failure occurring in the context of fulminant hepatitis or end-stage liver disease. Transplant recipients subsequently have a normal donor phenotype with respect to copper metabolism, and with rare exception, they do not require further therapy specific to Wilson disease.

Pharmacologic treatments for Wilson disease include chelating agents and zinc salts (Table 35.4). Chelating agents (e.g., penicillamine, trientine, BAL, and tetrathiomolybdate) remove copper from potentially toxic sites within cells and detoxify the remaining copper. Zinc salts act mainly by blocking the intestinal absorption of dietary copper but also stimulate the biosynthesis of endogenous chelators in the liver, such as metallothioneins, that help detoxify the remaining metal (41).

The treatment of asymptomatic patients and maintenance therapy for previously symptomatic patients are identical (Table 35.4). Patients with hepatic insufficiency or chronic active hepatitis evident only on biochemical testing or histologic examination of the liver should be considered symptomatic and treated with chelation therapy before their medications are changed or the doses reduced for maintenance therapy (see subsequent text). The largest experience for long-term treatment is still with penicillamine, whereas trientine and zinc salts are alternative agents with fewer potential

side effects. Both these alternative agents, previously used only for penicillamine-intolerant patients, should now be considered for the initial therapy of asymptomatic patients and for long-term use as maintenance therapy. Regardless of the specific agent chosen, monitoring for efficacy and patient compliance is crucial.

Chelation therapy is indicated as the primary therapy for symptomatic patients with hepatic or neurologic/psychiatric disease. As mentioned in the preceding text, the greatest experience thus far is with penicillamine. The reported incidence of penicillamine-induced side effects varies greatly (58,75), although worsening of neurologic symptoms has been observed in about 10% of symptomatic patients during the early phase of penicillamine therapy. Whether this worsening would have occurred with the use of alternative agents is uncertain and awaits the systematic evaluation of alternative agents as the primary treatment for neurologically affected patients. Late, dermatologic effects of penicillamine include progeric changes in the skin, often visible around the neck (Fig. 35.9), and the cheloid-like lesions of elastosis perforans serpiginosa, which may appear anywhere on the body (Fig. 35.10). Trientine has proved to be

an effective treatment for penicillamine-intolerant patients (76), and experience is growing in the utilization of this agent as a first-line therapy for hepatic and neurologic disease (76,77,78,79). Zinc salts may be used as an alternative initial therapy for patients who cannot tolerate penicillamine or trientine. Although it has been reported that zinc is an effective treatment for symptomatic patients, it may be delayed in its effective onset of action and therefore chelation agents are preferable in this setting. Once clinical and biochemical stabilization has been achieved, typically within 2 to 6 months of the initiation of treatment for most patients but somewhat longer for more severely affected persons, maintenance therapy should be considered. Tetrathiomolybdate, first used to treat animals with copper toxicosis, is currently an experimental agent undergoing evaluation as an initial treatment for patients with neurologic symptoms. Initial reports on the use of tetrathiomolybdate in this setting suggest no worsening of neurologic symptoms and a rapid reduction in circulating non–ceruloplasmin-bound copper during the first 8 weeks of therapy (80). Studies directly comparing the efficacy of this agent with either penicillamine or trientine will help determine its role in the treatment of Wilson disease.

▪ **Figure 35.9** Progeric change (appearance of premature aging) in the skin of the neck, characteristic of patients on long-term penicillamine treatment.

▪ **Figure 35.10** The cheloid-like lesions of elastosis perforans serpiginosa on the elbow of this penicillamine-treated patient may appear on different areas of the body.

BAL, the first available treatment for Wilson disease, is now rarely used, and only as adjunctive therapy for patients with neurologic/psychiatric symptoms refractory to chelation therapy with penicillamine or trientine alone (81). This drug, used in conjunction with oral therapy with penicillamine or trientine, is administered intramuscularly in an oil base. As a lipophilic compound, BAL has the theoretic advantage of possibly crossing the blood–brain barrier more easily. The main drawback of BAL therapy is the difficulty and discomfort involved in administering it and the lack of objective parameters outside clinical evaluation to determine its efficacy.

The dietary consumption of foods with a high copper content should be avoided during the initial phases of treatment. These include organ meats such as liver, in addition to nuts, shellfish, and chocolate. During the maintenance phase of therapy, liberalization of the diet is permitted.

OLT should be considered for patients with Wilsonian fulminant hepatic failure and for those with severe hepatic insufficiency unresponsive to medical therapy (66).

Two different series that retrospectively reviewed the data on OLT for patients with Wilson disease found 1-year survival rates after transplantation to be about 80% (66,82), and more recently, 1-year patient survival was found to be about 87% (83). In this last report, acute renal insufficiency was observed more often in patients who underwent transplantation for fulminant hepatic failure secondary to Wilson disease than in those who underwent transplantation for fulminant hepatic failure of other causes. The acute renal insufficiency resolved without long-term renal damage. During the acute phase of fulminant failure, when toxic copper complexes are being released into the circulation, plasmapheresis, exchange transfusion, and albumin dialysis have been utilized in an effort to further reduce copper-induced toxicity. These interventions may be helpful in

reducing comorbidity and stabilizing the patient, but they have not precluded the need for OLT. Neurologic symptoms may improve after transplantation (66,84). However, it is our opinion that medical therapy should be used for patients with neurologic symptoms in the absence of hepatic failure, especially given the current shortage of donor organs. After OLT in the perioperative period, with rare exceptions, no further specific therapy for Wilson disease is necessary.

Living donor transplantation has been performed for fulminant liver failure secondary to Wilson disease in a few children. Partial grafts from heterozygous parents have been successful, with good organ function in both donor and recipient (85). Currently, living donor transplantation remains limited mostly to children with fulminant hepatic failure, and further study is needed before this procedure can be utilized in adults, for whom a larger portion of the donor liver is required.

The treatment of pregnant women with Wilson disease and persons with Wilson disease who must undergo surgical interventions deserves special mention. The goal of treatment in pregnant patients is to maintain adequate disease control in the mother, reduce her risk for bleeding, and prevent interference with wound healing and the possibility of teratogenicity. Pregnancies have been successful in patients taking penicillamine, trientine, or zinc (86,87,88,89,90). For patients being maintained on chelation therapy, the dosage of penicillamine or trientine should be lowered whenever possible early in the course of the pregnancy. The suggested dosage is 500 mg/day. During the last trimester, the dosage can even be lowered further to 250 mg/day for the 6 weeks through delivery and during wound healing if cesarean section is performed. Zinc therapy can be maintained uninterrupted during pregnancy and postpartum (89).

When patients with Wilson disease maintained on chelating agents must undergo surgery, the dose of their medication should be reduced preoperatively and perioperatively to avoid interference with wound healing. The dosage of penicillamine or trientine can be reduced to 250 to 500 mg daily during this time and rapidly advanced to a maintenance dosage once wound healing has taken place. No adjustment of the dosage is required for patients on zinc therapy, either perioperatively or postoperatively.

We cannot overemphasize that the key to the long-term success of pharmacotherapy for Wilson disease is patient adherence to the use of medications. This can be monitored by history and clinical examinations to detect any changes in the symptoms or signs of liver or neurologic disease, pill counts, screening for biochemical evidence of hepatic dysfunction, measurement of urinary copper or zinc excretion, periodic slit-lamp examinations, and, importantly, biochemical testing for non–ceruloplasmin-bound copper. This last test is the standard by which pharmacotherapeutic doses should be determined and is the single best parameter for gauging the adequacy of treatment. Non–ceruloplasmin-bound copper is a derived number, estimated from the difference between the total serum copper content and the copper content of ceruloplasmin, determined by its oxidase activity (approximately three times the value for ceruloplasmin in milligrams per deciliter). In healthy persons and appropriately treated patients, the value for non–ceruloplasmin-bound copper should be 8 to 12 mg/dL or less. In untreated, inadequately treated, and noncompliant patients, this value is frequently elevated above 25 mg/dL.

The interpretation of the results of urinary copper excretion must take into account the mode of treatment, ability to collect a complete sample, avoidance of

contamination, and appropriate analysis of copper content. During the early phase of treatment with chelating agents, values for urinary copper excretion are frequently greater than 1,000 µg/24 hours. These decline to about 250 to 500 µg/24 hours over time, and despite the continuous use of chelation agents, the values for urinary copper excretion tend to remain at about this level. Values below 250 µg/24 hours suggest noncompliance with therapy, overtreatment, or an incorrect diagnosis from the outset.

The values for 24-hour urinary copper excretion in patients on zinc therapy are not significantly elevated because zinc acts to prevent copper absorption (91). However, a rise in urinary copper excretion to above 150 to 250 µg/24 hours may indicate noncompliance or inadequate therapy, and, if so, they are likely to be accompanied by an increase in non–ceruloplasmin-bound copper level. Urinary and plasma levels of zinc may also be used to monitor compliance with zinc therapy.

The prognosis for patients who comply with pharmacotherapy for Wilson disease is excellent, even if cirrhosis or chronic hepatitis is present at the time of diagnosis (92). Patients with neurologic or psychiatric

symptoms of Wilson disease may continue to recover for months to years after the initiation of treatment. In some patients with neurologic disease or hepatic insufficiency, symptoms or biochemical abnormalities persist but stabilize with treatment. At present, the best way to determine whether and to what extent a patient's disease is reversible is to await a response to treatment.

*This article and accompanying editorial highlight the dilemmas encountered in the management of female patients with Wilson disease during pregnancy. Brewer et al. who favor zinc as an alternative to chelating agents for primary and maintenance therapy, reported 26 pregnancies in 19 patients that were successful for both mother and fetus, except for two developmental defects (one major) in a fetus. Sternlieb in his accompanying editorial offers combined data from three groups representing major international referral centers that attest to the safety and efficacy of penicillamine and trientine when the dose is appropriately adjusted. In the light of this information, we see no reason to change a woman's treatment, except for dose adjustments, if the treatment of choice before pregnancy is achieving the desired objectives (see text) (*90,91*).*

Chapter 36

Hemochromatosis and Iron Storage Disorders

Bruce R. Bacon

Robert S. Britton

Key Concepts

- An increase in systemic iron levels is the consequence of (a) inherited excessive intestinal absorption of dietary iron (hereditary hemochromatosis), (b) ineffective erythropoiesis or chronic liver disease, or (c) parenteral iron administration. Excessive intracellular deposition of iron ultimately results in tissue and organ damage.
- Hereditary hemochromatosis (HH) constitutes several inherited disorders characterized by an increased intestinal absorption of iron with its subsequent accumulation in tissues. Most (approximately 90%) patients with HH have mutations in *HFE*, and *HFE*-related HH is one of the most common inherited disorders among whites, with a frequency of about 1 in 250.
- Two independent mutations of the *HFE* gene are principally responsible for *HFE*-related HH. These mutations result in a change of cysteine to tyrosine at amino acid 282 (C282Y) and of histidine to aspartic acid at amino acid 63 (H63D) of the HFE protein. Approximately 95% of persons with *HFE*-related HH are homozygous for the C282Y mutation. Population studies indicate that the penetrance of the C282Y mutation is incomplete, and genetic modifiers may be involved. Some compound heterozygotes with copies of both the C282Y and H63D mutations have a clinically significant degree of iron overload.
- Mutations in the iron-related genes encoding for hemojuvelin, hepcidin, ferroportin, transferrin receptor 2 (TFR2), divalent metal transporter 1 (DMT1), and ferritin result in non–*HFE*-related HH.
- The pathogenesis of nearly all forms of HH involves inappropriately low expression of the iron-regulatory hormone hepcidin, which acts to decrease the export of iron from absorptive enterocytes and reticuloendothelial (RE) cells. Hepcidin is highly expressed in hepatocytes, and it is proposed that HFE protein, TFR2, and hemojuvelin all play a role in the hepatic iron-sensing pathway that regulates hepcidin expression. The C282Y mutation causes functional inactivation of the HFE protein, leading to low hepcidin expression with a resultant increase in duodenal iron absorption.
- In *HFE*-related HH, the excess iron is preferentially deposited in the cytoplasm of parenchymal cells of various organs and tissues, including the liver, pancreas, heart, endocrine glands, skin, and joints. Damage can result in micronodular cirrhosis of the liver and atrophy of the pancreas (primarily islets). Hepatocellular carcinoma, usually in the presence of cirrhosis, is another consequence of excess iron deposition in the liver. Symptoms are related to damage of the

involved organs and include liver failure (from cirrhosis), diabetes mellitus, arthritis, cardiac dysfunction (arrhythmias and failure), and hypogonadotropic hypogonadism.
- The diagnosis of iron overload includes serum iron studies (elevated transferrin saturation [TS], elevated serum ferritin levels), genetic testing, and sometimes liver biopsy to assess the hepatic iron concentration and degree of liver injury. In cases of

HFE-related HH, liver biopsy is usually not indicated if the patient has normal liver enzyme levels and a serum ferritin level below 1,000 ng/mL. Because regular phlebotomy therapy prevents or reverses the accumulation of excess iron and prevents the complications of HH, it is important to identify persons with this inherited disorder early in the disease process.

History

The first medical description of a patient with hemochromatosis was by Trousseau (1) in the French pathology literature in 1865 (Table 36.1). Twenty-four years later, the German pathologist von Recklinghausen (2) was the first to use the term *hemochromatosis*; he thought that the pigmentation ("chrom") in the tissues of patients with the disorder was caused by something circulating in their blood ("hemo"). In 1935, Joseph Sheldon (3), a British geriatrician, published a monograph describing the 311 cases of hemochromatosis that existed in the world literature up to that time. Sheldon concluded that hemochromatosis is an inherited disorder in which tissue injury and damage results from excess iron deposition. He drew accurate conclusions without the techniques of modern molecular medicine available today. The situation was somewhat confused by MacDonald (13), a pathologist at the Boston City Hospital, who believed that hemochromatosis was a nutritional disorder, possibly because he saw many alcoholic patients who happened to be of Irish descent.

It is now known that the prevalence of homozygosity for *HFE*-related hereditary hemochromatosis (HH) is high in the Irish population, approaching 1 in 70 persons (14). In 1976, Marcel Simon et al. (7) definitively showed that classic hemochromatosis is inherited as an autosomal recessive disorder, with linkage to the human leukocyte antigen (HLA) region of the human genome; the gene for hemochromatosis is located on the short arm of chromosome 6. It took another 20 years until the research group at Mercator Genetics successfully identified and cloned the hemochromatosis gene by means of a positional cloning approach using deoxyribonucleic acid (DNA) samples from well-documented patients with hemochromatosis in the United States (9). In 1996, Feder et al. (9) identified *HFE*, a novel major histocompatibility complex (MHC) class I–like gene; homozygosity for a single missense mutation (C282Y) of *HFE* was found in 83% of the patients who were studied. Quickly, several other groups reported their findings in series of patients with hemochromatosis, and homozygosity for the C282Y mutation was found in about 85% to 90% of typical patients (15,16,17,18,19). This discovery has yielded significant benefits in clinical medicine and hepatology, including

more accurate diagnosis of *HFE*-related HH, improved family screening, and evaluation of the role of *HFE* mutations in other liver diseases. Additionally, there has been a wealth of new information about the cellular and molecular mechanisms of iron homeostasis, including the discovery of the iron-regulatory hormone hepcidin. In this chapter, we highlight the new advances in the area of HH and other iron storage disorders, interdigitating these discoveries with the classic pathologic and clinical features seen in these patients.

Table 36.1. Milestones in *HFE*-Related Hereditary Hemochromatosis

Year	Authors (refs.)	Event
~1–300 AD	—	C282Y mutation of *HFE* in Celtic population
1865	Trousseau (1)	First case described

1889	von Recklinghausen (2)	Coined the term *hemochromatosis*
1935	Sheldon (3)	Postulated HH is an inherited defect of iron metabolism
1950	Davis et al. (4,5)	First liver biopsy in HH, and first phlebotomy therapy
1976	Bomford and Williams (6)	Benefit of phlebotomy therapy described
1976	Simon et al. (7)	Linkage to HLA-A
1985	Niederau et al. (8)	Benefit of early diagnosis and therapy
1996	Feder et al. (9)	*HFE* gene cloned, and C282Y and H63D mutations described
1998	Zhou et al. (10)	*HFE* knock-out mouse has iron overload
2001	Nicolas et al. (11)	Hepcidin as iron-regulatory hormone
2003	Bridle et al. (12)	Low hepcidin expression in *HFE*-related HH
1997–present	Many	Cell biology of iron-related proteins

HH, hereditary hemochromatosis; HLA, human leukocyte antigen.

Classification of Iron Overload Syndromes

Many terms have been used in the past to describe HH, such as *idiopathic*, *primary*, and *familial*. The term *hereditary hemochromatosis* should be reserved to describe inherited disorders of iron metabolism that lead to tissue iron loading (Table 36.2). The most common form of this disease, *HFE-related HH*, is caused primarily by homozygosity for the C282Y mutation in the *HFE* gene. However, other heritable forms of iron overload have also been recognized (*non–HFE-related HH*). These include (a) autosomal recessive forms of HH characterized by rapid iron accumulation and caused by mutations in the genes for hemojuvelin and hepcidin (also called *juvenile hemochromatosis*) (20,21), (b) an autosomal dominant form of HH caused by mutations in the ferroportin gene (22,23), (c) an autosomal recessive form of HH resulting from mutations in the gene for transferrin receptor 2 (TFR2) (24,25), and (d) rare forms of HH resulting from mutations in the *divalent metal transporter 1* (*DMT1*) gene (26) or in the regulatory region of ferritin messenger ribonucleic acid (mRNA) (27). Some other types of iron overload may have a heritable component but the genes involved have not yet been identified. For example, *African iron overload* is a familial disorder of iron loading prevalent in sub-Saharan Africa

that is exacerbated by the ingestion of iron-rich home-brewed beer (28,29,30). The degree of iron loading can be similar to that in *HFE*-related HH, but the cellular and lobular distribution of iron is different. In addition, a rare disorder termed *neonatal iron overload* is characterized by increased hepatic iron and severe liver injury present at birth (31,32,33).

Table 36.2. Classification of Iron Overload Syndromes

HEREDITARY HEMOCHROMATOSIS
***HFE*-related**
C282Y/C282Y
C282Y/H63D
Other *HFE* mutations
Non–*HFE*-related
Hemojuvelin (*HJV*) mutations (autosomal recessive)
Hepcidin (*HAMP*) mutations (autosomal recessive)
Ferroportin (*SLC40A1*) mutations (autosomal dominant)
Transferrin receptor 2 (*TFR2*) mutations (autosomal recessive)
Divalent metal transporter 1 (*SLC11A2*) mutations (rare)
Ferritin regulatory mutations (rare)
Miscellaneous
African iron overload
Neonatal iron overload (rare)
SECONDARY IRON OVERLOAD
Anemia caused by ineffective erythropoiesis
Thalassemia major
Sideroblastic anemias
Congenital dyserythropoietic anemias
Congenital atransferrinemia
Aceruloplasminemia

Miscellaneous
Excessive iron ingestion
PARENTERAL IRON OVERLOAD
Red blood cell transfusions
Iron–dextran injections
Associated with long-term dialysis

Several noninherited syndromes of iron overload are known. In *secondary iron overload*, an underlying disorder causes an increase in iron absorption; examples are disorders of ineffective erythropoiesis and liver disease (34,35). *Parenteral iron overload* is an iatrogenic disorder in which blood transfusions or iron–dextran injections are given to patients who are anemic (36).

In *HFE*-related HH, it has become clear from population studies that not all individuals who have the C282Y/C282Y genotype become iron loaded. This observation indicates that there are many nonexpressing C282Y homozygotes in the population (37,38,39) and has led to a four-category description of *HFE*-related HH: (a) Genetic predisposition with no other abnormality, (b) iron overload (approximately 2 to 5 g) but without symptoms or tissue damage, (c) iron overload with early symptoms (i.e., lethargy, arthralgias), and (d) iron overload with organ damage, particularly cirrhosis.

HFE-Related Hereditary Hemochromatosis

Since the work of Simon et al. in the mid-1970s (7), it has been known that the major gene for HH is located on the short arm of chromosome 6 in the HLA region of the genome. In 1996, investigators at Mercator Genetics used a positional cloning approach to identify *HFE*

as the responsible gene (9). *HFE* codes for a novel MHC class I–like protein that requires interaction with β_2-microglobulin (β_2M) for normal presentation on the cell surface (9). Structural homology with other MHC class I proteins and x-ray crystallographic studies indicate that HFE protein has a large extracellular domain with three α loops, a single transmembrane region, and a short cytoplasmic tail (9,40). In the original work by Feder et al. (9), two missense mutations were identified in *HFE*, one resulting in a change of cysteine to tyrosine at amino acid 282 (C282Y) and the second causing a change of histidine to aspartate at amino acid 63 (H63D). Other *HFE* mutations have been identified, but their frequency appears to be low and their clinical impact is limited. Feder et al. (9) reported that 148 (83%) of 178 patients with typical phenotypic HH were homozygous for the C282Y mutation while 8 (4%) patients were compound heterozygotes, with one allele containing the C282Y mutation and the other allele containing the H63D mutation. These findings were confirmed by subsequent studies that showed that 60% to 100% (mean value, 84%) of patients with typical phenotypic HH were homozygous for C282Y (15,16,17,18,19). Of interest, approximately 6% of patients in these studies, in aggregate, had a clinical syndrome phenotypically similar to that of patients with typical HH but were negative for either *HFE* mutation (19). Some of these patients may have had mutations in known iron-related genes or in as yet unidentified genes involved in iron metabolism.

HFE Gene and Protein

The *HFE* gene is expressed at relatively low levels in most human tissues (9), and Northern blot analysis of lineage-specific human cell lines demonstrates an abundant expression of *HFE* mRNA in cells of epithelial or fibroblastic origin (41). However, unlike other classic MHC class I genes, *HFE* is rarely expressed in lymphopoietic and hematopoietic cells (9). Little is known of the regulation of *HFE* gene expression. In contrast to the expression of genes for other MHC molecules, *HFE* expression is not induced in cultured cells by various cytokines (42). Although in one study of a human intestinal cell line (Caco2) the levels of *HFE* mRNA and protein increased as iron status increased (43), in another study, neither iron chelation nor iron replacement affected *HFE* mRNA levels (44). Sequences known to confer transcriptional regulation by cellular metal ion content have not been identified in the *HFE* gene. Furthermore, sequences homologous to iron-responsive elements (IREs) have not been identified in either the 3′- or 5′-untranslated region of *HFE* mRNA. However, several splice variants of human *HFE* mRNA have been identified. An HFE transcript lacking exons 6 and 7 has been detected (by means of reverse transcription followed by polymerase chain reaction) in human duodenum, spleen, breast, skin, and testicle (45). Because this transcript does not include the sequences encoding the transmembrane and cytoplasmic domains, it is predicted to encode a secretory form of HFE protein. HFE splice variant transcripts lacking exon 2 and/or a portion of exon 4 have been identified in a human liver cell line, a colon carcinoma cell line, and an ovarian cell line (46). Deletion of exon 2 is predicted to eliminate the α_1 loop of HFE protein, whereas deletion of a portion of exon 4 is predicted to affect the α_3 loop. The levels of protein expression and physiologic roles of the splice variant HFE transcripts are not yet known.

The *HFE* gene encodes a 343–amino acid protein consisting of a 22–amino acid signal peptide, a large extracellular domain, a single transmembrane domain, and a short cytoplasmic tail (9). HFE protein is widely expressed in several organs including the liver, placenta, and gastrointestinal tract (i.e., epithelium of esophagus, stomach, duodenum, small intestine, and colon) (47,48,49,50,51). The extracellular domain of HFE protein consists of three loops (α_1, α_2, and α_3), with intramolecular disulfide bonds within the second and third loops. The structure of HFE protein is therefore similar to that of other MHC class I proteins. The two common *HFE* mutations, C282Y and H63D, are in the

extracellular domain. Crystallographic studies demonstrate that the α_1 and α_2 loops of HFE protein form a superdomain consisting of antiparallel β strands topped by two antiparallel α helices (40). The groove between the antiparallel α helices is analogous to the peptide-binding groove in antigen-presenting MHC class I proteins. Several lines of evidence, however, suggest that HFE protein does not participate in antigen presentation. The groove between the α helices in HFE protein is physically narrower than that in antigen-presenting MHC class I molecules, so that the ability to bind peptides is precluded. Indeed, N-terminal sequencing performed on acid eluates from HFE protein found no evidence of peptide binding (40). HFE protein, like other MHC class I molecules, is physically associated with β_2M. This association has been demonstrated in the human duodenum (48) and placenta (47), and in cultured cells (52,53,54).

C282Y mutation of *HFE*

The C282Y mutation results in the substitution of tyrosine for cysteine at amino acid 282 in the α_3 loop and abolishes the disulfide bond in this domain (9). Loss of the disulfide bond was predicted to interfere with the interaction of β_2M with HFE protein (9). Indeed, C282Y mutant protein expressed in cell culture systems demonstrates diminished binding with β_2M and

decreased presentation at the cell surface in comparison with wild-type HFE protein (52,53). The C282Y mutant protein is retained in the endoplasmic reticulum and middle Golgi compartments, fails to undergo late Golgi processing, and is subject to accelerated degradation (53). However, some C282Y mutant protein in patients with HH reaches the cell surface, as detected by immunohistochemistry, although at reduced levels (51). Definitive proof that this mutation can cause HH was provided when knock-in of the C282Y mutation in mice resulted in iron overload (55).

The C282Y mutation is present in most, but not all, patients with a clinical diagnosis of HH. The proportion of patients with HH who are homozygous for C282Y varies in different populations. In the United States, Britain, Australia, Canada, and France, approximately 85% to 90% of patients with a clinical diagnosis of HH are homozygous for C282Y (19), but a lower frequency (60%) has been reported in Italy (56). Conversely, population studies have revealed that the clinical features of HH do not develop in many C282Y homozygotes (37,38,39). This observation suggests incomplete penetrance of the C282Y mutation and raises the possibility that other genes involved in iron homeostasis may act as modifiers of the HH phenotype (57,58,59).

The prevalence of the C282Y mutation is greatest in whites of European ancestry. In this population, the carrier frequency ranges from 10% to 15% (14,19,32,33,34). In other ethnic populations, the C282Y mutation is less common and is always associated with the ancestral white haplotype (60,61). Such studies suggest that the C282Y mutation occurred once on an ancestral (possibly Celtic) haplotype that spread from northern Europe to other regions of the world (62,63). The observation that the haplotype containing the C282Y mutation extends for approximately 7 megabases suggests that the mutation arose during the last 2,000 years (64). It has been proposed that the C282Y mutation, associated with increased iron absorption and the accumulation of body iron stores, provided a selective advantage to a population in which the availability of dietary iron was limited or in which intestinal parasitic infections caused a loss of iron.

H63D mutation of *HFE*

The most common *HFE* mutation in the general population is a missense mutation that results in the substitution of histidine for aspartate at amino acid 63 (H63D) of the HFE protein (9). The H63D mutation is found at a frequency of 15% to 40% in white populations (19), but homozygosity for H63D appears to increase the risk for iron loading only slightly (65). However, the frequency of compound heterozygosity for the H63D and C282Y mutations is greater in patients with iron overload than that predicted for the general population (9,19). It is estimated that the risk for iron loading of the C282Y/H63D compound heterozygote is nearly 200-fold lower than that for the C282Y homozygote (66).

The population distribution of the H63D mutation differs somewhat from that of C282Y. The highest frequencies of H63D are found in European countries bordering the Mediterranean, the Middle East, and the Indian subcontinent (63). The H63D mutation has been found on many haplotypes, which suggests that this less consequential mutation may have arisen historically multiple times and in different populations. Because the haplotype comprising the H63D mutation is shorter (approximately 700 kb) than that of the C282Y mutation, it is thought to be evolutionarily older (64).

Other mutations of *HFE*

HFE mutations other than C282Y and H63D have been identified in isolated patients with iron overload (67,68). These include missense mutations (e.g., S65C, G93R, I105T, and Q127H), splice site mutations (e.g., IVS3+1 G/T and IVS5+1 G/A), frame shift mutations (e.g., V68ΔT, P160ΔC), and nonsense mutations (e.g., R74X, E168X, W169X). Each symptomatic patient carrying one of the missense mutations has carried the C282Y or H63D mutation on the other allele. The two identified splice site mutations cause altered mRNA splicing and exon skipping, resulting in abnormal variants of HFE protein. The frameshift and nonsense mutations result in the production of truncated forms of HFE protein. The relative contribution of *HFE* mutations other than C282Y or H63D to the overall incidence of *HFE*-related HH appears to be small.

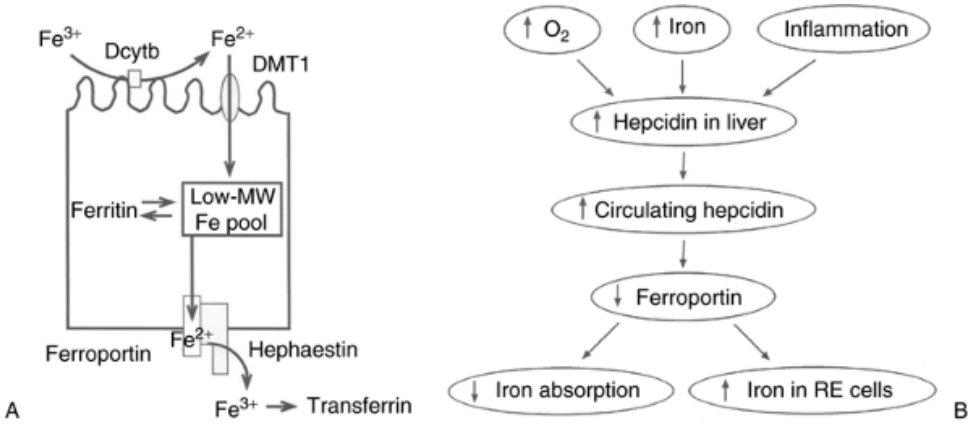
Experimental disruption of the *HFE* gene

Transgenic methodology has provided important information about the functional consequences of *HFE* gene disruption in the whole animal. Four different murine models have been generated: An exon 4 knock-out (10), an exon 3 disruption/exon 4 knock-out (55), an exon 2–3 knock-out (69), and a C282Y knock-in (55). These mice manifest increases in hepatic iron levels (10,55,69), transferrin saturation (TS) (10), and intestinal iron absorption (69). No immunologic consequences of *HFE* disruption have been observed in mice (69). Like patients with *HFE*-related HH, these mice demonstrate relative sparing of iron loading in reticuloendothelial (RE) cells (10,55). Interestingly, iron loading in mice that are homozygous for the C282Y mutation is less severe than that in *HFE* knock-out mice, which indicates that the C282Y mutation is not a null allele (55). Strain differences determine the severity of iron accumulation in *HFE* knock-out mice, supporting the concept that there are genetic modifiers of the HH phenotype (58,70).

Determinants of Duodenal

An increase in intestinal iron absorption is a key characteristic of HH (71,72,73), and, therefore, understanding the pathogenesis of HH requires a review of the determinants of duodenal iron absorption. Because there are no significant physiologic mechanisms to regulate iron loss, iron homeostasis is dependent on tightly linking body iron requirements (approximately 1 mg/day) with intestinal iron absorption. Nearly all absorption of dietary iron occurs in the duodenum, where iron may be taken up either as ionic iron or as heme (73). The absorption of both forms of iron is increased in patients with HH. Uptake of heme occurs by an as yet unidentified transporter. Absorption of ionic iron across the enterocytes occurs in two stages: Uptake across the apical membrane and transfer across the basolateral membrane (Fig. 36.1). Before uptake, ionic iron requires reduction from the ferric to the ferrous state. This is accomplished by the ferric reductases (such as Dcytb), which are expressed on the luminal surface of duodenal enterocytes (74). The ferrous iron crosses the apical membrane using the transporter divalent metal transporter 1 (DMT1) (75,76). Iron taken up by the enterocyte may be stored as ferritin (and excreted in the feces when the senescent enterocyte is sloughed) or transferred across the basolateral membrane to the plasma. This latter process occurs through the transporter ferroportin (77,78,79). The basolateral transfer of iron requires oxidation of iron to the ferric state by the ferroxidase, hephaestin (80). In addition to increased uptake of iron from the diet, patients with *HFE*-related HH demonstrate increased basolateral transfer of iron from the enterocytes to the plasma, and this may be a driving force behind the increased intestinal iron absorption observed in *HFE*-related HH (72). Some studies on

patients with *HFE*-related HH (81,82,83) and *HFE* knock-out mice (84,85) have demonstrated increased expression of mRNAs encoding DMT1 and ferroportin. However, not all investigators have observed upregulation of DMT1 and ferroportin in patients with HH (86,87) or in *HFE* knock-out mice (88,89). In *HFE* knock-out mice, these discrepancies may be due to differences in mouse strain (70) or age (90).



▪ **Figure 36.1** Iron absorption and the role of hepcidin. **A:** Absorption of dietary ionic iron across the duodenal villus enterocyte occurs in two stages: Uptake across the apical membrane and transfer across the basolateral membrane. Before uptake, ionic iron has to be reduced from the ferric to the ferrous state. This is accomplished by the ferric reductases (such as Dcytb), which are expressed on the luminal surface of duodenal enterocytes. The ferrous iron crosses the apical membrane through the divalent metal transporter 1 (DMT1). Iron taken up by the enterocyte is thought to enter a low-molecular-weight (MW) iron pool and then stored as ferritin or transferred across the basolateral membrane to the plasma. This latter process occurs through the transporter ferroportin. The basolateral transfer of iron requires oxidation of iron to the ferric state by the ferroxidase, hephaestin. Ferric iron is then bound to transferrin in the circulation. **B:** Hepcidin expression by the liver is upregulated by increased iron, inflammation, or increased oxygen availability. Circulating hepcidin acts to decrease the functional activity of the iron exporter ferroportin by binding to it and causing its internalization and degradation. In reticuloendothelial (RE) cells, this results in iron sequestration while in duodenal enterocytes it leads to decreased basolateral iron transfer and, therefore, decreased dietary iron absorption. Patients with hereditary hemochromatosis have low hepcidin expression with a consequent increase in iron absorption.

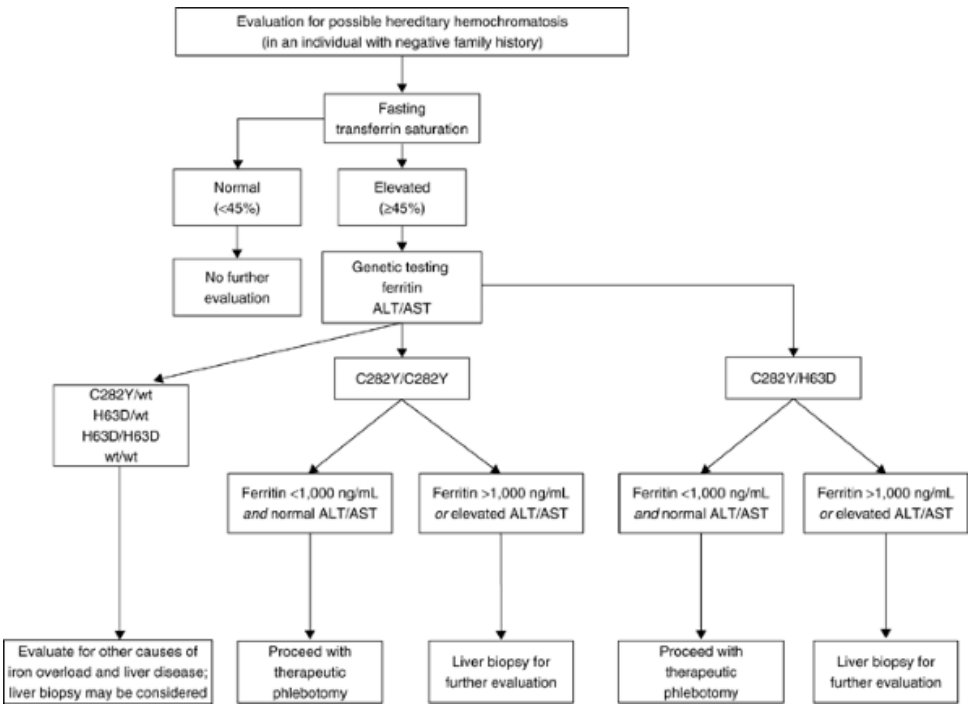
Several biologic factors influence the rate of dietary iron absorption. Reduction in body iron stores, increased erythropoietic activity, decreased blood hemoglobin content, and decreased blood oxygen saturation increase the absorption of iron from the diet (73). In contrast, the presence of systemic inflammation decreases dietary iron absorption. All these factors are thought to act by influencing the levels of hepcidin, an iron-regulatory hormone.

Dysregulation of Hepcidin in Hereditary Hemochromatosis

Hepcidin is a 25–amino acid peptide, first identified in urine and plasma as an antimicrobial peptide (91,92,93). However, its role in influencing systemic iron status has become paramount, and it is now considered to be the

principal iron-regulatory hormone (94,95). The first evidence that hepcidin is involved in iron homeostasis came from the observation that liver hepcidin mRNA expression is

increased in mice with dietary iron loading (93). The fortuitous discovery that knock-out of the hepcidin gene in the mouse led to a HH-like phenotype established the critical role of hepcidin as a negative regulator of intestinal iron absorption (11,96). It was later discovered that hepcidin mutations are responsible for one form of juvenile hemochromatosis (21). Factors regulating intestinal iron absorption (i.e., iron status, erythropoietic activity, hemoglobin levels, oxygen content, and inflammation) also regulate liver hepcidin expression (Fig. 36.2). In each of these situations, intestinal iron absorption varies inversely with liver hepcidin expression. For example, animals with dietary iron overload (93) or systemic inflammation (97) have higher hepatic hepcidin mRNA levels, whereas animals subjected to hypoxia or hemolytic anemia have lower mRNA levels (98,99). Hepcidin is an acute-phase reactant and plays a central role in the hypoferremia of inflammation (i.e., anemia of chronic diseases) (97,100). Hepcidin acts to decrease the functional activity of the iron exporter ferroportin by binding to it and causing its internalization and degradation (101). In the duodenal enterocyte, this leads to decreased basolateral iron transfer and, therefore, decreased dietary iron absorption.



▪ **Figure 36.2** Algorithm for the evaluation of possible hereditary hemochromatosis in a person with a negative family history. ALT, alanine aminotransferase; AST, aspartate aminotransferase; wt, wild type.

Dysregulation of hepcidin expression is thought to play a key role in the pathogenesis of HH. Bridle et al. (12) demonstrated that patients with *HFE*-related HH have low hepatic expression of hepcidin, as do *HFE* knock-out mice, despite excess hepatic iron stores (12,102,103). Overexpression of hepcidin in *HFE* knock-out mice prevents the HH phenotype (104). Although technical problems have hindered the measurement of the mature hepcidin peptide in serum, urinary hepcidin concentrations can be determined. Urinary hepcidin levels are low in patients with HH caused by mutations in *HFE*, *TFR2*, and *HJV* (97,105,106,107,108). Therefore, it is proposed that low circulating levels of hepcidin in these forms of HH cause increased ferroportin-mediated efflux of iron from both RE cells (resulting in iron sparing) and duodenal enterocytes (resulting in increased iron absorption).

The molecular mechanisms by which hepcidin expression is regulated by body iron status

have not been determined. However, it is hypothesized that *TFR2* in hepatocytes may act as an iron "sensor" (24,109). Mutations of *TFR2* cause a rare form of HH in humans (24,25) and *TFR2*-mutant mice have a HH phenotype (110). Despite hepatic iron loading, hepcidin expression is low in patients with *TFR2*-related HH (108) and in *TFR2*-mutant mice (111). This suggests that *TFR2* is necessary for the appropriate transduction of the signal between body iron status and hepcidin expression (24,109). It has been proposed that hepatocytes may modulate hepcidin expression by sensing the circulating levels of diferric transferrin. The concentration of diferric transferrin in portal blood reflects the rate of iron absorption. The binding of diferric transferrin to TFR2 on hepatocytes might transduce a signal that modulates the expression of hepcidin. Likewise, HFE protein and hemojuvelin may participate in this signaling pathway within hepatocytes because inactivating mutations of both these proteins result in low hepcidin expression and iron overload (24,109). HFE protein binds avidly to the classic transferrin receptor 1 (112), but it is not yet clear whether this interaction plays a part in the signaling pathway to hepcidin.

Although the hepatocyte is a strong candidate as the cell type requiring HFE protein for a normal hepcidin response to iron status, some evidence suggests that HFE expression by Kupffer cells may also play a role in the regulation of hepcidin expression. For example, hepatocytes in culture do not respond to changes in iron content with an increase in hepcidin expression (97,113), raising the possibility that another cell type is needed for functional iron sensing. Indeed, *HFE* knock-out mice demonstrate improved iron status after their Kupffer cells are repopulated using transplanted bone marrow from mice with wild-type *HFE* (114).

While it is clear that dysregulation of hepcidin is central to the pathogenesis of *HFE*-related HH, HFE may also be able to influence body iron homeostasis independent of hepcidin. It has been shown that transfection of *HFE* into cultured cells directly influences their iron status (115). Possibly, loss of functional HFE protein in certain cell types (e.g., duodenal crypt cells) could directly contribute to the iron homeostasis abnormalities observed in *HFE*-related HH. Duodenal crypt cells express HFE protein and have been proposed to act as sensors of body iron status through the uptake of plasma diferric transferrin (116). In support of this concept, the duodenal uptake of plasma iron is impaired in *HFE* knock-out mice (117). This observation supports the possibility that functional loss of HFE protein may decrease the iron pool in duodenal crypt cells, resulting in a relatively iron-deficient state in these cells. This could cause increased expression of iron transporter genes in daughter villus enterocytes and lead to increased dietary iron absorption. Although this "crypt cell hypothesis" was proposed to try to explain the excess dietary iron absorption in *HFE*-related HH (116,118), the effect of HFE protein on liver hepcidin expression appears to be paramount.

Non–*HFE*-Related Hereditary Hemochromatosis

Although *HFE* mutations account for the vast majority of HH, other forms of HH have been recognized and are generally grouped together as non–*HFE*-related HH (119) (Table 36.1). Mutations in two different genes, *HJV* and *HAMP*, cause forms of juvenile HH. The *HJV* gene encodes hemojuvelin, a glycosylphosphatidylinositol-anchored protein that has substantial expression in hepatocytes. More than 25 disease-causing mutations have been described in *HJV* (20). Hemojuvelin may be involved in regulating the hepcidin pathway because patients with *HJV*-associated HH (107) and *HJV* knock-out mice (120,121) have low hepcidin expression that may be responsible for increased iron absorption. Inactivating mutations of the *HAMP* gene (that encodes hepcidin) also produce a form of juvenile HH (21).

Two distinct types of ferroportin mutations cause autosomal dominant HH (122,123). The first type of mutation results in ferroportin inactivation, while the second type interferes with the interaction between ferroportin and hepcidin (but ferroportin retains its iron export capability). Inactivating ferroportin mutations cause a cellular distribution of iron loading that differs from that of *HFE*-related HH because iron is retained primarily in RE cells rather than hepatocytes (124). Moreover, TS values tend to be lower than that in *HFE*-related HH. Individuals with the second type of ferroportin mutation fail to respond to

hepcidin and therefore demonstrate a more classical HH phenotype. In both forms of ferroportin-related HH (unlike other types of HH), hepcidin expression is elevated rather than decreased (124).

Mutations in the *TFR2* gene produce an autosomal recessive type of HH that is clinically similar to *HFE*-related HH (24,25). It is not yet known how these uncommon mutations of *TFR2* result in iron overload, but it is possible that they cause abnormal iron sensing by hepatocytes, the predominant site of *TFR2* expression (109).

DMT1 mediates iron uptake at the intestinal brush border and across the membrane of acidified endosomes in cells such as erythyroid precursors (125,126). A single patient with severe hypochromic microcytic anemia and iron overload has been reported to carry

a homozygous mutation (E399D) of DMT1 (26). Cell biology studies suggest that E399D DMT1 protein has a partial loss of function that may limit iron availability to erythyroid precursor cells. The resulting anemia may subsequently stimulate dietary iron absorption, mediated by the partially functional DMT1 in enterocytes (127). This may explain the distinguishing iron overload seen in this patient, along with microcytic anemia.

Ferritin, which is composed of H and L subunits, plays an important role in iron storage and intracellular iron distribution. Synthesis of both ferritin subunits is controlled by an iron-regulatory protein, which binds to the IRE in the 5′-untranslated region of the H- and L-ferritin mRNAs (128). Kato et al. (27) identified a single point mutation (A49U) in the IRE motif of H-ferritin mRNA in four members of a Japanese family affected by dominantly inherited iron overload. When the mutated H-ferritin mRNA is expressed in cultured cells, there is an increase in iron uptake, suggesting that the A49U mutation may be responsible for tissue iron deposition.

Clinical Features of Hereditary Hemochromatosis

In older series of patients with typical phenotypic HH, a number of symptoms and physical findings generally associated with the disorder have been delineated (Tables 36.3, 36.4). Symptoms include fatigue, malaise, abdominal pain, arthralgias, and impotence. Physical findings include hepatomegaly, skin pigmentation, diabetes, and cardiac abnormalities (8,129,130). All physicians should be aware of this constellation of symptoms and findings, but most patients who now come to medical attention have few of these signs or symptoms. More recent series in which patients were identified by family studies, abnormal iron study results on routine screening chemistry panels, or population surveys indicate that most patients are asymptomatic, even on specific questioning about the symptoms of HH (131,132). When symptoms are present, they are the same as those described above, with fatigue and arthralgias being the most common. Therefore, in the face of abnormal iron study results, clinicians should not expect to see the usual symptoms or findings of "classic" HH but should recognize that many C282Y homozygotes are asymptomatic. Alcohol and chronic hepatitis C are potentiating factors in the development of hepatic fibrosis in patients with *HFE*-related HH (133,134,135).

Table 36.3. Symptoms in Patients with Hereditary Hemochromatosis

ASYMPTOMATIC
Abnormal serum iron study results on routine screening chemistry panel
Evaluation of abnormal liver test results
Identified by family screening
Identified by population screening
NONSPECIFIC, SYSTEMIC SYMPTOMS
Weakness
Fatigue
Lethargy

Apathy
Weight loss
SPECIFIC, ORGAN-RELATED SYMPTOMS
Abdominal pain (hepatomegaly)
Arthralgias (arthritis)
Diabetes (pancreas)
Amenorrhea (cirrhosis)
Loss of libido, impotence (pituitary, cirrhosis)
Congestive heart failure (heart)
Arrhythmias (heart)

Increased pigmentation
Endocrine
Diabetes
Testicular atrophy
Hypogonadism
Hypothyroidism

Diagnosis of Hereditary Hemochromatosis

Once the diagnosis of HH is being considered for a patient after either an evaluation of the symptoms and findings listed in Tables 36.3 and 36.4 or a workup for abnormal results of screening iron studies or a family study, then a definitive diagnosis is relatively

straightforward (133,134,135). The fasting TS (serum iron level divided by transferrin level or total iron-binding capacity, multiplied by 100) and the serum levels of ferritin and liver enzymes should be determined (Table 36.5). It is important that the TS be obtained in the fasting state because the serum iron level varies diurnally, and many breakfast cereals that are highly fortified with iron can raise the serum iron level shortly after ingestion. An elevated TS (≥45%) is recognized as the most common early phenotypic marker of HH; some patients who are homozygous for the C282Y mutation have elevated TS with a normal ferritin level. The sensitivity and specificity of these tests are difficult to determine when young persons are being evaluated (in whom increased iron stores may

not have developed) or when patients have comorbidities, such as chronic liver disease (in which values may be "falsely" elevated). For example, serum ferritin levels are elevated in more than 50% of patients with alcoholic liver disease (136,137), nonalcoholic steatohepatitis (NASH) (138), or chronic viral hepatitis (139,140,141) in the absence of HH. Furthermore, other inflammatory disorders (e.g., inflammatory arthropathies) and various neoplastic disorders (e.g., lymphoproliferative disorders) may cause ferritin levels to rise without any increase in iron stores. Therefore, many results of serum iron studies can be false-positive or false-negative, and reliance on these laboratory values alone may cause significant problems in the diagnosis. The use of *HFE* mutation analysis significantly improves diagnostic accuracy in these challenging patients.

When evaluating the results of *HFE* genotyping obtained from screening family members or from population studies, it is valuable to remember that the C282Y mutation has incomplete penetrance. This is highlighted by the results of two large North American population studies comprising approximately 100,000 and 41,000 primary care patients (38,39). In these two populations, a substantial proportion (27% and 60%, respectively) of female C282Y homozygotes had a TS of less than 45% or 50%, respectively, while the values were smaller (16% and 25%, respectively) for male C282Y homozygotes, with a TS of less than 50%. Similarly, more than 40% of female C282Y homozygotes (43% and 46%, respectively) in these populations had serum ferritin levels in the normal range (<200 ng/mL), while the corresponding values in male C282Y homozygotes were 12% and 24% (serum ferritin levels of <300 ng/mL or 250 ng/mL, respectively). Therefore, for C282Y homozygotes without increases in TS or ferritin level (termed *nonexpressing C282Y homozygotes*), it seems likely that many will not develop a clinically significant degree of iron overload in their lifetimes. Periodic follow-up measurements of serum ferritin levels at about 5-year intervals may be warranted in such individuals, with initiation of phlebotomy therapy if the values rise above normal.

Table 36.5. Diagnostic Criteria for HFE-Related Hereditary Hemochromatosis

Measurements	Normal subjects	Patients with *HFE*-related HH
BLOOD (FASTING)		
Serum iron (µg/dL)	60–180	180–300
Serum transferrin (mg/dL)	220–410	200–300
Transferrin saturation (%)	20–50	45–100
Serum ferritin (ng/mL)		
Men	20–200	150–6,000
Women	15–150	120–6,000
***HFE* MUTATION ANALYSIS**	wt/wt	C282Y/C282Y (homozygote)

		C282Y/H63D (compound heterozygote)
LIVER Hepatic iron concentration		
µg/g dry weight	300–1,500	1,500–30,000
µmol/g dry weight	5–27	27–550
Liver histology

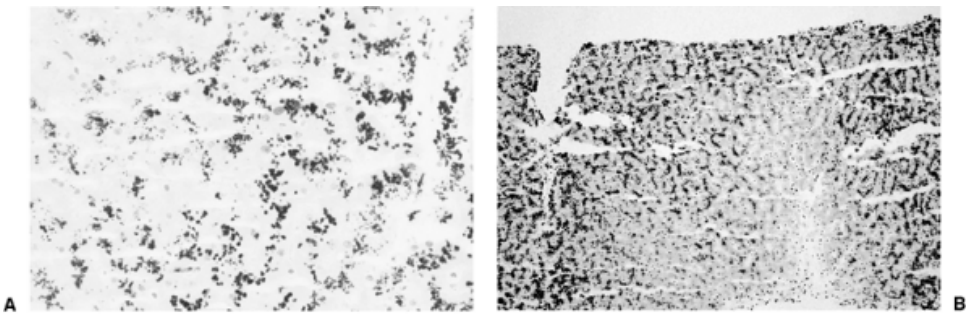
wt, wild-type.

In the past, if either a fasting TS or a ferritin level was elevated in an otherwise uncomplicated patient, a liver biopsy was performed to establish or disprove the diagnosis of HH. Perls' Prussian blue staining was used for histochemical iron analysis, and the hepatic iron concentration was measured, with subsequent calculation of the hepatic iron index (HII). In current practice, if a patient has an abnormal result on iron studies, *HFE* mutation analysis is performed; if the patient is found to be a C282Y homozygote or a compound heterozygote (C282Y/H63D), and has normal liver enzymes and a serum ferritin level below 1,000 ng/mL, then a liver biopsy is not required before commencing phlebotomy

treatment. Accordingly, as genetic testing has become more widely available and better understood, fewer liver biopsies are being performed. Four reports from France, United States, and Australia have shown that if the parameters mentioned earlier are used, no patient with significant fibrosis will be missed even if a liver biopsy is not performed (135,142,143,144). An algorithm for the evaluation of possible *HFE*-related HH is shown in Figure 36.2.

On the other hand, if a patient has elevated liver enzymes or a ferritin level above 1,000 ng/mL, a liver biopsy may be performed, and the typical findings of *HFE*-related HH should be recognized. Iron deposition occurs preferentially within the hepatocytes in the periportal region (acinar zone 1) of the hepatic lobule; the gradient of iron deposition decreases toward the pericentral region (acinar zone 3) (Fig. 36.3). With high levels of iron loading, Kupffer cell aggregates (siderotic nodules), iron deposition in bile duct epithelial cells, and increased fibrosis are found in the portal tracts. In other liver diseases associated with increased iron deposition (e.g., alcoholic liver disease, NASH, chronic viral hepatitis), the distribution of iron is usually panlobular, with increased amounts of iron found in sinusoidal lining cells (Kupffer cells) and hepatocytes. The histologic evaluation of iron staining, with a recognition of the pattern seen in *HFE*-related HH as opposed to that associated with secondary iron overload, provides important complementary information to the clinician caring for a patient with liver disease and abnormal results of iron studies. It has been reported that a non-HH pattern of iron distribution reliably predicts the absence of homozygosity for C282Y or the compound heterozygous state (145). Conversely, the HH pattern of iron deposition can be seen in other forms of liver disease in the absence of C282Y homozygosity (145).



▪ **Figure 36.3** Liver biopsy specimen from a patient with *HFE*-related hereditary hemochromatosis stained for storage iron with Perls' Prussian blue stain. The hepatic iron concentration was elevated to 9,840 µg/g dry weight. Iron deposition is found preferentially in hepatocytes (**A**, ×400) in the periportal region (acinar zone 1) of the hepatic lobule, with a decrease in the gradient toward the pericentral region (acinar zone 3) (**B**, ×200). (Courtesy of Elizabeth M. Brunt, MD)

The HII was introduced in a classic paper by the Brisbane group in 1986 (146). It is based on the concept that in patients with HH, the hepatic iron concentration increases progressively with age, whereas in HH heterozygotes or in patients with various forms of liver disease with secondary iron overload, it does not. The HII was originally introduced as a means of differentiating HH homozygotes from both HH heterozygotes and patients with alcoholic liver disease and secondary iron overload, but it quickly came to be used as a surrogate test for HH homozygosity. The HII is calculated by dividing the hepatic iron concentration (in micro moles per gram of liver dry weight) by the patient's age (in years). In several studies, patients with homozygous HH had an HII above 1.9. Now that investigations have been performed with *HFE* mutation analysis used as the "gold standard" for the diagnosis of *HFE*-related HH, it is clear that many patients who are C282Y homozygotes have an HII below 1.9 (143). Therefore, with the availability of genetic testing, the determination of the hepatic iron concentration and HII has little diagnostic value for *HFE*-related HH.

Treatment of Hereditary Hemochromatosis

The treatment of HH remains relatively straightforward (133,134,135). Once the diagnosis has been established by standard iron studies, genetic testing, or liver biopsy, treatment should be initiated with routine therapeutic phlebotomy. Patients should be encouraged to undergo weekly therapeutic phlebotomy with removal of 500 mL (1 U) of whole blood, which represents approximately 200 to 250 mg of iron, depending on the hemoglobin level. Some patients can tolerate the

removal of 2 or even 3 U of blood per week, but 1 U per week is comfortable for most patients. Occasionally, older patients may only be able to tolerate the removal of 0.5 U every other week. Therapeutic phlebotomy should be performed until iron-limited erythropoiesis develops, which is identified by the failure of the hemoglobin level and hematocrit to recover before the next phlebotomy. It is reasonable to monitor the TS and ferritin levels periodically (every 3 months) to predict the return to normal iron stores and encourage patients who are undergoing phlebotomy. Phlebotomy should be continued until the serum ferritin level is less than 50 ng/mL and the TS is less than 50%. It is not necessary for patients to become iron deficient, just depleted of their excess iron stores. Usually, in otherwise uncomplicated patients, each unit of blood removed reduces the serum ferritin level by about 30 ng/mL. This can be a useful way of predicting depletion of

iron stores. Once standard therapeutic phlebotomy has been completed, patients require maintenance phlebotomy. Because in most patients approximately 2 to 3 mg of iron is absorbed per day in excess of their needs, they can be maintained in normal iron balance if 1 U of blood (200 to 250 mg of iron) is removed from them every 3 months.

With treatment, patients generally have an improved sense of well-being, and pain/fullness in the right upper quadrant is reduced (Table 36.6). If liver enzyme abnormalities are present, they will normalize with treatment. Also, if patients require management of diabetes, the need for insulin or oral agents may decrease with successful phlebotomy therapy. On the other hand, testicular atrophy, arthropathy, and established cirrhosis generally are not reversible. Patients with established cirrhosis are still at risk for the development of hepatocellular carcinoma (8,147,148,149), and they should be screened periodically (every 6 months) with abdominal imaging and measurement of α-fetoprotein levels.

Table 36.6. Response to Phlebotomy Therapy in Hereditary Hemochromatosis

- Reduction of tissue iron stores to normal levels
- Improved survival if condition diagnosed and treated before development of cirrhosis and diabetes
- Improved sense of well-being, energy level
- Improved cardiac function
- Improved control of diabetes
- Reduction in abdominal pain
- Decrease in skin pigmentation
- Normalization of elevated liver enzymes
- Reversal of hepatic fibrosis (approximately 30% of cases)
- No reversal of established cirrhosis
- No (or only minimal) improvement in arthropathy
- No reversal of testicular atrophy

Family and Population Screening for Hereditary Hemochromatosis

Once a proband with *HFE*-related HH has been identified, family screening is necessary (133,134,135,150). It is recommended that all first-degree relatives undergo *HFE* mutation analysis. In the past, HLA haplotyping was recommended as a surrogate genetic test, but with the availability of *HFE* mutation analysis, HLA typing is no longer recommended. Both the C282Y and H63D mutations should be analyzed. If a family member is found to be a C282Y homozygote or a compound heterozygote (C282Y/H63D), then therapeutic phlebotomy may be initiated if serum parameters indicate iron overload, such as an elevated ferritin level or TS. Individuals who are C282Y heterozygotes (C282Y/wt), H63D homozygotes (H63D/H63D), or H63D heterozygotes (H63D/wt) are not at risk for progressive iron overload. The issue of screening children by genetic testing raises questions of possible genetic discrimination and stigmatization (150). These issues are not yet resolved at a societal level, but it may be useful to have the spouse of a proband undergo genetic testing to predict the genotype in a child (151). Because C282Y and H63D are such common mutations, occurring in approximately 35% of persons singly or in combination, the chance that the spouse will have a mutation of *HFE* is approximately 1 in 3. If the spouse is homozygous for wild-type *HFE*, then the children do not require genetic testing because they are obligate heterozygotes and are not at increased risk for excess iron storage. In children who are C282Y homozygotes or compound heterozygotes, ferritin levels should be measured yearly and phlebotomy instituted when ferritin levels become elevated.

After the original discovery of *HFE*, it was thought that population screening using genetic testing might be ideal for *HFE*-related HH. Some of the reasons favoring screening are that

C282Y homozygosity is common in white populations, there is a long latent phase before the development of disease manifestations, and treatment is simple and effective (37,38,39,152,153). More than 15 studies have used *HFE* genotyping in population studies, and it has become evident that the C282Y mutation has incomplete penetrance, both in terms of serum iron parameters (i.e., TS, ferritin) and clinical impact (i.e., signs, symptoms, morbidity) (37,38,39,152). Incomplete penetrance of the C282Y mutation raises serious concerns about the cost-effectiveness of large-scale population screening, as does the issue of genetic discrimination about health and life insurance (154,155). Alternative screening approaches such as targeted screening of high-risk groups (e.g., patients with diabetes) and workplace screening may prove efficacious (156,157). At the present time, population

screening requires further evaluation and the most cost-effective methods of early detection of *HFE*-related HH appear to be family screening and evaluation of potential cases by primary care physicians with a high index of clinical suspicion (155,158).

Analysis of *HFE* Mutations in Patients with Liver Disease

Clinicians must frequently determine whether a patient has liver disease with abnormal parameters of iron metabolism or *HFE*-related HH with elevated liver enzymes. Abnormal results of blood iron studies are common in patients with a variety of liver diseases. These are generally associated with hepatocellular types of liver disease rather than the cholestatic syndromes. Approximately 50% of patients with alcoholic liver disease (136,137), NASH (138,159), or chronic viral hepatitis (B and C) (139,140,141) have abnormalities in serum iron parameters. Typically, these abnormalities are limited to an elevated serum ferritin level, but some patients may also have an elevated TS. The hepatic iron concentration is typically normal or slightly elevated, and if the HII is calculated, it is usually normal. *HFE* mutation analysis has been applied to groups of patients with alcoholic liver disease, chronic hepatitis C virus (HCV), NASH, and porphyria cutanea tarda (PCT).

It has been known for more than 20 years that results of iron studies are frequently abnormal in patients with alcoholic liver disease (136,137). Patients with acute alcoholic hepatitis can present with ferritin levels above 1,000 ng/mL and a TS above 100%. These values return to normal with abstinence and recovery from alcoholic hepatitis. Parameters of iron metabolism can also be abnormal in patients with chronic alcoholic liver disease. When *HFE* mutations are examined in patients with chronic alcoholic liver disease, the prevalence of C282Y or H63D is not greater than that in the control population (160,161). Additionally, the absence of a relationship between *HFE* mutations and hepatic iron levels in patients with alcoholic liver disease suggests that the abnormal iron parameters (whether blood studies or hepatic iron concentration) are caused by factors other than *HFE* mutations (160).

A relationship between the hepatic iron concentration and the response to treatment with interferon monotherapy of patients with chronic HCV has been reported (162,163). Studies in the 1990s demonstrated a higher hepatic iron concentration in patients with chronic HCV who did not respond to treatment with interferon monotherapy than in those who did (162,163,164,165). This concept led to the use of therapeutic phlebotomy to deplete iron stores before initial interferon therapy or retreatment with interferon. Iron depletion results in reduced levels of serum alanine aminotransferase (ALT) but does not significantly improve the rate of sustained virologic response (HCV RNA levels undetectable after 6 months without therapy) (166,167,168,169). A recent report indicates that pretreatment hepatic iron concentration is not an independent predictor of response to combined therapy with interferon and ribavirin (170). In a long-term study in patients with HCV who failed to respond to interferon, phlebotomy combined with a low iron diet decreased ALT activity, histologic inflammation and fibrosis, and the hepatic levels of 8-hydroxy-deoxyguanosine (a marker of DNA damage) (171). These results suggest that iron depletion can slow the progression of liver damage in HCV and may reduce the risk for developing hepatocellular carcinoma.

Other studies have suggested that the effect of an increased hepatic iron concentration may be synergistic with that of HCV in causing hepatic fibrosis (172,173,174,175). Studies in which *HFE* mutation analysis was performed in patients with HCV, like those carried out in patients with alcoholic liver disease, showed no difference in the prevalence of C282Y or H63D mutations in comparison with a control population (167,173,174,176,177,178). Some studies have reported that the presence of *HFE* mutations (especially C282Y) in patients with HCV is associated with an increase in fibrosis and cirrhosis (167,173,179), but other studies have not confirmed this association (175,177,178,180). Further investigation is needed to determine the potential role of *HFE* mutations and iron in HCV-induced liver injury and to confirm that long-term iron removal by phlebotomy decreases the progression of hepatic fibrosis and the incidence of hepatocellular carcinoma in patients with HCV.

Results of serum iron studies are often abnormal in patients with NASH (138,159,181,182,183,184) and stainable hepatic iron may also be present. A number of investigations have assessed the prevalence of *HFE* mutations in NASH and the potential role of hepatic iron in disease severity. In several studies, it has been observed that patients with NASH have a higher prevalence of the C282Y mutation (usually heterozygotes) (183,184,185,186), but this is not always the case (187). Not all patients with NASH with elevated hepatic iron levels have the C282Y mutation, indicating that other factors are involved. Some studies also observed an increase in hepatic fibrosis in patients with NASH who carry the C282Y mutation (183,184). While two reports found an association of increased hepatic iron with the development of fibrosis in NASH (183,184), other investigations have not found this association (185,187,188). Regardless of iron levels and *HFE* mutations, several small trials indicate that phlebotomy therapy decreases ALT levels in patients with NASH (189,190,191,192), but the

potential beneficial effects on hepatic histopathology have not been systematically evaluated.

In PCT, the role of abnormal iron stores in disease progression has been known for many years (193,194). In addition, some patients with PCT also have chronic HCV, and alcohol consumption is known to be another risk factor. Studies from the United States, Europe, and Australia have shown that 16% to 49% of patients with PCT have at least one C282Y mutation in *HFE* and 6% to 19% are C282Y homozygotes (195,196,197,198,199,200,201) (Table 36.7). The situation is different for Italian patients with PCT, in whom the prevalence of the C282Y mutation is not increased; rather, the prevalence of the H63D mutation is elevated (202). Therapeutic phlebotomy is beneficial in PCT, inducing a reduction in liver enzyme abnormalities and regression of the skin lesions (193,194). Patients should also be counseled about abstaining from alcohol, and if they have HCV, they should be offered a course of antiviral therapy once their excess iron stores have been depleted.

In summary, all patients with PCT should undergo *HFE* mutation analysis and HCV testing, and phlebotomy therapy is definitely beneficial. For patients with alcoholic liver disease, the role of *HFE* mutation analysis seems to be limited because *HFE* mutations do not appear to contribute to the iron abnormalities seen in these patients. For patients with chronic HCV and NASH, it is reasonable to request *HFE* mutation analysis if the parameters of iron metabolism are abnormal (elevated ferritin level or TS), but the relationships between *HFE* mutations and abnormal iron parameters are not as clear as those in PCT. In patients with HCV or NASH, phlebotomy may be beneficial in decreasing ALT activity and ameliorating liver damage, but additional long-term studies of iron depletion are needed to further assess the possible beneficial effects on the development of cirrhosis and hepatocellular carcinoma.

Table 36.7. Prevalence of *HFE* Mutations And Hepatitis C Virus In Patients With Porphyria Cutanea Tarda

Country (refs.)	No. of patients	Percentage with C282Y/C282Y	Percentage with at least one C282Y mutation	Percentage with at least one H63D mutation	Percentage HCV antibody–positive
United States (195)	70	19	42	31	56
United States (196)	108	19	41	29	59
Britain (197)	41	17	44	32	NR

Germany (199)	190	12	49	54	15
Australia (200)	27	11	44	44	26
Hungary (201)	50	6	16	36	44
Italy (202)	68	0	3	50	78

HCV, hepatitis C virus; NR, not reported.

Other Iron Storage Disorders

Secondary and Parenteral Iron Overload

Disorders of erythropoiesis and some forms of chronic liver disease can cause increased iron absorption and deposition in tissues (Table 36.2). In these disorders, the iron overload is said to be secondary because the increased absorption of dietary iron is a consequence of an underlying condition (34,35,203,204). A common factor in the iron-loading anemias is refractory anemia, characterized by hypercellular bone marrow and ineffective erythropoiesis. These conditions, which include β-thalassemia and the sideroblastic anemias, can be associated with clinical and pathologic consequences similar to those seen in *HFE*-related HH. In patients with disorders of erythropoiesis who undergo blood transfusions, the iron burden can be increased rapidly by the combined effects of increased iron absorption and the transfusion of iron (in hemoglobin). Therefore, iron toxicity to the liver, heart, and pancreas may develop many years earlier than in patients with *HFE*-related HH (34,205). To minimize iron-induced toxicity in patients with iron-

loading anemias, intensive chelation therapy with deferoxamine is required; this is started at the time when a commitment to long-term transfusion is made (34,35).

Parenteral iron overload is iatrogenic and results from transfusions of red blood cells, injections of iron–dextran, or long-term dialysis (34,35,36). Parenteral iron deposition is initially confined to cells of the RE system, including the Kupffer cells of the liver. When transfusions are required in disorders of erythropoiesis, parenchymal and RE iron overload can coexist. With long-term parenteral iron overload, iron also accumulates in the parenchyma, presumably through the uptake of iron released from RE cells. The degree of structural and functional damage

to the liver and endocrine organs generally parallels the degree of parenchymal iron overload. Sensitive magnetic resonance imaging (MRI) techniques are now available that accurately measure hepatic iron concentration noninvasively (206,207,208), and these may be particularly useful for ongoing assessment of chelation efficacy in patients with disorders of erythropoiesis.

African Iron Overload and Neonatal Iron Overload

The iron overload that occurs in people living in sub-Saharan Africa is now considered to be the result of a non–*HFE*-related genetic trait that can be exacerbated by dietary iron loading (28,29,30). Some persons with African iron overload consume an iron-rich beverage made from fermented maize, but iron overload also occurs in persons who do not drink this beverage. The distribution of accumulated iron in African iron overload is different from that in *HFE*-related HH in that the ratio of the splenic iron concentration to the hepatic iron concentration is higher in African iron overload (28). In addition, iron-loaded Kupffer cells are prominent in African iron overload, whereas the Kupffer cells are relatively spared in *HFE*-related HH. Nevertheless, both African iron overload and *HFE*-related HH can result in portal fibrosis and cirrhosis (28), and the risk for hepatocellular carcinoma is increased (209). Associations of African iron overload with diabetes mellitus, peritonitis, scurvy, and osteoporosis have been described (30). It has been reported that non–*HFE*-related iron overload may occur in African Americans (210,211,212), but further investigations are needed to determine the genetic basis, prevalence, and clinical consequences of this condition. A recent study indicates that approximately 20% of a cohort of Africans and African Americans with iron overload have a novel mutation (Q248H) in the ferroportin gene, suggesting that this mutation may contribute to iron loading (213).

Neonatal or perinatal iron overload is a rare disorder (fewer than 250 cases reported in the literature) in which severe liver disease is associated with parenchymal iron loading, relative sparing of Kupffer cells, and destruction of the normal liver architecture (31,32,33). Most cases have a fatal outcome, and treatment with deferoxamine or an antioxidant cocktail has not been effective (214). Several successful orthotopic liver transplantations have been performed in infants with neonatal iron overload, but long-term survival after this procedure has been disappointing (214). Some cases show evidence of autosomal recessive inheritance, but without mutations in the genes for *HFE*, β_2M, heme oxygenase, transferrin receptor 1, or ferritin (32,215). Neonatal iron overload recurs within sibships at a rate higher than that predicted for simple Mendelian autosomal recessive inheritance, suggesting the role of a maternal factor (32). Immunomodulation with intravenous high-dose immunoglobulin during pregnancy lessens the severity of disease, suggesting that recurrent neonatal iron overload may have an alloimmune component (33).

Summary

With the discovery of *HFE* and other genes involved in iron homeostasis, our understanding of the normal physiology of iron absorption and the pathophysiology associated with mutations of these genes has been dramatically enhanced. *HFE* mutation analysis has greatly improved the ability to diagnose *HFE*-related HH accurately, perform careful family screening, and evaluate patients with liver disease and abnormal results of iron studies.

Interestingly, population studies have revealed that many C282Y homozygotes do not have clinically significant iron overload, suggesting the influence of modifier genes. With a better understanding of the genes that modulate iron homeostasis, the reasons for the phenotypic variability of C282Y homozygotes may be discovered. Mutations in the iron-related genes encoding for hemojuvelin, hepcidin, ferroportin, TFR2, DMT1, and ferritin result in non–*HFE*-related HH. The pathogenesis of nearly all forms of HH involves an inappropriately low expression of hepcidin, an iron-regulatory hormone that acts to decrease the export of iron from duodenal enterocytes and RE cells. As a consequence of this low hepcidin expression, patients with HH having phenotypic expression have increased absorption of dietary iron and elevated TS. Timely phlebotomy treatment of patients with *HFE*-related HH prevents cirrhosis and other iron-induced toxicity.

Chapter 37

α_1-Antitrypsin Deficiency

David H. Perlmutter

Key Concepts

- Homozygous protease inhibitor phenotype ZZ (PIZZ) α_1-antitrypsin (α_1-AT) deficiency, which has an incidence of 1 in 1,600 to 1 in 2,000 live births, is the most common genetic cause of liver disease in children. It is also associated with chronic liver disease and hepatocellular carcinoma in adults. It is a well-known cause of pulmonary emphysema.
- α_1-AT is an approximately 55-kDa secretory glycoprotein that inhibits destructive neutrophil proteases, elastase, cathepsin G, and proteinase 3. Plasma α_1-AT is predominantly derived from the liver, and its level increases threefold to fivefold during the host response to tissue injury and inflammation. It is the archetype of a family of structurally related circulating serine protease inhibitors termed *serpins*.
- Although emphysema is caused by uninhibited proteolytic destruction of the connective tissue backbone of the lung, liver disease is thought to result from the toxic effects of the mutant α_1-AT molecule retained within the endoplasmic reticulum (ER) of liver cells.
- Screening studies by Sveger in Sweden have shown that only 8% of the PIZZ population have clinically significant liver disease in the first 20 years of life. One series of studies has suggested that a subgroup of PIZZ individuals are predisposed to liver injury because of an inefficient degradation of mutant α_1-ATZ within the ER.
- Altered migration of the abnormal α_1-AT molecule in isoelectric focusing gels is the basis of the diagnosis of α_1-AT deficiency.
- Management of α_1-AT deficiency–associated liver disease is mostly supportive. Liver replacement therapy has been used successfully for severe liver injury.
- Although the clinical efficacy has not been demonstrated, many patients with emphysema due to α_1-AT deficiency are being treated by means of intravenous and intratracheal aerosol administration of purified plasma α_1-AT. An increasing number of patients with severe emphysema are undergoing lung transplantation.

Incidence

The incidence of homozygous protease inhibitor phenotype ZZ (PIZZ) α_1-antitrypsin (α_1-AT) deficiency is highest among people of Scandinavian and northern European descent. This condition is present in approximately 1 in 1,600 to 1 in 2,000 live births (1). Although the incidence of the homozygous deficiency state in North American white populations was originally reported to be 1 in 6,700 live births (2),

more recent studies have demonstrated an incidence almost identical to that in Scandinavian populations (3).

Liver Disease: Clinical Manifestations

Liver involvement is often first noticed at the age of 1 to 2 months because of persistent jaundice. Conjugated bilirubin levels in the blood and serum transaminase levels are mildly to moderately elevated. The liver may be enlarged. Such infants are usually admitted to the hospital with a diagnosis of neonatal hepatitis syndrome and undergo a detailed diagnostic evaluation (4). Infants may also be initially evaluated for α_1-AT deficiency because of an episode of gastrointestinal bleeding, bleeding from the umbilical stump, or bruising (5). A small number of affected infants have hepatosplenomegaly, ascites, and liver synthetic dysfunction in early infancy. An even smaller number have severe fulminant hepatic failure in infancy (6). A few cases are recognized initially because of a cholestatic clinical syndrome characterized by pruritus and hypercholesterolemia. The clinical features among these infants resemble those of extrahepatic biliary atresia, but histologic examination shows a paucity of intrahepatic bile ducts.

Liver disease associated with α_1-AT deficiency may be discovered in late childhood or early adolescence, when the patient is seen with abdominal distension due to hepatosplenomegaly or ascites or with upper intestinal bleeding caused by esophageal variceal hemorrhage. In some of these cases, there is a history of unexplained prolonged obstructive jaundice during the neonatal period. In others, there is no evidence of any previous liver injury, even when the neonatal history is carefully reviewed.

α_1-AT deficiency should be considered in the differential diagnosis for any adult who has chronic hepatitis, cirrhosis, portal hypertension, or hepatocellular carcinoma of unknown origin. An autopsy study in Sweden showed a higher risk of cirrhosis among adults with α_1-AT deficiency than was previously suspected and indicated that α_1-AT deficiency has a strong association with primary liver cancer (7). This study raised the possibility that the risk of clinical liver disease is as high as 25% among men in the fifth and sixth decades of life (Table 37.1).

The only prospective data on the course of α_1-AT deficiency–associated liver injury are from the Swedish nationwide screening study conducted by Sveger (1). In this study, 200,000 newborn infants were screened and 127 PIZZ individuals were identified. Fourteen of the 127 had prolonged obstructive jaundice and 9 of the 14 had severe liver disease, as indicated by clinical and laboratory criteria. Another 8 of the 127 PIZZ infants had mildly abnormal serum bilirubin or serum transaminase levels or hepatomegaly. Approximately 50% of the rest of the 127 only had abnormal transaminase levels (8). Published results of follow-up studies of the original cohort of 127 PIZZ children at 18 years of age (9) show that more than 85% had persistently normal serum transaminase levels with no evidence of liver dysfunction. At 26 years of age, only 10% of the original population had evidence of elevated serum transaminase levels (Sveger T., personal communication, 2001). Issues not addressed by the Sveger study are whether 18-year-olds with α_1-AT deficiency have persistent subclinical histologic abnormalities, despite a lack of clinical or biochemical evidence of liver injury, and whether liver disease will eventually become clinically evident during adulthood.

Table 37.1. Liver Disease Associated With α_1-Antitrypsin Deficiency

CLINICAL FEATURES

- Prolonged jaundice in an infant
- Neonatal hepatitis syndrome
- Mild elevation of transaminase levels in a toddler
- Portal hypertension in a child or adolescent
- Severe liver dysfunction in a child or adolescent
- Chronic hepatitis in an adult
- Cryptogenic cirrhosis in an adult
- Hepatocellular carcinoma in an adult

DIAGNOSTIC FEATURES

- Diminished serum levels of α_1-antitrypsin
- Abnormal mobility of α_1-antitrypsin in isoelectric focusing (PIZ)
- Periodic acid–Schiff–positive, diastase-resistant globules in liver cells

It is still not clear what clinical manifestations or abnormal laboratory test results can be used to predict a poor prognosis for patients with α_1-AT deficiency–associated liver disease. Results of one study suggested that persistence of hyperbilirubinemia, hard hepatomegaly, early development of splenomegaly, and progressive prolongation of prothrombin time were indicators of poor prognosis (10). In another study, elevated transaminase levels, prolonged prothrombin time, and a lower trypsin inhibitor capacity correlated with a worse prognosis (11). However, the author and his colleagues have found that some children with α_1-AT deficiency–associated liver disease can lead relatively normal lives for years after the development of hepatosplenomegaly and mild prolongation of prothrombin time. In a review of 44 patients with α_1-AT deficiency seen in the specialty practice at St. Louis Children's Hospital, 17 patients had cirrhosis, portal hypertension, or both (12). Nine of the 17 patients with cirrhosis or portal hypertension had a prolonged, relatively uneventful course for at least 4 years after the diagnosis of cirrhosis or portal hypertension. Two of these patients eventually underwent liver transplantation, but seven were leading relatively healthy lives for as long as 23 years after being diagnosed as having severe α_1-AT deficiency–associated

liver disease. Patients with the prolonged stable course could be differentiated from those with a rapidly progressive course on the basis of overall life functioning but not on the basis of other more conventional clinical or biochemical criteria. Therefore, prediction of poor prognosis for α_1-AT deficiency–associated liver disease and for the timing of liver transplantation depends more on the overall functioning of the child than on the histologic findings or laboratory data.

There is currently no evidence that the heterozygous α_1-AT phenotype causes liver disease in children by itself. It is not clear whether heterozygous adults are predisposed to liver injury. Early studies of liver biopsy collections suggested that there was a relation between heterozygosity and the development of liver disease (13). A retrospective study at the Mayo Clinic showed a higher prevalence of heterozygosity for α_1-ATZ in liver transplant recipients than in the general population, including a group of patients without another explanation for liver disease (14). However, both these studies were biased in ascertainment and did not include concurrent prospective controls. Results of a cross-sectional study of patients with α_1-AT deficiency in a referral-based Austrian university hospital, who were reexamined with the most sophisticated and sensitive assays available, suggested that liver disease in heterozygotes can be accounted for, to a great extent, by infections with hepatitis B or C virus or by autoimmune disease (15).

Although the foregoing findings taken together give a strong impression that heterozygotes for α_1-ATZ are susceptible to liver disease, the literature does not provide convincing evidence that liver injury can be explained by the α_1-AT heterozygous state alone.

Liver disease has been described for several other allelic variants of α_1-AT. Children with compound heterozygosity type PISZ are affected by liver injury in a manner similar to that of PIZZ children (1,8,9). There are several reports of liver disease in α_1-AT deficiency–type PIMMalton (16,17). This is a particularly interesting association because the abnormal PIMMalton α_1-AT molecule has been shown to undergo polymerization and retention within the endoplasmic reticulum (ER) (17). Liver disease has been detected in single patients with several other α_1-AT allelic variants, such as PIMDuarte (18), PIW (19), and PIFZ (20), but it is not clear whether other causes of liver injury for which there are more sophisticated diagnostic assays, such as infection with hepatitis C and autoimmune hepatitis, have been completely excluded in these cases.

Lung Disease: Clinical Manifestations

The association between α_1-AT deficiency and the premature development of pulmonary emphysema is well documented (21). Cigarette smoking markedly accelerates this destructive lung disease, reduces the quality of life, and markedly shortens the longevity of these persons (22). There is still, however, wide variability in the incidence and severity of destructive lung disease within the α_1-AT–deficient population (23). There are even PIZZ individuals who smoke but do not have any symptoms of lung disease or pulmonary function abnormalities or do not experience them until the seventh or eighth decade of life. Although results of one study have suggested the possibility that a subtle degree of hyperinflation can be detected with pulmonary function testing in infants with α_1-AT deficiency (24), results of another study did not show any significant difference between the pulmonary function of PIZZ individuals aged 13 to 17 and that of an age-matched control group (25). True clinical symptoms of α_1-AT deficiency–associated emphysema do not begin until the third decade of life. The usual initial symptoms are shortness of breath, wheezing, cough, sputum production, and frequent chest infections (26).

There is still limited information about the incidence of liver disease among persons with α_1-AT deficiency and emphysema. In one recent study of 22 PIZZ patients with emphysema, there was an elevated transaminase level in 10 patients, and cholestasis was present in 1 patient (27). Liver biopsies were not performed in this study and may be necessary for the accurate determination of the extent of liver injury in these patients.

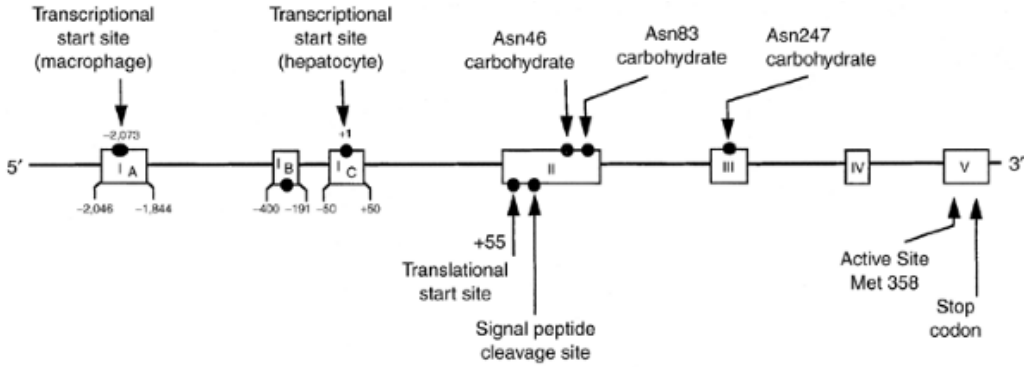
α_1-Antitrypsin Structure, Function, and Physiology

α_1-Antitrypsin Gene Structure

α_1-AT is encoded by a 12.2-kb gene on chromosome 14q31-32.3 (28). There is a sequence-related gene approximately 12 kb downstream. Because there is no evidence that it is expressed, the downstream gene is considered a pseudogene.

The gene (Fig. 37.1) is composed of five exons and four introns (29). Exon I_C, the 5′ portion of exon II, and the 3′ portion of exon V are noncoding regions. The first intron is 5.3 kb long, contains a short open reading frame, an Alu family sequence, and a pseudotranscription initiation codon. Apparently, the short open reading frame does not code for protein. The α_1-AT messenger ribonucleic acid (mRNA) expressed in the liver is 1.4 kb long (30). In macrophages, the α_1-AT mRNA is slightly longer (30). There are three forms of α_1-AT mRNA in macrophages, depending on

transcription initiation sites in two upstream exonic structures (exons I_A and I_B) (30, 31).



▪ **Figure 37.1** Schematic representation of the structure of the α_1-antitrypsin gene (*not to scale*).

α_1-Antitrypsin Protein Structure

α_1-AT is a single-chain, approximately 55-kDa polypeptide with 394 amino acids and three asparagine-linked complex carbohydrate side chains (32). There are two major serum isoforms depending on the presence of a biantennary or triantennary configuration of the carbohydrate side chains. α_1-AT is the archetype of a family of structurally related proteins called *serpins* (serine protease inhibitors), which includes antithrombin III, α_1-antichymotrypsin, C1 inhibitor, α_2-antiplasmin, protein C inhibitor, heparin cofactor II, plasminogen activator inhibitors I and II, and protease nexin I (33). A serpin-like structure is also found in several cellular proteins, trophic factors, and circulating carrier proteins, such as corticosteroid- and thyroid hormone–binding globulin.

Many studies of the structural characteristics of α_1-AT have shown that it is essentially composed of two central β sheets surrounded by a small β sheet and nine α-helices (33). The dominant structure is the five-stranded, β-pleated sheet called the *A sheet* (Fig. 37.2). A mobile reactive center loop rises above a gap in the center of the A sheet (34,35,36).

The Protease Inhibitor System for Classification of Structural Variants of α_1-Antitrypsin

Variants of α_1-AT in humans are classified according to the PI phenotype system, as defined by agarose electrophoresis or isoelectric focusing of plasma in polyacrylamide at acid pH (37). The PI classification system assigns a letter to variants according to migration of the major isoform. For example, the most common normal variant migrates to an intermediate isoelectric point, designated M. Persons with the most common severe deficiency have an α_1-AT allelic variant that migrates to a high isoelectric point, designated Z (Fig. 37.3). Even greater polymorphic variation of α_1-AT has been detected by means of restriction fragment length and direct deoxyribonucleic acid (DNA) sequence analysis. With these techniques, in addition to isoelectric focusing, investigators have identified more than 100 allelic

variants (38).

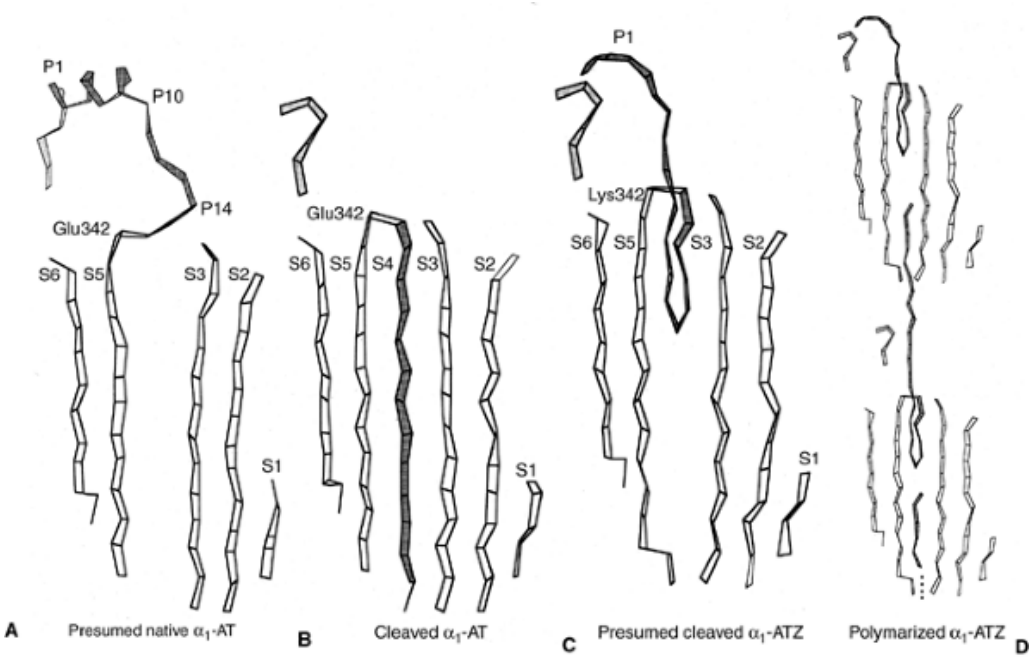
Normal allelic variants

The most common normal variant of α_1-AT is termed *M1* and is found in 65% to 70% of whites in the United States (2). There are many rare normal allelic variants with allelic frequencies of less than 0.1%. For each of these variants, serum concentration and functional activity of α_1-AT are within the normal range.

Null allelic variants

α_1-AT variants in which α_1-AT is not detectable in serum are called *null allelic variants* (Table 37.2). The inheritance of a null allelic variant with another null variant or a deficiency variant is associated with premature development of emphysema (39,40). There is no evidence for liver injury in persons with null variants who were examined in detail (41). Potential molecular mechanisms for the null phenotype have been identified by DNA sequence analysis of a number of null variants (38,39,40,41,42,43,44). They include deletion of all α_1-AT coding exons, substitutions that result in stop codons, frameshift mutations, and single base substitutions. In at least three cases, the frameshift mutation resulted in an abnormal truncated protein that is retained in the ER ($null_{Hong\ Kong}$, $null_{Clayton}$, $null_{Saarbrucken}$) (41,42,43,45). Detailed study of some of these variants has raised questions about the classification. Although α_1-AT was not detected in the serum of a patient with what has been called α_1-AT $null_{Ludwigshafen}$ (44), this mutant molecule is synthesized and secreted in transfected heterologous cells (46). Its rate of secretion is slightly decreased and

the secreted mutant protein lacks functional activity. It is not yet known whether instability or accelerated catabolism in vivo is the explanation for the inability to detect this mutant α_1-AT molecule in serum specimens.



▪ **Figure 37.2** Ribbon diagrams of the A sheet and reactive-site loop of α_1-antitrypsin (α_1-AT) in several different states. **A:** Presumed native α_1-AT. This state is presumed because it has not been crystallized; however, it is generated

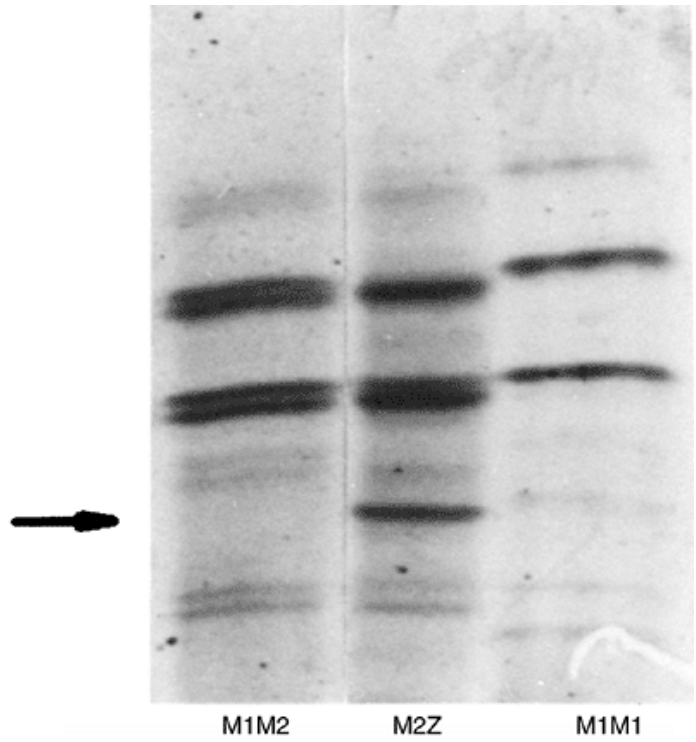
by computer models on the basis of the crystal structures of cleaved α_1-AT and native ovalbumin. The reactive-site loop is shown as a densely dotted ribbon. The β-helices of the A sheet are shown in white and are referred to as S1 to S6. The position of glutamate 342 is indicated. There is a gap in the A sheet between S3 and S5. **B:** Cleaved α_1-AT. The reactive-site loop is cleaved. It inserts into the A sheet and is now referred to as S4. **C:** Presumed cleaved α_1-ATZ. The reactive-site loop spontaneously collapses into the gap in the A sheet, but because of the substitution of lysine at residue 342, it cannot fully insert. **D:** Polymerized α_1-ATZ. The gap in the A sheet of the upper α_1-ATZ molecule is now filled with the reactive-site loop of the lower α_1-ATZ molecule. The gap in the A sheet of the lower α_1-ATZ molecule is filled with the reactive-site loop of another α_1-ATZ molecule represented by a *dotted line*. (Adapted from Carrell RW, Evans DL, Stein DE. Mobile reactive centre of serpins and the control of thrombosis. *Nature* 1991;353:576and Lomas DA, Evans DL, Finch JT, et al. The mechanism of Z α1-antitrypsin accumulation in the liver. *Nature* 1992;357:605, with permission.)

Dysfunctional variants

α_1-$AT_{Pittsburgh}$ is the most well-characterized dysfunctional variant (47), which was identified in a 14-year-old boy who died of an episodic bleeding disorder. A single–amino acid substitution, Met to Arg at residue 358, converted α_1-AT from an elastase inhibitor to a thrombin inhibitor. The episodic nature of the illness was attributed to changes in the synthesis of the mutant protein during the host response to acute inflammation and tissue injury, the acute-phase response. The α_1-AT $M_{Mineral\ Springs}$ (46,48) and $null_{Ludwigshafen}$ (44,46) probably are other examples of dysfunctional variants.

Deficiency variants

Several variants of α_1-AT that are associated with a reduction in serum concentrations have been described and are called *deficiency variants* (Table 37.3). Some of these variants are not associated with clinical disease, such as the S variant (29,49). Other deficiency variants are associated only with emphysema, such as $M_{Heerlen}$ (50), $M_{Procida}$(51), and P_{Lowell} (52). In two persons with M_{Malton} and one with M_{Duarte}, hepatocyte α_1-AT inclusions and liver disease have been found with emphysema (16,17,18). In one person with the α_1-AT S_{Iiyama} variant, emphysema and hepatocyte inclusions were reported, but this patient did not have liver disease (53). The most common deficiency variant, the Z variant, is associated with emphysema and liver disease, as discussed later.



▪ **Figure 37.3** Isoelectric focusing of human serum samples for diagnosis of α_1-antitrypsin deficiency. Serum samples from a person with the normal M1M2 variant, from an M2Z heterozygote, and from a person with the normal M1M1 variant were subjected to isoelectric focusing with the anode at top and cathode at bottom. Migration of the Z allele is indicated by the *arrow.* (Gel provided by JA Pierce, St. Louis, MO. From Perlmutter DH. Alpha-1-antitrypsin deficiency. In: Snape WJ, ed. *Consultations in gastroenterology*. Philadelphia: WB Saunders; 1996:793, with permission.)

Function

α_1-AT is an inhibitor of serine proteases in general, but its most important targets are neutrophil elastase, cathepsin G, and proteinase 3, proteases released by activated neutrophils. Several lines of evidence suggest that inhibition of neutrophil elastase is the major physiologic role of α_1-AT. First, persons with α_1-AT deficiency are susceptible to premature development of emphysema, a lesion that can be induced in experimental animals by means of instillation of excessive amounts of neutrophil elastase (54). These observations have led to the concept that destructive lung disease may result from perturbations of the net balance of elastase and α_1-AT within the local environment of the lung (55). Second, the kinetics of association for α_1-AT and neutrophil elastase are more favorable, by several orders of magnitude, than those for α_1-AT and any other serine protease (56). Third, α_1-AT constitutes more than 90% of the neutrophil elastase inhibitory activity in the one body fluid that has been examined—pulmonary alveolar lavage fluid (55).

