Endoscopic Therapy

Endoscopic injection sclerotherapy

In endoscopic injection sclerotherapy, a substance that induces thrombosis in the vessel and inflammation of the surrounding tissue is injected into the variceal lumen (intravariceal technique) or adjacent to the varix (paravariceal technique) to obliterate the varix. The injection needle is passed through a flexible endoscope. Injections are initiated at or just above the gastroesophageal junction and proceed upward. About 1 to 3 mL of sclerosant is injected at each site; the risk for complications increases as the volume of sclerosant injected increases. Variceal obliteration is usually achieved after three to six sclerotherapy sessions. After variceal obliteration, follow-up endoscopic procedures are carried out at 3-month intervals for the first 6 months and at 12-month intervals thereafter to detect and treat recurrent varices.

The most widely used sclerosing agents are 1% to 3% polidocanol, 5% ethanolamine oleate, 1% to 2% sodium tetradecyl sulfate, and 5% sodium morrhuate. No significant differences have been shown between sclerosants, in terms of either efficacy or complications.

Complications of sclerotherapy are relatively frequent and sometimes severe enough to require treatment discontinuation (218). Minor complications such as low-grade fever, retrosternal pain, transient dysphagia, and asymptomatic pleural effusions are common, occur within the first 24 to 48 hours, and do not require treatment. Asymptomatic transient bacteremia has been reported after treatment in 30% to 50% of cases. Esophageal ulcers occur in up to 90% of patients within 24 to 48 hours of injection and heal rapidly in most cases. The ulcers that follow sclerotherapy are frequently asymptomatic but may precipitate bleeding in up to 20% of patients. Esophageal ulcers hamper further injections, delay successful variceal obliteration, and prolong the risk for bleeding that is associated with varices. Sucralfate and omeprazole have been suggested as being potentially useful in healing esophageal ulcers, but convincing proof of such an effect is not available. Esophageal stenosis may occur in 2% to 10% of patients and frequently requires dilatation. Full-thickness esophageal wall necrosis resulting in esophageal perforation is rare but almost always fatal. PVT, seizures, and sepsis have also been reported. Altogether, the procedure-related mortality is approximately 1% in elective cases (218). Morbidity and mortality are higher when the procedure is performed on an emergent basis in actively bleeding

patients.

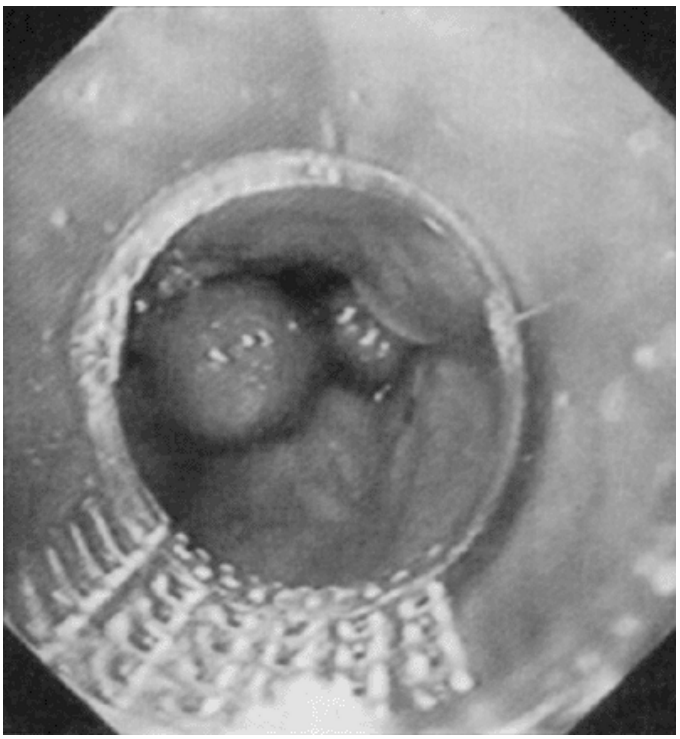
Variceal obturation

The injection of tissue adhesives such as *N*-butyl-2-cyanoacrylate (Histoacryl) and isobutyl-2-cyanoacrylate (Bucrylate) have been used for both esophageal and gastric varices (218). The adhesives polymerize within seconds of injection, forming a solid cast that obliterates the injected vessel. After 2 to 3 weeks, the overlying mucosa sloughs off, and a glue cast is extruded into the lumen of the gastrointestinal tract. The ensuing ulceration, which may be extensive and deep, usually heals rapidly. Pulmonary embolism and cerebrovascular accidents resulting from dissemination of the tissue adhesive into the systemic circulation have been reported.