α_1-AT acts competitively by allowing its target enzymes to bind directly to a substrate-like region within its reactive center loop. The reaction between enzyme and inhibitor is essentially of second order, and the resulting complex contains one molecule of each of the reactants. A reactive-site peptide bond within the inhibitor is

hydrolyzed during the formation of the enzyme–inhibitor complex. The complex of α_1-AT and serine protease is a covalently stabilized structure resistant to dissociation by denaturing compounds, including sodium dodecyl sulfate and urea. The interaction between α_1-AT and serine protease is suicidal in that the modified inhibitor is no longer able to bind with or inactivate the enzyme. There is also a profound alteration in the structure of the enzyme, including disruption of the catalytic site, such that the enzyme becomes inactive and subject to proteolytic destruction (57). Studies have shown that the irreversible trapping of target enzyme is mediated by a profound conformational change in α_1-AT, such that the cleaved reactive-loop binding enzyme inserts into the gap in the A sheet (58). Carrell and Lomas (58) likened the inhibitory mechanism to a mousetrap: The active inhibitor circulates in the metastable, stressed form and then springs into the stable, relaxed form to lock the complex with its target protease.

The net functional activity of α_1-AT in complex biologic fluids may be modified by several factors. First, the reactive-site methionine may be oxidized and thereby rendered inactive as an elastase inhibitor (59). In vitro, α_1-AT is oxidatively inactivated by oxidants released by activated neutrophils and alveolar macrophages of cigarette smokers (60,61). Second, the functional activity of α_1-AT may be modified by proteolytic inactivation. Several members of the metalloproteinase family, including collagenase and *Pseudomonas* elastase, and the thiol protease family can cleave and inactivate α_1-AT (62). Studies have shown that the pathogenesis of bullous pemphigoid may involve uninhibited neutrophil elastase activity at the dermal–epidermal junction because α_1-AT is cleaved and inactivated by matrix metalloproteinase-9 (MMP-9)–gelatinase B in the skin (63,64). Third, DNA, which is often released from neutrophils at sites of inflammatory activation and phagocytosis, can impair the cathepsin G inhibitory activity of α_1-AT (65).

Although α_1-AT from the plasma or liver of persons with PIZZ α_1-AT deficiency is functionally active (66), there may be a decrease in its specific elastase inhibitory capacity. Ogushi et al. (67) showed that the kinetics of association with neutrophil elastase and the stability of complexes with neutrophil elastase were significantly decreased for α_1-AT isolated from PIZZ plasma. There was no decrease in the functional activity of α_1-AT in individuals homozygous for the S variant.

Results of several studies have indicated that α_1-AT protects experimental animals from the lethal effects of tumor necrosis factor (68,69). Most of the evidence from these studies indicates that this protective effect

is due to inhibition of the synthesis and release of platelet-activating factor from neutrophils (69,70), presumably through the inhibition of neutrophil-derived proteases. The antiapoptotic effect of α_1-AT on vascular smooth muscle cells (71) also probably involves the inhibition of extracellular matrix degradation by neutrophil-derived proteases.

Table 37.2. Null Variants of α_1-Antitrypsin

Results of several studies indicate that α_1-AT has functional activities other than the inhibition of serine protease. The carboxyl-terminal fragment of α_1-AT, which can be generated during the formation of a complex with serine protease or during proteolytic inactivation by thiolproteinases or metalloproteinases, is a potent neutrophil chemoattractant (72). The chemotactic response is equivalent to that elicited by formyl-methionyl-leucyl-phenylalanine. The carboxyl-terminal fragment of α_1-AT is also responsible for an increase in synthesis of α_1-AT in human monocytes

and macrophages when these cells are incubated with exogenous neutrophil elastase (73). In each case, the biologic effect is mediated by the interaction of a pentapeptide neodomain within the carboxyl-terminal fragment of α_1-AT and a novel cell-surface receptor, the serpin–enzyme complex (SEC) receptor (74,75,76).

Results of a provocative series of experiments suggested that α_1-AT inhibits human

immunodeficiency virus 1 (77). Separate mechanisms for inhibition of infectivity and production of intact virus were implicated, but the results have not been independently corroborated.

There have been several reports that α_1-AT alters immune function through effects on lymphocytes (2,78). However, there are inherent conflicts in some of the reports, and data have not been duplicated. There is no evidence that the immune response is systemically altered in persons with α_1-AT deficiency.

Biosynthesis of α_1-Antitrypsin

The predominant site of synthesis of plasma α_1-AT is the liver. This is most clearly shown by conversion of plasma α_1-AT to the donor phenotype after orthotopic liver transplantation (79). α_1-AT is synthesized in human hepatocellular carcinoma cells as a 52-kDa precursor; undergoes post-translational, dolichol phosphate–linked glycosylation at three asparagine residues (80); and undergoes tyrosine sulfation (81). It is secreted as a 55-kDa native single-chain glycoprotein with a half-time for secretion of 35 to 40 minutes.

Tissue-specific expression of α_1-AT in human hepatocellular carcinoma cells is directed by structural elements within a 750-nucleotide region upstream of the hepatocyte transcriptional start site in exon I_C. Within these regions are structural elements that are recognized by nuclear transcription factors, including hepatocyte nuclear factor-1α (HNF-1α), HNF-1β, CCAAT/enhancer-binding protein (C/EBP), HNF-4, and HNF-3 (82). HNF-1α and HNF-4 appear to be particularly important for the expression of the human α_1-AT gene in liver cells and intestinal epithelial cells (83). Two distinct regions within the proximal element bind these two transcription factors. Substitution of five nucleotides at positions 77 to 72 disrupts binding of HNF-1α and dramatically reduces expression of the human α_1-AT gene in the liver of transgenic mice (84). Substitution of four nucleotides at positions 118 to 115 disrupts the binding of HNF-4 but does not alter expression of the human α_1-AT gene in the liver of adult transgenic mice. The latter mutation does reduce expression of human α_1-AT in the liver during embryonic development.

Plasma concentrations of α_1-AT increase threefold to fivefold during the host response to inflammation or tissue injury (85). The source of this additional α_1-AT has always been considered the liver; therefore, α_1-AT is known as a *positive hepatic acute-phase reactant*. Synthesis of α_1-AT in human hepatocellular carcinoma cells (e.g., HepG2, Hep3B) is upregulated by interleukin-6 (IL-6) but not by IL-1 or tumor necrosis factor (86). Plasma concentrations of α_1-AT also increase during oral contraceptive therapy and pregnancy (87). α_1-AT is also synthesized and secreted in primary cultures of human blood monocytes and bronchoalveolar and breast milk macrophages (88). Expression of α_1-AT in monocytes and macrophages is influenced by products generated during inflammation, such as bacterial lipopolysaccharide (89) and IL-6 (86).

A series of studies has elucidated a feed-forward regulatory loop that probably represents the dominant mechanism for regulating the synthesis of α_1-AT in cells and tissues. In this regulatory loop, elastase–α_1-AT complexes mediate an increase in the synthesis of α_1-AT through a specific cell-surface receptor (74). The effect on α_1-AT synthesis can be elicited by synthetic peptides corresponding to a domain in the carboxyl-terminal fragment of the α_1-AT molecule that is exposed only after the structural rearrangement that accompanies complex formation or proteolytic modification. These synthetic peptides bind specifically and saturably to a single class of receptors on the cell surface of monocytes and human hepatocellular carcinoma HepG2 cells (dissociation constant [K_d], approximately 40 nmol/L; 4.5×10^5 plasma membrane receptors per cell). This class of receptor molecules is now

called *SEC receptors* because the receptors recognize the highly conserved domains of other SECs, such as antithrombin-III–thrombin, α_1-antichymotrypsin–cathepsin G, and, to a lesser extent, C1 inhibitor–C1s and tissue plasminogen activator–plasminogen activator inhibitor I complexes, as well as that of α_1-AT–elastase complexes (74,90). Substance P, several other tachykinins, bombesin, and the amyloid-β peptide bind to the SEC receptor through a similar pentapeptide sequence (91). Results of our most recent studies indicate that the SEC receptor can mediate endocytosis of soluble amyloid-β peptide, but it does not recognize the aggregated form of amyloid-β peptide, which is toxic to neurons and other cell types (92). Therefore, the SEC receptor may play a role in preventing amyloid-β peptide from accumulating in the amyloid deposits associated with Alzheimer's disease.

α_1-AT mRNA has been isolated from several tissues in transgenic mice (93), but in many cases it has not been possible to determine whether this mRNA is in ubiquitous tissue macrophages or other cell types. α_1-AT is synthesized in enterocytes and Paneth cells, as indicated by the results of studies with intestinal epithelial cell lines, ribonuclease protection assays of human intestinal ribonucleic acid (RNA), and in situ hybridization analysis in cryostat sections of human

intestinal mucosa (94). Expression of α_1-AT in enterocytes increases markedly during differentiation from crypt to villus, in response to IL-6, and during inflammation in vivo. α_1-AT is also synthesized by pulmonary epithelial cells (95,96). Synthesis of α_1-AT in pulmonary epithelial cells is less responsive to regulation by IL-6 than by a related cytokine, oncostatin M (96). Moreover, there is evidence that HNF-1β, and not HNF-1α, HNF-4, or HNF-3, plays a predominant cell-specific role in transcription of the α_1-AT gene in pulmonary epithelial cells (97).

Clearance and Distribution

The half-life of α_1-AT in plasma is approximately 5 days (98). It is estimated that the daily production rate of α_1-AT is 34 mg/kg body weight, 33% of the intravascular pool of α_1-AT being degraded daily. There is a slight increase in the rate of clearance of radiolabeled PIZ α_1-AT compared with that of PIM α_1-AT when infused into PIMM individuals, but this difference does not account for the decrease in serum levels of α_1-AT in persons with the deficiency (99). The low-density lipoprotein receptor–related protein (LRP) family probably plays a major role in the clearance and catabolism of α_1-AT when it is in complex with neutrophil elastase (100,101). The SEC receptor may be involved in the clearance and catabolism of both complex and modified forms of α_1-AT (90,102), but this has not yet been tested in vivo. The mechanism of clearance of native α_1-AT is not yet known (103).

α_1-AT diffuses into most tissues and is found in most body fluids (55). Its concentration in lavage fluid from the lower respiratory tract is approximately equivalent to that in serum. α_1-AT is also found in feces, and increased fecal concentrations of α_1-AT correlate with the presence of inflammatory lesions of the bowel (104). In each case, it is assumed that α_1-AT is derived from serum. However, local sites of synthesis, such as macrophages and epithelial cells, may make important contributions to the α_1-AT pool in these tissues and body fluids.

Pathogenesis of Liver Injury in PIZZ Individuals

There are several theories for the pathogenesis of liver injury in α_1-AT deficiency. According to the *immune theory*, liver damage results from an abnormal immune response to liver antigens (105). This theory is based on the observation that peripheral blood lymphocytes from PIZZ infants are cytotoxic for isolated hepatocytes; however, this is probably a nonspecific effect of liver injury, in that peripheral blood lymphocytes from PIMM infants with a similar degree of liver injury

due to idiopathic neonatal hepatitis syndrome are also cytotoxic for isolated hepatocytes. More recent studies have indicated an increase in the human leukocyte antigen (HLA)-DR3-DW25 haplotype in α_1-AT–deficient persons with liver disease (106). However, there is no difference between the expression of major histocompatibility complex (MHC) class II antigen in the livers of these persons and its expression in healthy controls (107). Moreover, an increase in the prevalence of a particular HLA-DR haplotype in the affected population does not by itself imply altered immune function. Because of the linkage disequilibrium displayed by genes within the MHC, it is possible that increased susceptibility is caused by the products of unrelated but linked genes. For example, the MHC contains genes for several heat-shock/stress proteins (108), which play an important role in the biogenesis and transport of other proteins through the secretory pathway.

The *accumulation theory*, in which liver damage is thought to be caused by accumulation of mutant α_1-AT molecules in the ER of liver cells, is the most widely accepted. Experimental results with transgenic mice are most consistent with this theory and completely exclude the possibility that liver damage is caused by "proteolytic attack" as a consequence of diminished serum α_1-AT concentrations. Transgenic mice carrying the mutant Z allele of the human α_1-AT gene develop periodic acid–Schiff-positive, diastase-resistant intrahepatic globules and liver injury early in life (109,110). Because there are normal levels of α_1-AT and presumably other antielastases in these animals, as directed by endogenous murine genes, the liver injury cannot be attributed to proteolytic attack. Therefore, liver damage in this deficiency is thought to involve a gain-of-toxic function mechanism.

It has been difficult to reconcile the accumulation theory with the observations of Sveger and Eriksson (8,9), who showed that only a subset of PIZZ α_1-AT–deficient persons sustain marked liver damage. The author and his colleagues have predicted that a subset of the PIZZ population is more susceptible to liver injury through the presence of one or more additional inherited traits or environmental factors that exaggerate the intracellular accumulation of the mutant Z α_1-AT protein or exaggerate the cellular pathophysiologic consequences of mutant α_1-AT accumulation (111). A direct examination of this prediction follows.

Mechanism for Deficiency of α_1-Antitrypsin in PIZZ Individuals

The mutant α_1-ATZ molecule is characterized by a single nucleotide substitution that results in a

single–amino acid substitution, Lys for Glu342 (112,113,114). There is a selective decrease in the secretion of α_1-AT, the abnormal protein accumulating in the ER (115,116,117,118). The defect is not specific to liver cells because it also affects extrahepatic sites of α_1-AT synthesis, such as macrophages (115) and transfected cell lines (117,118,119,120). Site-directed mutagenesis studies have shown that this single–amino acid substitution is sufficient to produce the cellular defect (118,119,120). Once translocated into the lumen of the ER, the mutant α_1-AT protein is unable to traverse the remainder of the secretory pathway because it is abnormally folded.

Several studies have provided evidence that the substitution of Glu342 by Lys in the α_1-ATZ variant decreases the stability of the molecule in its monomeric form and increases the likelihood that it will form polymers by means of a so-called loop-sheet insertion mechanism (99). In this mechanism, the reactive center loop of one α_1-AT molecule inserts into a gap in the β-pleated A sheet of another α_1-AT molecule (Fig. 37.2). Lomas et al. (121) were the first to notice that the site of the amino acid substitution in the PIZ α_1-AT variant was at the base of the reactive center loop,

adjacent to the gap in the A sheet. These investigators predicted that a change in the charge at this residue, as occurs with the substitution of Lys for Glu, would prevent insertion of the reactive-site loop into the gap in the A sheet during interaction with enzyme; therefore, the mutant α_1-ATZ would be susceptible to the insertion of the reactive center loop of adjacent molecules into the gap in its A sheet. This would cause the mutant α_1-ATZ to be more susceptible to polymerization than the wild-type α_1-AT. The results of these experiments showed that α_1-ATZ undergoes this form of polymerization spontaneously to a certain extent, and to a greater extent during relatively minor perturbations, such as an increase in temperature. Presumably, an increase in body temperature during systemic inflammation would exacerbate this tendency in vivo. Polymers have also been detected by means of electron microscopic examination of the ER of hepatocytes in a liver biopsy specimen from a PIZZ individual (121). Similar polymers have been found in the plasma of patients with the PIS_{Iiyama} α_1-AT variant and the PIM_{Malton} α_1-AT variant (122,123). The mutations in α_1-AT PIS_{Iiyama} (Ser53 to Phe) (53) and α_1-ATPIM_{Malton} (Phe52 deletion) (17) affect residues that provide a ridge for the sliding movement opening the A sheet. Therefore, these mutations would be expected to interfere with the insertion of the reactive center loop into the gap in the A sheet and therefore leave the gap in the A sheet available for spontaneous loop-sheet polymerization. It is interesting that the hepatocytic α_1-AT globules have been found in a few patients with these two variants. Recent observations suggest that the α_1-ATS variant also undergoes loop-sheet polymerization (124) and that this may account for its retention in the ER, although to a milder extent than that for α_1-ATZ (49).

Loop-sheet insertion also appears to be responsible for polymerization of other serpins in clinical deficiency states, including antithrombin deficiency (125) and C1 inhibitor deficiency (126). A striking example of this phenomenon is the familial dementia associated with Collins bodies. Studies by Davis et al. (127) have shown that these neuronal inclusion bodies contain a polymerized mutant neuroserpin.

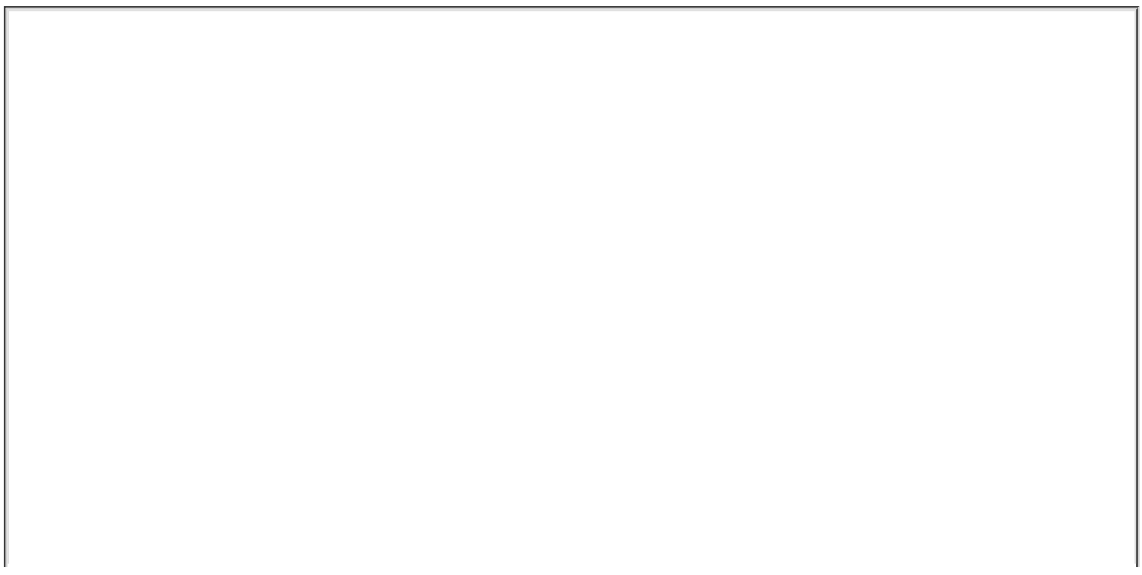
The precise mechanism by which the loop-sheet insertion develops is not yet completely understood and may be more complicated than previously predicted (123). Further studies to characterize the mechanism more precisely will, undoubtedly, be forthcoming.

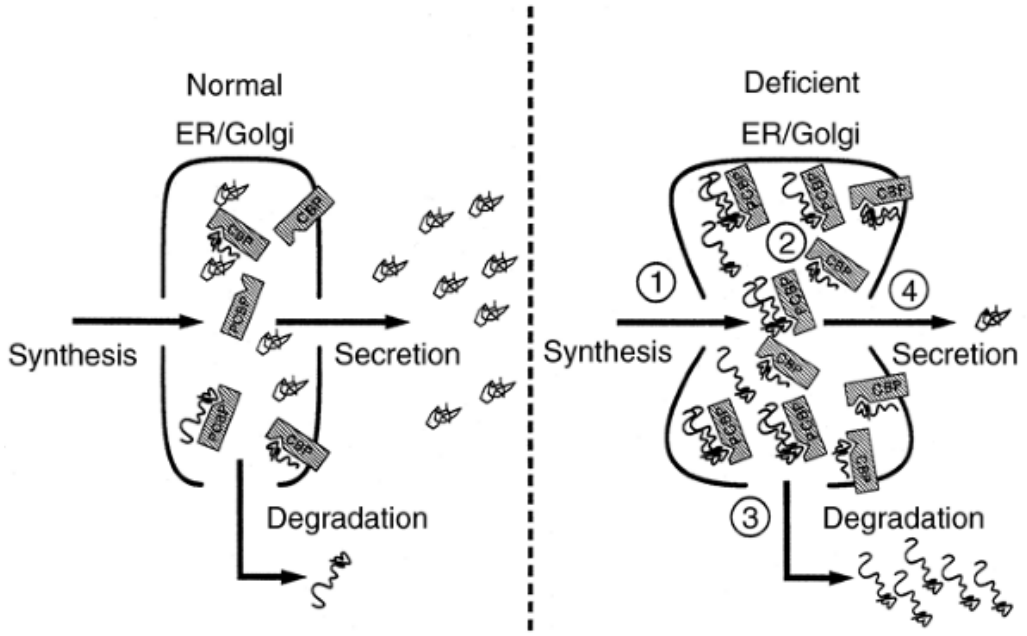
Yu et al. (128) compared the folding kinetics of α_1-ATZ in transverse urea gradient gels. The results of the study showed for the first time that α_1-ATZ folds at an extremely slow rate, unlike the wild-type α_1-AT, which folds in minutes. This folding defect leads to the accumulation of an intermediate that has a high tendency to polymerize, presumably by the loop-sheet insertion mechanism.

Several subsequent studies have suggested that polymerization is the cause of retention of α_1-ATZ in the ER of liver cells. The most powerful of these are studies showing partial correction of the secretory defect by insertion of a second mutation into the α_1-ATZ protein that suppresses loop-sheet polymerization (129,130,131). However, these studies do not exclude the possibility that there is an abnormality in folding that is distinct from the tendency to polymerize and is also partially corrected by the second, experimentally introduced mutation. More recent studies cast some doubt on the concept that polymerization is the cause of ER retention. First, naturally occurring variants of α_1-AT, in which the carboxyl-terminal tail is truncated, including a double mutant with the substitution that characterizes the Z allele together with the substitution that results in carboxyl-terminal truncation, are retained in the ER of liver cells although they do not form polymers (45). Second, only a minor proportion (approximately 18%) of the intracellular pool of α_1-ATZ at steady state in model cell lines is in the form of polymers (45,132). Moreover, because the remainder of α_1-ATZ in the ER in vivo is in the form of heterogeneous

soluble complexes with multiple ER chaperones (132), the principles by which purified α_1-ATZ polymerizes in vitro are probably not applicable to what happens in live cells in vivo. Taken together, the extant data suggest that polymerization is not the cause by which α_1-ATZ is retained in the ER of liver cells but rather is the result of its retention. Nonetheless, the polymerogenic properties of the Z mutant are still likely to be critical determinants in the pathobiology of liver disease.

To understand how polymerization of α_1-AT or alteration in the folding of monomeric α_1-AT might result in retention within the ER, we must consider what is known about the biology of protein secretion. Most newly synthesized secretory proteins are translocated into the lumen of the ER together with membrane proteins. Before being transported to their final destination, these nascent secretory and membrane polypeptide chains undergo a series of post-translational modifications, including glycosylation, formation of disulfide bonds, oligomerization, and folding. It is still not clear, however, whether the mechanism by which the secretory proteins are transported out of the ER involves one of three possible alternatives: (a) The protein encodes a transport signal by which it is recognized for selective removal from the ER and is concentrated as cargo in a departing vesicle, (b) the protein encodes a signal for retention in the ER and restricts it from entering a departing vesicle, or (c) the protein lacks both transport and retention signals and enters, by means of bulk flow, the budding vesicles at its prevailing concentration in the ER (133). Recent studies have provided evidence for the involvement of each of these mechanisms (134). Several cargo receptors, which direct transport out of the ER, have been identified, but so far we know of only a select group of secretory protein ligands governed by this mechanism. Retention within the ER is thought to constitute the quality control apparatus of the cell by which incompletely assembled, improperly folded, and mutant proteins are recognized and ultimately degraded to prevent them from causing damage to the cell. Several families of resident ER proteins, termed *molecular chaperones*, appear to be involved in this quality control apparatus. One family has been referred to as the *polypeptide chain binding protein family* and includes several heat-shock and heat-stress proteins, GRP78/BiP and GRP94, protein disulfide isomerase, and Erp72 (135). Several calcium-binding phosphoproteins of the ER, most notably calnexin and calreticulin, also have molecular chaperone activity within the ER. Calnexin is an approximately 88-kDa transmembrane ER resident phosphoprotein that was originally discovered in association with MHC class I molecules (136). It facilitates the assembly of the MHC class I with antigenic peptide. It has also been shown to interact transiently with folding and assembly intermediates of a wide array of soluble proteins (137).





▪ **Figure 37.4** Conceptual model for liver injury in α_1-antitrypsin (α_1-AT) deficiency. Polypeptide chain–binding proteins (*PCBP*) and membrane-associated calcium-binding proteins (*CBP*) are shown as *hatched bars*. The α_1-AT molecules that are unfolded or misfolded are shown as *long wavy lines*, and those that are maturely folded are shown as *condensed masses*. In the normal state, α_1-AT enters the secretory pathway (endoplasmic reticulum [*ER*]) unfolded. Interaction with PCBP or CBP facilitates folding into a mature state and allows dissociation from the PCBP or CBP in a form competent for secretion. A relatively minor proportion of the α_1-AT molecules that do not fold into the mature state are directed into a pathway for degradation in, or through, the ER. In a person with α_1-AT deficiency, only a minor proportion of the mutant α_1-AT molecules achieve the mature, folded state that allows secretion. There is a net accumulation of α_1-AT molecules in the ER and an increase in α_1-AT molecules directed into the pathway for degradation. Further intracellular accumulation of α_1-AT, which is potentially hepatotoxic, could result from increased synthesis of α_1-AT (1), abnormalities in interaction with PCBP or CBP (2), abnormalities in degradative enzymes (3), or abnormalities in bulk flow that allow secretion (4) of 10% to 15% of the newly synthesized mutant α_1-ATZ molecules.

Polymerization of α_1-ATZ or alteration in the folding of monomeric α_1-ATZ could result in ER retention because it prevents an essential transport signal from being recognized or because it newly exposes a signal for retention (Fig. 37.4). Net retention of mutant α_1-ATZ in the ER also depends, to a certain extent, on its rate of degradation in the ER. A number of studies have provided evidence of degradative systems in the ER and evidence that such systems are involved in the degradation of misfolded or incompletely assembled proteins (137). Any defect in the interaction between α_1-ATZ and ER molecular chaperones or in an ER degradation pathway could predispose a person

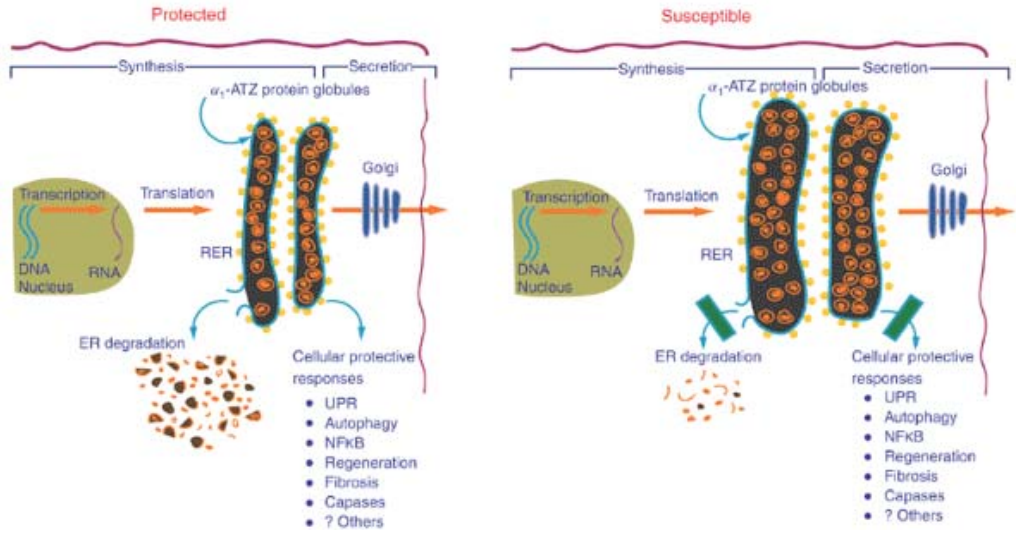
with α_1-AT deficiency to greater accumulation of the presumably hepatotoxic α_1-ATZ molecule in the ER (Fig. 37.5). Such a defect, whether determined by a genetic trait or an environmental factor, would be silent in the general population, which is not

exposed to a chronic burden of mutant, misfolded secretory protein.

With these considerations in mind, the author and his colleagues predicted a number of years ago that any unlinked genetic trait or environmental factor that impairs ER degradation would predispose a subgroup of α_1-AT deficient, PIZZ individuals to liver injury (111). To address this prediction experimentally, we transduced skin fibroblasts from PIZZ individuals, with or without liver disease, with amphotropic recombinant retroviral particles designed for constitutive expression of the mutant α_1-ATZ gene. Human skin fibroblasts do not express the endogenous α_1-AT gene but are presumed to express other genes involved in the postsynthetic processing of secretory proteins. The results show that expression of the human α_1-AT gene was conferred on each fibroblast cell line. Compared with the effect when the same cell line was transduced with the wild-type α_1-AT gene, there was selective intracellular retention of the mutant α_1-ATZ protein in each case. However, there was a marked delay in the degradation of the mutant α_1-ATZ protein after it accumulated in the fibroblasts from PIZZ individuals with liver disease (susceptible hosts) compared with the effect in PIZZ individuals without liver disease (protected hosts) (Fig. 37.5). These data provide evidence that other factors that affect the fate of the abnormal α_1-ATZ molecule, such as a lag in ER degradation, at least in part determine susceptibility to liver disease.

Because the pathway for degradation of α_1-ATZ that is retained in the ER is an obvious candidate for genetic variations associated with protection from, or susceptibility to, liver injury by the gain-of-toxic function mechanism, the author, his colleagues, and others have sought to characterize the pathway. The results indicate that it is much more complex than initially envisioned, with multiple mechanisms depending on a number of characteristics such as the specific substrate and the concentration of that substrate in the ER. Studies in multiple laboratories and in multiple systems have indicated that the proteosome is involved (137,138,139,140,141,142). The proteasome is a large cytoplasmic multiprotein complex that degrades many cellular proteins, particularly denatured proteins. Degradation by the proteasome depends on adenosine triphosphate; involves trypsin-like, chymotrypsin-like, and peptide glutamyl peptide hydrolyzing activity; and, for the most part, targets proteins that have been conjugated by ubiquitin. Although it is relatively easy to conceptualize how a transmembrane protein such as CFTRΔF508 might be accessible on the cytoplasmic aspect of the ER membrane for ubiquitination and degradation by the proteasome, it is more difficult to conceptualize how this might occur for a luminal polypeptide, such as α_1-ATZ. To address this issue, we used a cell-free system and found that α_1-ATZ must interact with the transmembrane molecular chaperone calnexin and induce ubiquitination of the cytoplasmic tail of calnexin to

undergo degradation by the proteasome (138). Results of further studies have indicated that there are at least two other mechanisms for ER degradation of α_1-ATZ, including a ubiquitin-independent proteasomal mechanism and one or more nonproteasomal mechanisms. The ubiquitin-dependent mechanism, in which the α_1-ATZ–calnexin complex is targeted, requires recruitment of the ubiquitin conjugating enzyme E2-F1 from the cytoplasm onto the ER membrane and polybiquitination of the cytoplasmic tail of calnexin (138). Studies in yeast (137) have also shown that calnexin and the proteasome are involved in ER degradation of α_1-ATZ.



▪ **Figure 37.5** Difference in endoplasmic reticulum (*ER*) degradation of α_1-ATZ protein in protected and susceptible hosts. The blocks in ER degradation and cellular response pathways in susceptible hosts are represented by *small dark bars*. RER, rough endoplasmic reticulum; DNA, deoxyribonucleic acid; RNA, ribonucleic acid; UPR, unfolded protein response; ?, not proven.

We do not yet know exactly how the entire α_1-ATZ–calnexin complex, including the luminal domain of calnexin associated with α_1-ATZ, is degraded. The proteasome may initiate a process that is completed by other enzymes within the ER membrane or within the ER lumen. Several other mechanisms by which the ubiquitin system and the proteasome gain access to membrane-bound and luminal substrates of the ER degradation pathway have been discussed in the literature. Although the retrograde translocation mechanism in which substrates are transported from the ER lumen to the cytoplasm had been demonstrated for some luminal substrates of the proteosome, limited evidence exists for retrograde translocation of α_1-ATZ. Werner et al. (137) detected α_1-ATZ in the cytosolic fraction of yeast when the proteosome was inhibited, but it was only a small fraction of the total α_1-ATZ in the ER and there has been no other evidence for retrotranslocation. This may mean that other mechanisms provide for transporting α_1-ATZ from the ER to the cytoplasm such as proteosome-mediated extraction through the ER membrane, as has been demonstrated for model ER degradation substrates (143). This "membrane extraction" mechanism, or "dislocation" mechanism, may be particularly relevant to degradation of α_1-ATZ because ER degradation of this substrate appears to involve polyubiquitination on the cytoplasmic tail of the transmembrane ER chaperone calnexin only when it has bound α_1-ATZ at the luminal surface of the ER membrane. It is also possible that the proteasome gains access to α_1-ATZ or the α_1-ATZ–polyubiquitinated calnexin during the formation of autophagic vacuoles. Our studies have shown that retention of α_1-ATZ in the ER is associated with the induction of an autophagic response (144), which is thought to be a general mechanism by which intracellular organelles, or parts of organelles, are degraded. It is a highly evolutionarily conserved process that occurs in many cell types, especially during stress states, such as nutrient deprivation, and during the cellular remodeling that accompanies morphogenesis, differentiation, and senescence. Results of several studies have suggested that autophagic vacuoles are derived in part from subdomains of ER (145). Autophagosomes initially form as invaginations from

ribosome-free areas of the ER membrane. Together with constituents of the ER, autophagosomes engulf cytosolic constituents, including components of the ubiquitin system and the proteasome (146,147). Therefore, it is possible that degradation of α_1-ATZ is mediated by proteasomal machinery engulfed during the formation of the autophagosome. In our studies an intense autophagic response was found in cell culture model systems with ER retention of mutant α_1-ATZ and in liver biopsy specimens from patients with α_1-AT deficiency (144). Moreover, α_1-ATZ and calnexin were colocalized within autophagosomes, as well as within the ER. Finally, degradation of α_1-ATZ in the cell culture model system is partially abrogated by inhibitors of autophagy, including wortmannin, 3-methyladenine, and LY294002, and recently, degradation of α_1-ATZ was abrogated in a cell line genetically engineered to be deficient in autophagy (141). However, it is also possible that α_1-ATZ molecules taken up into autophagosomes are degraded by a nonproteasomal mechanism when the autophagosomes merge or fuse with the lysosomal pathway and that the autophagic and proteasomal pathways constitute completely independent mechanisms for degradation of α_1-ATZ.

Several possible nonproteasomal mechanisms could contribute to ER degradation of mutant α_1-ATZ. In addition to the autophagic pathway (111), there is a mechanism, described by Cabral et al. that is sensitive to tyrosine phosphatase inhibitors (148). These authors found that degradation of α_1-ATZ in a transfected mouse hepatocellular carcinoma cell line was not sensitive to proteasomal inhibitors but was sensitive to tyrosine phosphatase inhibitors, suggesting that this nonproteasomal mechanism was the predominant pathway for ER degradation of α_1-ATZ in liver cells. Studies in the author's laboratory have shown that degradation of α_1-ATZ in the same hepatocellular carcinoma cell line, as well as in other lines, is sensitive to proteasomal inhibitors (140). These findings indicate that the mechanism observed by Cabral et al. is probably cell line specific rather than cell type specific for hepatocytes.

Together the results of the foregoing studies indicate that degradation of α_1-ATZ is a complex process that may involve more than one pathway and at least several sequential steps in each pathway. Theoretically, each of these pathways or its individual steps may be affected in an α_1-AT–deficient patient who is "susceptible" to liver disease; that is, there may be heterogeneity among susceptible hosts in the mechanism by which ER degradation is delayed.

Mechanism of Liver Injury

There is still relatively little information about the mechanism by which ER retention of α_1-ATZ leads

to liver cell injury. In transgenic mice that express the human α_1-ATZ gene, there are focal areas of liver cell necrosis, microabcesses with an accumulation of neutrophils, regenerative activity in the form of multicellular liver plates, and focal nodule formation during the neonatal period (149). Nodular clusters of altered hepatocytes that lack α_1-AT immunoreactivity are also found during the neonatal period. With aging, there is a decrease in the number of hepatocytes containing α_1-ATZ globules; there is also an increase in the number of nodular aggregates of α_1-AT–negative hepatocytes and development of perisinusoidal fibrosis (149). Within 6 weeks, there are dysplastic changes in these aggregates. Adenoma occurs within 1 year, and invasive hepatocellular carcinoma occurs between 1 and 2 years of age (150). The histopathology of α_1-ATZ transgenic mice is remarkably similar to that of hepatitis B virus surface antigen in transgenic mice and is particularly interesting because hepatitis B virus is retained in the ER or the ER–Golgi intermediate compartment of hepatocytes, often called *ground-glass hepatocytes* (151). It is still

unclear why the liver injury in the transgenic mouse model of α_1-AT deficiency is somewhat milder and less fibrogenic than that in children with α_1-AT deficiency–associated liver disease. It is possible that strain-specific factors condition the response to injury, just as there are apparently host-specific factors that affect the response to injury in α_1-AT–deficient infants (111).

In one of the recent studies by the author and colleagues we found evidence for hepatic mitochondrial injury in α_1-AT deficiency (152), raising the possibility that liver damage is mediated by oxidative mechanisms. Mitochondrial damage was evident in both cell line and transgenic mouse models of α_1-AT deficiency including mitochondrial depolarization and activation of caspase-3. Treatment of the PIZ mouse model with cyclosporin A, an inhibitor of mitochondrial depolarization, resulted in less histologic damage and complete reversal of mortality associated with the experimental stress of starvation (152).

In another recent study, Rudnick et al. examined the proliferation of hepatocytes in the PIZ mouse model (153), and the results have led to a new theory for the mechanism by which α_1-AT deficiency is predisposed to hepatocellular carcinoma. This study showed that there was increased hepatocellular proliferation in the liver at baseline. The increase was 5- to 10-fold above that in controls and highly significant statistically; it did represent a relatively low number of BrdU-positive hepatocytes (2% to 3% detected over 72 hours of continuous labeling). These data indicate that liver injury in the mouse model is relatively mild and appropriately corresponds to the smoldering and slowly progressing liver disease seen in most α_1-AT–deficient patients. Four other important observations were made. First, the increase in proliferation was proportional to the number of hepatocytes with globules containing the retained α_1-ATZ. This suggested that the globule-containing hepatocytes were producing a regenerative signal or signals. Second, the proliferating hepatocytes were almost entirely the ones devoid of globules. This suggested that retention of α_1-ATZ inhibits cell proliferation and that cells with lesser accumulation of α_1-ATZ have a selective proliferative advantage in the damaged liver. Third, both globule-containing and globule-devoid hepatocytes proliferated when the PIZ mice were subjected to partial hepatectomy. This suggested that the block in proliferation of globule-containing hepatocytes is relative; that is, that they would proliferate if the stimulus were as powerful as the one generated after partial hepatectomy. Fourth, globule-containing hepatocytes were not disproportionately affected by signs of cell death. This suggested that the globule-containing hepatocytes were "sick but not dead."

These observations constitute the basis for a new paradigm for the pathogenesis of hepatic cancer in α_1-AT deficiency and, perhaps, other chronic liver diseases. Globule-devoid hepatocytes, which are probably progenitors or at least young cells with lesser time to accumulate the mutant protein, have a selective proliferative advantage in the liver of the deficient individual. They are chronically stimulated in "trans" by signals that are generated by globule-containing hepatocytes that are "sick but not dead." The cancer-prone state is then engendered by having cells that are unable to die at the appropriate time and cells that are chronically dividing in the inflamed milieu. This paradigm is consistent with what has been found in the liver of the Z#2 mouse model of α_1-AT deficiency (150). Most of the liver (>90%) becomes α_1-AT negative as the mouse ages. This probably represents the selective proliferation of the globule-devoid hepatocytes, the progenitor cells. Adenomas and then carcinomas arise in these regions in greater than 80% of the mice. This paradigm also appears to apply to the predilection for hepatic cancer in several other forms of chronic liver disease (154).

Further understanding of how hepatocytes respond to the accumulation of α_1-ATZ in the ER is likely to provide more clues about the pathogenesis of this liver disease.

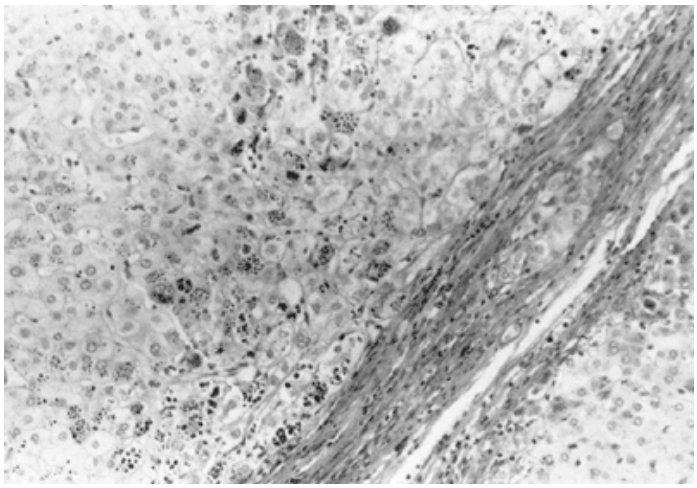
Hidvegi et al. have used cell line and transgenic mouse models with inducible expression of mutant α_1-ATZ, which are ideally suited for elucidating the signal transduction pathways that are activated and for determining how they may protect from, or contribute to, liver damage (155). So far these studies have shown that accumulation of the mutant protein in the ER of the model systems does not activate the unfolded protein response but does activate autophagy, nuclear factor κB (NFκB), ER-caspases and BAP31, an ER protein that appears to be involved in the proapoptotic effects of ER on mitochondria. The latter may be the mechanism by

which mitochondrial damage and mitochondrial caspases are activated in the liver in α_1-AT deficiency. The rest of this signaling profile is also consistent with the conceptual model of the globule-containing hepatocytes as "sick but not dead" (154).

Diagnosis

Diagnosis of α_1-AT deficiency is established by means of serum α_1-AT phenotype determination in isoelectric focusing or by means of agarose electrophoresis at acid pH. Serum concentrations can be used for screening, with follow-up PI typing of any values below normal (85 to 215 mg/dL). A retrospective study of all pediatric patients who had both serum concentrations and PI typing done at one center indicated that the serum concentration determination had a positive predictive value of 94% and a negative predictive value of 100% for homozygous α_1-AT deficiency (156). However, because of the inherent limitations of retrospectively defining a patient population for the analysis, the results of the study are not necessarily applicable to each diagnostic situation that might be encountered. It is wise to get a phenotype together with the serum level in most cases of neonatal hepatitis or unexplained chronic liver disease in older children, adolescents, and adults. Serum concentrations of α_1-AT may be helpful, when used with the phenotype, to differentiate persons homozygous for the Z allele from SZ compound heterozygotes, both of whom may develop liver disease. In some cases, phenotype determinations of parents and other relatives are necessary to ensure the distinction between ZZ and SZ allotypes, a distinction important for genetic counseling. Serum concentrations of α_1-AT are occasionally misleading. For example, serum α_1-AT concentrations may increase during the host response to inflammation, even in homozygous PIZZ individuals and give a falsely reassuring impression.

The distinctive histologic feature of homozygous PIZZ α_1-AT deficiency, periodic acid–Schiff-positive, diastase-resistant globules in the ER of hepatocytes, substantiates the diagnosis (Fig. 37.6). The presence of these inclusions should not be interpreted as confirming the diagnosis of α_1-AT deficiency. Similar structures are occasionally found in PIMM individuals with other liver diseases (157). The inclusions are eosinophilic, round to oval, and 1 to 40 μm in diameter. They are most prominent in periportal hepatocytes but may also be present in Kupffer cells and cells of biliary ductular lineage (158). There may be evidence of variable degrees of hepatocellular necrosis, inflammatory cell infiltration, periportal fibrosis, or cirrhosis. There may also be evidence of bile duct epithelial cell destruction, and occasionally there is a paucity of intrahepatic bile ducts.



▪ **Figure 37.6** Histologic appearance of liver biopsy specimen of a patient with homozygous PIZZ α_1-AT deficiency. Micrograph shows periodic acid–Schiff-positive, diastase-resistant globules in hepatocytes, especially periportal ones, adjacent to a broad band of fibrous tissue (periodic acid–Schiff, diastase, 40× original magnification). (Photomicrograph provided by Dr. C. Coffin, St. Louis, MO.)

Treatment

The most important principle in the treatment of patients with α_1-AT deficiency is avoidance of cigarette smoking, which markedly accelerates the destructive lung disease associated with α_1-AT deficiency, reduces the quality of life, and significantly shortens the longevity of these patients (2).

There is no specific therapy for α_1-AT deficiency–associated liver disease. Therefore, clinical care largely involves supportive management of symptoms caused by liver dysfunction and prevention of complications. Progressive liver dysfunction and failure in children have been managed with orthotopic liver transplantation, with survival rates approaching 90% at 1 year and 80% at 5 years (159). Nevertheless, a number of PIZZ individuals with severe liver disease, even cirrhosis or portal hypertension, may have a relatively low rate of disease progression and lead a relatively normal life for extended periods. With the availability of living–related-donor transplantation techniques, it may be possible to treat these patients expectantly for some time. Children with α_1-AT deficiency, mild liver dysfunction (elevated transaminase levels or hepatomegaly), and without functional impairment may never need liver transplantation.

Several studies have shown that a class of compounds called *chemical chaperones* can reverse the cellular mislocalization or misfolding of mutant plasma membrane, and lysosomal, nuclear, and cytoplasmic proteins, including CFTRΔF508, prion proteins, mutant aquaporin molecules associated with nephrogenic diabetes insipidus, and mutant galactosidase

A associated with Fabry's disease (160,161,162). These compounds include glycerol, trimethylamine oxide, deuterated water, and 4-phenylbutyric acid (PBA). The author and his colleagues have found that glycerol and PBA mediate a marked increase in the secretion of α_1-ATZ in a model cell culture system (163). Oral administration of PBA was also well tolerated by PIZ mice (transgenic for the human α_1-ATZ gene) and

consistently mediated an increase in blood levels of human α_1-AT, reaching 20% to 50% of the levels present in PIM mice and healthy humans. PBA did not affect the synthesis or intracellular degradation of α_1-ATZ. The α_1-ATZ secreted in the presence of PBA was functionally active, in that it could form an inhibitory complex with neutrophil elastase. Because PBA has been used safely for years as an ammonia scavenger to treat children with urea cycle disorders and because results of clinical studies have suggested that only partial correction of the deficiency state is needed for the prevention of both liver and lung injury in α_1-AT deficiency (164), PBA is an excellent candidate for the chemoprophylaxis of target-organ injury in α_1-AT deficiency.

It also appears now that several iminosugar compounds may be useful for chemoprophylaxis of liver and lung disease in α_1-AT deficiency. These compounds are designed to interfere with oligosaccharide side chain trimming of glycoproteins and are being examined as potential therapeutic agents for viral hepatitis and other types of infection (165,166). The author and colleagues examined several of these compounds to determine the effect of inhibition of glucose or mannose trimming of carbohydrate side chains on the fate of α_1-ATZ in the ER. They found, to their surprise, that one glucosidase inhibitor, castanospermine (CST), and two α-mannosidase I inhibitors, kifunensine (KIF) and deoxymannojirimicin (DMJ), mediated increased secretion of α_1-ATZ (167). The α_1-ATZ secreted in the presence of these drugs has partial functional activity. KIF and DMJ are less attractive candidates for chemoprophylactic trials because they delay degradation of α_1-ATZ and increase its secretion. These drugs, therefore, have the potential to exacerbate susceptibility to liver disease. However, CST has no effect on the degradation of α_1-ATZ and, therefore, may be targeted for development as a chemoprophylactic agent. The mechanism of action of CST on α_1-ATZ secretion is not yet known. An interesting hypothesis for the mechanism of action of KIF and DMJ is that mutant α_1-ATZ interacts with ERGIC-53 for transport from ER to Golgi apparatus when mannose trimming is inhibited.

Patients with α_1-AT deficiency and emphysema have undergone replacement therapy with α_1-AT purified from recombinant plasma and administered intravenously or by means of intratracheal aerosol (40). This therapy is associated with improvement in α_1-AT serum concentrations and in α_1-AT and neutrophil elastase inhibitory capacity in bronchoalveolar lavage fluid without significant side effects. Although results of initial studies have suggested that there is a slower decline in forced expiratory volume in patients undergoing replacement therapy, this occurred only in a subgroup of patients, and the study was not randomized (168). This therapy is designed for persons with established and progressive emphysema. Protein replacement therapy is not being considered for patients with liver disease because there is no information to support the notion that deficient serum levels of α_1-AT are mechanistically related to liver injury.

A number of patients with severe emphysema from α_1-AT deficiency have undergone lung transplantation in the last 10 years. The latest data from the St. Louis International Lung Transplantation Registry show that 91 patients with emphysema and α_1-AT deficiency underwent single or bilateral lung transplantation by 1993. The actuarial survival rate among patients in this category who underwent transplantation between 1987 and 1994 was approximately 50% for 5 years. Lung function and exercise tolerance were significantly improved (169).

Replacement of α_1-AT by means of somatic gene therapy has been discussed in the literature (40). This strategy is potentially less expensive than replacement therapy with purified protein and can alleviate the need for intravenous or inhalation therapy. Again, this form of therapy will be useful only in ameliorating emphysema because liver disease associated with α_1-AT deficiency is not caused by deficient

levels of α_1-AT in the serum or tissue. Of course, it would be helpful to know whether replacement therapy with purified α_1-AT, as it is currently applied, is effective in ameliorating emphysema in this deficiency before embarking on clinical trials involving gene therapy. There are still major issues that must be addressed before gene therapy becomes a realistic alternative (170). Several novel types of gene therapy, such as repair of mRNA by means of trans-splicing ribozymes (171,172) and chimeric RNA/DNA oligonucleotides (173,174,175), triplex-forming oligonucleotides (176), small fragment homologous replacement (177), or RNA silencing (178,179), are theoretically attractive alternative strategies for the management of liver disease in α_1-AT deficiency because they would prevent the synthesis of mutant α_1-ATZ protein and ER retention.

Studies have shown that transplanted hepatocytes can repopulate the diseased liver in several mouse models, including a mouse model of a childhood metabolic liver disease called *hereditary tyrosinemia* (180,181). Stem cells from the bone marrow or pancreas can be used instead of adult hepatocytes (182,183). Replication of the transplanted cells occurs only when there is injury or regeneration in the liver (181). These results

provide evidence that it may be possible to use hepatocyte transplantation techniques to manage hereditary tyrosinemia and, perhaps, other metabolic liver diseases in which the defect is cell autonomous. For example, α_1-AT deficiency involves a cell-autonomous defect and would be an excellent candidate for this strategy.

Genetic Counseling

Restriction fragment length polymorphisms detected with synthetic oligonucleotide probes (184) and family studies (185) allow prenatal diagnosis of α_1-AT deficiency. Nevertheless, it is not clear how prenatal diagnosis of this deficiency should be used and how families should be counseled about the diagnosis. The data reviewed earlier indicate that 85% to 90% of individuals with α_1-AT deficiency do not have evidence of liver disease at 18 years of age and that nonsmoking PIZZ individuals may not develop emphysema or even pulmonary function abnormalities until 60 to 70 years of age. These data could support a counseling strategy in which amniocentesis and abortion are discouraged. The only other data on this subject come from two studies with conflicting results. Results of one study suggested that the incidence of significant liver disease among siblings at risk is 78% (186). The results of the other suggested that the incidence is 21% (11). These studies, however, were retrospective and heavily influenced by bias in ascertainment of patients. The issue will not be resolved until it is studied prospectively, as, for example, in the Swedish population (1).

Population Screening

Results of several studies have suggested that population screening for α_1-AT deficiency would be efficacious. First, there is evidence that knowledge of and counseling about the consequences of α_1-AT deficiency are associated with a reduced rate of smoking among affected adolescents (187,188). Second, although there was initially some evidence for adverse psychological effects (189), more recent results have indicated that there are no significant negative psychosocial consequences in adults who were informed about their deficiency in a follow-up study after neonatal screening in Sweden (190). These data should give new momentum to reconsider screening programs for α_1-AT deficiency.

Chapter 38
Porphyrias

Joseph R. Bloomer
David A. Brenner

Key Concepts

- The porphyrias are metabolic disorders in which abnormalities in heme biosynthesis cause an excessive accumulation and excretion of porphyrins and porphyrin precursors. A defect in an enzymatic step in the heme biosynthetic pathway is present in each of the porphyrias.
- The genes that encode the enzymes of the heme biosynthetic pathway have been cloned and sequenced. This has made it possible to identify the gene mutations that cause the enzyme defects and has shown that each of the porphyrias has genetic heterogeneity (i.e., several different mutations have been found).
- The principal clinical manifestations are photocutaneous lesions, neurologic dysfunction, and structural liver disease. The photocutaneous lesions are caused by the photoactive properties of porphyrins in skin. Neurologic dysfunction, which underlies the acute porphyric attack, is probably caused by a toxic effect of δ-aminolevulinic acid and/or heme deficiency state. Therapy for the acute porphyric attack is designed to stop the factors that precipitate the attack and provide a high carbohydrate diet. Intravenous hematin is administered to restore hepatic heme homeostasis.
- Liver damage in porphyria cutanea tarda is due to the metabolic abnormality and additional factors, such as alcoholism and hepatitis C infection. Phlebotomy is the first line of therapy.
- Liver damage in protoporphyria is caused by the toxic effect of protoporphyrin on the liver. Liver transplantation has been carried out successfully in several patients, but protoporphyrin-induced damage may occur in the new liver.
- Several nonporphyric disorders, particularly those that cause hepatobiliary disease, may be associated with increased urine excretion of coproporphyrin. This is termed *secondary porphyrinuria*. It can usually be distinguished from the acute porphyrias by measuring the urinary excretion of δ-aminolevulinic acid and porphobilinogen (PBG).
- Pseudoporphyria describes a condition with clinical and histologic features similar to porphyria cutanea tarda, but with normal or near normal porphyrin levels.

The porphyrias are metabolic disorders that are characterized biochemically by the excess accumulation and excretion of porphyrins and porphyrin precursors. These compounds are intermediates of the heme biosynthetic pathway, and the elucidation of the biochemical features of the porphyrias follows the delineation of this pathway (1). An important milestone in understanding the pathogenesis of the biochemical abnormalities was in 1970, when a deficiency of porphobilinogen(PBG) deaminase activity

was demonstrated in tissues from patients with acute intermittent porphyria (AIP) (2). Subsequently, an enzyme defect was found for each type of porphyria. During the last decade, the gene mutations that cause the enzyme defects have been identified.

The liver and bone marrow are the major sites of heme production and, therefore, are the principal sites of expression of the biochemical abnormalities. This formed the basis for the early classification of the porphyrias as either hepatic or erythropoietic (3). When the hepatic mixed-function oxidase system is induced by the administration of drugs, the amount of heme synthesized in the liver increases and the rate of formation of the porphyrins and porphyrin precursors increases. Therefore, patients with acute hepatic porphyrias may have substantial variation in the biochemical abnormalities because of various factors that affect the rate of hepatic heme biosynthesis.

The liver also has an important role in the excretion of porphyrins (4). This causes the liver to be susceptible to the toxic effects of porphyrin accumulation. Conversely, hepatobiliary disease of many types causes an increase in the urinary excretion of porphyrins—in particular, coproporphyrin—because excretion of these compounds is diverted from bile to urine. This condition is called *secondary porphyrinuria*.

The principal clinical manifestations of the porphyrias are caused by their effects on the nervous system, skin, and liver. The diagnosis of a specific type of porphyria can be entertained based on the combination of the clinical features. A noteworthy feature of the porphyrias is the relationship between the clinical manifestations and biochemical abnormalities. The porphyrias associated with acute attacks of neurologic dysfunction are characterized by increased accumulation and excretion of the porphyrin precursors δ-aminolevulinic acid (ALA) and PBG. The porphyrias associated with photocutaneous lesions and liver disease are characterized by increased accumulation of the porphyrin compounds themselves.

Heme Metabolism

Heme Biosynthesis

Heme is a member of a group of compounds called *tetrapyrroles*. These compounds are composed of four pyrrole rings arranged into a larger ring by one-carbon bridges (Fig. 38.1). The four pyrrole nitrogen atoms are oriented toward the center of the ring. Because of the central cavity and the chemical properties of the central nitrogen atoms, tetrapyrroles have excellent metal-binding characteristics. Their complexes with iron (heme), magnesium (chlorophyll), and cobalt (vitamin B_{12}) are crucial to living organisms.

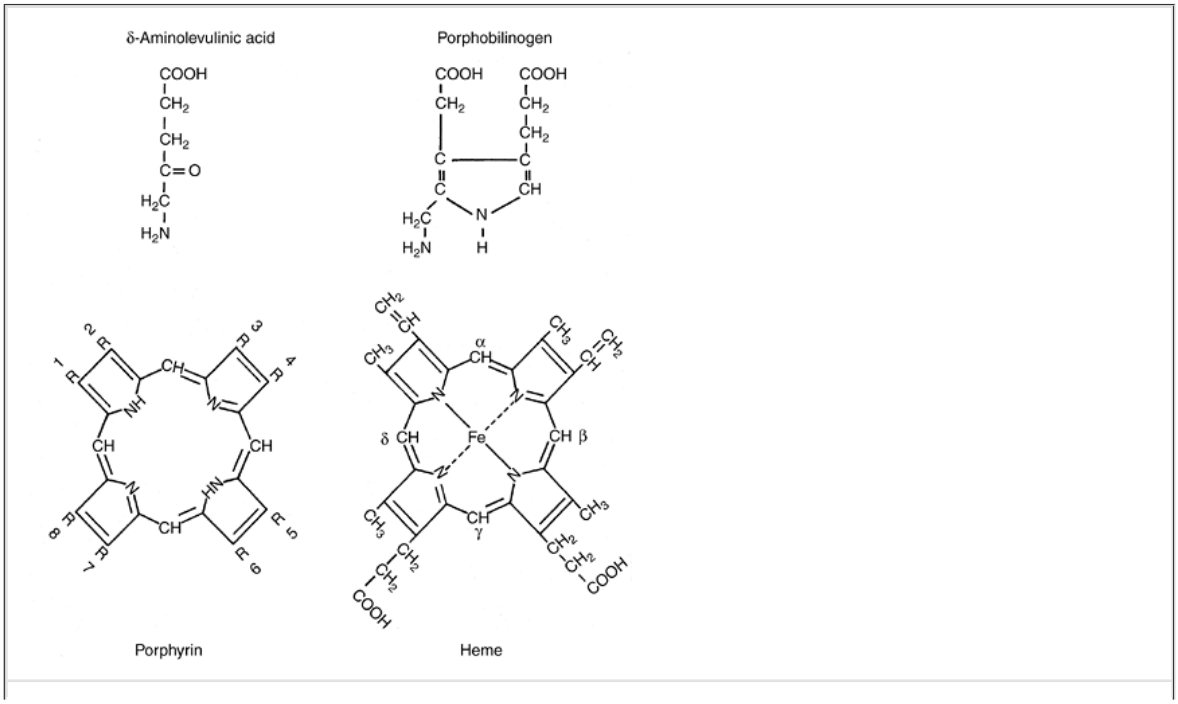
The iron in heme has four of its six coordination positions occupied by the four tetrapyrrole nitrogen atoms. The remaining two coordination positions may be occupied by heteroatoms on the side chains of proteins or by solvent or solute molecules, which, in turn, affect the chemical properties of the iron. The chemistry of the heme moiety is therefore dictated by its protein microenvironment and the nature of the fifth and sixth ligands to iron. Hemoproteins have a variety of chemical interactions, including oxidation–reduction reactions, activation of oxygen, and ligand binding (e.g., oxygen transport). Hepatic hemoproteins include mixed-function oxidases (e.g., cytochrome P-450), dioxygenases (e.g., prostaglandin cyclo-oxygenase), catalase, peroxidases, and tryptophan pyrrolase, all of which are involved in the modification or catabolism of endogenous substrates or potentially toxic compounds. Heme also serves as the oxidation–reduction center for the cytochromes of mitochondrial electron transport and the smooth endoplasmic reticulum.

Heme is synthesized in mammalian tissues in eight steps that are under enzymatic control (Fig. 38.2). In the first step, ALA is formed by the condensation of succinyl-CoA with glycine (5,6). The reaction is catalyzed by the enzyme ALA synthase and occurs in the mitochondrial matrix. Pyridoxal phosphate is required as a cofactor.

ALA diffuses into the cytoplasm of the cell, where two molecules are condensed in a side-to-side manner by the action of ALA dehydrase (7). The product is the monopyrrole PBG. Four molecules of PBG are then joined head to tail, with the displacement of four amino groups through a reaction catalyzed by PBG deaminase, forming the linear tetrapyrrole hydroxymethylbilane (8,9). Dipyrromethane, which is made from PBG by the same enzyme, is a critical cofactor in the reaction. Hydroxymethylbilane spontaneously forms the cyclic compound, uroporphyrinogen I. Porphyrinogens are structures comprising four pyrrole units joined by methylene ($-CH_2-$) groups; they are nonplanar and nonaromatic. Each pyrrole unit of uroporphyrinogen I has an acetate and a propionate side chain that alternate strictly. Enzymic formation of cyclic hydroxymethylbilane is catalyzed by uroporphyrinogen III synthase (also called *cosynthase*) (10,11). This alters the symmetry by reversing the sense of the last pyrrole unit (the D ring). The order of side chains after enzymic cyclization beginning with group R1 (Fig. 38.1) is acetate–propionate (A ring), acetate–propionate (B ring), acetate–propionate (C ring), propionate–acetate (D ring).

Uroporphyrinogen decarboxylase (uroporphyrinogen carboxylase) is a cytosolic enzyme that catalyzes the stepwise decarboxylation of each of the acetate side chains of uroporphyrinogen, leaving methyl substituents (12,13). It is a unique decarboxylating

enzyme in that no cofactors or coenzymes are involved. The enzyme is active with both uroporphyrinogen I and III but not with the oxidized form of the substrate, uroporphyrin. During the course of the decarboxylation, intermediates having seven, six, and five carboxyl groups are generated and are referred to as hepta-, hexa- and pentacarboxylate porphyrinogens, respectively. The final product of the reaction is the tetracarboxylate coproporphyrinogen.



▪ **Figure 38.1** Structures of the porphyrin precursors δ-aminolevulinic acid, porphobilinogen (PBG), porphyrin, and heme. All porphyrins have the same tetrapyrrole ring structure, but they differ in the composition of side chains (R1 to 8) attached to the ring. Uroporphyrin has eight carboxylic acid side chains, coproporphyrin has four, and protoporphyrin has two. Porphyrinogens are the reduced forms of the porphyrins, in which the methene bridges linking the four pyrrole groups are replaced by methylene groups.

The next step is catalyzed by coproporphyrinogen oxidase. The propionate side chains at R2 and R4 of coproporphyrinogen III are oxidatively decarboxylated, forming the vinyl ($-CH=CH_2$) substituents of protoporphyrinogen IX (14). The enzyme, which is located between the outer and inner mitochondrial membranes (15), is active only with coproporphyrinogen III; no other isomer serves as substrate.

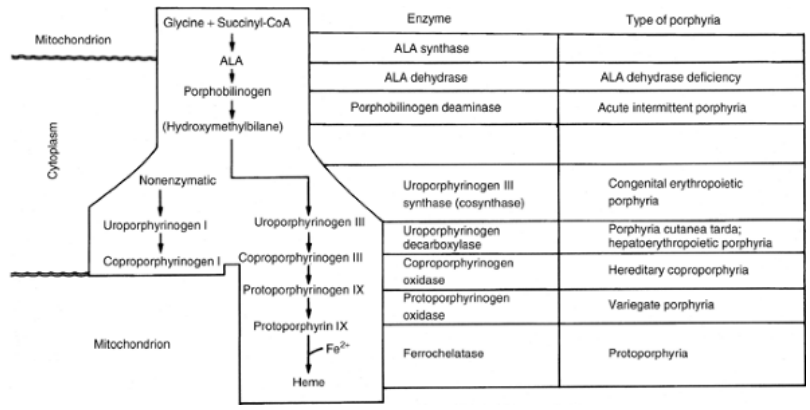
Protoporphyrinogen IX undergoes a six-electron oxidation catalyzed by protoporphyrinogen oxidase (16). In mammalian liver, the reaction requires molecular oxygen as the final electron acceptor, but the primary electron acceptor and electron pathway to oxygen are unknown. The enzyme is located in the inner mitochondrial membrane (17).

The final step in heme biosynthesis involves the insertion of divalent (ferrous) iron into protoporphyrin IX, forming heme; the reaction is catalyzed by ferrochelatase (18), which is located on the matrix side of the inner mitochondrial membrane (19). Human ferrochelatase contains a [2Fe–2S] cluster that is essential for activity (20). The enzyme is active with other dicarboxylic porphyrin substrates and with other divalent metal ions, such as Co^{2+} and Zn^{2+}; it is not active with trivalent metals [e.g., Fe^{3+} or Co^{3+}]. Its functional state is a homodimer, as revealed by its crystal structure (21).

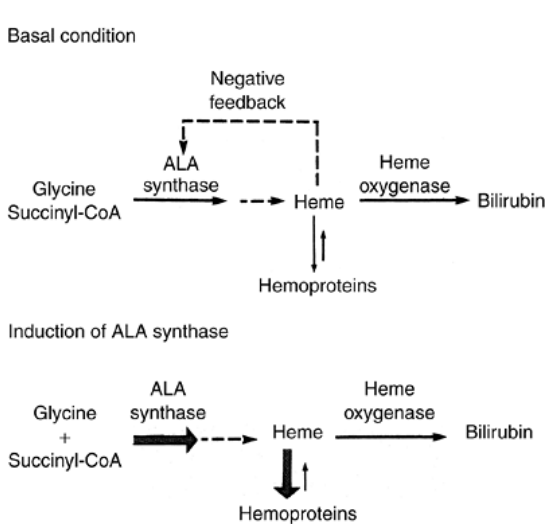
Hepatic Heme Metabolism

The synthesis of heme in liver is controlled primarily by the level of ALA synthase activity, which is, in turn, controlled by a regulatory heme pool through negative feedback inhibition (Fig. 38.3). Two forms of ALA synthase—erythroid and nonerythroid—are encoded by different genes (22). The nonerythroid or housekeeping form of the enzyme, which is present

in the liver, is induced by a variety of chemicals. Heme controls hepatic ALA synthase activity by repressing the synthesis of the enzyme and also by inhibiting its transport from the cytoplasm into mitochondria (23,24). The synthesis is repressed by a decrease in the level of ALA synthase messenger ribonucleic acid (mRNA) (25,26). A heme regulatory motif in the enzyme has been implicated in the inhibition of its transport into mitochondria (27).



▪ **Figure 38.2** Heme biosynthetic pathway, illustrating the enzyme abnormalities that characterize the different types of porphyria. Heme biosynthesis is distributed between the mitochondria and cytoplasm of the cell, as shown. ALA, δ-aminolevulinic acid.



▪ **Figure 38.3** Control of hepatic heme biosynthesis. Under basal conditions, the rate-limiting enzyme in the pathway, δ-aminolevulinic acid (ALA) synthase, is under negative feedback control by a putative regulatory heme pool. An increased demand for hepatic heme biosynthesis, as occurs when there is formation of more cytochrome P-450 or other hemoproteins, may deplete this pool. This removes the negative feedback control and causes induction of ALA synthase and thereby increases the synthesis of porphyrins and porphyrin precursors.

It is estimated that, in humans, the liver accounts for approximately 15% to 20% of the total body production of heme (28). Most heme produced in the hepatocyte enters the hepatic hemoprotein pool. Because heme is formed at the inner mitochondrial membrane, it must be distributed to apoproteins throughout the hepatocyte for hemoprotein activity to be constituted. A heme-binding protein in liver cytosol, which appears to be identical to the liver fatty-acid–binding protein, may have a role in the efflux of heme from mitochondria (29). The microsomal cytochrome P-450 system utilizes most of the hepatic heme, accounting for more than 60%. Other hemoproteins—such as cytochrome b_5, the mitochondrial cytochromes, and catalase—also have critical functions in the liver.

Heme is catabolized to bilirubin through the combined actions of microsomal heme oxygenase and biliverdin reductase (30,31,32). Heme oxygenase is found in both hepatocytes and Kupffer cells, the latter having high activity. Heme oxygenase opens the heme ring, releasing carbon monoxide and iron in the process, to form the green pigment biliverdin. Biliverdin is then reduced by biliverdin reductase to form bilirubin.

Because the hepatocyte has heme oxygenase activity, it can degrade the heme that it produces. Most of the heme that is degraded comes from the functional hemoprotein pool, but a portion of newly formed heme is catabolized to bilirubin before it is incorporated into hemoproteins (33). Some hepatic heme is degraded

through a pathway that does not form carbon monoxide and bilirubin (34).

Hepatic heme oxygenase is a heat-shock protein that is induced by stimuli that cause oxidative stress (30,35), suggesting that it may have a role in the response to hepatic injury. Heme oxygenase may additionally modulate hepatic vascular perfusion through the production of carbon monoxide (36), which causes smooth muscle relaxation.

Biliary Excretion of Heme

Isolated hepatocytes secrete newly synthesized heme into the culture medium (37). There is no evidence that heme synthesized in the liver of the intact organism is secreted into the blood, but studies in the bile fistula of animals and humans indicate that heme is excreted in bile (38,39).

Heme excreted in bile does not enter the enterohepatic circulation because heme is catabolized by the mucosal cells of the intestine. In healthy subjects, the fractional absorption of radioactive iron from food containing inorganic iron salts is 1%, compared with 16% from food containing iron in hemoglobin (40). Microsomal heme oxygenase activity in the intestinal mucosa is at a level similar to that in the liver and spleen; this increases significantly in animals made iron deficient (40). Therefore, heme excreted in bile is absorbed by mucosal cells in the intestine, where heme oxygenase catalyzes its cleavage to release inorganic iron for use in the body.

Excretion of Porphyrins and Porphyrin Precursors

The excretory routes of porphyrins and porphyrin precursors are determined primarily by the solubility of the compounds: Water-soluble compounds are excreted in the urine, whereas water-insoluble compounds are excreted in bile. The porphyrin precursors ALA and PBG are soluble in aqueous solution and are excreted in urine. Uroporphyrin is also water soluble because of the presence of eight carboxyl groups and is excreted

predominately in urine. Protoporphyrin, which has only two carboxyl groups, is poorly water soluble and is excreted almost entirely in bile. Coproporphyrin has four carboxyl groups and is excreted in both bile and urine, with the symmetric coproporphyrin I isomer being preferentially excreted in bile. When hepatobiliary disease occurs, biliary excretion of coproporphyrin diminishes and urinary excretion increases. Therefore, hepatobiliary disease is a cause of increased coproporphyrin excretion in the urine, a condition termed *secondary porphyrinuria*. The porphyrinogens are excreted in a pattern similar to their corresponding porphyrins, except that coproporphyrinogen is excreted in a proportionately greater amount in urine than is coproporphyrin. Unlike bilirubin, none of the porphyrinogens or porphyrins is conjugated before excretion.

In healthy individuals, the predominant porphyrin in bile is coproporphyrin, with small amounts of protoporphyrin and negligible amounts of uroporphyrin (41,42). Protoporphyrin and other 2-, 3-carboxyl porphyrins are predominant in feces. Therefore, most of the protoporphyrin in normal stool is probably derived from bacterial metabolism and ingested food (43).

The mechanism by which the liver excretes protoporphyrin into bile has been investigated extensively in isolated perfused rat liver (44,45,46). In this system, the uptake of protoporphyrin from the perfusing medium occurs by simple or facilitated diffusion and continues at a significant rate, even when excretion into bile is impaired. Intracellular transport is not inhibited by colchicine or monensin, indicating that nonvesicular carriers are targeted to the canalicular membrane. Bile acids facilitate the excretion of protoporphyrin into bile, primarily by increasing the concentration of protoporphyrin that can be attained rather than by increasing bile flow. This is related to the structure of the bile acid. Cholate increases the biliary excretion of protoporphyrin more than that of chenodeoxycholate, which, in turn, has a greater effect than ursodeoxycholate.

Secretion of protoporphyrin into bile appears to be mechanistically linked to the secretion of phospholipid (46). An mdr P-glycoprotein is essential for biliary phospholipid excretion (47), translocating phospholipid from the inner to the outer canalicular membrane leaflet. Protoporphyrin secretion into bile after a protoporphyrin load is reduced by 90% in mice that are homozygous for disruption of the mdr2 P-glycoprotein (48).

Biochemical Abnormalities in the Porphyrias

Enzyme Defects

Each of the eight types of porphyrias is associated with an enzyme defect in the heme biosynthetic pathway that produces a characteristic pattern of abnormal accumulation and excretion of porphyrins and/or porphyrin precursors (Fig. 38.2; Table 38.1) (2,49,50,51,52,53,54,55,56,57,58,59,60,61,62). For example, the deficiency of PBG deaminase activity in AIP causes the excess accumulation and excretion of ALA and PBG, whereas a deficiency of ferrochelatase activity in protoporphyria causes the excess accumulation and excretion of protoporphyrin. The diagnosis of a specific porphyria is made by documenting the pattern of abnormal porphyrin and/or porphyrin precursor

excretion that is characteristic for that type of porphyria. In some types, the diagnosis may be confirmed by demonstrating a deficiency of activity for the enzyme that leads to the biochemical abnormality. This has been most effectively applied to the measurement of erythrocyte PBG deaminase activity to diagnose AIP (Fig. 38.4) (63,64). However, approximately 5% of patients with AIP have a splicing mutation in which normal erythrocyte PBG deaminase activity is preserved (65).

Table 38.1. Biochemical Features of the Porphyrias

Type of porphyria	Enzyme defect	Chromosome location	Major site of biochemical abnormality	Principal biochemical features
Acute intermittent porphyria	PBG deaminase	11q23.3	Liver	ALA and PBG in urine
Variegate porphyria	Protoporphyrinogen oxidase	1q22	Liver	ALA, PBG, and coproporphyrin in urine; protoporphyrin in feces
Hereditary coproporphyria	Coproporphyrinogen oxidase	3q12	Liver	ALA, PBG, and coproporphyrin in urine; coproporphyrin in feces
ALA dehydrase	ALA dehydrase	9q34	Liver	ALA in urine

deficiency				
Porphyria cutanea tarda	Uroporphyrinogen decarboxylase	1p34	Liver	Uroporphyrin in urine; isocoproporphyrin in feces
Hepatoerythropoietic porphyria	Uroporphyrinogen decarboxylase	1p34	Liver and bone marrow	Zinc protoporphyrin in red cells; uroporphyrin in urine; isocoproporphyrin in feces
Congenital erythropoietic porphyria	Uroporphyrinogen III synthase	10q25.2 q26.3	Bone marrow	Uroporphyrin in red cells and urine; coproporphyrin in feces
Protoporphyria	Ferrochelatase	18q21.3	Bone marrow (liver variable)	Protoporphyrin in red cells, bile and feces
PBG, porphobilinogen; ALA, δ-aminolevulinic acid.				

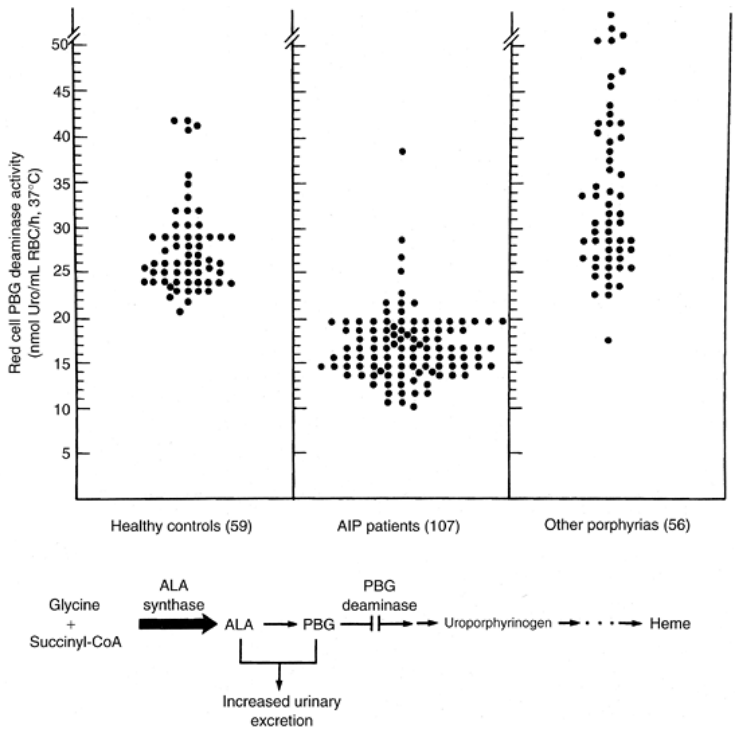
Some of the porphyrias (e.g., AIP, hereditary coproporphyria, and variegate porphyria) have a marked increase in the level of hepatic ALA synthase activity during acute exacerbations of the disease (i.e., acute porphyric attack) (2,66). The increased demand for hepatic heme biosynthesis depletes the regulatory heme pool and thereby removes the negative feedback control on ALA synthase (Fig. 38.3). In AIP, the increased hepatic production of ALA also causes excess formation of PBG. Because of deficient hepatic PBG deaminase activity, ALA and PBG accumulate in greater amounts than they do under basal conditions and are excreted in greater amounts in the urine as well (Fig. 38.4). The acute attack abates when sufficient heme is produced to return hepatic ALA synthase activity to normal, and the excretion of ALA and PBG returns to the basal level. Therefore, patients with AIP may have substantial variation in biochemical abnormalities because of various factors that affect the rate of hepatic heme biosynthesis.

Variegate porphyria is unique in that protoporphyrinogen, which accumulates because of a defect in protoporphyrinogen oxidase, inhibits PBG deaminase (67). This functionally causes a situation same as that in AIP; therefore, excess amounts of ALA and PBG are formed and excreted in the urine when hepatic ALA synthase activity is induced.

Molecular Pathogenesis of Enzyme Defects

The cloning of complementary deoxyribonucleic acid (cDNA) and genes that encode the enzymes of the heme biosynthetic pathway has made it possible to identify the gene mutations that cause enzyme defects; AIP has been the most intensively studied. PBG deaminase activity is usually reduced by approximately 50% in all tissues of patients with this disorder, although for some families the enzyme deficiency is restricted to nonerythropoietic tissues because mutations in exon I selectively affect the nonerythroid form of the enzyme (68,69). More than 200 different mutations have been reported for AIP, demonstrating significant genetic heterogeneity (70,71). These result either in the absence of the protein encoded by the mutant allele or in the synthesis of the protein that has abnormal catalytic properties. The mutations produce abnormal splicing of PBG deaminase mRNA, insertions or deletions in exons that cause premature termination of protein synthesis, nucleotide changes producing stop codons that prevent complete translation of PBG deaminase mRNA, and nucleotide changes causing the substitution of

an amino acid that affects catalytic activity (70). The prevalence of the different mutations is highly variable among different populations. In the United States, no specific mutation has been predominant, whereas in Sweden, nearly half of the families share the same mutation (72).



▪ **Figure 38.4** Enzyme defect in acute intermittent porphyria (AIP). (*Top*) Porphobilinogen (PBG) deaminase activity is deficient in tissues of patients with AIP compared with healthy controls and patients with other types of porphyria. (*Bottom*) As a consequence of deficient PBG deaminase activity, patients with AIP excrete increased amounts of δ-aminolevulinic acid (ALA) and PBG in their urine, particularly when ALA synthase is induced. RBC, red blood cell; nmol Uro/mL, nmol uroporphyrinogen formed per mL red cells. (From Pierach CA, Weimer MK, Cardinal RA, et al. Red blood cell porphobilinogen deaminase in the evaluation of acute intermittent porphyria. *JAMA* 1987;60:257; with permission.)

Genetic heterogeneity has also been found in other types of porphyria. This includes the rare types, such as ALA dehydrase deficiency. The mechanism for variegate porphyria among South Africans is unique in that more than 90% of patients with the disorder have the same mutation in the protoporphyrinogen oxidase gene (73). This strongly supports the founder hypothesis that has been proposed for variegate porphyria in South Africa.

Sporadic porphyria cutanea tarda (PCT) may be an exception to the "rule" that gene mutations are responsible for deficient enzyme activity. Mutations in uroporphyrinogen decarboxylase cDNA or the promoter region of the uroporphyrinogen decarboxylase gene have not been identified, which suggests that sporadic PCT is not caused by mutations at the uroporphyrinogen decarboxylase locus (74). If other inherited factors are responsible for the pathogenesis of human sporadic PCT, the findings in animal models of the disorder may be relevant. In these models, the differences in the expression of liver-specific cytochrome P-450 compounds that generate inhibitors of uroporphyrinogen decarboxylase are inherited (75,76). Inheritance of a hemochromatosis gene mutation may also increase the susceptibility for sporadic PCT (77,78).

However, there has been no clear-cut relationship between specific mutations in porphyric disorders and the severity of clinical and biochemical manifestations.

This is not surprising because clinical expression of a disease is quite variable, even among members of a family. It means that identification of a specific mutation in an individual at an early age probably cannot be used to predict the severity of disease expression.

DNA analysis has not become an established method of diagnosing porphyria. Because of genetic heterogeneity, it may not be a practical way to establish the diagnosis initially, except in geographical areas where a specific mutation has a high prevalence. In a patient with a known mutation, however, DNA analysis should be the method of choice for evaluating family members (71).

The Acute Porphyrias

Three of the porphyrias—AIP, variegate porphyria, and hereditary coproporphyria—are characterized by episodic attacks of neurologic dysfunction, the so-called acute porphyric attack (Table 38.2). These are inherited as autosomal dominant disorders. Porphyric attacks also occur in ALA dehydrase deficiency porphyria, which is inherited as an autosomal recessive disorder (See "Rare Types of Porphyria").

In 1955, Berger and Goldberg proposed the name *hereditary coproporphyria* for a disorder characterized by

acute episodes of neurologic dysfunction accompanied by elevation of urinary ALA and PBG levels. Unlike patients with the previously described porphyrias, these patients had a marked increase in the urinary and fecal excretion of coproporphyrin (88,89). They also had dermatologic lesions. The disorder is much less common than AIP.

Table 38.2. Clinical Features of the Porphyrias

Type of porphyria	Usual inheritance	Neurologic dysfunction	Photocutaneous lesions	Structural liver disease	Hepatocellular carcinoma
Acute intermittent porphyria	AD	+	-	-	+
Variegate porphyria	AD	+	+	-	+
Hereditary coproporphyria	AD	+	+	-	-
ALA dehydrase deficiency	AR	+	-	-	-
Porphyria cutanea tarda	AD (familial type)	-	+	+	+
Hepatoerythropoietic porphyria	AR	-	+	±	-
Congenital erythropoietic porphyria	AR	-	+	-	-
Protoporphyria	AD	-	+	+	-

ALA, δ-aminolevulinic acid; AD, autosomal dominant; AR, autosomal recessive; +, present; –, absent.

Clinical Features of the Acute Porphyric Attack

The clinical features of the porphyric attack are similar for each of the acute porphyrias (Table 38.3) (90), although they tend to be worse in AIP. The severity of an episode depends in part on how much neurologic damage occurred before appropriate intervention was instituted. Women more frequently have acute attacks and appear to have more severe attacks. The episodes may be precipitated by the use of medications (Table 38.4) and by periods of fasting. For some women, attacks occur regularly just before menses, suggesting the importance of female hormones. However, pregnancy is well tolerated by most patients (91).

Abdominal pain is nearly always present. It is caused by autonomic nerve dysfunction. The pain is colicky in nature and often localized to the lower quadrants. An abdominal examination reveals decreased or absent bowel sounds, and abdominal x-rays show alternating areas of spasm and dilatation in the bowel. Pain is relieved by ganglionic blockade; a postmortem study showed destruction of visceral nerve myelin sheaths (92,93). The patients also complain of nausea, vomiting, and constipation or, more rarely, diarrhea. Because there is often an associated leukocytosis, the patient may have to undergo laparotomy for the evaluation of intra-abdominal infection before the diagnosis can be established (90).

Other signs and symptoms of autonomic dysfunction include tachycardia and labile hypertension. When these are present, the patient should be monitored carefully because sudden death has been reported (94,95). Fever, bladder distension, disturbed sweating, and postural hypotension may also occur (90,96).

The peripheral nervous system has both motor and sensory dysfunction. Motor damage occurs early and involves proximal muscle groups; unlike the Guillain Barré syndrome, it tends to involve the upper extremities first (90,96). Electrophysiologic findings indicate an axonal polyradiculopathy or neuropathy (97). Respiratory paralysis can be life threatening, necessitating intubation with ventilator support. Fortunately, this complication usually occurs late in an attack. Diffuse pain involving the extremities, chest, and back is common. Patients also complain of dysesthesias and paresthesias. Deep tendon reflexes are normal at first but are lost progressively in

prolonged attacks. Of note, the ankle reflexes may be selectively preserved.

Central nervous system involvement is also common (90,96). Increased irritability may be the first indication of an impending attack. Insomnia, anxiety, and behavioral changes develop as the attack continues. The patient may become violent and may be labeled as being hysterical, which, in turn, may lead to taking medications that exacerbate the attack. A psychiatric evaluation may reveal severe depression or paranoia; frank psychosis and hallucinations are also seen. Following the acute attack, chronic psychiatric disorders—especially depression—are seen more frequently than in the general population.

Seizures can occur during an acute attack, presenting a difficult clinical problem (90,98,99). Most of the common antiepileptics have a potential for exacerbating the attack. Gabapentin appears to be an exception, presumably because it is not metabolized appreciably

by the liver in humans (100). Inappropriate secretion of antidiuretic hormone with concomitant hyponatremia has been observed, and hypothalamic lesions have been found at necropsy (101,102). Abnormalities in electroencephalograms can occur in the absence of seizure activity, with nonspecific slowing being the most common. Progressive somnolence and eventual coma develop during the advanced attack. The mortality for patients with AIP who required hospitalization was three times that of the general population during the last 50 years, with most deaths occurring during a porphyric attack (103). Survival appears to have improved since the advent of hematin therapy in 1971 (103,104).

Table 38.3. Signs and Symptoms in Acute Porphyric Attacks

Signs and symptoms	Occurrence	%
Autonomic neuropathy	Abdominal pain	95
	Tachycardia (>100 bpm at rest)	80
	Constipation	48
	Nausea, vomiting	43
	Labile hypertension	36
	Postural hypotension	21
	Bladder distension	12
	Dyshidrosis	12
	Fever	9
	Fecal impaction	6
Peripheral neuropathy	Peripheral motor deficit (including respiratory)	60
	Extremity pain, paresthesias	50
	Back pain	29
	Absent reflexes	29
	Chest pain	12
Central nervous system involvement	Bulbar neuropathy	46
	Mental confusion/hallucinations	40
	Seizures	20
	Coma	10

bpm, beats per minute.

Table 38.4. Drugs and the Porphyrias

Drug	Unsafe	Thought to be safe
Analgesics	Antipyrine, oxycodone, pentazocine, phenacetin	Acetaminophen, aspirin, codeine, diflunisal, fenoprofen, fentanyl, ibuprofen, indomethacin, methadone, morphine, sulindac
Anesthetics	Chloroform, enflurane, halothane, isoflurane, lignocaine, prilocaine	Cyclopropane, ether, nitrous oxide, propofol, procaine, succinylcholine

Anticonvulsants	See text	See text
Antimicrobials	Chloramphenicol, dapsone, erythromycin, griseofulvin, ketoconazole, miconazole, nitrofurantoin, rifampin, sulfonamides, trimethoprim, doxycycline (Vibramycin)	Acyclovir, aminoglycosides, amoxicillin, amphotericin, ampicillin, ciprofloxacin, flucytosine, gentamicin, norfloxacin, ofloxacin, penicillin, streptomycin, ticarcillin, vancomycin, zidovudine
Cardiovascular drugs	Amiodarone, nifedipine, simvastatin, verapamil	Adrenaline, atropine, clofibrate, digoxin, heparin, procainamide, quinidine, warfarin
Diuretics and antihypertensives	α-Methyldopa, captopril, clonidine, enalapril, furosemide, hydralazine, hydrochlorothiazide, lisinopril, spironolactone	Acetazolimide, amiloride, bumetamide, ethacrynic acid, guanethidine, labetalol, metoprolol, propanolol, reserpine, timolol, tolazoline
Sedatives and tranquilizers	Alprazolam, amitriptyline, carisoprodol, chlordiazepoxide, diazepam, flurazepam, glutethimide, hydroxyzine, imipramine, loxapine, meprobamate	Chloral hydrate, chlorpromazine, droperidol, prochlorperazine, triazolam
Others	Aminophylline, baclofen, bromocriptine, busulphan, chlorpropamide, cyclosporine, danazol, diclofenac, ergot compounds, glipizide, methotrexate, metoclopramide, tamoxifen, theophylline, tolbutamide	Beclomethasone, chlorpheniramine, colchicine, dexamethasone, famotidine, glucagon, insulin, lithium, quinine

Biochemical Evaluation

For the undiagnosed patient who presents with signs and symptoms of an acute porphyric attack, it is not critical to identify the specific type of porphyria because therapy is the same for all. The urinary excretion of ALA and PBG should be quantitated because excretion of these compounds is increased in acute porphyrias during the porphyric attack. Sodium carbonate (4 g) should be added to the urine collection bottle to prevent degradation of PBG. Four screening tests can be used to detect increased PBG levels in the urine while proceeding with the quantitative measurement: The Watson-Schwartz test, the Hoesch test, the Mauzerall-Granick test, and the Trace PBG kit (Thermo Trace/DMA, Arlington, Texas) (105,106,107). All the tests rely on the reaction of PBG with Erlich's reagent in an acidified solution to form a red compound. An expert panel recently recommended the Trace PBG kit, which detects urine PBG concentrations greater than 6 mg/L, to screen for acute porphyria attacks (107). Because urobilinogen also reacts with Erlich's reagent to form a red compound, particular care must be taken in the Watson-Schwartz test to extract the solution with organic solvents so that a false-positive result is avoided. When allowed to stand in the light and air, urine containing excess PBG may also turn black because of the conversion of PBG to porphobilin and other pigments. In a critically ill patient, these screening studies can be used as a basis for beginning therapy.

After the diagnosis of acute porphyria is made, the specific type of porphyria can be established by measuring erythrocyte PBG deaminase activity (e.g., AIP), the fecal excretion of protoporphyrin and plasma porphyrin fluorescence pattern (e.g., variegate porphyria), and fecal and urinary coproporphyrin excretion (e.g., hereditary coproporphyria).

Pathogenesis of the Acute Porphyric Attack

The mechanism of the neurologic dysfunction that underlies the acute porphyric attack remains unclear. Several factors may be responsible. The development of mice that are made PBG deaminase deficient by gene targeting may provide a means of sorting out the different possibilities (105,106,107,108).

A central role for ALA in the development of the acute attack has been postulated (Fig. 38.5). The level of this compound is increased in blood and urine during an attack of any acute porphyria and normal in the porphyrias

without neurologic crises. Also, in hereditary tyrosinemia and lead intoxication, a marked elevation in ALA level is associated with neurologic features that are indistinguishable from those in the acute porphyrias (109,110,111,112).

ALA is structurally similar to γ-aminobutyric acid (GABA), the major inhibitory neurotransmitter in the central nervous system (113). It is a potent GABA receptor agonist (114,115); the interaction of ALA with this receptor may be responsible for some of the symptoms in the acute attack. Intraventricular injection of ALA in experimental animals results in neurotoxicity, and, at high concentrations, ALA inhibits neural Na^+/K^+-adenosine triphosphatase (ATPase) and leads to the breakdown of membrane anion gradients (115).

Although it is reasonable to speculate that ALA may be a major toxin involved in the neurologic dysfunction of the acute porphyrias, the severity of the attack does not correlate well with serum or urine ALA levels (90). Moreover, high serum and urine levels occur in patients without demonstrable neurologic abnormalities (116). The cerebrospinal fluid may also be devoid of ALA during an acute attack, although the significance of this is uncertain because cerebrospinal fluid levels do not correlate with intracellular neural levels (116). Many of the aforementioned effects of ALA occur at concentrations that are unlikely to exist in tissues during acute porphyric attacks.

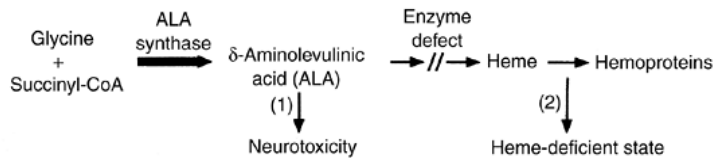
Another potential cause of neurologic dysfunction is impaired heme synthesis. This can produce a decrease in intracellular hemoproteins, leading to depressed cellular respiration in nerve tissue. Impaired hepatic metabolism can also be a consequence of abnormal heme synthesis. A deficiency of hepatic tryptophan pyrrolase, which catalyzes the first step of tryptophan degradation, can result and cause an elevation in the level of 5-hydroxytryptophan (serotonin). Increased excretion of serotonin has been reported in a few patients with acute porphyria (117). Limited heme synthesis in PBG deaminase–deficient mice produces a specific deficiency in the hemoprotein cytochrome P-450 2A5.

Necropsy findings vary with the duration of the attack. If the attack is of short duration, no discernible nerve damage is seen. With prolonged duration, axonal damage and, eventually, demyelinization of autonomic, motor, and sensory nerves occurs (92). This correlates with the observation that early therapeutic intervention (i.e., prior to neuronal death) is associated with complete and rapid recovery. Once paralysis is established, recovery depends on axonal regeneration. Recovery of proximal muscle groups occurs earlier than it does in the distal groups, which are innervated with longer axons. PBG deaminase–deficient mice develop a progressive motor neuropathy with normal or minimally elevated ALA levels (106). These data are most consistent with a dysfunction of hemoproteins causing the neuropathy of porphyria (106).

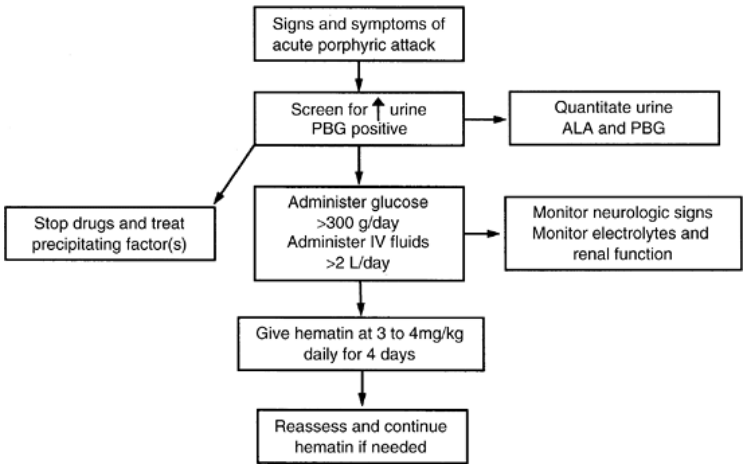
Management of the Attack

Because of the unpredictable nature of an acute porphyric attack, it is generally advisable to hospitalize the patient early during an episode. Therapy should follow several steps (Fig. 38.6). First, any porphyrinogenic drug should be discontinued, and drugs that may exacerbate the attack should be avoided (Table 38.4). If the attack is precipitated by an infection, the infection should be treated promptly. An adequate caloric intake should be maintained because diminished oral intake can precipitate or aggravate an attack (118,119). The diet should provide at least 400 g of glucose or another rapidly metabolized carbohydrate daily. A high carbohydrate intake is beneficial because of its suppressive effect on hepatic ALA synthase activity (120). Patients who cannot take carbohydrates by mouth should be given a high carbohydrate feeding through a nasogastric feeding tube and/or intravenously as 10% glucose. Intravenous fluids should be given at a rate more than 2 L/day in the form of normal saline. The patient should

be monitored for the development of hyponatremia, which may occur because of the inappropriate secretion of antidiuretic hormone. The patient should also be monitored for the progression of neuropathy, with particular attention to changes in respiratory function. Serial measurements of vital capacity and forced expiratory volume should be taken, and ventilatory support should be provided if respiratory depression develops.



▪ **Figure 38.5** Schematic showing that neurologic dysfunction in the inducible porphyrias is linked with the biochemical abnormalities. It may be caused by the neurotoxic effect of δ-aminolevulinic acid (ALA), a heme-deficient state, or a combination of both.



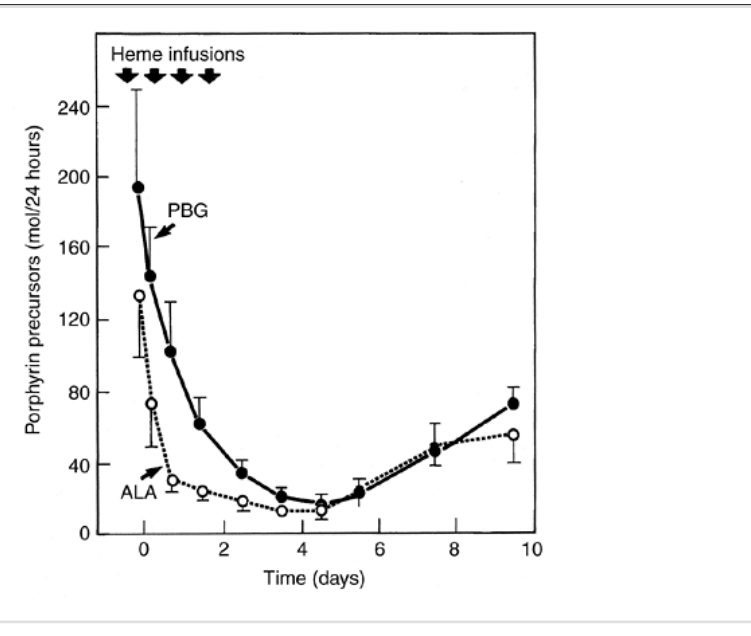
▪ **Figure 38.6** Scheme for the management of acute porphyric attack. ALA, δ-aminolevulinic acid; PBG, porphobilinogen.

Although the product labeling recommends an initial trial of intravenous glucose, an expert panel recommends starting hematin therapy early for most acute porphyric attacks (104). *Hematin* (ferriheme hydroxide) is the chemical form of heme in aqueous solution at physiologic pH. Exogenously administered hematin suppresses hepatic ALA synthase activity (23,121,122,123). Hematin was first administered to a patient with an acute porphyric attack in 1971 (124) and became available as an orphan drug in 1983. It is available in the United States as lyophilized powder for reconstitution into sterile water just before infusion (Panhematin, Ovation Pharmaceuticals, Deerfield, Illinois). In Europe, it is also available as heme arginate (Normosang, Leiras Oy Pharmaceuticals, Helsinki, Finland).

Hematin, administered intravenously in a dose of 3 to 4 mg/kg body weight once daily for 4 days, causes a prompt decline in serum and urine levels of ALA and PBG (Fig. 38.7) (125,126). Antipyrine metabolism also improves (127,128,129,130), suggesting that apoproteins of cytochrome P-450 are reconstituted with heme therapy. Despite its impressive pharmacologic effects, the clinical effect of hematin is less predictable. There have, in fact, been no randomized, double-blind studies that show a clinical benefit for hematin during an acute porphyric attack, although many physicians who manage such patients believe that it is of benefit. Hematin should be given before advanced neuronal damage occurs because this is usually not reversed.

The most common complication of hematin therapy is thrombophlebitis, which can be prevented by

administering the solution for 15 to 30 minutes in a free flow through an intravenous line. A transient coagulopathy may be caused by breakdown products of hematin; therefore, it should be given as soon as possible after it has dissolved in an aqueous solution. Dissolving hematin in human serum albumin protects it from degradation (129). Tin protoporphyrin, which inhibits heme oxygenase and thereby prevents the breakdown of heme, has been used in combination with hematin to prolong biochemical remission (131).



▪ **Figure 38.7** Effect of intravenous infusion of heme arginate (3 mg/kg) on the excretion of δ-aminolevulinic acid (ALA) and porphobilinogen (PBG) in six patients with acute intermittent porphyria (mean ± SE). (From Mustajoki P. Acute intermittent porphyria. *Semin Dermatol* 1986;5:155, with permission.)

The symptoms and signs of the attack should be treated while glucose and/or hematin is given. Pain, which can be very severe, should be controlled with narcotics, if necessary. Agitation can be controlled with chloral hydrate or chlorpromazine, and ondansetron can be used to relieve nausea and vomiting. Propranolol, in a dosage of 20 to 200 mg/day, can be used for hypertension and tachycardia, although it should be used cautiously (132). Seizure activity is a particularly difficult problem because most of the anticonvulsants (particularly the barbiturates and phenytoin) precipitate acute attacks. Bromides are safe but difficult to use. Clonazepam in low doses that produce levels up to 6 mg/dL may be administered, and new drugs, such as gabapentin, are promising (100). Status epilepticus can be controlled with diazepam (up to 10 mg intravenously), paraldehyde (8 to 10 mL rectally), or magnesium sulfate (0.5 to 1.0 g/hour by intravenous infusion).

Many patients have a limited number of porphyric attacks in their lifetime and do well if they avoid porphyrinogenic drugs, fasting, and excessive alcohol intake. However, some patients have recurrent attacks and pose a challenging problem. They are prone to narcotic addition, and pain management becomes a critical feature of their care. Available studies have not clearly shown that the regular administration of hematin is beneficial in this situation (133). For such patients liver transplantation may be considered because this has corrected the biochemical and clinical abnormalities in one patient with AIP (134).

In some women, attacks are related to the menstrual cycle, beginning a few days before the onset of menses and ending after it has begun. The attacks are probably caused by endogenous progesterone. Analogs of gonadotrophin-releasing hormone have been used in the management of these cases (135). These agents prevent the normal cyclic secretion of luteinizing hormone and follicle stimulating hormone by the pituitary. Oral hormonal contraceptive use is associated with acute attacks in some patients, but menopausal hormone replacement therapy only rarely affects acute porphyries. Pregnancy is usually well tolerated, but there is an increased frequency of miscarriage.

Prevention of Attacks

Individuals who have suffered acute porphyric attacks should wear bracelets stating that they have porphyria. They should also be provided a list of drugs that are safe for use, as well as those that are unsafe. They should be instructed to avoid fasting and excess intake of alcohol and to have infections treated promptly. Treatment with erythropoietin may reduce the severity of porphyric attacks in some patients (136).

Measurement of erythrocyte PBG deaminase activity has shown that many individuals related to patients with AIP are latent carriers of the gene defect. They have no clinical manifestations, and many have normal excretion rates for ALA and PBG. Although the natural history of the latent state remains unclear, carriers of the gene defect have the potential to develop acute attacks and should therefore avoid factors that are incriminated in precipitating attacks (e.g., sulfonamides, barbiturates, hydantoins, fasting, and excessive intake of alcohol).

Erythrocyte PBG deaminase activity should be measured in first-degree relatives of patients with AIP. Children should be assessed as they approach puberty. As gene testing develops, it should also be utilized for families in which acute porphyria is present. Patients in whom the enzyme abnormality/gene defect is found should be managed along the guidelines outlined for latent individuals.

Hepatocellular Carcinoma in Acute Porphyrias

Limited information is available about structural liver changes in the acute porphyrias. Fatty infiltration and siderosis, together with a mild inflammatory process, have been seen in liver biopsy specimens, and crystalline material has been found within mitochondria (134,137). Functional studies have shown there is impaired hepatic mixed-function oxidase activity (137).

There is an association between the acute porphyrias and hepatocellular carcinoma (138,139,140). The relative risk of developing hepatocellular carcinoma in acute porphyrias is 30 to 60 times that for the general population (138,141). It has been speculated that carcinogenic substances may accumulate because the hepatic detoxification mechanism is impaired (140).

Porphyria Cutanea Tarda

PCT is traced to Günther's description, in 1911, of adult patients who had cutaneous lesions but no neurologic abnormalities (142). The term was first used by Waldenström to distinguish the disorder from the

porphyrias in which both cutaneous lesions and neurologic dysfunction occur (80). *Tarda* was included in the name because the disorder occurred late, commonly after the fourth decade of life. However, the familial form of PCT may begin in childhood (143,144).

PCT is the most common porphyria with clinical expression in the United States, although its exact prevalence is unknown. It is frequently associated with ethanol use. Among the Bantu of South Africa, a high prevalence is seen; this has been attributed to the ingestion of a local beer brewed in iron pots (145). The disorder was previously identified much more commonly in men, but the proportion of women diagnosed with PCT has

increased. This reflects, in part, the increasing use of oral contraceptives and estrogen preparations, which also precipitate PCT (146).

Although most cases are sporadic, families with PCT have been identified, in which there is autosomal dominant inheritance with variable penetrance (54,57,147). In contrast to the sporadic cases, in which the abnormality in uroporphyrinogen decarboxylase is restricted to the liver, the familial cases also have a deficiency of erythrocyte uroporphyrinogen decarboxylase activity (148).

PCT can also be acquired through toxic exposure. In the late 1950s, an epidemic occurred in Turkey after the widespread ingestion of seed grain that had been treated with the fungicide hexachlorobenzene (149). Experimental porphyria mimicking PCT has been induced with a number of structurally related compounds, including polychlorinated and polybrominated biphenyl and dioxin compounds (150).

Disorders Associated with Porphyria Cutanea Tarda

Several disorders are associated with the development of PCT. Most notable has been the striking association with chronic hepatitis C (See "Porphyria Cutanea Tarda and Hepatitis C"). Systemic lupus erythematous, rheumatoid arthritis, Sjögren's syndrome, and acquired immunodeficiency syndrome (AIDS) have also been associated with PCT (151,152,153,154,155). Increased porphyrin levels in the dialysate and plasma of patients on long-term hemodialysis have been reported (156,157,158). This may occur irrespective of the development of cutaneous lesions (158).

Porphyria Cutanea Tarda and Hepatitis C

There is a significant increase in the prevalence of chronic hepatitis C in patients with PCT compared with the general population (151,152,153,154,155,159,160,161,162,163,164). There is striking geographic variation in this association. The highest prevalence is found in southern European countries, where chronic hepatitis C is found in 60% to 90% of patients with PCT (152,159). A large study in the United States found the prevalence to be 56% in 70 unselected patients with PCT (78). Hepatitis C virus (HCV) infection was documented by a positive test for both hepatitis C antibody and RNA. The patients with PCT who had hepatitis C infection did not differ from those without infection in terms of the type or severity of skin lesions, or in the level and pattern of urinary porphyrin excretion. However, this condition was more frequent in men and among those with a higher rate of alcohol use.

The causal relationship between hepatitis C and PCT, if any, remains unclear (165). Only about 1% to 5% of patients with chronic hepatitis C have clinical PCT (159), and conversely many patients with PCT do not have chronic hepatitis C. Viral parameters of hepatitis C such as genotype and viral level do not appear to be important (166). Other possibilities are that hepatitis C alters hepatic iron metabolism or promotes oxidative stress in hepatocytes, which brings out overt PCT in susceptible individuals. Overall, PCT is now considered to be an extrahepatic manifestation of HCV infection.

Porphyria Cutanea Tarda and HFE Mutations

Hepatic iron overload is common in patients with overt PCT. Because iron removal returns porphyrin excretion to normal and ameliorates the clinical features in PCT, hepatic iron overload appears to be an important factor in causing the disease. Before the identification of the *HFE* gene, it was controversial whether patients with PCT may have inherited a gene mutation for hemochromatosis, which caused hepatic iron overload. Subsequently, studies from many countries demonstrated that 40% to 50% of patients with PCT carry the C282Y mutation in the *HFE* gene, with 10% to 20% being homozygous (77,166,167). A study from the United States showed that 42% of patients with PCT carried the C282Y mutation (15% were homozygous) and another 31% carried the H63D mutation (8% were homozygous). Therefore, there appears to be an increased prevalence of the hemochromatosis gene mutations in patients with PCT (168), suggesting a mechanism by which some patients with PCT have increased hepatic iron levels.

Biochemical Evaluation of Porphyria Cutanea Tarda

The diagnosis of PCT is generally made on a clinical basis, but biochemical confirmation, by demonstrating increased urine excretion of uroporphyrin, should be made. Urine heptacarboxyl and hexacarboxyl porphyrin levels are also elevated. Coproporphyrin and

pentacarboxyl porphyrin levels are elevated to a lesser degree. Urinary PBG is not increased, but a slight elevation in ALA level is common. Fecal porphyrin analysis demonstrates that porphyrins are present in the form of isocoproporphyrins.

Photocutaneous Lesions in Porphyria Cutanea Tarda

The presenting clinical manifestation of PCT is nearly always the development of bullous lesions in areas of sun exposure (Fig. 38.8). The lesions occur after minor trauma because of increased skin fragility. The dorsum of the hand is most frequently involved. Other sites include the forehead, neck, and ears. The bullae may become infected, causing delayed healing that produces scarring and pigment changes. Hypertrichosis occurs in the periorbital area, a feature that was prominent in the Turkish epidemic. Milia, which are small white papular lesions, form as a chronic manifestation of the disorder. Sclerodermoid changes may also develop.

The skin lesions in PCT are the same as those in variegate porphyria and hereditary coproporphyria. The rare disorder, hepatoerythropoietic porphyria, also features skin lesions similar to those in PCT. In contrast to PCT,

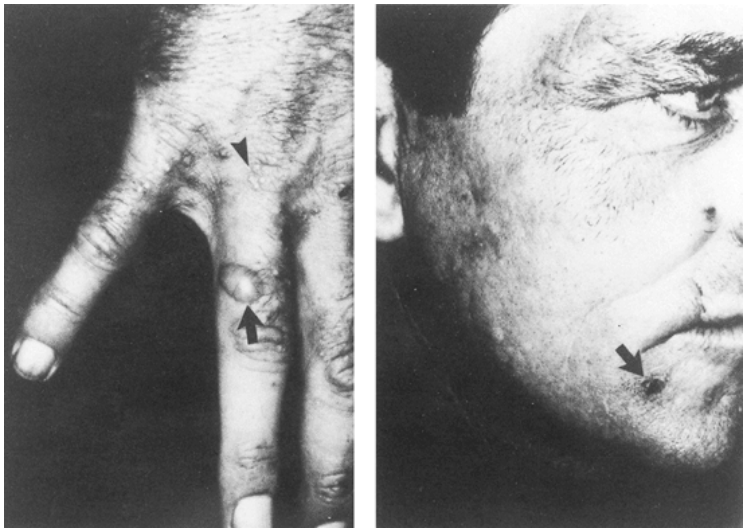
skin lesions occur in infancy and tend to diminish with age.

Porphyrins are produced in excess and accumulate in the skin of patients with the cutaneous porphyrias. In the disorders in which bullous lesions occur, hydrophilic porphyrins accumulate within lysosomes of cells (169). The severe lesions in PCT may be due to the release of proteolytic enzymes from lysosomes into the cytoplasm (Fig. 38.9) (170). Complement activation may also contribute to the pathogenesis of the cutaneous lesions in PCT. Complement compounds are deposited at the dermal–epidermal junction near bullae, and elevated levels of complement components and cleavage products are found in the fluid contained in the lesions (171). Complement levels in serum containing excess porphyrin decline after ultraviolet irradiation (171). Uroporphyrin also stimulates collagen biosynthesis by fibroblasts, which may contribute to the sclerodermoid skin changes in PCT.

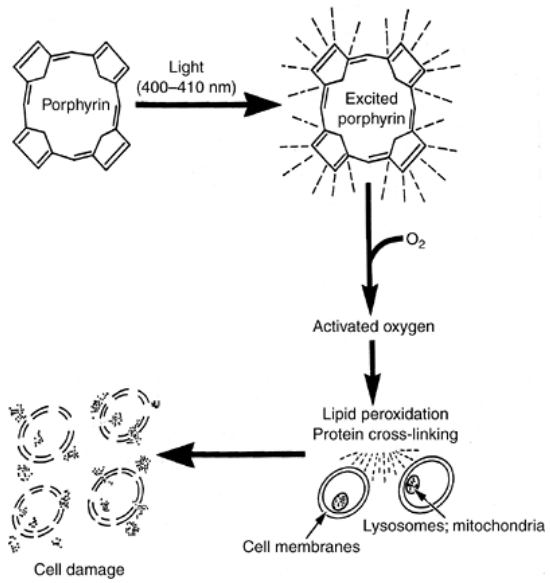
Liver Damage in Porphyria Cutanea Tarda

Patients with clinically overt PCT usually have liver damage. Approximately two thirds of patients have an elevation in the serum transaminase level at the time of diagnosis (172,173,174,175). The liver may have a patchy gray discoloration when viewed grossly (172). Liver biopsy specimens exhibit red fluorescence when exposed to

ultraviolet light (176). If a water-free preparation of tissue is used, a cytoplasmic distribution of fluorescence is observed. Needle-like cytoplasmic inclusions are found in specimens from untreated patients (Fig. 38.10) (177). The inclusions, which appear to be uroporphyrin crystals, are water soluble and are lost during tissue processing unless water-free fixation is used.



▪ **Figure 38.8** Skin lesions in porphyria cutanea tarda. Erosions and bullae (*arrows*) occur in sun-exposed areas after minor trauma. Milia (*arrowhead*) are small, whitish papules found on the dorsal aspects of the hands. There is increased facial hair in the periorbital region. Similar skin changes are found in variegate porphyria, hereditary coproporphyria, and hepatoerythropoietic porphyria. (From Bloomer JR. The hepatic porphyrias. *Gastroenterology* 1976;71:689, with permission.)



▪ **Figure 38.9** Sequence by which damage to skin and other tissues may be produced when porphyrins are exposed to light in the presence of molecular oxygen. Uroporphyrin preferentially causes injury to lysosomes in cells, whereas cell membranes and mitochondria appear to be the principal targets in protoporphyrin-induced damage.

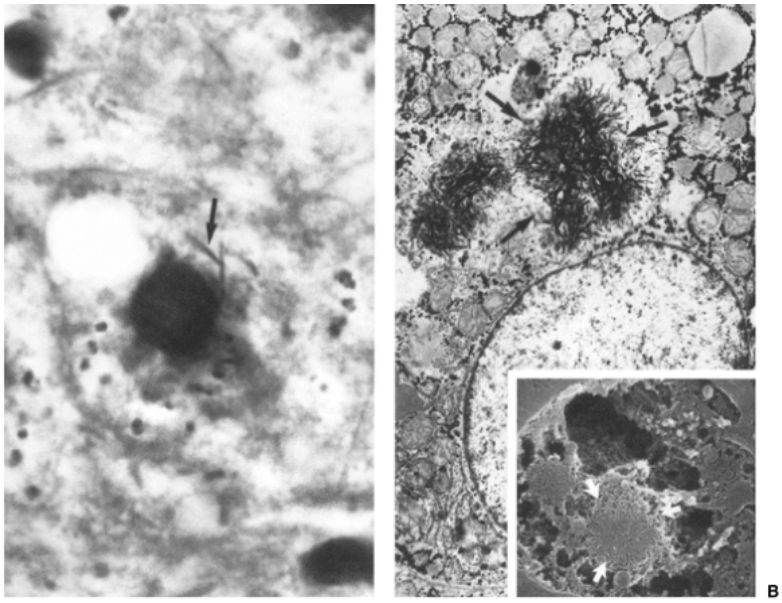
Patients with PCT commonly have some degree of hepatic iron overload, and hemosiderosis is usually demonstrated with iron stains (134,172,174,175). The accumulation of iron occurs not only in patients who abuse ethanol but also in familial and estrogen-induced PCT (134,174). The iron is distributed diffusely but is most frequent in Kupffer cells and clusters of macrophages.

Fatty infiltration of the liver is also common, having been reported in most biopsy specimens. Although this may be related in part to underlying ethanol abuse, one study found no difference in the prevalence of fatty liver in alcoholic versus nonalcoholic patients with PCT (174). The fatty changes are usually mild.

Granuloma-like clusters of mononuclear cells, Kupffer cells, hemosiderin, and ceroid have been described as lobular lesions of PCT (175). They occur with variable frequency and may represent a reaction to collections of iron and uroporphyrin.

Hepatitis C may contribute to the liver damage in PCT. Liver biopsy specimens from patients with PCT who are positive for hepatitis C antibody have changes similar to those from patients with hepatitis C alone, including lymphoid follicles, bile duct damage, and hepatocellular necrosis (153).

The extent of hepatic damage is variable, ranging from minimal injury to cirrhosis, and appears to be related, in part, to the duration of PCT (175). No definite relationship has been established between ethanol abuse and progression of liver damage, and alcoholic hepatitis is infrequent in PCT (172,174). Although hepatic iron overload may contribute to liver damage, the correlation between the degree of siderosis and the severity of liver damage is poor. Nevertheless, phlebotomy produces improvement in some, but not all, of the abnormalities. Hemosiderosis disappears as total iron stores are depleted. Fluorescence and the crystalline material, as well as the granuloma-like lesions, disappear. The liver enzyme abnormalities return toward normal. Improvement usually occurs irrespective of continuation of the use of ethanol (173).



▪ **Figure 38.10** Hepatic crystals in porphyria cutanea tarda and protoporphyria. **A:** Light micrograph shows intracytoplasmic crystals (*arrow*) in a hepatocyte of a patient with porphyria cutanea tarda (hematoxylin and eosin stain). **B:** Transmission electron micrograph shows a cluster of crystals (surrounded by *arrows*) in a hepatocyte of a patient with protoporphyria. A scanning electron micrograph shown in the *inset* also demonstrates the crystalline material (surrounded by *arrows*). (From Rank JM, Straka JG, Bloomer JR. Liver in disorders of porphyrin metabolism. *J Gastroenterol Hepatol* 1990;5:573, with permission.)

PCT has been associated with hepatocellular carcinoma. The first report of this relationship was in 1957, when apparent PCT was noted in a patient with a hepatic tumor that fluoresced when exposed to ultraviolet light (178). After surgical removal of the tumor, the patient's skin lesions improved and porphyrin excretion returned to normal. There have been other reports of porphyrin-excreting tumors in which the biochemical abnormalities were somewhat different from those usually seen in PCT, with increased excretion of several porphyrin compounds in addition to uroporphyrin (179).

The more common association is the development of hepatocellular carcinoma in patients with long-standing PCT. The frequencies of cirrhosis and hepatocellular carcinoma were 63% and 53%, respectively, in a 1979 autopsy series (180). The diagnosis of PCT had been made several years before death in all cases. A 1972 autopsy series of patients with PCT in Czechoslovakia found cirrhosis in 64% and carcinoma in 47% (181). The severity of liver disease and the development of carcinoma correlated with the length of time after the diagnosis of PCT was made. The duration was 3.7 years for patients without cirrhosis, 6.3 years for those with cirrhosis but no carcinoma, and 11.7 years for those with carcinoma. Cirrhosis was present in all cases with hepatocellular carcinoma. Ethanol use was not universal, and the degree of hepatic hemosiderosis was variable. In two other studies, conducted in 1982 and 1985, an increased incidence of hepatocellular carcinoma was also found (182,183). The presence of carcinoma correlated with male sex, duration of time after the diagnosis of PCT, and cirrhosis. There was no correlation with ethanol use or hepatitis B serology. However, none of 96 Italian patients screened with radionuclide liver scan and measurement of serum α-fetoprotein had evidence of tumor (184).

Because these studies were carried out before the discovery of the HCV, the role of chronic hepatitis C in the development of hepatocellular carcinoma could not be determined. A recent study from the Netherlands found the incidence of hepatocellular carcinoma to be 13% in the 38 patients with PCT who were followed up for 2 to 18 years (161). There was no difference in the prevalence of hepatitis C infection in patients with hepatocellular carcinoma (20%) compared to those

without (18%). Therefore, hepatocellular carcinoma may develop in patients with PCT irrespective of the presence of hepatitis C infection.

These studies suggest that there is an increased risk for developing cirrhosis and hepatocellular carcinoma for patients with long-standing PCT. Additional studies are needed to clarify the role of hepatitis C in this process. In any event, it is probably prudent to screen patients with long-standing PCT, particularly those with chronic hepatitis C and/or cirrhosis, for hepatocellular carcinoma by measuring serum α-fetoprotein and by hepatic ultrasonography.

Management in Porphyria Cutanea Tarda

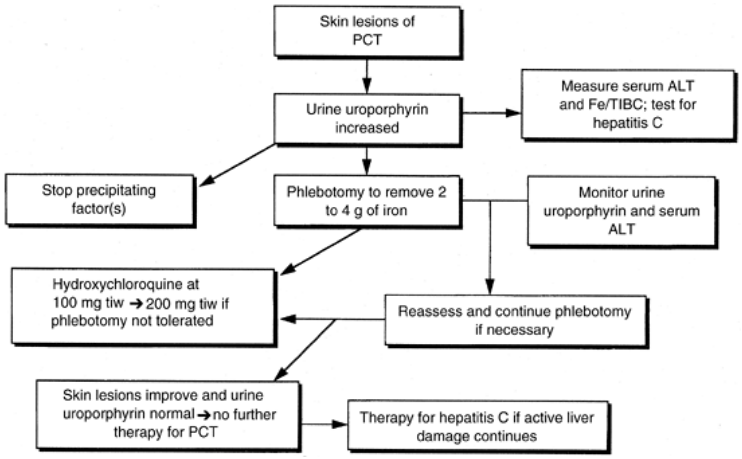
The patient with active PCT should avoid wavelengths of light that may excite porphyrins. This occurs maximally at a wavelength of 400 to 410 nm. Light of this wavelength is not filtered by window glass; therefore, the patient should take precautions when driving a car. Fluorescent lights should also be avoided.

Patients should stop ingesting ethanol, and women taking birth control pills should use another form of contraception. Patients should also not take iron-containing compounds. Despite discontinuing the precipitating factors, improvement will be slow unless other therapy is used (Fig. 38.11). The mainstay of therapy is phlebotomy (185,186), which is based on the observation that hepatic siderosis is common and that iron probably plays an important role in the pathogenesis of the disease. The liver typically contains an excess of 2 to 4 g iron, and the amount of phlebotomy needed will be on the order of 4 to 8 L of blood. After phlebotomy is completed, urine levels of uroporphyrin will continue to decrease toward normal, and more than 90% of patients will have normal levels after 6 to 12 months. Resolution of skin fragility will accompany the decrease in uroporphyrin excretion, and patients will no longer develop vesicles or erosions. Hirsutism and hyperpigmentation may take months to clear after phlebotomy is completed, and sclerodermoid changes may not resolve for several years. Iron-containing compounds should not be ingested because this may cause a relapse.

For patients who do not tolerate phlebotomy or who continue to have cutaneous symptoms despite an adequate course of phlebotomy, chloroquine or related compounds can be administered (186). These compounds appear to form complexes with uroporphyrin and heptacarboxyl porphyrin, enhancing their removal from tissues and excretion in urine. The initial dose should be 100 mg of hydroxychloroquine or 125 mg of chloroquine three times a week. Larger doses may cause hepatic injury related to the massive removal of uroporphyrin from the liver. In an uncontrolled clinical trial, high-dose vitamin E reduced urine uroporphyrin levels in five patients with PCT (187).

It is unclear how the patient with PCT and concomitant chronic hepatitis C should be managed. A few reports suggest that interferon therapy may reduce

the manifestations of PCT. However, until this has been studied more carefully, it is probably best to institute a course of phlebotomy before starting antiviral treatment.



• **Figure 38.11** Scheme for management of the patient with active porphyria cutanea tarda (PCT). ALT, alanine aminotransferase; TIBC, total iron-binding capacity; tiw, three times a week.

For the patient with chronic renal failure who develops cutaneous lesions of PCT while on hemodialysis, standard phlebotomy is usually contraindicated because of anemia. In this situation, erythropoietin therapy accompanied by small-volume phlebotomies has been used successfully (188).

Erythropoietic Protoporphyria

In 1961, Magnus et al. (189) described a 35-year-old man who had lifelong itching and edema of his skin on exposure to sunlight. His urinary excretion of porphyrins and porphyrin precursors was normal, but his red cells and feces contained excess protoporphyrin; therefore, they proposed the name *erythropoietic protoporphyria* (*EPP*) for his condition. *Erythrohepatic protoporphyria* and *protoporphyria* have also been used as names for the disorder.

EPP occurs in all ethnic groups, but the precise prevalence has not been determined for any group. The pattern of inheritance was previously considered to be that of an autosomal dominant disorder with variable expression. Some individuals who carry a mutant ferrochelatase gene in one allele have no clinical manifestations of the disease, and their porphyrin levels may be normal. Most patients with symptomatic protoporphyria have ferrochelatase activity that is significantly less than the expected 50% of normal in a classic autosomal dominant disease (190). These results are explained in part by the inheritance of a mutation in one ferrochelatase allele that structurally alters the protein together with a low-expressing nonmutant ferrochelatase allele caused by a polymorphism in an intron (IVS 3–48 T/C) (191,192). There is no difference between sexes in

the frequency of the disorder, either for the gene defect or for the clinically expressed disease.

Biochemical Evaluation of Erythropoietic Protoporphyria

The biochemical hallmark of EPP is an increased level of protoporphyrin in red cells and feces. The excess protoporphyrin does not form complexes with a metal, unlike iron deficiency and lead poisoning, in which excess red cell protoporphyrin is chelated to zinc (193). The diagnosis is established by demonstrating an elevated red cell protoporphyrin level in a patient who has the typical clinical features.

Patients with EPP do not excrete increased amounts of PBG and ALA in urine. This implies that hepatic ALA synthase activity is not increased, although in vitro measurements have shown otherwise in some instances (194). In most patients normal amounts of heme are synthesized in liver tissue and bone marrow, but in approximately 25% there is mild anemia characterized by microcytic indices (195). Iron metabolism is normal (196), and iron deficiency can exacerbate the accumulation of protoporphyrin in red cells (197). Once the red cell enters the circulation, protoporphyrin is released into the plasma within a few days (unless liver disease is present) and is then excreted by the liver into bile (Fig. 38.12) (See "Excretion of Porphyrins and Porphyrin Precursors") (198).

Bone marrow is the major source of excess protoporphyrin in most patients. Studies using radiolabeled precursors of protoporphyrin have indicated that the liver also contributes to excess protoporphyrin production (199,200), although the interpretation of these studies has been controversial (201). Metabolic balance studies comparing fecal protoporphyrin excretion with the total mass of red cell protoporphyrin have occasionally demonstrated a significant discrepancy, also indicating a hepatic contribution (202).

Photosensitivity in Erythropoietic Protoporphyria

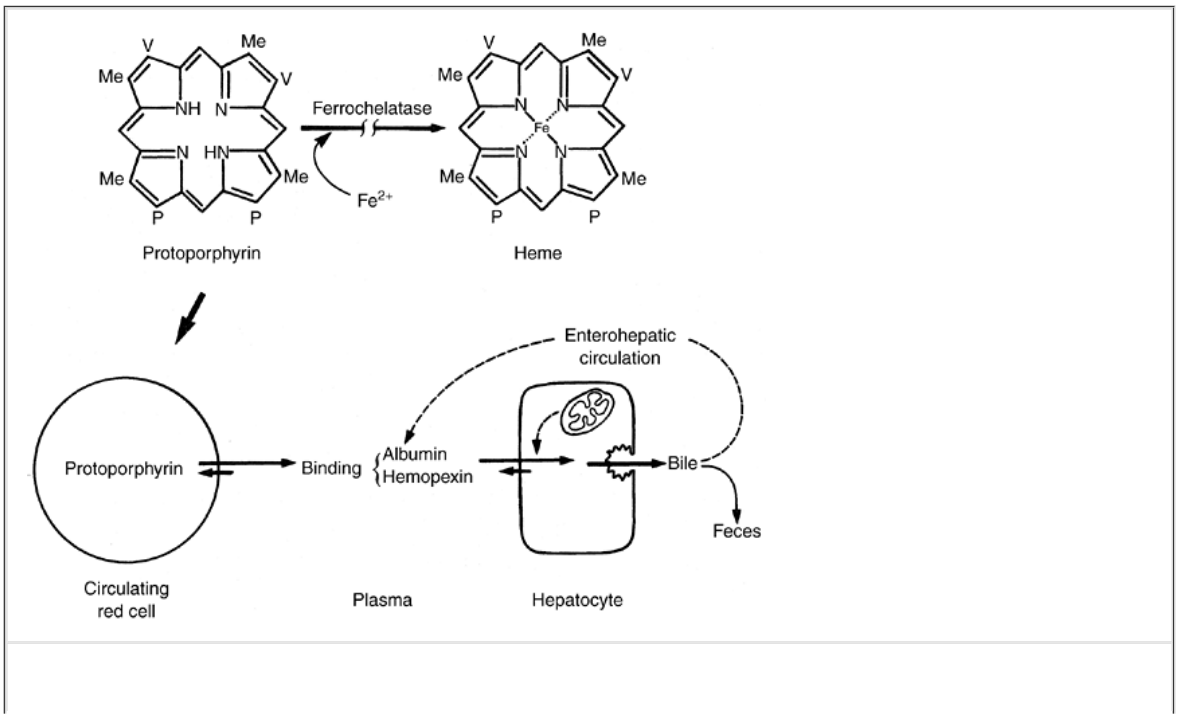
The principal clinical manifestation in EPP is photosensitivity. This is usually lifelong, often beginning in infancy. Rarely, the photosensitivity has onset in adulthood (203). Patients experience burning or stinging of the skin on exposure to sunlight. Window glass does not prevent the reaction because the wavelength of light that causes the photosensitivity (400 to 410 nm) is not filtered by window glass. For some patients, photosensitivity is caused by light emitted from fluorescent fixtures. Erythema and edema of the skin develops and may persist for several days (Fig. 38.13). Unlike PCT, the development of vesicles and erosions is rare. Chronic skin changes are characterized by thickening and lichenification of the skin over the nose and the dorsum of the hand, as well as shallow scars (Fig. 38.13. Microscopic examination of the skin demonstrates the deposition of periodic acid schiff (PAS)-positive material around the walls of capillaries in the dermis (204).

Photosensitivity is caused by excess protoporphyrin circulating in blood or deposited in skin tissue, or a combination of the two. Absorption of light energy by the porphyrin molecule raises the molecule to an excited state in which it reacts with molecular oxygen to produce reactive oxygen species (Fig. 38.9). Cell membranes and mitochondria appear to be the principal targets for protoporphyrin-induced damage (169). The damage is attributed to cross-linking of membrane proteins and peroxidation of membrane lipids (205,206).

P.1104

P.1105

The activation of complement may also be a factor because complement is depleted in serum containing protoporphyrin when the serum is exposed to light (207). Mast cells release serotonin and arachidonic acid when incubated with protoporphyrin and exposed to ultraviolet light; this may contribute to the photosensitivity as well (208).



▪ **Figure 38.12** Protoporphyrin metabolism in protoporphyria. As a consequence of deficient ferrochelatase activity, protoporphyrin accumulates in heme-forming tissues—primarily the bone marrow, with a variable contribution from the liver. This excess protoporphyrin undergoes biliary excretion. Enterohepatic circulation of protoporphyrin contributes to the amount that the liver must excrete in bile. (From Bloomer JR. The liver in protoporphyria. *Hepatology* 1988;8:407, with permission.)

▪ **Figure 38.13** Cutaneous lesions in protoporphyria. **A:** Acute photosensitivity reaction showing edema of the face and erythema on the bridge of the nose following sun exposure. **B:** Chronic skin changes on the hand of a patient with protoporphyric liver disease. There is thickening and lichenification of the dorsum of the hand in areas where there was repeated sun exposure.

Hepatobiliary Disease in Erythropoietic Protoporphyria

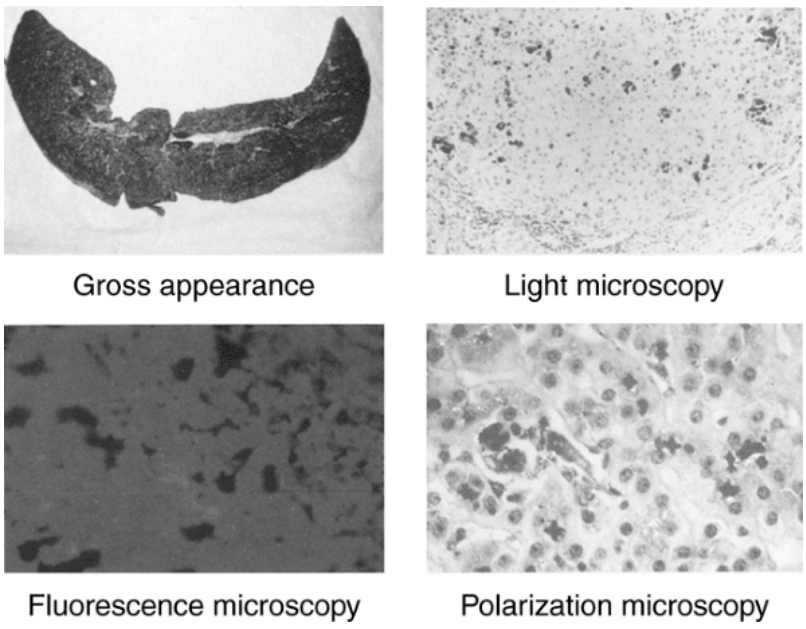
In 1963, a 6-year-old boy who had the biochemical features of EPP along with hepatosplenomegaly and abnormal liver chemistries was described. At the time of subsequent splenectomy, he was found to have a cirrhotic liver (209). In 1968, it was reported that patients with EPP may develop a liver disease that progresses to liver failure (210). The frequency remains uncertain, although less than 10% of patients appear to develop this complication.

Severe liver disease has occurred in both men and women, and in children and adults. A synergistic effect with alcohol has been reported (211), but liver disease usually develops in the absence of other causes of liver injury. Laboratory study results are nonspecific, showing variable hyperbilirubinemia with mild to moderate increases in serum transaminase and alkaline phosphatase levels. Red cell protoporphyrin levels are significantly higher than those in the usual patient with EPP, ranging from 1,404 to 36,800 µg/dL (211). Along with signs and symptoms of hepatic decompensation, patients have neurologic symptoms that include severe abdominal pain that often radiates into the back (212). Prognosis is poor once jaundice develops in a patient with liver disease due to EPP.

The livers of patients who die of hepatic failure or undergo liver transplantation are black in color (Fig. 38.14) because of massive deposits of protoporphyrin pigment in hepatocytes, macrophages, Kupffer cells, and biliary structures. The pigment deposits are birefringent when examined by polarization microscopy (213,214) because of the fact that they contain crystals (Fig. 38.10) (215).

The liver damage appears to be caused by the progressive accumulation of protoporphyrin in the liver. Regardless of the source of the excess protoporphyrin, the only means for its excretion is by hepatic clearance and secretion into bile (4). During this process, protoporphyrin is kept in solution through protein binding because it is a poorly water-soluble compound that aggregates in aqueous solution. Protoporphyrin may aggregate and form crystalline deposits within hepatocytes and small biliary radicals when concentrations are high. These deposits obstruct bile flow and damage hepatocytes. Experimental studies have demonstrated that protoporphyrin is also toxic to the liver when in solution. Perfusion of the isolated rat liver with protoporphyrin causes a reduction in bile flow (216). Histologic examination of the perfused liver shows canalicular dilatation and distortion, and membrane ATPase activity is reduced (217). Membrane dysfunction presumably occurs when the lipophilic protoporphyrin molecule intercalates into the membrane and alters the physical and chemical properties of the membrane (218,219). Studies with a mouse model of EPP also indicate that there may be formation of cytotoxic bile containing high concentrations of bile salts and protoporphyrin that cause biliary

fibrosis by damaging bile duct epithelium (220).



▪ **Figure 38.14** Liver disease in protoporphyria. Resected liver of a patient who underwent liver transplantation shows the liver to be black and fibrotic (*top left*). Light microscopy demonstrates diffuse pigment deposits in liver cells and the biliary radicles (*top right*). Fluorescence microscopy demonstrates hepatocytes to be fluorescent because of the presence of protoporphyrin, and polarization microscopy demonstrates birefringence (note the Maltese cross formation) because of protoporphyrin crystals (*bottom figures*).

Because protoporphyrin accumulation in the liver appears to be responsible for liver damage in EPP, patients with this complication presumably should have a greater abnormality in protoporphyrin metabolism than the usual patient. Indeed, red cell and plasma protoporphyrin levels are significantly higher in patients with liver disease than in the usual patient, and the distribution of protoporphyrin in red cells changes (221,222). The ratio of fecal protoporphyrin excretion to the total red cell protoporphyrin content decreases (221), and the ratio of the concentration of protoporphyrin to that of bile salts in bile increases (215).

Although the frequency of severe liver disease is not high in patients with EPP, histologic abnormalities are often found in liver biopsy specimens (223,224). These consist of focal deposits of protoporphyrin pigment, portal fibrosis, and inflammation. Changes in bile canalicular ultrastructure occur early in

the course of hepatic involvement (225). Patients also appear to have an increased frequency of gallstones, which contain protoporphyrin.

Management in Erythropoietic Protoporphyria

Most patients with EPP will require therapy only for photosensitivity. Sunscreens that protect against the wavelength of light (400 to 410 nm) that activates protoporphyrin should be used. Films can be installed on windows to provide protection against light of this wavelength. The oral administration of β-carotene in a daily dosage of 60 to 180 mg reduces photosensitivity in many patients.

For the patient in whom liver disease has developed, therapeutic approaches can be tried to diminish the production of protoporphyrin or facilitate its excretion. The oral administration of chenodeoxycholic acid has reduced protoporphyrin levels in some patients (226), as has the correction of iron deficiency (197). However, iron therapy must be used cautiously because in some patients, protoporphyrin metabolism worsens (227). Red cell transfusions and the administration of hematin have also been successful in diminishing protoporphyrin levels (222,228,229). Oral administration of cholestyramine and activated charcoal has been used to interrupt the enterohepatic circulation of protoporphyrin (230,231). A randomized placebo-controlled trial demonstrated that cysteine (500 mg orally twice a day) increased the time of symptom-free light exposure (232). Each of these approaches has a rational basis and does not pose a major risk to the patient. For the patient with early liver damage, administration of cholestyramine should be tried and liver chemistries and red cell protoporphyrin levels should be monitored during therapy.

If liver disease is advanced when the diagnosis is established, medical therapy cannot effectively reverse the situation. These patients often have a crisis, showing some of the features that occur during acute porphyria attacks. Their symptoms include severe abdominal pain that may radiate into the back, as well as mild hypertension, tachycardia, and weakness (212). Limited studies indicate that the condition can be stabilized by

a combination of plasmapheresis and hematin administration, which will allow the patient to be maintained until liver transplantation is carried out (229).

Liver Transplantation in Erythropoietic Protoporphyria

Liver transplantation has become the main option for patients with EPP in whom liver disease is advanced, and there have been several reports of success (233,234,235,236,237,238). During transplantation, patients are susceptible to unique problems because of their high protoporphyrin levels. They are at risk for photodamage to skin and abdominal tissue during exposure to fluorescent lights used in operating rooms (236,237,238); therefore, filters should be placed over the lights (238,239). Their tissues should also be protected from light as much as possible during the operation. Paralysis has occurred during the perioperative period from a severe axonal polyneuropathy, which is probably due to the neurotoxic effect of protoporphyrin (236,237,238,240). Exchange transfusion should not be carried out before transplantation because transfused red cells are sensitive to photohemolysis caused by the circulating protoporphyrin (241). However, plasmapheresis should be considered.

Unfortunately, liver transplantation does not correct the ferrochelatase defect in the bone marrow, and erythrocyte protoporphyrin levels remain high. Grafts are therefore susceptible to the toxic effects of protoporphyrin (238,242,243). The percentage of patients who developed significant damage in the new liver was 65% in a series of North American patients that was recently reported (244).

Rare Types of Porphyria

δ-Aminolevulinic Acid Dehydrase Deficiency Porphyria

Porphyria due to ALA dehydrase deficiency has been described in a few individuals (245,246). This autosomal recessive disorder results from the homozygous deficiency of the second enzyme in the heme biosynthetic pathway. Enzyme activity in affected patients is less than 3% of normal, and in obligate heterozygotes, 50% of normal. As predicted from the enzyme defect, patients excrete markedly elevated amounts of ALA in the urine. Of interest, urinary coproporphyrin and erythrocyte protoporphyrin levels are also increased, the mechanisms of which are not understood.

Children with this disorder have severe recurring porphyric attacks that respond poorly to medical therapy, including the use of intravenous glucose and hematin. As outlined in the management of the more common types of acute porphyria, patients with this disorder should avoid medications that may precipitate neurologic crises. There has been one report of successful liver transplantation, which resulted in resolution of the symptoms (247).

Congenital Erythropoietic Porphyria

Despite its rarity, congenital erythropoietic porphyria was the first type of porphyria to be described in the medical literature. In 1874, Schultz (86) reported

a patient who had dark urine and fragile skin since infancy. Fewer than 200 cases have subsequently been described. It is an autosomal recessive disorder that is usually diagnosed in infancy (248); only a few cases of adult onset have been reported (249,250). Skin lesions are indistinguishable from those in PCT. The teeth develop a reddish brown color and fluoresce when examined with ultraviolet light because of porphyrin deposition in the dentin. The bone marrow is filled with red cell precursors that fluoresce with ultraviolet irradiation. Unlike PCT, the liver shows little or no fluorescence. The disorder is associated with chronic hemolysis, and splenomegaly is common (251,252). The cause of hemolysis is not well understood but may be related to the toxic effect of porphyrin on the erythroid cells. Neurologic symptoms do not occur.

Treatment is difficult. Therapy is usually directed at hemolysis in an attempt to decrease heme turnover. Splenectomy is associated with a variable response, ranging from no effect to long-term remission of disease (253). Red cell transfusions decrease porphyrin excretion and ameliorate clinical symptoms but may cause iron overload (252). Intravenous administration of hematin has also been shown to decrease uroporphyrin excretion (250,252), but this has not been used as long-term therapy.

Hepatoerythropoietic Porphyria

Hepatoerythropoietic porphyria was first described by Gunther in 1967 and received its name in 1975 (244,254). It manifests early in infancy with discolored urine, photosensitivity, and skin fragility. Hemolytic anemia and splenomegaly may be present. As the patient reaches adulthood, the skin manifestations may diminish (255).

As the name implies, significant amounts of porphyrins are produced in both the liver and bone marrow, and normoblasts in bone marrow aspirates fluoresce. Markedly elevated levels of uroporphyrin are present in the urine. Erythrocyte protoporphyrin levels are also increased, mainly as the zinc chelate. The disorder is caused by a marked deficiency of uroporphyrinogen decarboxylase activity in heme-forming tissues (256,257,258,259). Studies of relatives of patients demonstrate mutations in both alleles of the gene coding for uroporphyrinogen decarboxylase enzyme (259,260). This contrasts with familial PCT, which is associated with heterozygous deficiency of uroporphyrinogen decarboxylase activity (257,261). Although a deficiency of uroporphyrinogen decarboxylase activity explains the increased excretion of uroporphyrin, the cause of elevated zinc protoporphyrin levels is unexplained.

A nonspecific hepatitis has been reported, and mild increases in serum transaminase levels are common. In

contrast to PCT, hepatic siderosis has not been reported and serum iron study results are normal. Fibrosis/cirrhosis is also uncommon.

There is little information available about therapy. Treatment is designed primarily to protect the skin from sunlight.

Dual Porphyrias and Harderoporphyria

Occasionally families have been described in which individuals have a deficiency of more than one enzyme of the heme biosynthetic pathway. This includes patients who have coexistent variegate porphyria and PCT (262) and those in whom deficiencies of PBG deaminase and uroporphyrinogen decarboxylase activity cause symptoms of AIP, PCT, or both (263). These conditions are called *dual porphyria*.

A French family has been described in which coproporphyrinogen oxidase activity is approximately 10% of normal in three homozygous individuals and 50% of normal in heterozygotes. Instead of increased urinary excretion of coproporphyrin, which would be expected as a result of the enzyme deficiency, the affected individuals excreted 3-carboxyl porphyrin (harderoporphyrin) in excess amounts (264). Kinetic studies indicated that the defect in the mutant enzyme caused 3-carboxyl porphyrinogen to dissociate from the enzyme more readily than normal. Harderoporphyria has also been reported in a German family (265).

Secondary Porphyrinuria

Several nonporphyric disorders are associated with an increase in the urinary excretion of porphyrins, particularly coproporphyrin, in a condition termed *secondary*

porphyrinuria (Table 38.5). Patients with these disorders may also have abdominal pain and other symptoms of acute porphyria, which can present a diagnostic dilemma. If this situation is encountered, it is important to remember that patients who are symptomatic with acute porphyric attacks have increased urinary excretion of ALA and PBG. With the exception of lead poisoning and hereditary tyrosinemia, urinary excretion of these compounds is normal in all the conditions associated with secondary porphyrinuria. The amount of urinary ALA and PBG excretion should therefore be determined to distinguish between acute porphyria and secondary porphyrinuria.

Table 38.5. Causes of Secondary Porphyrinuria

Hepatobiliary disorders	Acute and chronic hepatitis Alcoholic liver disease Cirrhosis (alcoholic and nonalcoholic) Cholestatic disorders
Toxins	Heavy metal poisoning (e.g., lead, arsenic, gold, iron) Benzene and benzene congeners Haloalkanes and haloaromatic compounds
Hematologic disorders	Aplastic, hemolytic, and pernicious anemias Leukemias Hodgkin's disease
Miscellaneous	Diabetes Hereditary conjugated bilirubin disorders (Dubin-Johnson and Rotor's syndromes) Bronze baby syndrome

Lead Poisoning

Lead poisoning is associated with several abnormalities in porphyrin metabolism because lead inhibits more than one enzyme (i.e., ALA dehydrase, coproporphyrinogen oxidase, and ferrochelatase) in the heme biosynthetic pathway. Erythrocyte levels of zinc protoporphyrin are elevated in patients with lead poisoning (193); this measurement has been used to screen for the disorder. Lead poisoning is also associated with increased urinary excretion of ALA and coproporphyrin. Because abdominal pain is a prominent clinical feature, and patients may also have peripheral neuropathies, it is possible that the mechanism for neurologic dysfunction in lead poisoning is the same as that in the acute porphyrias. Indeed, hematin has been used as adjunctive therapy in lead poisoning and causes a significant diminution in urinary ALA excretion (266).

Hereditary Tyrosinemia

Hereditary tyrosinemia type I is a metabolic disorder characterized by liver damage that develops during infancy and may progress rapidly to cirrhosis, with the subsequent development of hepatocellular carcinoma. Patients with this disorder accumulate succinylacetone (4,6-dioxoheptanoic acid) and succinylacetoacetate because of a

block in tyrosine metabolism at the level of the fumarylacetoacetase reaction (112). Succinylacetone is a potent inhibitor of ALA dehydrase (267,268) and therefore results in increased urinary excretion of ALA. Some patients also have neurologic manifestations resembling those of the acute porphyrias (269). The mechanism of neurologic dysfunction may be the same because patients with tyrosinemia respond to the intravenous administration of hematin (270). The biochemical abnormalities are corrected by liver transplantation, although minor defects, which are thought to be of renal origin, persist (271).

Miscellaneous Hepatobiliary Diseases

Because bile is a route of porphyrin excretion, any hepatobiliary disease in which bile formation is impaired may cause a diversion of porphyrins to the urine (272,273). Therefore, urinary excretion of coproporphyrin increases the most in hepatobiliary diseases. Uroporphyrin levels may also increase, but protoporphyrin is not excreted in urine, even in the face of severe cholestasis, because of its poor water solubility.

When there is biliary obstruction, urinary coproporphyrin, whose excretion is increased, contains a higher proportion of the type I isomer than usual (274). Two patterns of excretion have been observed in parenchymal liver diseases. In alcoholic cirrhosis, the increased excretion of urine coproporphyrin is associated with a proportion of coproporphyrin I in urine similar to that seen in normal individuals, whereas the pattern in other types of parenchymal disease is more like that seen in biliary obstruction. However, because of a significant overlap among these conditions, the coproporphyrin isomer distribution in urine cannot be used in the differential diagnosis of hepatobiliary disorders. Acute ingestion of alcohol may also cause a significant increase in urinary excretion of coproporphyrin, usually beginning 2 to 4 days after intoxication.

Although impaired biliary excretion is probably the main factor responsible for increased urinary porphyrin excretion in hepatobiliary disorders, there may also be an alteration in heme synthesis. Hepatic ALA synthase activity is increased in homogenates of cirrhotic livers (275), which suggests that there may be an increased rate of porphyrin production. Experimentally, it has been shown that acute ethanol administration also increases hepatic ALA synthase activity (276).

Pseudoporphyria

Pseudoporphyria is an entity with clinical and histologic features similar to those of PCT but with normal or near normal porphyrin levels (277,278,279). Pseudoporphyria is characterized by vesicles, bullae, skin fragility, milia, and scarring on the sun-exposed skin. Like PCT, the dorsal surface of the hands are most commonly affected. The histologic and immunofluorescent characteristics of pseudoporphyria are similar to those of PCT. Histologically, there are subepidermal bullae. Direct immunofluorescence reveals granular deposits of immunoglobulin G (IgG) and C3, most commonly at the dermoepidermal junction. Pseudoporphyria has been described in patients with chronic renal failure with or without dialysis, with certain medications, and with ultraviolet A radiation. The medications include nonsteroidal anti-inflammatory drugs

(highest reported incidence with naproxen), antibiotics including tetracycline, multiple sulfur-bearing diuretics, and isotretinoin (280). Ultraviolet exposure includes ultraviolet A tanning beds, psoralens plus ultraviolet A therapy, and excessive sun exposure. The exact pathogenesis is unknown but may involve photosensitivity and oxidation stress. Treatment involves discontinuation of suspected agents and sun protection. Two children with hemodialysis-associated pseudoporphyria were successfully treated with the antioxidant *N*-acetylcysteine (277).

Semin Hematol 1989;26:1–9.

This paper summarizes the effects of heme administration to patients with porphyria and hematologic disorders, such as myelodysplastic syndromes and sideroblastic anemias. There is an excellent bibliography that includes all the clinical trials with heme administration.

Poh-Fitzpatrick MB. Pathogenesis and treatment of photocutaneous manifestations of the porphyrias. *Semin Liver Dis* 1982;2:164–176.

The review discusses the pathophysiology of cutaneous manifestations in porphyrias and their treatment.

Schmid R, ed. The porphyrias. *Semin Liver Dis* 1998;18:1–101.

Several experts provide a summary of the clinical and biochemical abnormalities that are seen in the different types of porphyria.

Chapter 39

Nonalcoholic Fatty Liver Disease

Stephen H. Caldwell
Abdullah M.S. Al-Osaimi
Curtis K. Argo

Key Concepts

- Nonalcoholic fatty liver disease (NAFLD) is emerging as the most common liver disorder in industrialized countries and in many developing countries. It exists as a histologic spectrum, ranging from simple steatosis or steatosis with only mild inflammation (types 1 and 2 NAFLD) to more severe steatohepatitis (types 3 and 4 NAFLD or nonalcoholic steatohepatitis [NASH]). Types 1 and 2 NAFLD infrequently progress to cirrhosis but types 3 and 4 NAFLD (i.e., NASH) progress to cirrhosis in as many as 15% to 20% of patients. Progression is often silent, and paradoxically, it is often associated with normalization of the aminotransferases. In histologically advanced cases, the characteristic microscopic findings are lost and patients often present with "cryptogenic cirrhosis." In addition to the usual complications of cirrhosis and portal hypertension, hepatocellular carcinoma is now recognized as a late complication of NAFLD.
- Although NAFLD can occur in relatively lean individuals, obesity and type 2 diabetes remain the best characterized risk factors and are predictive (along with older age and hypertriglyceridemia) of the severity of underlying liver histology. Many lean patients with fatty liver actually have increased mesenteric fat deposits (central obesity), and ethnic variation exists in the relationship between body mass index (BMI) and visceral adiposity. In a past series of obese patients, liver biopsy results were normal in only 10%. Approximately 5% of patients have occult cirrhosis and 85% will have steatosis. In the latter, one third have NASH. The prevalence of liver disease among patients with type 2 diabetes and/or hyperlipidemia has not been as well characterized but is thought to be high. Underlying liver disease in these patients has potentially serious implications for treatment of obesity, diabetes, hypertension, and hyperlipidemia—all features of the metabolic syndrome.
- Although insulin resistance is neither absolutely essential nor sufficient for the development of steatohepatitis, the association is so strong that NAFLD, and more importantly NASH, can be considered a part of the metabolic syndrome and systemic lipotoxicity. As such, it is not surprising that lipid peroxidation is now recognized as the underlying mechanism of hepatocyte injury leading to cytokine activation and fibrosis. Steatosis results from excessive delivery of fatty acids to the liver as a result of peripheral insulin resistance, but de novo hepatic synthesis of triglycerides and impaired export of fatty acids (apolipoprotein metabolism) also contribute to the condition. Variation in the antioxidant influences the risk of subsequent cellular injury.

P.1118

- Exercise and dietary alterations are cornerstones of therapy and may result in histologic improvement. Simple steatosis probably does not warrant pharmacologic therapy but the presence of fibrosis needs a more aggressive approach. Weight loss supplements and weight-reduction surgery may be successful in some but carry a risk of complications. Other potential therapeutic modalities include the use of antioxidants and cytoprotective agents, insulin sensitizers (e.g., biguanides and thiazolidinediones [TZD]), and possibly antihyperlipidemic agents (e.g., fibric acid derivatives and 3-hydroxy-3-methylglutaryl coenzyme A [HMG-CoA] reductase inhibitors), although the latter have been inadequately studied. Confounding variables (e.g., exercise and diet) and sampling error on liver biopsy samples limit interpretation of existing literature. These limitations have led to the need for incorporation of other endpoints in controlled treatment trials including anthropometric indices, measures of physical conditioning, hepatic fat content, indices of lipid peroxidation, measures of insulin signaling, and possibly systemic measures of hepatic fibrosis.

Nonalcoholic fatty liver disease (*NAFLD*), is an umbrella term that includes a range of conditions ranging from simple steatosis to nonalcoholic steatohepatitis (NASH) (1,2). As apparent from the volume of literature published in just the last 3 years (well over 1,000 articles), it is increasingly recognized as a potentially serious condition, which can progress to cirrhosis, liver failure, and hepatocellular cancer (HCC) and has a worldwide distribution (3,4,5,6,7,8,9). The spectrum of clinical severity, in part, reflects the normal role that the liver plays in fat metabolism— a fat storage site where lipid peroxidation can lead to injury and activation of profibrotic cytokines in some individuals. The explanation for why some people develop steatosis and others do not and why some with steatosis develop injury is related to variable expression of obesity, type 2 diabetes, and the metabolic syndrome—conditions that represent a complex mixture of genetic predisposition and environmental factors (10). Several mechanisms appear to promote the accumulation of hepatic fat: De novo synthesis of triglycerides, impaired secretion of lipoprotein and, perhaps the most important in typical patients, increased delivery of fatty acids to the liver. These abnormalities correlate with central obesity and physical conditioning, providing the basis for conservative management of NAFLD with exercise, dietary changes, and weight loss. The prominent role of insulin resistance provides the basis for several of the most promising forms of pharmacologic intervention with insulin-sensitizing agents. Between these two broad categories of treatment, cytoprotective and antioxidant therapy remain under investigation as possible means of reducing oxidative injury.

Clinical and Histologic Criteria and Terminology

Although the exact histologic criteria continue to be debated, the term *NASH* is now widely regarded as the more severe form of "NAFLD." Not as widely accepted is the distinction between "primary" NASH (usually associated with obesity and diabetes without other precipitating factors) and "secondary" NASH (associated with a specific disease or some medications) (Table 39.1). This distinction is limited because shared risk factors point to a common pathogenesis of "primary" NASH and some of the conditions that have been associated with "secondary" NASH. The presence or absence of insulin resistance may be a useful distinguishing feature. As such, steatohepatitis associated with toxin exposure may qualify as a distinct entity while many other "secondary forms" may actually represent an exacerbation of "primary" NASH (See "Epidemiology" and "Other Conditions Associated with Nonalcoholic Fatty Liver Disease/Nonalcoholic Steatohepatitis—"Secondary" Nonalcoholic Steatohepatitis").

Clinical Criteria

By definition, the criteria for NASH require exclusion of alcohol as an etiology. The acceptable level of alcohol consumption is variable but the daily alcohol intake can be conservatively fixed as not exceeding 20 g/day in men and 10 g/day in women—levels below the risk level associated with increased risk of cirrhosis (30 g/day in men and 20 g/day in women) (11,12,13). However, these "cutoffs" leave an unresolved gray area in which a patient prone to NASH may consume alcohol

P.1119

Sclose to the threshold for liver injury or may have consumed more significant alcohol (measured as lifetime exposure) in the past,

leaving open the question of one chronic problem (NASH) superimposed on a past injury. These issues are further discussed in the subsequent text.

Table 39.1. Definitions and Terms

1. *NAFLD.* Indicates the presence of fatty infiltration of the liver, defined as fat exceeding 5%–10% of liver weight and frequently taken as fat in >5%–10% macrosteatotic hepatocytes in biopsy specimens. Microsteatosis is an underappreciated aspect because of limitations of routine staining techniques. The term *NAFLD* includes the term *NASH*.
2. *Simple steatosis.* A type of fatty infiltration (NAFLD) with no or minimal inflammation and no fibrosis. This is synonymous with type 1 disease, as classified by Matteoni (7) (see Table 39.2).
3. *NASH*. A type of NAFLD with inflammation, ballooned hepatocytes, and/or fibrosis, usually beginning around the central vein, which may progress to cirrhosis. This is synonymous with type 3 or 4 disease, as classified by Matteoni (7) (see Table 39.2).
4. *"Primary" NAFLD or NASH*. A term occasionally encountered in the literature but not uniformly accepted. It indicates typical NAFLD or NASH associated with central obesity and often type 2 diabetes mellitus but without a specific, additional etiology. The likelihood that many cases of "secondary" NAFLD or NASH represent unrecognized or exacerbated "primary" NAFLD or NASH makes the term less useful.
5. *"Secondary" NAFLD or NASH*. NAFLD or NASH associated with a specific problem such as a toxin. Use of the term *secondary* NAFLD or NASH implies the absence of insulin resistance. Many patients previously classified as "secondary" may have exacerbation of underlying "primary" NASH, making this distinction less useful.
6. *"Presumed" NASH or NAFLD.* Several epidemiologic and pediatric studies have utilized a presumptive diagnosis of NAFLD or NASH on the basis of abnormal liver enzyme levels, negative results of viral studies, and echogenic or "bright" liver on ultrasonography consistent with fatty infiltration. (See "Imaging in Nonalcoholic Fatty Liver Disease: Ultrasonography, Computed Tomography Scan, Magnetic Resonance Imaging and Magnetic Resonance Proton Spectroscopy").

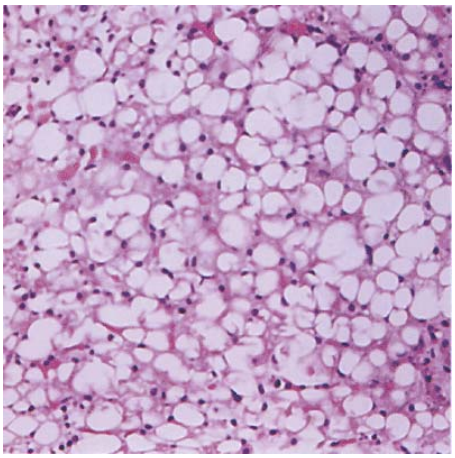
NAFLD, nonalcoholic fatty liver disease; NASH, nonalcoholic steatohepatitis.

Histologic Criteria

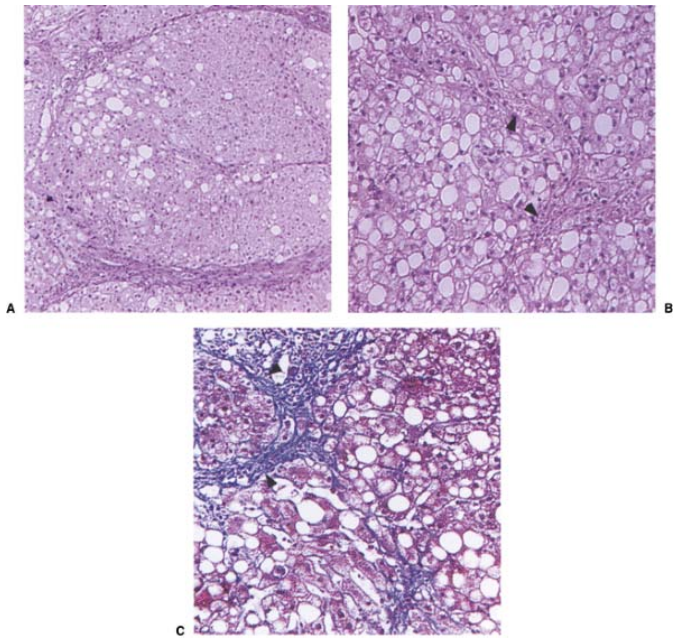
Steatosis, defined as hepatic fat exceeding 5% to 10% of total weight (14) and usually taken as fat identifiable in more than 5% to 10% of hepatocytes by light microscopy, is an essential feature of NAFLD. Within the spectrum of NAFLD, the term *NASH* indicates a more severe type of liver injury and worse prognosis compared to "simple steatosis," which is distinguished by the absence of inflammation or fibrosis and appears to have a long-term stable course (Fig. 39.1) (15). Beyond this distinction, even accomplished pathologists debate the relative importance of specific histologic variables (16). Interestingly, more or less restrictive definitions of the term *NASH* appear to influence patient demographics, suggesting the presence of gender-based variation in disease expression (17).

Important histologic variables include fibrosis (usually sinusoidal in a pericentral vein or zone 3 distribution), ballooned hepatocytes sometimes containing Mallory hyaline and lobular inflammation (Figs. 39.2 and 39.3). Glycogenated nuclei are common (18,19). Other variables include portal injury, apoptotic bodies, microvesicular steatosis (much more evident using specialized fixation techniques such as osmium), and lipogranulomas (Figs. 39.3 and 39. 4) (20,21). Substantial concordance between observers has been reported for the extent of steatosis, location and severity of fibrosis, and balloon degeneration (22). The degree of fibrosis has been organized into a staging system developed by Brunt et al. (Table 39.2) (23). In addition, although not uniformly accepted, a useful histologic classification scheme (Table 39.2) for NAFLD has been proposed and is widely referenced. It ranges from simple steatosis to the more severe steatosis with balloon degeneration and Mallory bodies or fibrosis (7). Other scoring systems have also been proposed (24) but the most significant refinements in the histologic assessment has been the development of NASH activity

index (NAI) and NASH activity score (NAS), discussed further under "Scoring of the Biopsy (Nonalcoholic Steatohepatitis Activity Index, Nonalcoholic Steatohepatitis activity score)."



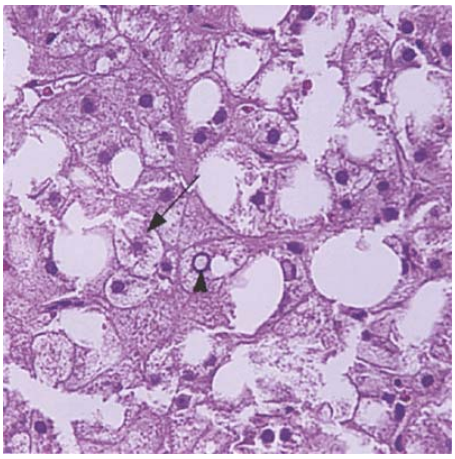
• **Figure 39.1** Simple steatosis: The patient is a 47-year-old woman with mild obesity and an idiopathic, neurodegenerative disease and hepatomegaly. The biopsy specimen showed only minimal inflammation and no fibrosis. No inciting agents were identified to explain the liver condition (hematoxylin and eosin, 200×).



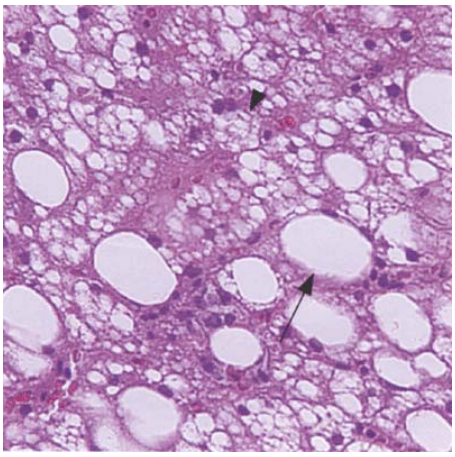
• **Figure 39.2 A:** Nonalcoholic steatohepatitis (NASH) with cirrhosis (stage 4). **B:** Early stage 3 (bridging fibrosis) with hematoxylin and eosin stain. **C:** The same biopsy accentuating the presence of bridging with a Masson trichrome stain. The specimen in **(A)** is from a 65-year-old women with moderate obesity and type 2 diabetes. She does not have complications of portal hypertension. The presence of macrovesicular steatosis, inflammation, and cirrhosis allows the diagnosis of NASH with cirrhosis (stage 4) (100×, hematoxylin and eosin). Specimens **(B)** (200×, hematoxylin and eosin) and **(C)** (200×, trichrome) are from her 40-year-old son who has mild liver enzyme abnormalities and mild (mostly truncal) obesity (body mass index = 30) without diabetes. NASH with fibrosis, mildly apparent on the hematoxylin and eosin stain **(B)**, is accentuated with trichrome staining **(C)**, which demonstrates bridging consistent with stage 3. *Arrowheads* in **(B)** and **(C)** define a fibrotic bridge bordering a regenerative nodule. These slides also illustrate a familial pattern seen in approximately 20% of patients.

"Presumed" Nonalcoholic Fatty Liver Disease

In several large epidemiologic studies, the diagnosis of "presumed NAFLD" has been made on the basis of noninvasive testing (See "Epidemiology") (12). In general, such studies have utilized abnormal transaminases in the absence of other known liver disease and/or liver ultrasonography to make the diagnosis of fatty liver disease. However, the relationship between the diagnosis of "presumed" NAFLD and the histologic activity, stage, and prognosis is unreliable. Indeed, one of the major limitations of these studies is the inability to distinguish NASH from less severe forms of fatty liver such as simple steatosis.



• **Figure 39.3** Balloon degeneration, Mallory hyaline, and glycogenated nucleus in nonalcoholic steatohepatitis. *Long arrow* indicates accumulation of perinuclear eosinophilic material (Mallory hyaline) in a ballooned hepatocyte (400×, hematoxylin and eosin). Agreement on what constitutes Mallory hyaline is sometimes hard to obtain. Ubiquitin stain, although infrequently used, can be employed to highlight Mallory hyaline (not shown). Also shown is a pale, glycogenated, nucleus (*arrowhead*), which is more typical of NASH compared to alcohol-related liver disease.



• **Figure 39.4** *Micro-* and *macrovesicular steatosis* in nonalcoholic steatohepatitis. *Arrowhead* indicates a cell with small droplets of fat in addition to the more apparent and typically large droplet in macrovesicular steatosis (*long arrow*, 400x, hematoxylin and eosin). Special stains or fixation techniques, such as osmium tetroxide fixation (not shown), can be used to accentuate the often overlooked microvesicular component.

Cryptogenic Cirrhosis

Serial biopsy studies have established the potential progression of NASH to a stage of "bland" cirrhosis with loss of characteristic histology (Fig. 39.5) (25,26). The loss of fatty infiltration may be due to altered blood flow or decreased sinusoidal permeability and impaired lipoprotein delivery as the liver becomes fibrotic (27,28,29). A number of additional studies have strongly suggested that many cases of "cryptogenic" cirrhosis, a remarkably homogenous group (Fig. 39.6), are the result of such a process (30,31,32,33,34,35,36,37,38). Approximately two thirds of patients with this diagnosis, among the most common indications for liver transplantation, have major risk factors for NAFLD (e.g., obesity and diabetes). In a series of patients undergoing transplantation for "cryptogenic" cirrhosis, definitive features of NASH were evident in 17 of 30 and minor features were seen in an additional 10 patients (39). The significantly increased frequency of steatosis and steatohepatitis after transplantation for cryptogenic cirrhosis further support this relationship (40). On the basis of these associations and predominant histologic findings (and recognizing that other conditions are also involved with cryptogenic cirrhosis), a classification system of cryptogenic cirrhosis can be formulated, as shown in Table 39.3 (41).

Table 39.2. Classification and Stages of Nonalcoholic Fatty Liver Disease/Nonalcoholic Steatohepatitis

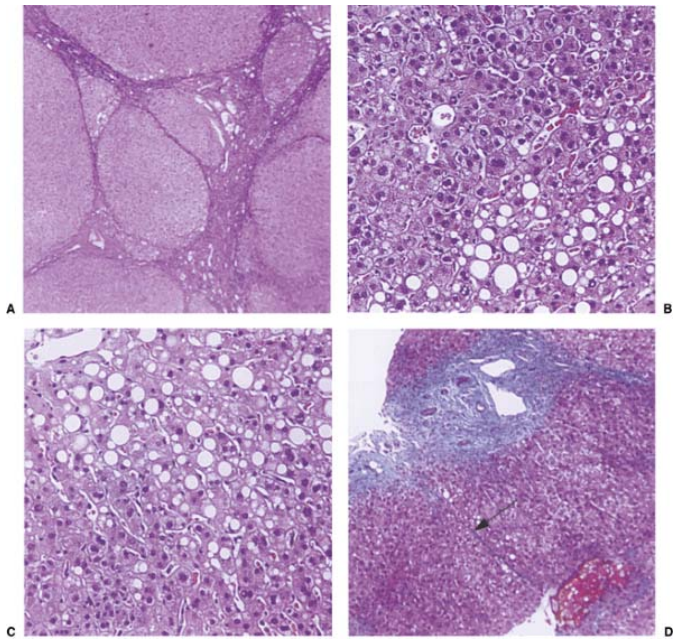
Fibrosis *Stages* of NASH (Brunt et al. (23))
Stage 1: Zone 3, pericentral vein, sinusoidal or pericellular fibrosis
Stage 2: Zone 3 sinusoidal fibrosis and zone 1 periportal fibrosis
Stage 3: Bridging between zone 3 and zone 1
Stage 4: Regenerating nodules, indicating cirrhosis
***Types* of NAFLD (Matteoni et al. (7))**
Type 1: Simple steatosis (no inflammation or fibrosis)
Type 2: Steatosis with lobular inflammation but absent fibrosis or balloon cells
Type 3: Steatosis, inflammation, and fibrosis of varying degrees (NASH)
Type 4: Steatosis, inflammation, ballooned cells, and Mallory hyaline or fibrosis (NASH)

NASH, nonalcoholic steatohepatitis; NAFLD, nonalcoholic fatty liver disease.

Focal Steatosis and Focal Sparing

In a series of patients with various forms of fatty liver disease detected radiographically, focal steatosis was evident in approximately 15% and focal sparing (usually of the caudate lobe) was seen in 9% (42). Variation in blood flow (with resulting differences in

insulin exposure and nutrient delivery) is thought to explain both focal-sparing and focal steatosis (43,44). A relationship to insulin exposure has long been suspected as a factor because of the development of focal steatosis in continuous ambulatory peritoneal dialysis (CAPD) patients exposed to insulin in the peritoneal dialysis fluid (45,46). Histologically, the lesions vary from simple steatosis to steatohepatitis (45). Cirrhotic nodules have also been shown to occasionally have focal fatty change, possibly unrelated to fatty liver disease (47,48).



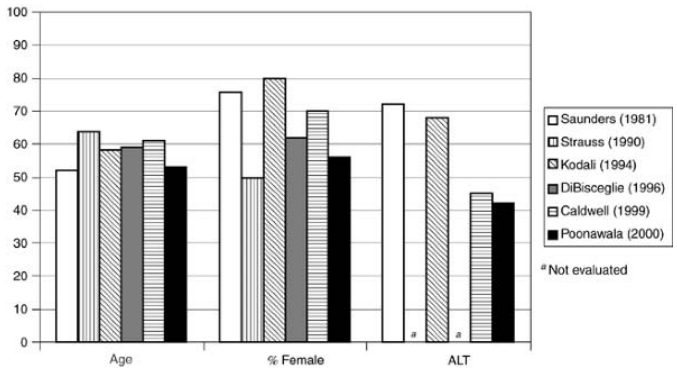
• **Figure 39.5** Development of nonalcoholic fatty liver disease (NASH) after transplantation for cryptogenic cirrhosis. **A:** Explanted liver from an obese, diabetic man showing "bland" cirrhosis (40×, hematoxylin and eosin). **B:** Two years later (200×, hematoxylin and eosin), a repeat biopsy for abnormal liver enzymes revealed steatosis that was persistent and associated with mild inflammation at 3 years **(C)** (200×, hematoxylin and eosin). **D:** Four years after transplantation the patient developed ascites and repeat biopsy showed early cirrhosis with bridging and diminished fatty infiltration (100×, hematoxylin and eosin). *Long arrow* demonstrates a fibrous band.

Historic Perspective

Early Observations

A long-recognized association between the liver and fat storage is mirrored in a popular explanation of the origin of the Latin term for liver, *ficatum*, and the corresponding modern Greek term, *sycoti*, both of which were derived from the common name for fattened animal livers, *iecur ficatum* and *hepar sykoton*, respectively (D. Tniakou, personal,

2005). A more scientific appreciation of fatty liver emerged in the 19th century when Virchow classified various types of fatty infiltration of the liver (49). The color, shape, and firmness of a fatty liver were described and fat-globules were proven to be within hepatic cells (50). Morgan, in the 1870s, described an association with obesity and overeating (51). This was extended many years later by Zelman, who reported the existence of liver damage with fibrosis and early cirrhosis in obese patients without a significant history of alcohol consumption (52). More recently, this concept resurfaced in patients who had undergone bypass surgery for morbid obesity (53,54,55,56,57,58). This was widely attributed at the time to postoperative, protein-calorie malnutrition or intestinal bacterial overgrowth, although a correlation between obesity and diabetes and potential liver damage was not strongly emphasized.



• **Figure 39.6** Past series of patients with cryptogenic cirrhosis. Previous case series have shown a female predominance, onset in sixth or seventh decade, and mildly abnormal alanine transaminase (ALT) levels. [Series from references (30,31,32,33,34,35).]

Table 39.3. Cryptogenic Cirrhosis—Proposed Classification

Class 1—cirrhosis with features of steatohepatitis including scattered steatosis, ballooned hepatocytes, possibly with Mallory

bodies, and glycogenated nuclei
Class 2—cirrhosis with features of autoimmune disease including plasma cells or granulomas
Class 3—cirrhosis with features of biliary obstruction including proliferation of bile ducts and cholestasis
Class 4—bland cirrhosis: Cirrhosis lacking other distinguishing features

From Contos MJ, Cales W, Sterling RK, et al. Development of nonalcoholic fatty liver disease after orthotopic liver transplantation for cryptogenic cirrhosis. *Liver Transpl* 2001;7:363–373 and Ayata G, Gordon FD, Lewis WD, et al. Cryptogenic cirrhosis: clinicopathologic findings at and after liver transplantation. *Hum Pathol* 2002;33:1098–1104.

The Ethanol Conundrum

As previously noted, the cutoff levels for classification of "nonalcoholic" versus "alcoholic" steatohepatitis (ASH) remain unresolved. Clearly, there are many patients with NASH and related cirrhosis without a history of current or past ethanol exposure ("teetotalers"). Before this recognition, a common experience was nicely summarized by Ludwig in his original description of NASH:

> *"…we have encountered patients who did not drink, who had not been subject to bypass surgery, and who had not taken drugs that may produce steatohepatitis, yet had in their liver biopsy specimens changes that were thought to be characteristic of alcoholic liver disease. In these instances, the biopsy evidence sometimes caused clinicians to persevere unduly in their attempts to wrench from the patient an admission of excessive alcohol or to obtain a confirmation of such habits from relatives of the patients. Thus, the misinterpretation of the biopsy in this poorly understood and hitherto unnamed condition caused embarrassment to the patient and physician."*(2)

Nonetheless, it is widely suspected and recently documented that approximately 10% of patients classified as having NASH actually have had a significant lifetime exposure to ethanol when a more structured

history is obtained (59). Intuitively, synergy between ASH and NASH seems likely by the association of more severe alcohol-related liver disease with obesity (60,61,62,63). However, one study has indicated a lower risk of severe steatohepatitis among obese patients consuming moderate alcohol, possibly mediated by effects on insulin signaling (64,65). Because of the widely perceived health benefits of moderate ethanol ingestion (e.g., red wine), the difficulty in sorting out NASH from alcohol-related liver injury is likely to persist. Immunohistochemical stains for insulin receptors and regulators may provide a means of distinguishing the prominence of one pathway over another but they have not been validated and clinical utility not yet confirmed (66). With the possible exception of glycogenated nuclei (increased in NASH), other histologic features do not reliably distinguish between ASH and NASH (18,67).

A number of laboratory tests have been proposed to make this distinction including carbohydrate-deficient transferrin; however, none has proved satisfactory (68). Transaminase ratios may provide guidance: The aspartate transaminase (AST) to alanine transaminase (ALT) ratio is typically less than 1 in early or mild NASH, between 1 and 2 in more severe NASH, and more than 2 in more severe ASH (See "Clinical and Laboratory Findings"). The extent of elevation of γ-glutamyl transpeptidase (GGT) levels may also be useful (seldom >400 in NASH), but none of these relationships is entirely reliable and may be obscured by concomitant medication use. For these reasons, the history remains the most commonly used means of assessing alcohol consumption, especially when repeated by multiple health care providers over time.

"Hepatogenous" Diabetes

Complicating the relationships between insulin resistance, hyperinsulinemia, and NAFLD is the relationship between liver disease and diabetes, which has long been referred to as *hepatogenous diabetes* (a term coined by Naunyn in the early 1900s) (69). The issue is whether hyperinsulinemia coincides with the development of liver disease, as appears to be the case in NAFLD, or follows the development of liver disease, as in hepatogenous diabetes. A number of papers have established an increased prevalence of diabetes in cirrhosis of various etiologies (70). Impaired insulin sensitivity rather than decreased insulin metabolism from portosystemic shunting, are postulated to explain this condition (71,72). The role of cirrhosis-related abnormal skeletal muscle metabolism, a major target of insulin and one of earliest abnormalities detectable in type 2 diabetes, is yet to be investigated (73).

Epidemiology and Prevalence in High-Risk Groups

NAFLD is one of the most common of all liver disorders, especially in industrialized countries, and represents a significant source of disease (74,75,76,77,78,79,80). The estimated prevalence in the general population ranges from 2.8% to 20%, depending on the criteria used for estimation (81). In a series of 150 consecutive patients with abnormal liver enzymes for at least 6 months, 40% had steatosis, 15% had hepatitis C, and 2% had nonalcoholic steatohepatitis (82). In another series of 81 patients with abnormal liver enzymes and a negative serologic workup, 50% of the patients had steatosis and 32% had steatohepatitis (83). In the primary care setting, NAFLD accounts for approximately one third of cases of suspected chronic liver disease cases (84). Obesity, type 2 diabetes and hyperlipidemia have been the most constant conditions associated with steatosis and steatohepatitis and are predictors of more severe histologic disease (85). In a large study of risk factors for the presence of NAFLD at autopsy, Wanless and Lentz found mild to severe steatosis in approximately 70% of obese patients compared to 35% of lean patients and steatohepatitis in 18.5% of obese patients compared to just 2.7% of lean patients (86). Diabetes has also been identified as an independent risk factor for NASH. Bellentani et al. identified a 4.6-fold increased risk of fatty liver in obese patients compared to nonobese patients and also identified hypertriglyceridemia as a significant predictor of steatosis on liver ultrasonography (12). An overview of major conditions associated with NAFLD and NASH is shown in Table 39.4.

Obesity

Biopsy studies in obese patients (body mass index [BMI] usually >30) showed steatosis in 85%, mild to moderate fibrosis in approximately 25% to 30%, and cirrhosis in 1% to 2% (87,88). Ratzui et al. found that approximately 30% of consecutive obese patients with abnormal liver enzymes had at least septal fibrosis and 10% had cirrhosis (89). In another series of obese patients undergoing gastroplasty, Garcia-Monzon et al. observed NASH in 69%, while 22% had simple steatosis and only 8% had a normal biopsy (90). Similar to other studies, one half of those with mild or severe steatohepatitis had normal liver enzymes (91). In another group of patients undergoing bariatric surgery, Dixon et al. reported that only 4% had normal results of biopsies; 71% had simple steatosis and 26% had steatohepatitis with variable degrees of fibrosis (64). Similar results were noted in a more recent study. A compilation of histology in these series of obese patients is shown in Figure 39.7 (92).

Table 39.4. Conditions Associated with Nonalcoholic Fatty Liver

Metabolic factors
- Obesity (especially truncal or central obesity)
- Type 2 diabetes mellitus
- Hyperlipidemia (especially hypertriglyceridemia)
- Systemic lipotoxicity

Specific conditions associated with fatty infiltration of the liver
- Metabolic syndrome (hyperinsulinemia, hypertension, obesity, polycystic ovary disease)
- Lipodystrophy
- Mitochondrial diseases
- Weber-Christian disease

Bariatric (weight loss) surgery
- Jejunoileal bypass (no longer performed)
- Gastric bypass or gastroplasty (less frequent compared to jejunoileal bypass)

Medications
- Methotrexate
- Amiodarone
- Tamoxifen
- Nucleoside analogs

Parenteral nutrition and malnutrition
- Total parenteral nutrition
- Kwashiorkor
- Celiac disease

Miscellaneous
- Wilson disease
- Toxins (CCl_4, perchloroethylene, phosphorous, ethyl bromide, petrochemicals)

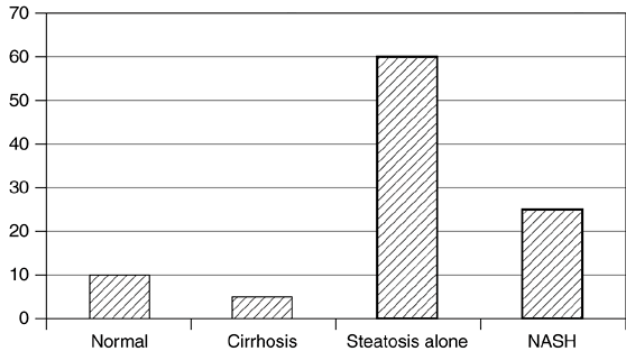
Type 2 Diabetes Mellitus

Insulin resistance is common in patients with NASH, and hyperinsulinemia plays a pathogenic role in the progression of NASH even in the absence of overt diabetes (93,94). It is estimated that up to 75% of patients with type 2 diabetes have fatty infiltration (93,95,96), although ethnicity appears to influence the prevalence significantly (see subsequent text) (97). Fatty infiltration has been noted to commonly precede the development of overt diabetes in earlier studies (98). The progression to more overt diabetes in these patients depends on peripheral fat and skeletal muscle metabolism and pancreatic islet cell vitality. The severity of liver injury worsens with the degree of abnormal glucose metabolism among obese patients (99) and the impact on the overall clinical course is significant—the standardized mortality ratio in patients with type 2 diabetes is actually higher for cirrhosis than for cardiovascular disease (100,101). Younossi et al. further demonstrated that the coexistence of diabetes in patients with NAFLD more than doubled the prevalence of cirrhosis on diagnostic biopsy from 10% to 25% (102).

Hyperlipidemia

As with type 2 diabetes, large studies revealing the true prevalence of NAFLD and associated histology within different forms of hyperlipidemia are lacking. In one study using noninvasive imaging, it was shown that two thirds of patients with hypertriglyceridemia and one third of those with hypercholesterolemia have fatty liver (103). This is probably an underestimation because significant hyperlipidemia (i.e., triglyceride, total cholesterol, or high-density lipoprotein [HDL] cholesterol) was reported in 96% of patients with NASH in one large, well-characterized series (104), although a lower range (3% to 92%) was noted in a compilation of 13 series summarized by McCullough (105). It is likely that ethnic, presumably genetic, factors will influence the true prevalence (see "Genetic Variation"). However, the close relationship between hyperlipidemia and fatty liver disease raises further practical concerns about the effects of antihyperlipidemic medications. Although acute hepatitis appears to be rare

among patients with suspected NAFLD treated with 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (See "Treatment of Nonalcoholic Fatty Liver Disease"), the long-term effects have not been adequately explored (106,107,108,109).



• **Figure 39.7** Liver histology in series of obese patients. Only 10% of obese subjects have normal histology while 5% have previously unidentified cirrhosis. Approximately 85% have steatosis and one third of these have, in addition, nonalcoholic steatohepatitis (NASH) with varying degrees of fibrosis. (Adapted from findings in references 64,87,88,89,90,91,92.)

Metabolic Syndrome

Unexplained elevation of liver enzyme levels, attributed largely to NAFLD, are seen in approximately 7% of individuals meeting the criteria for the metabolic syndrome, defined by the Adult Treatment Panel-III criteria (Table 39.5) (110,111). However, this is probably an underestimation of the true prevalence, given the high prevalence of NAFLD in the general population, the high prevalence of features of the metabolic syndrome among patients with NAFLD, and the frequency of normal liver enzymes even in the setting of significant

histologic disease (the last factor obscures the true prevalence if NAFLD is detected depending on abnormal aminotransferases) (112). It has been suggested that NAFLD can cause metabolic syndrome. However, current data indicate that both hepatic steatosis and central adiposity are independent risk factors for metabolic syndrome and all three conditions appear to be united by variable degrees of insulin resistance and systemic lipotoxicity (see subsequent text) (113,114,115).

Normal Body Mass Index

NAFLD has been well documented in patients with normal BMI (5,17,116). This group appears to contain relatively younger males with milder histology, visceral or central adiposity (without overt obesity by BMI), and hyperinsulinemia. Such individuals, possibly more common in Asian populations where visceral adiposity is seen with lower BMI, are thought to represent an initial stage of the insulin resistance syndrome (117,118,119,120). These findings are consistent with the major role of body fat distribution as opposed to simply the amount of body fat in the development of insulin resistance and NAFLD (121,122,123,124).

Table 39.5. Adult Treatment Panel-III Criteria for the Metabolic Syndrome (110)

Risk factor	Definition
Abdominal obesity	Waist circumference
Men	≥102 cm (≥40 in.)
Women	≥88 cm (≥35 in.)
Triglycerides	≥150 mg/dL
High-density lipoprotein cholesterol	
Men	<40 mg/dL
Women	<50 mg/dL
Blood pressure	≥130/85 mm Hg
Blood glucose	≥110 mg/dL

Pediatric Patients

In parallel to the increasing problems of obesity, a number of papers have now established NAFLD and NASH as potentially serious problems in children (125,126,127,128,129). As with adult fatty liver disease, the problem appears to exist worldwide. The histologic severity appears to vary substantially but fibrosis and cirrhosis have been described in 18 of 24 patients in one Canadian series (130). Recently acquired rather than long-standing obesity increases the risk of fatty infiltration in this group. Ethnic variation, male preponderance, and prominent portal tract injury standout in pediatric NASH (126,131). Ethnic influences appear similar to those in the adult disease (see subsequent text), with a greater risk among children, especially boys, of Hispanic or northern European descent compared to African American pediatric patients (132).

Nonalcoholic Steatohepatitis as a Factor in Other Liver Diseases

NAFLD is so common that it can be expected to coexist with virtually any other liver disease and to possibly influence the course of that disease (133). Several studies have indicated that steatosis (possibly mediated by core protein metabolism) (134) is associated with hepatitis C (especially genotype 3) and accelerates liver disease progression (135). The association with insulin resistance and type 2 diabetes has been sufficiently strong to dub hepatitis C as a metabolic disease (136), and a measure of insulin resistance in hepatitis C has been shown to predict fibrosis (137). Although viral metabolism may be important in this association (138), many patients with hepatitis C virus and features of NASH have coexisting risk factors for metabolic syndrome and, therefore, for NASH, suggesting a synergistic effect rather than a causal relationship (139,140). Iron loading of the liver has also been suggested as a factor in the progression of NASH, although this is controversial (141,142). As recently pointed out by Powell et al. hyperferritinemia in NAFLD correlates more closely with insulin resistance than with iron overload or *HFE* gene mutations and can be reversed with weight loss (143).

Genetic Factors in Nonalcoholic Fatty Liver Disease

Ethnic Variation

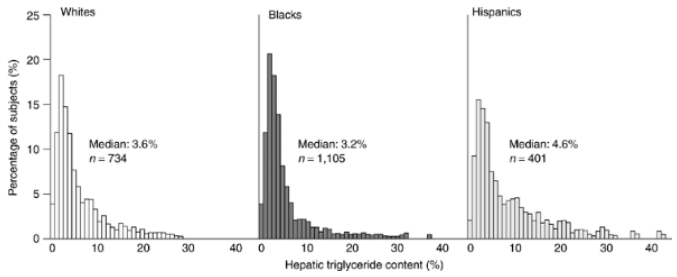
Several reports have described significant ethnic variation in the prevalence of NAFLD/NASH (144,145,146,147). This is explained, in part, by ethnic differences in the

distribution of body fat because central adiposity correlates better with fatty infiltration of the liver (and to insulin sensitivity) than does total body fat (148,149,150,151,152,153). The observation is consistent with the genetic associations of obesity and diabetes and the ethnic variation described in lipoprotein metabolism (154,155,156,157,158). Similar ethnic variation has been described in cryptogenic cirrhosis (144,159). Most of these studies, including the large epidemiologic study by Weston et al. have indicated that people primarily of African American descent seem to have a lower than expected prevalence of steatosis relative to the rates of obesity and diabetes (160). The most convincing data comes from Browning et al. who studied 2,287 subjects with magnetic resonance spectroscopy (MRS) (see subsequent text) to measure liver triglyceride content (161). The authors again noted that African Americans tended to have significantly less steatosis than Hispanic or non-Hispanic whites independent of the presence of obesity or diabetes, suggesting that additional factors influence the development of steatosis (Fig. 39.8). Similar variation in the prevalence of NAFLD among patients with diabetes has also recently been described. (Fig. 39.9).

Familial Factors

A high prevalence of afflicted first-degree relatives has been described in at least two studies of NASH (162,163). Both these studies reported an association with obesity and diabetes, and one showed a relationship with cryptogenic cirrhosis within kindreds, perhaps

explaining prior reports of familial cirrhosis (164). However, it remains unclear whether these associations represent genetic mechanisms, common environmental exposures, and shared risks or perhaps some combination of both genetic risk and common health habits. The demonstration of impaired skeletal muscle mitochondrial metabolism associated with insulin resistance in the offspring of patients with type 2 diabetes further suggests a genetic risk closely related to handling and disposition of intracellular fat (165).

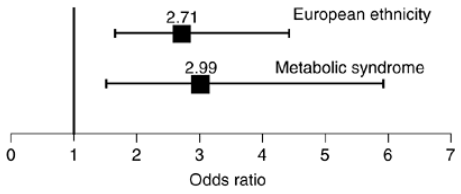


• **Figure 39.8** Distribution of hepatic triglyceride content by ethnicity as assessed by ^{1}H-magnetic resonance spectroscopy. Browning et al. (162) showed that the distribution of hepatic triglycerides content was skewed toward lower levels in blacks and slightly higher levels in Hispanics. (Reprinted with permission of Wiley-Liss Inc., a subsidiary of John Wiley & Sons, Inc.)