Endoscopic banding ligation

In banding ligation, rubber rings are placed on the varices, which are sucked into a hollow cylinder attached to the tip of an endoscope (Fig. 15.25). The blood flow is completely interrupted; ischemic necrosis

of the mucosa and submucosa follows, and granulation takes place thereafter, with sloughing of the rubber rings and necrotic tissue. The whole process leaves shallow mucosal ulcerations that heal in 14 to 21 days (219,220). Multiple-shot devices allowing the placement of four to ten bands at a time have made the technique easier to perform than was possible with the one-shot devices previously available. Application of the bands is started at the gastroesophageal junction and progresses upward in a helical arrangement for approximately 5 to 8 cm until four to eight bands have been applied. Banding ligation sessions are repeated at 14-day intervals until the varices are obliterated, which usually requires two to four ligation sessions.



▪ **Figure 15.25** Esophageal band ligation. Variceal nodule ligated with an elastic band. (Courtesy of Drs. J. M. Bordas and J. Llach.)

As with sclerotherapy, minor complications such as transient dysphagia and chest discomfort are relatively frequent. The shallow ulcers that develop at the site of ligation bleed less frequently than the ulcers that form after sclerotherapy (219,220). Mechanical complications that follow use of the overtube (formerly required when only one-shot devices were available), which range from mucosal tears that cause bleeding to complete esophageal perforation, are less frequent now that multiple-band ligating devices are coming into widespread use (218).

Detachable miniloops

Detachable nylon miniloops have been tested as an alternative to endoscopic band ligation to treat both esophageal and gastric varices. The technique is similar to band ligation. A varix is sucked into the cylinder, and a miniloop (similar to a polypectomy snare) is passed through the working channel of the endoscope, tightened around the entrapped varix, and detached from its shaft. The procedure can be repeated several times, and multiple varices can therefore be ligated with a single insertion of the endoscope. The initial results of the procedure are promising (221), but the technique must be compared with multiple ligation devices in a much larger number of patients.

Both endoscopic injection sclerotherapy and banding ligation have been used to prevent first variceal bleeding, mostly with unconvincing results.

Endoscopic treatment

Endoscopic injection sclerotherapy has been compared with no treatment in 22 RCTs including 2,052 patients (141,218). The results of these studies are significantly heterogeneous because of marked differences in the baseline bleeding risk (the risk of untreated controls). Sclerotherapy significantly reduced the risk of bleeding in RCTs with baseline bleeding risk over 40%, had no effect in RCTs with baseline risk between 20% and 40%, and was harmful with baseline risk below 20% (Fig. 15.26). Because no criteria are available in clinical practice to accurately select patients at such a high risk as to benefit from prophylactic sclerotherapy, there is a wide consensus (118) that sclerotherapy should not be used for the prevention of first variceal bleeding.

In two of these 22 studies a three-arm design (placebo or no treatment vs. sclerotherapy vs. propranolol) was used. A total of 226 patients were included in the arms comparing sclerotherapy with propranolol. Patients were not selected for variceal size. No significant differences were found in the risk of variceal bleeding, but in one of these studies, a significant difference in favor of propranolol was found regarding bleeding from any portal hypertensive source.

The combination of sclerotherapy with propranolol has been found to be less effective than propranolol alone in one RCT (141).

The efficacy of *endoscopic banding ligation* compared with no treatment has been assessed in six RCTs (three still available only in abstract) including 675 patients (222,223). Although these studies were questionable from an ethical point of view because controls were left without treatment when it was already known that nonselective β-blockers significantly reduce the risk of bleeding in such cases, the studies showed that banding ligation significantly reduces both bleeding and risk of death. However, it is notable that the only trial assessing banding ligation in patients who could not tolerate β-blockers (224) failed to show any benefit from banding.