Genetic Variation

The search for genetic factors has involved seeking specific polymorphisms of candidate genes involved in fat metabolism, oxidative stress and cytokine activity, and genome-wide comparative surveys of single nucleotide polymorphisms (SNPs) (166,167). Experimentally, variation in hepatic lipogenic gene expression was seen in mouse strains in which, paradoxically, greater hepatic steatosis was associated with less insulin resistance (168). In humans, microarray analysis has shown that patients with NASH underexpress genes

associated with the mitochondrial antioxidant system and overexpress acute-phase reactants that may play a role in insulin resistance (169,170). Variation in adiponectin and hormone-sensitive lipase polymorphisms (important in flux of fatty acids between the liver and periphery) has been described, as has variation in SNPs of microsomal triglyceride transfer protein (171,172). Other potential factors include the CD36 protein (e.g., fatty acid translocase—a scavenger-receptor expressed in adipose tissue where it functions as a transporter of fatty acids and oxidized low-density lipoprotein), lamin A mutations (associated with lipodystrophy), mitochondrial mutations (see subsequent text), iron overload, cytochrome P-450, peroxisome metabolism, and variation in the function of antioxidants (e.g., glutathione, vitamin E and superoxide dismutase) that are known to be depleted in conditions associated with hepatic lipid peroxidation (173,174,175,176,177,178,179,180,181,182). As previously described in patients with hepatitis C infection, a synergistic association between high expression of angiotensinogen and of transforming growth factor-β1 genotypes has also been described in obese patients with more severe NASH (183,184).



• **Figure 39.9** Diabetes, ethnicity, and nonalcoholic fatty liver disease (NAFLD). Sundaram et al. demonstrated significantly increased odds ratios for NAFLD in patients with diabetes who were of predominantly European descent compared to patients of African American descent and in patients with metabolic syndrome (97).

Clinical and Laboratory Findings

Symptoms and Signs

Specific symptoms in NASH are infrequent. Associated signs and symptoms and laboratory findings are summarized in Table 39.6. In a compilation of several studies, Reid noted an absence of specific symptoms in 48% to 100% of patients (8). However, in another study, Sanyal noted fatigue in 45 of 62 patients (73%) and right upper quadrant pain in 30 of 62 (48%) (185). This discomfort is often mistaken for gallstone disease that can also be associated with obesity and hyperinsulinemia (186). Persistence of pain after cholecystectomy or an abnormal-appearing liver at the time of surgery often precipitates a referral to the liver clinic. Hepatomegaly is usually due to steatosis but may be due to hepatic glycogenosis in patients with diabetes (187). Acanthosis nigricans has been noted in some children with NASH. The presence of palmar erythema or spider angiomas suggests cirrhosis that may very subtle—we have seen a number of patients whose initial presentation of NASH with cirrhosis was the presence of rectal varices detected at screening colonoscopy. A family history of fatty liver, unexplained liver abnormalities, or cryptogenic cirrhosis is seen in approximately 20% to 25%. A subacute form of NASH with cirrhosis probably represents unrecognized chronic disease with unexplained sudden decompensation (188,189).

Table 39.6. Signs, Symptoms, and Laboratory Features

SYMPTOMS
Asymptomatic (48%–100%)
Fatigue (~70%)
Right upper quadrant pain (up to 50%)
Occasional neurological deficits (possibly part of systemic lipotoxicity)
SIGNS
Hepatomegaly
Acanthosis nigricans in children
Palmar erythema and spider angiomas (if cirrhosis has developed)
LABORATORY FEATURES
Elevated aspartate transaminase and alanine transaminase levels (usually <2 × normal)
Mildly elevated γ-glutamyl transpeptidase level
Mildly elevated alkaline phosphatase level
antinuclear antibody positive in ~30%
Increased immunoglobulin A
Abnormal iron indices in 20% to 60% (usually not with definite hemochromatosis)

See text references.

Not surprisingly, clinical findings associated with the metabolic syndrome, including obesity, type 2 diabetes, hyperlipidemia, hypertension, hyperuricemia, polycystic ovary syndrome (i.e., insulin resistance, diabetes, obesity, hirsutism, oligomenorrhea, or amenorrhea), and gallstone disease, are common (93,94,186,190,191,192,193,194,195,196,197). Changes in body composition due to aging and cirrhosis (both associated with loss of muscle and adipose tissue) may mask a history of prior, severe, and long-standing obesity (198,199). The relationships between the hypercoagulable component of metabolic syndrome (due to plasminogen activator inhibitor-1 increased with central obesity), systemic endothelial/vascular abnormalities, and steatohepatitis have not yet been fully explored (200,201,202).

Laboratory Features

Many patients present with only abnormal liver test results, especially ALT and/or AST often detected on routine screening or during institution of weight loss therapy, or antihypertensive, antidiabetic, or antihyperlipidemic therapy. Transaminase levels are usually less than two times the upper limit of normal; from a compilation of five earlier studies reviewed by Harrison and Neuschwander-Tetri, the average AST and ALT levels were 79 IU/L and 64 IU/L, respectively (203). AST, partly mitochondrial in origin (204), correlates imperfectly with the degree of inflammatory activity and injury as does the AST to ALT ratio, in that values less than 1 are consistent with mild disease while values greater than 1 often indicate fibrosis (205). Mild elevation of GGT and alkaline phosphatase levels may also

be present but are not as well studied. GGT was predictive of more severe histology in one study, although isolated GGT level elevation is of doubtful significance in this setting (89).

Nonalcoholic Fatty Liver Disease and Normal Aminotransferases

It is now well known that patients with significant histologic liver disease, including cirrhosis, may have normal aminotransferase levels (206,207). The lack of complete correlation between histology and aminotransferases is similar to that seen with hepatitis C—the relationship is present but imperfect. It is generally accepted that elevation of AST and ALT levels indicates hepatocyte injury or, possibly, the rate of cell turnover, which results from cell injury (208). Other explanations include the possibility that the "true normal" range in obese patients may be lower than that for lean individuals (209). Indeed, ALT levels are positively correlated with central obesity and hyperinsulinemia (leading to an ongoing effort to revise normal ranges) and negatively correlated with caffeine consumption (210,211,212). In addition, the use of a thiazolidinedione medication (troglitazone) was shown to normalize transaminase levels and improve parameters of inflammation, but all patients still met criteria for NASH on follow-up biopsy (213).

Other Laboratory Abnormalities

Abnormal sinusoidal deposition of immunoglobulin A (IgA), indistinguishable from that seen with alcohol-related liver disease, has previously been described in NASH (214). Serum IgA level elevation in alcohol-related liver disease results from neoantigen formation (215). Although not as well studied, isolated elevation of serum IgA level is seen in 25% of patients with NASH and a lower serum IgG to IgA ratio is associated with more severe fibrosis (216). Antinuclear antibody is seen in approximately 35% of patients with NASH (217,218). Abnormal iron indices, including ferritin and transferrin saturation, are seen in 20% to 60% of patients, but this is not usually associated with homozygous or heterozygous genetic hemochromatosis and the relationship to disease severity remains unsettled (219). Low platelets, often misdiagnosed previously as idiopathic thrombocytopenia, warrants an additional search for hypersplenism and cirrhosis (220).

Findings of Lipodystrophy

Fatty infiltration of the liver is a common feature of the lipodystrophies (221,222). These disorders, congenital or acquired, vary in the distribution of dystrophic fat. Common features include diabetes, hypertriglyceridemia, panniculitis, and focal or diffuse loss of subcutaneous fat. The mechanism is thought to involve failure of differentiation of preadipocytes, possibly due to lipin deficiency (223). The diagnosis depends on cross-sectional imaging of an involved area to demonstrate fat atrophy. Histologic NASH was observed in eight of ten patients in a recent small series that also demonstrated improvement with leptin replacement, supporting a role for leptin deficiency (224). Cirrhosis has been described among women with the acquired variety (225,226). A familial form of partial lipodystrophy has also been described in association with NAFLD (227). On the basis of the subtle presentation of lipodystrophy and lack of easily available tests, it seems likely that there is more overlap between NAFLD and lipodystrophy than is commonly appreciated. A potentially important distinguishing feature of the more severe forms of lipodystrophy is the characteristically low leptin level (228). Lipodystrophy related to antiretroviral therapy, perhaps now the most common form of this disorder, is discussed further in subsequent text.

Findings Suggestive of Mitochondrial Disease

The systemic nature of NAFLD and the presence of morphologic mitochondrial abnormalities in liver biopsy specimens (94,229) suggest that other mitochondria-related clinical manifestations may be prevalent in NAFLD (230). Features of systemic mitochondrial disease can be observed in patients with NASH including depression, ophthalmoplegia, neurodegenerative diseases, deafness, lipomatosis, and gut dysmotility (231). Few of these have been systematically investigated, although Al-Osaimi et al. recently reported an increased prevalence of a subtle form of gaze palsy in patients with NASH (232). Insulin resistance and dyslipidemia are features of symmetric lipomatosis or Madelung's disease (associated with mitochondrial deoxyribonucleic acid [DNA] mutations) (233,234) and of maternally inherited diabetes and deafness (MIDD) syndrome (also associated with mitochondrial mutation) (235). Similar hepatic mitochondrial

DNA mutations have been identified in some patients with NASH (236). In addition, cryptogenic cirrhosis has been described in certain mitochondrialopathies (237). Underlying these seemingly unrelated problems, mitochondrial heteroplasmy could play a role in the variable expression of a mitochondrial problem in different organs (238,239).

Weber-Christian Disease

Nodular panniculitis, especially over the lower extremities, is the most distinguishing feature of classical Weber-Christian disease (240,241). Steatohepatitis is a common finding, suggesting a systemic disorder of

fat metabolism. Liver chemistries may be only mildly increased or there may be an acute steatohepatitis with jaundice and Mallory bodies may be evident. The diagnosis can be established by demonstration of fat necrosis. In distinct contrast to many other forms of NAFLD, immunosuppression has been reported to be effective therapy, suggesting an autoimmune component (242).

Imaging in Nonalcoholic Fatty Liver Disease: Ultrasonography, Computed Tomography Scan, Magnetic Resonance Imaging, and Magnetic Resonance Proton Spectroscopy

Liver imaging plays an important role as an initial diagnostic tool, in epidemiologic studies, and in the evaluation of partial liver donors (Fig. 39.10) (243). Of particular relevance to epidemiologic studies, imaging is used to assess the distribution of body fat in comparison to anthropometric measurements (244,245). For example, computed tomographic (CT) measurement of abdominal visceral fat at the L4-5 intervertebral space, adjusted for age and sex (246), is the most established technique (247). Magnetic resonance imaging (MRI) (248,249) and ultrasonography (250) have also been utilized to quantitate body fat, especially central adiposity. However, none of the conventional imaging techniques can accurately grade or stage NASH (with the possible exception of advanced MRI), and the accuracy of even detecting steatosis is limited above levels of 20% to 30% (251,252).

Ultrasonography and Elasticity

Ultrasonography can detect the presence of hepatic steatosis through increased echogenicity and sound attenuation with defined criteria for fatty infiltration (253,254,255). However, its utility is limited because of difficulty in differentiating fibrosis from fatty infiltration (256,257), misinterpretation of focal fatty sparing as a hypoechoic mass (258), and poor detection if the degree of steatosis is less than 20% to 30%. Nonetheless, as initial testing in a suspected case and for large population screening, it is a reliable and economical means of assessment. Newer techniques including measurement of hepatic elasticity (decreased with fibrosis) are promising but have not been adequately evaluated in NAFLD in which fatty infiltration may present a problem by spuriously decreasing elasticity.

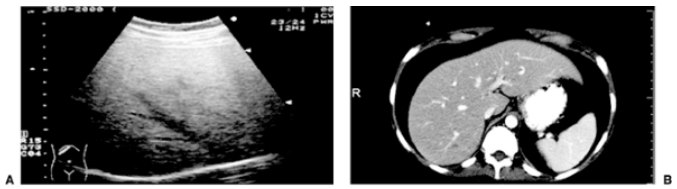
Computed Tomography

With CT, unenhanced scans remain the optimal technique to image hepatic fat when the diagnosis relies on attenuation differences between the liver and spleen (151,259,260). The sensitivity and specificity of detecting fatty liver (with spleen-minus-liver attenuation of 10 Hounsfield units) were 0.84 and 0.99, respectively, in one study (261). Recently, therapeutic trials have used the "liver-to-spleen ratio" (in Hounsfield units) in which values less than 1 are consistent with relatively greater steatosis. Contrast-enhanced CT scan has more limited utility because the optimal liver-minus-spleen attenuation differences are significantly influenced by the contrast injection rate and timing of measurement (262).

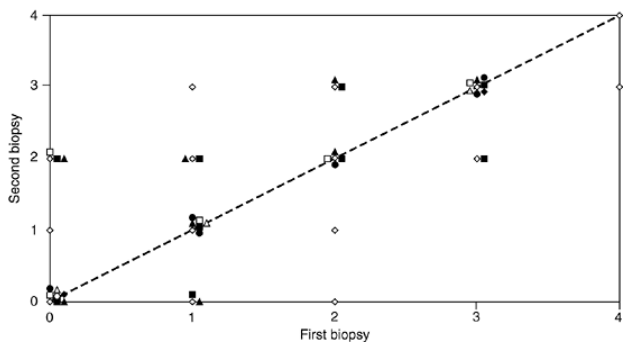
Magnetic Resonance Imaging and Spectroscopy

Conventional spin-echo MRI is insensitive in detecting fatty infiltration (263). This limitation is improved with refinements of the technique, including modified spin-echo and in-phase, out-of phase imaging (264,265). Proton (^{1}H)-MRS is another means of very accurately assessing the degree of hepatic steatosis (266,267). In one study, the correlation between fat concentration

measured in the liver biopsies and ^{1}H-spectroscopy was 0.9 ($P < 0.001$) (268). ^{31}P spectroscopy (Fig. 39.11) offers the futuristic prospect of measuring cellular chemistry and metabolic parameters including adenosine triphosphate (ATP) homeostasis in the liver, lipid peroxidation, and phospholipid content of the liver (270,271,272,273,274,275).



• **Figure 39.10** Radiologic imaging of nonalcoholic fatty liver disease (NAFLD). **A:** Sonographic appearance of NAFLD. **B:** Computed tomography (CT) appearance of NAFLD. **(A)** demonstrates a heterogeneous-appearing echotexture with findings of "bright liver" in the parenchyma; **(B)** shows a relatively hypodense liver compared to the spleen (liver-to-spleen ratio <1).



• **Figure 39.11** Biopsy sampling error. Ratziu et al. (269) show evidence of the sampling error that can occur if inadequate liver biopsy specimens are obtained. The biopsy specimens of 15 of 51 patients showed at least a one-stage difference in fibrosis stage, and 2 showed a two-stage difference from the same right flank site with slightly different needle orientation, indicating the need for samples of at least 2 to 3 cm in length using a standard 15–gauge width needle to minimize sampling error. The symbols represent the results of an individual patient's consecutive biopsies.

The Use of Liver Biopsy in Nonalcoholic Fatty Liver Disease

Liver biopsy remains the gold standard for confirming the diagnosis, staging the extent of injury, and grading the degree of activity. However, biopsy is often deferred, and a conservative course of exercise and diet is prescribed as initial steps unless the clinical evaluation indicates more advanced disease or when there is a question of medication-induced injury. Practically speaking, the importance of the biopsy is increasing as therapeutic interventions improve and with the recognition of occult cirrhosis as a significant consideration in the management of older patients with diabetes (see "Treatment of Nonalcoholic Fatty Liver Disease"). The use of surrogate tests such as serologic fibrosis markers, refined imaging techniques, or noninvasive measures of elasticity is promising but remains to be fully explored (276,277,278).

Predictors of Underlying Histology

Clinical predictors of findings on the initial biopsy specimen have been studied extensively (Table 39.7), although such noninvasive predictors should be regarded cautiously because of the high number of exceptions. Age (>40 to 50 years), the degree of obesity, the degree of diabetes or insulin resistance, hypertriglyceridemia, hypertension, family history of NASH or cryptogenic cirrhosis, complete abstinence from ethanol, transaminase level (AST and ALT) elevation (relatively weak marker), and an AST to ALT ratio more than 1 are often, but not invariably, predictive of more advanced histology, but conflicting studies exist (5,7,30,60,64,76,85,89,90,91,205,279,280,281,282,283,284,285). Other factors noted as predictive of more severe histology on the initial biopsy specimen include circulating antibodies to lipid peroxides (286) and the number of parameters positive from the Adult Treatment Panel-III criteria for metabolic syndrome (287). A number of these variables have been combined into composite scores, but these also have limited sensitivity and specificity and have not gained wide clinical acceptance. Incorporation of markers of collagen metabolism, such as serum hyaluronic acid, into a clinical score enhances the predictive value but still carries only a 76% accuracy rate in predicting significant injury on biopsy (288).

Table 39.7. Predictors of More Severe Histology in Nonalcoholic Steatohepatitis

Age >40–50 y or female gender
Degree of obesity or steatosis
Hypertension
Overt diabetes or increased insulin resistance
Hypertriglyceridemia
Elevated alanine transaminase level
Elevated aspartate transaminase level
Elevated γ-glutamyl transpeptidase level
Aspartate transaminase:alanine transaminase ratio >1
Elevated immunoglobulin A level
See text.

Limitations of the Biopsy

The major limitations of biopsy include patient inconvenience, the potential for complications, performance in obese patients, and sampling error. In general, complication rates with liver biopsy are infrequent, and the variety of available techniques offer improved safety and applicability (289,290,291,292). Sampling error on percutaneous biopsy is well recognized but can be minimized by obtaining an adequate specimen more than 2 to 3 cm in length by 1.5 mm wide (15 to 16 gauge) (293,294,295). In the most convincing study, Ratziu et al. demonstrated a 10% to 15% risk of a two-stage error and roughly 40% risk of one-stage error in the fibrosis stage when specimens are less than about 2 to 3 cm in length (Fig. 39.11) (269).

Scoring of the Biopsy (Nonalcoholic Steatohepatitis Activity Index, Nonalcoholic Steatohepatitis Activity Score)

Although the Brunt score remains the most commonly used method of assessing the biopsy, recent introduction of composite scores have provided a useful means of assessing response to treatment particularly in clinical investigations (Table 39.8). Key parameters have been combined into the NAI and NAS (297,298). The NAI ranges from 0 to 12 and accounts for steatosis, necroinflammatory activity, and hepatocyte injury (ballooned cells), each of which is scored from 0 to 4. The more refined NAS uses a scale of 0 to 8

to score steatosis, lobular inflammation, and cellular ballooning. Fibrosis stage is scored separately in both composites.

Table 39.8. Histology Scoring Systems in Nonalcoholic Fatty Liver Disease

	Steatosis	Inflammation (lobular)	Hepatocyte injury (ballooning)	Maximum score	Fibrosis
NAS-I (NAFLD activity score) (Brunt et al., 1999) (23)	0–3	0–3	0–2	8	0–4
	0—none	0—no foci	0—absent		0—none
	1—<33%	1—1–2 foci/mpf	1—present-z3		1—sinusoidal
	2—33%–66%	2—3–4 foci/mpf	2—marked-z3		2—sinusoidal and periportal
	3—>66%	3—>4 foci/mpf			3—bridging fibrosis
					4—cirrhosis
NAI (NASH activity index) (Promrat et al. 2004) (296)	0–4	0–4	0–4	12	0–4
	0—<5%	0—no foci	0—absent		0—none
	1—5%–25%	1—<1 foci/mpf	1—only z3, <50% of CVs		1—perisinusoidal
	2—>25%–50%	2—1 foci/2 mpf	2—only z3, >50% of CVs		2—perisinusoidal and periportal
	3—>50%–75%	3—1–2 foci/mpf	3—both z2 and z3, (1/3–2/3)		3—bridging fibrosis
	4—>75%	4—>2 foci/mpf	4—all zones (>2/3)		4—cirrhosis/regeneration
NAS-II (NASH clinical research network revision) (Kleiner et al., 2005) (297)	0–3	0–3	0–2	8	0–4
	0—<5%	0—no foci	0—absent		0—none
	1—5%–33%	1—<2 foci/mpf	1—few ballooned cells		1—perisinusoidal or periportal 1A—mild, z3, perisinusoidal 1B—moderate, z3, perisinusoidal 1C—portal/periportal
	2—>33%–66%	2—2–4 foci/mpf	2—many/prominent ballooning		2—perisinusoidal and portal/periportal
	3—>66%	3—>4 foci/mpf			3—bridging fibrosis 4—cirrhosis

NAS, NASH activity score, nonalcoholic stestohepatitis; NAI, NASH activity index, nonalcoholic steatohepatitis; NAFLD, nonalcoholic fatty liver disease; z2, zone 2; z3, zone 3; mpf, medium power field—200× magnification; CVs, central veins.

Natural History and Prognosis

Mortality Overview

Although patients with NAFLD frequently have substantial comorbid conditions that could influence survival, progressive liver disease often becomes the dominant problem. Consistent with this, obesity was recognized as a major risk factor for cirrhosis-related deaths in people who consume little or no alcohol (299). Among patients with type 2 diabetes in Japan, the cause of death was cirrhosis in 6.4% (compared to 19.5% from heart disease) (300). However, the observed versus expected deaths ratio (O/E ratio) was actually higher for cirrhosis than for heart disease (2.67 vs. 1.81). In another report, the five- and ten-year survival in NASH was estimated at 67% and 59%, respectively (301). These figures were lower than those for a matched population, but the difference did not reach statistical significance. In a 12-year follow-up, Cortez-Pinto et al. showed that patients with NASH had a liver-related death rate similar to that for ambulatory patients with ASH—both rates were significantly better than those for hospitalized patients with ASH (302). In one of the largest natural history studies published to date, Adams et al. showed that liver disease is the third leading cause of death in a group of 420 patients with NAFLD followed up for a mean of 8 years compared to liver disease as the thirteenth most common cause of death in the general population (303,304).

Variation Based on Initial Histology

In a retrospective study of adult patients in the United States, the overall mortality among those with fatty liver accompanied by inflammation, fibrosis, balloon cells, or Mallory hyaline was increased compared to crude death rates, and cirrhosis-related deaths were also increased when fatty infiltration was accompanied by the presence of these more severe histologic markers (7). In contrast, several prior studies have shown that simple steatosis or steatosis with minimal inflammation (Matteoni type 1 and 2) is a relatively stable condition (15,305). The relative stability of these milder forms of fatty infiltration indicates that NASH (fatty infiltration plus fibrosis and/or balloon cells) probably begins at the higher stage rather than progressing through stages from simple steatosis to more severe forms. However, this has not been established and such a transition can be seen with rapid weight loss (and perhaps with other forms of metabolic stress) (306,307).

Serial Biopsy Studies

A number of studies reporting serial biopsy in patients with NASH have now been published (5,25,26,89,308,309,310,311). Although the studies have a number of shortcomings, including variable biopsy techniques, different entry criteria, and incomplete data on confounding variables such as voluntary lifestyle changes and antidiabetic or antihyperlipidemic medications (312), there is sufficient data to draw some reliable observations. Compiling the studies, 177 patients have undergone a second biopsy after a mean of 4.5 years (Table 39.9). Cirrhosis developed in 10% of patients while fibrosis progressed in 33%, remained stable in 41%, and improved in 22%. In some of the patients, the progression to cirrhosis was surprisingly rapid over 1 to 2 years. Most papers show that as fibrosis progresses, aminotransferases, steatosis scores, and inflammation improve paradoxically. This is of some concern in the clinical setting in which normalization of the aminotransferases should be regarded with cautious optimism, especially in older patients. Normalization of these parameters is consistent with the progression of NASH to a "burned out" state, which is often recognized as "cryptogenic" cirrhosis (see preceding text).

Table 39.9. Serial Biopsies in Patients with Cryptogenic Cirrhosis

Author	Number	Years of follow-up	Progressed to stage 4	Progressed to stage 2–3	No change	Improved
Lee (1989) (308)	12	3.5	2	3	7	0
Powell (1990) (24)	13	4.5	3	3	6	1
Bacon (1994) (5)	2	5	1	0	1	0
Ratziu (2000) (89)	4	5	1	1	2	0
Harrison (2003) (308)	19	5.7	2	4	9	4
Fassio (2004) (309)	22	4.3	0	7	11	4
Adams (2005) (310)	98	3.2	9	24	35	30
Totals/Average	177	4.5	18 (10%)	59 (33%)	73 (41%)	39 (22%)

Nonalcoholic Steatohepatitis–Related Cirrhosis and Cryptogenic Cirrhosis

NASH-related cirrhosis appears, like other forms of cirrhosis, to progress through several stages. A small number of studies have addressed the natural history of this form of cirrhosis. Hui et al. compared the course of 23 patients with well-defined NASH cirrhosis to 46 matched patients with cirrhosis from hepatitis C (313). Nine of 23 patients with NASH–cirrhosis developed major complications of portal hypertension (e.g., ascites, encephalopathy, and variceal bleeding) during a mean follow-up of 7 years, with complication-free survival of 83%, 77% and 48% at 1, 3 and 10 years, respectively. Ratziu et al. compared the course of 27 overweight patients with cryptogenic cirrhosis to 10 lean patients with cryptogenic cirrhosis and 391 patients with hepatitis C–related cirrhosis in a retrospective follow-up cohort study (314). With a mean follow-up of 22 months, 2 of the 15 patients presenting only with abnormal liver test results developed major complications of portal hypertension and 5 developed HCC. The overall severity and risk for either a complication of portal hypertension or HCC were greater in obese patients with cryptogenic cirrhosis compared to the lean cryptogenic cirrhosis group but not different from patients with hepatitis C. The authors concluded that obesity-related cirrhosis behaves as aggressively as hepatitis C–related cirrhosis.

Hepatocellular Cancer

A number of studies have now shown an increased risk of HCC in obese patients and in those with diabetes (315,316,317,318,319). In addition to the natural history studies noted in the preceding text, there are also a number of well-documented NASH case reports and series indicating this progression (320,321,322). Although animal models of fatty liver exist in which HCC develops without cirrhosis, most human studies suggest that silent progression of NASH to cirrhosis is the more predominant pathway (323,324). The association of NASH with cryptogenic cirrhosis (see preceding text) and the risk of HCC in cryptogenic cirrhosis further strengthens the idea that for many patients with progressive NASH, HCC is an increasingly common late complication (325,326,327). Although the molecular events leading to HCC are yet to be fully defined, the proliferation of oval cells (hepatocyte progenitor cells) observed in human and experimental NAFLD may be a contributing factor (328) in addition to mutations in regulator genes such as *PTEN* that regulate certain aspects of both fat metabolism and cell proliferation (329).

Experimental and Animal Models of Nonalcoholic Fatty Liver Disease

Small Animal Models

Many advances in the understanding of NAFLD have resulted from the development of small animal models—usually mice or rats. This field has been reviewed extensively by Koteish and Diehl (330), Farrell (331), and Nanji (332). Several of the best known models include

the hyperphagic ob/ob mouse, which has a congenital deficiency of leptin; the FA/FA rat, which has an impaired leptin receptor; and the methionine–choline–deficient (MCD) rodent. Studies in these animals, as well as the numerous transgenic models, have led to many seminal observations in NASH about hepatic fat metabolism and its regulation. Although providing insight into specific pathways, these models share the common problem of inadequately imitating the common form of human NAFLD. For example, the ob/ob mouse requires other provocative measures to produce significant injury in addition to simple steatosis, and the MCD model, although producing hepatic injury without further provocation, lacks insulin resistance (333).

Large Animal Steatosis and the Liver as a Normal Fat-Storing Organ

Fatty liver disease is a well-known problem in veterinary medicine. Variants of the disorder are seen in cows (334,335,336), hens (337), and cats (338,339) and can occur spontaneously or with phosphorous supplements in pigs (340,341,342). Hepatic "lipidosis" is reported to be one of the most common liver disorders in domestic cats and, similar to human steatohepatitis, has been associated with mitochondrial morphologic abnormalities (343). Seasonal variation in hepatic fat has been observed in deer (344). These observations suggest a close integration of the liver into the adipose system, which is evident experimentally in studies demonstrating the upregulation of genes governing adipocyte differentiation during liver regeneration (345,346).

Palmipedes (migratory geese) develop fatty liver before migration and utilize fat as a preferred source of energy for muscles through the expression of fatty acid–binding protein (347). This has been exploited in the production of foie gras in which geese are fed a corn-based diet, resulting in a 8- to 10-fold increase in liver size in as little as 2 weeks (from 100 to 800 g). The goose hepatocyte enlarges to three to four times the original diameter, with fat droplets observable as mixed micro- and macrosteatosis. Although early harvest limits the natural course, degenerative changes

is seen and cirrhosis is anecdotally noted (348). In addition, accidental exposure to moldy corn (mycotoxins) is associated with liver failure with ascites (349). Interestingly, significant subspecies variation exists in the lipogenic capacity (350). Indirect evidence suggests that the main mechanism involves increased lipid synthesis and altered very low density lipoprotein (VLDL) synthesis and secretion (351,352,353). These observations further illustrate the role of the liver within a broadened concept of the adipose system, with its inherent plasticity (transdifferentiation of fat stores) and its role in energy metabolism and thermoregulation (354,355,356,357). It has been hypothesized that skeletal muscle fat metabolism, which interacts with hepatic fat stores and strongly influences insulin sensitivity, confers a survival advantage under harsh conditions (358).

Pathogenesis of Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatitis

Although many of the metabolic abnormalities noted in NAFLD have yet to be assimilated into a cohesive "story," the importance of lipotoxicity as underlying insulin resistance, the metabolic syndrome and cellular injury in steatohepatitis, is emerging as the most likely primary pathway in typical cases of human NAFLD (359). In this light, NAFLD can be viewed as a potential adverse occurrence within the realm of the metabolic syndrome and more specifically as a possible adverse outcome of systemic lipotoxicity (360). Excessive fatty acids have a broad effect on many tissues and even influence gene expression and, hence, adipocytokine production in adipose tissue (361). However, it is very likely that there is substantial variation between groups or individuals in the relative importance of different mechanisms, as suggested in the wide ethnic variation in the development of steatosis—the first "hit" in the path to hepatic fibrosis. A plausible pathway for some of the most common abnormalities is shown in Figure 39.12.

Steatosis

The normal, healthy liver contains no more than 5% lipid by weight (362). The levels of both triglycerides (mostly unsaturated fatty acids) and free fatty acids (mostly saturated) are increased in the liver of obese patients (363). The development of cellular injury involves a cascade of events beginning with the development of steatosis (NAFLD) and the subsequent development of oxidative stress, lipid peroxidation, and cell injury, and activation of profibrotic cytokines, resulting in NASH (364). Increased hepatic fat stored in the form of triglyceride can be derived from the plasma fatty acid pool mostly released from peripheral adipose tissue by lipolysis, from dietary fat through chylomicron remnants, or from de novo synthesis within the liver. De novo lipid synthesis, largely from glucose, is governed by two main transcription factors that signal transcription of the enzyme systems responsible for fatty acid synthesis and subsequently for their esterification into triglyceride: Sterol regulatory element–binding protein (SREBP), which is governed by insulin, and carbohydrate response element–binding protein (CREBP), which is governed by glucose levels (365,366,367,368). SREBP-1 level appears to be increased in animal models of NAFLD, and it is suspected that a similar process is going on human NAFLD.

The disposition of fatty acid in the liver proceeds by one of several routes: Storage as triglyceride, export as VLDL, or oxidation. Regulation of the predominant form of disposition depends on a number of interacting factors based on energy homeostasis and influenced by peroxisome proliferators activated receptor (PPAR) activity and probably by the activity of the adrenergic nervous system (369,370,371). Although focal fat necrosis may occur from direct release of fat from swollen hepatocytes in NAFLD (372), toxicity, as noted by Bass and Merriman, results primarily from the indirect effects of lipid peroxidation and to a lesser extent from direct toxicity of fatty acids (369).

Insulin Resistance

Although epidemiologic work indicates that peripheral insulin resistance is neither sufficient nor essential for NAFLD, it is present in most patients with NAFLD and, therefore, is so closely intertwined with the disease as to be virtually inseparable in most cases. Insulin resistance is characterized by a reduced sensitivity to insulin in target tissues (e.g., muscle, adipose tissue, and liver), where it normally favors glucose transport into the cell, storage of glycogen, inhibition of lipolysis in adipose tissue, and inhibition of gluconeogenesis from the liver. The expected manifestations of insulin resistance include decreased peripheral (muscle) glucose utilization, enhanced lipolysis and mobilization of fatty acids from peripheral fat stores, and increased hepatic glucose output (normally suppressed by insulin). Insulin resistance, primarily mediated by excessive fatty acids (373,374,375,376,377,378,379), is observed in NAFLD using a variety of techniques (112,380,381,382). The relationship between fatty liver and insulin resistance represents a (sometimes precarious) balance between the three main target organs—skeletal muscle, adipose tissue, and the liver (383). Using modifications of the insulin "clamp" test, Sanyal et al. convincingly demonstrated that the predominant site of resistance in NAFLD is in the peripheral fat and skeletal muscle as opposed to the liver (94,384,385,386,387). Recent work using MRS of skeletal

muscle indicates that insulin resistance in metabolic syndrome results from skeletal muscle lipotoxicity and secondary changes in mitochondrial metabolism (388). Excessive skeletal muscle fatty acid also leads to inhibition of insulin-stimulated glucose transport through the effects on insulin receptor substrate-1 (IRS-1) (389). Teleologically, insulin resistance in this setting can be seen as a normal response to excessive energy substrate availability (diet and obesity) and underutilization (activity).

Lipid Peroxidation and Hepatic Lipotoxicity

Lipid peroxidation reflects an imbalance between pro- and antioxidant substances (oxidative stress) (390). It is a branching, chain reaction stimulated by a free radical attack on unsaturated fatty acids (Fig. 39.12) (391). Free radicals, which initiate the process, may be derived from mitochondrial, peroxisomal, or cytochrome P-450 fat metabolism, with the formation of superoxide, hydrogen peroxide, and hydroxyl radicals. The products of the reaction are another free radical and a lipid hydroperoxide, which, in a reaction catalyzed by iron, forms a second (lipid) free radical and, therefore, amplifies the process. Damage involves chemical bonding with other cellular constituents including membrane lipids, proteins, and DNA (392). Although difficult to measure directly, lipid peroxidation is the main process leading to inflammation, activation of cytokines, stimulation of stellate cells, and fibrosis (393,394). Levels of the markers of

lipid peroxidation (e.g., nitrotyrosine, 4-hydroxynonenal [4-HNE], and malonic dialdehyde [MDA]) are increased in human NASH and are associated with mitochondrial abnormalities (94,395,396). The latter may be an injury response or due to increased activity of uncoupling protein (UCP), which decreases oxidative stress and is associated with abnormal oxidative phosphorylation and an adenosine triphosphate deficit (94,270,397,398,399,400). Cytokine level elevation activates stellate cells with secondary fibrosis. Interestingly, a major site of oxidative injury appears to be the border area of small fat droplets that consist of a unique phospholipid monolayer (401,402).

Cytokine Activation and Fibrosis

Cytokine level elevation, especially tumor necrosis factor-α (TNF-α), has been well described in NAFLD (403). In animal models, obesity itself appears to sensitize the liver to cytokine-mediated injury (404,405), TNF-α has been shown to induce mitochondrial UCP in regenerating liver in animal models of nonalcoholic fatty liver, and transforming growth factor-β (TGF-β) and interleukin-6 (IL-6) have also been implicated as mediators of fibrosis in NASH (403,406,407). Cell culture experiments indicate that stimulation of TNF-α results from fatty acid–mediated destabilization of lysosomes (408). Indirect evidence suggests that lipoperoxide-induced expression of inflammatory cytokines is mediated by the transcription factor nuclear factor-κB (409). A number of additional transcription factors (e.g., PTEN) and cytokines (e.g., osteopontin) are being recognized that, at least in experimental conditions, appear to interact with each other and influence insulin signaling and fibrosis pathways (410,411,412).

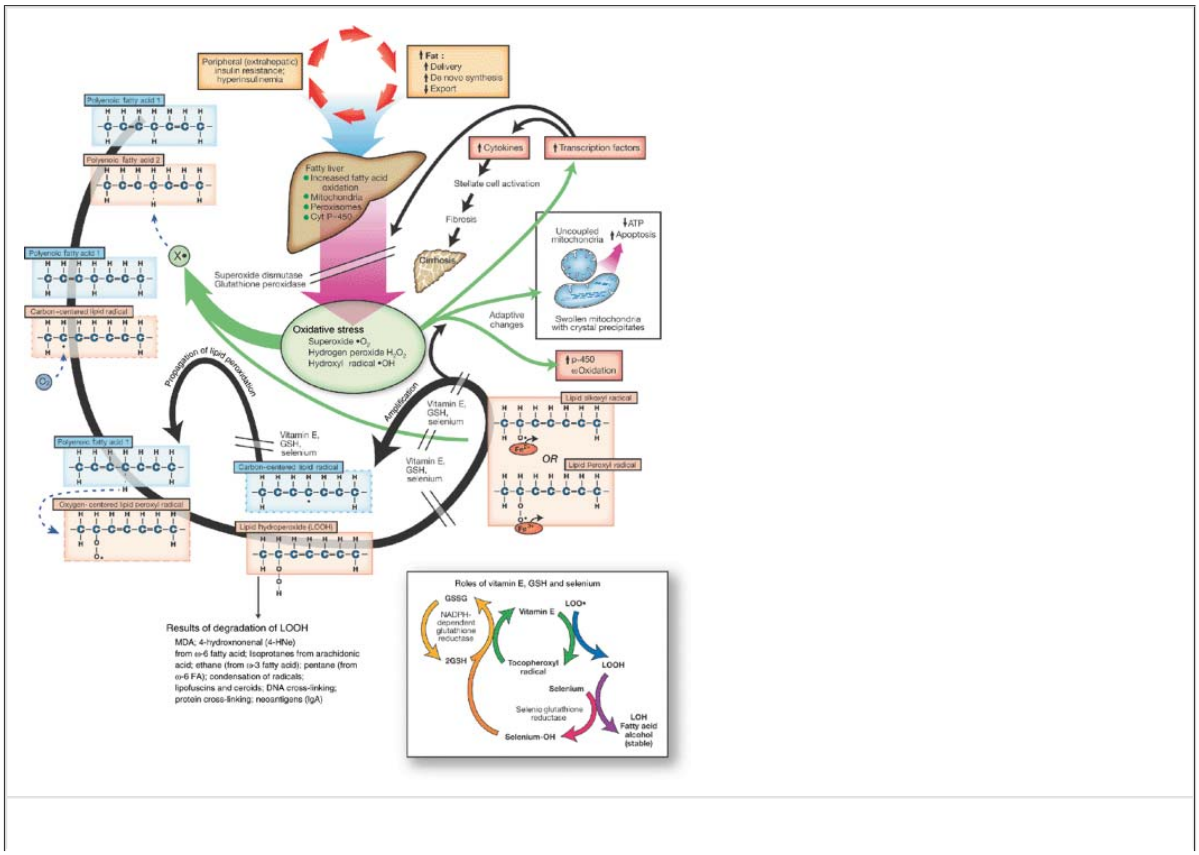
Adiponectin and Leptin (Adipocytokines)

Adiponectin is the most abundant protein in the adipocyte and participates in glucose homeostasis and insulin signaling through receptors in the muscle (adipoR1) and liver (adipoR2) (413,414,415,416,417). Its level is decreased in both obese/diabetic mice and humans and in patients with NASH compared to body fat–matched controls (416,418,419). Unlike leptin (see subsequent text) or TNF-α, adiponectin levels appear to be significantly different in patients with simple steatosis versus those with NASH, suggesting a more significant role for it in disease pathogenesis including a possible anti-inflammatory effect (420,421,422,423). Leptin is a circulating protein coded for by the obesity gene (chromosome 7q31 in humans) and produced primarily in white adipose tissue and its level is increased in cirrhosis (424,425,426,427). Its primary role is to govern satiety through action at the hypothalamus; however, human obesity is usually associated with elevated leptin levels (428). It has been variably implicated in the development of histologic injury in human and experimental NAFLD (429,430,431,432,433). In a recent study from Angulo et al. elevated leptin levels in progressive NASH were attributed to factors involved in production; no difference in leptin was seen between patients with worsening injury or those without on serial biopsy (434).

Other Cellular Injuries (Ballooning and Apoptosis)

Although the ballooned hepatocyte constitutes a marker for more progressive injury, a consensus definition remains elusive. The normal diameter of the hepatocyte varies from 13 to 30 μm (435). On light microscopy, ballooned cells are described as 1.5 to 2 times the normal size, located predominantly in zone 3 compared to other zones, and have rarefied cytoplasm. Ballooning in viral hepatitis involves hydropic changes and irregular dilatation of the smooth endoplasmic reticulum (436,437). However, electron microscopy using osmium fixation, which highlights fat droplets, suggests that most such cells in NASH

are microsteatotic (438). Coupled with observations of localization of lipid peroxidation (see preceding text) and localization of Mallory bodies (439), these observations suggest that handling of small-droplet storage fat is a significant source of injury in NASH. Apoptotic bodies are only occasionally seen in NASH specimens, although signal pathways for apoptosis are significantly activated in human NASH (440). This paradoxical situation is the result of rapid "cleanup" of apoptotic bodies such that they are infrequently seen or it may represent the result of a (sometime precarious) balance of pro- and antiapoptotic factors involving adaptive changes in the mitochondrion that play a central role in the regulation of apoptosis (441,442,443). Such adaptive (or maladaptive) changes may make the fatty liver more resilient in terms of localized cell death but more prone to necrosis because these processes are closely interrelated and coregulated (444).



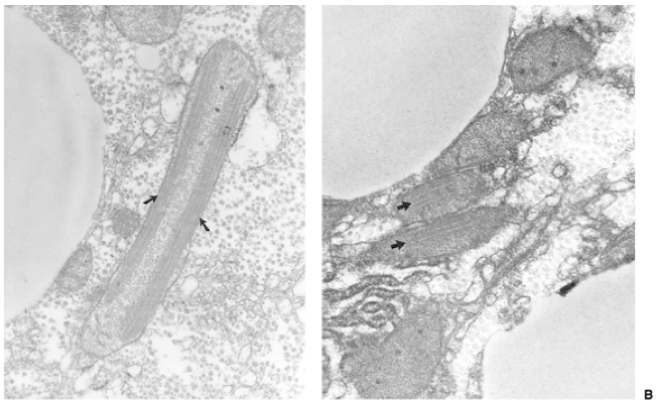
• **Figure 39.12** Mechanism of steatohepatitis—increased hepatic fat stores result from increased delivery of fatty acids, increased de novo synthesis, and decreased export of fat. The excessive free fatty acids both result from and promote extrahepatic insulin resistance. Fatty acid oxidation leads to the formation of free radicals, which derive from mitochondrial, peroxisomal, and cytochrome P-450 oxidation. Free radicals (e.g., super oxide, hydrogen peroxide, and hydroxyl radical) can directly activate transcription factors, resulting in overexpression of cytokines and, if not neutralized by the antioxidant system (superoxide dismutase and glutathione peroxidase), the free radicals ($X^{\bullet}$) can trigger the chain reaction of lipid peroxidation (rancidification). Unsaturated, polyenoic fatty acids are especially susceptible. This produces a *carbon-centered lipid radical*, which reacts with oxygen to form an *oxygen-centered lipid peroxyl radical*. This substance subsequently reacts with a second fatty acid to form another lipid free radical (propagation) and a *lipid hydroperoxide*. The latter is unstable and, in the presence of iron and another fatty acid, reacts to form yet another lipid radical (amplification). Alternatively, the lipid hydroperoxide may degrade to malonic dialdehyde (MDA) (detected by the thiobarbituric acid reactant [TBAR] reaction) or to ethane or pentane (detected in breath tests), react with other radicals to form a stable pigment (e.g., ceroids and lipofuscins), or may cross-link with deoxyribonucleic acid (DNA) or other cellular proteins (neoantigen formation). This oxidative stress induces cytochrome P-450 fatty acid oxidation and causes mitochondria changes with enlargement and formation of crystalline bodies possibly a result of abnormal expression of uncoupling protein. This leads to an adenosine triphosphate (ATP) deficit that increases the risk of necrosis and probably stimulates apoptosis, resulting in sporadic cell death and increased cell turnover. Lipid peroxidation also causes transcription of profibrotic cytokines that activate stellate cells, producing fibrosis. Countering the process of lipid peroxidation is the antioxidant system, which neutralizes lipid radicals by combination with vitamin E. The latter is then restored by shuffling the radical groups to glutathione through selenium. GSH, glutathione; NADPH, nicotinamide adenosine dinucleotide phosphate, reduced form; GSSG, oxidized glutathione; IgA, immunoglobulin A.

Mitochondrial Changes and Adenosine Triphosphate Homeostasis

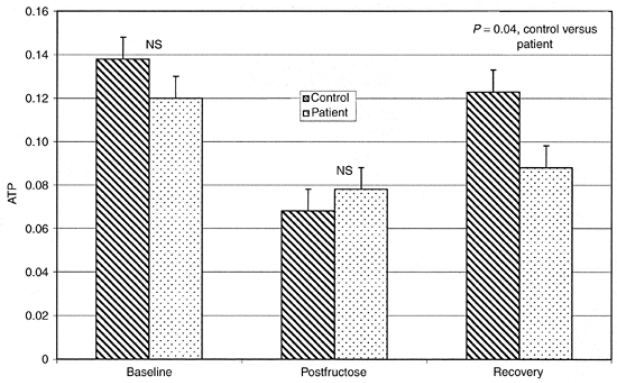
The mitochondrion may be both an especially important source of reactive oxygen species and a target for injury resulting from lipid peroxidation (196,445,446). Its unique evolutionary history places it in a central position of several major metabolic pathways, including fatty acid synthesis and β-oxidation, oxidative phosphorylation (ATP generation), and signaling pathways for the process of apoptosis (447). Mitochondrial morphologic abnormalities (Fig. 39.13) have been observed in both ASH and NASH (94,229,448,449,450). Commonly noted intramitochondrial inclusions are thought to be either a protein or phospholipid precipitate (451). It is thought that these morphologic abnormalities correlate with functional abnormalities, including respiratory chain dysfunction, and by their distribution may be part of the adaptive process to oxidative stress that make the liver more tolerant to reactive oxygen species but more susceptible to ischemic injury (398,452,453). For example, the poor function of steatotic livers in transplantation has been attributed in part to abnormal ATP homeostasis with depletion of electron transport components and increased susceptibility to ischemic injury (454,455,456,457).

Impaired function of the mitochondrial electron transport chain (ETC) in NAFLD has been described in several studies (458,459), attributable in part the to overexpression of UCP induced by increased fatty acids (460). Perez-Carreras et al. noted reduction in the ETC activity to 40% to 70% of normal in all the major complexes (I to V) in human NASH. In vivo impairment of ATP synthesis was observed by Cortez-Pinto et al. using ^{31}P MRS of the liver in controls compared to patients

with NAFLD (Fig. 39.14) (270). In experimental conditions, complex I and V (ATP synthase) dysfunction have been implicated in reperfusion injury, and these results open inquiry as to what the optimal protective mechanism is for the ETC during liver transplantation. (461,462). In a recent exhaustive review of the subject, Pessayre and Fromenty proposed that NASH is primarily a "mitochondrial disease." Although this may initially seem to be an overstatement, a cogent argument is presented on the fundamental role of the mitochondrion in hepatic fat metabolism, skeletal muscle physiology, insulin resistance, and pancreatic islet cell vitality, placing the mitochondrion at a central point in the overall pathophysiology of NAFLD (463).



• **Figure 39.13** Deformed mitochondria with crystalline inclusions in nonalcoholic steatohepatitis: **A:** An elongated mitochondrion with two bundles of parallel, crystalline structures (*arrows*) near a large fat droplet. **B:** Two mitochondria cut tangentially showing crystalline inclusions in an area of cytoplasm between two large fat droplets (*arrows*). Note the paucity of normal cristae.



• **Figure 39.14** Abnormal adenosine triphosphate (ATP) homeostasis in nonalcoholic fatty liver disease. Initial fructose metabolism requires the expenditure of energy in the form of ATP. Intravenous injection of fructose normally produces a significant drop in hepatic ATP stores, as measured by magnetic resonance spectroscopy, followed by return to baseline. The baseline in patients with fatty liver is similar to that in healthy controls, but there is a blunted recovery indicating the presence of a relative energy deficit in the fatty liver. NS, not significant. (Adapted from Cortez-Pinto, Chatham J, Chacko VP, et al. Alterations in liver ATP homeostasis in human nonalcoholic steatohepatitis: a pilot study. *JAMA* 1999;282:1659–1664.)

Cytochrome P-450

Similar to alcohol-related liver disease, induction of cytochrome CYP 2E1 in NAFLD has been described as a possible source of oxidative stress and activation of cytokines (464,465,466) through enhanced microsomal ω-oxidation of fatty acids (normally a minor pathway of fatty acid metabolism). Expression of CYP 2E1 is influenced by a high-fat, low-carbohydrate diet and colocalizes in immunohistochemical stains to fatty cells and markers of lipid peroxidation (467,468). It is associated with increased activity of mitogen-activated protein kinases (MAPKs) through the activity of extracellular signal–regulated kinases 1 and 2 (ERK1/2), which participate in the regulation of cell death (apoptosis) pathways (469). On the basis of animal studies, it is unlikely that P-450 2E1 plays a singular role in NASH because CYP 2E1 nullizygous, transgenic mice also develop a steatohepatitis-like picture (470). Indeed, Schattenberg et al. (469) showed experimentally that overexpression of CYP 2E1 is protective against oxidative injury and decreases apoptosis but increases the risk of necrosis induced by fatty acid exposure. Consistent with this adaptive process, inhibition of CYP 2E1 in experimental conditions increases formation of Mallory bodies (471).

Abnormal Lipoprotein Metabolism

Consistent with its close association with hyperlipidemia and metabolic syndrome, NASH has been associated with abnormal apolipoprotein (apo) metabolism (472). Two groups have reported decreased apoB-100 secretion in NASH, indicating possible impairment of VLDL synthesis (a major component of which is apoB-100) (473,474), and another group has described differences in apoA-I (a component of HDL) in patients with NAFLD compared to controls (475). Isolation of small lipid droplets from hepatocytes of rats in experimental studies has demonstrated that the lipid droplets

are composed of neutral fats consisting mainly of esters of linoleic, oleic, and palmitic acid (24). Similar studies in human liver biopsy samples from patients with ASH have shown that the lipid composition of accumulating lipid droplets is similar regardless of size but that the smallest droplets, based on size, density, and lipid composition, resemble a precursor of plasma VLDL (476,477). Taken together with observations of cellular ballooning (see preceding text), these observations again point to the abnormal handling of the small storage lipid droplets as being significant in NASH progression.

Peroxisomal Metabolism

The peroxisome is involved in numerous metabolic pathways including synthesis of plasmalogens, bile acids, and cholesterol, and oxidation of very long chain fatty acids, branched-chain fatty acids, dicarboxylic acids, polyunsaturated fatty acids (PUFA), L-pipecolic acid, and phytanic acid (478,479). Steatohepatitis develops in mice lacking peroxisomal fatty acyl-CoA oxidase (480), and morphologic abnormalities with diminished size but increased number of microsomes have been described in human fatty liver (481). Peroxisomal fatty acid oxidation represents another potential source of reactive oxygen species including superoxide and hydrogen peroxide that form during peroxisomal oxidation of very long chain fatty acids and metabolism of dicarboxylic acids (derived from cytochrome P-450 ω-oxidation of very long chain fatty acids) (482). Multiple inherited disorders of peroxisomal metabolism have been described including Zellweger's syndrome, adrenoleukodystrophy, and Refsum's disease. Although disturbed peroxisomal metabolism does not appear to be a primary factor in most patients with NASH (based on normal levels of dicarboxylic acid (94) and normal very long chain fatty acid profiles in patients with NASH—Caldwell et al.), it is possible that genetic abnormalities, nutritional abnormalities, or adaptive changes in the peroxisome may contribute to the condition in some patients.

Other Conditions Associated with Nonalcoholic Fatty Liver Disease/Nonalcoholic Steatohepatitis—"Secondary" Nonalcoholic Steatohepatitis

The foregoing discussion has largely centered on what some refer to as "primary" NASH or NAFLD typically associated with insulin resistance and the metabolic syndrome. The presence of other factors may suggest a separate disease with overlapping features of NASH (Tables 39.1 and 39.4) distinguished primarily by the lack of insulin resistance. However, this does not exclude the likelihood that many such patients have underlying "primary" NASH exacerbated by some other insult.

Bariatric Surgery

Historically, weight-reduction therapy played an important role in the recognition of NAFLD/NASH because of the unexpected exacerbation that was noted in some patients after early jejunoileal bypass (483). Stimulation of TNF by bacterial endotoxin has been postulated as an etiologic factor, but this was not supported by efforts to prevent injury using oral antibiotics (484) or by reports of a similar process after gastroplasty, in which bacterial overgrowth is less of a problem (485). Micronutrient deficiency has also been proposed. The rate of weight loss may be a key factor by increasing the rate at which intra-abdominal fat is mobilized. In spite of its historical association with exacerbation of NASH, weight loss surgery (particularly gastric bypass) remains a viable option in some patients (see subsequent text).

Medication Induced

A number of medications have been implicated as causes of steatohepatitis. In several cases, particularly with nifedipine and diltiazem (486,487), the association may be one of common drug use in patients at high risk for NASH. Similarly, Chitturi and Farrell pointed out in a recent paper that the risks for methotrexate-induced steatohepatitis are almost identical to those of NASH, suggesting a high degree of overlap between these entities (466,488). Tamoxifen-induced steatohepatitis presents a particularly difficult balance of risk–benefit in patients on therapy for prior breast cancer (489,490). Although liver injury was not considered a side effect in a recent review of adjuvant breast cancer therapy (491), the authors and others have observed severe steatohepatitis with cirrhosis in this setting (492,493,494). The risk factors for tamoxifen-induced steatohepatitis are, as with methotrexate, similar to those of NASH, suggesting a possible synergistic effect of the drug in a patient prone to NASH. Amiodarone, which has long been associated with phospholipidosis and steatohepatitis (495,496,497), has become an extremely common medication in cardiology. As with tamoxifen, its use should not be undertaken without some consideration of the high likelihood that many recipients will have preexisting fatty liver because of shared risks between NASH and heart disease. The issue again becomes one of risk versus benefit. We have observed advanced cirrhosis with death due to

liver failure in this setting and associated litigation. To our knowledge, an adequate risk–benefit analysis has not been done.

Human Immunodeficiency Virus Therapy

An acquired lipodystrophy, associated with insulin resistance and steatosis and sharing features with multiple symmetrical lipomatosis, has been described with nucleoside analog therapy for human immunodeficiency virus (HIV) infection (on highly-active antiretroviral therapy [HAART]) (498,499,500,501). The syndrome may be increased in women, may present acutely, and can be associated with a Reye's syndrome–like picture, neuropathy, myopathy, and pancreatitis (502). There are increased concerns that patients with this syndrome are at increased risk of developing NAFLD and the possibility of progression to NASH and cirrhosis. The pathogenesis of NAFLD from HAART therapy is related to insulin resistance (383), mitochondrial DNA damage (503), and the development of lactic acidosis (504).

Parenteral Nutrition, Malnutrition, and Celiac Disease

Liver disease, often with macro- and microvesicular steatosis, is one of the most common and potentially severe side effects of total parenteral nutrition (TPN) (505). In one series of patients on extended TPN, macrovesicular steatosis was seen in 63% of patients with cholestasis and 100% of those without cholestasis (506). Microvesicular steatosis and phospholipidosis (fat-laden cells in the sinusoidal space or portal tract) are also common features. Both the amount of lipid infusion and its composition appear to affect the expression of liver disease in this setting (507). Choline deficiency may play a role in some patients. At the opposite end of the nutrition spectrum, fatty liver is a common finding in kwashiorkor, in which export of lipid from the liver because of protein deficiency (diminished apoprotein B) is thought be the primary mechanism (508). In both types of nutritional fatty liver, zone 1 (periportal) involvement may predominate. There have been reports suggesting an association between NASH/NAFLD and celiac disease (509,510,511). Bardella et al. examined 59 consecutive patients with elevated transaminase levels and NAFLD and found that 6 patients had positive tissue transglutaminase antibodies and 2 (3.4%) were positive for antiendomysial antibodies. Overall, two patients (3.4%) were positive for both antibodies and had positive histology (512). In another report, Nehra et al. observed that 1 out of 47 patients with NASH was positive for antiendomysial antibodies (514).

Solvents and Industrial Agents

A variety of toxins have been implicated in the development of fatty liver diseases (514). Better described agents include carbon tetrachloride (now rarely used), dimethylformamide, perchloroethylene, and petrochemical derivatives (515,516,517,518). Other compounds and elements that have been implicated include phosphorous (See "Experimental and Animal Models of Nonalcoholic Fatty Liver Disease"), ethyl bromide, ethyl chloride, and rare earths. Synergy between exposure to these agents and disease progression in an obese patient and/or a patient with diabetes is suspected but not established. Cotrim et al. have demonstrated a potentially progressive form of NAFLD that results from petrochemical exposure and occurs in the absence of insulin resistance (519).

Wilson Disease

Macro- and microvesicular steatosis are well-known features of Wilson disease (520,521). Consideration of Wilson disease should be made especially with steatohepatitis in a younger individual. It is not known how often the carrier state for mutations in the nuclear-encoded gene for copper-transporting ATPase (522) could play a role in more typical cases of NASH. We have noted borderline values of ceruloplasmin occasionally in patients with some features of obesity-related steatohepatitis (S. Caldwell, unreported clinical observation, 2004). Mitochondrial injury, mutations, and premature oxidative aging were recently described in patients with Wilson disease, suggesting a possible overlap (through mitochondrial dysfunction) with more typical NAFLD and NASH (523).

Inherited Metabolic Diseases

Macrovesicular steatosis can be seen in a variety of inherited metabolic diseases, most, but not all, of which present in childhood. Disorders include glycogen storage diseases (524), galactosemia (525), tyrosinemia (526), heterozygous hypobetalipoproteinemia (527,528), and abetalipoproteinemia. Both of the latter disorders are characterized by impaired formation of VLDL due to decreased synthesis of apolipoprotein B. A number of lipid storage diseases, (e.g., cholesterol ester storage, Niemann-Pick disease, Tay-Sachs disease, and Gaucher's disease) can have excessive fatty infiltration of the liver with cholesterol esters, sphingolipids, phospholipids, sphingomyelin, gangliosides, or glucocerebrosides. Presentation as systemic diseases in infancy (although not exclusively so) and the distribution (predominantly in the reticuloendothelial cells) distinguish the lipid storage disorders from typical NAFLD/NASH (21,529).

Managing the Obese Patient with Diabetes and Cirrhosis

Silent progression of NASH to cirrhosis, often in association with normalization of the liver enzymes, has led to the common situation in which otherwise stable patients with type 2 diabetes are found incidentally to have cirrhosis (299,312). Although early data indicates that therapy aimed at diabetes may ameliorate steatohepatitis (See "Antidiabetic Agents"), there is little knowledge on the effects of other commonly employed medications such as antidepressants, sulfonylureas, HMG-CoA reductase inhibitors, or even insulin itself. Moreover, other adjunct treatments that are commonly used in these patients (e.g., aspirin for coronary disease or angiotensin-converting enzyme inhibitors for prevention of diabetic kidney disease) may have adverse effects if cirrhosis has developed (530). This situation arises because of the insidious development of the hyperdynamic state of cirrhosis as a result of portosystemic shunting. One of the hallmarks of this striking change in physiology is systemic vasodilatation with associated changes in renal hemodynamics. Therefore, in addition to considering disease-specific conditions such as the possibility of varices or HCC, broad treatment considerations need to include a reconsideration of certain tenets of diabetes management. Unfortunately, this aspect of NAFLD has not been adequately investigated.

Treatment of Nonalcoholic Fatty Liver Disease

Who Should be Treated?

Patient selection and the relative risk–benefit of different interventions remain one of the most challenging aspects of treating NAFLD. Although less severe forms of NAFLD, such as simple steatosis or steatosis with only inflammation (types 1 and 2 NAFLD), may progress to cirrhosis, most studies support an increased risk of progression, mainly in the presence of more severe histology at baseline such as ballooned cells and fibrosis (NASH or types 3 and 4 NAFLD) (7,15,305,309,531,532). These data indicate the need for careful patient selection in studying the effects of as yet unapproved pharmacologic interventions (Table 39.10). In general, there is a consensus that dietary changes and increasing activity are cornerstones and that these lifestyle changes are typically part of standard recommendations in spite of limited data and variable acceptance by the patient (see subsequent text). Voluntary adoption of these recommendations complicate the interpretation of pharmacologic therapy—most of the existing publications have lacked controls and, although most have included anthropometric indices such as weight and some have accounted for dietary changes, none has accounted for the degree of conditioning that could influence steatosis and may not be reflected in anthropometric measurements.

Endpoints of Therapy

The primary endpoint of therapy remains changes in the histology (See "Scoring of the Biopsy (Nonalcoholic Steatohepatitis Activity Index, Nonalcoholic Steatohepatitis activity score)"). However, sampling error, especially with cores less than 2 cm, is a potential problem and few of the studies reviewed in the subsequent text have provided sufficient details of the biopsy to account for this confounding variable (269,293,294,295). Novel markers of histologic injury especially applicable to the research setting include stains for lipid peroxide by-products, electron microscopy to assess mitochondrial morphology, and markers of stellate cell activation (557). The major surrogate markers for liver injury include the serum aminotransferase levels (approximation of inflammatory activity), imaging to assess hepatic fat content (e.g., ultrasonography, CT scan, MRI, MRS), and serologic fibrosis panels that are in development. Other important measures include anthropometric indices (e.g., weight, BMI), the degree of physical conditioning (e.g., lactate threshold), measures of insulin signaling (e.g., glucose tolerance testing, HOMA or Quicki, insulin clamp tests), serologic or urinary markers of lipid peroxidation (e.g., malondialdehyde or hydroxynonenal), and cytokine levels such as TNF-α, TGF-β, and adiponectin.

Initial Intervention

Lifestyle changes remain a cornerstone of initial management (558,559,560). Optimistically, diet modification and exercise can be accomplished in obese patients, with as many as 80% of patients achieving dietary goals and 36% achieving exercise goals (561). Pessimistically, even intensive counselling to reduce fat intake (<30% of daily calories) and engage in regular physical activity produces only a modest 5% sustained weight loss (562,563,564). In NAFLD, surprisingly little is known about the effects of specific diet types or how much exercise should be recommended or how best to convey this advice.

Exercise Alone

Visceral adiposity and steatosis have been shown to correlate inversely with the degree of cardiorespiratory fitness (114,565). However, the relative benefit of

exercise *without* weight loss (i.e., the "fit fat" individual) versus aggressive dieting has not been extensively explored in NAFLD (566). Exercise affects insulin signaling primarily through its effect on skeletal muscle substrate utilization and mitochondrial oxidative phosphorylation (567,568). The most effective "conditioning" exercise is the one that just passes beyond the lactate threshold—a level usually associated with some degree of discomfort (569). A number of studies have shown that increasing activity reduces expression of the metabolic syndrome, suggesting that a similar effect might be found with NAFLD (570,571). However, even trained athletes who are obese and with high calorie intake (e.g., Sumo wrestlers) have increased features of metabolic syndrome, indicating a limited benefit of exercise without concomitant weight loss (572).

RCT, randomized controlled trial; CT, computerized tomography; MRI, magnetic resonance imaging; U/S, ultrasonography; UDCA, ursodeoxycholic acid.

Dietary Weight Loss and Exercise

Diet- and exercise-induced weight loss has shown promise in treating NAFLD but may also be associated with progression of liver disease if the rate of loss is greater than 1.6 kg/week and especially with drastic calorie reduction (306,573,574,575,576,577). In addition, weight loss may not restore normal insulin secretory pulses, suggesting persistent islet cell dysfunction in some patients (578). However, improvement in liver enzymes and histology has been shown with nutritional counselling and weight reduction (579,580). Ueno et al. reported significant improvement in liver enzyme levels and degree of steatosis in 15 obese patients treated with diet (25 kcal/kg ideal body weight per day) and exercise (walking and jogging) for 3 months compared to a control group, but fibrosis was not significantly altered (581). Not surprisingly, clinical improvement has been correlated with improving insulin signaling (582). Nonetheless, the paucity of more definitive data on this practical form of intervention is striking (583).

Weight Loss in Children

A number of small studies support the use of weight loss therapy in children. In one study, 33 obese children underwent a moderate hypocaloric diet (35 kcal/kg per day) and aerobic activities (6 hour/week or more) to achieve weight loss of approximately 500 g/week over a period of 6 months (584). All patients who lost at least 10% body weight had normalized liver enzyme levels and improved ultrasonographic findings. In a similar study, seven patients were treated with hypocaloric diet and exercise to obtain a weight loss approximately 500 g/week. All had significant reduction of aminotransferase levels; four out of five patients who had previous ultrasonography showed decreased evidence of steatosis. One patient who had a follow-up liver biopsy showed improvement in steatohepatitis (585).

Dietary Composition

Dietary lipid composition may be especially important for both insulin signaling and risk of lipid peroxidation (586). Dietary fat predominantly (98%) consists of triglyceride (glycerol and three fatty acids). Fatty acids affect the phospholipid composition of cell and organelle membranes and influence insulin sensitivity, gene regulation (PPARs), differentiation in adipocytes, and prostaglandin physiology (361,587,588,589). Fatty acids reach the liver from albumin-bound fatty acids released by adipose tissue and from chylomicron remnants directly from dietary fat (361,590). Diets enriched in PUFA (fish oil or ω-3 fatty acids) have not been adequately investigated for their potentially beneficial or detrimental effects in NAFLD, but some encouraging data (see subsequent text) has begun to emerge in spite of concerns for the role of ω-3 fatty acids in alcohol-related liver disease (591,592,593).

A study in MCD mice demonstrated that hepatic fatty acid content influences PPARα activity, which subsequently influences the activity of cytochrome P-450; this appears to promote lipid turnover in vivo and improves steatohepatitis (594). Supplementation of the diet with ω-3 fatty acids reduced collagen content in mice exposed to thioacetamide, whereas a mixture of ω-3 and ω-6 fatty acids had no effect (595). Lipid composition has also been shown to influence the expression of UCP-2 in the rat liver (596), and supplementing of ω-3 fatty acids in both the ob/ob mouse model and in the Fisher 344 leptin-resistant rat increased fat degradation factors (PPARα) and decreased hepatic fat synthetic factors (SREBP-1) (597,598). Conjugated dienoic derivatives of linoleic acid (conjugated linoleic acid [CLA]), have variable effects on hepatic and peripheral fat stores, depending on the content of other dietary fats (599). In humans, ongoing trials using indirect indices of NASH (e.g., aminotransferases, echotexture, Doppler blood flow, TNF) indicate improvement with ω-3 supplements (e.g., eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA]) (600,601,602).

Weight Loss Supplements

Orlistat (tetrahydrolipostatin) decreases fat absorption by inhibiting lipase. Harrison et al. have reported benefit in weight loss (mean of 10 kg) and histologic parameters (i.e., steatosis and fibrosis) in two pilot studies (603,604). Other existing studies are of relatively short duration and uncontrolled but have shown general improvement in surrogate markers of injury (605). Malabsorption of fat-soluble vitamins (including vitamin E) is of theoretic concern. There is presently too little data on sibutramine (a serotonin and norepinephrine reuptake inhibitor that is approved as a weight loss agent), although one uncontrolled study

has suggested improved aminotransferases with associated weight loss (575,605).

Weight-Reduction Surgery

Variations of gastric bypass or gastric restriction are becoming increasingly popular, although these interventions are not without the risk of hepatic decompensation (606,607). Early studies showed a reduction in the levels of markers of metabolic syndrome (e.g., glucose, insulin, fibrinogen, triglycerides, and uric acid) and ALT levels and a reduction in steatosis but a slight overall increase in inflammation and no significant change in fibrosis. However, reduced perisinusoidal fibrosis was reported in another study by Silverman et al. (99). Moreover, resolution of histologic NASH was observed in one study using adjustable gastric banding, and an even more substantial reduction in fibrosis was recently reported in one large series, although caution is warranted, given the potential for deterioration with too rapid weight loss (608,609,610). Prebypass treatment with ursodeoxycholic acid (UDCA) and vitamin E has been advocated in patients with active NASH but has not been studied in a controlled trial.

Ursodeoxycholic Acid and Cytoprotective Agents

The potential benefits of UDCA derive from its effects on mitochondrial membrane stability, improved blood flow, and/or immunomodulation (611,612,613,614,615,616). Several studies, some published only as abstracts, suggested a potential benefit of

UDCA (544,545,546,547,548,549). In a fully published paper, Laurin treated 24 patients with NASH using UDCA (13 to 15 mg/kg) and observed improvement in liver enzyme levels and amelioration of steatosis (without change in fibrosis or inflammation) on biopsy at 12 months. Similarly, Ceriani et al. demonstrated normalization of liver enzymes in 14 of 16 patients treated with UDCA (10 mg/kg) compared to 4 of 15 on placebo and Guma et al. demonstrated liver enzyme normalization in 10 of 13 treated patients (10 mg/kg per day) versus 3 of 11 patients in a placebo group. However, in the largest study, Lindor et al. conducted a randomized trial in 166 patients (550). All patients were encouraged to lose weight and randomized to UDCA (13 to 15 mg/kg per day) or placebo for 2 years. Both groups had similar improvement in aminotransferases, and follow-up biopsy, available in two thirds of the patients, revealed similar levels of improvement in both groups. Whether negative results from this controlled trial reflect a true lack of response from UDCA is debatable (617). The surprising improvement in the placebo group in this study has pointed out the need for controlling for voluntary lifestyle changes when assessing pharmacologic intervention. Another recent randomized controlled trial of 48 patients (available only as abstract), in which patients were treated with the combination of UDCA (12 to 15 mg/kg) and vitamin E (800 IU/day) for 2 years versus single or double placebo controls, showed significant improvement in NAS only in the group treated with combination therapy (618).

Other agents with potential cytoprotective properties include taurine, an amino acid that alters bile acid physiology and that has been reported to normalize liver enzymes in children with NAFLD (619). Triacetyl uridine is another potentially important cytoprotective agent in experimental choline-deficient rats but has not been tested in humans (620).

Antioxidants and Nutritional Supplements

Vitamin E supplementation has been studied in both experimental and clinical settings (621). "Vitamin E" refers to a family of tocopherols and tocotrienols (each with different forms named α, β, γ, and δ) that exhibit antioxidant activity. Commercially available vitamin E supplements usually contain only α-tocopherol—the relative efficacy of mixed tocopherols compared to α-tocopherol alone is not established (622,623,624,625). Experimentally, a number of encouraging studies have been published (626,627). Similarly, human studies have shown reduced lipid peroxidation and cytokine levels with vitamin E therapy (552,556). However, pilot studies and two randomized controlled studies have produced varying results (551,553,554,555). A placebo-controlled trial in 14 children showed liver enzyme improvement with vitamin E (400 IU daily for 2 months followed by 100 IU daily for 3 months), but the placebo group also demonstrated a significant improvement in liver test results in parallel with weight loss. In adults, Harrison et al. randomized 45 patients with biopsy-proven NASH to vitamin E (1,000 IU daily) plus vitamin C (1,000 mg daily) versus placebo. Repeat liver biopsy after 6 months showed a small improvement in fibrosis score in the vitamin E group; however, there was no significant improvement in inflammation or necrosis score on biopsy. A second controlled study in 16 adults showed no benefit of vitamin E over diet and exercise alone. Although caution is warranted in patients with prior coronary artery disease where vitamin E is associated with blunted efficacy of statin drugs (628), significant toxicity has not been observed in these studies, but concerns over doses exceeding 400 IU/day (629) and the limited efficacy have tempered enthusiasm (630). On the other hand, its use in combination with other agents (e.g., UDCA and pioglitazone) has been more encouraging.

P.1147

Betaine (trimethylglycine), a methyl donor in an alternative pathway for remethylation of homocysteine to methionine and *S*-adenosyl-methionine (SAMe), promotes the conversion of phosphotidylethanolamine to phosphotidylcholine (lecithin), which, in turn, promotes the export of fat from the liver as VLDL (631). Substantial benefit has been reported by Abdelmalek et al. in ten patients with NASH treated with betaine solution (20 g/day for 10 to 12 months) in terms of biochemical and multiple histologic parameters including steatosis, inflammation, and fibrosis (632). These agents may also serve to replenish glutathione and improve mitochondrial membrane fluidity (633,634,635). Silymarin, the active component of milk thistle extract, is an extraordinarily popular over-the-counter supplement that has been observed to decrease the expression of CYP 3A4 and decrease mitochondrial respiration in hepatocyte culture but has not, to our knowledge, been carefully studied in NASH (636). *N*-Acetylcysteine, which is converted to glutathione in the liver, has produced improvement in liver enzymes (histology not done) in a small pilot study at a dosage of 1 g/day for 3 months (637). Lecithin increases plasma free choline and decreases hepatic steatosis in long-term TPN patients (638,639). Experimentally, probiotics have shown some encouraging results, possibly through their effects on secondary mediators of inflammation (640). Lazaroids, or 21-aminosteroids, are additional antioxidants that have not been studied in NASH but warrant consideration (641).

Antidiabetic Agents

Because insulin resistance appears to be the crucial problem in most patients with NASH, insulin-sensitizing agents have emerged as the most promising form of pharmacologic therapy, especially in those with progressive fibrosis (Figs. 39.15, 39.16 and 39.17) (642). Other antidiabetic strategies agents have been less well studied (643). For example, neither insulin nor sulfonylureas have been carefully studied for effects on fatty liver. The major adverse effects of insulin is weight gain with truncal obesity that could exacerbate NAFLD (644). On the other hand, control of blood sugar level in patients with overt diabetes will likely decrease de novo fat synthesis in the liver through effects on CREBP. Acipimox is an inhibitor of lipolysis that is thought to improve insulin sensitivity by lowering free fatty acid levels but its effect on NAFLD has not been studied (645). Similarly, experimental antidiabetic agents such as D-chiro-inositol and newer agents such as the incretins have not, to our knowledge, been studied in NAFLD (646,647).

Thiazolidinediones

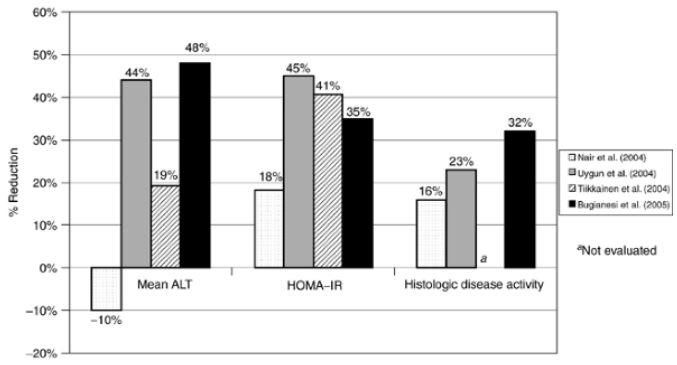
TZDs are a group of agents that act as ligands for the peroxisome-proliferator–activated receptor-γ (PPAR-γ) (expressed in adipose tissue, intestines, macrophages, and muscle and activated by fatty acids),

P.1148

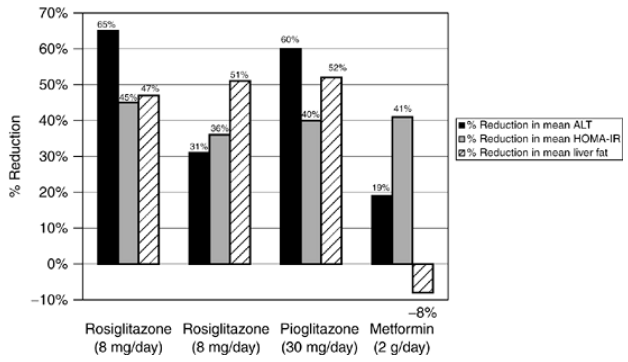
which is a member of a nuclear receptor superfamily that regulates gene expression of enzymes involved in lipid and glucose metabolism. The PPAR-γ receptor, the ligand, and a coactivator form a heterodimer with retinoid X receptor, which binds to the PPAR-γ response element of specific genes (648). The most profound effect of TZDs is in adipocyte differentiation (649). As a result, TZDs are often associated with increased peripheral but decreased central adiposity (650,651). Other effects include increased expression of glucose transporters (652), increased mitochondrial mass (653) and altered thermogenesis (through effects on UCP) (654), decreased cytokine expression, and inhibited inducible nitric oxide synthase, as well as decreased ceramide-induced apoptosis in pancreatic islet cells (655,656). Because PPAR-γ receptors are not

P.1149

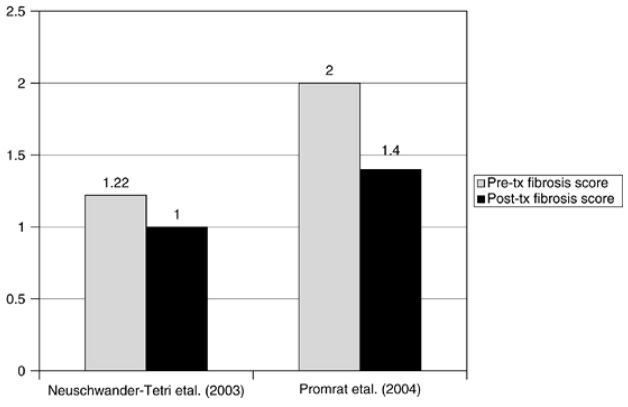
highly expressed in liver, the benefit to patients with NASH is likely to primarily involve indirect mechanisms.



• **Figure 39.15** Improvement in insulin resistance and histology with metformin in patients with nonalcoholic steatohepatitis. Since 1999, several studies have demonstrated metformin's beneficial effects on biochemical, histologic, and metabolic parameters associated with NASH. The histologic parameter was standardized across all four studies by calculating the nonalcoholic fatty liver disease activity score (NAS) from data presented in the studies. ALT, alanine transaminase. (Adapted from references 537,541,542,543.)



• **Figure 39.16** Comparison of thiazolidinediones (TZDs) with metformin shows greater improvement in biochemical, metabolic, and hepatic steatosis in the former. Equivalent doses of TZDs show similar effects on alanine transaminase (ALT), insulin resistance, and hepatic steatosis, which are thought to be due to their effects on mobilization of central fat to peripheral areas. Although these data are not conclusive, metformin appears to have a more modest effect compared with the TZDs. (Adapted from references 296, 536, 537.)



• **Figure 39.17** Thiazolidinediones appear to improve fibrosis after treatment. In the studies by Neuschwander-Tetri et al. and Promrat et al., fibrosis scores on posttreatment (tx) liver biopsies had significantly decreased after 6 months of treatment with either rosiglitazone or pioglitazone. (Adapted from Neuschwander-Tetri BA, Brunt EM, Wehmeier KR, et al. Improved nonalcoholic steatohepatitis after 48 weeks of treatment with the PPAR-γ ligand rosiglitazone. *Hepatology* 2003;38:1008–1017.and Promrat K, Lutchman G, Uwaifo GI, et al. A pilot study of pioglitazone treatment for nonalcoholic steatohepatitis. *Hepatology* 2004;39:188–196.)

A 4- to 6-month course of troglitazone normalized liver enzymes in seven of ten patients with NASH and improved inflammation in four of seven with follow-up biopsies (most with loss of polymorphonuclear cells) with no change in fibrosis scores (213). Long-term histologic follow-up 4 to 5 years after completing the study in these patients has shown near resolution in one patient who had subsequent success with weight loss and diet and progression to uncomplicated cirrhosis in another patient who was unable to achieve

lifestyle changes (657). Rosiglitazone has been evaluated in two publications by Neuschwander-Tetri et al. (536,658). These studies showed significant improvement in the posttreatment biopsy and almost one half of the patients no longer met the histologic criteria for NASH. These changes were paralleled by improvement in indices of insulin activity and decreased hepatic fat content. Consistent with the effect of TZD on peripheral fat stores, 67% gained weight during the study (median increase of 7.3%). Laboratory follow-up on this group of patients also showed a relapse of the aminotransferase levels to baseline levels, indicating that the changes obtained were not sustained.

A similar effect of pioglitazone in both aminotransferase levels and histologic parameters has also been observed (533,535,659). Sanyal et al. performed a controlled trial of pioglitazone versus vitamin E, showing superiority of TZD in terms of histologic remission (534). The most detailed report available is that by Promrat et al. who treated 18 patients with pioglitazone, 30 mg daily, for 48 weeks with endpoints of histologic activity, insulin activity, body composition (dual-energy x-ray absorptiometry), and hepatic fat content by MRI (296). All patients received recommendations for increased physical activity, reduced calorie diet, and a daily multivitamin. Therapy was associated with normalization of the aminotransferase levels, a significant reduction in a composite histologic score (the NAI—see preceding text), a reduction in steatosis confirmed by MRI, and improved insulin sensitivity. Sustained weight gain was seen in 72% of patients (average of 3.5 kg). Preliminary results from a placebo-controlled trial indicate a correlation between higher adiponectin levels, reduced steatosis, and improved fibrosis in the treated group (660).

In the existing pilot studies (including troglitazone), elevation of liver enzyme levels during treatment has been reported in approximately 3 of 79 patients (one each for the major TZDs studied). No cases of severe hepatitis or exacerbation of NASH has been noted. Although troglitazone was well tolerated even in the presence of stable cirrhosis, a rare but potentially severe idiopathic toxicity led to its removal from the market (661,662,663). Even more rare toxicity has been reported with rosiglitazone and pioglitazone (664,665,666). The mechanism of idiosyncratic toxicity with TZDs is uncertain, but several lines of evidence (including a combined toxicity of troglitazone with an HMG-CoA reductase inhibitor) (667) point to rare but potentially significant mitochondrial dysfunction. Weight gain is the most common side effect noted in the existing studies. It is suspected that successful dietary and exercise intervention can prevent this development, but predictive factors remain to be defined. The effect of shifting fat stores on myocyte function, exercise tolerance, and endurance in these patients has not been adequately addressed. Edema, sometimes associated with congestive heart failure, has been reported, but the relationship between the medication and cardiac dysfunction is debated (668,669).

Metformin

Metformin is an insulin-sensitizing, oral biguanide approved for use in type 2 diabetes in the United States since 1995 (670). The biguanides exert substantial changes in cellular bioenergetics without inducing weight gain, by reducing hepatic glucose production and increasing peripheral glucose utilization (671). Its major site of action is the mitochondria and causes a reduction of ATP in isolated rat hepatocytes, reduced activity of complex I in the mitochondrial respiratory chain, reduced fatty acid oxidation, and increased lactate production in preadipocytes under experimental conditions (653,672,673). Signaling is through adenosine monophosphate–activated protein kinase—this pathway is similarly activated with exercise, suggesting that in some ways metformin simulates the effects of exercise on glucose transport (674).

Favorable studies of metformin in the fatty liver of ob/ob mouse (675) along with a favorable side effect profile, especially the absence of weight gain seen with the TZDs, have led to sustained interest in this agent in treating NASH. Coyle et al. noted that metformin improved overall histology in two patients in one of the first reports of histologic changes (538). Less favorably, Tiikkainen et al. in a human study in patients with type 2 diabetes examining the relative effects of metformin (2 g/day) and rosiglitazone (8 mg/day), for 16 weeks, on steatosis and serum adiponectin levels, revealed that both drugs similarly increased insulin sensitivity but only rosiglitazone reduced hepatic steatosis (537). However, Marchesini et al. demonstrated improved liver enzymes, reduced hepatomegaly, and improved hepatic perfusion in patients treated with metformin (1,500 mg/day) for up to 6 months, and in a follow-up study, Bugianesi et al. reported improvement in several histologic parameters (e.g., steatosis, necroinflammation and fibrosis) independent of dietary changes (539,543,676).

Lavine and Schwimmer reported similar histologic improvement in ten children along with reduced steatosis by MRS (540). However, less definitive improvement in histologic parameters were observed in two other studies by Uygun et al. and Nair et al. (541). The overall safety profile of metformin is favorable and lactic acidosis appears to be rare, but caution is warranted in renal insufficiency (677).

Antihyperlipidemic Agents

Fibrates are lipid-lowering agents that act on PPAR-α receptors located primarily in the liver, heart, muscle, and kidney (normally activated by adipose tissue–derived fatty acids) that increase fatty acid uptake, mitochondrial β-oxidation, peroxisomal oxidation of fatty acids, and ω-oxidation of fatty acids in the P-450 system (648). However, histology-based studies of fibrates have not shown significant beneficial effects, although the available data is limited and some studies have reported improved transaminase levels (546,678,679).

With statin drugs (HMG-CoA reductase inhibitors), some type of interaction with NAFLD seems likely because the drugs are acting in part on hepatic fat metabolism and two thirds to three fourths (noninvasive testing) of hyperlipidemic patients have NAFLD. Not much is known about the long-term effects of these agents on NAFLD; however, the incidence of acute hepatitis, judged by the aminotransferase levels, appears to be quite low (108,680). On the other hand, induction of SREBP (a transcription factor governing hepatic fat synthesis), diminished secretion of VLDL and perhaps depleted ubiquinone raise concern about long-term effects (106). The anti-inflammatory effects of the statins may cause decreased cellular injury although there is reason to suspect that these agents will increase liver fat stores. However, limited available studies suggest an overall beneficial effect in NAFLD (107,601,681,682). It seems likely that this complex interaction represents the interaction between a number of covariables including the degree of physical conditioning (insulin signaling), ethanol use, dietary fatty acid composition, and genetic variables in fatty acid metabolism. Additional data is needed, especially in light of efforts to make these agents available "over-the-counter" (683).

Other Agents

Recent experimental data from Diehl et al. indicate that modulation of the adrenergic system may significantly influence NAFLD (370,684). A close association between the sympathetic nervous system (SNS) and the fatty liver seems likely on the basis of the close association between obesity and the SNS (685). Whether pharmacologic manipulation of the system in humans might be beneficial in select cases remains to be investigated. Other agents, also related more classically to the cardiovascular system, include angiotensin receptor blockers (ARBs). One small uncontrolled study in human patients with NASH and hypertension treated with losartan has shown histologic benefit after 48 weeks (686).

Liver Transplantation, Disease Recurrence, and Donor Organs

Transplantation for patients with advanced NASH is often complicated because of the presence of comorbid conditions related to obesity, diabetes, and hyperlipidemia (687,688). Although guidelines do not exist, these conditions warrant careful consideration of the long-term benefits of transplantation in this setting. Recurrence of disease is an additional concern. A number of reports have now documented the recurrence of NAFLD and NASH after transplantation (689,690,691,692). In addition, two series have shown a high risk for the development of NAFLD in patients with cryptogenic cirrhosis after liver transplantation (see "Cryptogenic Cirrhosis"). Immunosuppression regimens likely play a role: Steroid therapy promotes fatty change and cyclosporine interacts with the mitochondrial transition pore that regulates the electrochemical gradient across the mitochondrial membrane (693). The relative risks and benefits of different immunosuppression regimens in these patients are not established but the course may be severe. Steatosis in donor livers is associated

with poor graft function likely due to abnormal mitochondrial function and disturbed ATP homeostasis (see "Pathogenesis of Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatitis") (694). The problem has become magnified with efforts to develop living-related donor programs in which prediction of steatosis in a partial donor can be difficult (695). The role of preoperative dietary changes in prospective living donors remains to be fully investigated (696).

Ratziu V, Giral P, Charlotte F, et al. Liver fibrosis in overweight patients. *Gastroenterology* 2000;118:1117–1123.

These papers have provided important observations about the prediction of severity of underlying liver disease in consecutive obese patients or, in the Angulo paper, among consecutive patients with NASH. Among the salient findings were associations of more severe histology with increased obesity, more severe insulin resistance, hypertension, hypertriglyceridemia, elevation of transaminases (not invariably present) and/or AST:ALT ratio more than 1, age over 40 to 50 years, and female gender. From serial biopsy studies in patients with NASH, cirrhosis develops in about 10% while fibrosis progresses in 33%, remains stable in 41%, and improves in 22% over about 5 years. Once cirrhosis develops, there is a significant risk of decompensated portal hypertension and hepatocellular carcinoma.

Matteoni CA, Younossi ZM, Gramlich T, et al. Nonalcoholic fatty liver disease: a spectrum of clinical and pathological severity. *Gastroenterology* 1999;116:1413–1419.

The paper by Matteoni et al. elucidated the relationships between types of NAFLD, including simple steatosis or steatosis with mild inflammation (types 1 and 2), and more severe histology associated with fibrosis (types 3 and 4). Types 3 and 4 are associated with greater likelihood of progression. The paper by Brunt et al. provided a widely referenced scoring scheme for grading and staging NASH. Many of the key histologic parameters have subsequently been combined by Kleiner et al. into a composite score (the NASH activity score or NAS) that will facilitate assessment of therapeutic interventions and comparison between different treatments.

Powell EE, Cooksley WG, Hanson R, et al. The natural history of nonalcoholic steatohepatitis: a follow-up study of forty-two patients for up to 21 years. *Hepatology* 1990;11:74–80.

The paper by Powell et al. demonstrated a key observation that NASH may progress to a "bland" cirrhosis with loss of histologic features. This relationship was extended by Caldwell et al. to show that many cases of cryptogenic cirrhosis likely result from prior, unrecognized NASH in obese patients—especially women. An age difference of approximately 10 years (mean age 50 in NASH and 60 in cirrhosis) suggests that the sixth decade is commonly associated with progression to cirrhosis in patients with NASH. The high occurrence (recurrence) of NASH after liver transplantation shown in studies by Contos et al. and Ong et al. indicates the potential severity of the disease and further strengthened the suspected relationship between NASH and cryptogenic cirrhosis.

Pessayre D, Fromenty B. NASH: a mitochondrial disease. *J Hepatol* 2005;42:928–940.

Accumulation of hepatic lipid, the first step in the "two-hit" hypothesis (steatosis and oxidative stress) of NASH results from both increased uptake of fatty acids from the periphery and from de novo lipogenesis within the liver. Resulting lipid peroxidation underlies many of the changes that ultimately develop into progressive NASH including mitochondrial dysfunction (in both liver and other organs), activation of apoptosis pathways, cytokine synthesis, and activation of stellate cells with resulting fibrosis. The "communications," through cytokines and adipocytokines, between fat stores and targets of insulin activity appear to play a significant role in the ultimate stability of the problem or the development of cellular injury.

Ratziu V, Charlotte F, Heurtier A, et al. LIDO Study Group. Sampling variability of liver biopsy in nonalcoholic fatty liver disease. *Gastroenterology* 2005;125:1898–1906.

Although there is yet surprisingly limited data, diet and exercise, most likely through their effect on insulin signaling and energy regulation, are the cornerstones of therapy, as demonstrated in the report by Huang et al. These voluntary lifestyle changes (diet and exercise) and sampling variability on liver biopsy noted in the study by Ratziu et al. are two of the most significant confounding variables that must be considered in assessing clinical trials of pharmacologic therapy (aimed especially at patients with evidence of ongoing histological injury). Using a variety of clinical endpoints in addition to histology—such as global measures of hepatic steatosis, anthropometric measures, insulin signaling, and cytokine levels—the insulin-sensitizing agents known as thiazolidinediones (e.g., rosiglitazone and pioglitazone) are emerging as the most promising agents, although side effects and durability of the response are yet to be fully defined in controlled trials.

Sanyal AJ, Campbell-Sargent C, Mirshahi F, et al. Nonalcoholic steatohepatitis: association of insulin resistance and mitochondrial abnormalities. *Gastroenterology* 2001;120:1183–1192.

Using different methods to assess insulin activity, these two papers demonstrated insulin resistance as a key feature of NAFLD. Salient observations including demonstration of insulin resistance in obese and lean patients with fatty liver, shown by Marchesini et al. and extensive analysis of fat metabolism in NASH, by Sanyal et al. indicated diminished

suppression of lipolysis with insulin infusion and increased rates of fatty acid oxidation associated with oxidative stress and mitochondrial injury in NASH.

Chapter 40
Vascular Diseases of the Liver

Mical S. Campbell
Mark A. Rosen
Thomas W. Faust

Key Concepts

- Budd-Chiari syndrome occurs as a consequence of thrombotic occlusion of hepatic venous outflow.
- Hypercoagulable states account for most cases of Budd-Chiari syndrome. Anticoagulation is the mainstay of medical management.
- Webs and membranes in the inferior vena cava develop from prior thrombosis and represent the most common subtype of Budd-Chiari syndrome in the Far East.
- Acute or subacute Budd-Chiari syndrome may present with abdominal pain, hepatomegaly, and ascites, whereas symptoms and signs of portal hypertension are prominent with chronic disease.
- Doppler ultrasonography is a useful noninvasive screening test for Budd-Chiari syndrome. Contrast-enhanced computed tomography and magnetic resonance imaging can also demonstrate hepatic vein occlusion and associated parenchymal abnormalities secondary to venous outflow obstruction. Venography and liver biopsy remain the gold standard for diagnosis.
- Angioplasty and thrombolysis may be of benefit in highly selected cases. Decompressive surgery and transjugular intrahepatic portosystemic shunt are often reserved for progressive liver disease despite medical management. Liver transplantation may be performed for patients with decompensated cirrhosis or acute liver failure.
- Hereditary hemorrhagic telangiectasia, also known as *Rendu-Osler-Weber syndrome*, is a multisystemic vascular disorder that may involve the liver.
- Peliosis hepatis is characterized by blood-filled cystic lesions in the hepatic parenchyma, which may occur in the setting of immunosuppression or human immunodeficiency virus (HIV) infection. *Bartonella henselae* is the cause of bacillary peliosis hepatis in patients with HIV infection.

Budd first described a clinical triad of abdominal pain, ascites, and hepatomegaly in 1845 (1). Chiari later provided pathologic correlation (2). Today, Budd-Chiari syndrome refers to the thrombotic obstruction of the hepatic venous outflow system. Occlusion may occur in hepatic venules, hepatic veins, and the inferior

vena cava up to the right atrium. Budd-Chiari syndrome must be distinguished from other causes of hepatic venous outflow obstruction, including right heart failure and veno-occlusive disease. In the Far East, occlusion of the inferior vena cava with webs and membranes is more common, whereas in the West, hepatic vein thrombosis is typical. Hypercoagulable states are responsible for most cases of Budd-Chiari syndrome, and anticoagulation is the mainstay of medical treatment. Clinical presentation is variable and may depend on the extent and speed of occlusion, as well as the development of collateral circulation. Acute, subacute,

chronic, and asymptomatic presentations have all been well described. Hepatic venography is the diagnostic standard and is of value when contemplating surgical or percutaneous shunting. In the absence of rigorous, prospective studies, treatment algorithms are difficult to define. Angioplasty and thrombolysis may be used in highly selected patients. Transjugular intrahepatic portosystemic shunt (TIPS) and surgical decompression are options for progressive liver disease despite anticoagulation and other medical therapy. Patients with decompensated cirrhosis or acute liver failure may require liver transplantation.

Hereditary hemorrhagic telangiectasia (HHT), also known as *Rendu-Osler-Weber syndrome*, is characterized by presence of epistaxis, mucocutaneous telangiectasias, and visceral arteriovenous malformations. Hepatic involvement is variably present but is usually asymptomatic. Hepatic arterial embolization has been used for symptomatic disease, but recent experience highlights the dangers of this approach.

Peliosis hepatis is characterized by cystic, blood-filled lesions in the liver. It occurs in patients who are immunosuppressed or have human immunodeficiency virus (HIV) infection. *Bartonella henselae* is the causative agent of bacillary peliosis hepatis associated with HIV. Treatment of these generally asymptomatic lesions consists of either administering antibiotics to treat *Bartonella* infection or addressing the underlying cause of immunosuppression.

Budd-Chiari Syndrome and Related Disorders

Etiology

The most frequent causes of venous obstruction are prothrombotic disorders, particularly myeloproliferative diseases (3,4,5) (Table 40.1). In one of the largest series, 45% of patients with Budd-Chiari syndrome had polycythemia rubra vera and 9% were diagnosed with essential thrombocythemia (6). Occult myeloproliferative states, demonstrated by spontaneous endogenous erythroid colony formation in the absence of erythropoietin stimulation, are also common (7). An increasing number of thrombotic disorders have been associated with Budd-Chiari syndrome (8,9,10,11,12,13). In over 25% of cases, more than one thrombophilic state may be present (13). Careful, systematic evaluation for prothrombotic disorders has lowered the proportion of cases labeled as idiopathic to less than 10% (7,13,14). Factor V Leiden mutation is the most frequent cause of hereditary thrombophilia and is thought to be the second most common cause of thrombotic occlusion of the hepatic veins and vena cava (8,9,10,11,12,13,14,15,16,17,18). Other hypercoagulable states associated with Budd-Chiari syndrome include antiphospholipid antibody syndrome, paroxysmal nocturnal hemoglobinuria, prothrombin G mutation, methylene-tetrahydrofolate

reductase mutation, antithrombin III deficiency, and deficiencies of protein C and protein S (13,15,19,20,21,22,23,24). Patients who are pregnant or are taking oral contraceptives and develop Budd-Chiari syndrome usually have an underlying thrombophilic state (8,9,10,11,12,13,14,15,16,17,18).

Table 40.1. Etiology of Budd-Chiari Syndrome

MYELOPROLIFERATIVE DISORDERS Polycythemia rubra vera Essential thrombocytosis Occult myeloproliferative disorders	**LOCAL COMPRESSION** Neoplasms Infection
OTHER HYPERCOAGULABLE STATES Factor V Leiden mutation Prothrombin G20210A gene mutation Antiphospholipid antibody syndrome Methylene-tetrahydrofolate reductase mutation Paroxysmal nocturnal hemoglobinuria Protein C and S deficiency Antithrombin III deficiency Oral contraceptives Pregnancy	**SYSTEMIC DISEASES** Behçet's disease Inflammatory bowel disease Sarcoidosis Idiopathic

Frequently more than one condition may be present.

Local compression by adjacent tumor, abscess, or inflammation may lead to a secondary Budd-Chiari syndrome. Neoplasms associated with outflow obstruction include primary hepatocellular, renal, adrenal, pulmonary, pancreatic, and gastric carcinomas (25,26,27,28,29). Benign and malignant vascular neoplasms arising within the hepatic veins or vena cava (e.g., cavernous hemangiomas, leiomyomas, leiomyosarcomas, and rhabdomyosarcomas) have also been associated with Budd-Chiari syndrome (30,31,32,33). Other rare causes of hepatic venous outflow obstruction have been identified. Bacterial, viral, and parasitic infections; collagen vascular diseases; inflammatory bowel disease; and Behçet's disease may result in venous occlusion (29,34,35,36,37,38,39,40,41,42).

Inferior vena cava thrombosis

Budd-Chiari syndrome includes thrombosis anywhere along the hepatic venous outflow tract. It has been proposed that obstruction principally affecting the inferior vena cava should be termed *obliterative hepatocavopathy* (43). Primary inferior vena cava thrombosis appears to be more common in India, China, Japan, Nepal, and South Africa for unclear reasons. Compared to classic

Budd-Chiari syndrome, obliterative hepatocavopathy is more often considered idiopathic (43,44,45,46,47). It has also been found in association with hepatocellular carcinoma (43,44,45,46,47). However, systematic investigation

frequently reveals an underlying thrombophilic state (44,48). The obstruction results from caval webs or membranes, which may also involve the ostia of the hepatic veins. Although the lesions were formerly thought to be congenital, it is now recognized that they represent the transformation of inferior vena cava thrombosis (43,49). Widespread acceptance of obliterative hepatocavopathy as a distinct entity has not occurred because its etiology, prognosis, and management are similar to those of classic Budd-Chiari syndrome (Table 40.2) (50).

Occlusion of the terminal hepatic venules (veno-occlusive disease)

Veno-occlusive disease refers to obstruction of the hepatic sinusoids or small intrahepatic veins. In contradistinction to Budd-Chiari syndrome, occlusion is not thrombotic but results from fibro-obliterative endophlebitis (Table 40.2). Occasionally, Budd-Chiari syndrome may involve only small intrahepatic veins. Sparing of the large hepatic veins can be seen with allergic phlebitis, granulomatous disease, paroxysmal nocturnal hemoglobinuria, and other thrombophilic states (13,50). Distinction from veno-occlusive disease can generally be accomplished by recognition of etiology and in some cases by demonstration of clot. Outside the setting of bone marrow transplantation, the two conditions may be indistinguishable.

Initial reports of veno-occlusive disease were attributed to ingestion of herbal teas containing large quantities of pyrrolizidine alkaloids (51,52). Today, veno-occlusive disease is seen almost exclusively in the setting of bone marrow transplantation, and the reader is referred to Chapter 60 for a detailed review. Hepatotoxic agents, particularly certain chemotherapeutic conditioning regimens, account for most cases (Table 40.2). Recipients of liver and renal allografts and patients exposed to azathioprine are also at risk for developing veno-occlusive lesions. Other rare conditions associated with veno-occlusive disease include vitamin A toxicity; arsenic poisoning; exposure to insecticide; administration of 6-thioguanine, intra-arterial 5-fluoro-2’-deoxyuridine, Thorotrast, and a combination of norethisterone with conditioning chemotherapeutic agents (51,53,54,55,56,57).

Table 40.2. Budd-Chiari Syndrome Subtypes and Veno-Occlusive Disease

CLASSIC BUDD-CHIARI SYNDROME
Thrombosis principally of hepatic veins
More common in western countries
Thrombophilic state most common etiology
OBLITERATIVE HEPATOCAVOPATHY
Webs and membranes (representing prior thrombosis) in inferior vena cava
More common in China, Nepal, India, Japan, and South Africa
Thrombophilic state, idiopathic and hepatocellular cancer common
VENO-OCCLUSIVE DISEASE
Nonthrombotic fibrosis of hepatic sinusoids and small intrahepatic veins
Almost exclusively seen in the setting of bone marrow transplantation
Mainly caused by conditioning chemotherapy

Pathology

Hepatic venous outflow obstruction is caused by thrombotic occlusion of the terminal hepatic venules, hepatic veins, or inferior vena cava. Generally, the disease is silent if only one hepatic vein is occluded. Obstruction may manifest as fibrous cord remnants of hepatic veins, short-length stenoses, membranes, webs, or occlusions of the hepatic venous ostia (19,43,49,58). In acute Budd-Chiari syndrome, the liver appears enlarged, smooth, and red purple because of congestion. In chronic disease, direct outflow from the caudate lobe to the inferior vena cava may compensate for venous outflow obstruction of major hepatic veins, resulting in caudate lobe hypertrophy with atrophy and cirrhosis of the remaining segments (59). In some cases caudate lobe hypertrophy may obstruct the intrahepatic portion of the inferior vena cava.

Histologic changes may be uneven and result in liver biopsy sampling errors. Centrilobular congestion and sinusoidal dilatation are seen with acute obstruction, whereas atrophy, necrosis, and centrizonal hepatocyte dropout with extension to periportal regions are associated with severe injury. Venous stasis and congestion lead to hypoxic damage and oxidative injury to hepatocytes (60,61). In chronic disease, there is complete obliteration of the central veins associated with centrilobular fibrosis that may culminate in cirrhosis (62,63,64). Periportal fibrosis may be more prominent if branches of the portal vein are concomitantly thrombosed because of stasis (65). Large, regenerative nodules are also commonly reported in areas exposed to a compensatory increase in arterial blood flow (60,65).

Clinical Presentation

About two thirds of patients with Budd-Chiari syndrome are women, with onset of symptoms usually in the late 30s (6,66). Clinical presentation is variable and depends on the extent and rate of outflow obstruction, as well as the development of collaterals (19,62) (Table 40.3). Presentation may range from

an asymptomatic state to fulminant hepatic failure, or to cirrhosis with

complications of portal hypertension (15,29,67,68). More than 85% of patients have hepatomegaly and ascites, whereas esophagogastric varices and splenomegaly may be seen in 40% to 60% of individuals (67). The presence of dilated subcutaneous veins over the body and trunk are more often associated with inferior vena cava obstruction (43,69). Acute obstruction is commonly accompanied by right upper quadrant abdominal pain, nausea, vomiting, hepatomegaly, and ascites (67). Jaundice and splenomegaly may be present with acute occlusion but are usually mild. Rarely, massive hepatocellular necrosis with acute hepatic failure may follow rapid and complete occlusion of all major hepatic veins (29,67). A subacute presentation of less than 6 months is characterized by vague right upper quadrant discomfort, hepatomegaly, mild-to-moderate ascites, and splenomegaly (67,68). Jaundice is either absent or mild. Chronic Budd-Chiari syndrome of greater than 6 months' duration generally presents with progressive ascites. It may also be accompanied by other complications of portal hypertension, such as bleeding varices, encephalopathy, coagulopathy, renal insufficiency, fatigue, and muscle wasting (19,29,62,67,68). Generally, cirrhosis is found only in patients with chronic disease. However, the demonstration of cirrhosis in biopsy specimens taken from patients with acute outflow tract obstruction provides argument that the current classification system leaves room for improvement (47,70).

Table 40.3. Clinical Manifestations of Budd-Chiari Syndrome

Right upper quadrant pain
Hepatomegaly
Ascites
Splenomegaly (rare)
Jaundice
Acute liver failure (rare)
Weight gain
Nausea and vomiting
Pleural effusions
Lower-extremity edema
Complications of portal hypertension

Diagnostic Evaluation

Laboratory investigation

Standard laboratory investigation is rarely helpful in patients with Budd-Chiari syndrome. Nonspecific mild transaminase level elevation can be seen in 25% to 50% of patients but does not aid in establishing the diagnosis (25,37). Transaminase values over 1,000 IU/L are possible in acute outflow obstruction or hepatic failure, especially if there is accompanying portal vein thrombosis (25). Serum bilirubin and alkaline phosphatase levels and prothrombin time are usually normal or mildly elevated and are also not specific (25,71,72). Ascitic fluid analysis is consistent with portal hypertension. Myeloproliferative and thrombotic disorders are common. Therefore, systematic, comprehensive evaluation for hypercoagulable disorders should be undertaken. The following tests should be performed: Plasma clotting factors and inhibitors, factor V Leiden factor

mutation, prothrombin G gene analysis, antiphospholipid antibodies and lupus anticoagulant, flow cytometry for paroxysmal nocturnal hemoglobinuria, blood smear analysis, and in select cases determination of total red cell mass, bone marrow biopsy, and measurement of serum erythropoietin levels (50,62). Caution must be exercised in the interpretation of protein C, protein S, and antithrombin III because compromised hepatic synthetic function may provide alternative explanations.

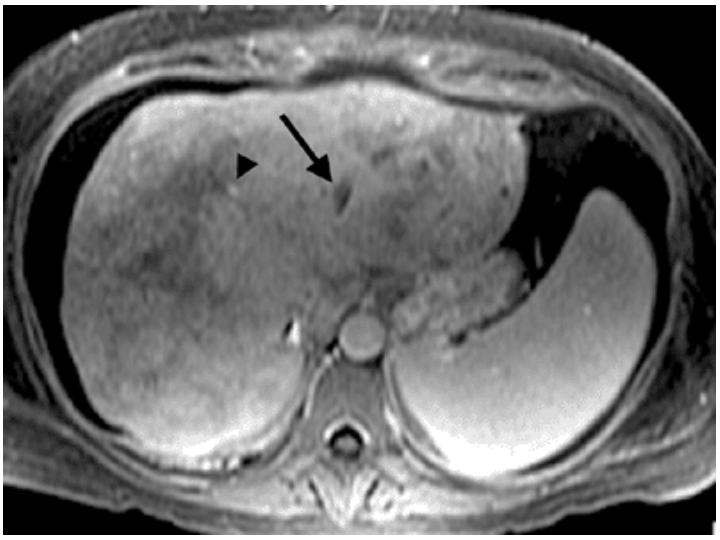
Medical imaging

Doppler ultrasonography allows for noninvasive evaluation of the hepatic veins, inferior vena cava, and portal vein. In experienced hands the sensitivity of ultrasonography for detecting venous obstruction approaches 85% to 95% (15,19,73). Real-time evaluation of acute venous occlusion reveals enlarged, stenotic, or tortuous hepatic veins, whereas the major hepatic veins of patients with chronic disease may not be seen (73,74,75,76). Intrahepatic venous-to-venous spider web collaterals and/or the presence of intrahepatic or subcapsular hepatic venous collaterals are highly suggestive of Budd-Chiari syndrome (50,73,74). Ultrasonography may also show caval compression by a hypertrophied caudate lobe or obstruction of the vena cava by thrombus, tumor, or membranes (73,74,75,76). Visualization of a caudate vein is over 90% specific for Budd-Chiari syndrome, although only 50% sensitive (77). The addition of Doppler to conventional ultrasonography increases sensitivity. Doppler is effective for evaluating not only the perihepatic vascular anatomy but also the direction of blood flow and site of obstruction. Loss of the normal triphasic wave variation in the vena cava or hepatic veins has a sensitivity of 88% for occlusion (78).

Computed tomography (CT) scan and magnetic resonance imaging (MRI) are complementary investigations to Doppler ultrasonography (79,80,81,82). Abnormalities seen may include nonvisualization of vessels or obstruction by thrombus (73,76,83,84,85). Acute thrombus may be demonstrated as an expanded nonenhancing vein (Fig. 40.1), whereas more chronic changes are suggested when vessels are narrowed or not visualized.

A "mosaic" pattern of abnormal parenchymal enhancement (Fig. 40.2), representing the effects of relative venous outflow obstruction, is commonly seen

in contrast-enhanced CT and MRI. This pattern is not specific for Budd-Chiari syndrome and can also be seen in severe right-sided heart failure. In cases of chronic venous outflow obstruction, parenchymal changes of nodular regeneration (including macroregenerative nodules) and cirrhosis may ensue (Fig. 40.3) (76,78,84,86). When portal hypertension develops, characteristic imaging findings (e.g., splenomegaly, ascites, collateral vessels) are often depicted as well.



▪ **Figure 40.1** Gadolinium-enhanced magnetic resonance imaging of a 67-year-old woman with Budd-Chiari syndrome and acute hepatic decompensation. Delayed post gadolinium images demonstrate expanded nonenhancing left hepatic vein (*arrow*), representing acute thrombus. A narrowed but enhancing middle hepatic vein is also shown (*arrowhead*). Vessel narrowing suggests prior thrombosis with recanlization. Portal vein thrombus and ascites were also present. Patient decompensated and underwent transplantation. Explant pathology confirmed acute left hepatic vein thrombus. The middle and right hepatic veins with chronic thrombotic changes and recanalization were also demonstrated.

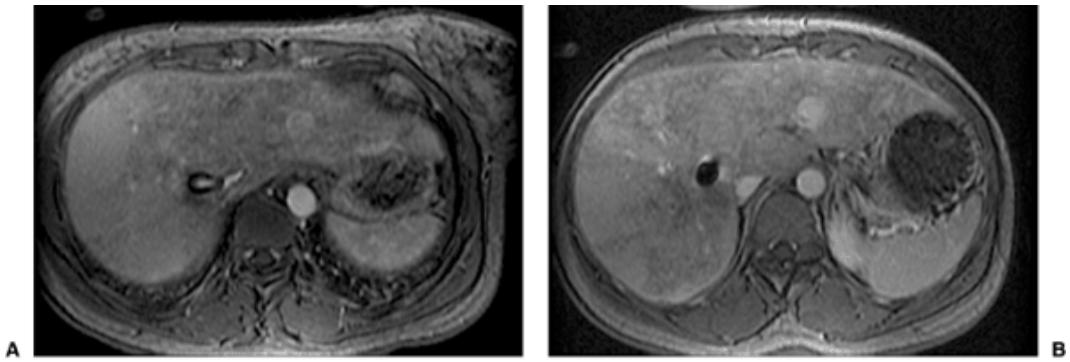
Venography remains the standard of reference for diagnosis and is key to planning optimal therapy. Typical venographic findings include narrowed, irregular hepatic veins with or without occlusive thrombi. Thrombi may be found either at the junction of the hepatic veins with the cava or just distal to the venous orifices (25,29,72). Replacement of hepatic veins with the classic "spider web" appearance, intrahepatic collaterals, and recanalized veins can also be appreciated (25,29,72,78,87). Angiographic assessment of the vena cava provides important information about the location and extent of obstruction, as well as its amenability to angioplasty and stenting (25,29,71,72,87). Both catheter-based and magnetic resonance venography (Fig. 40.4) can be used to depict stenoses or webs of the inferior vena cava. Local installation of thrombolytics may be performed at the time of venography in patients with fresh clots (less than 3 to 4 weeks) (88). Liver biopsy may also be obtained at the time of catheter venography. Furthermore, pressure measurements obtained at the time of venography can provide useful information before surgical decompression (25,29,71,72,87).

Liver biopsy

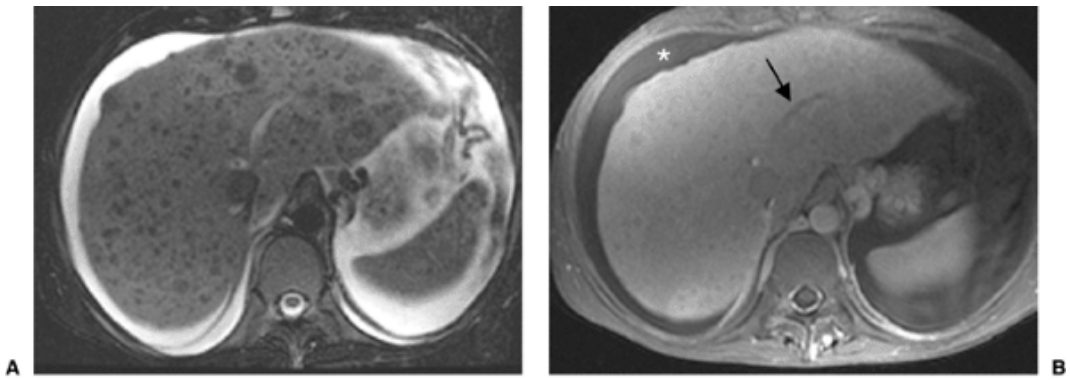
Although not mandatory, liver biopsy is complementary to medical imaging and clinical patient assessment. Generally, the diagnosis can be established by medical imaging. In select patients, biopsy may be required to distinguish Budd-Chiari syndrome from veno-occlusive disease or cirrhosis from other causes.

Biopsy specimens may establish the presence of fibrosis and cirrhosis and may also grade the severity of hepatocellular necrosis. However, caution should be used when interpreting results because sampling error is common. Bilobar biopsy may provide a higher diagnostic yield (87). However, it is not clear whether results from liver biopsy determine the prognosis (89,90,91). In one multivariate analysis, age, Child-Pugh score, responsiveness to diuretics, and creatinine were predictive of survival. Data from carefully documented

biopsies did not predict survival (90). A follow-up study found that diagnosis of acute or chronic Budd-Chiari syndrome, as opposed to acute on chronic injury only, was an important prognostic indicator for survival (91).



▪ **Figure 40.2** Gadolinium-enhanced magnetic resonance imaging (MRI) of a 57-year-old woman with chronic Budd-Chiari syndrome and prior transjugular intrahepatic portosystemic shunt. The MRI demonstrates heterogeneous (mosaic) enhancement in the left lobe **(A)** and portions of the right lobe **(B)**.



▪ **Figure 40.3** Magnetic resonance imaging of the liver of a 31-year-old man with long-standing Budd-Chiari syndrome. In the T2-weighted image **(A)**, liver parenchyma is abnormally edematous, with signal intensity elevation

(comparable to that of spleen). Multiple regenerative nodules characteristic of long-standing Budd-Chiari syndrome are hypointense to the edematous liver parenchyma. In the postgadolinium image **(B)**, nodular enhancement heterogeneity is shown. A portion of the thrombosed left hepatic vein is demonstrated (*arrow*). Ascites is also noted (*asterisk*).

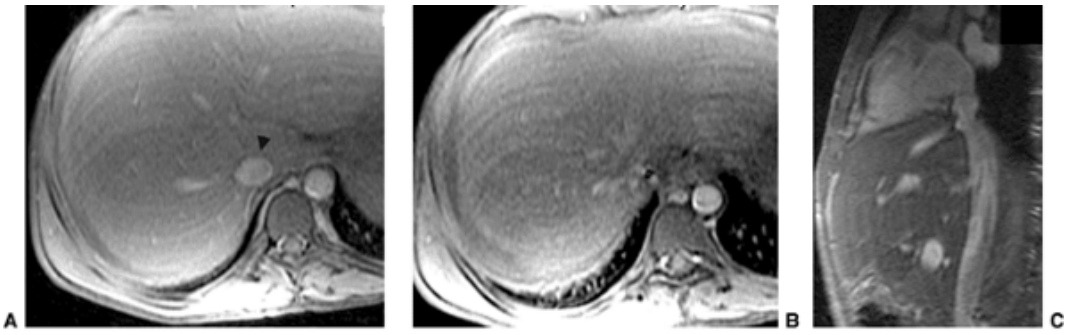
Management

In the absence of prospective natural history studies of untreated and unselected patients and randomized, controlled trials of treatment options, firm management recommendations cannot be made; however, some general principles have emerged. Anticoagulation is recommended for most patients. Thrombolytics may be of benefit in fresh thrombosis. Angioplasty with or without stenting may be considered for focal obstruction. If symptoms are progressive despite medical therapy, then decompressive therapy with TIPS or surgical shunting is advised. Some investigators recommend decompressive procedures early in the course or if extensive necrosis is seen on liver biopsy. Generally, liver transplantation is reserved for acute liver failure or decompensated cirrhosis.

Medical therapy

Early series demonstrated poor survival in untreated Budd-Chiari syndrome; most patients died within

3 years of diagnosis (25,72). More recent studies show improved survival. In one study, 5-year survival was 50% before 1985 and 75% afterwards (90). Widespread adoption of anticoagulation with warfarin is thought to be the cause of this improved trend. It seems prudent to recommend anticoagulation even in the absence of an identifiable prothrombotic state. It is possible that in some patients with myeloproliferative disorders, hydroxyurea and aspirin may be more appropriate (92). Patients with ascites should be placed on low-sodium diets and diuretics. Responsiveness to such measures is an independent predictor of survival (90,91). If ascites is not easily controlled after anticoagulation and medical therapy, patients should then undergo decompressive therapy.



▪ **Figure 40.4** Cardiac-gated bright-blood (cine) vascular imaging 2 cm below **(A)** and at **(B)** the level of the hepatic vein confluence of a 20-year-old man with lower extremity swelling and liver dysfunction. In **(A)**, a patent inferior vena cava (IVC) with flow is demonstrated (*arrowhead*). In **(B)**, the IVC is narrowed. Dark areas within IVC lumen represent turbulent (nonlaminar) flow. Cavogram (*not shown*) demonstrated IVC stenosis with thrombus, severely narrowing the lumen with a large pressure gradient. Angioplasty relieved both lower extremity symptoms and hepatic abnormalities. Repeat cine magnetic resonance imaging in the sagittal plane after angioplasty **(C)** demonstrates a patent IVC with mild structuring at the site of prior stenosis.

In carefully selected patients with clots no older than 3 or 4 weeks, the prompt administration of thrombolytics (e.g., streptokinase, urokinase, or recombinant tissue plasminogen activator) has been effectively used to dissolve thrombi and relieve hepatic congestion (88,93,94). Thrombolysis may be more effective when thrombolytics are administered locally into the hepatic vein and combined with angioplasty with or without stenting (88).

Interventional radiology

Percutaneous transluminal balloon angioplasty has been used to treat focal stenoses of the inferior vena cava and/or hepatic vein (95). Although excellent short-term results are achievable, sustained patency rates of only 50% are seen at 2 years (96). Wire-, laser-, or needle-assisted angioplasty is appropriate for stenoses refractory to standard techniques (97,98). For salvage of failed angioplasty or as primary therapy for focal stenoses, percutaneous intraluminal stenting is an option (19,96,97,98). More than 80% of stents remain patent 3 years after placement, with good control of symptoms (19,99). Stenting has also been used to treat intrahepatic inferior vena cava obstruction caused by compression from caudate lobe hypertrophy, which would otherwise preclude portacaval shunting. After stenting, portacaval shunting has been successfully performed (100).

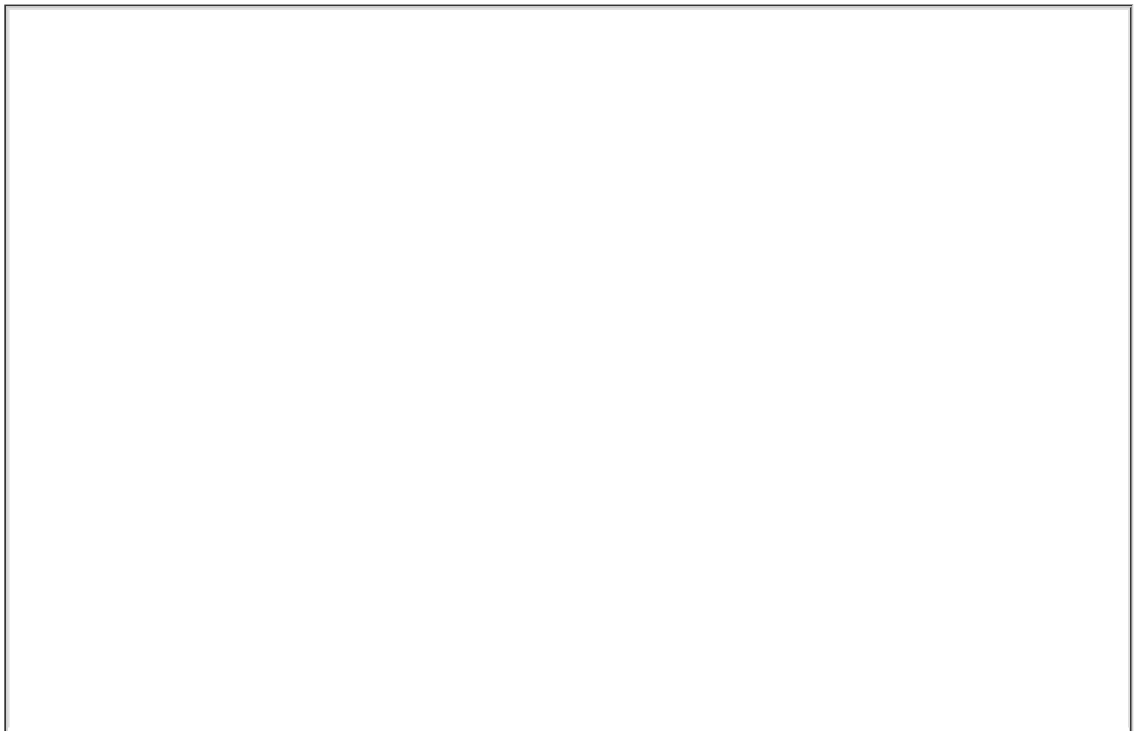
TIPS is being increasingly used as an alternative to decompressive surgical procedures because it is less invasive and does not carry the high perioperative mortality associated with surgical shunting. TIPS may have a role as a bridge to transplantation for patients with end-stage liver disease and ascites refractory to diuretics and sodium restriction (101,102,103,104) or in patients who present with fulminant hepatic failure (101,102,103,104,105,106). Recent series have reported on the use of TIPS after progressive, symptomatic liver disease with ascites despite anticoagulation and medical therapy. Control of symptoms, improvement of Child-Pugh class, and good 5-year survival without liver transplantation (74%) have been reported after TIPS (66,70). Survival after TIPS compares favorably with historical controls from surgical series. Shunt dysfunction often develops over time because of thrombotic occlusion. Therefore, surveillance with ultrasonography or angiography and chronic anticoagulation are recommended (70,102,106). Recent introduction of polytetrafluoroethylene-coated stents may dramatically reduce TIPS thrombosis. In one study, only 33% of patients with covered stents experienced dysfunction after TIPS within 1 year of the procedure, compared to 87% of patients with bare stents (107).

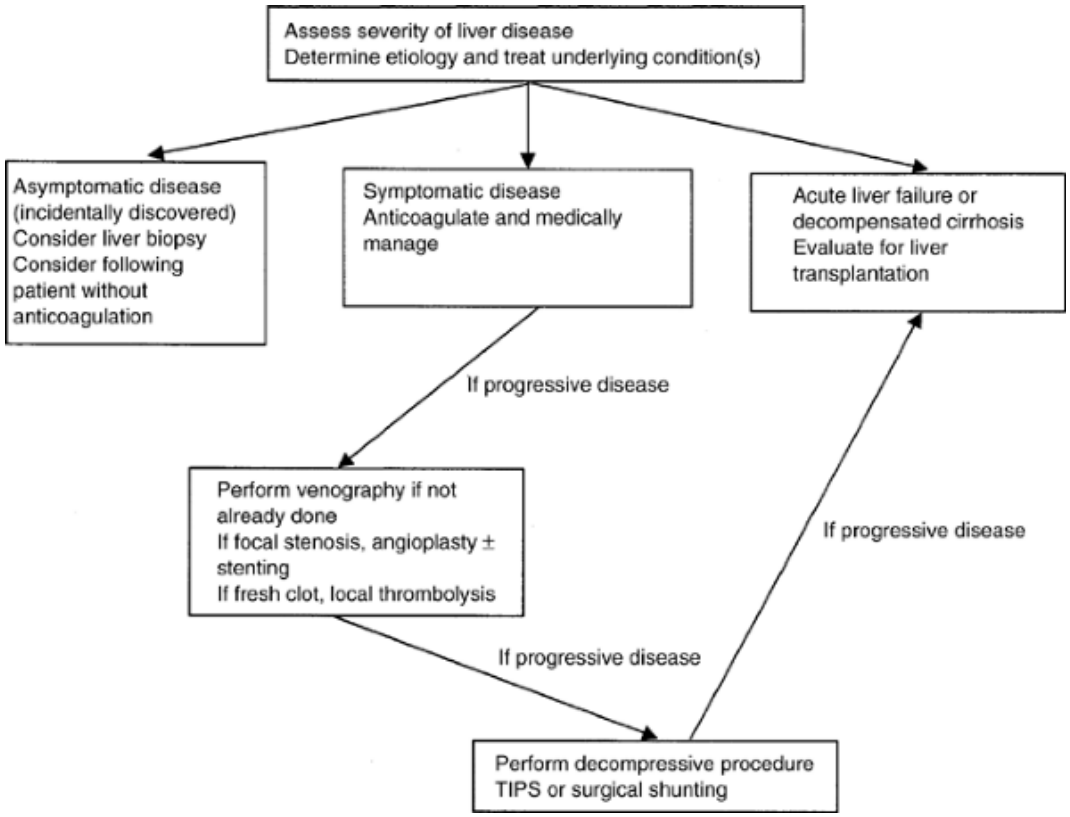
Surgical decompression

There is currently a divergence of opinion about whether surgical decompressive procedures should be offered early in the course of Budd-Chiari syndrome or should be reserved for patients who have progressive symptomatic disease despite medical therapy. One approach emphasizes the role of liver biopsy in determining which patients should undergo early surgical shunting. Anticoagulation alone is recommended if biopsy reveals only centrilobular congestion and sinusoidal dilatation, whereas surgery is reserved for those with hepatocyte necrosis (71,108). A second strategy advocates early surgical decompression, regardless of biopsy findings. Presumably, early relief of hepatic congestion may prevent ongoing necrosis and fibrosis. Such a strategy is supported by recent studies that found carefully collected data from liver biopsy to be not predictive of prognosis (89,90). Furthermore, in one retrospective study after adjustment for case severity, surgical shunting was associated with improved outcomes (89). If biopsy does not predict outcome, but performance of a surgical shunt does, then perhaps early surgery is preferable. However, caution must be exercised because no rigorous prospective study has been performed to test this strategy.

A third treatment approach has been increasingly used. Patients are first treated medically with anticoagulation and diuretics if ascites is present. If symptoms and serum tests of hepatic synthetic function do not improve within days for subacute Budd-Chiari syndrome and within weeks for slower presentations, then decompressive shunting is advised. Patients selected for surgery exhibited a nonsignificant trend toward improved survival (6). Similar treatment strategies using TIPS in place of surgical decompression have achieved excellent results (66,70). Success with TIPS has led to recommendations that decompressive surgery be relegated to third-line therapy. Moreover, surgical decompression is associated with high perioperative mortality (5% to 30%) and cannot be safely

performed for patients with Child-Pugh class B or C cirrhosis (19,50,70). The authors offer their own therapeutic algorithm (Fig. 40.5).





▪ **Figure 40.5** Proposed algorithm for management of Budd-Chiari syndrome. TIPS, transjugular intrahepatic portosystemic shunting.

A variety of portosystemic shunts is available to relieve sinusoidal hypertension of Budd-Chiari syndrome. Side-to-side portacaval shunts have been successfully used to convert the portal vein into an outflow tract (15,25,29,71,82,109). A pressure gradient of more than 10 mm Hg between the portal vein and the inferior vena cava is required for adequate shunt flow. For patients with compression of the intrahepatic portion of the inferior vena cava by a hypertrophic caudate lobe, inferior vena cava shunting may not be possible. Mesocaval shunts between the superior mesenteric vein and vena cava provide effective portal decompression for these patients (25,29,37,108). As with the side-to-side approach, caval pressure must be considerably lower than portal pressure. Shunt thrombosis remains a problem for 20% to 55% of patients who receive mesocaval shunts (15,37). Other shunts have been described, including splenocaval, cavoatrial, hepaticoatrial, and mesojugular shunts (110,111). Interposition synthetic grafts are also occasionally used. Finally, transatrial membranotomy with finger fracture or excision may be effective for patients with fenestrated membranes (29,37,112,113).

Liver transplantation

Liver transplantation is the preferred treatment for patients with Budd-Chiari syndrome and either acute liver failure or decompensated cirrhosis (15,29,37,87,109,114,115). Patients with significant liver disease who decompensate after receiving decompressive shunts or those with shunt failure

may be rescued with transplantation (112). Excellent 5-year patient and graft survival have been achieved, with rates similar to those for patients undergoing transplantation for other diseases (116,117). Transplantation is curative for protein C, protein S, and antithrombin III deficiency. All patients should receive indefinite anticoagulation for hypercoagulable states not curable by liver replacement (115). Aspirin and hydroxyurea effectively reduce platelet aggregation and number, respectively, and may be appropriate for preventing recurrent thrombosis after transplantation in patients with underlying myeloproliferative disorders (92,118). Patient selection is critical because individuals with short life expectancies due to underlying medical conditions are not appropriate for transplantation. However, most underlying myeloproliferative and other disorders associated with Budd-Chiari syndrome have near normal 10-year

life expectancies, which should not preclude transplantation (117). It is possible that immunosuppression could accelerate malignant transformation after transplantation, but this has not yet been reported.

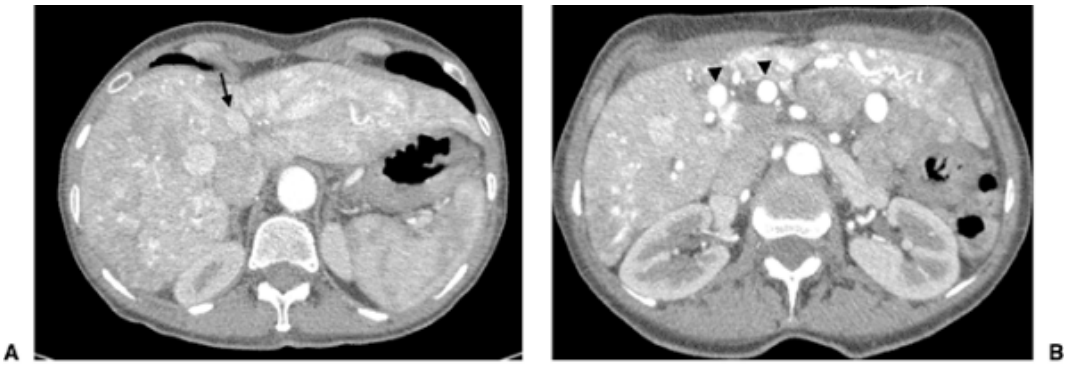
Liver Involvement in Hereditary Hemorrhagic Telangiectasia

HHT, also known as *Rendu-Osler-Weber syndrome*, is a multisystemic vascular disorder that variably affects the liver. Curacao criteria require presence of three of the four following criteria for definitive diagnosis: Recurrent and spontaneous epistaxis, multiple mucocutaneous telangiectasias, visceral arteriovenous malformations, and diagnosis of HHT in a first-degree relative (119). The disease is autosomal dominant and exhibits age-dependent penetrance. Identification of endoglin (*ENG*) and activin receptor-like kinase (*ALK-1*) gene mutations have allowed subclassification of HHT into types 1 and 2 (120,121). Both ENG and ALK-1 encode membrane glycoproteins expressed on vascular endothelial cells involved in vascular remodeling (122). Patients affected with HHT1 tend to have ENG mutations and are more likely to have pulmonary arteriovenous malformations. HHT2 is associated with ALK-1 mutations and is often clinically milder and more commonly associated with hepatic involvement.

Retrospective studies suggested radiologic evidence for hepatic involvement in only 8% to 30% of patients with HHT (123,124). However, a recent prospective study using multiphasic helical CT scan demonstrated hepatic vascular abnormalities, including arterioportal shunts, arteriosystemic shunts, telangiectasias, vascular masses, and parenchymal perfusion disorders, in up to 74% of 70 serial patients with HHT (125). Hepatic vascular abnormalities may be visualized with Doppler ultrasonography, CT angiography (Fig. 40.6), direct catheter angiography, or magnetic resonance angiography (126). Using contrast-enhanced CT or catheter angiography as the gold standard, sensitive and specific sonographic criteria for HHT have been defined. These include a dilated common hepatic artery (>7 mm) and the presence of intrahepatic hypervascularization on Doppler evaluation (127). Therefore, absence of these findings on a sonographic study may obviate the need for additional imaging. Furthermore, screening for hepatic involvement in HHT is not generally required because most hepatic lesions remain asymptomatic and do not require treatment (125,128).

There are several possible symptomatic presentations of HHT with hepatic involvement (Table 40.4). High-output cardiac failure presenting with dyspnea and edema may be related to extensive hepatic artery to hepatic vein shunting

(129). Portal hypertension resulting from shunting between the hepatic artery and portal vein may present with ascites or variceal hemorrhage (129). Hepatic encephalopathy may develop in the presence of portal vein to hepatic vein shunting (130). Finally, cholestasis and biliary abnormalities may result from ischemic injury related to hepatic artery to hepatic vein shunting (129). Symptomatic disease can often be managed conservatively. Hepatic arterial embolization of vascular lesions was initially used with some success, but more recent reports have highlighted the high mortality rates associated with postembolization hepatic and biliary necrosis (131). Hepatic arterial embolization can no longer be recommended for the treatment of hepatic HHT. Liver transplantation has been successfully performed despite technical difficulties with vascular reorganization (132). However, a recent report suggests the possibility that in some patients vascular abnormalities may reoccur after transplantation (133).



▪ **Figure 40.6** Contrast-enhanced computed tomography scan in a female patient with Rendu-Osler-Weber syndrome and hepatic involvement. In upper liver **(A)**, heterogeneous hypervascularity of the liver parenchyma is shown. Hepatic veins are markedly dilated (*black arrow*). At the level of porta hepatis **(B)**, the dilated tortuous proper hepatic artery is shown (*black arrowheads*).

Table 40.4. Hepatic Involvement of Hereditary Hemorrhagic Telangiectasia: Clinical Presentations

Clinical presentation	Type of shunting
High-output cardiac failure Dyspnea Edema	Hepatic artery to hepatic vein
Portal hypertension Ascites	Hepatic artery to portal vein

Variceal bleeding	
Hepatic encephalopathy	Portal vein to hepatic vein
Biliary abnormalities Cholestasis Cholangitis	Hepatic artery to hepatic vein

Peliosis Hepatis

Peliosis hepatis is characterized by blood-filled cystic cavities in the hepatic parenchyma lined by hepatocytes or endothelial cells (134). Similar lesions may also develop in the spleen. Peliosis has been well described in immunosuppressed patients, including those with HIV infection, tuberculosis, and cancer, and after solid organ transplantation (135,136,137). Medications associated with peliosis hepatis include anabolic and androgenic steroids, azathioprine, and cyclosporine (136,138).

Bartonella henselae, associated with cat-scratch disease, is the causative agent of bacillary peliosis hepatis in patients with HIV infection (135). Exposure to cat bites, scratches, and fleas are risk factors for acquisition of *Bartonella henselae* (135). This fastidious gram-negative bacillus has a granular and purple appearance on Warthin-Starry stain of affected hepatic specimens (134). Infection with the bacteria may also be demonstrated by blood culture, serologies, and polymerase chain reaction–based tests, although no single test is reliable. Some patients with bacillary peliosis hepatis also develop bacillary angiomatosis, characterized by vascular lesions affecting the skin (most commonly red or purple papules), lymph nodes, bones, and central nervous system.

Imaging reports of peliosis hepatis are largely limited to isolated case reports (139,140,141,142). On sonography, vague areas of slightly decreased heterogeneous echotexture have been described. On unenhanced CT scan, irregular areas of low attenuation are shown. On MRI, lesions are usually of low-signal intensity on T1-weighted imaging and high-signal intensity on T2-weighted imaging. However, appearance on MRI may vary if lesions are complicated by hemorrhage, with variable T1 brightening. On both CT and MRI, dynamic contrast enhancement demonstrates an early central enhancement, with gradual centripetal fill-in. This pattern is distinct from that of other vascular liver lesions, including hemangioma, adenoma, and focal nodular hyperplasia and may be the key to diagnosis.

Peliosis hepatis is often an incidental finding. Among patients with HIV infection, fever, lymphadenopathy, anemia, elevated alkaline phosphatase level, and lower CD4 counts are more common in affected patients than in controls (143). Treatment of bacillary peliosis hepatis consists of several months of

administration of erythromycin (500 mg four times daily) or an alternative macrolide. Nonbacillary peliosis is best treated by stopping the offending medication or addressing the underlying etiology. Performance of liver transplantation for treatment of severe peliosis hepatis has been reported (144).

Summary

Budd-Chiari syndrome is an uncommon disease associated with thrombotic obstruction of the terminal hepatic venules, hepatic veins, vena cava, and/or right atrium. Sinusoidal congestion and centrilobular necrosis occur as a consequence of venous outflow obstruction and can lead to fibrosis and cirrhosis. Most patients present with chronic signs and symptoms of portal hypertension, although some may present subacutely or even acutely. Doppler sonography is an excellent screening test for evaluating the patency of the major hepatic veins and vena cava. CT scan and MRI are complementary studies. Venography remains the standard of reference for the diagnosis of venous occlusion and may either show the classic "spider web" appearance of hepatic vein obstruction or demonstrate intrahepatic or subcapsular collaterals. Liver biopsy and pressure measurements made during venography may also guide treatment selection.

Rigorous studies are not available to derive definitive treatment algorithms. Generally, anticoagulation is offered to all patients. Diuretics and low-sodium diets are prescribed for those with ascites. If symptoms and hepatic synthetic function do not resolve after medical therapy, then decompressive procedures are offered. Some investigators recommend performance of surgical shunting or TIPS early in the course of disease. Thrombolytic therapy may be useful for fresh thrombosis. Angioplasty with or without stenting may treat focal stenoses. TIPS can effectively decompress hepatic sinusoids with symptomatic improvement. Surgical shunting has been used successfully for those with adequate hepatic reserve, although perioperative mortality can be high. Liver transplantation is preferred for patients with acute liver failure or decompensated cirrhosis. Survival after transplantation is similar to that of patients undergoing transplantation for nonmalignant cirrhosis of other causes.

HHT is characterized by epistaxis, mucocutaneous telangiectasias, and visceral arteriovenous malformations. Whereas liver transplant has been demonstrated frequently, patients with hepatic lesions are generally asymptomatic. Possible symptoms can include high-output cardiac failure, complications of portal hypertension, hepatic encephalopathy, and symptoms related to cholestasis. Management is most often conservative, and hepatic arterial embolization has been associated with unacceptably high mortality.

Peliosis hepatis is often an incidental finding. Characteristic blood-filled cystic cavities may occur in the setting of immunosuppression or HIV infection. *Bartonella henselae* is the cause of bacillary peliosis hepatis in patients with HIV infection. Generally, treatment consists of addressing the underlying cause of immunosuppression or treating *Bartonella* infection.

This is an informative, well-written review of all aspects of Budd-Chiari syndrome.

Murad SD, Valla DC, de Groen PC, et al. Determinants of survival and the effect of portosystemic shunting in patients with Budd-Chiari syndrome. *Hepatology* 2004; 39:500–508.

The authors present a large retrospective series of patients with Budd-Chiari syndrome (n = 237). On multivariate analysis encephalopathy, ascites, prothrombin time, and bilirubin were the only independent predictors of survival. Portosystemic shunting showed a trend towards improved survival in a select group of patients.

Okuda K. Inferior vena cava thrombosis at its hepatic portion (obliterative hepatocavopathy). *Semin Liver Dis* 2002; 22:15–16.

Okuda proposes that inferior vena cava obstruction, characterized by webs and membranes, and typically seen in Nepal, South Africa, China, India, and Japan,

should be considered a distinct disease from classic Budd-Chiari syndrome. He proposes a new term, obliterative hepatocavopathy.

Chapter 41

The Liver in Circulatory Failure

Mitchell L. Shiffman

Key Concepts

- A dual blood supply protects the liver from developing ischemic injury during periods of systemic hypotension. When ischemia does occur it is typically limited to zone 3 of the hepatic lobule and resolves rapidly and spontaneously when systemic blood pressure is restored.
- Ischemic hepatitis occurs in the setting of acute and severe hypotension and is associated with an abrupt and profound elevation in the levels of serum liver transaminases, which return to the normal range within several days. The serum bilirubin level rises and peaks 3 to 5 days after the peak in serum liver transaminase levels.
- Occlusion of the hepatic artery or one of its branches will lead to infarction of the area supplied by the occluded vessel. Large hepatic infarcts may become infected and develop into a hepatic abscess.
- The hepatic artery provides the only blood supply to the biliary ductal system. Injury to or occlusion of hepatic arterial branches may cause ischemic cholangiopathy. This results in stricture formation of bile ducts, which is often associated with dilatation proximal to the stricture.
- Passive hepatic congestion may develop as a consequence of right ventricular failure and elevated central venous pressure. Ascites may develop from passive hepatic congestion in the absence of cirrhosis. Cardiac cirrhosis may develop after a prolonged period of passive hepatic congestion.
- Passive hepatic congestion alone is only rarely associated with hepatic synthetic dysfunction even when cardiac ascites or cardiac cirrhosis is present. Liver dysfunction in this setting is most commonly the result of biventricular failure in which periods of hypotension and hepatic ischemia are superimposed on chronic hepatic congestion.

The liver has a dual blood supply and receives blood from both the hepatic artery and portal vein. These blood supplies mix within hepatic sinusoids and subsequently drain through multiple hepatic veins (1). Blood flow through the liver is therefore somewhat protected from the acute and chronic changes in cardiac output and systemic blood pressure. However, severe acute and/or prolonged changes in cardiac function may lead to hepatic dysfunction (2). Furthermore, the type of cardiac dysfunction may affect the liver in different ways. For example, cardiovascular failure associated with hypotension could

affect hepatic arterial blood flow and oxygen delivery to the liver (3). If abrupt, severe, and self-limited, this could lead to a marked elevation in levels of liver aminotransferases (ATs) without affecting hepatic function and without long-term sequela. If less severe but chronic, only minor elevations in liver AT levels may occur but progressive fibrosis secondary to chronic hepatic ischemia may result. In contrast, cardiac dysfunction secondary to right ventricular failure may lead to an elevation in hepatic venous pressure, passive hepatic congestion, and

the development of ascites with or without cirrhosis (4). Hepatic injury caused by acute or chronic circulatory failure may therefore present with a wide spectrum of biochemical, histologic, and pathophysiologic patterns.

This chapter focuses on liver injury caused by acute or chronic cardiac disease secondary to left ventricular dysfunction, right ventricular failure, valvular heart disease, constrictive pericarditis, congenital heart disorders, or circulatory failure secondary to heatstroke. Disorders of the liver that result from cardiac dysfunction include passive hepatic congestion, ischemic hepatitis, ischemic cholangiopathy, and hepatic infarction. The liver may also be injured or liver chemistries may become abnormal by many other disorders that affect hepatic blood flow. These disorders, which include hepatic vein thrombosis (see Chapter 40), portal vein thrombosis (see Chapter 40), hepatic veno-occlusive disease (see Chapter 40), sepsis (see Chapter 50), and various forms of immunologic disorders associated with vasculitis (see Chapter 11), will not be discussed in this chapter.

Anatomy and Physiology of Hepatic Blood Flow

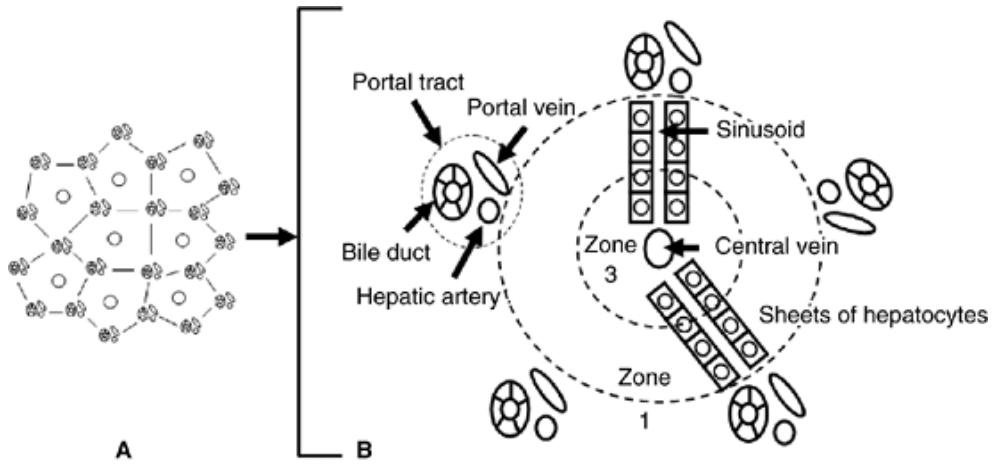
A detailed description of hepatic anatomy and the physiology of hepatic blood flow is provided in Chapter 7. This is only briefly reviewed here, with special emphasis on the pathophysiologic factors associated with circulatory failure.

The liver has a rich blood supply derived from two sources (1). Two thirds of the total hepatic blood flow enters the liver through the portal vein. Portal blood contains large amounts of nutrients absorbed from the intestine, particularly after a meal, including glucose, amino acids, water-soluble vitamins, and triglycerides, but a relatively low oxygen tension. The remaining one third of hepatic blood flow is supplied by the hepatic artery. Hepatic arterial blood contains little nutrients but is rich in oxygen. More than half of the oxygen delivered to the liver originates from the hepatic artery, which is also the only blood supply for both the extrahepatic and intrahepatic biliary ductal systems. As a result, the liver and, particularly, the biliary ductal system are more susceptible to ischemic damage after an abrupt reduction in hepatic arterial blood flow than portal blood flow. In animal studies, ligation of the hepatic artery was associated with massive hepatic necrosis and death, whereas ligation of the portal vein was not (5). Inadvertent ligation of hepatic arterial branches during laparoscopic cholecystectomy (6) or purposeful embolization of hepatic arterial branches for treatment of hepatocellular carcinoma (HCC) (7) may lead to hepatic infarction of the segment supplied by the occluded vessel. Hypotension may also result in subsegmental, segmental, or global hepatic infarction (8). Patients with portal vein thrombosis, in which the only hepatic blood supply is through the hepatic artery, are particularly susceptible to hepatic failure secondary to a disruption in hepatic arterial blood flow. This may occur after chemoembolization of HCC or simply with hypotension.

The functional unit of the liver is the hepatic acinus or lobule. This is a roughly

pentagonal-shaped structure with a single central hepatic vein bound by five portal tracts (Fig. 41.1). Each portal triad contains a branch of the hepatic artery, portal vein, and a bile duct. Sheets of hepatocytes, one to two layers in thickness and lined

by hepatic sinusoids, stretch between the portal triads and central vein. Both portal and hepatic arterial blood enter the liver lobule through portal tracts, zone 1 of the hepatic acinus in the Rappaport classification (9). Blood from both of these sources then enters and mixes within hepatic sinusoids, flows to the center of the hepatic lobule (Rappaport zone 3), and exits the liver through a branch of the hepatic vein. As a result, zone 1 of the hepatic acinus contains oxygen- and nutrient-rich blood, and as this flows through the sinusoids, it is gradually depleted of both nutrients and oxygen. Zone 3 contains the smallest amount of nutrients and oxygen and is therefore the most susceptible to ischemic injury.



▪ **Figure 41.1 A:** Schematic drawing of a section of liver. The functional subunit of the liver is the hepatic lobule or acinus, a roughly pentagonal-shaped structure with a central vein in the center and portal triads at each corner. Each portal triad is shared by several hepatic lobules. **B:** Schematic drawing of a hepatic lobule or acinus. Each portal triad contains a branch of the hepatic artery, portal vein, and bile duct. Sheets of hepatocytes extend between the central vein and portal triads at the edges of the lobule. Hepatic arterial and portal venous blood enters the acinus through the portal triad mix and then flow through hepatic sinusoids to the central vein. Zone 1 of the lobule lies at the periphery of the hepatic acinus (*outer dashed circle*). Zone 3 of the lobule lies in the center of the acinus (*inner dashed circle*).

Blood flow into the hepatic lobule is self-regulated by the hepatic microvasculature. Blood entering the liver through the low-pressure portal vein is slow, constant, only marginally affected by system blood pressure, and unregulated. In contrast, high-pressure hepatic arterial flow is tightly regulated so that total blood flow, the sum of portal and arterial blood flow, entering the liver lobule remains within a relatively narrow range (10). The buffering response of hepatic arterial blood flow to changes in portal blood flow is regulated by adenosine, a potent vasodilator of arterial smooth muscle cells (11,12). Adenosine is continuously secreted into the portal triad, and its local

concentration is controlled by the blood entering the hepatic lobule. Therefore, as portal blood flow increases, the local adenosine concentration is diluted, hepatic arterioles constrict, and arterial blood flow declines. Alternatively, as portal blood flow declines, the local concentration of adenosine increases, hepatic arterioles dilate, and arterial blood flow increases. The response of hepatic arterial smooth muscle to adenosine is maintained in patients with cirrhosis (13). Infusion of adenosine has been shown to reduce hepatic ischemic injury in experimental animals (14,15) and reduce ischemic injury following reperfusion after liver transplantation (16). Adenosine appears to act locally by the synthesis of nitric oxide (17,18).

Ischemic Hepatitis

Ischemic hepatitis refers to the disorders that cause liver injury by reducing oxygen delivery to the liver (19). This is most commonly seen in the setting of severe hypotension and global hepatic hypoperfusion (Table 41.1). In many patients ischemic hepatitis results from a severe acute decline in cardiac output associated with myocardial infarction, pulmonary embolus, or congestive heart failure. In other patients ischemic hepatitis may result from hypovolemia associated with massive hemorrhage, dehydration and heatstroke (20), sepsis, or hypoxia associated with acute respiratory failure. When associated with severe hypotension and shock, the term *shock liver* is frequently utilized.

Table 41.1. Causes of Ischemic Hepatitis

HYPOTENSION
Cardiac dysfunction
Right of left ventricular myocardial infarction
Cor pulmonale
Pulmonary embolus
Acute exacerbation of congestive heart failure
Hypovolemia
Hemorrhage with or without preceding trauma
Dehydration
Burns associated with severe dehydration
Miscellaneous causes
Sepsis
Heatstroke
Sickle cell crisis
HYPOXIA
Acute respiratory failure or acute exacerbation of chronic respiratory disease
Obstructive sleep apnea

Pathophysiology

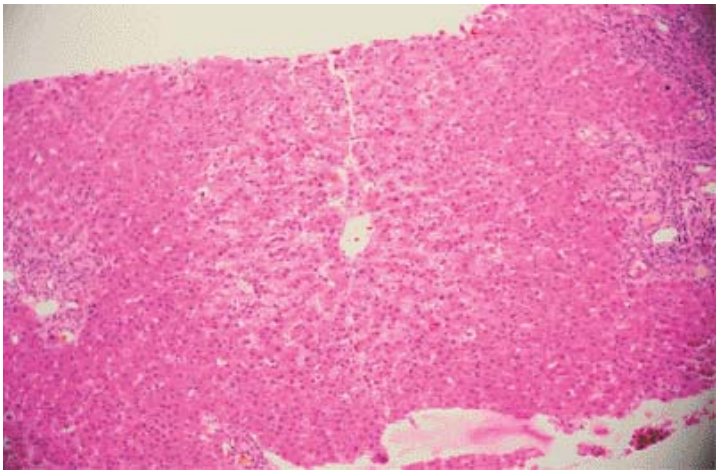
Ischemic hepatitis is not a true hepatitis because inflammation is uniformly absent on histologic examination. Rather, the hallmark of this disorder is zone 3 hepatic necrosis along with variable degrees of hepatic lobular collapse, depending on the duration and severity of the insult (Fig. 41.2). Fibrosis is characteristically absent unless there is a separate preexisting underlying chronic

liver disorder or a long-standing circulatory disease associated with passive congestion, hypovolemia, or hypoxia. In patients with right ventricular infarction, changes associated with both acute passive congestion (see subsequent text) and ischemic hepatitis may be present. The histologic features of ischemic hepatitis resolve spontaneously, hepatocytes regenerate, and liver histology returns to normal in most patients. In patients with preexisting fibrosis and/or other histologic features of a chronic liver disorder, these changes either remain or recur after resolution of ischemic hepatitis.

Clinical Features and Outcome

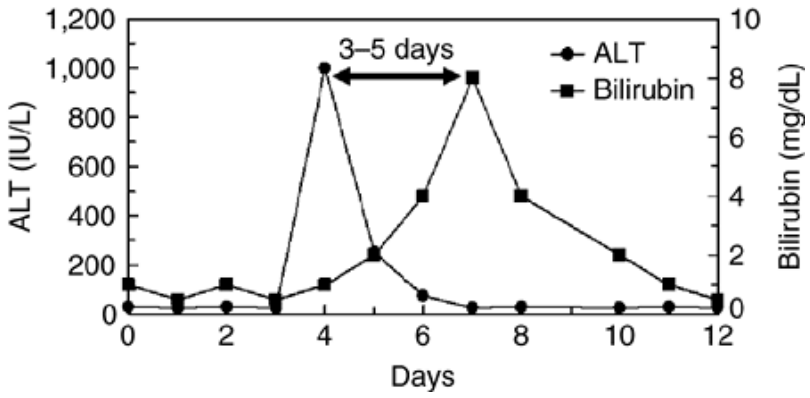
The clinical hallmark of ischemic hepatitis consists of an abrupt elevation in the levels of serum liver ATs, aspartate aminotransferase (AST) and alanine aminotransferase (ALT), and lactate dehydrogenase (LDH), which peak within 1 to 3 days of an episode of severe hypotension (Fig. 41.3). This is readily detected because patients with ischemic hepatitis typically are acutely ill and hospitalized, and undergo frequent biochemical testing of their renal, liver, and cardiac function. The peak in AT levels is typically in the 500 to 1,500 IU/L range, and these values return to normal within another 3 to 7 days as long as the hypotensive event is effectively treated and/or resolves (3,21,22,23).

The serum bilirubin level begins to rise 1 to 2 days after the elevation in serum AST and ALT levels and peaks 3 to 5 days after the maximum rise in liver AT levels. The maximal value for serum bilirubin observed in patients with ischemic hepatitis will vary greatly and depend on the inciting event and the presence of any underlying chronic liver disorder. Serum alkaline phosphate value may remain in the normal range or increase by only mild to moderate amounts. The international normalized ratio (INR) usually remains within normal limits. However, in particularly severe cases of ischemic hepatitis the patient may develop a mild prolongation in INR that rapidly corrects after administration of vitamin K. Changes in mental status are common in patients with ischemic hepatitis. However, this is usually secondary to cerebral hypoperfusion and hypoxia associated with the acute cardiocirculatory process. True hepatic encephalopathy associated with an elevation in serum ammonia level is distinctly rare.



▪ **Figure 41.2** Histology of ischemic hepatitis. There is necrosis and

ballooning degeneration of hepatocytes adjacent to the central vein, zone 3 of the hepatic lobule, with preservation of hepatocytes in zone 1 and portal structures.



▪ **Figure 41.3** Pattern of serum alanine aminotransferase (ALT) and bilirubin level variation in patients with ischemic hepatitis. There is an abrupt and marked rise in serum aspartate aminotransferase (AST—not shown) and ALT levels to values of 200 to 1,000 IU/L. This is followed by a delayed rise in serum bilirubin level, which usually reaches a maximum 3 to 5 days after the peak in serum AST and ALT levels.

The possibility that the abrupt rise in serum liver AT levels in a patient with presumed ischemic hepatitis may actually result from an acute viral or nonviral hepatitis should always be considered. However, this rapid rise and fall in AST and ALT levels is unusual in acute viral hepatitis in which the transaminase levels return to normal over weeks rather than days. In addition, acute viral or nonviral hepatitis is frequently symptomatic and is associated with nausea, vomiting, anorexia, malaise, and/or right upper quadrant discomfort (19,24). These symptoms are only rarely present in patients with ischemic hepatitis. Despite this, serologic studies to exclude viral hepatitis A, B, and C may need to be performed in some cases. Nonviral causes of acute hepatitis that could present with an abrupt marked elevation in the values serum liver ATs include Wilson disease and autoimmune hepatitis (25,26). In most cases these disorders can be excluded simply by evaluating the clinical presentation, although appropriate serologic testing may also rarely be required. Finally, ischemic hepatitis is frequently associated with signs or symptoms of hypoxic or hypotensive injury to another organ; the one most commonly affected is the kidney. Therefore, a parallel rise in serum creatinine level is frequently observed in patients with ischemic hepatitis (3,23).

Although the inciting event is readily apparent in most patients with ischemic hepatitis, a transient or subclinical hypotensive event may occasionally trigger this process and lead to uncertainty in the diagnosis. This is particularly common in patients with chronic right or left ventricular failure associated with chronic

hypotension and/or passive hepatic congestion in which the liver is quite sensitive to even minor changes in hepatic arterial blood flow (24,27,28). Ischemic hepatitis may also be difficult to recognize in patients with hypoxia secondary to exacerbations in chronic pulmonary disease or sleep apnea in the absence of hypotension (29).

The severity and prognosis of ischemic hepatitis is primarily dependent on the outcome of the inciting cardiocirculatory event. If the cause for hypotension is rapidly corrected the hepatic event is self-limited and resolves promptly. In contrast, if hypotension is extremely severe and/or persists despite prolonged resuscitative efforts multiorgan failure and death is likely to ensue. Ischemic hepatitis may lead to fulminant hepatic failure and death, but this is uncommon and typically occurs only in the setting of chronic congestive heart failure associated with passive hepatic congestion or cardiac cirrhosis (27) or in patients with cirrhosis from another form of chronic liver disease. The later situation is most frequently

encountered when a patient with cirrhosis develops hypotension secondary to massive variceal hemorrhage and/or sepsis. Ischemic hepatitis in patients with cirrhosis is associated with a mortality in excess of 60% (30,31).

Treatment

The treatment of ischemic hepatitis is directed at restoring normal circulatory hemodynamics and correcting the cause of the hypotensive event. No specific therapy for enhancing hepatic recovery from ischemic hepatitis currently exists. One study has suggested that intravenous low-dose dopamine may augment hepatic blood flow but the benefit of this on hepatic recovery from ischemic hepatitis has not been demonstrated (32). Adenosine has been utilized in animal models but not in humans except to reduce reperfusion injury in donor liver grafts (14,15,16).

Hepatic Infarction

Hepatic infarction represents the most severe form of ischemic hepatitis. Whereas ischemic hepatitis is associated with a global decline in hepatic blood flow and/or oxygen delivery secondary to a cardiocirculatory or other systemic process and is typically reversible, hepatic infarction occurs when blood flow to the liver, a particular lobe, segment, or subsegment, is interrupted secondary to occlusion of the hepatic artery or one of its branches. The involved segment of liver has no ability to recover and heals through the process of scar formation (33). Fortunately, only a branch or sub-branch of the hepatic artery is typically involved and the amount of liver rendered ischemic is limited to a segment or subsegment. In these cases, global hepatic function is only marginally impaired. However, if a major branch of the hepatic artery is occluded and the amount of liver rendered anoxic is too large the patient may develop acute liver failure and die without emergent liver transplantation.

The various etiologies of hepatic infarction are listed in Table 41.2. Hepatic infarction may occur when the artery is injured during liver transplantation (34,35), cholecystectomy, (6,36) placement of a transjugular intrahepatic portosystemic shunt (TIPS) (37), administration of intra-arterial chemotherapy or purposeful embolization of the artery for treatment of HCC or cancer metastasis to the liver (7,38). Hepatic infarction may also result from a hypercoagulable state associated with vasculitis or polyarteritis (39,40,41,42,43), septic emboli

(44), sickle cell crisis (45,46), polycythemia vera (33), and the use of oral contraceptives (47) and is seen in patients with toxemia of pregnancy (48,49). Severe arteriolar vasospasm associated with cocaine use may also lead to hepatic infarction (50,51).

Table 41.2. Causes of Hepatic Infarction

IATROGENIC ARTERIAL INJURY
Liver transplantation
Laparoscopic or open cholecystectomy
Intra-arterial chemoembolization or chemoinfusion
Placement of transjugular intrahepatic portosystemic shunt
SYSTEMIC DISORDERS
Polyarteritis
Systemic lupus erythematosus
Sickle cell crisis
Emboli from infectious endocarditis
HYPERCOAGULABLE STATES
Abnormalities in coagulation system
Polycythemia vera
MISCELLANEOUS CAUSES
Aortic dissection
Toxemia of pregnancy
Cocaine intoxication

Pathophysiology

Hepatic infarction represents the most extreme form of ischemic injury to the liver, in which complete occlusion of the arterial supply renders the involved segment anoxic. Histologically there is complete coagulative necrosis of the entire hepatic acinus including all hepatocytes and portal structures that lie within the center of the involved segment. This is surrounded by a zone of inflammatory reaction. The periphery of the involved segment contains a zone of partial necrosis that closely resembles that seen in ischemic hepatitis, necrosis within zone 3 of the hepatic lobule with preservation of zone 1 structures (36). This area likely receives partial blood flow from an adjacent segment and will recover both histologically and functionally.

Clinical Features and Outcome

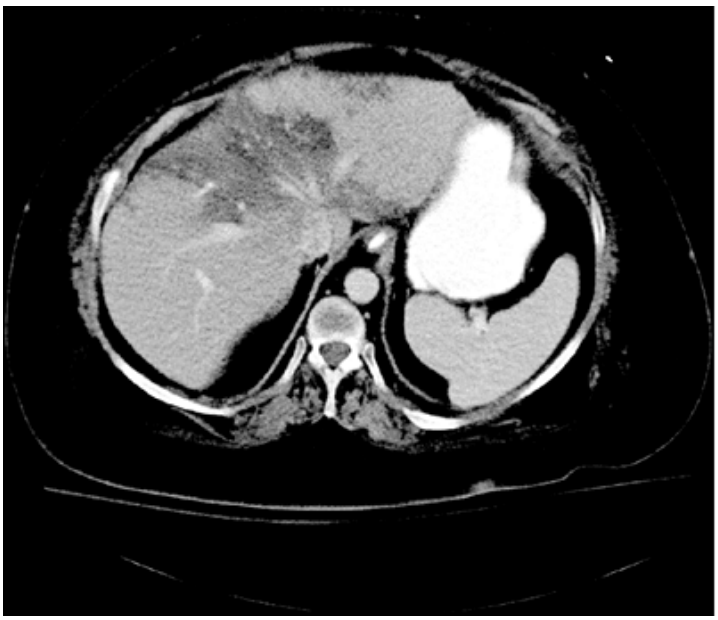
Patients who develop hepatic infarction may be asymptomatic if the occlusion occurs during a surgical or invasive procedure. In such cases the hepatic infarction may be suspected when liver AT levels are found to be markedly elevated after the procedure. In other cases, particularly if liver chemistries are not monitored and the infarction is of limited size, the diagnosis may be missed and the infarction will only be identified incidentally if and when an imaging study is performed. In nonsurgical settings patients may experience right upper quadrant pain of variable intensity that radiates to the back or right shoulder and is associated with fever, nausea, and vomiting (36).

Leukocytosis is common and there is a dramatic rise in serum liver AT levels

similar to what is observed in ischemic hepatitis. The serum bilirubin level may or may not rise depending on the size of the infarcted area. If a major branch of the hepatic artery is involved a large proportion of the liver will become infarcted and liver failure may occur (52).

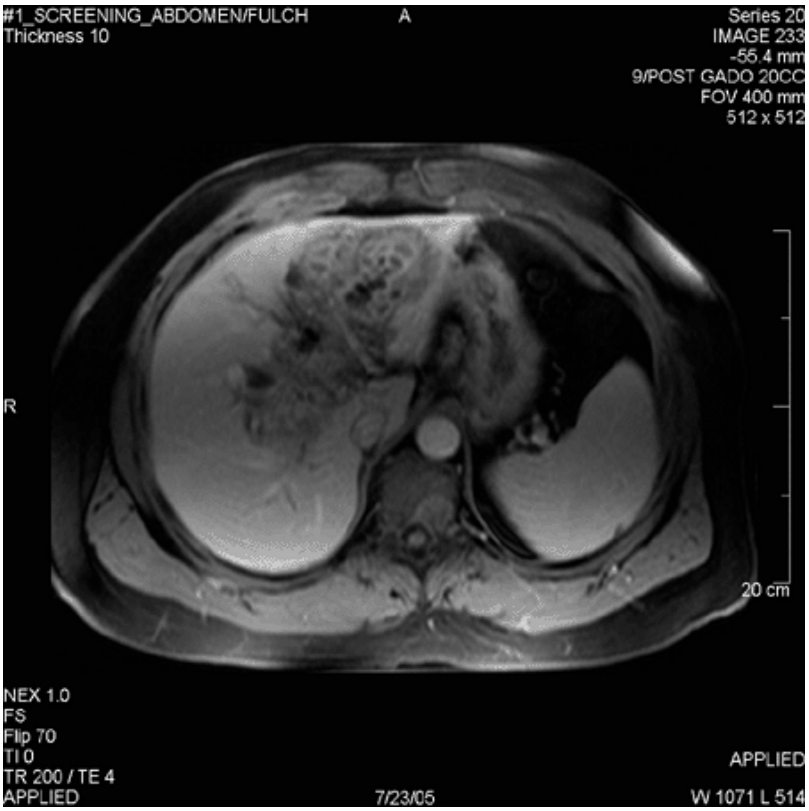
The diagnosis of hepatic infarction is confirmed with radiographic studies (53,54,55,56). If recognized acutely, ultrasound may demonstrate a focal hypoechoic area, and if the occlusion is of a large hepatic artery, Doppler flow ultrasonography may demonstrate the absence of flow in the involved vessel. Ultrasound is unlikely to detect the absence of flow in a smaller subsegmental branch of the hepatic artery. Abdominal computed tomography (CT) scan demonstrates a segmental area of low attenuation. The lesion may be wedge shaped and extend outward to the periphery of the liver (Fig. 41.4). Round or oval infarcted lesions are usually located within the center of the liver, or the lesion may be irregular and follow the course of the intrahepatic vasculature and biliary tracts (53,54). In such cases, marked biliary dilatation in the involved area occurs as the lesion heals (Fig. 41.5). With magnetic resonance (MR) imaging the lesion has diminished T1 and increased T2 signal intensity. MR angiography may also demonstrate the area of occlusion if a sufficiently large branch of the hepatic artery is involved (56,57).

It is rarely necessary to perform biopsy in an area of hepatic infarction. The diagnosis is based on the clinical history and radiographic findings. There is frequently a history of gallbladder, biliary tract, or hepatic surgery; a recent angiographic infusion to the involved area; a known hypercoagulable state; or another associated event (Table 41.2). In cases in which the diagnosis is uncertain and the lesion is radiographically atypical in its appearance, an ultrasound-directed biopsy may be useful. The major short-term concern is that the infarcted area will become infected and develop into an hepatic abscess. This is most commonly encountered after embolization of a hepatic tumor (38,58,59). In cases in which abscess formation is suspected broad-spectrum antibiotics should be initiated and needle aspiration of the lesion performed.



▪ **Figure 41.4** Computed tomography scan of a patient with a segmental

hepatic infarct. Note the wedge-shaped region of infarction that extends from the center of the liver to the periphery and the liver capsule.



▪ **Figure 41.5** Magnetic resonance image of a patient who developed an hepatic infarction and ischemic cholangiopathy after an episode of severe acute cholecystitis and cholecystectomy. Note that the area of infarction follows the course of the biliary tree and is associated with dilatation of bile ducts. Hepatic arteriogram (not depicted) demonstrated occlusion of intrahepatic branches of the left and middle hepatic artery corresponding to the area of infarction and cholangiopathy.

Treatment

No specific treatment for hepatic infarction is required. However, if the infarcted area is large the likelihood for abscess formation is increased and such patients should be closely monitored for signs of sepsis and/or treated with empiric antibiotics (58,59). Abscess formation is extremely common in patients who develop hepatic infarction after liver transplantation and is the major reason why such individuals undergo emergent retransplantation (34,35). Patients with massive hepatic infarction and liver failure should be considered candidates for emergent liver transplantation. Finally, if the cause for the infarction is not readily apparent a diagnostic evaluation for a source of emboli or an underlying hypercoagulable state is warranted.

Ischemic Cholangiopathy

The bile ducts receive their blood supply exclusively from branches of the hepatic artery and are therefore more sensitive to alterations in hepatic arterial flow than is the liver parenchyma, which also has a portal blood supply (1). Hepatic arterial injury or occlusion associated with hepatic infarction or profound hypotension associated with ischemic hepatitis frequently causes injury to the biliary ductal system. However, ischemic cholangiopathy may also occur in the absence of hepatic ischemia. Ischemic bile duct injury is most commonly observed after cholecystectomy, biliary tract surgery, hepatectomy, and liver transplantation but may also be caused by any of the etiologies listed in Table 41.2 (60,61,62,63,64).

Ischemic injury to the bile ducts results in the development of biliary strictures. This is commonly accompanied by dilatation of the biliary tree proximal to the lesion. Typically there is only a single focal stricture. However, in some cases the stricture may be quite long or there may be multiple strictures with intervening dilatation. In some cases these strictures may resemble those seen in cholangiocarcinoma or primary sclerosing cholangitis (PSC). However, most ischemic bile duct strictures have a smooth symmetric appearance and are confined to a focal segment of the liver. This is unlike that seen in patients with PSC, in which the strictures tend to be located throughout the liver. The development of an ischemic biliary stricture may be asymptomatic and only recognized when imaging studies are performed to evaluate the liver for an elevation in alkaline phosphatase level. The serum bilirubin level is usually normal. However, a mild to moderate elevation in serum bilirubin level or jaundice may develop if the stricture totally occludes the bile duct or is located in a major large bile duct.

Patients in whom ischemic cholangiopathy is suspected should undergo extensive imaging of the biliary ductal system with either an MR or endoscopic cholangiogram and serologic testing to exclude PSC (see Chapter 23) and/or cholangiocarcinoma (see Chapter 4). Placement of an endoscopic biliary stent or surgical revision of the bile duct is indicated if the bilirubin level is elevated. In an asymptomatic patient, liver biopsy of the involved lobe proximal to the stricture is frequently useful because this can identify histologic changes consistent with bile duct obstruction and patients at risk for developing secondary biliary cirrhosis. Intrahepatic bile duct dilatation and duplication proximal to the stricture has been identified histologically (65). Placement of an endoscopic stent should probably be performed in such patients, although no data currently exists to demonstrate that this reduces the risk for developing biliary cirrhosis. One study in a group of pediatric liver transplant recipients has suggested that the use of ursodeoxycholic acid in addition to stenting may prevent secondary biliary cirrhosis (62). In the liver transplant recipient, hepatic artery thrombosis in the immediate post-transplantation period is associated with extensive stricture formation of the biliary tree, intrahepatic abscess formation, and graft failure and is therefore an indication for emergent retransplantation (34,63). The development of biliary strictures months to years after liver transplantation is best treated endoscopically as in the nontransplantation setting.

Heatstroke and the Liver

Heatstroke is a severe systemic and potentially fatal disorder with a mortality

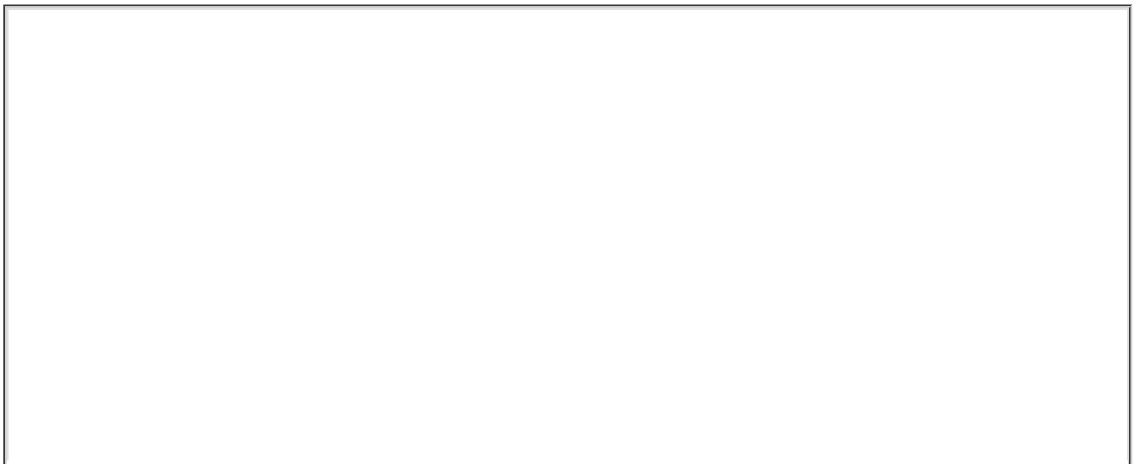
rate approaching 25% (20,66,67). The syndrome is characterized by hyperexia (a body temperature above 41°C), profound hypotension, neurologic impairment, heat-induced tissue injury, sepsis, disseminated intravascular coagulation, and multiorgan failure. The liver is frequently injured by heatstroke; excessive body temperature itself causes hepatic necrosis, and severe hypotension is associated with a superimposed ischemic hepatitis. Serum AT and LDH levels are markedly elevated in patients with heatstroke. However, the elevation in AST level is frequently much greater than the elevation in ALT level because of thermal injury to muscles, the brain, and kidneys (20,66,67). The elevation in serum ALT level is rarely greater than 20 times the upper limit of normal, and bilirubin level frequently remains normal or is only mildly elevated. The peak in serum AT levels, like that observed in ischemic hepatitis, occurs 1 to 2 days after the event. However, as opposed to ischemic hepatitis, serum levels of liver ATs recover much more slowly—over weeks rather than days (20). Elevations in serum ALT levels to values greater than this and/or a progressive rise in serum bilirubin level is associated with high mortality.

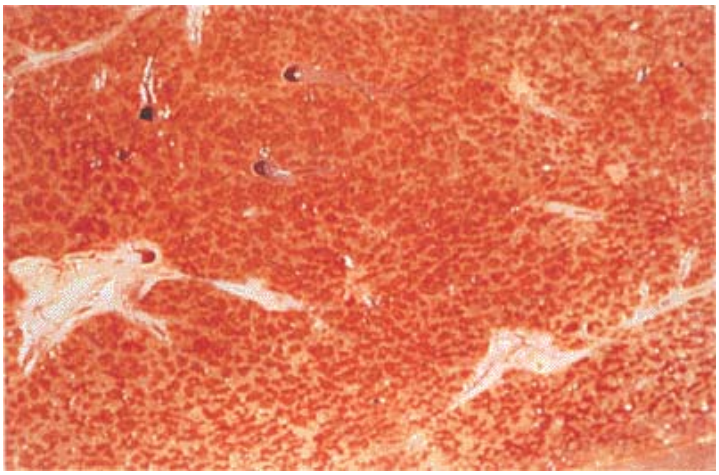
The histologic changes observed in patients with heatstroke consist of zone 3 necrosis, similar to that observed in patients with ischemic hepatitis. However, steatosis, dilatation of hepatic and portal veins, sinusoidal dilatation, and cholangiolar proliferation are also observed (68,69,70). These changes resolve spontaneously and liver histology returns to normal without the development of fibrosis in patients who recover from this insult.

Passive Hepatic Congestion

Passive hepatic congestion occurs in patients with isolated right-sided heart failure or cardiopulmonary

disease associated with a persistent elevation in right atrial pressure (2,4,71). This may include biventricular heart failure secondary to alcoholic or ischemic dilated cardiomyopathy, isolated right coronary artery occlusion and right ventricular myocardial infarction, severe pulmonary hypertension, cor pulmonale, mitral stenosis, and various forms of congenital heart disease. Passive hepatic congestion may also develop in patients with hypertensive restrictive cardiomyopathy and end-stage renal failure. All patients with passive hepatic congestion have elevated central venous pressure, which is transmitted backwards through the hepatic veins, to the central veins of the hepatic acinus, and into the sinusoids of the hepatic lobule. Chronic liver injury resulting from this process is referred to as *congestive hepatopathy*. Over time this process may lead to cardiac fibrosis or cardiac cirrhosis.





▪ **Figure 41.6** Gross appearance of the cut surface of the liver in a patient with passive hepatic congestion. The characteristic appearance is of a "nutmeg" liver, small reddish areas surrounded by paler areas.

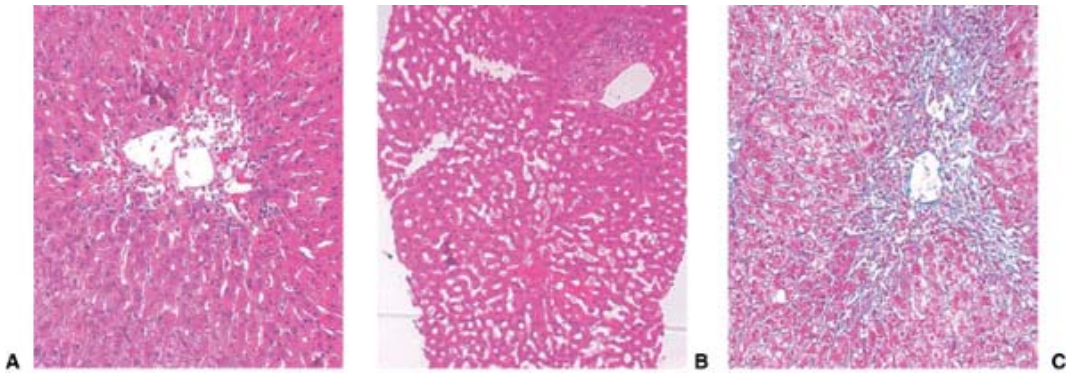
Pathophysiology

Evidence of congestive hepatopathy can be seen on gross pathologic examination of the liver. The liver is enlarged and appears congested and purplish with prominent hepatic veins. The cut surface of the liver reveals the classic description of "nutmeg liver" (Fig. 41.6); reddish central areas correspond to central vein congestion and hemorrhage into zone 3 of the hepatic lobule, surrounded by pale or yellowish areas representing zones 1 and 2 that are either histologically normal or contain fatty change. Microscopic examination reveals prominent central veins, central vein hemorrhage, dilated sinusoids, and hemorrhagic necrosis within zone 3 (2,72). Variable degrees of fibrosis may be seen circumscribing central veins (Fig. 41.7). Over time bridging fibrosis may extend between central veins, and this will eventually progress to form cirrhotic nodules. Histologically, this form of cirrhosis is unique compared to that resulting from all other forms of chronic liver disease in which portal-to-portal fibrosis occurs. In some cases, regeneration of periportal hepatocytes within zone 1 may yield discrete nodules lacking surrounding fibrosis. Such nodules do not represent cirrhosis and are referred to as regenerative nodular hyperplasia (see Chapter 42).

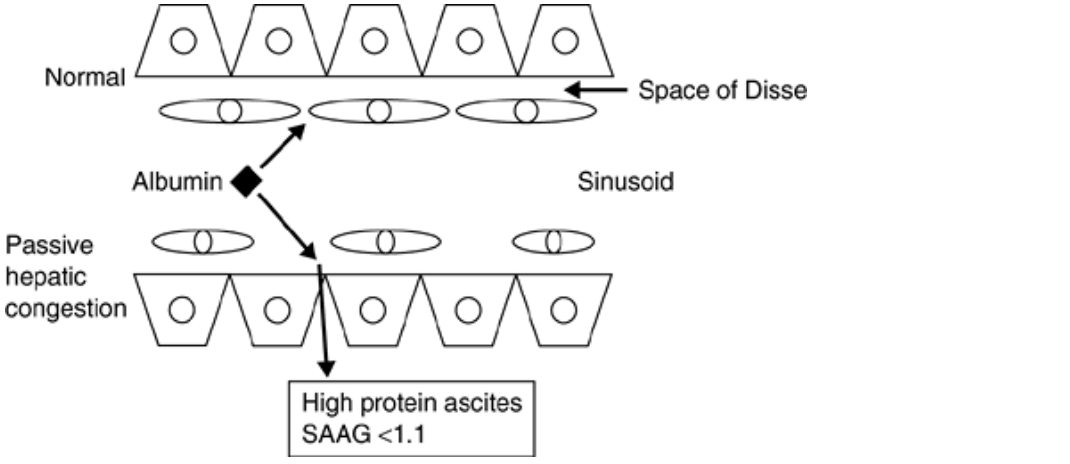
Chronic passive congestion of the hepatic lobule leads to a series of pathophysiologic alterations that causes cardiac cirrhosis and ascites formation and that renders zone 3 hepatocytes more susceptible to ischemic injury (72). When exposed to high pressure, as occurs with passive congestion, sinusoidal fenestrae enlarge and this allows large amounts of protein-rich fluid to enter the space of Disse (1). Accumulation of fluid within the space of Disse is typically drained by hepatic lymphatics. But when the capacity to drain hepatic lymph is

exceeded by the hemodynamic forces associated with passive congestion, high protein–containing fluid within the space of Disse leaks into the peritoneal cavity and produces high-protein ascites (Fig. 41.8) (4,73). Chronic passive congestion also leads to sinusoidal fibrosis that impairs the diffusion of nutrients and oxygen

across the space of Disse and into zone 3 hepatocytes, and it is this process that appears to increase the susceptibility of zone 3 hepatocytes to hypoxic injury in patients with coexistent left ventricular cardiac dysfunction. There appears to be no correlation between the elevation in right atrial pressure and the severity of liver injury in patients with passive hepatic congestion (2). In addition, zone 3 necrosis is rarely, if ever, seen in patients with isolated right ventricular failure in the absence of left ventricular failure and hypotension (3,24,28). It is therefore apparent that although patients with passive hepatic congestion may develop progressive fibrosis, cirrhosis, and ascites, hepatic function in patients with passive congestion is generally well preserved and liver-related mortality is rare except in the setting of coexistent left ventricular failure, hypotension, and hepatic ischemia.



▪ **Figure 41.7** Microscopic appearance of the liver with passive hepatic congestion. **A:** Congestion, dilatation, and hemorrhage at the central vein. **B:** Dilatation of sinusoids radiating outward from the central vein and sinusoidal fibrosis. **C:** Fibrosis of the central vein with extension of fibrosis radiating outward along hepatic sinusoids.



▪ **Figure 41.8** Schematic drawing of the pathophysiologic mechanisms

involved in the formation of ascites in patients with passive hepatic congestion. The normal hepatic sinusoid (*top half*) is lined with sinusoidal epithelium containing small fenestrae. In patients with passive hepatic congestion (*lower half*) the elevated hepatic venous pressure causes the sinusoidal epithelial fenestrae to increase in size. Large amounts of albumin and other plasma proteins enter the space of Disse, pass through hepatocyte junctions, and form ascites containing a high concentration of protein and a low serum to ascites albumin gradient (SAAG).

Clinical Features and Outcome

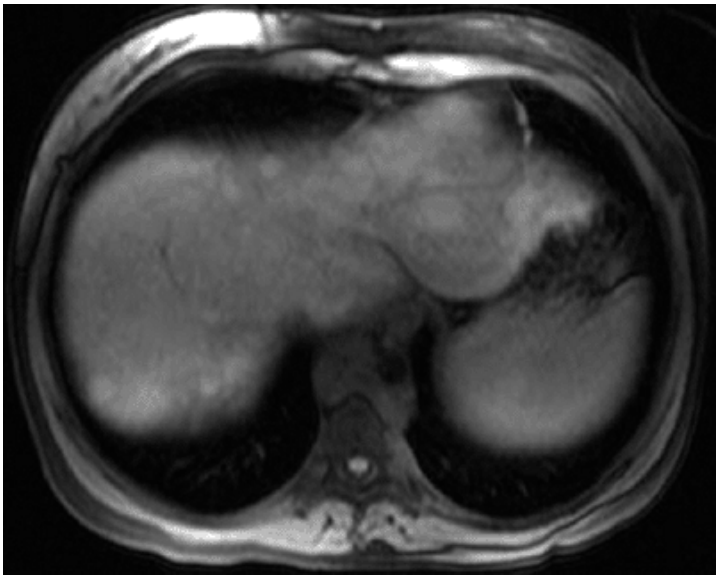
Patients with passive hepatic congestion are typically identified in one of three ways: They are asymptomatic and are found to have mild abnormalities in serum liver chemistries, a mild elevation in total bilirubin, or a mild prolongation in the INR; they present with symptoms of hepatic congestion, usually a dull ache in the right upper quadrant; or they present for evaluation of ascites. At the time of presentation, patients may already be known to have right ventricular failure or the accompanying cardiac disease may not have been appreciated. Regardless of the presentation, physical findings of right ventricular failure and passive hepatic congestion can be found. The most common of these include jugular venous distension, hepatomegaly, and hepatojugular reflux. In patients with marked tricuspid insufficiency, presystolic pulsations may be felt through the liver (74). Lower extremity edema may be absent in patients with isolated right ventricular failure but is typically present in patients with biventricular failure.

Laboratory studies may demonstrate mild elevations in the levels of serum liver AT, alkaline phosphatase, and bilirubin, although each of these chemistries may also be within the limits of normal. When an elevation in total bilirubin level is present, it is frequently the unconjugated fraction (4). In addition, the increase in serum bilirubin level appears to correlate with the severity of passive congestion and the elevation in right atrial pressure (2). In some patients with severe acute right ventricular failure and marked elevations in right atrial pressure the total bilirubin level may approach 20 mg/dL. Serum albumin level is typically normal or only slightly reduced. The most consistent abnormal laboratory value in patients with passive hepatic congestion is the INR, which is almost always prolonged to approximately 1.5. Serum ammonia level may be elevated in some patients but is only rarely associated with symptoms of hepatic encephalopathy (75). In patients with biventricular failure, episodes of hypoperfusion and hypoxia secondary to exacerbations of left ventricular failure may lead to more severe or abrupt abnormalities in serum liver chemistries.

Echocardiography findings are frequently abnormal and may demonstrate right ventricular contraction defect, tricuspid insufficiency, and/or an elevation in pulmonary arterial pressure. Hepatic ultrasound demonstrates hepatomegaly and diffuse increased echogenicity throughout the liver. Reversal of flow in the hepatic veins may be seen with Doppler ultrasonography. Contrast-enhanced CT scan and MR imaging demonstrate a heterogeneous appearance of the liver parenchyma (76). This is consistent with the gross “nutmeg” appearance of the liver that results from intervening areas of central vein hemorrhage and preserved portal blood flow (Fig. 41.9). Enlargement of the hepatic veins may also be present.

Ascites is a frequent finding in patients with passive hepatic congestion and this typically occurs in the absence of cirrhosis. The ascitic fluid contains a high concentration of protein, typically greater than 2.5 g/dL with a serum to ascites albumin gradient (SAAG) of less than 1.1 (77). When cardiac cirrhosis has developed from long-standing passive hepatic congestion, the SAAG usually remains below 1.1 but may approach or exceed this value, particularly in patients in whom a

coexistent underlying liver disorder has contributed to the development of cirrhosis. It is therefore helpful to assess liver histology in a patient with passive hepatic congestion, even in those with a low SAAG. Because it is difficult to perform percutaneous liver biopsy in most patients with ascites, a biopsy may need to be performed through the transjugular approach. In such patients, measuring hepatic venous pressure and calculating the hepatic venous pressure gradient (HVPG) is an excellent complementary way to help determine whether ascites is secondary to chronic passive congestion or is caused by a secondary liver disorder that has led to the development of cirrhosis. In patients with passive hepatic congestion both the free and wedged hepatic venous pressures are elevated and the HVPG is normal. This may also be true for patients with cardiac cirrhosis. In contrast, patients with passive congestion and cirrhosis, but who develop cirrhosis from another underlying chronic liver disease (i.e., chronic viral or nonviral hepatitis), will not only have an elevated free hepatic venous pressure but also an elevated HVPG.



▪ **Figure 41.9** Magnetic resonance image of a patient with severe pulmonary hypertension, right ventricular failure, tricuspid regurgitation, and jugular venous distension. Note the mottled appearance of the liver parenchyma that corresponds histologically to centrilobular areas of passive congestion with intervening areas of preserved portal blood flow.

Patients with passive hepatic congestion typically have stable hepatic function for prolonged periods, even with the presence of ascites and even after they have developed cardiac cirrhosis (2). Esophageal varices are rarely present even in

patients who have developed cardiac cirrhosis. The long-term mortality associated with passive hepatic congestion is therefore dictated by the mortality associated with the underlying cardiac disease; this is considerably reduced in patients with biventricular failure. Acute liver failure and liver-related mortality is only observed in those patients with biventricular failure in whom episodes of left ventricular failure lead to hypotension and a superimposed ischemic hepatitis (21,27,78).

Treatment

The treatment for passive hepatic congestion is to improve forward cardiac output. This is associated with an improvement in serum liver chemistries and a reduction in ascites formation. Ascites should be treated with diuretics. However, excessive use of diuretics could lead to dehydration, hypotension, and hepatic ischemia (78). Paracentesis should not be performed repeatedly as a treatment for refractory ascites in patients with passive hepatic congestion because this leads to severe protein loss and accentuates protein malnutrition owing to the high protein content of the ascitic fluid. Placement of a TIPS is contraindicated in the treatment for refractory ascites in this setting (79). This stent would provide a direct communication between the high-pressure central venous system and the portal system, lead to a marked increase in portal hypertension, and may precipitate massive variceal hemorrhage. Placement of a peritoneal–venous shunt is also contraindicated. In the setting of cardiac failure the delivery of additional volume to the heart is likely to exacerbate the underlying cardiac disease. In addition, the high pressure within the jugular vein of these patients will typically prevent flow of ascites from the lower-pressure abdominal cavity. Finally, the protein content of the ascitic fluid in patients with passive congestion tends to occlude the peritoneal–venous shunt within a relatively short period.

Several medications should be avoided or used with extreme caution in patients with passive hepatic congestion. These patients are extremely sensitive to warfarin (Coumadin); they have a baseline prolongation of INR, and this increases substantially when even very low doses of warfarin (Coumadin) are administered. Furthermore, acute exacerbations in cardiac failure will result in a marked prolongation in INR even in patients in whom this was previously well controlled. Patients with hepatic congestion also metabolize drugs more slowly. As a result, these patients are susceptible to toxicity from any drug that is metabolized by the liver and in cases in which an elevation in the blood level of the native drug may cause side effects.

Constrictive Pericarditis

Constrictive pericarditis produces clinical and pathologic changes similar to those observed in the Budd-Chiari syndrome (see Chapter 40). Indeed, it has been suggested that the original patient described by Budd actually had constrictive pericarditis as opposed to hepatic vein thrombosis (80). Constrictive pericarditis is

associated with marked elevations in central venous pressure that are sufficient to cause both zone 3 hemorrhage and necrosis. Cirrhosis develops much more rapidly in patients with constrictive pericarditis than in other forms of passive congestion. The physical examination is characterized by marked jugular venous distension that arises during inspiration (Kussmaul's sign), a pericardial knock, massive hepatomegaly, massive ascites, and peripheral edema. Liver AT levels

are variably elevated but jaundice is frequently absent (80,81). All signs and symptoms resolve after pericardiectomy.

Congenital Heart Disease

Congenital heart disease represents a wide spectrum of cardiopulmonary abnormalities that most commonly become apparent shortly after birth or within the first few years of life. Both passive hepatic congestion and/or hepatic ischemia can be seen in these children, the severity of which is determined by the particular cardiac anomaly present. As in adults, children with biventricular failure and both passive hepatic congestion and a low cardiac output state associated with hypotension and intermittent ischemic hepatitis develop the most severe liver injury and have the highest mortality. This is most commonly observed in children with hypoplastic left ventricle, coarctation of the aorta, and transposition of the great vessels (82,83,84). Major advances in the surgical treatment of congenital heart disease have significantly reduced early mortality in these infants and children. As a result, many now reach adulthood and develop side effects related to long-standing passive hepatic congestion (85).

Patients with passive hepatic congestion secondary to congenital heart disease present in a similar manner as other patients with this hepatic disorder. They are found to have abnormal liver chemistries or ascites. Their evaluation and management is likewise similar. However, many of these patients may also be found to have concomitant hepatitis C virus (HCV) infection from blood products they received at the time of cardiac surgery (86). In this situation, the underlying heart disease should not be considered an absolute contraindication for treatment of chronic HCV if indicated. As patients with congenital heart disease grow and reach adulthood, some may develop worsening heart failure and require cardiac transplantation (87). Passive congestion even with cardiac ascites should not be considered a contraindication to proceeding with cardiac transplantation as long as cirrhosis is absent. A complete evaluation of liver function, histology, and hemodynamics, to include the HVPG, should therefore be undertaken in patients with congenital heart disease who are being considered candidates for cardiac transplantation.

Chapter 42
Benign Solid Tumors

Arie Regev

Key Concepts

- Benign solid lesions of the liver are detected with increasing incidence due to the frequent use of imaging studies of the abdomen. They are usually found incidentally in patients with no liver disease.
- Hemangioma of the liver is the second most common benign focal hepatic lesion (simple cyst being the most common one) and the most common *solid* hepatic tumor (1% to 7.4% of the normal population). It is rarely of significant clinical consequence.
- Focal nodular hyperplasia (FNH) is less common than hemangioma (0.4% of the normal population) and only rarely poses any significant risk.
- There is rarely an indication for a surgical intervention in patients with a hemangioma, FNH, or most other benign solid lesions.
- In contrast to hemangioma and FNH, hepatic adenoma is a rare tumor (0.004% of the normal population), which may cause significant morbidity from bleeding, rupture, or malignant transformation, and usually requires surgical resection.
- There is a strong association between hepatic adenoma and oral contraceptives (OCPs), and a history of prolonged use of OCPs should be sought in every woman with a focal hepatic lesion.
- A strong relationship to OCPs has not been unequivocally shown for hemangioma or FNH, although this issue remains controversial.
- A focal lesion in a patient with cirrhosis should not be regarded as benign and should be considered a malignancy until proved otherwise.

Benign focal lesions of the liver are found with increasing incidence because of the frequent use of imaging studies of the abdomen. They represent a relatively common reason for referral to the hepatologist or gastroenterologist. Most benign lesions are detected incidentally by imaging studies performed for unrelated reasons. Technical advances in imaging modalities have led to the identification of smaller lesions that until recently were not detected. Many of the lesions that present as a focal liver mass are true neoplasms, while others result from reactive proliferation of different cells. In general, benign tumors of the liver may arise from hepatocytes, bile duct epithelium, the supporting mesenchymal tissue, or a combination of two or more of these (Table 42.1).

Although most patients with benign hepatic tumors are asymptomatic, a minority may present with symptoms that may be local or systemic. In these patients, the relationship between the symptoms and the hepatic lesions may be difficult to

correlate, and additional workup is necessary to rule out other causes for the patients' complaints. In most cases patients with benign hepatic lesions have no preexisting liver disease, and the finding of a coexisting chronic liver disease such

as chronic hepatitis B, hemochromatosis, or cirrhosis should raise a suspicion for a malignant tumor. A conclusive diagnosis of a focal hepatic lesion is essential because it may represent a primary or secondary malignancy, which may require immediate treatment. In addition, some benign lesions carry specific risks such as rupture, bleeding, malignant transformation, consumptive coagulopathy, and disseminated intravascular coagulation. Focal solid hepatic lesions often represent a diagnostic challenge for the clinician and frequently mandate extensive evaluation. They may be difficult to characterize and at times impossible to differentiate from malignant tumors by the clinical presentation. Nevertheless, the importance of a detailed history and physical examination in the assessment of a patient with a newly discovered focal liver lesion cannot be overemphasized. Often the clinical presentation provides important clues to a specific diagnosis and suggests whether the tumor is benign or malignant. Still, in many cases the clinical information and the first imaging study are nondiagnostic and the clinician must choose additional studies from an ever-increasing number of available options. Despite continuing advancement in sensitivity and accuracy, imaging studies fail to yield conclusive diagnosis in a sizable number of patients, and in these cases histopathologic assessment is necessary to characterize the lesion. A tissue sample may be obtained by an ultrasonography or computed tomography (CT)-guided percutaneous liver biopsy or by a laparoscopic liver biopsy. Histopathologic evaluation remains essential in the clinical management of a significant number of tumors or masses in the liver; possible exceptions include hemangioma, focal nodular hyperplasia (FNH), and focal fatty change, which may be unequivocally diagnosed by imaging studies. Unfortunately, in some benign lesions (e.g., hemangioma and hepatic adenoma) liver biopsy carries a high risk of bleeding and is therefore contraindicated. A fundamental knowledge of the various lesions and their characteristic features should help in the differential diagnosis.

Table 42.1. Benign Solid Tumors of the Liver

EPITHELIAL TUMORS
Hepatocellular adenoma
Bile duct adenoma
Biliary cystadenoma
MESENCHYMAL TUMORS
Hemangioma
Infantile hemangioendothelioma
Fibroma
Angiomyolipoma
Lipoma
Lymphangioma
Benign mesenchymoma
MIXED TUMORS
Teratoma
TUMOR-LIKE LESIONS
Focal nodular hyperplasia
Nodular regenerative hyperplasia
Mesenchymal hamartoma

Microhamartoma (von Meyenburg complex)
Inflammatory pseudotumor
Focal fatty change
Pseudolipoma
Macroregenerative nodule

Focal Nodular Hyperplasia

Epidemiology

FNH is a benign tumor-like lesion of unclear etiology. It is the second most common benign solid mass of the liver (after hepatic hemangioma), and its incidence has been reported between 0.31% and 0.6% (1,2). It is diagnosed predominantly in adult women but has also been reported in men (female-to-male ratio of approximately 8:1) and children. In most cases, it is an incidental finding on abdominal imaging or surgery performed for unrelated reasons. FNH is solitary in most cases and is located in the right lobe more often than in the left (3). Two or more lesions are encountered in approximately 20% of the patients and a distinct minority may have more than five lesions (3,4,5). The size may range from 1 mm to more than 20 cm; however, most (64%) are smaller than 5 cm in diameter (3). Although many of the patients may have a history of oral contraceptive (OCP) use (6), the association of FNH with OCPs is controversial. Some authors have suggested increased prevalence and increase in size in women who use OCPs (7), but most studies found no relationship between estrogens and the size or number of FNH (8). Although these are two distinct lesions, there are rare reports of FNH coexisting with hepatic adenoma (9,10).

Pathogenesis

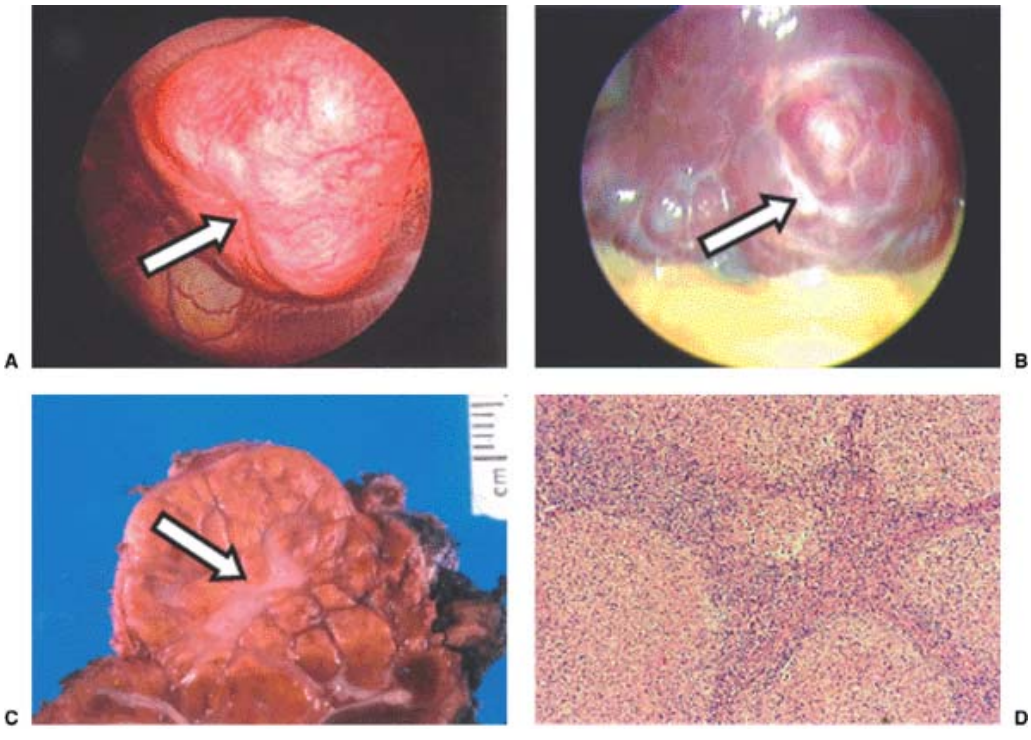
FNH is considered to be hyperplastic rather than neoplastic in origin, although its exact pathogenesis remains a matter of controversy. It typically occurs in the background of a healthy liver. It is believed by many to be a hyperplastic response to a preexisting vascular anomaly in the location of the lesion. According to this theory, the initial injury may be arterial malformation, which leads to increased arterial blood flow to a specific region compared to the adjacent parenchyma, which in turn leads to high sinusoidal pressure, resulting in hepatocellular hyperperfusion. This may be followed by local angiogenesis, leading to hyperplasia and causing the typical arterial branching in the center of the FNH (1). A recent report of FNH diagnosed in the same hepatic segment in identical twins supports the theory of a congenital anomaly being an initial event in the

pathogenesis of this lesion, at least in some patients (11). Because of the female predominance, a link with OCPs has been postulated; however, this relationship remains debatable. Some studies and case reports have suggested that the development of the vascular malformation or the growth of the FNH may be influenced by estrogen; however, this has never been unequivocally proved

(7,12,13). In contrast, other clinical studies have found no association between the use of OCP or pregnancy and FNH. One retrospective study found no such association in 216 women with FNH (8). Most FNHs are supplied by a single artery, which is typically enlarged. In contrast to the usual situation, this artery is not accompanied by a portal vein or a bile duct. In some cases, the FNH is predominantly supplied by the portal vein (13), which may result from thrombosis of the central artery in large lesions. Although some reports suggested that FNH may be a clonal lesion on the basis of a uniform pattern of X-chromosome inactivation (14,15), others have shown it to be of a clear polyclonal nature (16). Recently, several authors suggested a causal relationship between systemic cytotoxic chemotherapy (usually alkylating agents such as busulfan or melphalan) and subsequent development of FNH in adults and children (17,18). Injury to the intrahepatic vascular endothelium with ensuing localized circulatory disturbances was postulated as a possible mechanism.

Pathology

The typical macroscopic appearance is of a firm, nodular, mass with a dense central stellate scar and radiating fibrous septa that divide the lesion into lobules of various size (6,19,20) (Fig. 42.1A–C). The lesion is sharply demarcated from the surrounding liver tissue but has no true capsule. The central scar is clearly seen macroscopically in approximately 50% of the cases (3); however, in some of the cases it is absent and the fibrous septa may be poorly developed. The lesion is light brown or yellowish gray and usually occupies a superficial position. The average size is 5 cm and the lesion uncommonly exceeds 10 cm in diameter. Occasionally, it is exophytic or pedunculated. Larger lesions may have foci of hemorrhage or necrosis.



▪ **Figure 42.1** Focal nodular hyperplasia (FNH). **A** and **B:** Laparoscopic appearance of FNH. Both images show protruding lesions with central depressions *(arrows)* corresponding to central scars. **C:** Cut surface of a resected specimen of FNH showing a central scar *(arrow)* and cirrhosis-like appearance. **D:** Low-power view of an FNH shows a central fibrous scar, with

fibrous septa forming nodule-like structures.

Microscopically, FNH closely resembles the cirrhotic liver because the fibrous septa create a picture that is similar to that of regenerative nodules (Fig. 42.1D). The differentiation may be difficult in the absence of clinical information. However, a confident diagnosis of FNH can be made with a needle biopsy if the sample is known to come from a mass. The hepatic parenchyma between the septa may include all the components of normal liver including cords of hepatocytes, sinusoids, and Kupffer cells; however, it often lacks the normal liver architecture and may be devoid of central veins and portal tracts (6,20,21,22). Features of chronic cholestasis with accumulation of copper (demonstrated by rhodanine stain) and copper-binding protein (demonstrated by Victoria blue stain) are common (22). The Kupffer cells are usually active and show normal uptake of technetium-99m (^{99m}Tc) sulfur colloid, which is different from most cases of hepatic adenomas. Characteristically, the fibrous septa contain numerous bile ductules and blood vessels, as well as chronic inflammatory cells that may form a dense infiltrate. Branches of the hepatic artery and portal vein may show intimal and smooth muscle hyperplasia with thickening of their walls (6,20,21,22).

Telangiectatic FNH is considered an atypical variant of FNH in which the central scar is replaced by a telangiectatic lesion with radiating septa (13,23,24). This rare subtype is more likely to be symptomatic as a result of hemorrhage and necrosis. Recently, it has been suggested that telangiectatic FNH may be closer to hepatic adenoma and should be referred to as *telangiectatic hepatocellular adenoma* (23). Another rare subtype is mixed adenomatous and hyperplastic FNH (3,9).

Clinical Manifestations and Natural History

In most of the cases, FNH is asymptomatic and detected incidentally on imaging studies performed for unrelated reasons or during surgery. Hepatic biochemical tests are typically normal and the serum level of α-fetoprotein is not elevated.

Abdominal discomfort may be the presenting symptom in a minority of patients (25,26). Abdominal pain is rare and should prompt an evaluation for other causes. Early reports have suggested that women taking OCPs were more likely to be symptomatic (27,28) but this has not been supported by reported in later publications. Some patients may present with hepatomegaly, abdominal mass, or abdominal tenderness but most (approximately 85%) will have normal findings in the physical examination (3). Sudden abdominal pain may be related to rupture or bleeding that is distinctly rare (29,30). The association of rupture with OCPs, although suggested by early studies, remains doubtful (27,29,30,31,32,33). Fibrolamellar hepatocellular carcinoma (HCC) may be mistaken for FNH (34) or may occur in the same liver (35). However, malignant transformation has not been unequivocally described in FNH, and there is no evidence that FNH it is a precursor of HCC or fibrolamellar carcinoma. This is in contrast to hepatic adenoma in which malignant transformation has been well documented.

The prognosis of patients with FNH is almost invariably excellent. Most patients remain asymptomatic and exhibit no significant changes in lesion size over time (36). Occasionally, FNH may regress (37,38) and only a small minority (<10%) may show some increase in size (38). Any significant increase in size should therefore prompt an evaluation for another diagnosis such as HCC or fibrolamellar carcinoma.

Imaging Studies

In most imaging studies, the typical appearance of FNH is related to the characteristic central scar, the hypervascularity, and the distinctive arterial blood supply, which begins in the center of the lesion with peripheral ramification in a spoke wheel pattern (39).

Standard ultrasonography is highly sensitive but nonspecific for the diagnosis of FNH. It usually demonstrates the lesion as a well-demarcated nodular mass but is frequently nondiagnostic (37,40). Ultrasonography detects the central scar in approximately 20% of the cases (41), although the addition of Doppler imaging may reveal arterial signals within the lesion in other cases (42). Power Doppler imaging has been reported to increase the rate of detection of the feeding artery from 22% to nearly 90% (43); however, arterial signal within the lesion may also be seen in malignant lesions. Ultrasonography–Doppler is therefore insufficient as a single modality to make the diagnosis of FNH.

Contrast-enhanced harmonic sonography (*CEHS*) has recently been demonstrated to show the typical spoke wheel pattern of the central arteries during the vascular phase in more than 90% of individuals with FNH (44). In addition, it produces a typical pronounced enhancement during the hepatic arterial phase and the early portal-venous phase that may help differentiate it from hepatic adenoma (45). This technique, which is based on the injection of a microbubble contrast agent, has been used for various focal liver lesions and may be a promising modality for the diagnosis of FNH.

CT scan should always be used in the multiphase contrast-enhanced mode for the evaluation of a possible FNH. The enhancement pattern may be helpful in suggesting the diagnosis or ruling it out (46,47,48). On precontrast images, FNH can be hypodense or isodense to the surrounding normal liver parenchyma. It is typically

hyperdense on arterial phase images (20 to 30 seconds after contrast injection) (Fig. 42.2A–C), becoming less prominent on portal-venous phase images (70 to 90 seconds) (Fig. 42.2D), and may become completely isodense (41,49). A central scar is seen in 43% to 60% of cases (50). It is typically hypodense on the precontrast and the arterial phase (Fig. 42.2A–C), becoming hyperdense on the portal-venous phase (Fig. 42.2D) (49). The scar may remain hyperattenuated on the delayed images because of slow washout of the contrast from the myxomatous tissue, but in contrast to hemangiomas FNH does not exhibit venous pooling (51,52). Occasionally, FNH may show imaging characteristics suggestive of a primary or metastatic malignancy. These may include the absence of a central scar, rapid washout, calcifications, or the presence of a capsule (53). Dynamic CT during hepatic arteriography has been shown to be helpful in such questionable situations because it clearly demonstrates the centrifugal blood supply through the fibrous stellate scar (54). However, CT arteriography has largely been replaced by advanced noninvasive imaging methods. The use of three-dimensional volume-rendered CT angiography (CTA) may demonstrate the characteristic anomalous feeding artery and may be helpful in distinguishing FNH from other lesions (55). Calcifications have been reported in 1.4% of 295 patients with FNH (34). This finding raises the suspicion of fibrolamellar carcinoma and usually mandates a surgical exploration to rule out this diagnosis.

▪ **Figure 42.2** Focal nodular hyperplasia (FNH). **A:** Arterial phase of a contrast-enhanced computed tomography (CT) scan shows an enhanced lesion protruding from the left hepatic lobe, with a nonenhancing central scar *(arrow)*. **B:** Arterial phase of a contrast-enhanced CT scan shows an enhanced lesion in the right hepatic lobe (segments 5 and 6), with a nonenhancing central scar *(arrow)*. **C:** Arterial phase showing enhanced lesion in segment 6 *(arrow)* with a central scar. **D:** Portal-venous phase shows the same lesion *(arrow)*, which is now mildly hypodense, but still showing the central scar.

Magnetic resonance imaging (*MRI*) usually shows FNH as a homogenous lesion that is isointense to mildly hypointense on T1-weighted images and isointense to slightly hyperintense on T2-weighted images. The margins are usually not well defined and the central scar may be identified by T2-weighted images in approximately 50% of the cases (49,52,56,57,58). On gadolinium-enhanced imaging, the lesion shows an early homogenous enhancement in the arterial phase and becomes isointense or slightly hyperintense compared to the surrounding liver in the venous and delayed phases. The central scar shows slowly progressive enhancement, which becomes maximal on delayed images. This characteristic appearance may differentiate FNH from malignant hypervascular tumors (59) and has a sensitivity of 70% to 80% and specificity of

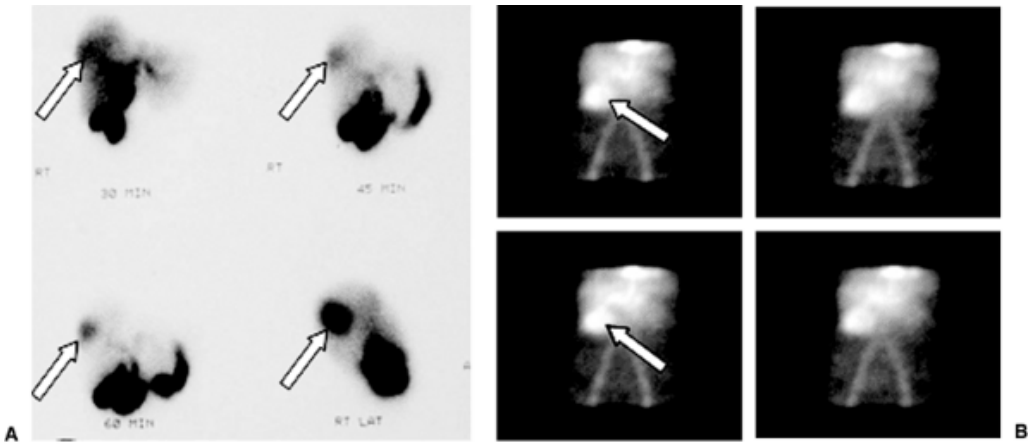
98% in lesions that are larger than 2 cm in size. Another distinguishing feature on gadolinium-enhanced images is the lack of capsule enhancement that is commonly seen in adenomas and HCCs. Small FNH (<1 to 2 cm) may appear more uniform in enhancement and the central scar may not be perceived.

Despite the distinguishing features, fibrolamellar carcinoma may look similar to FNH on imaging studies. Fibrolamellar carcinoma is typically larger, usually over 10 cm, at presentation. Its central scar frequently shows lower intensity than the surrounding tumor on T2-weighted images (in contrast to the higher signal produced by the central scar in FNH), with radiating enhancing bands on postgadolinium

images. Three-dimensional gadolinium-enhanced MR angiography (MRA) may increase the accuracy of the test for the diagnosis of FNH by demonstrating the characteristic vessels radiating from the center to the periphery of the lesion (the so-called star sign) (60). The use of liver-specific MRI contrast agents (i.e., reticuloendothelial and hepatobiliary agents) offers greater lesion-to-liver contrast than the conventional extracellular contrast agent, gadolinium chelate, which has a nonspecific distribution (57,61). These agents may be helpful in a small fraction of cases that remain ambiguous. Administration of superparamagnetic iron oxide (SPIO) particles, which undergo phagocytosis by Kupffer cells, may help distinguish benign from malignant lesions (62,63,64,65). Serial use of different liver-specific contrast agents such as gadolinium 1,4,7,10-tetraaza-dodecane-1,4,7,10-tetraacetic acid (Gd-DOTA) followed by SPIO and gadolinium ethoxybenzyl diethylenetriaminepentaacetic acid (Gd-EOB-DTPA) may further increase the specificity of MRI for FNH (66). Unlike SPIO, Gd-EOB-DTPA is taken up by the hepatocytes and is excreted through the biliary system (67). Recently, the use of the hepatocyte-selective contrast agent gadobenate-dimeglumine (Gd-BOPTA) has been shown to improve the differentiation between FNH and adenoma with a sensitivity of 80% and specificity of more than 96% (68,69).

^{99m}*Tc sulfur colloid scintigraphy* is currently used less commonly by most centers for the diagnosis of FNH (49,61). FNH takes up ^{99m}Tc sulfur colloid at the same or greater rate compared to the surrounding liver parenchyma in 50% to 70% of patients. Hyperconcentration of the colloid by the lesion (Fig. 42.3A) is uncommon (approximately 7%) but is considered typical of FNH because of the highly active Kupffer cells within the lesion (70,71). Nevertheless, the reliability of this modality is poor in lesions smaller than 3 to 4 cm in size. Single photon emission computed tomography (SPECT) has a greater sensitivity compared with planar scintigraphy (72); however, lesions smaller than 2 cm in size are detected in only 11% to 45% of the cases (73). Scintigraphy with specific agents has been shown to improve the specificity of the test. The hepatocytes receptor ligand ^{99m}Tc-galactosyl-neoglycoalbumin (^{99m}TcNGA) has shown normal or increased uptake by FNH compared to the normal liver and, with concurrent use of SPECT, was useful in the differential diagnosis of FNH and malignant hepatic tumors (74). Scintigraphy with ^{99m}Tc-labeled derivatives of iminodiacetic acid (IDA) may also show a characteristic hyperconcentration (73). Combinations of scintigraphy, ultrasonography, and

contrast-enhanced CT scan or MRI have yielded a sensitivity of 82% to 90% and a specificity of 90% to 97% for the diagnosis of FNH (38,75,76).



▪ **Figure 42.3** Focal nodular hyperplasia (FNH) and hepatic hemangioma. **A:**

FNH—^{99m}Tc sulfur colloid liver scan demonstrates a focal lesion with enhanced uptake in the right hepatic lobe *(arrows)*. **B:** Hemangioma—tagged red blood cells (^{99m}Tc pertechnetate-labeled red blood cells [^{99m}Tc-RBC]) study in a patient with a single large hemangioma in the right hepatic lobe showing increased concentration of the isotope within the lesion *(arrows)*.

Positron emission tomography (PET) scan using ^{l8}F-fluorodeoxyglucose (^{18}F-FDG) has been shown to be helpful for the differentiation of FNH from liver metastases in patients with cancer (77). Whereas in malignant liver lesions the accumulation of ^{18}F-FDG is typically increased because of increased glucose metabolism, FNH lesions show normal or even decreased accumulation of ^{18}F-FDG (77,78). Although PET scan is not specific for FNH, it may be helpful when radiologic methods are not diagnostic.

Angiography is used infrequently because of the advances in noninvasive imaging methods. FNH typically appears as a highly vascular mass with an intense capillary blush (6,71). The central feeding artery is seen in approximately 60% of the cases. Hepatic arteriography has been used in combination with dynamic CT for the diagnosis of FNA. This combined technique may clearly demonstrate the characteristic centrifugal blood supply through the fibrous stellate scar even in small lesions (54). Occasionally, angiography is used before surgery as part of the preoperative evaluation.

Diagnosis

The diagnosis of FNH may be a complex and challenging process for the clinician.

The differential diagnosis includes numerous types of focal lesions, some of which may appear indistinguishable from FNH on initial workup (Tables 42.1 and 42.2). Malignant tumors such as HCC, fibrolamellar carcinoma, intrahepatic cholangiocarcinoma, and vascular hepatic metastases should be ruled out as early as possible (49). Typically, the patient with FNH will be asymptomatic and present with normal hepatic biochemical test results. Significant symptoms and any abnormality in the liver biochemistry should raise the suspicion of a neoplastic lesion. FNH is characteristically stable in size, whereas malignant lesions such as HCC may show growth on consecutive imaging studies.

Hypervascular metastases usually present in older individuals with a history of malignancy. They do not have a central scar and are typically hypodense

with a ring enhancement on the vascular phase of enhanced CT scan (79). HCC may show vascular invasion, lymphadenopathy, and metastases, which are all characteristic of a malignant lesion rather than FNH. HCC commonly shows a peripheral capsule on the delayed phases of contrast-enhanced CT scan or MRI (80); however, rim enhancement may occasionally be seen in FNH as well. In fibrolamellar carcinoma a central scar is seen in as many as 55% of cases, making the differential diagnosis from FNH extremely difficult. The appearance of calcifications should also alert the clinician to the possibility of fibrolamellar carcinoma rather than FNH. Central necrosis or hemorrhage may be seen in fibrolamellar carcinoma, hepatocellular adenoma, and HCC and may be confused with a central scar. MRI can usually assist in differentiating the central scar of FNH from necrosis or hemorrhage. The central scar typically appears hyperintense on T2-weighted images, whereas necrosis and hemorrhage appear hypointense. PET scan with ^{18}F-FDG may assist in the differential diagnosis from malignant lesions because FNH shows no increase in glucose metabolism, in contrast with many malignant tumors (77). Large

hemangiomas may have a central scar due to a previous hemorrhage or fibrosis. However, they exhibit a characteristic behavior in the early phases of contrast enhancement, as well as on delayed images on CT scan or MRI. The signal intensity of hemangioma on T2-weighted images may also assist in its differentiation from an FNH. Some hemangiomas may show calcifications.

Table 42.2. Imaging Features of Focal Nodular Hyperplasia, Hemangioma, and Hepatic Adenoma

	Focal nodular hyperplasia	Hemangioma	Adenoma
Ultrasonography	Usually nondiagnostic Variable echogenicity Occasionally central scar	Hyperechoic lesion with well-defined borders	Usually nondiagnostic
Doppler	Arterial flow within the lesion	No internal flow	Venous signals within the lesion (nondiagnostic)
Contrast-enhanced triple phase CT scan	Precontrast: Hypo- or isodense lesion Homogenous arterial enhancement with a hypodense central scar May turn isodense post contrast	Precontrast: Hypodense lesion Centripetal globular enhancement Retained contrast on delayed venous phase	Precontrast: Hypo- or isodense lesion Irregular enhancement with peripheral arterial enhancement postcontrast
MRI unenhanced	Low signal on T1 Slightly hyperintense on T2 Central scar hyperintense on T2	Well-circumscribed homogenous lesion Low signal on T1 Very high signal on T2	Low to slightly hyperintense area on T1 Well-defined low-intensity capsule Heterogeneous enhancement on T2
Gadolinium-enhanced MRI	Homogenous arterial enhancement Hypodense	Progressive centripetal enhancement Similar to CT	Enhancement as in CT scan

	central scar Contrast accumulates in central area on delayed T1	scan	
Angiography	Dilated hepatic artery Highly vascular lesion, with a central vascular supply Spoke wheel pattern in one third of the patients	Venous lakes with well-defined circular shape Displaced arterial branches Delayed venous phase	Hypervascular lesion—50% Hypovascular lesion—50% Peripheral vascular supply
Scintigraphy with ^{99m}Tc-labeled RBC	Equal or increased uptake in 50%–70% of the patients	Increased uptake by the lesion during venous phase Retention on delayed images	Hypoconcentration of the colloid (focal defect) in most patients

CT, computed tomography; MRI, magnetic resonance imaging; RBC, red blood cells.

Differentiating FNH from hepatic adenoma is important because their complications and management are different, but it may be difficult and occasionally impossible. Hepatic adenoma is strongly associated with the long-term use of OCPs. It tends to be larger (10 cm in size) and typically does not have a central scar. ^{99m}Tc sulfur colloid scintigraphy classically shows decreased uptake in most patients with adenoma compared to an uptake which is the same as or greater than that of the surrounding hepatic parenchyma, occurring in 50% to 70% of patients with FNH (Fig. 42.3A) (49,71).

Patients with atypical or equivocal lesions should undergo a CT scan or ultrasonography-guided needle biopsy to confirm the diagnosis. When imaging studies suggest a highly vascular lesion such as adenoma, hemangioma, or a vascular metastasis, a laparoscopic or surgical biopsy or resection should be performed to avoid the risk of uncontrolled bleeding associated with a percutaneous liver biopsy.

Management

Because the incidence of complications is extremely low, the recommended

treatment in asymptomatic FNH is observation (31). To ensure stability of the lesion size, it is recommended to repeat abdominal imaging 3, 6, 12, and 24 months after the diagnosis. If the lesion is highly suggestive of FNH and does not change over a period of 1 to 2 years, no further specific observation is indicated. In symptomatic patients, it is important to corroborate a causative relationship to the lesion and rule out other causes for the symptoms. If the lesion is enlarging or is clearly symptomatic, surgical intervention should be considered. It has been recommended that pedunculated lesion be resected to prevent the rare risk of torsion; however, there is scant evidence to support or oppose this recommendation. Although the role of OCPs remains controversial, there are a few reports of lesions that decreased in size after the discontinuation of OCPs (12,36,81). Discontinuation of OCPs should probably be considered in a large or symptomatic FNH; however, there is not enough convincing data to support early termination of pregnancy in a patient with a newly diagnosed FNH or preventive resection of FNH when pregnancy is contemplated.

When surgery is indicated wedge resection and enucleation are generally the recommended approaches (12,38,81). In many cases, they can be performed laparoscopically with excellent results because the lesions tend to be smaller and peripheral (82). In patients with a large FNH, a segmental resection or a formal lobectomy may be required. Angiographic embolization and hepatic artery ligation are alternative approaches for unresectable lesions (24,36,83,84).

Hemangioma

Epidemiology

Hemangioma is the most common benign *solid* lesion of the liver. The reported prevalence at autopsy ranges from 0.4% to 7.4% (19,21). Among the benign focal hepatic lesions, it is second in prevalence only to simple cysts. Hemangiomas are most often found incidentally and have no major clinical implications. They are more prevalent in women and in the right hepatic lobe; the sex ratio is between 4:1 and 6:1. Hemangiomas may present at any age but are most common between the third and fifth decades and rare in young children. There is some controversy about the term *cavernous hemangioma*. Whereas some authors use it as a general name for hemangiomas, others use it to describe a stage of development of the lesion (20).

Pathogenesis

Hepatic hemangiomas are congenital vascular malformations. They enlarge by ectasia rather than hyperplasia or hypertrophy and are considered hamartomas by

most investigators (85). They compress, rather than infiltrate, the surrounding liver parenchyma, which results in a dissectible plane between the hemangioma and liver tissue. There is an ongoing controversy about the role of estrogen in their growth. Although most researchers found no association (86), some have reported growth or initial symptoms during pregnancy or in women receiving OCPs (87,88,89). These reports suggest that although hemangiomas are unrelated to estrogens in most women, they may play a role in individual cases.

Pathology

On gross examination hemangioma appears as a dark purple compressible spongy lesion (Fig. 42.4A,B) that may replace considerable portions of liver parenchyma (Fig. 42.4C). On microscopic examination, a hemangioma is typically composed of multiple vascular spaces of varying sizes, which are lined by a single layer of endothelial cells and are separated by fibrous septa (Fig. 42.4D). Intraluminal thrombi may be present and may lead to local calcifications. Nevertheless, biopsy is

usually unnecessary and may be associated with significant morbidity because of bleeding.

Clinical Manifestations

In most cases, hemangiomas are small and asymptomatic. Infrequently, they may grow to a large size, causing pressure or displacement of adjacent structures. Hemangiomas larger than 4 cm in size have been referred to as *giant hemangiomas* (90,91). Large hemangiomas are uncommon; however, they are more likely to cause symptoms. The most common complaints are of abdominal pain or discomfort; however, early satiety, nausea, and vomiting may also occur (90,92,93,94). Pain may be intermittent and is likely due to distension of the liver capsule or pressure on adjacent structures. Severe sudden pain may be caused by infarction, necrosis, or bleeding into the hemangioma. Other rare manifestations related to giant hemangiomas include gastric obstruction, obstructive jaundice (95), and symptoms resembling polymyalgia rheumatica (96). The relationship between symptoms and the hemangioma may be difficult to ascertain, and in many cases other

causes are discovered, such as peptic ulcer, gastroesophageal reflux disease (GERD), hernias of the abdominal wall, or tumors of the gastrointestinal tact. In one series of 87 patients with hepatic hemangiomas, 54% of patients were ultimately found to have other causes for their symptoms (97). In these cases, symptoms may resolve after treatment of the concomitant illness and therapy for the hemangioma is not required (93,97).

(Courtesy of P.A. Bejarano, MD, Department of Pathology, University of Miami School of Medicine.)

Physical examination findings are usually unremarkable. Occasionally, there is abdominal tenderness over the right upper quadrant and a palpable mass may be encountered. Rarely, a bruit may be heard over a large hemangioma.

Hepatic biochemical tests are usually normal and are therefore of little help in the diagnosis of hepatic hemangioma. On rare occasions, serum aminotransferases or alkaline phosphatase level may be mildly elevated. Serum levels of α-fetoprotein and carcinoembryogenic antigen (CEA) are invariably normal.

Complications and Natural History

Spontaneous bleeding into a hemangioma, although extremely rare, was reported by several authors (93). This complication typically presents with abdominal pain in the right upper quadrant and declining hematocrit, in the absence of trauma. The diagnosis is usually made on an abdominal CT scan and in some cases the treatment is removal of the hemangioma by lobectomy or enucleation. Thrombosis within a hemangioma may also present with right abdominal pain and occasionally with fever and increase of the erythrocyte sedimentation rate (95). Spontaneous rupture of hepatic hemangiomas is exceedingly rare (97,98); however, there are several reports of rupture of giant hemangiomas of the right lobe after abdominal trauma (99). A few patients presented with obstructive jaundice due to pressure on bile ducts (95,100) or portal hypertension due to pressure on the portal vein (101). Hemangiomas have rarely been reported to grow rapidly during pregnancy, and after the use of estrogens; however, the effect of pregnancy and estrogens on growth is

inconsistent (87,88,89,102). Rarely, patients with giant hemangiomas may develop consumption coagulopathy within the hemangioma and may present with evidence of disseminated intravascular coagulation (DIC), the so-called Kasabach-Merritt syndrome (87,93,103,104). The pathogenesis is likely platelet trapping in the hemangioma that leads to activation of the clotting cascade and consumption of both platelet and clotting factors.

Despite rare reports of complications, the long-term clinical course of most hepatic hemangiomas is benign (105,106), and most patients will never experience symptoms. When followed up for periods of 15 and 20 years, most patients remained asymptomatic and showed no significant changes in quality of life (85,98). In one of the largest series, 158 hemangiomas in 123 subjects were followed up for 12 to 60 months. No complications were observed during the follow-up period. Only one patient developed new symptoms, and only one hemangioma showed a significant change in size (107).

Imaging Studies

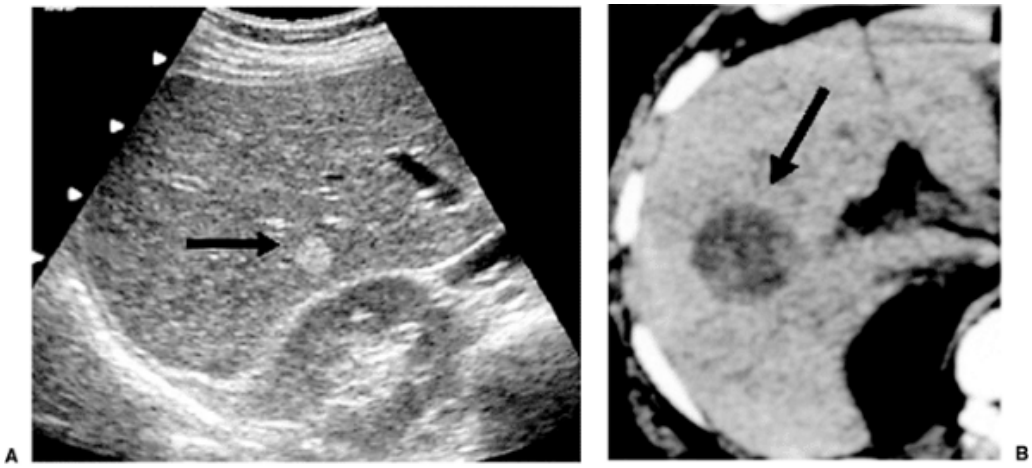
Plane abdominal radiographs are usually unhelpful for the detection or diagnosis of hemangiomas. Rarely they may show calcifications, which are more commonly seen in larger hemangiomas and elderly patients (108,109).

The typical *ultrasonographic* appearance of a hemangioma is of an echogenic, well-demarcated homogenous lesion with well-defined borders (Fig. 42.5A) (40). Ultrasonography can establish the diagnosis of a hemangioma in 80% of lesions smaller than 6 cm in size (97,110). However, approximately 20% to 30% of the patients may present with an atypical sonographic appearance (40). Posterior acoustic enhancement is a common feature. Doppler does not usually detect flow within the hemangioma because of the slow blood flow (111). Larger hemangiomas are more heterogenous and occasionally contain central fibrosis due to a previous hemorrhage. These usually require further imaging studies (112). Recent evidence suggest that contrast-enhanced harmonic ultrasonographic images using a microbubble contrast agent may be superior to conventional Doppler ultrasonography in differentiating hepatic hemangioma from HCC or hepatic metastases (109,113,114). A slow centripetal filling of the lesion by the contrast agent may be diagnostic of a hemangioma and may obviate the need for additional imaging studies.

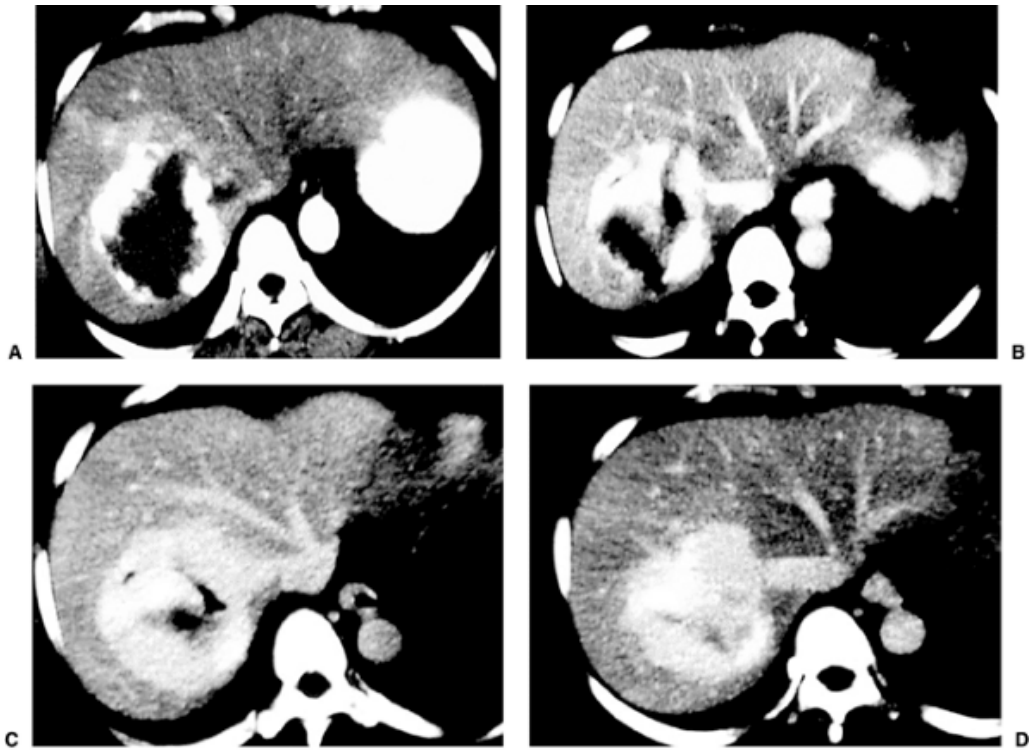
Dynamic CT scan offers a few advantages to ultrasonography in the diagnosis of hepatic hemangioma and is often performed to verify the diagnosis suggested by the ultrasonography. Almost all hepatic hemangiomas measuring 2 cm or more can be diagnosed by this technique. The hepatic triphasic CT scan technique is the most effective way to visualize a hemangioma. Before the administration of intravenous contrast, the typical appearance is that of a well-defined hypodense lesion (Fig. 42.5B). Serial images in the arterial phase of contrast administration show early peripheral enhancement with subsequent progressive globular centripetal filling (79,115,116) (Fig. 42.6A–D). Globular enhancement in the arterial phase represents venous lakes within the hemangioma and may be seen in 94% of large

lesions. It accurately differentiates between a hemangioma and a metastatic lesion (79,116,117). It usually takes about 3 minutes for complete opacification of the lesion to occur; however, it may take 10 to 15 minutes to complete opacification, and in many patients the center of the lesion may remain hypodense because of a central hemorrhage or fibrosis (118,119). Smaller lesions generally fill more rapidly and larger lesions are more likely to show slower central filling. Large hemangiomas (>4 cm) typically develop central areas that fail to fill in on the delayed enhanced

images. The center of the hemangioma is more likely to remain hypodense as the size increases. The contrast agent classically remains within the hemangioma for a long time (as long as 60 minutes) after the injection. This will not be demonstrated on standard images and the clinician should specifically ask for delayed images to obtain this typical picture. Occasionally, calcifications may be seen within a large hemangioma. The sensitivity and specificity of *dynamic CT scan* are more than 90% in lesions larger than 2 cm in size; however, they are significantly lower in smaller lesions (118,119,120,121).



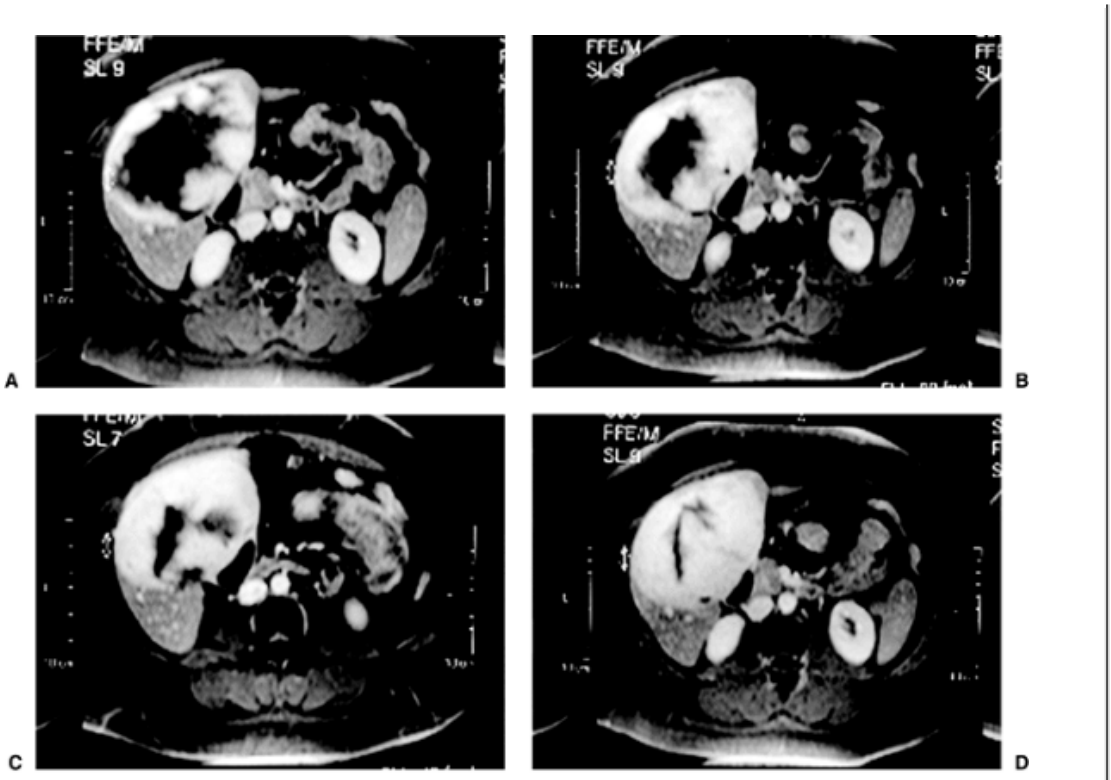
▪ **Figure 42.5** Hepatic hemangioma. **A:** Ultrasonography. A transverse view of the right hepatic lobe shows a well-circumscribed echogenic mass *(arrow)* that is consistent with a hemangioma. **B:** Computed tomography scan, precontrast injection, shows a well-circumscribed mass with low attenuation in the right hepatic lobe *(arrow)*.



▪ **Figure 42.6** Hepatic hemangioma. Dynamic, contrast-enhanced computed tomography (CT) scan demonstrates globular peripheral enhancement with gradual diffusion of the contrast from the periphery to the center of the lesion **(A)** 40 seconds, **(B)** 60 seconds, **(C)** 90 seconds, and **(D)** 120 seconds after intravenous contrast injection.

MRI shows a high degree of sensitivity and specificity (both >90%) in the diagnosis of hemangioma and is generally considered to be superior to CT scan for this purpose (57,122,123,124,125). It has a special value for the diagnosis of hemangiomas smaller than 2 cm in size and in patients with contraindications to the use of iodine-based intravenous contrast. A hemangioma usually appears as a well-circumscribed lesion that shows a moderately elevated signal on T2-weighted images and a low signal on T1-weighted images. The increased signal on T2-weighted images is typically less intense than that demonstrated by a simple cyst. Similar to the findings on CT scan, contrast enhancement with gadolinium shows a centripetal nodular filling on the arterial phase, which is considered by many to be a pathognomonic finding (Fig. 42.7A–D). Venous and delayed phases show progressive enlargement and coalescence of the peripheral nodules with variable degree of central filling (124,126). As in CT scan, larger hemangiomas commonly do not fill in on delayed enhanced images. They may show central cystic areas that are as bright as simple fluid, such as cerebral spinal fluid. Small (<1 cm) lesions may

fill quickly and may be difficult to delineate from other arterial phase-enhancing neoplasms such as small HCC or hypervascular metastases. In such cases, the distinguishing features can be found on venous and delayed images in which other vascular neoplasms commonly show rapid washout whereas hemangioma demonstrates persistent enhancement. Breath-hold images may improve the quality of the images and decrease motion artifacts (127).



▪ **Figure 42.7** Hepatic hemangioma. Contrast-enhanced magnetic resonance imaging (T1-weighted images) shows a low-signal lesion with peripheral globular enhancement on the arterial phase followed by progressive central filling—**(A)** 40 seconds, **(B)** 60 seconds, **(C)** 90 seconds, and **(D)** 120 seconds after intravenous gadolinium injection.

^{99m}Tc pertechnetate-labeled red blood cells (^{99m}Tc-RBC) pool scintigraphy may occasionally be helpful in controversial cases, but the use of this technique is decreasing in most medical centers. It typically shows initial hypoperfusion during the arterial flow phase followed by a gradual increase in the isotope in the lesion, which peaks at 30 to 50 minutes after the injection (Fig. 42.3B). Delayed images usually show retention of the tracer, which is typical of hemangioma. ^{99m}Tc-RBC scan has low sensitivity for lesions smaller than 2 cm in size. Furthermore, false-negative results may occur in the presence of fibrosis or thrombosis of the hemangioma. The sensitivity for lesions larger than 2 cm in size varies from 69% to 82% and the specificity approaches 100% (70). False-positive results are rare but well documented. Both HCC and angiosarcoma may rarely masquerade as a hemangioma on ^{99m}Tc-RBC scintigraphy (128), and the diagnosis should never be made solely on the basis of this study.

SPECT using ^{99m}Tc-RBC has been shown to increase the resolution of planar scintigraphy (75) and has a clear advantage over ultrasonography in differentiating large hepatic hemangiomas from other solid masses (129). The sensitivity and specificity of ^{99m}Tc-RBC SPECT may be as high as 90% to 97% in lesions larger than 2 cm in size, which is close to the accuracy of MRI (130,131), but the specificity may decrease to 50% in lesions with mixed echoic pattern (132). In patients with small lesions (<2 cm in size) MRI is considered more sensitive but less specific than SPECT; however, the use of dynamic three-view display of ^{99m}Tc-RBC SPECT improves its sensitivity in small lesions (between 1 and 2 cm in size) (133). Three-headed high-resolution SPECT shows a sensitivity of 100% for lesions of size 1.5 cm

or larger, but only 33% for lesions smaller than 1.5 cm in size (134,135). As in planar ^{99m}Tc-RBC scintigraphy, HCC may rarely mimic a hemangioma on ^{99m}Tc-RBC SPECT (136).

^{99m}Tc-RBC SPECT is best used to clarify a doubtful lesion on CT or to confirm a suspected hemangioma seen as a hyperechoic lesion on ultrasonography. Conventional *SPECT* with no ^{99m}Tc-RBC is less accurate for the diagnosis of hepatic hemangioma and may be of limited value for lesions less of 2.5 cm in size that are close to the heart or major intrahepatic vessels (137).

Catheter angiography is rarely used for the diagnosis of hepatic hemangioma, usually in uncertain or atypical cases in which other modalities have failed to yield a definitive diagnosis. Even in these cases, many centers prefer advanced imaging techniques such as CTA and MRA to standard catheter angiography. The contrast injected to the common hepatic artery rapidly fills the vascular spaces, creating a "starry night" appearance in the early phase and vascular lakes in later phases, which remain opacified beyond the venous phase (>40 seconds) (138). The borders may be irregular but are well defined, and the feeding vessels are typically displaced and curled at the margins of the lesion. Arteriovenous shunting is typically absent and its presence should raise suspicions of HCC. Still, hepatic hemangiomas may show atypical features mimicking HCC such as early fading after arterial enhancement (139,140), arteriovenous shunting (141), and centrifugal rather than centripetal enhancement pattern (142). Conversely, HCC may rarely mimic cavernous hemangioma on angiography (143). Discrepancy in different imaging studies should therefore warrant further follow-up and evaluation. A combination of ultrasonography, contrast-enhanced CT scan, and ^{99m}Tc-RBC scintigraphy was shown in one study to have a sensitivity of 86%, specificity of 100%, and accuracy of 91% in differentiating hepatic hemangioma from FNH and adenoma in 437 patients (38).

Management

Because most hemangiomas are asymptomatic, rarely enlarge in size or rupture, and have no malignant potential, surgical intervention is rarely indicated (25,97,144). When the diagnosis of hemangioma is conclusive, observation is sufficient and the rare risk of rupture should not be considered as an indication for surgery. Surgical therapy is indicated only in patients with severe symptoms, complications, or inconclusive diagnoses that cannot be resolved with imaging studies. Biopsy should be avoided because of high risk of bleeding (145). Overall, surgical resection is indicated in about 2% of diagnosed hemangiomas (97). This percentage may increase considerably in referral centers because of selection bias. The most common cause for surgical intervention in patients with hemangiomas is symptoms. The causative relationship between the hemangioma and symptoms should be confirmed and additional tests should be considered to rule out other potential causes such as gastroesophageal reflux disease, peptic ulcer, or gallstones. When symptoms are clearly related to the hemangioma, resolution may be observed in as many as 96% of the patients after surgical treatment (93). Another major reason for surgery is to exclude the presence of malignancy. In one series from Memorial Sloan-Kettering Cancer Center, suspicion or inability to exclude malignancy was the indication in

36% of the patients subjected to surgery (93). The surgical mortality in experienced centers is zero or nearly zero (93,97,144,146,147,148). Nevertheless, even in specialized centers the frequency of postoperative complications may be as high as 25% (93). Enucleation is the preferred approach by many groups because it allows resection of large hemangiomas with less blood loss and preservation of more hepatic parenchyma compared to resection. Enucleation is performed using the interface between the hemangioma and the surrounding normal liver tissue

(38,92,93,149,150,151,152). Laparoscopy is currently used as the procedure of choice in many centers when the diagnosis is well established (93,146).

Although surgical resection remains the main definitive treatment for symptomatic hemangioma, other less effective options are occasionally used. Transarterial embolization has been used for symptomatic lesions (89,153), acute bleeding (154), and consumption coagulopathy (155). However, there is little data on its long-term efficacy, and the procedure may have to be repeated or may lead to liver abscesses (156). Transarterial embolization was used preoperatively to decrease blood supply to the hemangioma and improve the safety of the surgery (155). Hepatic artery ligation (93), radiation therapy (88,157), radiofrequency ablation (158), and liver transplantation (159,160,161) were used on rare occasions for unresectable giant hemangiomas. Recurrence has been described after surgical, intra-arterial, and radiation therapy (88,156).

Hepatocellular Adenoma

Epidemiology and Risk Factors

Hepatocellular adenoma, also termed *liver cell adenoma* or *hepatic adenoma*, is a benign tumor of epithelial origin occurring primarily in women of childbearing age. It is considerably less common than hemangioma or FNH, occurring in less than 0.004% of the population at risk. Adenomas may be solitary or multiple and may reach more than 20 cm in size. In contrast with hepatic hemangioma and FNH, in which the association with OCPs is variable and controversial, hepatocellular adenoma has very strong association with OCPs and other estrogens. Hepatocellular adenoma was rarely encountered before the introduction of OCPs in the 1960s. Shortly after their introduction, the incidence of hepatocellular adenoma has increased significantly (28,162,163). The annual incidence in long-term users of OCPs has increased to 3 to 4 per 100,000 compared to 1 to 1.3 per million in nonusers (164). The use of OCPs with high hormonal potency, use for more than 5 years, and age over 30 years may further increase the risk (164,165). However, in 10% of patients diagnosed with hepatocellular adenoma the exposure to OCPs may be as short as 6 to 12 months (166). Androgen steroids, anabolic steroid, and diabetes mellitus have also been associated with increased incidence of hepatocellular adenoma (167,168,169).

Hepatocellular adenomas (typically multiple lesions) are commonly encountered in association with type I and III glycogen storage diseases (170,171,172). The incidence is 22% to 75% in type I and 25% in type III (171,173,174). In sharp contrast to hepatocellular adenomas in general, which show a strong female preponderance, those associated with glycogen storage disease show a male-to-female ratio of 2:1 (170). Furthermore, adenomas associated with glycogen storage diseases develop before the age of 20.

A condition in which more than ten lesions are present has been termed *liver adenomatosis* (175,176). This condition has been reported in men and women in the absence of OCP use or glycogen storage disease (175,176,177,178).

Pathogenesis

The pathogenesis of hepatocellular adenoma is still unclear. The strong association with OCPs and pregnancy suggests a possible trophic effect of estrogen on this tumor (179). Adenomas tend to be larger and are more likely to bleed in patients on OCPs than in those with no history of OCP intake (28,163). Furthermore, regression of adenomas after discontinuation of OCPs is well documented (179,180). It has been assumed that there may be hormone receptors within the cytoplasm or nucleus

of adenoma cells that mediate tumor growth in response to stimulation. However, there has been lack of consensus about the presence of such receptors, and a study using specific monoclonal antibodies showed no evidence of their existence in adenoma cells (181). Furthermore, single or multiple adenomas may occur in men and children without known predisposing factors.

The association of adenomatosis with glycogen storage disease and diabetes mellitus has also been unclear and various theories have been suggested as possible explanations (169,170). Recently, a germline mutation of the hepatocyte nuclear factor (HNF)-1α has been described in two families that exhibited both liver adenomatosis and diabetes mellitus (169). The analysis of tumor cells showed biallelic inactivation of HNF-1α.

Pathology

Hepatocellular adenoma is usually a large, well-circumscribed yellow to light-brown tumor. It arises in an otherwise normal liver and a complete or partial capsule is frequently present, although it may occasionally be absent. It is typically solitary but may be multiple, and it ranges in size from 1 to 30 cm, most being 8 to 15 cm

in diameter (19,28,165,182,183,184). Adenomas tend to be larger in women taking OCPs. They occur more commonly in the right lobe and are usually subcapsular, projecting slightly from the surface. Occasionally, they may be pedunculated. The cut surface may show ill-defined lobulation but is never nodular or fibrotic. Foci of central hemorrhage or necrosis are frequently observed.

Microscopically, this tumor is composed of cells closely resembling normal hepatocytes. Frequently, these cells may look slightly atypical and may be either larger or smaller than the surrounding normal hepatocytes; however, they may also appear indistinguishable from normal liver cells. Adenoma cells may also contain more glycogen than the surrounding liver and hence appear relatively pale. Occasionally, they may have a relatively increased nuclear/cytoplasmic ratio, resembling well-differentiated HCC. They are arranged in plates separated by sinusoids, which may be focally dilated. The plates may be thicker than those in normal liver tissues (more than two cells). Bile-containing acinar structures may be seen, and as many as 10% may show giant cell transformation (183,184). A variety of cytoplasmic changes and inclusions can be seen, including Mallory hyaline, lipofuscin, and giant mitochondria. Typically, there are few or no portal tracts or central veins within the adenoma (19,28,183,184). Vascular elements, particularly thick-walled arteries and arterioles, are seen at the periphery of the tumor. Peliosis hepatis may also be seen.

Absence of Kupffer cells was initially reported in hepatocellular adenoma; however, studies using immunoperoxidase staining for lysozyme demonstrated the presence of Kupffer cells in variable numbers within the adenoma (183,184,185). Nevertheless, hepatocellular adenomas usually do not demonstrate the uptake of ^{99m}Tc sulfur colloid, which is typically taken up by Kupffer cells. Possible explanations are decreased numbers of Kupffer cells in some adenomas, decreased function of Kupffer cells (183,184,185), or altered blood flow in some lesions (186).

Adenomas are perfused predominantly by peripheral arterial feeders. The arterial perfusion and their hypervascular nature, with dilated sinusoids and poor connective tissue support, may explain their tendency to bleed. A percutaneous needle liver biopsy carries a high risk of bleeding and may not be diagnostic because of a lack of pathognomonic features (187).

Clinical Manifestations and Complications

Hepatocellular adenoma may present in different ways, and there are conflicting numbers in the literature with regard to the frequency of each type of presentation. In most published studies and case series, most of the diagnosed patients presented with abdominal symptoms (28,182,188); however, this may be due to a selection bias. The typical patient is a woman aged between 20 and 50 years who has a long history of OCP use, often more than 5 years (31). Typically, the symptomatic patients present with abdominal symptoms, most commonly pain or discomfort in the epigastrium or right upper quadrant. This may be accompanied by anorexia, nausea, and vomiting. The pain may be severe or sudden in onset in the setting of an acute hemorrhage or rupture (10,28,182). In these cases, the patient may present with hypotension and shock due to rapid blood loss. Mortality may be as high as 6% (28,148,189). The general risk of bleeding has not been established accurately. It increases considerably in large adenomas, in rapidly growing ones, and in patients on OCPs or after menstruation (165,188). It has been reported to be as high as 25% to 30% in patients at high risk.

In some patients, the tumor is asymptomatic and may be detected as an incidental finding on abdominal imaging study or surgery. These tend to be the smaller adenomas and those that are not associated with OCPs. Others (as many as 25%) present with an abdominal mass or hepatomegaly.

Hepatic biochemical tests are usually normal. Occasionally, serum levels of alkaline phosphatase and γ-glutamyl transpeptidase may be elevated. This occurs more commonly in patients with bleeding or rupture (6,190).

Malignant transformation of hepatocellular adenoma is uncommon but well documented (177,189,191,192). It may occur despite the discontinuation of OCPs (193,194). An enlarging lesion, local and systemic symptoms, progressive abnormality in hepatic biochemical tests, and rising blood levels of α-fetoprotein may all be signs of transformation to HCC.

Patients with adenomatosis (more than ten lesions) usually present with abdominal pain and hepatomegaly (175). They commonly have elevated blood levels of alkaline phosphatase and γ-glutamyl transpeptidase, and their tumors are more likely to bleed, rupture and undergo malignant transformation (163,175).

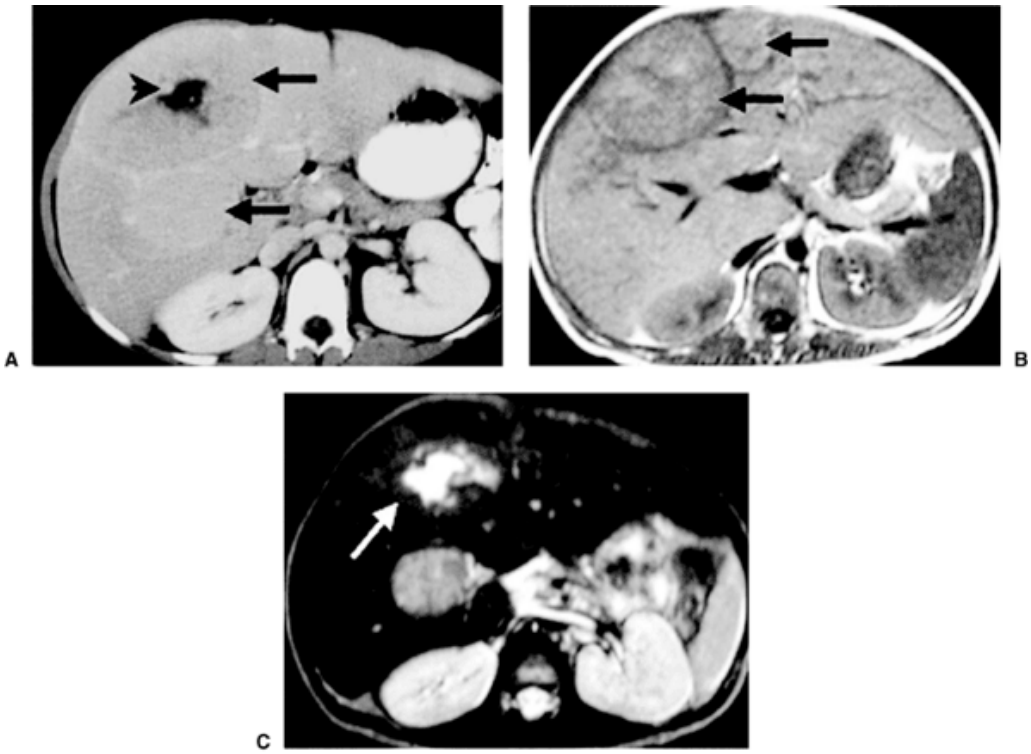
Imaging Studies

Ultrasonography shows a well-demarcated mass with smooth borders and variable echogenicity (40,110). Doppler may show venous signals within the lesion that correspond to intratumoral veins (195). However, despite the development of color Doppler, power Doppler imaging, and intravenous–ultrasound contrast agents, the findings on ultrasonography and Doppler are nonspecific and further studies are required.

CT scan does not provide a diagnostic picture either, although findings on multiphasic contrast-enhanced CT scan can help in suggesting the diagnosis (48,196). On precontrast images, the adenoma appears as a hypo- or isodense mass, which may show high-density areas, consistent with intratumoral hemorrhage (51,196,197). After contrast injection, the mass shows irregular enhancement with areas of normal, increased, and decreased density. This characteristic finding occurs in 75% of patients with hepatocellular adenoma (76) (Fig. 42.8A). The center may be hyperdense on contrast injection in the setting of an acute hemorrhage. In the presence of an old hemorrhage, the center usually remains hypodense after contrast injection, making the differential diagnosis from a central scar difficult. On the portal–venous phase, the lesion will usually show a uniform enhancement, which is

suggestive of the diagnosis (197).

MRI shows a well-demarcated lesion that on T1-weighted images may show a mildly hypointense to mildly hyperintense signal (Fig. 42.8B) (57,198,199). T2-weighted images show isointense to slightly hyperintense signal that may be heterogenous because of areas of bleeding. A peripheral rim is seen in 30% of patients (76). Central necrosis typically appears as low signal intensity on T2-weighted images, whereas a recent hemorrhage may show increased signal on T1 images (Fig. 42.8C). Gadolinium enhancement shows an arterial phase blush followed by a rapid fading in the venous and delayed phases to hypointensity or isointensity, with persistence of an enhancing rim related to the capsule. These features may be indistinguishable from those of HCC. In contrast to FNH, the signal intensity is usually not increased in the center of the lesion on gadolinium-enhanced images. An enhancing scar may be observed in a minority of patients with adenoma, but this scar does not produce a high signal on T2-weighted images as in FNH.



▪ **Figure 42.8** Hepatocellular adenoma. **A:** Abdominal computed tomography (CT) scan shows two well-circumscribed mass lesions in the right-hepatic lobe *(arrows)*. The anterior lesion shows central necrosis *(arrowhead)*. **B:** Abdominal magnetic resonance imaging (MRI) (T1-weighted image) of the same patient shows two lesions with slightly decreased intensity and well-defined low-intensity capsule *(arrows)*, which are suggestive of hepatocellular adenoma. **C:** T2-weighted image shows a central high signal intensity *(arrow)*, which is consistent with central hemorrhage.

Hepatocyte-selective contrast agents such as Gd-BOPTA have been shown to improve the differentiation between FNH and adenoma with a sensitivity of 80% and specificity of more than 96% (68,69). This

contrast agent is selectively taken up by functioning hepatocytes and excreted into

the bile. It results in prolonged enhancement of the liver parenchyma. In one recent study, 1 to 3 hours after contrast injection, 97% of FNH lesions appeared hyper- or isointense, whereas 100% of hepatocellular adenomas appeared hypointense (68).

^{99m}*Tc sulfur colloid scintigraphy* may be helpful in the diagnosis of hepatocellular adenoma because it typically shows no uptake of the colloid. This has been attributed to decreased activity of Kupffer cells within the adenoma (183,184,185) and may assist in distinguishing adenoma from FNH, which typically shows normal or increased colloid uptake.

Catheter angiography has been replaced in many centers by advanced imaging techniques such as CTA and MRA. It is used occasionally in problematic cases to rule out HCC, or as part of preoperative evaluation. In hepatocellular adenoma catheter angiography, CTA and MRA typically demonstrate enlargement of the hepatic artery and displacement of the hepatic vessels; however, these findings also appear in up to 40% of patients with FNH. In contrast to FNH the blood flow in adenoma is from the periphery to the center of the lesion, creating a homogeneous blush during the venous phase (189). Similar to FNH, adenoma may show a central hypovascular area because of hemorrhage or central necrosis. Vascular leakage, arteriovenous shunting, and portal-venous invasion suggest a malignant lesion (189).

Diagnosis

The diagnosis of hepatocellular adenoma is usually made in the setting of women aged 20 to 50 years, with a long history of OCP use, and symptomatic focal hepatic lesions.

Although many radiologic features of hepatocellular adenoma mimic HCC, the latter is usually associated with a background of chronic liver disease, usually with evidence of cirrhosis. In patients with risk factors for HCC such as chronic hepatitis B or cirrhosis, any suspicious focal lesion with radiologic features consistent with both HCC and adenoma should be regarded as HCC until proved otherwise. High or increasing serum levels of α-fetoprotein, significant increase in size, abnormal hepatic biochemical test results, and involvement of the portal vein may direct toward the diagnosis of HCC, whereas a history of long-term use of OCPs points toward hepatocellular adenoma. Despite the advanced imaging modalities, the diagnosis remains uncertain in many patients and histologic examination may be necessary. In hepatocellular adenoma, a percutaneous needle liver biopsy carries a high risk of bleeding and should be avoided. A laparoscopic approach may be necessary to improve visualization and hemostasis.

Hepatic adenomatosis (more than ten lesions) should be considered a diagnosis of exclusion because metastatic disease and multifocal HCC are more common causes of multiple solid liver masses. Histologic confirmation is required to establish the diagnosis (200).

Management

Generally, surgical treatment is recommended whenever possible to avoid the risks of rupture, hemorrhage, and malignant transformation (31,152,189,201). Some authors have suggested that adenomas smaller than 5 cm in size are less likely to rupture and bleed and, therefore, should not be resected, and should be followed by periodical imaging studies (202,203). Others have recommended a period of observation after OCPs have been discontinued to assess whether the tumor size decreases (126,202). Hepatocellular adenomas have been shown to decrease in size and even disappear after withdrawal of OCPs (28,173,180,193,204,205,206). However, there are rare reports of cancer occurring even in adenomas that have decreased in size or disappeared after discontinuation of OCPs (193,194). We

therefore recommend, like others, surgical resection for all hepatocellular adenomas if technically possible (192). Nevertheless, the risk–benefit ratio should be assessed for every case and the final decision should be made on an individual basis.

Surgical approaches for hepatocellular adenoma have included enucleation, resection, and liver transplantation (21,38,189,201). Enucleation is associated with less blood loss and preservation of normal liver tissue (207). Both resection and enucleation are performed laparoscopically in many centers with excellent results, when technically feasible (82,201). The mortality of an elective surgery is 1%, but it increases to 5% to 8% for emergency resection (82,207,208,209). Intraperitoneal bleeding from hepatocellular adenoma has been associated with 21% mortality (164). Arterial embolization has been used to control bleeding (202), reduce the tumor size preoperatively, or relieve symptoms in patients with inoperable tumors (189,210).

In rare patients with multiple adenomas, orthotopic liver transplantation (OLT) may be the only way to remove all the lesions (171,177). In type I glycogen storage disease OLT also corrects the metabolic defect (211).

If an adenoma is not resected, the patients should be followed up periodically by imaging studies and by determining the blood levels of α-fetoprotein, although there is scarce evidence to support the efficacy of this approach (171). Local or systemic symptoms, any increase in size, and any abnormality in hepatic

biochemical tests or α-fetoprotein levels should raise the suspicion of malignant transformation and should prompt a surgical intervention to remove the lesion. In addition, pregnancy should be avoided to prevent the risk of rapid tumor growth, rupture, and bleeding (194). Women who have had hepatocellular adenoma, whether resected or not, should avoid the use of OCPs permanently.

In patients with glycogen storage disease, pregnancy is probably safe. In the few reports of patients with glycogen storage disease and hepatocellular adenomas who became pregnant, there was no change in the size or number of the adenomas (212). This observation supports the notion that the pathogenesis of hepatocellular adenoma in patients with glycogen storage disease may be different from that of adenomas occurring in healthy individuals.

Macroregenerative Nodules

There is ongoing discussion about the characterization and classification of hepatocellular nodules found in the cirrhotic liver. Improvement of imaging techniques has led to frequent detection of focal lesions in cirrhotic livers, many of which are benign nodules with various degrees of atypia. They may occur in cirrhotic livers of any cause. Several groups have suggested nomenclatures and diagnostic criteria to describe these lesions; however, none of these are used consistently (213,214). Terms such as *regenerative nodules*, *macroregenerative nodules* (*MRNs*), *adenomatous hyperplastic nodules* (215,216), *dysplastic nodules* (213), *atypical adenomatous hyperplastic nodules* (217), and *borderline nodules* (214) have been suggested by different authors to describe what is believed to be different stages of the same lesion.

An MRN is typically larger than 0.8 cm. It develops because of the regeneration of an islet of viable cells within an area of destroyed liver tissue, hence its nodular appearance. MRNs may be seen in less than 2% of cases of acute massive necrosis and in 14% to 21% of patients with cirrhosis (218). The expanding nodule typically compresses the surrounding liver tissue. It may be solitary but many livers contain multiple MRNs. It is separated from the rest of the liver parenchyma by fibrous connective tissue. Needle biopsy specimens from these lesions are commonly

classified as benign, but in some cases they may demonstrate varying degrees of atypia and occasionally foci of overt HCC. The characteristic histologic findings of MRN include normal thin plates of hepatocytes (two cells thick) and lack of cytologic atypia (normal nuclear/cytoplasmic ratio). The nodule may include multiple portal areas. Larger hepatocytes may be seen and are considered an acceptable finding as long as the normal nuclear/cytoplasmic ratio is maintained.

MRNs have been classified according to degree of atypia to type I and type II (219). Type I MRN shows no cell atypia and is probably an ordinary adenomatous hyperplasia, whereas type II MRN represents atypical adenomatous hyperplasia, which is probably a true precursor of HCC (219). The clonality of MRNs suggests that at least some of them are neoplastic and probably premalignant (217). The incidence of progression to malignancy is still unclear (220,221,222,223); however, some authors recommend treating atypical (type II) MRN in a patient with cirrhosis as a malignant lesion (221). In a study of 307 patients with cirrhosis, multivariate analysis showed dysplasia to be the most important independent risk factor for the development of HCC (224).

Imaging studies may be suggestive of MRN, although they may not be sufficient to establish the diagnosis or distinguish MRN from HCC. On T1-weighted MRI, MRNs are typically isointense to slightly hyperintense compared to the surrounding hepatic parenchyma. On T2-weighted images the lesions are hypointense. In contrast, HCC has variable diminished signal intensity on T1, becomes hyperintense on T2, and enhances during the arterial phase of gadolinium injection. HCC also has a characteristic capsule of low signal intensity (57,124), which is typically absent in MRNs. MRA usually shows sparse arterial supply in MRN. Uniform arterial opacification is seen without neovascularity. The transition of MRN to dysplastic nodule and subsequently to HCC is associated with vascular proliferation within the nodule and preferential blood supply from branches of the hepatic artery (57,225).

Benign Focal Lesions of Bile Duct Origin

Two main types of intrahepatic benign bile duct proliferation have been characterized: Bile duct adenomas (184,226) and bile duct hamartomas (also called *von Meyenburg complexes*).

Intrahepatic Bile Duct Adenoma

Intrahepatic bile duct adenoma is a rare non-neoplastic focal lesion that is usually discovered incidentally. Most cases are reported in men older than 40 years. Typically, it is a solitary subcapsular lesion measuring 0.5 to 2 cm in size (227). Microscopically, it consists of numerous, uniform, normally appearing bile duct–like structures that are surrounded by a small amount of fibrous stroma (184). This lesion is occasionally confused with cholangiocarcinoma or metastatic adenocarcinomas on frozen sections. The distinction should be made by the absence of nuclear hyperchromasia, mitotic activity, and vascular invasion (13,184). It is believed that bile duct adenoma is a reactive process to a focal injury rather than a true neoplasm or a developmental anomaly (227).

Biliary Hamartoma (Von Meyenburg Complex)

Biliary hamartoma is an anomalous proliferation of dilated bile ducts embedded in connective tissue. It is often visible grossly as a tiny (up to 0.5 cm) white liver nodule and may be single or multiple (228). Biliary hamartoma is most often seen in otherwise normal liver tissue, but it may be associated with congenital hepatic fibrosis and Caroli's disease. There is also a strong association with adult polycystic

disease. It is usually detected as an incidental finding at surgery, autopsy, and rarely percutaneous liver biopsy performed for other reasons. Its pathogenesis likely involves developmental arrest of the primitive ductal plate. The ectatic ducts may contain bile or even small calculi. Von Meyenburg complex was found in 5.6% of adults in 2,843 autopsies. Of the patients with von Meyenburg complex, 11% had adult polycystic kidney disease, whereas 97% of the patients with adult polycystic kidney disease had the von Meyenburg complex (229). There is a rare association with cholangiocarcinoma (230).

Other Benign Mesenchymal Tumors

Infantile Hemangioendothelioma

Infantile hemangioendothelioma is a vascular tumor derived from endothelial cells, which is the most common benign hepatic tumor in children. It accounts for approximately 12% of all childhood hepatic tumors and for more than 50% of benign tumors of the liver diagnosed in infancy and childhood (231). It can be solitary (55% of the patients) or multiple (45% of the patients) and may vary in size from a few millimeters to more than 20 cm (183,184). More than 90% are diagnosed before the age of 6 years. The typical presentation is of hepatomegaly, hemangiomas of the skin, and heart failure resulting from massive arteriovenous shunting (232). In addition to heart failure, this tumor may cause consumption coagulopathy (Kasabach-Merritt syndrome) and obstructive jaundice (102,233).

Although well circumscribed, this tumor is not encapsulated and often has scattered calcifications. Microscopically, this tumor consists of multiple small vessels lined by plump endothelial cells and surrounded by fibrous stroma. Two types of hepatic hemangioendotheliomas exist. The more common, type I, has a prominent endothelium closely related to the portal tract and tends to displace, rather than infiltrate, the liver parenchyma. It consists of small vascular channels lined by flattened or rounded endothelial cells with rare mitotic figures. Extramedullary hematopoiesis may occasionally be seen. Type II lesions are composed of tortuous vascular channels, with endothelial cells proliferating into the adjacent hepatic tissue. They exhibit larger, irregular channels lined by pleomorphic endothelial cells. Differentiation of type II hemangioendothelioma and the rare malignant angiosarcoma may be difficult. In many cases, infantile hemangioendothelioma is associated with extrahepatic hemangiomas that may be found in the skin, lung, lymph nodes, pancreas, retroperitoneum, and bone. The most frequently involved site is the skin, where single or multiple lesions may be present. Other associated abnormalities include atrial septal defect, patent ductus arteriosus, myelomeningocele, renal agenesis, and absent common bile duct (233). Rarely, infantile hemangioendothelioma may undergo transformation to angiosarcoma (234).

The diagnosis is suggested when an infant presents with an enlarged liver, congestive heart failure, and cutaneous hemangiomas (235). The bilirubin level is elevated in one third of patients. Biliary obstruction is rarely present (233,236).

Ultrasonography usually shows hepatomegaly and solitary or multiple hepatic lesions, which may vary from anechoic to hyperechoic. The unenhanced CT scan demonstrates the lesion as a well-defined hypoattenuating mass, occasionally with calcifications. After contrast injection the lesion may show enhancement resembling hemangioma and may become isodense on delayed images. Angiography shows dilated, irregular vascular lakes that commonly persist beyond the venous phase. ^{99m}Tc sulfur colloid scintigraphy shows the lesion as a cold spot because of lack of Kupffer cells within the tumor.

The prognosis of this lesion is dependent on its size and its effect on the heart

function. Spontaneous regression is frequent but death may occur within the first 6 months of life because of cardiac failure or replacement of the normal hepatic parenchyma (102). The prognosis is usually good if heart failure is managed successfully. In one large series, the 6-month survival was 70% (237).

The treatment is dictated by tumor-related symptoms produced by tumor size. Management of congestive heart failure may be sufficient in some cases. If symptoms are not relieved, treatment should be aimed at decreasing the tumor size. Several studies have confirmed the success of steroid therapy (238). However, failure of some tumors to respond to steroids has led to the use of other drugs such as cyclophosphamide (239) and interferon α-2a (240). Other treatments include hepatic artery ligation (241), transcatheter endovascular embolization (242), and radiation therapy (243). Liver transplant is increasingly recognized as a viable treatment modality for infantile hemangioendothelioma when other treatments fail (244).

Mesenchymal Hamartoma

Mesenchymal hamartoma is a rare slow-growing tumor of childhood that comprises approximately 5% of pediatric liver tumors. It has a male predominance and is diagnosed in most cases before the age of 3 years (245,246,247), although it has been reported in adults (248). The tumor is usually a solitary, large (average size of 16 cm), well-demarcated mass with a predilection for the right hepatic lobe. The cut surface shows multiple cysts separated by solid, pink tan areas. The solid portions have a mixture of hepatic cells and mesenchymal cells with vascular proliferation and bile duct–like structures. The cystic spaces are filled with fluid or solid gelatinous material. The islands of hepatocytes within the mesenchymal stroma may show reactive and regenerative changes (184). Most patients present with abdominal enlargement or an abdominal mass. Few have pain or respiratory distress. Ultrasonography and CT demonstrate a large tumor, with central cystic changes showing internal septations (245). Angiography reveals a hypovascular or avascular lesion. It is important to differentiate this tumor from embryonal sarcoma because both may demonstrate loose edematous myxoid stroma. In most cases of embryonal sarcoma, the cellularity of the tumor is readily evident, and the neoplastic cells show distinctive cytologic features of highly malignant cells. Resection is recommended when the tumor is large and compresses adjacent abdominal organs. It is curative in most cases. A simultaneous involvement of the liver by mesenchymal hamartoma and infantile hemangioendothelioma requiring liver transplantation has been reported (249).

Benign Lipomatous Tumors and Tumor-like Lesions

Focal Fatty Change

Focal fatty change is a localized area of steatosis that can sometimes be misinterpreted on imaging studies as a neoplastic growth. It is usually an ill-defined area that may be single or multiple. Multiple areas of fatty change may mimic metastatic disease on imaging studies (250). Focal fatty change is associated with alcoholism, obesity, malnutrition, total parenteral nutrition, corticosteroid treatment, cytotoxic chemotherapy, acquired immunodeficiency syndrome (AIDS), hypertriglyceridemia, and diabetes mellitus. Hepatic biochemical tests may be normal or mildly abnormal.

Ultrasonography shows a hyperechoic area with ill-defined borders. On CT scan, focal fatty change appears as a hypodense area, which is usually sharply demarcated without mass effect on the hepatic or portal veins (251,252,253). The demonstration

of normal-caliber vessels coursing through the hypodense lesion on CT scan is characteristic (254) and can help in distinguishing this lesion from primary or metastatic malignancy. MRI shows increased intensity on T1-weighted images. This finding is characteristic for focal fatty change appearing in 100% of the cases compared with less than 4% of other benign tumors. The differential diagnosis of a hyperintense focal hepatic lesion on T1-weighted images includes hemorrhage, malignant melanoma, and iron or copper overload (255,256). Fat-suppressed T1-weighted images may be helpful in identifying fatty infiltration because the hyperdense area typically becomes hypodense in a fat-containing lesion (255). ^{99m}Tc sulfur colloid scintigraphy shows no focal lesion; however, areas of steatosis show retention of xenon-133 (257,258). Biopsy is diagnostic but not always required. Microscopically, the lesion shows macrovesicular fatty change within the lesion, which is indistinguishable from other forms of steatosis.

The treatment of focal fatty change is directed against the underlying disease. Resolution has been described after weight loss and abstinence from alcohol (259).

Angiomyolipoma

Angiomyolipoma is a rare benign lipomatous tumor resembling the more common renal angiomyolipoma. It is usually solitary, ranging in size from 0.3 to more than 20 cm. It is typically asymptomatic and is detected as an incidental finding between the second and eighth decades, predominantly in women (260,261,262). It is composed of variable proportions of adipose tissue and smooth muscle with thick-walled blood vessels. Adipose tissue varies from as little as 55% to more than 90% (184). Tumors with extensive extramedullary hematopoiesis have been termed *myelolipoma* or a*ngiomyelolipoma* (263). Flow cytometry shows a deoxyribonucleic acid (DNA) diploid pattern, consistent with a benign lesion (264).

Angiomyelolipoma is a homogenous well-circumscribed tumor that is highly echogenic on ultrasonography. On enhanced CT scan, the density measurements are characteristic of fat (-2 to -115 Hounsfield units) (265); MRI is also diagnostic. The prognosis is usually excellent. Budd-Chiari syndrome related to compression of the hepatic veins by angiomyelolipoma has been described (266,267). Malignant transformation has not been reported. For symptomatic lesions or lesions in which the diagnosis cannot be confirmed, resection is the treatment of choice (260).

Pseudolipoma

Pseudolipoma is a small encapsulated lesion located on the capsular surface of the liver or immediately under the capsule. It consists of mature lipocytes and is presumed to originate from adherent epiploic appendices that became detached. Fat necrosis and calcifications may occur. The importance of this rare and asymptomatic lesion lies in its differential diagnosis from primary or metastatic tumors. There are no clear predisposing factors (184,268).

Inflammatory Pseudotumor

Inflammatory pseudotumor of the liver is a rare benign disease presenting as a localized parenchymal mass. It is considered by some to be secondary to an infectious process (269,270), although the exact pathogenesis remains unclear, and few microscopic studies of hepatic tissue have disclosed pathogenic microorganisms (271). An association with extrahepatic infectious conditions (270) and with Crohn's disease (272,273) has been reported in a few patients. The lesion may be solitary or multiple and its size ranges from 1 to 25 cm. It is usually well circumscribed and may be encapsulated. It affects patients at any age and has a predilection for men

with a male-to-female ratio of 3 to 8:1.

The patients usually present with fever, abdominal pain, and malaise. Jaundice and weight loss may occur. Elevated sedimentation rate, leukocytosis, and mildly abnormal hepatic biochemical tests are common. Ultrasonography reveals a heterogeneous lesion that may show a mosaic pattern. CT scan shows an irregular, clearly demarcated heterogeneous mass that is typically hypodense compared to surrounding liver parenchyma.

The differential diagnosis includes pyogenic hepatic abscess, as well as malignant and metastatic tumors. Needle liver biopsy is usually needed to establish the diagnosis.

Histologically, the mass is composed of fibrous tissue and myofibroblasts and infiltrated by dense mixed inflammatory infiltrate with numerous plasma cells. Vascular invasion can sometimes be seen, and phlebitis may be present (184).

The prognosis of hepatic inflammatory pseudotumor is usually favorable. The lesion may regress and disappear spontaneously within a few weeks to months (270,274,275,276,277). In a few cases antibiotic treatment was used and was followed by complete resolution (270,271). Response to steroids has also been reported. In some cases the lesion was treated successfully by local resection (278), but surgical removal is unnecessary in most patients. When the diagnosis is unequivocal, observation is the treatment of choice (270,274,275,276,277).

Clinical Approach to a Focal Solid Lesion of the Liver

Focal solid hepatic lesions often represent a diagnostic challenge and frequently mandate an extensive evaluation and a multidisciplinary approach. Although there is a wide spectrum of conditions that needs to be considered when a focal lesion is detected in the liver, most lesions fall into a relatively small group of entities (Table 42.1). The clinician must decide at an early stage whether the lesion is malignant or benign, whether a biopsy is indicated, and whether surgical intervention is required.

A detailed history should be obtained and should include questions about the history of cancer and previous use of OCPs, androgens, and anabolic steroids. The specific approach may vary according to the type of presentation, demographics of the patient, and medical history. The diagnostic approach in a young, asymptomatic previously healthy woman should focus on the differential diagnosis of hemangioma, FNH, and adenoma. A history of prolonged treatment with OCPs will point toward a diagnosis of hepatocellular adenoma. In contrast, when the patient has a history of cancer, a focal hepatic lesion will often be a metastasis. In the presence of cirrhosis or chronic hepatitis B virus (HBV) infection, a focal solid lesion should be regarded as HCC until proved otherwise. A history of primary sclerosing cholangitis should point toward intrahepatic cholangiocarcinoma.

Presenting symptoms such as abdominal pain, weight loss, and malaise should raise the suspicion of malignancy. It should be remembered that most patients with benign hepatic lesions are asymptomatic, and the relationship between the symptoms and the focal lesion should be corroborated.

A thorough physical examination is important to assess whether an underlying liver disease or malignancy is present. Physical findings such as ascites, firm nodular liver, or splenomegaly should suggest the presence of a chronic liver disease and should point toward HCC. Hepatic biochemical tests are typically normal in patients with benign hepatic lesions, and a significant abnormality should raise the suspicion of a neoplastic lesion, a complication such as hemorrhage (usually in an adenoma), or an underlying liver disease. Tumor marker levels are also normal and are unhelpful in making the distinction between benign tumors. Nevertheless, any

abnormality in tumor marker should prompt an evaluation for malignancy.

If the patient has no history of cancer, no underlying liver diseases, and no abnormality in tumor marker levels or serologic tests for viral hepatitis, a solid lesion of the liver is most often benign (279,280).

Imaging studies are commonly helpful in distinguishing between focal hepatic lesions, but the differential diagnosis may be challenging because many of the lesions have overlapping radiographic features (48,57,281).

Although ultrasonography is an excellent modality for the initial detection of lesions and for determining a solid versus cystic lesion, the sonographic appearance of a solid liver mass is often nonspecific and many patients will require additional hepatic imaging. CT is a reliable and easily reproducible method for the evaluation of focal hepatic lesions. It allows the characterization of lesions as small as 1.5 cm in size and may also help in the evaluation of the entire abdomen for signs of cirrhosis, portal hypertension, or malignancy (48,282). CTA and CT arterial portography show improved sensitivity and may detect smaller lesions; however, MRI has the advantages of specificity and the ability to distinguish between different lesions (283). The use of specific MRI contrast media, such as SPIO and Gd-BOPTA has been shown to improve specificity and facilitate the differentiation between FNH, adenoma, and other lesions.

In a patient with cirrhosis or chronic HBV infection and a solid lesion, arterial enhancement on dynamic CT scan strongly supports the diagnosis of HCC (173). When a hemangioma is suspected, triphasic dynamic CT with late images should be performed. Dynamic CT scan may conclusively establish the diagnosis of a hemangioma and, occasionally, FNH without any further workup (284). Tagged RBC scan (^{99m}Tc-RBC pool scintigraphy) may be helpful in questionable hemangiomas, although gadolinium-enhanced MRI is superior to tagged RBC scan in most cases. ^{99m}Tc-RBC scan with SPECT is highly sensitive in hemangiomas larger than 2 cm in size and may be used to confirm the diagnosis. ^{99m}Tc sulfur colloid scintigraphy is usually not helpful for the differential diagnosis of focal hepatic lesions, but it may assist in distinguishing between FNH and adenoma. If no focal defect is seen or if the uptake is increased, FNH should be suspected. In contrast, decreased uptake is more consistent with an adenoma. PET scan proved to be highly sensitive in detecting hepatic metastases and distinguishing them from other focal lesions (285). At this point in time, PET scan has not been shown to have an advantage over current imaging modalities for the diagnosis of specific benign tumors. The finding of a central scar in a solid lesion, although suggestive of an FNH, may be misleading and should not be confused with a central hemorrhage or necrosis. Calcifications within a lesion suggest fibrolamellar carcinoma, whereas hemorrhage within a tumor is more suggestive of an adenoma.

In cases of uncertainty or when malignancy is suspected, a liver biopsy should be performed. A percutaneous liver biopsy is generally safe; however, it may be hazardous in adenomas and hemangiomas and should be avoided when these tumors are suspected, or when imaging studies indicate hypervascularity. In these cases, laparoscopic liver biopsy may be safer and may have the advantage of hemostasis under direct vision. Laparoscopy also offers a better evaluation of the extent of the lesion through direct vision and laparoscopic ultrasonography (286).

In a minority of patients, an accurate diagnosis cannot be established despite histopathologic examination. In these cases, resection may be indicated (208,287). Similarly, persistent symptoms, increasing levels of tumor markers, or evidence of tumor growth are indications for a surgical resection, regardless of the diagnosis. Benign hepatic lesions accounted for 5% of hepatic resections in a recent database

review in the United States (288). Resection of benign lesions is performed laparoscopically in many centers with excellent results. A recent European study reported 87 laparoscopic resections of benign tumors with zero mortality and a postoperative complication rate of 5% (82).

Chapter 43
Nodular and Cystic Lesions

Adrian M. Di Bisceglie
Alex S. Befeler

Key Concepts

- Dysplastic nodules are defined as a nodular region of hepatocytes at least 1 mm in diameter with dysplasia but without definite criteria of malignancy. When such nodules are larger than 10 mm, the term *macroregenerative nodule* (*MRN*) is applied.
- Nodular regenerative hyperplasia (NRH) is defined by hepatocellular nodules that are distributed throughout the liver in the absence of fibrous septae between the nodules. This condition is often associated with systemic diseases and is complicated by portal hypertension.
- Focal nodular hyperplasia (FNH) is a benign tumor-like lesion of the liver considered to be hyperplastic rather than neoplastic in origin. This lesion is related to an abnormal blood supply and is rarely of clinical significance.
- Hepatocellular adenoma is a benign neoplasm of the liver, often related to the use of oral contraceptives. This neoplasm can be complicated by rupture, hemorrhage, and, rarely, development of malignancy.
- Polycystic liver disease (PCLD) is an inherited disease in which multiple cysts develop within the parenchyma of the liver and produce disease from direct mechanical effects of the cysts.
- PCLD is often associated with other related diseases, such as autosomal dominant polycystic kidney disease (ADPKD), whereas the rarer congenital hepatic fibrosis (CHF) and choledochal cysts may occur in association with autosomal recessive polycystic kidney disease (ARPKD).
- PCLD is usually asymptomatic but can be complicated by the development of abdominal pain, portal hypertension, hepatic venous outflow obstruction, obstructive jaundice, and cyst infection.
- Cystadenoma is a benign tumor of the liver that is hypothesized to arise from congenital defects of the bile ducts or gallbladder. This condition carries a high risk of development of malignancy.
- Echinococcal cysts are related to infection with the parasites *Echinococcus granulosus* and *Echinococcus multilocularis* and may affect many organs, including the liver.

Nodular Diseases of the Liver

The classification and terminology of nodular diseases of the liver is somewhat confusing because different terms have been applied to the same type of lesion. In an attempt to standardize the terminology, the International Working Party proposed a new nomenclature, which has been widely adopted by pathologists (1). However, this terminology does not always lend itself to everyday clinical use, and the following discussion represents an attempt to combine this new standard terminology with the clinical features of hepatic nodules.

Hepatocellular Nodular Lesions with Cirrhosis

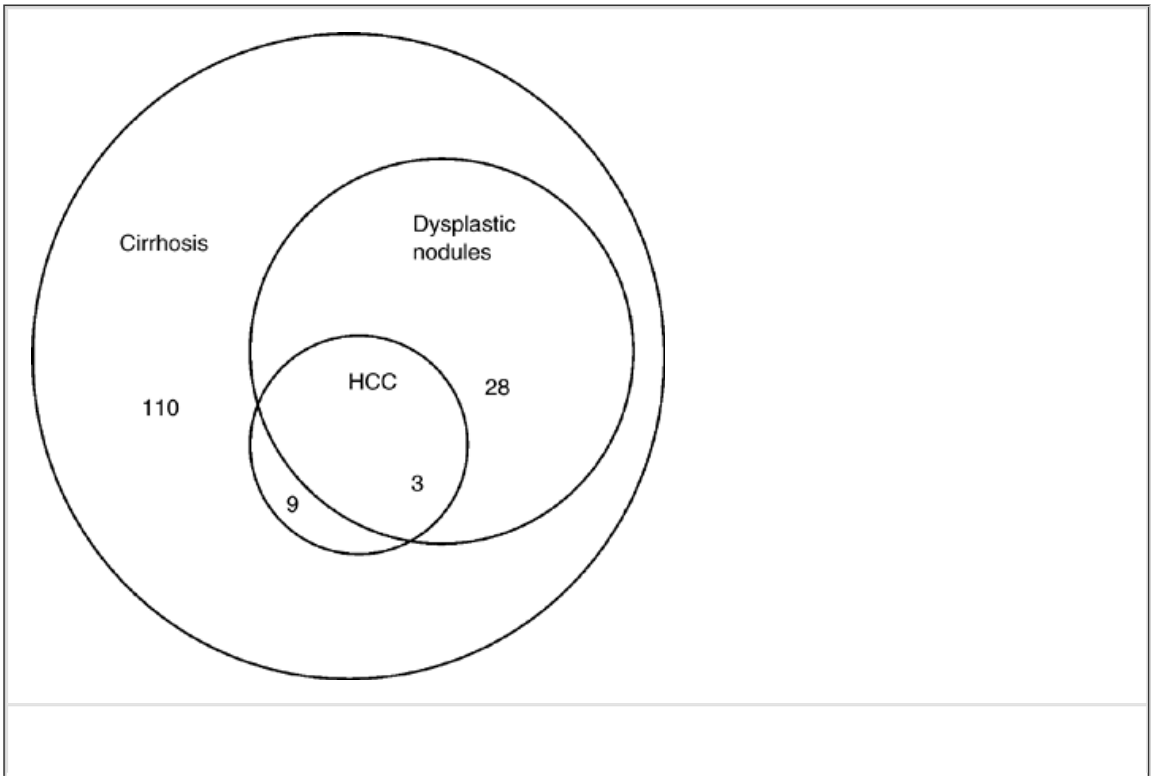
The definition of cirrhosis has three components based on gross or microscopic pathologic findings: (a) Nodules of regenerating hepatocytes (b) bands of fibrosis that surround these nodules, and (c) the process by which this occurs, which is diffuse throughout the liver. Many of the other forms of nodules described later are differentiated from cirrhosis by not meeting one of these three criteria. Cirrhosis is usually classified on the basis of morphologic findings as being *micronodular*, *macronodular*, or *mixed*. These terms refer to the sizes of the nodules of regenerating hepatocytes that are present. Therefore, in micronodular cirrhosis, the nodules are usually 2 to 3 mm in diameter. This pattern is characteristic of the cirrhosis caused by alcohol and hemochromatosis, whereas most other causes of cirrhosis result in macronodular or mixed macronodular and micronodular cirrhosis, in which the nodules typically range between 3 and 10 mm in diameter.

Dysplastic nodules

Among cirrhotic nodules, some stand out as being unusual on gross or microscopic examination. Therefore, dysplastic nodules are defined as a nodular region of hepatocytes at least 1 mm in diameter with dysplasia but without definite criteria of malignancy. For nodules larger than 10 mm, the term *macroregenerative nodule* (MRN) has been applied. Although the International Working Party abandoned it, this term may still have some value because clinicians and radiologists often encounter large regenerative nodules that seem to have a propensity to become malignant. Synonyms for this lesion include *large regenerative nodule* and *adenomatous hyperplasia*.

In two series of cases, investigators examined the incidence of MRNs in liver explants. Ferrell et al. (2) examined 110 sequentially explanted cirrhotic livers and found that 19 of them (17.3%) had nodules between 0.8 and 3.5 cm in diameter (Fig. 43.1). Ten livers had more than 1 nodule, and a total of 40 nodules were detected. Twelve of the nodules were hepatocellular carcinoma (HCC) and 28 were MRNs. Theise et al. (3) examined 44 explanted livers and identified 48 MRNs larger than 1 cm in diameter in 11 livers. Both these studies showed a close association between MRNs and HCC in the same liver.

There is debate about the origin of dysplastic nodules. It was thought that they are simply "overgrown" cirrhotic nodules. The observation that nearly all dysplastic nodules contain intact portal triads implies that these lesions are not derived from regenerating nodules but rather that they may represent the growth of nodules of transformed hepatocytes (4).



▪ **Figure 43.1** Dysplastic nodules and hepatocellular carcinoma (HCC) found in cirrhotic livers at the time of transplantation. (Adapted from Ferrell L, Wright T, Lake J, et al. Incidence and diagnostic features of macroregenerative nodules vs. small hepatocellular carcinoma in cirrhotic livers. *Hepatology* 1992;16:1372–1381, with permission.)

Dysplastic nodules rarely result in any clinical symptoms. Patients may have clinical features associated with cirrhosis, or the nodules may be detected radiographically if they are large enough, usually as an incidental finding. Nodules larger than 1 cm in diameter can be detected with either ultrasonographic examination or sensitive computed tomographic (CT) or magnetic resonance imaging (MRI) techniques. Unfortunately, large dysplastic nodules cannot be differentiated reliably from HCC by radiographic means; therefore, they present a challenge to the clinician caring for the patient. Biopsy of such nodules can be performed with CT or ultrasonographic guidance to rule out HCC, but if cancer is not present in the specimen, the possibility that the correct portion of the lesion has not been sampled cannot be excluded. Table 43.1 shows the high rate of development of malignant growth within large dysplastic nodules, ranging between 24% and 45% over a period of several years.

Hepatocellular Nodular Lesions without Cirrhosis

Nodular regenerative hyperplasia

Nodular regenerative hyperplasia (NRH) is defined by hepatocellular nodules distributed throughout the liver in the absence of fibrous septae between the nodules. Most reports have been of single cases or small series of cases. A recent autopsy study showed that NRH was

present in 2.6% of 2,500 consecutive autopsies. NRH has been reported to occur in children and even in fetal liver. Familial occurrence has been documented. NRH has been described in association with a variety of hepatic and systemic diseases (Table 43.2) but appears to be a nonspecific tissue adaptation to heterogeneous distribution of blood flow rather than a distinct disease entity. What many of these conditions appear to have in common is the disturbance of blood flow to the liver, which can involve the portal vein (through thrombosis), the hepatic artery (with arteritis), and the hepatic outflow tract (as in Budd-Chiari syndrome and congestive heart failure). Even some of the drugs associated with NRH probably act through their effect on blood vessels. For example, azathioprine may cause signs and symptoms that resemble those of veno-occlusive disease, and the use of this agent is causally linked with NRH. It seems that insufficient blood supply to portions of the liver, caused by conditions such as portal venous thrombosis, leads to atrophy of the parenchyma, with compensatory hyperplasia occurring in areas with adequate blood supply.

Table 43.1. Outcome of Radiographically Identified Dysplastic Nodules

Author	Number of nodules	Outcome of nodules		
		Disappeared (%)	Hepatocellular carcinoma (%)	Unchanged (%)
Takayama et al. (4a)	20	2 (10%)	9 (45%)	9 (45%)
Kondo et al. (4b)	17	4 (24%)	4 (24%)	9 (52%)
Borzio et al.	32	7 (22%)	8 (25%)	17 (53%)

(4c)				

At gross examination of the liver, there is diffuse fine nodularity of the liver approximately 1 to 2 mm in diameter. Microscopic examination shows that the normal architecture has been replaced with monoacinar regenerative nodules, which often contain portal tracts (4). The nodules are surrounded by compressed liver cell plates rather than fibrosis, and dilated sinusoids may be seen adjacent to nodules (Fig. 43.2). Although the nodularity may be visible with hematoxylin and eosin stain, it is best seen with a reticulin stain, which shows thick cell plates within the nodule and compressed plates surrounding the nodule.

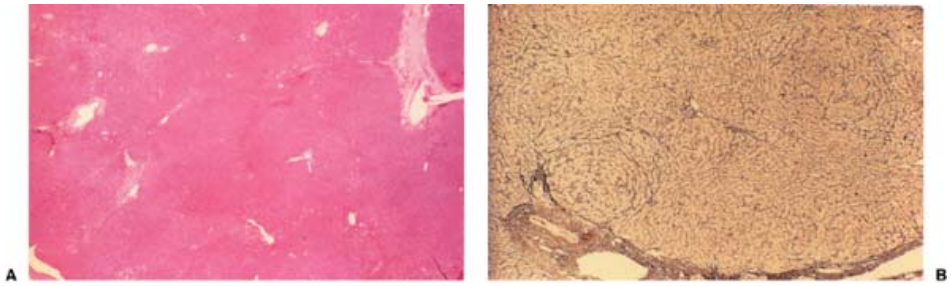
The clinical features of NRH are variable, and many patients have no symptoms. Patients range widely in age, although NRH is rare among children. Patients often have a history of another medical illness, which was presumably a predisposing factor for NRH. The main clinical consequence of NRH is portal hypertension, which manifests as splenomegaly and gastroesophageal varices. Ascites is uncommon because in most patients the hepatic synthetic function is preserved and, therefore, serum albumin levels are normal. Serum aminotransferase levels are characteristically normal, as are bilirubin values, although alkaline phosphatase levels are usually moderately elevated (5). Therapy is directed at removing the causative agent if possible and controlling portal hypertension. Patients with NRH who experience bleeding from varices usually tolerate this well because hepatic synthetic function is preserved. Surgical shunting or transjugular intrahepatic portosystemic shunt (TIPS) is rarely indicated, and the varices can often be controlled with injection,

sclerotherapy, or endoscopic banding. Patients with NRH have mistakenly undergone liver transplantation because they were thought to have cirrhosis, and they have done well (6).

Table 43.2. Conditions Associated with Nodular Regenerative Hyperplasia

Vascular disease
Budd-Chiari syndrome
Portal venous thrombosis
Drugs and toxins
Azathioprine
Thorotrast
Toxic oil syndrome
Thioguanine
Collagen vascular disease
Systemic lupus erythematosus
Scleroderma
Mixed connective tissue disease
Rheumatoid arthritis
Felty's syndrome
Polymyalgia rheumatica
Antiphospholipid antibody syndrome

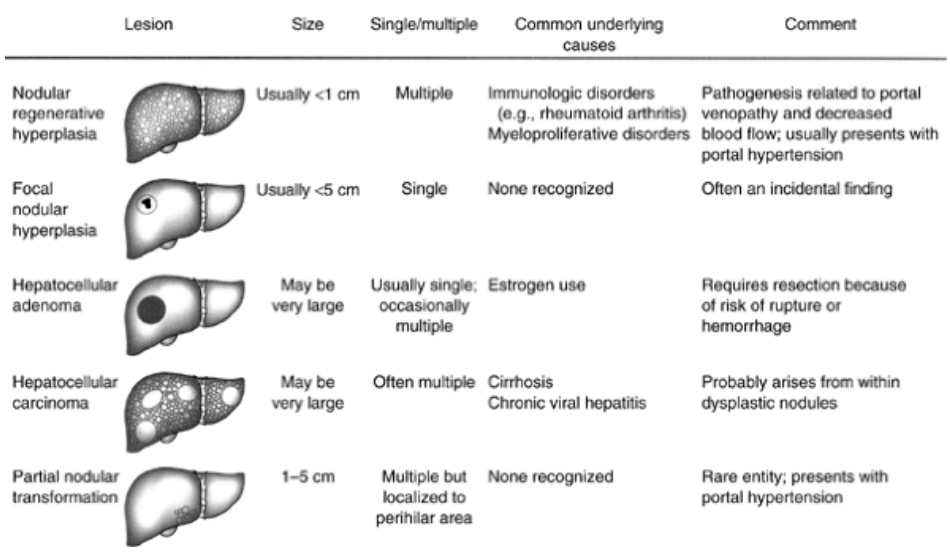
- Other liver disease
  - Primary biliary cirrhosis
  - After liver transplantation
  - Metastases from pancreatic cancer
  - Hepatocellular carcinoma
- Neoplastic conditions
  - Myeloproliferative disorders
  - After bone marrow transplantation
  - Non-Hodgkin's lymphoma
  - Castleman disease
- Immunodeficiency syndromes
  - HIV infection
  - Common variable immunodeficiency
- Miscellaneous
  - Primary pulmonary hypertension
  - Glomerulonephritis
  - Behçet's disease
  - Schnitzler syndrome
  - Diabetes mellitus
  - Congestive heart failure
- Idiopathic
  - Sporadic
  - Familial



▪ **Figure 43.2 A:** Photomicrograph of the liver shows nodules of nodular regenerative hyperplasia without surrounding fibrosis (hematoxylin and eosin). (Courtesy of Elizabeth M. Brunt, MD.) **B:** Nodular regenerative hyperplasia (reticulin stain). (Courtesy of Elizabeth M. Brunt, MD)

Unusual forms of nodular regenerative hyperplasia

Felty's syndrome is a rare complication of rheumatoid arthritis consisting of leukopenia and splenomegaly (7). Leukopenia may be associated with increased risk of bacterial infection. The splenomegaly is thought to be caused by portal hypertension. Most biopsy specimens of the liver from patients with Felty's syndrome show NRH, although a small proportion show only portal fibrosis or sinusoidal lymphocytosis. Felty's syndrome carries an increased risk of non-Hodgkin's lymphoma (8).



Lesion	Size	Single/multiple	Common underlying causes	Comment
Nodular regenerative hyperplasia	Usually <1 cm	Multiple	Immunologic disorders (e.g., rheumatoid arthritis) Myeloproliferative disorders	Pathogenesis related to portal venopathy and decreased blood flow; usually presents with portal hypertension
Focal nodular hyperplasia	Usually <5 cm	Single	None recognized	Often an incidental finding
Hepatocellular adenoma	May be very large	Usually single; occasionally multiple	Estrogen use	Requires resection because of risk of rupture or hemorrhage
Hepatocellular carcinoma	May be very large	Often multiple	Cirrhosis Chronic viral hepatitis	Probably arises from within dysplastic nodules
Partial nodular transformation	1–5 cm	Multiple but localized to perihilar area	None recognized	Rare entity; presents with portal hypertension

▪ **Figure 43.3** Nodular diseases of the liver. (Reproduced from Di Bisceglie AM, Buetow PC. Tumors of the liver. In: Maddrey WC, Feldman M, eds. *Atlas of the liver*, 2nd ed. Philadelphia, PA: Current Medicine, 2000:13.1–13.14, with permission.)

Partial nodular transformation

Partial nodular transformation (PNT) of the liver is a rare entity characterized by the formation of large hepatocellular nodules without marked fibrosis, particularly at the hepatic hilum or around large portal areas. It does not meet the criteria of cirrhosis because the condition is not diffuse and the nodules are not surrounded by fibrosis. It is similar to NRH, except that the nodules of NRH are diffuse throughout the liver and are usually much smaller (Fig. 43.3). PNT usually occurs as an isolated condition but has been reported in association

with vascular abnormalities such as persistent ductus venosus, portal venous thrombosis, and portal venous emboli of HCC (9,10,11). The pathogenesis is uncertain, but it has been suggested that PNT may represent a variant of NRH in which localized obstruction of blood flow causes formation of localized hepatic nodules (8). Because these nodules occur predominantly in or near the hepatic hilum, PNT often leads to presinusoidal portal hypertension.

PNT has been found in both adults and children. Patients usually have features of portal hypertension, such as bleeding from gastroesophageal varices and ascites. If the nodules are large enough, hepatomegaly resulting from portal hypertension may be present with splenomegaly. Serum aminotransferase activity is typically within the normal range. The diagnosis of PNT is often made only at autopsy or surgery, but it can be made with needle biopsy of the liver. No characteristic radiographic features of PNT have been described. Because PNT is such a rare condition, there are no specific treatment guidelines other than a recommendation for symptomatic management.

Focal nodular hyperplasia

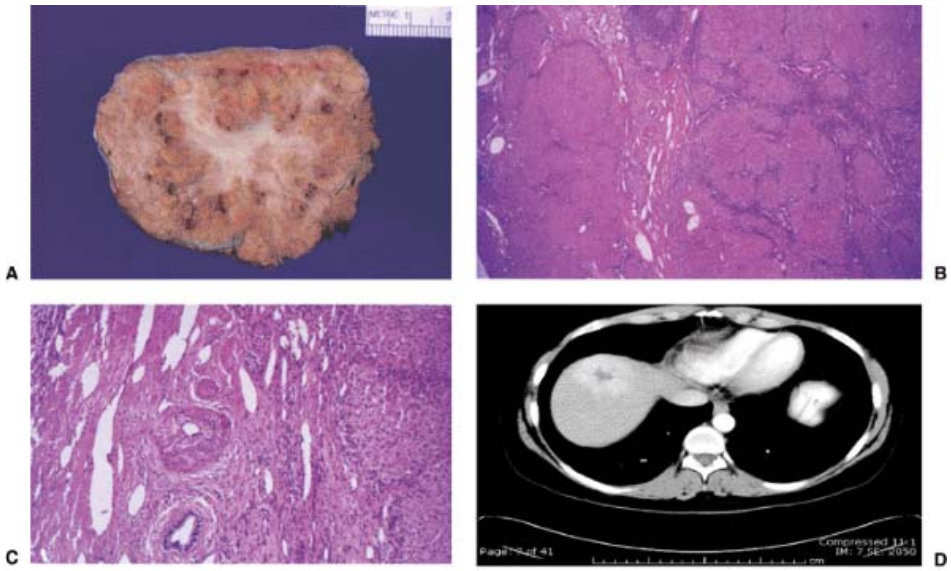
Focal nodular hyperplasia (FNH) is a benign, tumor-like lesion of the liver considered to be hyperplastic in origin rather than neoplastic. The exact frequency is not known, but large series of cases have been reported. FNH occurs predominantly in women but has also been found in men and children. It rarely causes clinical complications, but its importance lies mainly in being differentiated from hepatocellular adenoma and HCC. FNH classically occurs in noncirrhotic liver, but a recent report suggests that similar lesions may be seen in cirrhosis as well (12). This is discussed in detail in Chapter 42 of the book.

The cause of FNH is not known. It typically occurs in isolation but may be associated with

other liver diseases such as Budd-Chiari syndrome, pulmonary hypertension, primary sclerosing cholangitis, hemochromatosis, echinococcal cyst, and agenesis of the portal vein. Because of the female preponderance of this condition (female-to-male ratio approximately 8: 1), a link with oral contraceptive use has been postulated. However, Mathieu et al. (13), in a study in which the subjects were 216 women with FNH, examined tumors in patients taking oral contraceptives and those not taking these agents. The investigators found that neither the size nor the number of FNH lesions was influenced by oral contraceptive use. A more recent study identified an odds ratio of 2.8 for using oral contraceptives at any point of time among patients with FNH compared to controls (14). FNH may be associated with other vascular conditions affecting the liver, such as hemangioma and hereditary hemorrhagic telangiectasia (15,16).

In a study of the cases of 168 patients with FNH, investigators examined the gross and microscopic pathologic features of this condition (17). In 76% of patients, the mass was solitary and more often located in the right lobe than the left. In 21% of patients, between 2 and 5 nodules were found, whereas in the other 3% of cases between 15 and 30 nodules were detected. The lesions ranged in size from 1 mm to 19 cm in diameter. In total, 64% of masses were smaller than 5 cm in diameter. A central scar was visible on gross examination of 138 of 305 lesions (45%), and a large vascular pedicle was found in the periphery of 22 lesions (7%) (Fig. 43.4). Microscopic examination showed that all the lesions consisted of nodular hyperplastic parenchyma partially or completely surrounded by fibrous septae. Additional changes such as periodic acid–Schiff positive globules and Mallorys hyaline were sometimes found in hepatocytes within the lesion. A central scar was found on light microscopic examination of 153 lesions, and the lesions always contained malformed blood vessels of varying caliber. Histologic cholestasis was found in 36 cases, and some patients had hepatocellular steatosis. Portal tracts and terminal hepatic venules were not present.

FNH is often an incidental finding during abdominal surgery or imaging studies of the abdomen performed for another reason. Patients sometimes report abdominal pain or feel a right upper quadrant mass in the liver. The diagnosis is often suggested by certain characteristic radiographic features. The ideal technique is helical CT with images taken before infusion of contrast medium and in the arterial (early) and venous (late) phases. FNH typically becomes homogeneously enhanced with contrast material in the early phase, with rapid washout of contrast material such that the tumor becomes isodense to the liver on late portal venous and delayed images (18). On late portal venous and delayed images, enhancement of peripheral vascularity may be found. This gives the appearance of a rim around the tumor and corresponds to enlarged vessels or sinusoids at the periphery of the tumor. The central feeding artery may be seen in the arterial phase of the scan. On MRI, FNH is typically isointense or hypointense on T1-weighted images and slightly hyperintense or isointense on T2-weighted images (19). Most of these tumors are homogeneous, and the central scar appears hyperintense on T2-weighted images because of its vascularity. When gadolinium chelates are administered as contrast agents for MRI, a pattern identical to that seen on CT scans can be observed, that is, dramatic enhancement in the arterial phase followed by isointensity of the lesion during the portal venous phase. Technetium-99 sulfur colloid scans have been used to differentiate FNH from adenoma because the latter shows decreased uptake of radioisotope. This technology has largely been replaced by spiral CT and MRI.



▪ **Figure 43.4 A:** Macroscopic appearance of resected focal nodular hyperplasia. The typical central scar is evident. (Courtesy of Elizabeth M. Brunt, MD) **B:** Photomicrograph of focal nodular hyperplasia shows regenerating nodules of hepatocytes surrounding a central core that contains abnormal blood vessels and a bile duct. (Courtesy of Elizabeth M. Brunt, MD) **C:** Focal nodular hyperplasia with an abnormal, thick-walled artery adjacent to the center of the lesion. (Courtesy of Elizabeth M. Brunt, MD) **D:** Dynamic computed tomography scan of the liver showing focal nodular hyperplasia. Note hypervascular area in right lobe of the liver with a darker, central stellate scar.

Although the diagnosis of FNH can be made by the examination of a needle biopsy specimen of the liver, this approach is less than ideal because of sampling error. Needle biopsy samples only a small portion of the lesion. The specimen may contain only a group of hepatocytes that cannot be reliably differentiated from hepatocellular adenoma. Furthermore, the presence of fibrous septae within the lesion may give the appearance of cirrhosis (referred to as *pseudocirrhosis*). Therefore, if the results of radiographic studies are convincing and the patient has no symptoms, no further testing is needed. However, if there is uncertainty about the diagnosis, surgical resection or large surgical biopsy may be needed for accurate diagnosis of FNH (Table 43.3). A recent study suggests that application of a rigorous scoring system to liver biopsy specimens can aid in the accurate diagnosis of FNH (20).

Table 43.3. Comparison of Hepatocellular Adenoma and Focal Nodular Hyperplasia

Feature	Adenoma	Focal nodular hyperplasia
Sex	Female	Female
Oral contraceptive use	Strong association	Questionable
Symptoms	Occasional	Rare
Multiple	12%–30%	Approximately 30%

Central arterial scar	No	Yes
Treatment	Resection	Resection only if symptomatic

Adapted from Rodes J, Sherlock S. Focal nodular hyperplasia in a young female. *J Hepatol* 1998;29:1005–1009, with permission.

FNH rarely results in clinically important consequences or complications. Specifically, the risk of bleeding or rupture is very low, as is the risk of development of malignant changes. Few longitudinal studies have been done, but in one small series of 18 cases of FNH, the volume remained stable in 6, decreased in 10, and increased in 2 (21). Usually, no specific treatment is needed, but surgical resection is curative if the patient has symptoms. Resection is often performed in case of diagnostic uncertainty.

Unusual forms of focal nodular hyperplasia

The International Working Party has designated multiple FNH syndrome a distinct syndrome consisting of two or more FNH lesions in association with hemangioma of the liver, vascular malformations of the central nervous system, or tumors of meningeal or astrocytic origin (1). Of course, FNH is multiple in approximately 30% of cases, but most of these do not have the other features associated with this syndrome.

Nguyen et al. (17) found that approximately 20% of cases of FNH are *nonclassical*. This term refers to lesions lacking some of the typical histologic features, such as malformed vessels, a central scar, or abnormal nodular architecture. Notwithstanding these histologic differences, these cases were clinically identical to those with classic features.

Another variant of FNH is the telangiectatic form, which differs from typical lesions by the absence of a central scar and lack of architectural nodular distortion. Instead, there is sinusoidal prominence with associated hepatic plate atrophy. Telangietactic FNH (TFNH) is more likely to be monoclonal in origin than is classical FNH and is more likely to be multiple and perhaps even more likely to result in hemorrhage than typical FNH, making it more like adenoma (22,23).

Nodular Neoplasms

Hepatocellular adenoma

Hepatocellular adenoma, a benign neoplasm of hepatocytes, is described in detail in Chapter 42. It certainly manifests as a nodular condition of the liver that is usually solitary but is at times multiple. Adenoma nearly always occurs in women and only in those men taking sex hormones. Indeed, adenoma was an exceedingly rare tumor before the introduction of oral contraceptives. An important recent finding has been the genetic alterations in hepatocellular adenomas. Bilallelic mutations of the *TCF1* gene coding for the hepatocyte nuclear factor 1α (HNF1α) were identified in 60% of patients with adenoma (24). The Wnt pathway, also activated in approximately 25% of patients with HCC, seems to be activated in at least some cases of adenoma (25).

Although it can be detected incidentally while asymptomatic, adenoma often manifests as abdominal pain and can be complicated by hemorrhage or rupture. Adenoma can sometimes be difficult to distinguish from well-differentiated HCC, and there are reports of cancer developing within adenoma, whereas development of malignancy is exceedingly rare in case of FNH. Adenoma tends to grow, particularly in the presence of pregnancy or with continued

use of oral contraceptives.

It has been found that adenoma occurring in patients taking estrogens tends to shrink when these drugs are stopped. Adenoma occurring during pregnancy also tends to recede after the pregnancy is over. Surgical resection is usually recommended for adenoma to avoid the risk of rupture and hemorrhage. It may also be difficult to diagnose adenoma with confidence on the basis of radiologic findings on and needle biopsy, and with examination of the resected lesion is usually more conclusive.

Adenomatosis of the liver refers to the presence of more than four adenomata within the same liver and may have been confused at some time with NRH. The association with oral contraceptive use does not seem to be as strong with adenomatosis as it is with simple hepatic adenoma. Grazioli et al. (26) reported on a series of 15 patients with more than 10 adenomata and no history of glycogen storage disease or anabolic steroid use. Only one of the patients was of male gender but all were adults. Five of the 14 women gave a history of oral contraceptive use. Most of the patients had abdominal pain and hepatomegaly. In all patients the adenomata increased in size over time, and in two cases HCC developed. Four of the 15 patients underwent hepatic resection, and 5 underwent liver transplantation.

Comparison of hepatocellular adenoma and focal nodular hyperplasia

Hepatocellular adenoma is sometimes difficult to differentiate from FNH. The two conditions are compared in Table 43.3. Briefly, although FNH has a slight female preponderance, a link with female hormones in general and oral contraceptive use in particular has been difficult to prove, whereas these associations are very striking for adenoma. Whereas adenoma carries substantial risk of being complicated by hemorrhage and rupture, clinical complications of FNH are rare. Radiologic techniques to differentiate adenoma from FNH have improved considerably. Diagnosis of FNH relies on detection of the central scar, which is usually present and contains abnormal blood vessels. This central scar can be detected with ultrasonography, contrast-enhanced CT, MRI, and even angiography, whereas adenoma shows only nonspecific contrast enhancement and may be inhomogeneous because of the presence of hemorrhage or necrosis. Technetium-99 sulfur colloid liver scanning has also been suggested for differentiating these two liver tumors. This type of scan shows hepatocellular adenoma as an area of decreased or absent uptake in all patients. However, Herman et al. (27) found that approximately 60% of patients with FNH had a sulfur colloid scan showing decreased or absent uptake. Molecular analyses have shown β-catenin mutations in hepatic adenoma but not in FNH (28).

Hepatocellular carcinoma

HCC is a malignant neoplasm of hepatocytes and is described in Chapter 44. HCC has been described as

occurring in association with several of the nodular lesions described earlier, including NRH, dysplastic nodules, hepatocellular adenoma, and FNH. The link between HCC and NRH or FNH probably involves compromise of blood supply to the liver because of the presence of the malignant tumor, which causes direct pressure or microvascular invasion, whereas dysplastic nodules and adenoma may give rise to HCC.

Diagnostic Approach to Nodular Diseases of the Liver

In dealing with a patient with an unknown solid hepatic lesion, it is critical to determine whether the patient has underlying liver disease, and in particular whether cirrhosis is present. This involves serologic testing for various causes of liver disease and may even need liver biopsy away from the area of concern. If cirrhosis is present, HCC or dysplastic nodules are very likely to be found, whereas if there is not significant liver disease, FNH or adenoma should be considered. Imaging techniques have improved dramatically over the last decade and often allow excellent characterization of nodular lesions. Multiphasic CT scans using up-to-date equipment is capable of showing vascularity of hepatic tumors and nodules in great detail. Advances in diagnostic ultrasonography with color Doppler or the use of contrast agents may be useful in characterizing hepatic lesions (29,30). However, the greatest

advances appear to have occurred with MRI, and recent studies have demonstrated accurate differentiation of FNH from hepatic adenoma using contrast-enhanced MRI or distinction between adenoma or HCC and "nonsurgical" lesions such as FNH or regenerative nodules, although Krinsky and Israel found that dysplastic and nondysplastic nodules still cannot be separated (31,32,33).

Although needle biopsy of nodular hepatic lesions such as FNH may be difficult to interpret, there appears to be a recent impetus toward needle biopsy of lesions in cirrhotic livers in particular. Therefore, Bolondi et al. (34) have pointed out that a substantial number of nodules in cirrhosis are hypovascular, including HCC. Their observations call into question the validity of the noninvasive criteria for diagnosis of HCC. The accuracy and safety of ultrasonography-guided biopsy of these lesions has been documented (35).

Cystic Diseases of the Liver

Cystic diseases of the liver represent three groups of hepatic disorders that share the clinical feature of abnormal fluid-filled spaces in the liver and biliary tree. The first and largest group is fibrocystic diseases of the liver and biliary tree (Fig. 43.5). They are related hepatic disorders characterized by overgrowth of biliary epithelium leading to the production of fluid-filled dilated spaces, formation of portal fibrosis, and development of embryonic ductal plate malformations. The lesions result from malformations in different portions of the developing biliary tree and include polycystic liver disease (PCLD), simple hepatic cysts, congenital hepatic fibrosis (CHF), von Meyenburg complexes, and choledochal cysts (Table 43.4). The second group of disorders results from congenital defects of the embryonic foregut and includes cystadenoma and cystadenocarcinoma. The last disorder mimics the other cystic liver diseases and results from infection with the parasites *Echinococcus granulosus* or *Echinococcus multilocularis*.

Table 43.4. Bile Duct Segment Associated with Fibrocystic Disease of the Liver and Biliary Tract

Fibrocystic disease	Associated bile duct
Choledochal cysts	Common hepatic
Caroli's disease	Segmental area
Congenital hepatic fibrosis	Interlobular
Polycystic liver disease	Intralobular
Simple cysts	Intralobular

Fibrocystic Liver Disease

Polycystic liver disease

PCLD is a rare disease in which multiple cysts develop within the parenchyma of the liver. It is generally defined as the presence of four or more thin-walled cysts within the hepatic parenchyma because simple hepatic cysts are commonly characterized by one, two, or three cysts (36). PCLD occurs both in association with autosomal dominant polycystic kidney disease (ADPKD) and in isolation.

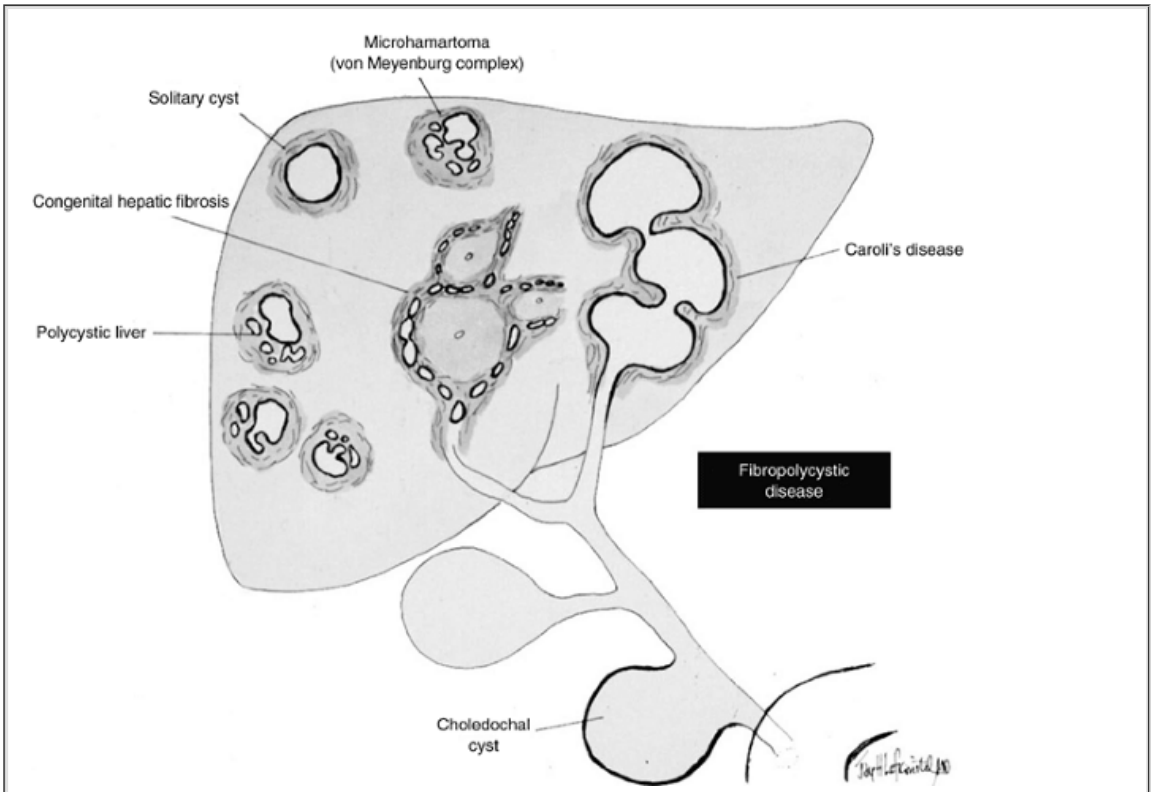
Epidemiology and course of disease

The true prevalence of PCLD is not known. Results in autopsy series suggest that the

prevalence ranges from 0.05% to 0.13% (37,38). The prevalence of multiple liver cysts in patients with ADPKD is 45% to 68% (38). Cyst prevalence in ADPKD increases from approximately 24% in the third decade of life to 80% in the sixth decade of life (39). The association of PCLD with ADPKD occurs in 16% to 93% of patients (40,41). This range is wide because the prevalence of PCLD in ADPKD depends on age and the amount of renal dysfunction (42).

When occurring with ADPKD, cysts generally begin to form in the liver after the onset of puberty. Although the proportion of men and women with liver cysts and ADPKD is the same, women tend to have both more and larger cysts (43). Cyst formation is thought to be

associated with estrogen exposure because the number and size of cysts correlate with number of pregnancies, use of oral contraceptives, and use of female hormone replacement therapy (43). Clinically relevant polycystic disease also correlates with advancing age, severity of renal cystic disease, and presence of renal dysfunction (42).



▪ **Figure 43.5** Diagram showing the relations between the fibrocystic diseases of the liver and biliary tract. (Artwork courtesy of Jay H. Lefkowitch, MD)

There are few published data on the frequency of symptomatic PCLD associated with ADPKD. Descriptions of symptomatic complications of PCLD are most often published in the form of case reports or reports of small series of patients over the course of many years. Most authors indicate that PCLD is predominantly a silent disease. The frequency of symptoms may be increasing because of the success of hemodialysis and renal transplantation; larger numbers of older patients with renal insufficiency are likely to have more and larger cysts within the liver. One report indicated that as much as 10% of the mortality among patients with ADPKD who undergo hemodialysis may be related to PCLD (44).

There is even less understanding of the epidemiology and course of isolated PCLD. Reports of old autopsy and surgical series suggest that multiple hepatic cysts may be present in the absence of renal cysts in as many as 50% of all patients with multiple hepatic cysts (45). This is probably an overestimation. Results of a more recent autopsy series suggested that only 7% of patients with PCLD did not have associated renal cysts (38). Several kindreds of

patients have been found to have multiple cysts in their livers and no evidence of ADPKD (37,46,47,48). Similar to ADPKD-associated PCLD, isolated PCLD is more severe in women and more severe disease is associated with pregnancy (49). Many patients are likely asymptomatic with clinically silent disease (49). Because these series represent small numbers of patients, there is no clear understanding of the course of isolated PCLD.

Genetics and molecular biology

ADPKD is one of the most common genetic defects, with a disease frequency of 1:1,000 in the white population (50). There are two genes associated with ADPKD—*PKD-1* and *PKD-2* (51). *PKD-1* is located on the short arm of chromosome 16 and is responsible for approximately 85% of cases of ADPKD (51). PKD-2 is located on the long arm of chromosome 4 and is responsible for about 15% of ADPKD (52). There are numerous mutations known for the *PKD-1* and *PKD-2* genes. The gene products, polycystin-1 and polycystin-2, are transmembranous glycoproteins that are thought to be involved in cell–cell or cell–matrix interactions. Polycystin-1 appears to interact with a G-protein signaling pathway that modulates calcium channels (52). Polycystin-2 is an integral membrane protein with the characteristics of a cation channel (52). Polycystin-1 and polycystin-2 complex in the cell membrane and localize in the primary cilium (52). The primary cilium is a microtubule-based cellular structure found on the luminal surface of epithelium, including biliary and renal tubular epithelium, which acts as a flow sensor and regulates Ca^{2+} influx. Loss of flow sensing has been hypothesized to lead to dedifferentiation, cell proliferation, and loss of restriction in tubule size, resulting in cyst formation (53). Although the genetic inheritance pattern is autosomal dominant, a cellular recessive two-hit model has been proposed. A germline mutation in *PKD-1* or *PKD-2* is not sufficient to produce disease, but a second somatic mutation in the functional *PKD* gene triggers monoclonally derived cyst formation (54,55).

Recent progress has been made in understanding the genetic basis of isolated PCLD. Reynolds et al. studied two large kindreds with autosomal dominant isolated PCLD and showed linkage to a putative causative gene on the long arm of chromosome 19 (48). Drenth et al. and Li et al. identified that mutations in PRKCSH are responsible for some cases of isolated PCLD (56,57). PRKCSH has been previously identified as protein kinase C substrate 80K-H, but the function of the protein product, hepatocystin, is unclear. Hepatocystin can function as the noncatalytic β-subunit of glucosidase II, which plays a major role in the regulation of proper folding and maturation of glycoproteins. PKD-1 and PKD-2 are glycoproteins, so it has been proposed that mechanistically there could be a link between ADPKD-associated PCLD and isolated PCLD if defective glycosylation from mutant glucosidase II results in improper functioning of polycystins (57,58). There is a preliminary report that mutations in SEC63 are associated with isolated PCLD in persons who have normal PRKCSH (58). SEC63 is also involved in the processing of integral and secreted proteins as a part of the multicomponent translocon involved in protein translocation (58). A similar two-hit model of ADPKD-associated PCLD has been proposed for isolated PCLD.

Pathology

The fluid-filled cysts of PCLD are usually scattered throughout the liver, although they can be present in only one lobe (Fig. 43.6). The cysts vary in size from less than 1 cm to more than 10 cm in diameter and cause massive enlargement of the liver. Microscopically, the cysts are close to or actually within the portal tracts (59). The cyst cavities are lined by flat or cuboidal epithelium, the presence of which is often associated with biliary microhamartoma (60). Fluid within the cysts is consistent with the bile salt–independent fraction of bile and increases with secretin stimulation. Therefore, the cysts are lined with biliary-type epithelium (61) and are hypothesized to form from the dilatation of biliary microhamartomata (39,60). The cysts may also arise from peribiliary glands (49). During their development the cysts become disconnected from the biliary tract (60). It is not clear whether the biliary microhamartomata are congenital or develop as the patient ages (60).

Clinical features

The symptoms of isolated and ADPKD-associated PCLD are most often caused by the

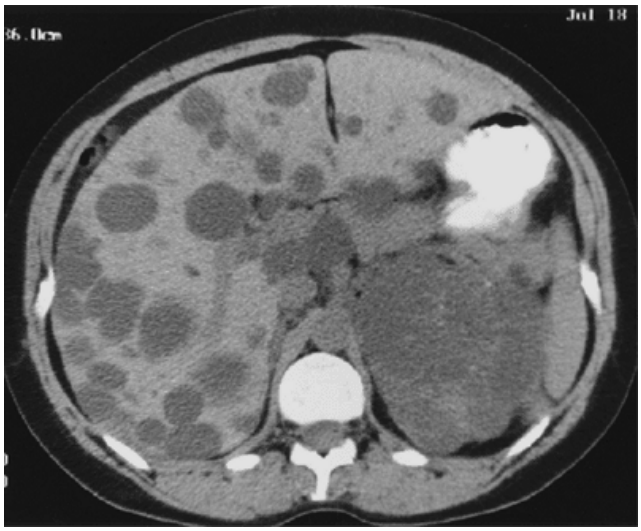
mechanical effect of the enlarged cystic liver. Most cases are asymptomatic (49). Some cases of PCLD may manifest as vague abdominal fullness or a palpable abdominal mass. Patients who underwent surgical intervention have been reported to have the following symptoms: Abdominal pain, abdominal distension, early satiety, fatigue, orthopnea, jaundice, ascites, and variceal bleeding (62). The right upper quadrant pain and shortness of breath experienced by patients with both PCLD and ADPKD correlate with larger liver volumes and not with kidney volume (63). Patients generally have preserved hepatic function on the basis of galactose elimination capacity and antipyrine clearance (62). Total hepatocyte volume remains normal, according to calculations of hepatic mass from CT images (42) (Fig. 43.7). Results of liver function tests are either normal or show a cholestatic pattern with usually mild elevations in alkaline phosphatase and total bilirubin levels. Serum albumin levels can be mildly depressed and prothrombin time elevated because of poor nutrition (49,62).

Complications of polycystic liver disease

The development of portal hypertension in PCLD is rare. There are 19 case reports of variceal bleeding related to PCLD in the literature (64). The pathophysiology of the development of varices is not clear. Some patients seem to have hepatic venous and or inferior

vena caval obstruction from direct compression of the cysts. Others may have associated CHF. Treatment involves obliteration of varices by means of repeated band ligation. Pharmacologic intervention with β-blockers or somatostatin analogs can also be attempted. TIPS is generally technically unfeasible because of the large cysts. Surgical debulking of the cysts can lead to relief of venous outflow tract obstruction and, therefore, of portal hypertension in some patients (62). Surgical portocaval shunts can be helpful. Liver transplantation can be considered in cases of refractory disease.

Brunt, MD) **C:** Photomicrograph of polycystic liver stained with hematoxylin and eosin showing cuboidal cyst lining. (Courtesy of Elizabeth M. Brunt, MD)



▪ **Figure 43.7** Abdominal computed tomography scan shows diffuse cystic involvement by polycystic liver disease.

Hepatic venous outflow tract obstruction has been reported in small case series (65). These patients have a history of PCLD and new development of ascites. Hepatic function is usually preserved, and the ascitic fluid has a high protein content. Findings on CT or MRI may suggest hepatic venous outflow tract obstruction, which can be confirmed with hepatic venography. Abdominal surgery may precipitate hepatic venous outflow tract obstruction. If there is no evidence of thrombus in the hepatic veins or vena cava, percutaneous or surgical treatment can be directed at the obstructing cyst. If thrombosis of vessels or the presence of multiple small cysts is the cause, surgical portosystemic shunting or liver transplantation should be considered. Transplantation should probably be reserved for patients with evidence of hepatic decompensation. Patients should be screened for hypercoagulable states with the appropriate laboratory studies.

Obstructive jaundice is a rare complication of PCLD, being described only in case reports. It results from direct obstruction of the biliary tree by a cyst. Endoscopic retrograde cholangiopancreatography (ERCP) is helpful to rule out other causes of biliary obstruction and to help identify the culprit cyst, usually with the aid of abdominal CT scan (66). Therapy can be with percutaneous drainage and sclerosis or with surgery.

Infection of hepatic cysts is a rare complication of PCLD. It occurs in 1% to 3% of patients with PCLD and ADPKD and appears to be more common in patients with renal failure (44). Most patients have fever and right upper quadrant or right flank pain (44). Leukocytosis or left shift is usually present, but results of liver function tests have a cholestatic pattern in fewer than one half of patients (44). Imaging with CT, ultrasonography, or MRI usually shows either a thickened cyst wall or different density of the cyst fluid (44). If there is doubt, an indium leukocyte scan appears to be more sensitive than a gallium scan in the diagnosis of cyst infection (44). Results of the culture of cyst fluid are almost always positive for single bacterial organisms, suggesting a hematogenous route of infection (44). Treatment is with percutaneous or surgical drainage and intravenous broad-spectrum antibiotics.

Both ADPKD-associated PCLD and isolated PCLD are associated with the development of intracranial aneurysms (67,68). Autopsy series show that 20% of patients with ADPKD have associated intracranial aneurysms (68). Screening for aneurysms is probably prudent before considering anticoagulation or surgical therapy.

Treatment

The method of management of liver cysts depends on the size, number, and location of the

cysts and on the clinical manifestations. Surgical options include both open and laparoscopic fenestration (deroofing) of the cyst, hepatic resection and cyst fenestration, and orthotopic liver transplantation (OLT). Percutaneous drainage has no role in treatment because of the almost universal recurrence rate, but drainage followed by addition of a sclerosing agent may be an alternative. Patients with one or a few cysts can be treated with laparoscopic fenestration or percutaneous drainage with sclerosis. The open surgical approach with cyst fenestration is more appropriate for larger numbers of and deeper cysts. Some surgeons have advocated open surgery with hepatic resection and cyst fenestration for patients with massive, highly symptomatic PCLD (62). This procedure is most appropriate for patients with multiple cysts and areas of parenchymal sparing. OLT is reserved for patients with massive diffuse bilobar disease, who are homebound and unable to perform activities of daily living, or who have evidence of hepatic failure (69).

Table 43.5. Selected Series of Patients who Underwent Open or Laparoscopic Surgery for Polycystic Liver Disease: Morbidity, Mortality, and Recurrence of Symptoms

Study	No. of patients	Operation	Mean follow-up period (y)	Morbidity (%)	Mortality (%)	Rate of recurrent symptoms (%)
Que (1995) (62)	30	R/F	2.7	58	3	3
Martin (1998) (69a)	6	OF	8	40	0	20
	9	R	0.75	67	0	0

R, resection; F, fenestration; O, open; L, laparoscopic; ns, not stated.

Table 43.5 lists selected series of both open and laparoscopic surgical results in the management of PCLD. In general, laparoscopic techniques have lower morbidity but higher rates of recurrence. Hepatic resection with cyst fenestration is the most effective technique in preventing recurrence, but it carries a high morbidity. Recurrence of symptoms is usually not caused by new cysts but by enlargement of the remaining cysts. Common postoperative complications include massive hemorrhage, biliary leaks, ascites, and infection. Careful patient selection is critical, especially with regard to the certainty that the symptoms are related to the liver cysts (70). If there is doubt, consideration should be given to percutaneous cyst aspiration to assess clinical response.

Several small series with limited follow-up evaluation have shown successful sclerosis of hepatic cysts with alcohol and minocycline hydrochloride. This technique is generally more successful for the management

of simple hepatic cysts than as therapy for PCLD. Complications include abdominal pain, fever, and ethanol intoxication. Care must be taken to avoid sclerosis of cysts that communicate with the biliary tree.

There are 76 case reports of patients who have been have undergone liver transplantation for highly symptomatic diffuse small cysts (71). Symptom relief was nearly universal among the surviving patients. The outcome of OLT is equal to or better than that of OLT performed for other typical indications. Previous attempts at surgery may increase the risk of perioperative complications. Earlier series typically performed liver and kidney transplantation, but more recent series suggest that combined transplantation is only necessary if significant renal dysfunction is present.

Simple hepatic cysts

Simple hepatic cysts are thought to result from congenital defects of intrahepatic bile ducts. They are lined with biliary-type epithelium but do not generally connect with the biliary tree. These cysts are estimated to have an incidence of 2.5% among the general population, with increased frequency with advancing age (36). They are most often asymptomatic incidental findings on abdominal imaging. When symptomatic, simple hepatic cysts can produce the same range of symptoms and complications as PCLD, although less frequently. Simple hepatic cysts can be differentiated from PCLD by lack of an autosomal dominant inheritance pattern, lack of associated renal cysts, and smaller numbers of cysts, usually less than four (48). Imaging with ultrasonography, CT, or MRI usually provides enough information for a diagnosis. On imaging the cysts appear as thin, smooth-walled anechoic masses or water densities. Any septations or papillary projections should raise suspicion for cystadenoma or cystadenocarcinoma Mergo and Ros (1998) (71a). Management of symptomatic cysts is by percutaneous sclerosis, open surgical or laparoscopic fenestration, or resection. Percutaneous treatment with aspiration followed by alcohol or another sclerosing agent is successful in most cases, and the recurrence rate is low. Open and laparoscopic fenestration can be performed with similar success but higher morbidity.

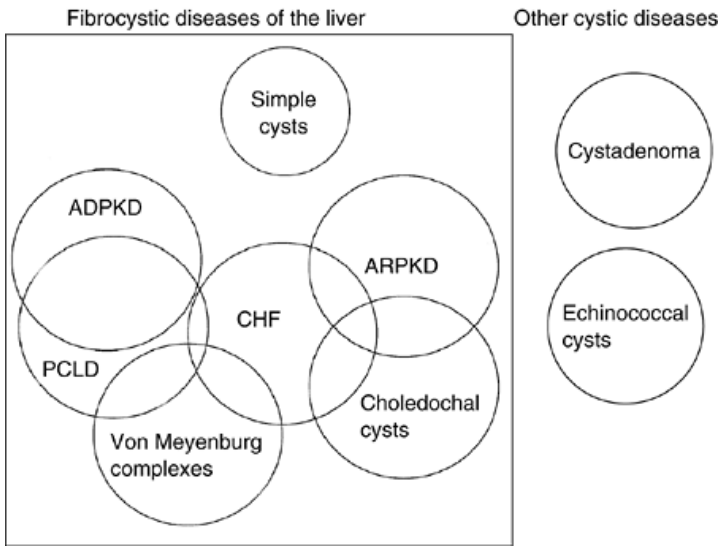
Congenital hepatic fibrosis

CHF is a rare disorder that results in fibrous destruction of interlobular bile ducts. The liver shows fibrous enlargement of the portal tracts; portal–portal bridging forms thick bands of scar that contain abnormal bile ducts. Normal-appearing cuboidal cells line the bile ducts in the scar (Fig. 43.8). CHF has been reported in association with other fibrocystic liver diseases, including adult PCLD, Caroli's disease, choledochal cysts, and von Meyenburg complexes (Fig. 43.9). CHF is most commonly associated with autosomal recessive polycystic kidney disease (ARPKD). It is not known whether the genetic defect in ARPKD is responsible for CHF. At least one half and probably more of patients with CHF have associated renal disease. CHF also has been associated with a variety of rare pediatric syndromes, including renal dysplasia; nephronophthisis; Joubert's syndrome; *c*erebellar vermis hypoplasia, *o*ligophrenia, congenital *a*taxia, *c*oloboma, *h*epatic fibrocirrhosis (COACH) syndrome; Meckel's syndrome type 1, Jeune's syndrome, vaginal atresia, tuberous sclerosis, phosphomannose isomerase 1 deficiency, Ivemark's syndrome type 2, short-rib syndrome, and osteochondrodysplasia (72).

The incidence of CHF is unknown. Because of the many clinical associations and the variable clinical presentation, some investigators believe that CHF is not a single entity but a spectrum of diseases. The cause of CHF is unknown. Desmet hypothesized that at birth,

patients who will eventually have CHF have ductal plate malformations of the interlobular bile ducts. These immature bile ducts undergo destructive cholangitis that results in loss of bile duct profiles and formation of fibrous scar. The destructive cholangitis progresses at variable rates and may arrest, explaining the variety of clinical presentations of the disease (72). The cause of the associated portal hypertension has been hypothesized to be hypoplasia or compression of small branches of the portal vein (72).



▪ **Figure 43.9** Interrelation between cystic diseases of the liver. ADPKD, autosomal dominant polycystic kidney disease; PCLD, polycystic liver disease; CHF, congenital hepatic fibrosis; ARPKD, autosomal recessive polycystic kidney disease.

The four patterns of clinical presentation of CHF are portal hypertensive, cholangitic, portal hypertensive–cholangitic, and latent. Serum aminotransferase levels are usually normal, although the alkaline phosphatase level is sometimes elevated. These patients usually do not have cirrhosis and maintain normal hepatic lobular architecture with normal hepatic function. The diagnosis is based on findings at liver biopsy. Surgical biopsy may be needed to obtain sufficient liver for diagnosis.

The portal hypertensive presentation is most common, representing approximately 70% of cases (73). Portal hypertensive CHF usually manifests in childhood or young adulthood as complications of portal hypertension, especially variceal bleeding with intact hepatic function. Hepatosplenomegaly may be present. Wedged hepatic venous pressure is normal, a finding consistent with presinusoidal portal hypertension. Symptomatic portal hypertension has traditionally been managed with surgical placement of a portosystemic shunt. Development of hepatic encephalopathy after shunting is extremely rare, probably because hepatic function is intact. Endoscopic variceal band ligation may be used to control acute bleeding. Endoscopic obliteration of esophageal varices is at least theoretically useful, although it would entail long-term endoscopic surveillance. Long-term follow-up evaluation of surgical shunts has shown that 39% of patients have jaundice, 17% have recurrent bleeding, and 17% have hepatic encephalopathy (74).

The cholangitic form of CHF manifests as fever, right upper quadrant pain, and a cholestatic pattern in the levels of the liver-associated enzymes. At least initially, patients with cholangitic CHF do not have evidence of portal hypertension. Treatment is with intravenous antibiotics. Either ERCP or percutaneous transhepatic cholangiography (PTC) can be used to image the biliary tree and relieve obstruction. These patients often have associated Caroli's disease, which results in the cholangitic signs and symptoms. Repeated bouts of cholangitis can lead to secondary biliary cirrhosis and the need for liver transplantation. Patients should be treated for Caroli's disease as described later.

The portal hypertensive–cholangitic or mixed presentation is a combination of symptoms of portal hypertension and cholangitis. Treatment is based on the presence of the symptoms described earlier. The latent form is typically discovered either at autopsy or during evaluation for other problems. It is generally asymptomatic and therefore requires no treatment.

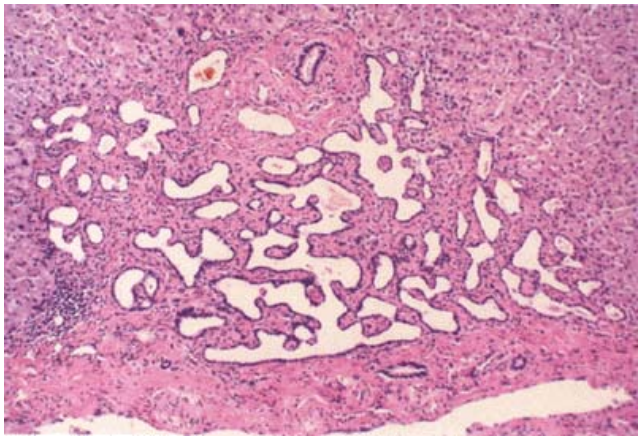
Rare reported associations with CHF include disease isolated to one lobe of the liver,

cholangiocarcinoma, ascites, and cavernous transformation of the portal vein.

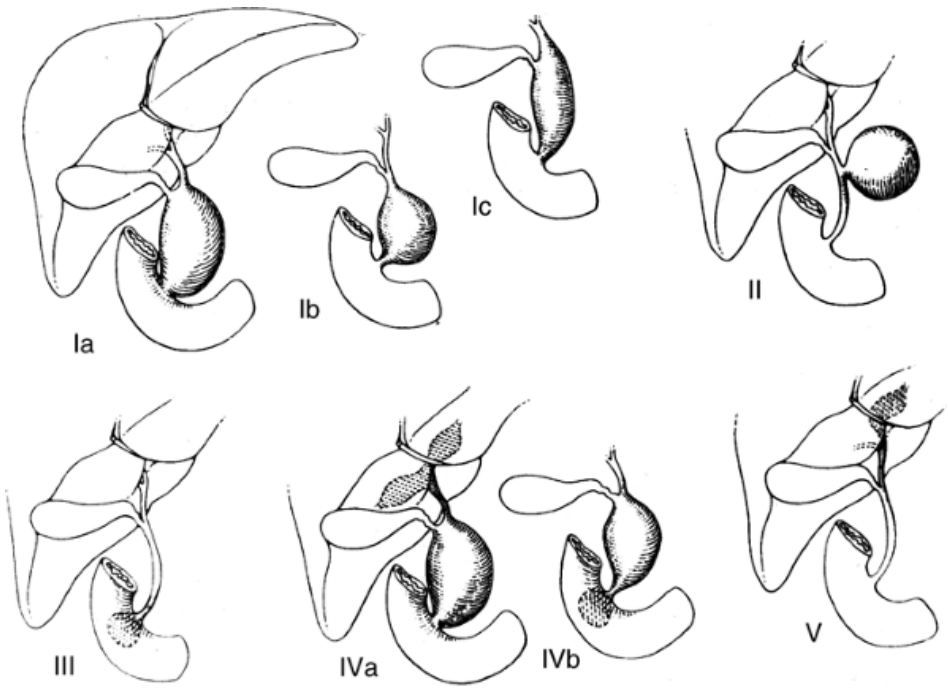
Von Meyenburg complexes

Von Meyenburg complexes, also called *biliary microhamartomata*, are usually incidental and asymptomatic

findings at liver biopsy. They are found in approximately 5% of adults and 1% of children in series of consecutive autopsies. The complexes consist of variable numbers of dilated bile ducts embedded in a fibrous stroma and occur in small groups adjacent to portal tracts (Fig. 43.10). The complexes may contain inspissated bile concretions and polypoid projections into the lumen. They are hypothesized to result from the fibrosis and occasionally from the involution of remnant ductal plate malformations of peripheral interlobular bile ducts (59). Von Meyenburg complexes are thought to be the origin of the cysts in PCLD. They are also found in association with Caroli's disease and CHF and in normal liver. There are rare reports of cholangiocarcinoma developing within a von Meyenburg complex.



▪ **Figure 43.10** Photomicrograph of the liver showing a typical von Meyenburg complex with a group of dilated bile ducts in fibrous stroma (hematoxylin and eosin stain). (Courtesy of Elizabeth M. Brunt, MD)



▪ **Figure 43.11** Drawing shows the Todani modification of the Alonso-Lej classification of choledochal cysts. (Adapted from Todani T, Watanabe Y, Narusue M, et al. Congenital bile duct cysts: classification, operative procedures, and review of thirty-seven cases including cancer arising from choledochal cyst. *Am J Surg* 1977;134:263–269, with permission.)

Choledochal cysts

Epidemiology, course of disease, and clinical features

Choledochal cysts are congenital dilatations of the intrahepatic and extrahepatic biliary tree. Vater and Elzer first described choledochal cysts in 1723 (75). The Todani modification of the Alonso-Lej classification of choledochal cysts is the system most often used for planning management of these cysts (76) (Fig. 43.11). The estimated incidence varies from 1 in 13,000 in Japan to 1 in 2 million in England (77,78). The frequency of diagnosis seems to be increasing, probably because of improvements in abdominal imaging (79). Type I cysts represent approximately 85% of most series (80). Type II cysts are rare, representing less than 2% of cases, and are sometimes called *common bile duct diverticulum* (81). Type III cysts or choledochoceles also are rare, representing approximately 2% of cases, although they may be more common in tertiary referral endoscopy centers (82). Type IV cysts represent the remaining approximately 10% of cases. Type V cysts are Caroli's disease.

The cysts usually manifest themselves in childhood but may be diagnosed in the prenatal period through late adulthood. Only approximately 20% of cases manifest themselves in adults (83). There is a female predominance (84). Neonates have jaundice and a palpable mass (84). In the first decade of life, ascending cholangitis is a more likely manifestation. The diagnosis is made

when ultrasonography, CT, hydroxy iminodiacetic acid (HIDA) imaging, endoscopic retrograde cholangiography, PTC, or magnetic resonance cholangiography shows characteristic dilatation of the biliary tree. Liver function tests may show elevated alkaline phosphatase, total bilirubin, and γ-glutamyl transpeptidase levels consistent with biliary obstruction (84). Manifestation in adulthood is often preceded by several years of vague right upper quadrant abdominal pain (85). At diagnosis the patient usually has a complication such as jaundice,

cholangitis, or pancreatitis (85). CHF is often associated with choledochal cysts, especially Caroli's disease.

Etiology

There are several theories about their etiology, although the true cause of choledochal cysts remains unclear. One theory suggests that failure of canalization of the fetal biliary tree results in obstruction and, later, dilatation of the common bile duct. Another theory suggests that obstruction occurs from anatomic kinking or external pressure on the developing bile ducts that results in cyst dilatation. Probably the most accepted theory was first proposed by Babbit, which stated that the high insertion of the common bile duct into the pancreatic duct leads to reflux of pancreatic juice into the biliary tree. This leakage causes weakening of the bile duct wall, inflammation, and fibrosis. The distal bile duct becomes obstructed and therefore results in proximal dilatation with cyst formation (86). There appears to be a high rate of anomalous pancreaticobiliary duct junction in the range of 90% in most series (87).

Treatment

Management of choledochal cysts is based on the type of cyst according to the Todani classification (Fig. 43.11). Some authors argue that the Todani classification scheme is misleading and overcomplicated (88). They propose a simplified naming system matched to the treatment and risk of future malignant transformation, which is described at the end of this section. The first premise of treatment is to obtain adequate drainage and antibiotic coverage for any patient with signs and symptoms of cholangitis. This may be achieved with PTC or ERCP.

The current standard of practice for type I and II choledochal cysts is complete cyst excision with anastomosis of the bifurcation of the hepatic ducts, common hepatic duct, or common bile duct with Roux-en-Y anastomosis to the jejunum or directly to the duodenum. Biliary enteric anastomosis at the bifurcation of the hepatic ducts appears to offer the advantage of a lower rate of late strictures (89). Cyst enterostomy is generally no longer performed because of the high rate of long-term complications, including anastomotic strictures that result in jaundice and cholangitis and late development of cholangiocarcinoma (85,90). Patients who have undergone previous cyst enterostomy and have late complications of surgery need complete cyst excision with Roux-en-Y hepaticojejunostomy. Patients with an asymptomatic cyst who are otherwise good surgical candidates should be considered for elective cyst excision and Roux-en-Y hepaticojejunostomy to prevent the development of cancer (85).

Type III choledochal cysts are also called *choledochoceles*. Patients have pancreatitis, obstructive jaundice, or biliary colic (91). They may have a history of cholecystectomy for acalculous cholecystitis with continued symptoms after surgery (91). The differential diagnosis includes papillary tumor, papillitis from an impacted stone, papillary fibrosis, pancreatitis, duodenal duplication, and submucosal contrast injection during ERCP (79). This broad differential diagnosis warrants cholangiography and biopsy to rule out tumors (73). Choledochoceles rarely develop into cancer, and therefore complete excision may not be mandatory (79,82). Large cysts should be excised either partially or completely and the ducts reanastomosed to the duodenum (91). Small choledochoceles can be managed with endoscopic sphincterotomy (79,92). Endoscopic pancreatic sphincterotomy may be necessary if the pancreatic duct does not drain well (82).

Type IVa choledochal cysts with both intrahepatic and extrahepatic components make total cyst excision difficult. Total excision of the extrahepatic cysts can usually be accomplished, and anastomosis with the enteric tract should be performed at the hilum to prevent a high rate of anastomotic strictures. Formation of a Hutson loop, which provides easy percutaneous access to the reconstructed biliary tree, has been advocated, especially if intrahepatic cysts are not resected (93). Partial hepatectomy, if technically feasible, has also been advocated for the removal of intrahepatic cysts because of malignant potential. The risk of biliary cancer in the retained intrahepatic cysts is not known but is probably low; only eight cases have been reported in the literature (94).

The presence of type V cysts, also known as *Caroli's disease*, results in multiple intrahepatic biliary cysts and makes treatment more difficult. Complete resection of biliary cysts is usually

impossible because of the location of the cysts. For this reason, conservative treatment of cholangitis with antibiotics is usually the initial choice. Rotating antibiotics to suppress episodes of cholangitis is advisable but is of unproven value. If the cysts are superficial and limited in number, hepatic resection can sometimes be curative. An alternative is to relieve obstruction with partial cyst excision and Roux-en-Y cyst jejunostomy. Liver transplantation is generally reserved for patients with hepatic failure. Prognosis is much worse for this type of choledochal cyst than for the others. Tsuchida et al. (95) found a

63% mortality in a survey of patients whose cases were reported in the literature.

Without therapy for choledochal cysts, biliary cancer, usually cholangiocarcinoma, develops in approximately 15% to 19% of patients older than 20 years and generally carries a dismal prognosis (85,90). The most common site of the cancer is the cyst wall, but as many as 40% of cases occur at other sites in the liver or pancreas, especially the gallbladder (81). For this reason and to prevent future gallbladder-related symptoms, cholecystectomy is usually performed during cyst surgery.

Complications include jaundice, pancreatitis, spontaneous cyst rupture, biliary cirrhosis, and signs of portal hypertension, including variceal bleeding and ascites (96). The postoperative rate of recurrence of symptoms can be as high as 32%, but the symptoms most often respond to conservative therapy with antibiotics (97).

The simplified system calls type I and IVa cysts "choledochal cysts" because they are variations of a single disease with dilatation of the extrahepatic biliary tree and varying levels of involvement of the intrahepatic tree. They represent the most common type of choledochal cysts, have the highest risk of malignant transformation, are associated with pancreaticobiliary maljunction, and require complete excision of the extrahepatic biliary tree with a high biliary enteric anastamosis. Type II cysts are rare diverticuli of the common bile duct that can be treated with simple excision of the cyst. Type III should be called *choledochoceles* because they are lined with duodenal mucosa, do not require complete excision, and rarely develop malignant transformation. Type V cysts should be called *Caroli's disease* and differ from the other types by affecting only the intrahepatic ducts, being associated with ductal plate malformation, having low malignant potential, and being associated with CHF and portal hypertension.

Cystic Neoplasms of the Liver

Cystadenoma

Cystadenoma is a benign tumor of the liver in which an epithelial layer surrounds a large, fluid-filled cyst in the hepatic parenchyma or rarely in the extrahepatic biliary tree. It represents less than 5% of cystic lesions of the liver. Cystadenoma is hypothesized to arise from a congenital defect of the bile ducts or gallbladder. It may form out of the rests of primitive foregut. It can be found in association with bile duct hamartoma.

Cystadenoma manifests itself any time from childhood onward, although 80% to 85% of cases occur among middle-aged women. The clinical manifestations are typically the result of compression of an expanding liver mass on adjacent structures. Approximately 70% of patients have epigastric or right upper quadrant pain, sometimes with radiation to the right shoulder. Approximately one half of patients have a palpable abdominal mass or increasing abdominal girth, and approximately one third of patients have compression of the biliary tree that leads to cholangitis or jaundice (98). Some patients have symptoms of gastric compression, such as nausea, vomiting, bloating, and anorexia. In some patients, the cysts are incidental findings on imaging of the abdomen. Extrahepatic cystadenoma typically manifests as abdominal pain and jaundice (99).

Complications are rare and have been reported to include sepsis, hemorrhage, and rupture. Transformation into malignant cystadenocarcinoma can occur and result in local invasion and occasional distant metastasis. Nearly all the reported cases of malignant transformation occur in patients who have the stromal layer.

The diagnosis of cystadenoma is suggested by the ultrasonographic findings of a multilocular anechoic fluid-filled cyst with thickened walls and multiple septations or papillary projections

(100). The cyst is usually located in the hepatic parenchyma, although extrahepatic cysts have been reported. There is usually no connection with the biliary tree. Levels of liver-associated enzymes are usually normal unless there is biliary obstruction. The serum level of cancer antigen 19-9 (CA19-9) may be mildly elevated, but levels of carcinoembryonic antigen (CA125) and α-fetoprotein are normal. Cyst fluid CA19-9 level is elevated, but aspiration carries a small risk of dissemination if carcinoma is present. The lesions should be differentiated from pyogenic abscess, amebic abscess, and echinococcal cyst on the basis of clinical manifestations and imaging findings.

Pathologic examination reveals cuboidal and columnar epithelial cells with vacuolizations lining the cysts. Usually adjacent to the epithelium is an area of spindle cell stroma (also called *mesenchymal stroma*) surrounded by a layer of collagenous connective tissue. Mesenchymal stroma are exclusively found in female patients and may represent a different form of the disease than those without stroma (101). The cyst fluid is usually mucinous, but it may contain bile or blood.

Treatment is complete surgical resection by means of either enucleation (excision of a mass with a thin layer of normal tissue) or anatomic resection. In the past, incomplete excision or drainage procedures led to a high recurrence rate and did not remove the risk of malignant transformation. There is a 50% rate of recurrence of extrahepatic cysts without sleeve resection with biliary enteric anastomosis (102).

Echinococcal Cysts

Hydatid disease caused by *Echinococcus granulosus* cystic echinococcosis is endemic in parts of western and southern Europe, the Middle East, northern Africa,

South and Central America, Russia, and China. The annual incidence ranges from less than 1 case to as many as 42 cases/100,000 persons in some regions (103). Humans are accidental hosts who ingest eggs from contaminated dogs that were usually infected from sheep. The liver is involved in one half to three fourths of cases. The cysts range from 1 to greater than 20 cm in size. Rarely, hydatid disease called *alveolar echinococcosis* can occur due to *Echinococcus multilocularis*. It is endemic in parts of North America, central Europe, and northern and central Eurasia. Incidence is generally less than 1/100,000 (103). Humans are accidental hosts who ingest eggs from foxes or forest rodents.

Diagnosis is based on a high index of clinical suspicion and findings on imaging with ultrasonography, CT or MRI. The initial symptoms are usually caused by complications of the cysts or physical compression of adjacent organs by the cysts. Symptoms such as epigastric or right upper quadrant pain, fatigue, fever, nausea, and dyspepsia may be present. Cyst rupture can produce jaundice, cholangitis, acute pancreatitis, and immune reactions such as anaphylaxis or asthma. Ultrasonography, CT, and MRI are sensitive and specific for hydatid disease, with cross-sectional imaging being superior in identifying the location of the cysts, including extrahepatic cysts, and type of cyst. Serologic tests, including an indirect hemagglutination test and enzyme-linked immunosorbent assay for antibodies to *Echinococcus* antigens are approximately 90% sensitive but have variable specificity because of cross-reaction with other parasites and may not distinguish cystic from alveolar disease.

There is controversy about the most appropriate treatment for cystic echinococcosis. Some advocate treatment even in asymptomatic patients to prevent complications such as rupture, infection, or anaphylaxis. Others have shown that small, nonsuperficial, and asymptomatic cysts can remain stable for more than 10 years. The choice of treatment depends on the type of cyst (usually defined by ultrasonographic appearance), the location of the cyst, the general medical status of the patient, and local experience. Because of its potential for aggressive infiltration of the liver and other organs and high mortality, radical surgical resection and at least 2 years of chemotherapy is the first choice of treatment for alveolar echinococcosis.

Open surgery with cyst removal or drainage and obliteration of the cyst cavity was until recently the primary mode of treatment for cystic echinococcosis. Although in the literature results of series of open surgical treatment are variable, they generally show a mortality ranging from 0% to 5%, morbidity from 8% to 25%, and long-term recurrence rates of 2% to 25%. Several series of laparoscopic cyst surgery have shown morbidity and mortality similar

to those of open surgery but they generally involve less difficult cyst types and locations. Any surgical or percutaneous therapy carries a risk of dissemination of daughter cysts into the abdomen, but modern techniques and experienced surgeons significantly limit the risk.

*P*uncture, *a*spiration, *i*ntroduction of protoscolicidal agent, and *r*easpiration (PAIR) is a percutaneous treatment developed by interventional radiologists in the mid-1980s. The connection of the cyst to the biliary tree is an absolute contraindication for this procedure, and only certain configurations of cysts are amenable to this treatment. Series of patients treated with PAIR and chemotherapy at experienced centers showed no mortality and less than 10% morbidity but the cysts were generally smaller, less complex, and amenable to a percutaneous approach. Long-term recurrence rates are not yet available but short-term results look promising.

Chemotherapy with benzimidazole compounds, mebendazole, or albendazole is generally reserved for patients not amenable to treatment by other means or as an adjunct to other treatment, especially PAIR (104). Chemotherapy has approximately a 30% cure rate, but up to 70% of cysts will reduce in size. Relapse rates are about 25%.

Chapter 44

Hepatocellular Carcinoma

Jordi Bruix

Fernanda S. Branco

Carmen Ayuso

Key Concepts

- Hepatocellular carcinoma (HCC) is a neoplasm that has well-defined risk factors, such as chronic viral infection and excessive alcohol intake. These induce chronic liver disease, that is, cirrhosis, and induce genetic damage, leading to cancer development.
- HCC is the leading cause of death in patients with cirrhosis.
- The sole option to reduce cancer-related death is to detect cancer at an early stage and apply effective therapy. Patients with cirrhosis who would be treated if diagnosed with liver cancer should enter screening protocols.
- Early detection of HCC should be based on hepatic ultrasonography every 6 months. Unfortunately, tumor marker determination lacks efficacy.
- Effective therapies for HCC with potential long-term cure include surgical resection, liver transplantation, and percutaneous ablation. Among palliative approaches, the sole approach with positive impact on survival is transarterial chemoembolization.
- Prevention of HCC should come from avoidance of risk factors by vaccination for the prevention of hepatitis B and maintenance of proper health standards and adequate lifestyle. Antiviral therapy may cure viral infection and hence prevent progression to cirrhosis and cancer.

Until recently, it was frequent to consider hepatocellular carcinoma (HCC) as a cancer with low incidence in the western world. However, recent data show that its incidence has increased in several western countries (1). In addition, cohort studies reveal that HCC is currently the leading cause of death in patients with cirrhosis (2,3). The feasibility of early detection associated with the availability of several effective therapies has permitted encouraging long-term survival after diagnosis, and as a result, the interest in all aspects related to diagnosis and treatment has sharply increased (4). In this sense, it has been recognized that hepatologists play a key role in the management of patients with HCC. They decide whether HCC surveillance is required in patients at risk and are responsible for disease staging and treatment indication. Among this, the most critical decision is the selection of candidates for liver transplantation and their management before and after surgery. In some countries, mostly in Asia, even surveillance and percutaneous treatment (i.e., alcohol injection and

radiofrequency ablation) are performed by hepatologists because they receive specific training to acquire the needed expertise.

In the present chapter we summarize the most relevant issues about epidemiology, diagnosis, and treatment of this neoplasm.

Epidemiology

Primary liver cancer is now the fifth most common cancer in the world and the third cause of cancer-related

mortality. More than half a million cases are diagnosed every year, there being major geographic differences in incidence. The annual incidence rates in eastern asia and sub-Saharan Africa exceed 15/100,000 inhabitants, while the figures are intermediate (between 5 and 15/100,000) in the Mediterranean basin and southern Europe and very low (<5/100,000) in northern Europe and America (1). Vaccination against hepatitis B virus (HBV) has induced a decrease in HCC incidence in countries where this virus is highly prevalent (5), whereas the contrary is true in areas where viral dissemination (mostly hepatitis C virus [HCV]) has occurred in the last decades (6). These data suggest that the geographic heterogeneity is related to differences in the exposure rate to risk factors and time of acquisition rather than to genetic predisposition. In this regard, studies in migrant populations have demonstrated that first-generation immigrants carry with them the high incidence of HCC that is present in their native countries, but in the subsequent generations the incidence decreases (7).

The age at which HCC appears varies according to gender, geographic area, and risk factors associated with cancer development. In high-risk countries with major HBV dissemination, the mean age at diagnosis is usually below 60 years, although it is not infrequent to observe HCC in childhood, thereby emphasizing the impact of viral exposures early in life (1). Contrarily, in intermediate- or low-incidence areas most cases appear beyond 60 years of age. In all areas, males have a higher prevalence than females, the gender ratio usually ranging between 2:1 and 4:1, and in most areas the age of occurrence in females is higher than that in males (1).

Risk Factors for Hepatocellular Carcinoma

Cirrhosis underlies HCC in more than 80% of the affected individuals (2,8). Therefore, any agent leading to chronic liver damage, and ultimately cirrhosis, should be seen as a risk factor for HCC. Obviously, the major causes of cirrhosis, and hence HCC, are HBV, HCV, and alcohol, but less prevalent conditions such as hemochromatosis, primary biliary cirrhosis, nonalcoholic steatohepatitis, and Wilson disease have been also associated with the development of HCC. The risk among those with cirrhosis increases in parallel with the impairment of liver function and is higher in males, patients older than 50 years, and subjects with increased α-fetoprotein (AFP) concentration (2). Pathologic characteristics such as increased proliferation, presence of dysplastic cells, or irregular regeneration have also been proposed as useful risk markers but are not fully validated.

Hepatitis B Virus

The evidence linking HBV with HCC is unquestionable (9). Active viral replication implies a higher risk, and long-standing active infection resulting in cirrhosis is the major event leading to increased risk (10,11). The incidence of HCC in

inactive HBV carriers without liver cirrhosis is less than 0.3% (8). The role of specific genotypes or mutations is not well established (12). HBV can be integrated into the host cellular genome and induce genetic damage. Deoxyribonucleic acid (DNA) integration in nontumoral cells in patients with HCC suggests that genomic integration and damage precede the development of tumor. Therefore, infection with HBV may be correlated with the emergence of HCC even in the absence of liver cirrhosis. In addition, some of the HBV proteins disrupt cellular functions (13) and favor neoplastic transformation, induce proliferation, and impede apoptosis (14).

Interestingly, occult HBV infection may become apparent if properly investigated by molecular techniques even in the absence of serologic markers of HBV (15). Identification of the HBV genome has been reported in liver tumors of patients who are HCV positive and HBsAg negative in the serum. The rate of occult infection in these patients can be as high as 63% (15). Finally, the implementation of vaccination against HBV has resulted in a significant decrease in the incidence of HCC (5), and this is the final proof of the importance of this virus in the genesis of HCC.

Hepatitis C Virus

The prevalence of HCV in HCC cohorts varies according to the penetration of the agent in the population of each geographical area. There is a single prospective population-based study of the risk of HCC in patients with hepatitis C (16). This study included 12,000 men and described a 20-fold increased risk of HCC in infected individuals, the figure being very close to the estimated risk obtained in a meta-analysis of 21 case–control studies (17). The risk is clearly related to the degree of liver damage induced by the virus (18). There are some case reports of healthy HCV carriers with HCC (19), but several cohort studies indicate that the incidence in patients with chronic hepatitis is low (below 1%) and that the risk increases sharply when cirrhosis is established (18). At this time, the annual incidence ranges between 2% and 8% (2). The transition from acute infection to cirrhosis may take 20 to 30 years. Some authors suggested the development of HCC even after a sustained response to interferon for the treatment of chronic hepatitis C (20).

Patients infected with human immunodeficiency virus (HIV) are now effectively treated with combined

regimes and, if coinfected with HCV, they present a faster evolution to cirrhosis (21) and, therefore, are at risk for the development of HCC. In fact, liver disease and/or HCC are the major causes of death in these patients (22).

Alcohol, Tobacco, and Coffee

A large proportion of patients with alcoholic cirrhosis are infected by HCV, and therefore, the risk-based studies before the recognition of this virus have surely overestimated the role of alcohol. The risk for HCC increases linearly beyond an estimated intake of 40 to 60 g/day of alcohol and also with the length of consumption and coinfection with HBV or HCV (23). On development of decompensated cirrhosis, the yearly incidence increases beyond 2%. Smoking slightly increases the oncogenic risk (24), whereas coffee consumption reduces the risk (25).

Pathogenesis

Active inflammation with oxidative damage is thought to be the key event leading to liver cancer, but the detailed molecular mechanisms are not known. Cumulative genetic changes occur and allow the appearance foci of high-grade dysplastic hepatocytes without overt malignant phenotype, which in one third of the cases may evolve into overt HCC after a follow-up of 5 years (26,27). Intense neoangiogenic activity accompanies this transition and results in enhanced blood supply derived from the hepatic artery that is known to permit radiologic characterization (28). The most frequently affected chromosomes are 1, 4, 8, 16, and 17, but none of them is abnormal in more than 60% of the cases (29). Downregulation of p53 is observed in up to 40% of the cases and G to T mutation reflects genetic damage due to aflatoxin intake.

Expression of several genes has been related to growth and dissemination, but none of them has been strongly validated to become part of the decision-making process in clinical practice.

Pathology

The appearance of HCC involves its transition from early to advanced stages (28). It is common to use the Edmondson and Steiner criteria to grade the degree of differentiation according to nuclear irregularity, hyperchromatism, and nuclear/cytoplasmic ratio. In HCC the cytoplasm shows fine granular eosinophils and may accumulate bile and fat, Mallory bodies, and α_1-antitrypsin globules. Fat deposition is seen in 30% to 40% of tumors approximately 1.5 cm in size and translates into increased echogenicity at ultrasonography (30). Immunostaining can recognize the presence of cytokeratins 7, 8, 18, and 19; carcinoembryonic antigen; AFP; and several other markers, but the findings are not sensitive or specific enough to be used to make the diagnosis. Malignant hepatocytes accumulate as thin (microtrabecular) or thick (macrotrabecular) layers separated by sinusoids that may contain Kupffer and stellate cells. Gross appearance may be described as expansive, infiltrative, and diffuse. The first type shows distinct margins and a surrounding reticulin pseudocapsule. No distinct margins are seen in the infiltrative type, and the diffuse type corresponds to a multinodular tumor that mimics a cirrhotic liver. Usually, HCC appears as a distinct nodule of varying size that increases together with the development of additional tumor sites first in the vicinity or in separate segments. Portal vein branches are invaded, and at late stages the entire liver may be occupied by malignant foci and the tumor spreads outside the liver (initially to lymph nodes and then to adrenal glands, lungs, and bone). The prevalence of portal vein invasion increases together with tumor size. Less than 20% of HCC smaller than 20 mm in size have microscopic vascular invasion, and recently, well-differentiated HCC without such an invasive profile and without minute satellite nodules has been named *very early HCC* or *carcinoma* in situ (31,32). This initial lesion still does not have increased vascularization and, currently, is only confidently diagnosed after resection.

Clinical Manifestations

Because most HCC cases appear in the setting of cirrhosis, a major part of the findings will be indistinguishable from the clinical picture observed in patients with advanced cirrhosis. Patients may present with jaundice, ascites, encephalopathy, or bleeding due to ruptured esophageal varices. Cancer-related symptoms such as abdominal pain or constitutional syndrome (e.g., weight loss,

anorexia, and malaise) reflect advanced tumor stage. Acute hemoperitoneum due to ruptured HCC or bone metastases is the first symptom in a minority of cases.

Advanced HCC is associated with increased bilirubin, alkaline phosphatase, and γ-glutamyl transpeptidase levels. Alanine transaminase (ALT)/aspartate transaminase (AST) concentration has no diagnostic value. Paraneoplastic manifestations include diarrhea and severe hypoglycemia, which in some cases are the most relevant concern. Other manifestations include hypercalcemia, sexual changes, polymyositis, thrombophlebitis, and skin rashes.

Diagnosis and Staging

Diagnosis at advanced stage, when cancer-related symptoms are present and a large mass can be recognized even by physical examination, is not difficult. The development of ultrasonography has permitted the detection of HCC at an asymptomatic stage, and its incorporation into the clinical workup of patients with known or suspected liver disease has sharply changed the diagnostic algorithm and prompted the establishment of early detection plans for HCC in the population at risk, that is, patients with cirrhosis. The efficacy of surveillance depends on the level of risk and on the availability of effective therapy. Hence, surveillance should be initiated on development of cirrhosis and be restricted to patients who would be treated if diagnosed with HCC. Therefore, screening should be limited to Child-Pugh A and B patients, while Child-Pugh C patients should be evaluated for liver transplantation and HCC in them could become a contraindication for the procedure. There is a single randomized controlled trial of surveillance versus no surveillance (33). It included more than 18,000 Chinese patients and has shown a survival benefit from a strategy based on a 6-monthly surveillance with AFP and ultrasonography. Several cohort studies have also shown that surveillance allows detection and diagnosis at an earlier stage and suggest an improvement in patients' survival.

AFP has very low sensitivity and slight increases may also be observed in patients with cirrhosis in the absence of malignancy (34,35). Therefore, it has no clinical role in screening and a very reduced role in the diagnosis, this probably being limited to patients with very advanced tumor stage in whom no treatment is provided. In these terminal patients, no imaging technique is needed after ultrasonography to confirm and stage the disease. Other tumor markers such as lectin-bound AFP (36), des-γ-carboxyprothrombin (37), or glypican (38) have been proposed to surpass the efficacy of AFP, but their clinical efficacy is yet to be unequivocally proved. Proteomic techniques may help identify new markers (39).

All these data indicate that surveillance programs should be based on regular ultrasonographic examination (Fig. 44.1). On the basis of the data on tumor volume–doubling time, most experts recommend patients with cirrhosis to be screened by ultrasonography every 6 months. It is important to note that increased risk does not mean faster tumor progression, and therefore, patients with cirrhosis who are at higher risk do not require screening at shorter periods. In the year 2000, the panel of experts of the European Association for the Study of the Liver (EASL) proposed an algorithm to diagnose nodules detected by ultrasonography that varied according to tumor size (2). Nodules less than 10 mm in size were considered not feasible to be confidently diagnosed and in some cases did not correspond to premalignant or malignant foci. Therefore, close follow-up was recommended, which is still valid. For nodules between 10 and 20

mm in size, the EASL recommended a positive result of the biopsy to establish the diagnosis, while for those larger than 20 mm a specific radiologic profile observed by two imaging techniques was considered to make the diagnosis if the patient was known to present with underlying cirrhosis. The improvement of dynamic imaging has allowed slight modification of the recommendations. Therefore, even in nodules between 1 and 2 cm in size the HCC diagnosis can be established if two dynamic imaging techniques (e.g., ultrasonography contrast, computed tomography [CT], and magnetic resonance imaging [MRI]) show that the nodule exhibits enhanced arterial uptake with contrast washout in the venous phase. In larger lesions, just one technique with a specific profile is enough to make the diagnosis; it is considered accurate enough. Therefore, biopsy of a nodule larger than 1 cm in size found on screening of a cirrhotic liver is needed if it does not show arterial enhancement with washout and if it is clearly not some other lesion, such as a hemangioma. It has to be noted that HCC nodules may appear echogenic because of the presence of fat in the cells, or may more usually be hypoechoic or even show a "target lesion" appearance (40). Obviously, a positive result of the biopsy confirms the diagnosis, but even if a nodule corresponds to an HCC, it might be negative for malignancy in up to 30% to 40% of cases. Accordingly, a negative result of the biopsy report does not confidently exclude malignancy.

▪ **Figure 44.1** A small nodule measuring less than 20 mm in size detected during ultrasonographic surveillance. It corresponds to an early hepatocellular carcinoma (HCC) site. Note its hypoechoic pattern as compared with the surrounding cirrhotic liver. This type of tumor is the target of early detection plans because at this stage effective therapy (e.g., resection, transplantation, or percutaneous ablation) may provide long-term disease survival.

Staging of HCC should be based on expert CT or MRI (40). Both techniques confidently detect tumors larger than 2 cm in size, while smaller tumors pose major difficulties in being accurately characterized as benign or malignant. Angiography has currently no role in diagnosis and staging, while lipiodol CT is not reliable (2). Detection of additional tumor sites and vascular invasion

indicates advanced tumor stage. Extrahepatic spread is infrequent at early stages but should be ruled out by chest CT scan. Bone metastases are usually symptomatic and should be evaluated if needed by bone scintigraphy.

Prognostic Prediction

Because cirrhosis underlies HCC in most patients, their prognosis depends on tumor burden, degree of liver function impairment, and the treatment received. At the same time, liver function and tumor extent determines the feasibility of treatment and all parameters should be considered for clinical predictions (41).

Therefore, systems that consider only one dimension such as the tumor-node-metastasis (TNM) classification (42), the Child-Pugh (43), or the Model for End-Stage Liver Disease (MELD) score (44) will be inaccurate. Similarly, scores that just consider general health status and physical capacity such as the performance status (45) or the Karnofsky index will have reduced value. In fact, the sole usefulness of all unidimensional systems is to identify patients with very advanced disease stage and poor short-term outcome. Although there are several scores combining liver function, tumor stage, and/or physical status, most just stratify patients according to expected outcome, but only the Barcelona Clinic Liver Cancer (BCLC) system links staging with treatment indication, and recent studies have validated its usefulness (46,47,48). This was constructed years ago by taking into account the outcome data of several cohort investigations and randomized clinical trials. Patients are divided into the relevant evolutionary stages according to tumor stage, liver function, and presence of symptoms, and within each stratum patients are classified using specific prognostic tools finally linking stage to therapy (41).

Treatment

The only options that can achieve long-term cure are surgical resection, liver transplantation, and percutaneous ablation. They are effective for patients diagnosed at early stages, which represent only less than 40% of the patients. Most cases are diagnosed at a more advanced stage and the only option that has been shown to have a positive impact on survival is transarterial chemoembolization (TACE) (49), but this benefits less than 20% of the advanced cases. Therefore, almost half of the patients will have no option for effective therapy and are candidates for research investigations.

Treatment indication requires a careful evaluation of tumor stage, degree of liver failure, and general health. Figure 44.2 shows the BCLC staging and treatment algorithm. Detection of vascular invasion or extrahepatic spread implies advanced disease stage and precludes any effective therapy. Although there is no functional impairment in patients with a normal underlying liver, in those with chronic liver disease, this aspect is of paramount relevance. Surgical resection is feasible only in patients with well preserved liver function, and decompensated cirrhosis precludes almost all forms of therapy, except liver transplantation.

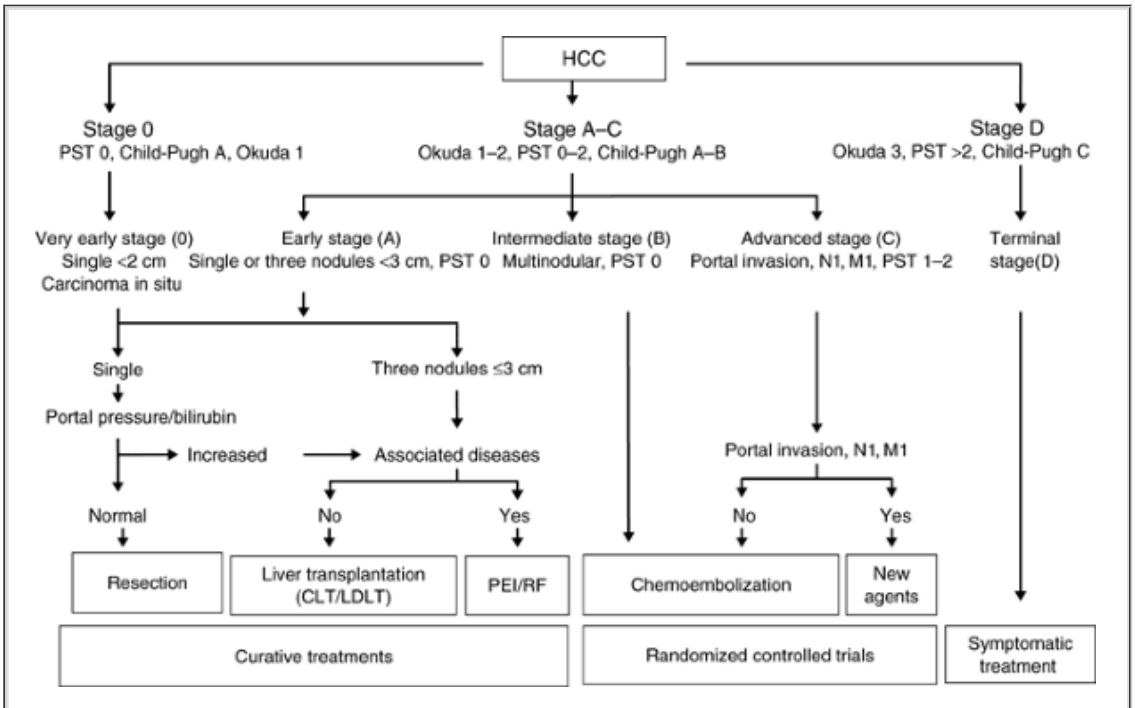
Surgical Treatment

There are no trials comparing resection with liver transplantation and therefore the decision about which should be the first option is highly controversial and should take into account the available resources and the survival expected by applying any of them.

Resection

This is usually restricted to patients with solitary tumors and is the optimal approach for patients with normal liver. Unfortunately, these are less than 5% of the patients with HCC in western countries, and cirrhosis considerably limits surgical resection. Selection of candidates with cirrhosis should aim at a perioperative mortality of less than 3%, a transfusion rate less than 10%, and a 5-year survival rate higher than 50%, and this requires careful selection (50). Allocation into Child-Pugh A stage does not suffice to identify the best candidates for resection. Studies in Barcelona (51) have shown that measurement of portal pressure and bilirubin concentration are the best parameters for this purpose. Patients with normal bilirubin level and without clinically relevant portal hypertension (PHT), defined as a hepatic vein pressure gradient of 10 mm Hg or more, esophageal varices, or splenomegaly with a platelet count of less than 100,000/mm^3, will achieve 5-year survival rates of 70%, whereas this decreases to 50% in patients with PHT and to 25% in those with PHT and a raised bilirubin level. HCC recurrence may affect more than 50% of patients at 3 years and its appearance deteriorates long-term survival (51,52,53). Early recurrence is thought to correspond to tumor spread before resection, while recurrence beyond 2 to 3 years may be due to the emergence of metachronic HCC in a separate cellular clone. The most powerful predictors of postoperative recurrence due to dissemination are

the presence of microvascular invasion, poor differentiation, and satellite lesions. Unfortunately, despite promising reports using interferon, selective radiation, adaptive immunotherapy, and retinoids, there is no effective method to diminish recurrence rate (50).



▪ **Figure 44.2** Barcelona Clinic Liver Cancer (BCLC) staging and treatment algorithm. PST, performance status test; CLT, cadaveric liver transplantation; LDLT, live donor liver transplantation; PEI, percutaneous ethanol injection; RF, radiofrequency ablation. (Modified from Llovet JM,

Burroughs A, Bruix J. Hepatocellular carcinoma. *Lancet* 2003;362 (9399):1907–1917.)

Transplantation

Transplantation provides excellent outcomes if restricted to patients with early stage disease, as defined by the Milano criteria: Solitary HCC less than 5 cm in size or with up to three nodules, each measuring less than 3 cm in size (54) (Fig. 44.3). Survival of patients selected according to this definition exceeds 70% at 5 years (50). Disease recurrence is approximately 15% and affects mostly the liver, lymph nodes, lung, and bones. Recurrence is more frequent if pathology evidences vascular invasion (macro- or microscopic) or additional tumor nests, characteristics that are highly prevalent in tumors exceeding 5 cm in size (55,56). The main limitation for liver transplantation is the scarcity of livers. As a result, the number of candidates exceeds the number of resources, which implies a waiting time between enlistment and transplantation. During this period the tumor may progress and impede successful therapy (51,57). Priority policy to advance patients with high risk of exclusion because of tumor progression has been attempted but still has to be refined to ensure equity between tumor and nontumor patients and avoid transplantation in those patients with more aggressive disease and therefore worse poor-term outcome. Locoregional treatments such as percutaneous ablation or chemoembolization are considered when

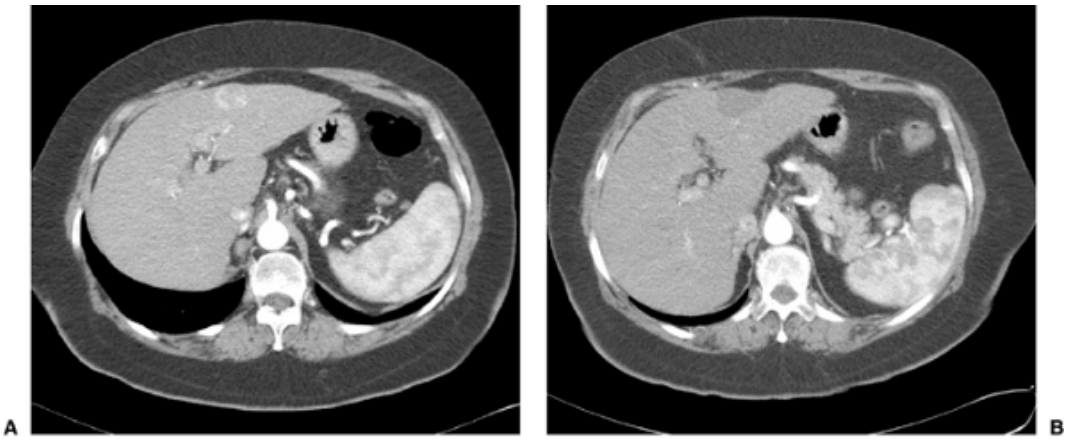
the waiting time exceeds 6 months because these techniques are able to delay tumor progression and hence decrease the risk of exclusion (58,59). The option that has raised more expectancy is live donor liver transplantation. This requires a healthy donor to offer the right or left hepatic lobe that would be implanted into the recipient. Donation implies a 0.5% donor mortality risk, and recent data from Japan suggest that outcome after live donation is very similar to that for cadaveric transplantation (60). At the same time, the validity of the Milano criteria for selection of the optimal candidates has been shown.

▪ **Figure 44.3** Explanted liver showing a hepatocellular carcinoma measuring

3 cm in size within a cirrhotic liver. The tumor has well-defined margins and exhibits a thin pseudocapsule. No satellite nodule is observed and the vessels appear free of invasion at macro- and microscopic examination. This pathology profile indicates a low recurrence risk during follow-up.

Percutaneous Treatments

Percutaneous treatment is a therapeutic option that has rapidly grown during the last decade. Destruction or ablation of tumor cells can be achieved by the injection of chemical substances (e.g., ethanol, acetic acid, and boiling saline) or by the insertion of a probe that modifies local tumor temperature (e.g., radiofrequency ablation, microwave, laser, and cryotherapy). This procedure can be done percutaneously with minimal invasiveness or during laparoscopy and is currently considered the best option for patients with early HCC who are not candidates for surgery. Treatment is repeated on separate days, and its efficacy is evaluated at 1 month by dynamic CT, in which the absence of contrast uptake reflects tumor necrosis (Fig. 44.4). However, some of the tumors initially classified as completely necrosed present as intratumoral recurrence later on; this should be seen as treatment failure that has not been detected immediately after therapy. Recurrence rate after percutaneous ablation is similar to that seen after surgical resection and presents as separate nodules in the vicinity of the earlier ones or in separate liver segments (61).



▪ **Figure 44.4 A:** Dynamic arterial computed tomography (CT) scan shows a tumor with heterogeneous arterial vascularization located in the left lobe corresponding to a solitary hepatocellular carcinoma less than 20 mm in size. **B:** Impaired liver function and associated conditions prevented resection or transplantation and, therefore, the tumor was treated by percutaneous injection of ethanol. Dynamic CT scan evidences that no enhancement is present in the treated tumor, which now appears as a hypodense necrotic residual lesion.

For several years, percutaneous ethanol injection (PEI) under ultrasonographic guidance was the optimal approach. Complete tumor necrosis is achieved in 90%

to 100% of HCCs smaller than 2 cm in diameter, while success is lower in larger tumors. This is due to the presence of septa that prevent diffusion of ethanol, a limitation that does not exist for radiofrequency ablation. This might be performed through single or multiple cooled-tip electrodes, percutaneously, laparoscopically, or intraoperatively. Its efficacy is similar to that of ethanol injection in HCCs less than 2 cm and is superior in larger lesions (62,63,64,65). In addition, the number of treatment sessions is less, and as a whole, radiofrequency ablation has become the preferred approach. However, there are specific locations (e.g., near to main biliary tree, abdominal organs, or heart) where application of radiofrequency is contraindicated because of the risk or severe complications, and this still leaves ethanol as a useful option. Several randomized controlled trials (RCTs) (62,63,64,65) have confirmed this superiority for the local control of tumor, although its impact on survival is less well established. The 3-year survival of patients treated percutaneously exceeds 50% at 3 years, and it has been shown that initial response to treatment is an independent predictor of better survival (61). Therefore, the 5-year survival of Child-Pugh A candidates with a complete response may exceed 50%.

Palliative Therapy

There are many options that have been proposed for patients with HCC, but unfortunately only chemoembolization has been recognized to have a beneficial

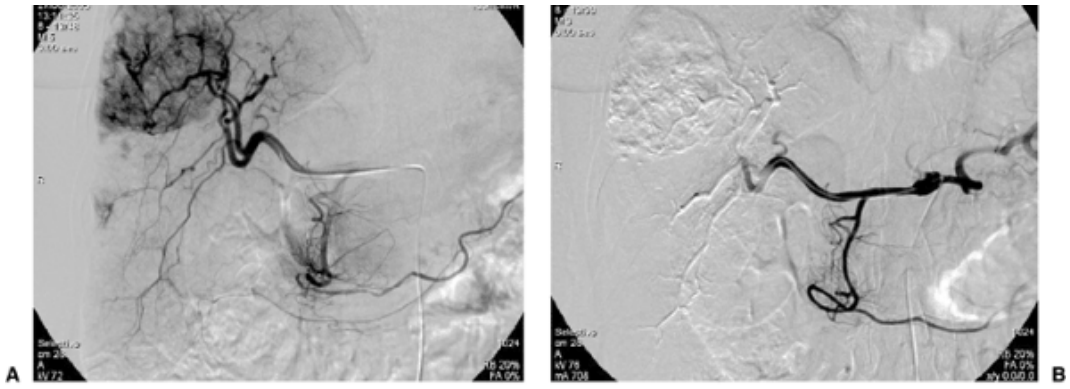
impact on survival (49). Systemic chemotherapy has no effect (<10% objective responses) and is frequently associated with toxicity and hence is usually not recommended. Estrogen blockade with tamoxifen has no benefit even if used at high doses, when it can also become toxic (49). Antiandrogenic therapy is also ineffective and induces hepatic toxicity that might even impair survival (66). Octreotide (67), vitamin D derivatives, and interferon (68) have also been tested with negative results. Radiation therapy has some effect but the need to avoid actinic hepatic damage has prompted the development of strategies for selective tumor targeting using highly focused equipment or intra-arterial injection of lipiodol ^{131}I (69) or radioactive spheres that have shown to have some efficacy, but their impact on survival is still unknown.

Transarterial chemoembolization

Because the blood supply to HCC comes mostly through the hepatic artery, any intervention that blocks this vessel will result in tumor ischemia and necrosis of variable extent. Obviously, the absence of portal blood flow (e.g., portal vein obstruction, portosystemic anastomosis, or hepatofugal flow) is a contraindication for the procedure that is also not indicated in patients with extrahepatic spread. Liver function should be preserved, and this limits its application to patients in Child-Pugh A class.

Hepatic artery obstruction requires an angiographic procedure with advancement of a catheter into the hepatic artery to interrupt blood flow to the tumor as selectively as possible and, therefore, to limit the injury of surrounding nontumor liver. There are several agents that can be used for arterial obstruction. The most common is Gelfoam prepared as 1 mm cubes, but active research aims to develop more effective obstructing agents (70). Mere obstruction of the hepatic artery is known as *transarterial*, or *bland*, *embolization*, whereas when combined with prior injection of a chemotherapeutic agent (e.g., doxorubicin, mitomycin, or cisplatin), the procedure is known as *TACE* (Fig. 44.5). The intervention is well

tolerated. More than half of the patients present with the so-called postembolization syndrome consisting of fever, abdominal pain, and a moderate degree of ileus. This recovers in 48 hours and overlaps with the potential side effects of chemotherapy.



▪ **Figure 44.5 A:** Selective hepatic angiography showing a large hepatocellular carcinoma located in the right lobe. Additional sites were also recognized and, according to staging, the appropriate treatment provided was chemoembolization. **B:** After injection of the chemotherapeutic agent suspended in lipiodol and arterial obstruction with Gelfoam cubes, the tumor vascularization was completely abolished. This combined therapy resulted in extensive tumor necrosis and improved the patient's survival.

Objective responses, as reflected by intratumoral necrosis and reduced tumor burden on dynamic CT scan or MRI, are seen in 15% to 55% of the patients. Objective response is associated with delayed tumor progression and, as a whole, results in an improvement of survival, as shown by recent RCTs (71,72) and cumulative meta-analysis (49).

Future Agents

It should be noted that the current treatment of HCC is mostly directed to the removal of the tumor by physical means. However, tumor development and progression is dictated by biologic events that are currently being actively investigated. As a result, new therapeutic agents will be directed to biologic targets and are expected to be highly selective on the tumor. Gene therapy to correct abnormal gene profile has been awaited for long and is still to show safety and benefit. On the contrary, several new molecules blocking tyrosine kinase signaling, angiogenic activity, or antiapoptotic tumor defense are entering human evaluation and hopefully will result

in a sharp change in the therapeutic management of these patients.

Chapter 45

Surgical Options for the Treatment of Hepatocellular Carcinoma

Jean F. Botha
Wendy J. Grant
Byers W. Shaw Jr.

Key Concepts

- Hepatocellular carcinoma (HCC) is among the most common fatal solid tumors worldwide. Surgical intervention provides the best hope for cure.
- Most patients with HCC are not candidates for surgery because of severe underlying liver disease, extrahepatic spread, larger tumor size, and major vascular involvement.
- The best surgical results are achieved in patients who have solitary lesions less than 5 cm in diameter or three or fewer multiple tumors, none measuring more than 3 cm. Absence of micro- or macrovascular invasion is also associated with a better long-term prognosis.
- Preoperative ablative measures are commonly performed in patients awaiting liver transplantation for HCC with the hope of improving long-term survival or preventing tumor growth while waiting. There is very little evidence that these treatments are effective for either the prevention of dropout from the waiting list or improvement of long-term outcome.
- Liver transplantation offers the advantage of total hepatectomy, removing not only the tumor but also the diseased liver. However, lifetime immunosuppression carries substantial risks, including enhancement of tumor growth in those patients in whom metastatic disease was not detected before surgery.
- Shortage of donor organs, which has traditionally limited the use of transplantation, has been partially addressed by the use of living donors. However, the risks and benefits for both donor and recipient remain undefined.

As emphasized elsewhere in this text, both the worldwide and North American incidence of chronic hepatitis type C virus (HCV) infection has not yet reached its peak. Only recently have we begun to recognize the potential threat of hepatocellular carcinoma (HCC) that two decades of proliferation of HCV infection may carry. In the continued absence of effective nonsurgical means for either prevention or treatment of HCC secondary to HCV infection, surgery remains the mainstay of our attempts to provide durable cures. Although resection has long been advocated as the first choice for those patients whose general condition, degree of liver dysfunction, and total tumor burden allow it, those patients with underlying chronic liver disease face a lifetime risk of developing additional malignancies in the diseased liver left behind. The appeal of total hepatectomy with transplantation is tempered by the lack of adequate donor livers, the risk of lifetime immunosuppression and what has become a dishearteningly high risk of recurrent hepatitis for those with chronic HCV.

What follows is a brief review of the variety of surgical options available at the beginning of the twenty-first century to treat HCC. Although our chapter in a prior edition of this text serves as the foundation, the current chapter has been completely rewritten with an eye toward updating both the data and the attitudes of

the authors and others toward the components of the varied armamentarium.

Preoperative Assessment

Patients with HCC without distant disease are candidates for surgical resection or other methods of tumor elimination. Standard preoperative work-up should include ultrasonography of the liver, computed tomography (CT) scan of the abdomen, pelvis, and thorax. Suspicious lesions found during metastatic evaluation should be biopsied using percutaneous techniques, if safe and practical. Histologic documentation of extrahepatic disease obviates curative resection and is considered a contraindication to transplantation.

Preoperative Biopsy

The need to establish a preoperative histologic diagnosis of HCC is controversial to some extent. HCC most often develops in patients with risk factors that include chronic hepatites (type C, HCV or type B, HBV) and cirrhosis. In this group of patients, those with CT scan and ultrasound evidence of a discrete solid mass may not need a tissue diagnosis before proceeding to surgery.

The usual method for establishing preoperative histologic diagnosis is by percutaneous needle biopsy or fine-needle aspiration for cytology. Although Caturelli et al. (1) report that cytology is both more accurate and more

sensitive than standard histology, biopsy with an 18- or 20-gauge needle is the more common approach. Seeding of the needle tract with tumor occurs in as many as 5% of cases (2). Isolated case reports of late recurrence of HCC in subcutaneous tissue illustrate the small risk associated with percutaneous needle biopsy (3,4,5,6).

Levy et al. (7) support their argument for not performing percutaneous biopsy preoperatively with a study involving 65 patients, with known risk factors for HCC and a lesion in the liver seen by radiographic evaluation, who were taken to surgery without preoperative histologic diagnosis. Only two of ten patients with lesions less than 3 cm and serum α-fetoprotein (AFP) levels less than 100 ng/mL preoperatively were found not to have HCC.

In reality, most patients are referred for surgical consideration, having already had a biopsy. It is our practice to proceed without biopsy in those patients with HCV, HBV, or cirrhosis. Patients with normal AFP and with no risk factors for development of HCC may require histologic evaluation to justify surgery. In those instances when the surgeon feels resection or ablation is needed regardless of histology, the value of preoperative histology becomes a matter of preference.

Radiographic Evaluation

Although this textbook provides a more thorough discussion of radiologic evaluation of the liver elsewhere, a brief discussion of our surgical perspective is offered.

Ultrasound is a comparatively cost-effective, noninvasive tool that can identify lesions as small as 1 cm. It also reveals information about the nature of the liver parenchyma. The accuracy, thoroughness, and hence, the value of ultrasound to the surgeon are more dependent on the skills of the operator than is the case with many other modalities of evaluation. Although bone and air interfaces may cause interfering reflections, the vasculature and biliary tree of the liver are generally easily visualized.

Doppler imaging is used to assess the direction of blood flow, patency of vessels and location of vessels in relation to the suspected tumor. Newer variants of ultrasound may increase the diagnostic yield of ultrasound. The use of harmonic ultrasound (8,9) and microbubble contrast (10,11) have been investigated with mixed results. The hope is that these adjuvants to traditional ultrasound will increase the sensitivity and specificity of this noninvasive diagnostic tool.

CT has always been a useful technique for imaging the liver. The use of helical CT with IV contrast gives clear cross-sectional images. Proper timing of the image acquisition to capture sequentially both arterial and portal opacification increases the sensitivity of CT for detecting intrahepatic lesions.

CT angiography allows for the definition of the hepatic arterial anatomy using three-dimensional reconstruction without the invasiveness of traditional angiography. CT arterial portography (CTAP) with angiography has been considered to be the most sensitive method of detecting hepatic masses. It requires arterial puncture with injection of contrast dye into the superior mesenteric artery or the celiac axis. At the time of this writing, CTAP is considered the gold standard against which newer imaging modalities are compared. Undoubtedly, advances in imaging techniques will make invasive angiography unnecessary for the evaluation of the liver. At present, all CT imaging techniques that require the use of intravenous contrast carry the risk of allergic anaphylactic reactions and nephrotoxicity.

Magnetic resonance imaging (MRI) is used for hepatic imaging not only to define parenchymal masses, but also to perform noninvasive cholangiography. MR angiography can also be used to define the hepatic arterial supply. Using either double contrast MRI (12) or ferumoxide-enhanced MRI (13,14), several investigators have shown a promising ability to distinguish between tumor and regenerating nodules in the cirrhotic liver. Traditional T1- and T2-weighted

turbo-spin echo MR images have a low sensitivity for detecting small HCC (15), but the sensitivity using ferumoxide-enhanced MRI rivals that of CT.

Positron emission tomography (PET) represents physiologic behavior of the tissue being imaged. The fluorine-labeled 2-deoxy-2 glucose (FDG) PET scan is the most commonly used test. Malignant tumors have a higher rate of glucose metabolism than nonmalignant tissue, therefore this radiolabeled glucose analog will concentrate in neoplastic tissue after intravenous injection and appear as a "hot" spot on the PET image (16,17). Although FDG PET has proven to be a sensitive test for hepatic colorectal metastases, the sensitivity for detection of HCC ranges from 50% to 70%. PET scan is therefore not currently recommended as a routine diagnostic test for the evaluation of suspected HCC (18).

Usually a combination of imaging techniques will give surgeons the most information for preoperative planning. By taking judicious advantage of the technology currently available, a careful surgeon should be able to identify those patients for whom laparotomy is fruitless owing to extrahepatic spread or unresectability of the liver lesion. The addition of intraoperative ultrasound not only aids in the determination of resectability, but can also define the plane of resection to ensure adequate surgical margins. As technology advances, preoperative imaging will be less invasive and carry less risk for the patient.

Prognostic Assessment

Hepatic resection remains the mainstay of curative treatment for HCC, and apart from liver transplantation, provides the only consistent long-term survival. The prognosis of patients with HCC undergoing surgical treatment is dependent on four major factors: (a) Tumor stage and aggressiveness (grade and differentiation); (b) severity of the underlying liver disease; (c) ability of the patient to withstand the treatment; and (d) proposed intervention. On the basis of an assessment of these factors, almost 75% of patients with HCC will be excluded from curative surgery. Patients deemed to have tumors not suitable for curative resection are offered one or more

of the increasing number of available palliative therapies.

Table 45.1. Child-Pugh Score

Criterion	1	2	3
Serum bilirubin (mg/dL)	<2	2–3	>3
Serum albumin (g/dL)	>3.5	3–3.5	<3
Ascites	None	Easily controlled	Poorly controlled
Encephalopathy	None	Minimal	Advanced
INR	<1.7	1.7–2.3	>2.3

5–6 points, Child-Pugh class A; 7–9 points, Child-Pugh class B; 10–15 points, Child-Pugh class C; INR, international normalized ratio.

Postoperative liver failure (0% to 40%) and intrahepatic recurrence (20% to 60%) are the two main reasons for treatment failure after liver resection (19,20). Prognostic risk factors for intrahepatic recurrence after resection for HCC have been extensively studied and the conventional pathologic features of the tumor are the most widely cited. Large tumor size (>5 cm) (21), gross or microscopic tumor involvement at the resection margin, vascular invasion (22,23), and macro- or microscopic satellite lesions (20,24) all predict a worse outcome after hepatic resection.

By contrast, the risk of postoperative liver failure has been less easy to predict. Although numerous tests and formulas have been proposed, there is no uniformly accepted method to assess functional hepatic reserve. Patients with HCC most often have cirrhosis, and it therefore comes as no surprise that liver failure after resection is a major cause of mortality. There are a number of clinical stratification scores that have been used to predict postoperative liver failure. Of these, the Child-Pugh score is the best established. It provides a score using simple clinical variables (encephalopathy and ascites) and blood tests (serum bilirubin and albumin and prothrombin time) (Table 45.1). Although the Child-Pugh score was originally developed to predict the survival of patients with cirrhosis and variceal hemorrhage undergoing portocaval shunts, numerous studies have failed to confirm its value in predicting morbidity and mortality after liver resection (25). In fact, Bruix et al. have shown that the presence of portal hypertension, defined as a wedged hepatic vein to hepatic vein pressure gradient, greater than 10 mm Hg is associated with hepatic decompensation in up to 60% of patients with Child A cirrhosis after liver resection.

The Okuda staging system combines the assessment of tumor volume and functional hepatic impairment. The variables evaluated with this system are tumor volume, presence of ascites, and serum concentrations of bilirubin and albumin (Table 45.2). The stage of the disease is based on the number of positive values: Stage I = no positives; Stage II = 1 or 2 positives; Stage III = 3 or 4 positives. In the absence of any treatment, median survival for patients with Okuda Stage I, II, and III disease are 8, 2, and 0.7 months respectively (26). Unfortunately, the Okuda system only provides a rough estimation of outcome after surgery. The same is true for

the tumor-node-metastasis (TNM) classification, which does not account for underlying liver dysfunction and in reality, provides little help in the preoperative assessment and decision making for patients with HCC (27).

Table 45.2. Okuda Staging Variables

Staging criteria	Positive	Negative
Tumor size (% of liver volume)	>50%	<50%
Presence of ascites	Detectable	Absent
Serum albumin	<3 g/dL	>3 g/dL
Serum bilirubin	>3 mg/dL	<3 mg/dL

More recently, the Cancer of the Liver Italian Program (CLIP) has proposed a new scoring system, the CLIP score, which includes assessment of both tumor characteristics and hepatic functional reserve. (28,29). The CLIP score

consists of four variables: Child-Pugh Score, tumor morphology, serum AFP level and portal vein invasion. This system overcomes some of the problems encountered with other classifications and may prove to have greater prognostic value.

In an attempt to overcome the limitations of clinical scoring systems, alternative methods of quantifying hepatic reserve such as the bromsulfophthalein retention test, the 14C-aminopyrine breath test, the indocyanine green (ICG) clearance test, and the monoethylglycinexylidide (MEGX) test, which measures the liver's ability to clear a lidocaine metabolite, have been evaluated. The ICG retention test is the most widely used adjunctive test. ICG is actively and solely removed from plasma by the liver. Clearance of ICG is considered to be impaired when 15% or more of the dye remains within the plasma 15 minutes after intravenous injection. These tests have not gained widespread acceptance, mostly because of the cumbersome nature of some of the tests, requiring numerous samples, and the fact that these tests measure only the severity of the underlying liver disease prior to resection and do not give a precise indication of the liver function that will remain following partial hepatectomy. It appears that no single test offers a better prediction of postoperative liver failure than the Child-Pugh score and an experienced surgeon (30).

Liver Resection

Preoperative Evaluation

Hepatic resection inflicts significant physiologic stress on the patient. Patients should be evaluated for possible cardiac disease with screening electrocardiogram (ECG) and a careful evaluation of the patient's level of activity. Hepatic resection carries a high risk for cardiac events according to the classifications presented by Eagle et al. (31). Further cardiac evaluations (stress testing and cardiac catheterization) are usually required for adequate evaluation of patients with risk factors for coronary artery disease. These risk factors include the following:

- Previous history of myocardial infarction
- History of congestive heart failure or angina pectoris
- Diabetes mellitus
- Advanced age
- Abnormal ECG
- Nonsinus rhythm on ECG
- Low functional capacity

Patients with unstable coronary syndromes, decompensated congestive heart failure, significant arrhythmias, or severe valvular disease most often require cardiac catheterization with or without revascularization prior to hepatic resection.

Patients with a known history of pulmonary disease should be evaluated with preoperative pulmonary function tests and an arterial blood gas. Strict exclusion criteria for patients with pulmonary disease are not well established. As with other patients undergoing major abdominal surgery, early ambulation and the use of incentive spirometry may help prevent atelectasis.

Patients undergoing hepatic resection for malignant tumors meet high-risk criteria for deep venous thrombosis (DVT) (32). Recommendations for prophylaxis include intermittent pneumatic compression (IPC) stockings and low-molecular-weight heparin. To reduce the risk of postoperative bleeding, anticoagulants are avoided.

All patients undergoing a hepatic resection should have blood products available for the operating room. We do not routinely use autologous shed blood recovery techniques when resecting malignancies in the liver. Patients with liver disease and prolonged prothrombin times should receive fresh frozen plasma (FFP) to correct the coagulopathy early in the surgery. Midorikawa et al. advocate the use of FFP routinely, both in the operating room and postoperatively, in all hepatic resections (33).

Surgical Resection

Surgical resection and liver transplantation are the only therapies that can be applied with curative intent. Resection is the treatment of choice for noncirrhotic patients with small tumors (<5 cm) and selected cirrhotic patients with minimal decompensation (Child A patients). The data from Barcelona have been quite convincing that if there is any evidence of portal hypertension, particularly hepatocellular dysfunction, the outcome of liver resection is poor. Improved patient selection in conjunction with advances in perioperative

management has resulted in lower operative morbidity and mortality. In general, a five-year survival rate of more than 50% can be expected in well-selected patients (Table 45.3A,B). Unfortunately, long-term survival is negatively affected by tumor recurrence rates over 50%. Recurrence may occur in the liver or at extrahepatic sites. Recurrence occurs not only because of the pathologic aspects of the tumor, but also because the remnant liver still has premalignant potential, with HCV-positive patients being at particular risk (34).

Table 45.3A. Results of Liver Resection for Hepatocellular Carcinoma

Author	Year	Number of patients	30-D operative mortality (%)	Recurrence (%)	Survival (%)			Comments
					1 Y	3 Y	5 Y	
Iwatsuki	1991	76	—	50 (5 y)	71	—	33	17/76 cirrhosis

Grazi	2001	264	100	4.9	—	63.1	41.1	49.3
Kanematsu	2002	303	55	3.3	—	67	51	41

The type of resection performed is dictated by the size and location of the tumor. Resections are usually segmental (based on Couinaud segmental anatomy—see Fig. 45.1) or lobar. The specifics of the technical approach to the resection are surgeon-dependent. Most commonly, a bilateral subcostal incision is used. Thoracoabdominal incision plays little or no role in our experience. Initial exploration of the abdomen should rule out extrahepatic disease. The arterial anatomy of the liver should be assessed to identify aberrant left or replaced

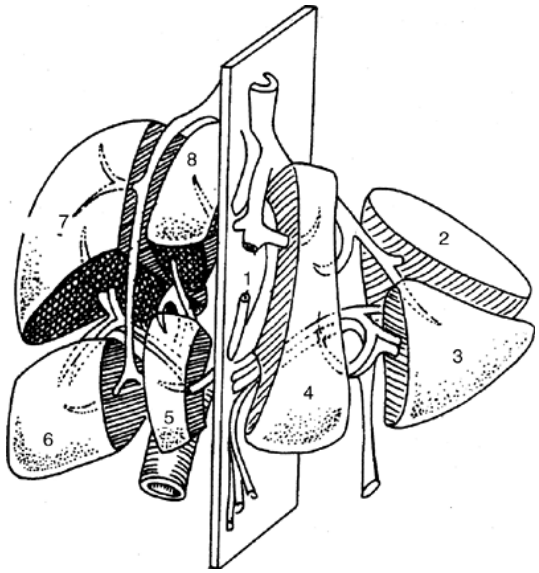
right hepatic arteries.

After the liver is mobilized, resectability of the tumor should be confirmed. The use of intraoperative ultrasound may give the surgeon information about the proximity of the tumor to hepatic veins and portal vessels. It also provides further assurance that no previously unidentified lesions are present in the liver.

Traditionally, the hilar structures (hepatic artery, portal vein and bile duct) leading to the lobe to be resected are identified and individually ligated prior to the parenchymal dissection. A Pringle maneuver may be used to occlude the inflow during the parenchymal division to minimize blood loss. Inflow can be occluded for up to 60 minutes—continuously or intermittently. An alternative approach is total vascular exclusion where the vena cava is isolated above and below the liver and a soft vascular clamp is placed across the hilum of the liver prior to parenchymal division. This technique is useful for segmental and lobar resections. Patients who do not tolerate the lack of venous return may be supported with veno–veno bypass.

Published results of hepatic resection for treatment of HCC in large series of patients underscore the current safety of liver resection in patients with cirrhosis (29,35,36,37,38,39,40,41). Strategies for improved survival include the use of perioperative nutritional support, FFP during and after resection and careful selection of patients. The use of preoperative portal vein embolization to enhance hypertrophy of the uninvolved segment or lobe of liver

can also help decrease the risk of postoperative hepatic failure (42).



▪ **Figure 45.1** Couinaud's segmental hepatic anatomy. (From Couinaud C. Le foie. The numbers refer to the names of each segment. *Etudes anatomiques et chirugicales*. Paris: Masson; 1957, with permission.)

The recurrence rate after resection remains high. Some groups advocate segmental or lobar resection rather than excision of the tumor to decrease the rate of local recurrence (30). Tumor-free margins of resection, lack of vascular invasion, and size of the tumor are variables that help predict the risk of recurrence (Table 45.3A,B).

Ablative Techniques

Most patients with HCC are not candidates for hepatic resection. This is because of multifocal intrahepatic disease, extrahepatic tumor, inadequate functional hepatic reserve, or involvement of the portal vein bifurcation. (43) For these reasons, several techniques have been developed in order to provide therapeutic options for this subgroup of patients with HCC. Treatment modalities include systemic and regional chemotherapy, percutaneous ethanol or acetic acid injection, and cryotherapy and thermal techniques such as laser, microwave, and radiofrequency ablation (RFA) (38,44). Here we describe the current surgically applicable ablative techniques, cryotherapy and RFA.

Cryotherapy

Hepatic cryotherapy employs the delivery of subfreezing temperatures by the placement of a cryoprobe directly into the tumor. At present, this technique requires a laparotomy or laparoscopy as well as sophisticated equipment that use liquid nitrogen or argon as the freezing agent. (45,46,47) Cell death is the consequence of intra- and extracellular ice crystal formation with the resultant destruction of cellular structures. (42,48,49) An ice ball is created around the tip of the probe. The development of the ice ball is monitored intraoperatively by ultrasound. A freeze–thaw cycle is usually repeated to achieve adequate tumor destruction; the freeze cycle is 10 minutes long followed by 5 minutes of thawing. This sequence is repeated on each lesion. The probe is then gently removed, the tract packed with Gelfoam, and manual pressure applied to control bleeding. Larger lesions require

the placement of multiple probes to achieve the required ablation margin of 1 cm of hepatic parenchyma around the tumor.

Complication rates range from 10% to 50% and mortality from 0% to 4%. Complications include hypothermia and its associated coagulopathy, bleeding, biliary fistula, liver surface cracking, and intrahepatic and subphrenic abscess. A rare complication is "cryogenic shock syndrome," a form of multiorgan failure and disseminated intravascular coagulation (38,40,50). The results of most clinical studies of cryotherapy for hepatic malignancies are difficult to interpret. Nonetheless, a study by Zhou et al. demonstrated acceptable long-term survival in 235 patients with HCC, although most patients in the study received some form of therapeutic intervention in addition to cryotherapy (51). Local early tumor recurrence rates are reported to be approximately 15%. The high risk of recurrence and the high complication rate have contributed to making cryotherapy a fairly unpopular mode of treatment.

Radiofrequency Ablation

The concept of thermal ablation of hepatic tumors is not a novel one. However, not until recent technologic advances made it possible to induce a predictable zone of tissue destruction did it become a practical tool. RFA of hepatic tumors has been the focus of increasing research recently. The technique involves delivery of high-frequency alternating current from a needle electrode to the tissue; the parenchyma is subsequently heated to above a cytotoxic temperature (42°C). The higher the temperature generated in the tissue the lower the exposure time required to cause cell death (38,43,52).

The simple straight needle electrodes are no longer used; modern RFA needles have the so-called multiple array hook electrodes that retract into the needle shaft. The needle shaft is an insulated 14- to 18-gauge needle of varying lengths (usually 15 to 25 cm). As

with cryotherapy, it is usual to perform RFA through laparotomy or laparoscopy. The needle is placed into the tumor under ultrasound guidance. The multiple array hooks are then deployed into the tumor. Once deployed, the array creates an umbrella-like cluster of electrodes with a 3.5 or 5.0 cm diameter. These electrodes can produce a zone of coagulation necrosis up to 4 to 7 cm in diameter.

Most series of RFA for HCC report a relatively low complication rate in the region of 2% to 3%. Careful surgical technique and good preoperative planning allow the avoidance of thermal injury to adjacent structures such as diaphragm and bowel. Early recurrence occurs in 2% to 5% of patients, with recurrences occurring at the periphery of the lesion, most likely related to incomplete ablation at the time of surgery. The recurrence rate with RFA is notably lower than that associated with cryotherapy. The study by Curley et al. demonstrated acceptable results, with 60% of their patients alive without radiographically detectable tumor recurrence at a median follow-up of 19 months (53). In a more recent review of their data, they show that 55.4% of their patients were alive at 5 years after RFA for tumors averaging 3.3 cm in diameter (53).

At present, RFA offers a relatively safe and effective treatment for patients with HCC who are not candidates for liver resection or liver transplantation. In comparison to other therapies, RFA and percutaneous ethanol injection (PEI) appear roughly comparable for smaller tumors. However, for tumors larger than 3.5 cm, the same ablation usually requires multiple outpatient PEI sessions, compared to a single inpatient treatment session with RFA. We currently recommend RFA over PEI and cryotherapy for unresectable HCC. PEI is reserved for small, unresectable HCC, such as for local control of small tumors in patients awaiting liver transplantation.

A newer therapy on the horizon is hepatic arterial infusion of Yttrium-90 (TheraSphere), which has been reviewed by a group in Pittsburgh. Sixty-five patients with unresectable, biopsy-proven HCC were treated. Twenty-five of the 64 patients had a partial response to therapy, as shown by CT scan. Deaths following the treatment were attributed to liver failure, HCC progression, and metastatic disease. There are no comparisons to a similar cohort to determine whether the TheraSpheres played a role in the demise of these patients (54). Another group has reported partial response rates of 78% (55) and there have been small single-center safety studies that conclude that patients with intact hepatocellular function can tolerate this therapy (56,57). This is a limited experience to date and large studies of safety and efficacy are needed before it is accepted as standard therapy.

Liver Transplantation

The first patient to survive liver transplantation for more than a year was a child with HCC. Foreshadowing the failure of our attempts to cure liver cancer reliably with total hepatectomy, the patient died with recurrent tumor 400 days following transplantation. Our collected experience during more than three decades since represents a frustrating mix of miraculous success and tragic failure. Nonetheless, total hepatectomy with transplantation remains the most attractive alternative for treating HCC, not only because it removes the diseased liver that is often associated with HCC, but also because it provides the widest surgical margins with low risk for hepatic failure.

On the basis of a review of the data available till 1983, a National Institutes of Health consensus development conference that year endorsed the use of liver transplantation for treatment of selected patients with HCC. As liver transplant centers proliferated throughout North America and Europe, wider experience underscored a serious concern. Although providing a chance for cure to patients with no other alternatives, when compared to the results for transplantation in the treatment of other liver diseases, the long-term survival probability for patients who underwent transplantation for HCC was disappointing in most and unacceptable in others. Five-year survival rates reported between 1985 and 1989 from three leading transplant centers were 25% to 40% (58,59,60). In 1991, Penn, relying on data submitted by numerous transplant centers to the Transplant Tumor Registry, reported that the overall 5-year survival observed was 18% (53). These reports arrived at a time when the shortage of donor livers was beginning to drive waiting times for most patients beyond the 1-year mark, leading to an

alarming increase in the risk of death for waiting candidates. With 5-year survival probabilities for other types of liver transplant recipients reportedly in excess of 80% to 85%, advocates for providing liver transplantation to patients with liver cancer were obliged to improve their results.

In the mid-1980s, investigators began focusing on two major strategies for improving results. One approach involved better patient selection through examination of retrospective information about tumor staging and histologic grade. The other included a variety of pre- and post-transplant treatment regimens designed to lessen the risk of recurrence.

Early reports suggested and subsequent experience has confirmed that the most favorable results are obtained in patients with so-called incidental HCC. These are tumors that were not known to be present prior to liver transplantation but that were discovered during careful examination of the resected liver. In the experience reported by Iwatsuki et al. in 1991,

no patients in this category experienced recurrence of tumor during the follow-up period (61). The same report, as well as data from other authors, has confirmed that among patients with known HCC, those with small tumors fare better than those with larger ones. Remarkably, in 1996 Mazzaferro et al. from Milan reported that 85% of patients with a single tumor less than 5 cm in diameter and 92% of those with three or fewer tumors, none larger than 3 cm, experienced a 4-year tumor-free survival (62).

Some authorities have advocated the TNM staging system as the standard method for comparing the results of various studies and for selecting patients for treatment with orthotopic liver transplantation (Table 45.4). Three previous studies have shown that patients with TNM stages I and II disease, particularly those with severe underlying chronic liver disease, obtain a survival benefit from transplantation compared to either resection or nonsurgical options (53,63,64). However, patients with stage III C and IV disease have a poor prognosis with all treatment options, including transplantation. At the same time, the authors and others have previously emphasized that patients with stage III disease are a heterogeneous group, particularly because patients with large (T3) tumors but without nodal disease are considered stage III. The presence or absence of nodal disease among stage III patients is thought to explain the striking difference between a 57% and a 16% five-year survival reported for patients undergoing transplantation in two large series in 1991 (53,55).

Factors with a demonstrated association with a poor prognosis for patients undergoing liver transplantation for HCC include male gender, tumor size, multiplicity, bilobar involvement, lymph node metastases, cirrhosis, and extrahepatic tumor (49,54,55,65,66,67,68). Histologic evidence of microvascular invasion has also been associated with an increased risk of tumor recurrence. All too often, in practice, the more important histologic factors are only determined on careful examination of the explanted native liver days after the transplantation.

The prognosis for allograft recipients treated for cancer is further affected by the need for long-term immunosuppression. In 1991, researchers at Pittsburgh examined the acceleration of growth rates among patients on antirejection medications with recurrent HCC (69). Despite continued advances in immunosuppressants in the subsequent decade, both cyclosporine and tacrolimus remain mainstays in modern maintenance protocols. Because both are potent inhibitors of interleukin-2 (IL-2) production, the mechanisms of natural tumor surveillance requiring natural killer cells and lymphokine-activated killer cells may be markedly reduced among transplant recipients (70,71).

Table 45.4. Staging of Hepatocellular Carcinoma

Stage	Primary tumor	Nodal status	Distant metastases
I	T1	N0	M0
II	T2	N0	M0
III	T1	N1	M0
	T2	N1	M0
	T3	N0, N1	M0
IVA	T4	Any N	M0
IVB	Any T	Any N	M1

Using known risk factors for recurrence of HCC, the Pittsburgh group has attempted to predict both the risk of tumor recurrence and the time to recurrence of HCC after liver transplantation. In 1996, Marsh et al. examined five known risk factors (gender, tumor number, lobar distribution, tumor size, and presence of vascular invasion) in an effort to assign patients to one of three groups:

1. Patients who should not develop recurrent HCC and therefore do not require adjunctive chemotherapy.
2. Patients who will suffer recurrence and for whom adjunctive chemotherapy increases survival time.
3. Patients who may or may not develop recurrent HCC and for whom recurrence may be prevented by chemotherapy.

The authors believed that by categorizing patients with their scoring system, they could use adjuvant treatment only for those patients who are most likely to benefit. The study was an exercise in statistics, however, and the model had yet to be validated with clinical data (72).

More recently, Iwatsuki et al. from Pittsburgh have further challenged the conventional wisdom that TNM staging offers useful prognostic information (73). Retrospective analysis of 344 consecutive patients who underwent liver transplantation for treatment of nonfibrolamellar HCC led to the development of a Prognostic Risk Score (PRS). Multivariate analysis showed that bilobar distribution of the tumor, tumor size of 2 to 5 cm or greater than 5 cm, and microscopic or unaided visual evidence of vascular invasion were the three most important predictive variables. PRSs of patients could be used to assign them to one of five categories of risk for recurrence (Table 45.5).

In 1983, Koo et al. recovered malignant tumor cells from the right atrium of patients undergoing hepatectomy for liver cancer (74). We first observed in 1985 that the most common pattern of recurrence for HCC following liver transplantation was a multifocal spread in the newly transplanted liver. We speculated then that efforts directed at circulating tumor cells might effectively reduce the risk of recurrence. A decade later, Kar and Carr showed that patients with HCC can have as many as one billion tumor cells in the

systemic circulation each day (75). Therefore, the use of neoadjuvant chemotherapy or pretransplant arterial chemoembolization has received widespread attention during the last decade (Table 45.6).

Table 45.5. Prognostic Risk Score

	Grade 1	Grade 2	Grade 3	Grade 4	Grade 5
PRS	0 to <7.5	7.5 to 11.0	>11.0 to 15.0	>15.0	+ nodes or DM
5-y tumor-free survival	100%	61%	40%	5%	0%

Prognostic Risk Score is calculated on the basis of bilobar distribution, tumor size 2–5 cm or >5 cm and vascular invasion. PRS, prognostic risk score; DM, distance metastases.
From Iwatsuki S, Dvorchik I, Marsh JW, et al. Liver transplantation for hepatocellular carcinoma: a proposal of a prognostic scoring system. *J Am Coll Surg* 2000;191(4):389–394.

The theoretical advantages of pretransplant chemoembolization are attractive. Because most, if not all, of the blood supplied to HCC is from the arterial system, the ischemia induced by arterial embolization makes the tumor more susceptible to the effects of the applied chemotherapeutic agent. In theory, one can also deliver higher doses of chemotherapeutic agents directly to the tumor than that possible through systemic use.

We and others have used chemoembolization both in an elective setting at the time the tumor is first discovered, and at the time of liver transplantation. Intraoperative chemoembolization is intended to reduce the number of viable tumor cells that liver mobilization associated with total hepatectomy releases into the bloodstream. For patients on the waiting list for transplantation, chemoembolization has been used to reduce the risk of continued tumor growth as well as to reduce the risk of spread at the time of hepatectomy.

In nonrandomized applications, several authors believe they have obtained improved survival with both methods of chemoembolization. In 1997 Majno et al. from Paris reported the successful use of chemoembolization to downstage tumors that were more than 3 cm in diameter (76). In some patients, they observed complete necrosis of the tumor. Patients with these responses who underwent subsequent transplantation experienced a significant improvement in tumor-free survival compared to patients with either an incomplete response or to those who did not receive chemoembolization (Fig. 45.2). More recent studies, though, have not shown a significant survival advantage to those patients undergoing transarterial chemoembolization (TACE) and liver transplantation (77,78). Tumor size seemed to be one of the most important prognostic factors among the patients in these reports, with those having a tumor greater than 5 cm in diameter experiencing a ten times greater incidence of recurrence than those with smaller tumors.

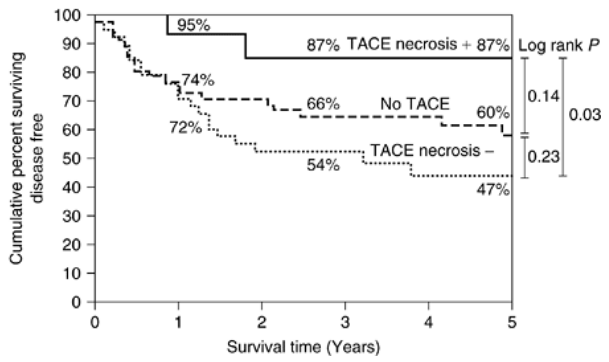
Table 45.6. Adjuvant Therapy with Liver Transplantation for Hepatocellular Carcinoma

Author	Year	N	Therapy	Survival	Recurrence (%)

Bismuth	1992	20	Arterial chemoembolization with ethiodized oil	2 y (49%)	—
Carr	1993	11	Pretransplant interferon arterial chemoembolization with doxorubricin and cisplatin postoperative chemotherapy	1 y (91%)	—
Stone	1993	20	Pre- and postoperative doxorubricin intravenously	3 y (59%)	45
Cherqui	1994	9	Preoperative chemoembolization and radiation (5 Gy); postoperative mitoxantrone	3 y (64%)	33
Olthoff	1994	25	Postoperative chemotherapy with doxorubricin and cisplatin fluorouracil	3 y (46%)	20
Majno	1997	54	Chemoembolization with lipiodol mixed with doxorubricin or cisplatin	5 y (55%)	—

As the waiting time for liver transplant candidates with hepatic tumors continued to increase during the last half of the 1990s, the effectiveness of preparative regimens for tumor control waned dramatically. The United Network for Organ Sharing (UNOS) allocation algorithm for cadaveric-donor livers assigned priority to patients with liver dysfunction. Patients with HCC but with preserved hepatic function were not able to

receive adequate priority until their waiting time (also a factor in the allocation algorithm) exceeded 1 to 2 years, depending on geographic location. Inevitably, continued tumor growth during the prolonged waiting period often obviated successful transplantation either because candidates developed evidence of metastatic disease and were removed from the waiting list or because those that finally received a graft were more likely to have developed unrecognized metastases by the time they received the transplant.



▪ **Figure 45.2** Cumulative disease-free survival after liver transplantation for hepatocellular carcinoma associated with cirrhosis: Complete necrosis of the lesion after transarterial chemoembolization TACE (necrosis positive: *n* = 15), no necrosis after TACE (necrosis negative: *n* = 39), and no TACE (*n* = 57). (From Majno PE, Adam R, Bismuth H, et al. Influence of preoperative transarterial lipiodol chemoembolization on resection and transplantation for hepatocellular carcinoma in patients with cirrhosis. *Ann Surg* 1997;226 (6):688–703 with permission.)

Although UNOS eventually allowed special consideration to patients with favorable hepatic tumors by allowing them to compete in a higher status category normally reserved for patients with severe liver dysfunction, the leaders of many liver transplant programs began advocating additional measures to provide expedited liver transplantation. In addition to the general advocacy to increase the available supply of cadaveric-donor livers through wider use of split-livers (79,80,81), many programs began examining the risks and benefits of using live volunteers to provide donor livers. Using a statistical decision analysis technique that considered a cohort of hypothetical patients with compensated Child A cirrhosis and an unresectable 3.5 cm HCC, Cheng et al. from Boston satisfied themselves that live-donor adult-to-adult liver transplantation offered a 4.5-year increase in tumor-free survival as compared to waiting for cadaveric-donor liver transplantation or no transplant. The advantage persisted in their model even in the face of varying severity of cirrhosis, age, tumor doubling time, tumor growth pattern, blood type, regional transplant volume, initial tumor size, and rate of progression of cirrhosis (82). A similar experience was reported by the Mount Sinai Hospital during the period from 1998 to

2001—the average waiting time for a deceased donor was 414 days as compared with 83 days for a living donor—proposing that HCC is an ideal indication for living-donor liver transplantation (83).

In February 2002, the Model of End-Stage Liver Disease (MELD) system was implemented in the United States. Livers from cadaveric donors are now allocated according to a patient's score that is based on their international normalized ratio (INR), creatinine level, and bilirubin level. Patients with HCC most often do not have decompensation of their cirrhosis so the transplant community decided to implement a separate point system that would provide HCC patients with access to organs before their disease progressed beyond the point that they were eligible for transplantation. The Milan criteria have been used to define which patients are eligible for liver transplantation by UNOS standards, that is, patients must have one tumor less than 5 cm or up to three tumors, none of which may exceed 3 cm in diameter. Documentation of the presence of tumor is through imaging and a positive biopsy, AFP more than 200 ng/mL, or previous ablative therapy of the lesion. Points were assigned on the basis of prediction of survival for patients with stage I and II disease (84). With the introduction of the MELD system for liver allocation in adult patients who underwent transplant, the incidence of transplantation for HCC has risen dramatically. In 2001, 2.8% of liver transplants in the United States were for a diagnosis of HCC with or without cirrhosis, and this rose to 7% (434 of 6,186) in 2004. Since the origination of the MELD system, the point allocation for patients with HCC has been adjusted and currently only patients with Stage II disease are eligible for point upgrades. Patient survival rates after liver transplantation for HCC are acceptable, with the 5-year survival being 61.1% in a recent review

of patients transplanted between 1996 and 2001. This rate is lower than that for patients transplanted without HCC (5-year survival approximately 70%), but remains acceptable (85).

As the full impact of our worldwide epidemic of HCV infection reaches its acme, the prospect of a similarly overwhelming population of patients with HCC ought to cause us considerable alarm. Whereas HCC may best be prevented by more effective early treatment of viral hepatitis, the absolute number of patients with established cirrhosis that are at risk for cancer—although a relatively small percentage of the total—is likely to be staggering. Therefore, under the assumption that transplantation offers the best chance of tumor-free survival for these patients, and with the supply of donor livers from cadaveric sources falling even further behind demand from all patients with liver disease (many with far better long-term survival prospects than patients with tumor), the burden on families, friends, and other volunteers to provide pieces of their livers should give us all pause. Although a case-by-case focus on the needs of our own patients ought to be our primary role as physicians, a more global oversight of our results, with a particular emphasis on donor safety and health, needs to be established.

Chapter 46

The Liver in Pregnancy

Yannick Bacq

Key Concepts

- During normal pregnancy, except for alkaline phosphatase, most values of serum liver tests remain below the upper normal limits established in nonpregnant women. Consequently, increased levels of aminotransferases, bilirubin, or serum bile acids usually indicate the presence of liver disease. By contrast, an increase in serum alkaline phosphatase levels in pregnancy is not specific for liver disease because it may be of placental origin.
- The liver disorders that occur in pregnancy can be divided into three groups: (a) Liver diseases unique to pregnancies that are specifically pregnancy related; (b) intercurrent liver diseases in pregnancy, that is, acute liver disease occurring fortuitously during pregnancy; and (c) chronic liver diseases that may be revealed by pregnancy, or more often diagnosed fortuitously during pregnancy.
- It is essential that liver disease in pregnancy is recognized and understood because certain disorders can threaten the lives of both mother and infant.
- Liver disorders unique to pregnancy include the exceptional primary hepatic pregnancy, liver dysfunction associated with hyperemesis gravidarum, intrahepatic cholestasis of pregnancy (ICP), liver disorders of preeclampsia including hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome, and acute fatty liver of pregnancy (AFLP).
- ICP is a benign disease for the mother but carries a risk for the baby because of the possibility of premature delivery and sudden fetal death. Generalized pruritus is the main symptom. Serum bile acid and aminotransferase levels are increased, although the γ-glutamyl transpeptidase levels may be normal or only slightly increased.
- AFLP is a form of hepatic failure associated with coagulopathy and occasionally encephalopathy and hypoglycemia. An association has been found between AFLP and a defect of long-chain 3-hydroxyacyl coenzyme A dehydrogenase (LCHAD) in the fetus. Women in whom AFLP develops and their offspring should undergo deoxyribonucleic acid (DNA) testing for the main associated genetic mutation (G1528C) in the gene coding for LCHAD.
- Certain liver diseases that can occur in anyone, pregnant or not, are more severe during pregnancy (e.g., viral hepatitis E and herpes simplex hepatitis). Other disorders can be precipitated by pregnancy or during postpartum, such as cholelithiasis and Budd-Chiari syndrome.
- Pregnancy in patients with advanced chronic liver disease is rare, although

patients with treatable liver diseases, such as autoimmune hepatitis and Wilson disease, may regain fertility and should be maintained on treatment during gestation. By contrast, successful pregnancy in patients with mild chronic liver disease, such as viral hepatitis B or C, is common. Pregnancy after liver transplantation may be associated with prematurity and increased maternal complications, but not with teratogenicity.

Liver disease in a pregnant woman can make the consulting physician uneasy. Most gastroenterologists and hepatologists are unfamiliar with the pregnant state and the liver diseases associated with it, and pregnancy is rarely seen in patients with severe chronic liver disease. Also, the stakes are higher for these patients, given the presence of a second life in the form of the fetus. The distress on the part of the consultant is well founded because pregnancy is a state of altered, although normal, physiology. Certain disorders of the liver are unique to pregnancy and not comparable with liver diseases in nonpregnant patients. Furthermore, some conditions that can affect anyone, pregnant or not, may follow an unusually severe course in the pregnant woman. Despite these problems, the care of these otherwise young and healthy women is gratifying, and most return to good health simply by being delivered of the infant. Recent advances in our understanding of liver diseases during pregnancy have simplified and rationalized the approach to these patients.

The Liver in Normal Pregnancy

The changes involving the liver during normal pregnancy have been discussed in a review of the literature (1).

Physical Examination

Spider angiomata and palmar erythema are common during pregnancy and usually disappear after delivery. In late pregnancy, physical examination of the liver is difficult because of the expanding uterus.

Ultrasonographic Examination

Ultrasonographic examination reveals no dilatation of the biliary tract, but increases in fasting gallbladder volume and residual volume after contraction are noted.

Pathology

Standard and ultrastructural examination of the liver during normal pregnancy reveals no or minimal abnormalities.

Hemodynamics

The plasma volume increases steadily between weeks 6 and 36 of gestation (by approximately 50%). The red cell volume also increases, but the increase is moderate (approximately 20%) and delayed. Consequently, the total blood volume increases, with hemodilution reflected by a decrease in the hematocrit value. It is necessary to bear this phenomenon of hemodilution in mind during the interpretation of all the serum concentrations during pregnancy. The plasma volume and red cell volume decrease rapidly after the termination of pregnancy, aided by the loss of blood at delivery. Cardiac output increases until the second

trimester and then decreases and normalizes near term. Absolute hepatic blood flow remains unchanged, but the percentage of cardiac output to the liver decreases.

Serum Protein and Lipids

The serum albumin levels decrease during the first trimester, and this decrease becomes more accentuated as the pregnancy advances. However, the serum concentrations of some proteins increase, such as α_2-macroglobulin, ceruloplasmin, and fibrinogen. The serum cholesterol and triglyceride concentrations increase markedly during pregnancy, and except when a pregnant woman is suffering from acute pancreatitis, the measurement of these serum lipid concentrations is rarely useful during pregnancy. The prothrombin time is unchanged during pregnancy.

Liver Tests

Knowledge of the changes associated with normal pregnancy is necessary for the interpretation of liver test values and the management of liver diseases during pregnancy (1,2). The serum alkaline phosphatase levels increase late in pregnancy, mainly during the third trimester, as a result of the production of the placental isoenzyme and an increase in the bone isoenzyme level. In most published studies, the serum levels of alanine transaminase (ALT) and aspartate transaminase (AST) have been found to remain within normal limits during pregnancy. Serum γ-glutamyl transpeptidase (GGT) activity decreases slightly during late pregnancy. The total and free bilirubin concentrations are lower than those in nonpregnant controls

during all three trimesters, as are the concentrations of conjugated bilirubin during the second and third trimesters. The serum 5′-nucleotidase activity is normal or slightly higher during the second and third trimesters compared to that in nonpregnant women. Fasting serum total bile acid (TBA) concentrations usually remain within normal limits, and their routine measurement remains useful for the diagnosis of cholestasis during pregnancy, especially when routine liver function test results are still within normal limits. Therefore, increased values of serum ALT and AST activity, and serum bilirubin and fasting TBA concentrations should be considered pathologic, as they are in nonpregnant women, and prompt further evaluation. The main changes in liver function test results during normal pregnancy compared to nonpregnant women are summarized in Table 46.1.

Table 46.1. Liver Tests in Normal Pregnancy

TESTS NOT AFFECTED BY PREGNANCY
Serum transaminase levels (alanine transaminase, aspartate transaminase)
Prothrombin time
Serum concentration of total bile acids (fasting state)
TESTS AFFECTED BY PREGNANCY[a]
Albuminemia (decreased from the first trimester)
Alkaline phosphatase levels (increased in second and above all in third trimester)

Bilirubinemia (slightly decreased from the first trimester) 5′ nucleotidase (slightly increased) γ-Glutamyltransferase (slightly decreased in late pregnancy)

[a]Increased or decreased in relation to values in nonpregnant women.

Liver Diseases Unique to Pregnancy

Liver diseases unique to pregnancy include primary hepatic pregnancy, hyperemesis gravidarum, intrahepatic cholestasis of pregnancy (ICP), the liver disorders of preeclampsia with HELLP syndrome, and acute fatty liver of pregnancy (AFLP). The main factors in the diagnosis of liver disease in pregnancy are given in Table 46.2. Gestational age at the time of the onset of signs and symptoms can be helpful in the differential diagnosis. Hyperemesis gravidarum begins in the early part of the first trimester. ICP can begin at any time but usually does not present until the second or third trimester. Preeclampsia is a disorder of the second half of pregnancy, and patients with HELLP syndrome usually present in the third trimester. Similarly, AFLP, which can be associated with preeclampsia, is usually a disorder of the third trimester of pregnancy. The main diagnostic features of these liver diseases are given in Table 46.3.

Table 46.2. Main Factors in the Diagnosis of Liver Diseases in Pregnancy

Jaundice Generalized pruritus Nausea or vomiting Pain in epigastrium or right hypochondrium Arterial hypertension and proteinuria Polyuria and polydipsia without diabetes mellitus Thrombocytopenia

Primary Hepatic Pregnancy

On exceedingly rare occasions, the inferior surface of the right lobe of the liver is the site of ectopic implantation (Fig. 46.1). Such patients may present early in gestation with hemoperitoneum resulting from hepatic hemorrhage. If the

pregnancy progresses toward term, the patient presents with a mass in the liver. Primary hepatic pregnancy can be diagnosed by ultrasound examination or computed tomography scan (3), and termination of pregnancy by laparotomy is recommended in view of the risk of rupture.

Hyperemesis Gravidarum

Nausea and vomiting are common symptoms of early pregnancy, occurring in up to 50% of all pregnancies, corresponding to "morning sickness." By contrast hyperemesis gravidarum occurs much less frequently, complicating approximately 0.5% to 1.5% of pregnancies (4,5). There is no clear demarcation between common symptoms and severe forms, and therefore, there is no universally accepted definition. Hyperemesis gravidarum can be defined as persistent vomiting associated with weight loss greater than 5% of prepregnancy body weight and large ketonuria (5). Hyperemesis gravidarum leads to dehydration, and hospitalization is usually required. Liver involvement, as described in the subsequent text, is common in this condition (6).

Pathology

Liver biopsy is rarely needed to confirm this diagnosis, given its typical clinical presentation. When performed, it shows surprisingly little. There is no inflammation, but centrilobular vacuolization, necrosis with cell dropout, and rare bile plugs may be seen (7).

Clinical and biochemical findings

This disorder presents early in the first trimester of pregnancy, during weeks 4 to 10 of gestation, with intractable vomiting and associated ptyalism. As a rule, it resolves by the 20th week, regardless of therapy. It is more common during a first pregnancy than in multiparous women. In the modern era, liver disease

is inconspicuous and jaundice is rare. This was not the case before the widespread use of intravenous fluids; for example, Charlotte Brontë, the author of Jane Eyre, died in 1855 with nausea, vomiting, and jaundice during the fourth month of her first pregnancy.

Table 46.3. Main Diagnostic Features of Liver Diseases in Pregnancy

QUESTIONING
Term of pregnancy, past medical history with emphasis on the history of pruritus during previous pregnancy or oral contraception, pruritus during current pregnancy, abdominal pain, nausea or vomiting, polyuria and polydipsia, drug treatment

CLINICAL EXAMINATION
Temperature, blood pressure, liver examination (difficult during late pregnancy), herpetic vesicles on skin or mucosa

BLOOD TESTS
Routine liver function tests (Table 46.1; liver function tests in normal pregnancy)

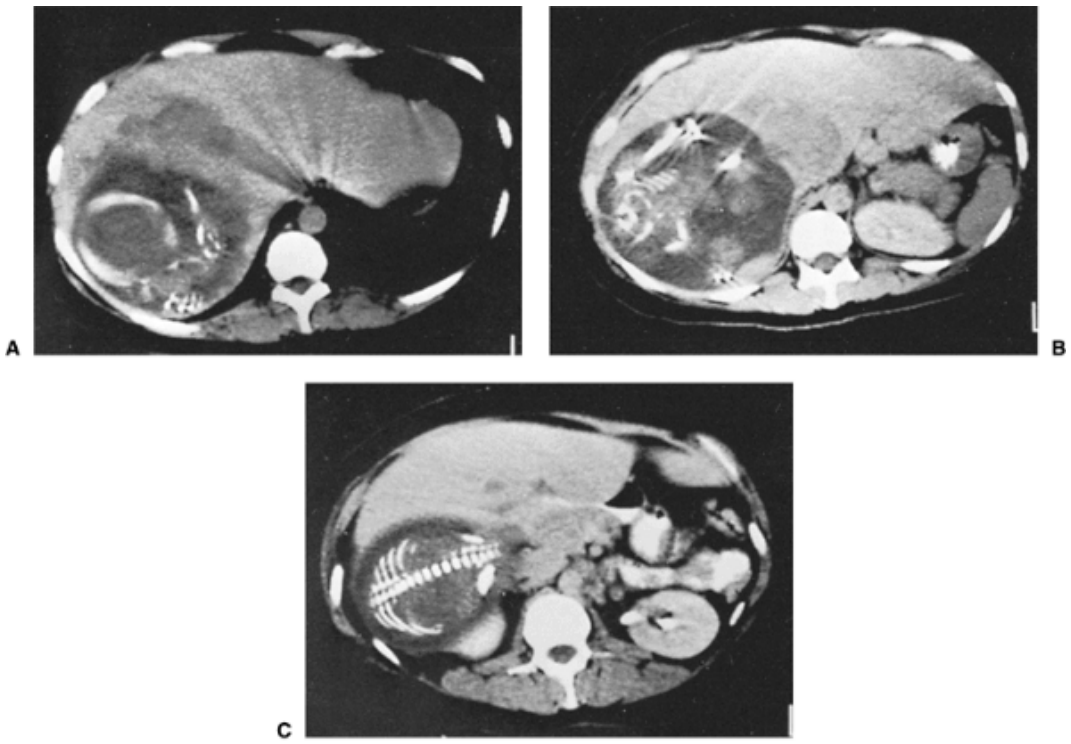
Glycemia, creatininemia, electrolytes and uricemia
Full blood count including platelets
Prothrombin time
Viral hepatitis and cytomegalovirus serology
Possible measurement of serum total bile acid levels when cholestasis is suspected (not a routine test)

URINE TESTS

Proteinuria and bacteriuria

ULTRASONOGRAPHY OF THE LIVER AND BILE DUCTS

EVOLUTION OF SYMPTOMS AND LIVER FUNCTION TESTS AFTER DELIVERY



▪ **Figure 46.1** Intrahepatic pregnancy demonstrated by computed tomography. **A:** A cut from below the dome of the liver showing skull bones of the fetus and the placenta invading the hepatic substance. **B, C:** Lower cuts demonstrating fetal position with the spine protruding from the inferior surface of the liver. (Permission of Professor Caroline A. Riely.)

When the liver is involved, the most striking abnormality is elevation of aminotransferase levels, with ALT levels exceeding AST levels and both readings usually in the low hundreds but rarely as high as 1,000 IU. Increases in bilirubin levels occur but are less striking. When the patient is treated with gut rest and intravenous fluids, the abnormalities resolve. Pregnancies complicated by hyperemesis gravidarum have been associated with transient hyperthyroidism, and an association between the liver involvement and the hyperthyroidism is

possible (8).

Affected patients may be thought to have hepatitis or gastric outlet obstruction resulting from peptic ulcer disease. Hepatitis serologies are useful in the differential diagnosis. Abdominal pain is not a typical complaint.

Maternal and fetal outcome

Many affected patients respond to rehydration and a short period of gut rest followed by reintroduction of a diet rich in carbohydrates and low in fat. Thiamine supplementation may be recommended for women who have vomited for several weeks to prevent Wernicke's encephalopathy. Antiemetics including promethazine, metoclopramide, ondansetron, and droperidol may be useful (9,10). Corticosteroids are reported to improve the appetite and have been proposed in this condition (11,12). Enteral nutrition through gastric or duodenal intubation is effective and preferable to the parenteral route (13). Despite the severity of the illness and attendant weight loss, infants born after affected pregnancies do not differ in regard to birth weight, gestational age, and birth defects from infants born after pregnancies unaffected by hyperemesis gravidarum (4,14).

Pathophysiology

The pathogenesis of this disorder remains unclear, but liver involvement, like thyroid involvement, appears to be secondary to the disorder itself, not a causative factor. Infection with *Helicobacter pylori* may play a role (15), and a predominance of female offspring in affected pregnancies has been noted (16). It is presumed that gestational hormones, many of which peak in the early part of pregnancy, affect both the liver and the thyroid.

Intrahepatic Cholestasis of Pregnancy

ICP occurs during the second or third trimester and disappears spontaneously after delivery. The prevalence of ICP varies widely by country. It is common in Scandinavia and even more common in Bolivia and Chile. In Chile, the prevalence in 1974 to 1975 was reported to be 15.6%, ranging from 11.8% to 27.7%, according to ethnic origin (17). For unknown reasons, the prevalence has more recently appeared to decrease (to between 4.0% and 6.5%) (18,19). Generally, ICP is more common in twin pregnancies (20).

Pathology

Liver biopsy is rarely necessary for the diagnosis. Histopathology is characterized by pure cholestasis, sometimes with bile plugs in the hepatocytes and canaliculi, predominantly in zone 3. Inflammation and necrosis are not usually observed, and the portal tracts are unaffected (21).

Clinical and biochemical findings

Pruritus, which is the main symptom, is very uncomfortable and difficult to tolerate. It is often generalized but predominates on the palms and soles. It is more severe at night and disturbs sleep. Pruritus usually disappears within the first few days of delivery. The clinical examination findings are normal except for evidence of scratching. Fever, if present, is usually caused by an associated urinary tract infection. Approximately 10% to 20% of patients have jaundice. The greater frequency of jaundice in some studies may be a consequence of

concomitant urinary tract infection (22). ICP with jaundice but without pruritus is rare. Patients do not experience abdominal pain or encephalopathy. Ultrasonographic examination reveals no dilatation of the biliary tract.

Measurement of serum ALT activity is a sensitive test for the diagnosis of ICP. Patients with ICP frequently exhibit significant increases in serum ALT activity that suggest acute viral hepatitis, which should be ruled out with suitable serologic tests (23). Liver histology usually does not reveal necrotic lesions, and the ALT level elevations may be secondary to an increase in membrane permeability. The serum GGT activity is normal or only slightly increased, the serum 5'-nucleotidase activity is often slightly increased, and the serum TBA concentrations are increased (24). A relationship between maternal serum bile acid levels and fetal distress has been found (25,26) and evaluation of the serum TBA concentration has been recently suggested as a means of fetal assessment in patients with ICP (27). At the present time, however, no consensus has been reached concerning the usefulness of evaluating the serum TBA concentrations in the obstetric management of patients with ICP (28). Little or no correlation has been found between the serum TBA concentrations and other liver test values (23). The serum bile acid concentration and serum ALT activity decrease rapidly after delivery and, as a rule, normalize in a few weeks.

Recently, the measurement of serum glutathione-*S*-transferase, a maker of hepatocellular integrity, has been proposed to distinguish ICP from "benign pruritus gravidarum" (29). The prothrombin time is usually normal. It may become abnormal in severe cholestasis with jaundice or in patients who have been treated with cholestyramine. The abnormality is caused by vitamin K deficiency, which should be anticipated and treated before delivery to prevent hemorrhage. Such therapy contributes to a good maternal prognosis.

Maternal and fetal outcome

The maternal prognosis is good, but cholestasis frequently recurs in subsequent pregnancies. The administration of oral contraceptives to women with a history of ICP may rarely result in cholestasis, but ICP is not a contraindication for oral contraceptives. Oral estroprogestogen contraception with a low dose of estrogen can be initiated after the liver test values have normalized. The patient should be informed of the possibility of pruritus during such contraception.

ICP does carry a risk for the fetus (30). The main complication of ICP is prematurity, which is more frequent in patients with ICP than in the general population (19). The rate of prematurity varies greatly according to the study and may be increased because of the high rate of multiple pregnancies in patients with ICP (23). The other complication of ICP is the risk of sudden fetal death. The prevalence is approximately 1% to 2% but varies according to studies. Sudden fetal death rarely occurs before the last month of pregnancy.

Pathophysiology

The cause of ICP is unknown. The results of previous epidemiologic and clinical studies suggest that genetic, hormonal, and exogenous factors play a role. Genetic factors may explain the familial cases and the higher incidence in some ethnic groups, such as the Araucanos Indians of Chile (17). A nonsense mutation of the *ABCB4* (*MDR3*) gene has been found in a child with progressive familial intrahepatic cholestasis type 3 (PFIC 3) and in three mothers suffering from cholestasis during pregnancy (31). In this familial study, the infant with PFIC 3

was homozygous for the *ABCB4* mutations, whereas the mothers with ICP were heterozygous. The *ABCB4* gene codes for the translator of phosphatidylcholine across the canalicular membrane into bile. In the absence of phospholipids in bile, bile acids can injure the canalicular membrane, leading to cholestasis. Several other mutations of the *ABCB4* gene were subsequently found in patients suffering from ICP (32,33,34). However, the role of ABCB4 in the pathogenesis of ICP has not been clearly established and the prevalence of such mutations in patients with a clearly defined phenotype of ICP is still under evaluation (35,36). Defects in the *ATP8B1* gene, which is associated with progressive familial intrahepatic cholestasis type 1 (PFIC1) and benign recurrent intrahepatic cholestasis (BRIC), have also been found in patients with ICP, but it seems that this gene is not a major contributor to ICP (37). A role of estrogens has been clearly established in ICP. Animal studies have shown that estrogens, in particular ethynyl estradiol, are cholestatic. Genetically determined abnormalities may lead to unique hepatic reactions to estrogens or to dysfunction of estrogen metabolism (30). Progesterone metabolism is also involved in the pathophysiology. Abnormalities of progesterone metabolism, especially elevated levels of serum sulfated metabolites, have been found in women with ICP (38). The formation of large amounts of sulfated progesterone metabolites, possibly related to greater 5-α and 3-α reduction, may in some genetically predisposed women result in a saturation of the hepatic transport system(s) involved in the biliary excretion of these compounds (39). One study has shown that oral natural progesterone prescribed for threatened premature delivery can trigger ICP in predisposed women (23). The intake of progesterone may place an additional load on the sulfated metabolite transport system. Progesterone treatment should therefore be avoided in pregnant women, especially late in pregnancy or when the patient has a history of ICP.

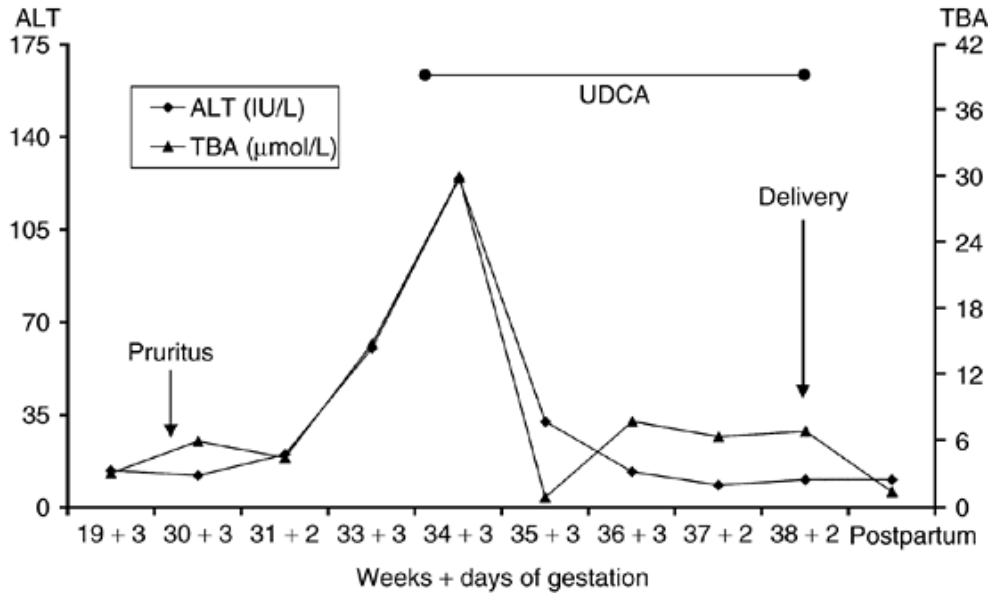
Some characteristics of ICP suggest that exogenous factors may be associated with an underlying genetic predisposition: (a) ICP recurs in only 60% to 70% of pregnancies in multiparous women, (b) seasonal variability has been observed in several countries, and (c) the prevalence of ICP has decreased in Sweden and Chile. For example, a deficiency in selenium may be a factor involved in the pathophysiology of ICP (40).

Medical and obstetric management

Hydroxyzine (25 to 50 mg/day) may alleviate the discomfort of pruritus. Cholestyramine (8 to 16 g/day) decreases the ileal absorption and increases the fecal excretion of bile salts. Its effect on pruritus is limited. The efficacy of *S*-adenosyl-L-methionine is a matter of debate (18,41,42). The most promising treatment is ursodeoxycholic acid. In some case reports and several open and controlled trials, ursodeoxycholic acid has been effective in ICP (38,42,43,44,45,46). The bile acid patterns in meconium are influenced by cholestasis of pregnancy and are not altered by treatment with ursodeoxycholic acid (45,46). Ursodeoxycholic acid relieves pruritus, improves liver function test values (Fig. 46.2), and prevents prematurity. No side effects have been reported for mothers or babies. Therefore, ursodeoxycholic acid (usually 500 mg twice a day or 15 mg/kg per day) appears to be safe during late pregnancy and may be useful in relieving cholestasis

and improving fetal prognosis in patients with ICP, especially those with severe disease. The mechanism of the beneficial effect of ursodeoxycholic acid for the mother and the baby in ICP remains speculative. Like in chronic liver diseases,

ursodeoxycholic acid, which is a hydrophilic bile acid, may decrease signs of cholestasis in the mother by affording cytoprotection against the hepatotoxic effects of the hydrophobic bile acids and by improving the hepatobiliary bile acid transport. In ICP, ursodeoxycholic acid may also have a specific effect by improving the transport of bile acid across the placenta.



▪ **Figure 46.2** Treatment of intrahepatic cholestasis of pregnancy (ICP) with ursodeoxycholic acid (UDCA). This patient had experienced ICP during a previous pregnancy. Regular surveillance during the current pregnancy was proposed and once the diagnosis of recurrent ICP had been confirmed treatment with UDCA was initiated. Serum total bile acid (TBA) concentration (TBA, upper normal limit: 6 µmol/L) and serum alanine aminotransferase (ALT) activity (ALT, upper normal limit: 35 IU/L) improved and the patient delivered at 38 weeks of gestation. (Yannick Bacq, personal data, 2005)

It is often difficult to decide the best time for delivery, and no consensus has been clearly established. When cholestasis is severe (e.g., if the patient has clinical jaundice), delivery should be considered at 36 weeks of gestation if the fetal lungs have matured, or as soon thereafter as possible (19).

Preeclampsia Liver Disorders

Livers disorders associated with preeclampsia are certainly the most frequent causes among the liver diseases unique to pregnancy (47). Preeclampsia is a multisystem disorder of enigmatic etiology and pathogenesis presenting in the latter half of pregnancy (48,49). It complicates 3% to 5% of all pregnancies and is a major cause of maternal and fetal mortality. Despite the importance of this disorder, even its definition is still debated (50). The disease is thought to start early in pregnancy, with abnormal implantation of the trophoblast, which leads to restricted perfusion of the placenta. The fall in systemic vascular resistance typical of normal pregnancy does not occur in patients with preeclampsia; their sensitivity to vasospasm is enhanced, with resultant poor perfusion of and injury to a variety of organs, including the liver. A variety of factors is suspected to

play an important role in the mechanism of the disease, some inherited, some immunologic. The disorder is more common in primiparas and in multiple gestations with twins or triplets (51,52). It is also more common in multiparous women whose first pregnancy was complicated by preeclampsia (53). Being the offspring of either a father or a mother who was born of a preeclamptic pregnancy increases the risk of preeclampsia in the next generation (54). A possible role for an inherited procoagulant state was suggested (55,56,57), but then refuted (58). A link to insulin resistance syndrome is possible (59,60). Abnormalities in endothelial function, probably mediated by nitric oxide, can be demonstrated in women with a history of preeclampsia (61). Antioxidant treatment was shown to decrease the incidence of preeclampsia in susceptible women (62), which suggests a role for oxidative stress in this condition (63). Preeclampsia may result from paternal or fetal effects, and immune factors may play a role (48). An excess of male offspring from affected pregnancies has been noted (64). Preeclampsia is more common in couples who have cohabited for only a short period (65) and in multiparous women who then become pregnant by a different partner (66).

The typical presentation is hypertension with proteinuria, although both conditions are not found in all patients with this multisystem disease. Patients may also have renal failure, seizures (eclampsia), pancreatitis, or pulmonary edema. Preeclampsia has long been

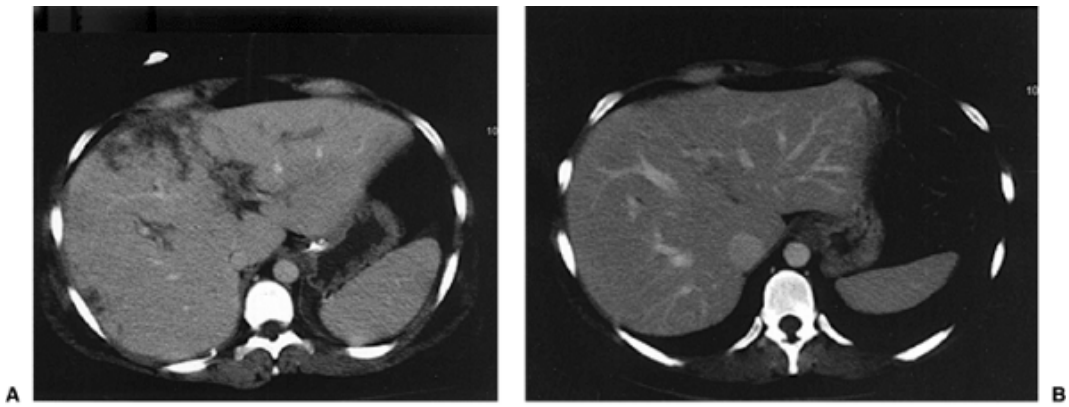
known to affect the liver in a variety of ways including HELLP syndrome.

Hemolysis, elevated liver enzymes, low platelets syndrome

The HELLP syndrome is defined as hemolysis (usually subclinical, with characteristic schistocytes and burr cells on smear), elevated liver enzyme levels (usually elevated aminotransferase levels, with AST exceeding ALT), and low platelet numbers in a patient with preeclampsia. Affected women are less likely to be primiparous and tend to be older than the average woman with preeclampsia (67). The hepatic histology is that of preeclamptic liver disease, with periportal hemorrhage and fibrin deposition. Little correlation is found between the degree of histologic aberration and the severity of the clinical findings. Fat may be seen, but as macrovesicular fat distributed in modest quantities throughout the liver lobule and not as the microvesicular centrizonal fat typical of AFLP (68). Despite similar settings and occasional clinical overlap, these two conditions are histologically distinct (69).

The clinical presentation of HELLP varies markedly, with no symptom other than abdominal pain recorded in more than 50% of patients (53). The pain is usually located in the midepigastric region, right upper quadrant, or substernal region. Many patients have nausea, vomiting, and malaise, which suggest a diagnosis of viral hepatitis. Jaundice is present in approximately 5% of patients (53). Most cases are diagnosed during the third trimester, although the condition may present postpartum. In a large series of 437 patients who had 442 pregnancies with HELLP syndrome, 70% of cases occurred before delivery and 30% after delivery, 11% developed before 27 weeks of gestation and 18% after 37 weeks (53). Most, but not all, patients have the hypertension and proteinuria that are typical of preeclampsia. The diagnosis usually rests on clinical grounds, although imaging studies, particularly computed tomography (Fig. 46.3) and magnetic resonance imaging, are useful in detecting the complications of hepatic infarct,

hematoma, and rupture (70). Hepatic hematoma may be missed by these techniques but detected laparoscopically (71). Liver biopsy should be approached with caution, given the association of hematoma and rupture with HELLP.



▪ **Figure 46.3** Hepatic involvement in a 24-year-old primipara with severe preeclampsia. **A:** Abdominal computed tomography performed after delivery by cesarean section showing subcapsular ischemic lesions in the right lobe. **B:** Follow-up image 7 months later showing complete recovery. (Courtesy of Béatrice Scotto, MD.)

The outcome for the mother is usually good, with a maternal mortality rate of 1.1% in a large series (53), and the condition starts to reverse with delivery. A review of deaths collected from many centers demonstrated that stroke is the most common cause of death, followed by cardiac arrest and disseminated intravascular coagulation (72). No correlation between any laboratory test value (e.g., platelet count, or aminotransferase or lactate dehydrogenase level) and adverse maternal outcome was reported in another study (73). Rare patients experience severe liver disease with fulminant hepatic failure leading to death (74). Diabetes insipidus has been reported in HELLP syndrome and also in AFLP (75). The main risk for the fetus is prematurity. These babies do not have any increased risk of liver disease or thrombocytopenia, and their outcome is similar to that of babies of a similar gestational age (76,77).

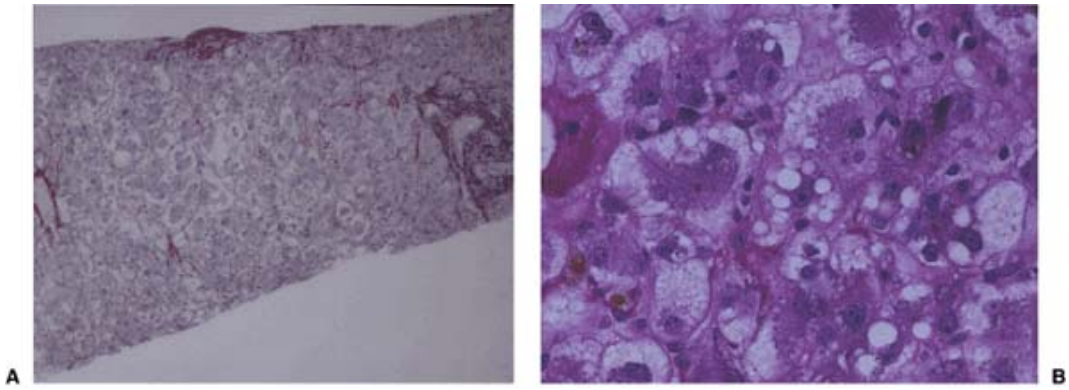
Management is supportive and may include transfer to a medical intensive care unit, with ventilatory support and dialysis provided in severe cases. The cornerstone of therapy is delivery, although temporizing management with intensive monitoring may be useful for some patients with mild disease (78). Corticosteroids have been shown to improve laboratory test

values and allow a delay in delivery (79,80,81). Long-term follow-up has shown an increased risk of obstetric complications in subsequent pregnancies but no tendency for a repetition of the HELLP syndrome (67).

Hepatic hematoma and rupture

In rare pregnant patients, a hematoma develops beneath the Glisson capsule. This may remain contained, or rupture of the liver capsule may result in hemorrhage into the peritoneal cavity from multiple lacerations in which the

capsule has been lifted from the surface. Rupture usually occurs in the setting of HELLP syndrome. Histology of the portion of the liver adjacent to the rupture shows periportal hemorrhage and fibrin deposition, along with neutrophil infiltrate, suggestive of hepatic preeclampsia (53,82). Some patients do not have thrombocytopenia or typical preeclampsia (83). Clinically, affected patients have abdominal pain and, when the liver has ruptured, swelling of the belly from hemoperitoneum, along with shock. The aminotransferase levels are usually slightly raised, but values in the range of 4,000 to 5,000 IU are occasionally seen. Computed tomography or magnetic resonance imaging of the body is more dependable than ultrasonography for detecting these lesions (70). The management of a contained hematoma is supportive. Patients with rupture are best managed by a team experienced in liver trauma surgery (84). Liver transplantation is used when the hemorrhage cannot be contained (85,86,87). Patients who survive have no hepatic sequelae and have been documented to have normal subsequent pregnancies (67). A report of recurrent episodes in subsequent pregnancies suggested a predisposition of affected women, resulting from some underlying condition, perhaps an inherited procoagulant state (88).



▪ **Figure 46.4** Acute fatty liver of pregnancy in a 24-year-old primipara. This woman had experienced nausea and vomiting, abdominal pains, and jaundice in late pregnancy. A transvenous liver biopsy was performed postpartum—**(A)** intact lobular architecture (hematoxylin and eosin, 200×) and **(B)** typical microvesicular fatty infiltration in hepatocytes and features of cholestasis (400×). Acute Fatty Liver of Pregnancy

AFLP was distinguished as a specific clinical entity unique to pregnancy in 1940 (89). It is a rare disease and its incidence was estimated to be 1 per 13,328 deliveries at the Los Angeles County University of the Southern California Medical Center (90) and 1 per 15,900 in Santiago, Chile (91). Early diagnosis and prompt delivery have dramatically improved both maternal and fetal prognosis, as perhaps has the recognition of the disease, and an article from Los Angeles County states the incidence to be 1 in 6,659 births (92). In addition, in a recent prospective study including 4,377 deliveries in Southwest Wales, AFLP was found in five patients (i.e., 1 per 875 deliveries) (47).

Pathology

Liver biopsy is the best way to confirm the diagnosis of AFLP, but because it is invasive, it is not always performed. Also, we can now take advantage of noninvasive procedures to demonstrate fat in the liver and exclude other liver diseases, such as viral hepatitis. Nevertheless, liver biopsy may be useful in atypical cases.

The overall architecture of the liver is not altered. The characteristic picture is a microvesicular fatty infiltration of the hepatocytes, which are swollen. The droplets are minute and surround centrally located nuclei, so that the cytoplasm has a foamy appearance (Fig. 46.4). In a few cases, rare, large fat vacuoles are associated with the microvesicular steatosis. The microvesicular fatty infiltration is most prominent in the pericentral zones and midzones (zones 2 and 3) and usually spares a rim of periportal cells. The droplets stain with oil red O, which is specific for fat. The histologic features of cholestasis (i.e., bile thrombi or bile

deposits within hepatocytes) are common. Inflammation is not prominent but is also common (93). The histologic features are not always evident, and cases of AFLP have been misdiagnosed as hepatitis. Necrosis with acidophilic bodies is inconspicuous, and massive panlobular hepatocellular necrosis, as in fulminant viral hepatitis, is not seen. On the other hand, the liver may appear disorganized, with impressive lobular disarray and pleomorphic hepatocytes (94). Electron microscopy confirms the presence of fat droplets and has shown nonspecific changes in mitochondrial size and shape (95). A stain specific for fat or electron microscopy is useful for pathologic confirmation of the diagnosis in patients with ballooning of the cytoplasm but no evident vacuolization. Therefore, whenever AFLP is suspected, a piece of the liver biopsy specimen should be reserved before paraffin embedding and processed appropriately with special stains to confirm the presence of fat in the hepatocytes. The pathologic changes normally reverse rapidly after delivery, and AFLP is not associated with progression to cirrhosis (94).

Clinical and biochemical findings

As a rule, AFLP is a disease of the third trimester that may occur during any period of gestation. However, some reports have detailed cases presenting at 22 (96) or 26 weeks of gestation (97). The onset of disease is never after delivery, but the diagnosis may be made after delivery. The frequency of twin gestations is increased among patients with AFLP (14% to 19% vs. approximately 1% in the general population), and 7% of triplet pregnancies have been reported to be complicated by AFLP (52). The most frequent initial symptoms are nausea or vomiting, abdominal pain (especially epigastric), anorexia, and jaundice. In the past, jaundice was almost always seen during the course of the disease, but because of earlier diagnosis, prompt delivery, and the diagnosis of milder cases, we now see affected patients without jaundice. The size of the liver is usually normal or small. Patients with AFLP rarely have pruritus but may have concurrent ICP (98). Approximately half of affected patients have high blood pressure or proteinuria, which are the main symptoms of preeclampsia (93). On the other hand, some affected patients do not have any of these signs. Patients may demonstrate asterixis and encephalopathy, with or without coma, and some have pancreatitis. Esophagitis and Mallory-Weiss syndrome related to severe vomiting have been reported. Gastrointestinal bleeding secondary to the esophageal lesions, in addition to gastric ulceration related to shock, has been reported.

Genital bleeding is frequent. These hemorrhages are exacerbated by associated coagulation disorders. Ascites may be present and is partially related to portal hypertension (91). Polyuria and polydipsia have been noted in about 5% of patients with AFLP (93), and an association between transient diabetes insipidus and AFLP has been reported (99).

The serum aminotransferase levels are raised, but usually the level is not as high as that in acute viral hepatitis. The bilirubin level is almost always increased. Patients may demonstrate hypoglycemia. In severe cases, the prothrombin time is increased and the fibrinogen level decreased. These coagulation disorders are caused by hepatic insufficiency, disseminated intravascular coagulation, or both. A low platelet count is usual in AFLP and is not always associated with other signs of disseminated intravascular coagulation. Thrombocytopenia may be the most striking laboratory feature and normalizes spontaneously after delivery. The diagnosis of AFLP should always be considered when thrombocytopenia occurs during late pregnancy and should always prompt the performance of liver function tests, particularly determination of the aminotransferase levels. Renal failure (mainly functional) and hyperuricemia are usual. Ultrasonography of the liver may show increased echogenicity (100). Computed tomography may be useful for the diagnosis, and a liver density lower than usual may be demonstrated by Hounsfield unit values in the liver that are equal to or lower than those in the spleen (101). The findings on imaging studies may be normal; a recent study showed that the findings on computed tomography, which is more sensitive than ultrasonography, were normal in half of the patients with AFLP (102). In clinical practice, these complementary examinations should not delay delivery, particularly in severe cases, which can usually be diagnosed on clinical grounds with routine biologic data.

Maternal and fetal outcome

The maternal mortality rate of AFLP was very high before 1970 (approximately 90%) (93). The maternal prognosis has currently improved greatly, and maternal mortality is less than 10%. This improvement is principally related to early delivery, advances in intensive care support for patients with severe forms, and also the detection of patients with less severe forms. Most recover completely after delivery, without sequelae. However, one patient remained in prolonged coma after hemorrhagic shock (103), and cases of neurohypophyseal insufficiency have been reported, which, in one case has been associated with definitive diabetes insipidus (104).

AFLP may recur during subsequent pregnancies, although recurrence is not the rule. At least 25 cases without recurrence have been reported; 17 patients had a normal pregnancy and 4 had two normal pregnancies after AFLP. However, at least six cases of recurrence have been reported since 1990. In the first case, both

episodes of AFLP were confirmed by histologic examination of the liver biopsy specimen, and the mother and babies recovered (105). In the second case, although healthy children were delivered by cesarean section, both babies died at 6 months (106). Steatosis of the liver was present in these neonates and associated with a deficiency of β-oxidation of fatty acids. The mother had a third pregnancy, which was uneventful, and the infant did not have such a deficiency. In the third case, the baby died in utero during the first episode of AFLP (91). During the recurrence 5 years later, emergency cesarean section performed at 36

weeks resulted in a live birth, and the outcome was good for both mother and baby. The outcome was favorable for mothers and babies in three other cases of recurrence reported in the literature. Mothers who have experienced AFLP should be informed of the risk for recurrence and closely followed up during subsequent pregnancies. Follow-up should be both clinical and biologic (e.g., liver function tests, tests for uricemia, and platelet counts twice monthly during the third trimester).

Until 1985, fetal mortality was reported to be as high as 50% (94). Early delivery has resulted in an improved fetal prognosis (107), and the final outcome for infants delivered alive is usually considered to be good. However, in view of the possibility of congenital enzyme deficiency involving intramitochondrial β-oxidation of fatty acids, these infants should be closely followed up from birth.

Pathophysiology

AFLP belongs to a group of liver diseases characterized by microvesicular steatosis, including Reye's syndrome, sodium valproate and tetracycline toxicity, and Jamaican vomiting sickness. All these conditions are considered to be caused by abnormalities of mitochondrial function. Microvesicular steatosis may occur in several other drug-induced, toxic, and viral liver diseases.

The cause of AFLP remains unknown, although good progress toward a better understanding of this disorder has recently been made. An association of inherited defects in the β-oxidation of fatty acids with AFLP is now well established. A case of long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency in a 4-month-old baby born to a mother who had had AFLP and HELLP syndrome at 36 weeks of pregnancy was reported in 1994 (108). Both parents were heterozygous for LCHAD deficiency. Hepatic steatosis or HELLP syndrome has also been reported in several mothers of babies with LCHAD deficiency (109,110). β-Oxidation of fatty acids, measured by the activity of LCHAD in skin fibroblast culture, was studied in 12 women who had had AFLP (110). LCHAD activity was reduced in eight of them, consistent with heterozygosity for LCHAD deficiency. Four women had no deficiency. The eight heterozygous women had a total of nine pregnancies complicated by AFLP. Of the nine offspring delivered from these pregnancies, four were confirmed to be homozygous for LCHAD deficiency. Three other infants died with a clinical picture compatible with this diagnosis. The two other infants were healthy at 18 and 24 months of age and had LCHAD activity in the heterozygous range. The five husbands tested were heterozygous (110). These findings show that a deficiency in the β-oxidation enzyme in the fetus may lead to maternal hepatic steatosis in late pregnancy, especially if the mother is heterozygous for the deficiency. Two mutations (G1528C and C1132T) have been observed in the gene coding for LCHAD in three families with children having LCHAD deficiency whose mothers had had AFLP or HELLP syndrome (111). More recent work shows that acute fatty liver may occur regardless of the mother's genotype if her fetus is deficient in LCHAD and carries at least one allele with the G1528C mutation (112). In affected families, a prenatal diagnosis based on sampling of chorionic villi has proved both feasible and accurate (113). These forms of AFLP associated with a genetic deficiency of β-oxidation have not been observed in all countries; the common mutation (G1528C) was not found in 14 women with AFLP observed consecutively in a French hospital (114). Another defect in β-oxidation, a deficiency of carnitine palmitoyltransferase I, has also been associated with AFLP (115), and DNA analysis for this deficiency is available (116). No familial cases (i.e., AFLP in

mother and daughter) have been reported.

Medical and obstetric management

AFLP must be considered an obstetric emergency. AFLP usually does not resolve before delivery, and if delivery is delayed, complications such as hemorrhage and intrauterine death may develop. Consequently, the primary therapy for AFLP is early delivery. The choice of the route of delivery remains the decision of the obstetrician and must be appropriate for the individual clinical situation. Generally speaking, if the patient is in labor and in good general condition and no sign of fetal distress is detected, then vaginal delivery may be attempted with careful monitoring of the mother and baby (117). For patients with severe disease, urgent delivery must be considered, usually by cesarean section, after correction of the coagulation disorders, especially those related to thrombocytopenia.

The etiology of AFLP is not known, and no specific medical treatment is available. Esophagitis should be treated with appropriate drugs to prevent bleeding. The blood sugar levels should be monitored and

hypoglycemia treated by a continuous intravenous infusion of glucose. Patients with fulminant hepatic failure are best managed in an intensive care unit before and after delivery; intensive care remains the cornerstone of management. Two patients with serious disease that continued after delivery (which is unusual) were treated successfully by liver transplantation (118,119), and auxiliary transplantation has been used successfully in this setting (120). Nevertheless, the role of liver transplantation in AFLP is probably limited. Early diagnosis and prompt delivery of the infant of a patient with AFLP should avoid the difficult decision about later liver transplantation.

Intercurrent Liver Disease in Pregnancy

In addition to the disorders unique to pregnancy, pregnant women are susceptible to diseases that can affect anyone. Some common disorders can take a fulminant course in pregnant women, hepatitis E being the most frequent example. Furthermore, pregnancy predisposes a woman to the development of the usual liver diseases, such as cholelithiasis.

Acute Viral Hepatitis

The response of a pregnant woman to acute infection with the viruses that cause hepatitis varies, depending on the virus.

Hepatitis A