Banding ligation was then compared to β-blockers in 12 RCTs (222). Overall, the results show a marginal benefit from banding ligation in terms of bleeding, but not in mortality. Of note, only seven studies (including only 574 patients) have been published as full reports (225,226,227,228,229,230,231). A meta-analysis of these seven studies (222) showed a nonsignificant trend toward a bleeding risk reduction with ligation (relative risk [RR] 0.66, 95% CI 0.44 to 1.01). The only study showing a significant benefit with ligation (225) used a dosage of propranolol remarkably lower

than the median dose of previous RCTs on prophylactic therapy (70 vs. 123 mg/day), and the bleeding rate in patients taking propranolol was unusually high. In fact this study behaves as an outlier with respect to the other six showing almost equivalent effect of ligation and propranolol (Fig. 15.27). Therefore, there is no solid evidence to support the use of banding ligation as first-line prophylactic therapy, although it may be considered for patients with high-risk varices and contraindications to β-blockers (8).

Recommendations for clinical practice

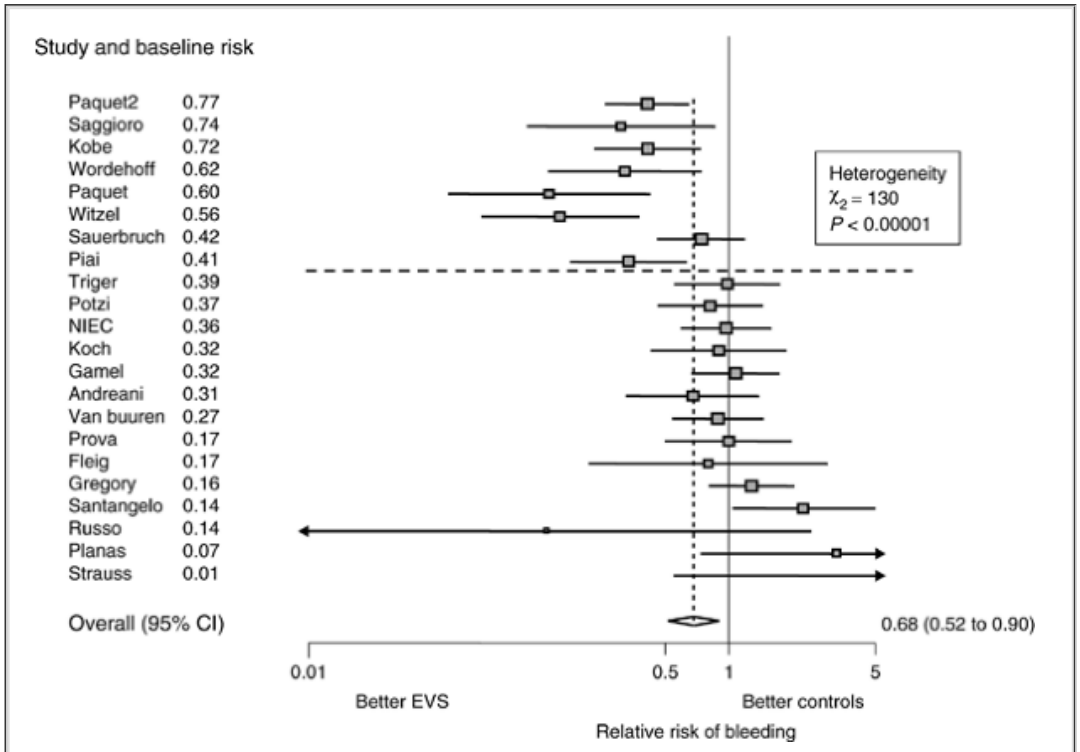
The recommendations for prophylaxis of variceal bleeding are as follows (Fig. 15.28):

- Patients without varices should be screened endoscopically for the appearance of varices every 2 to

P.460

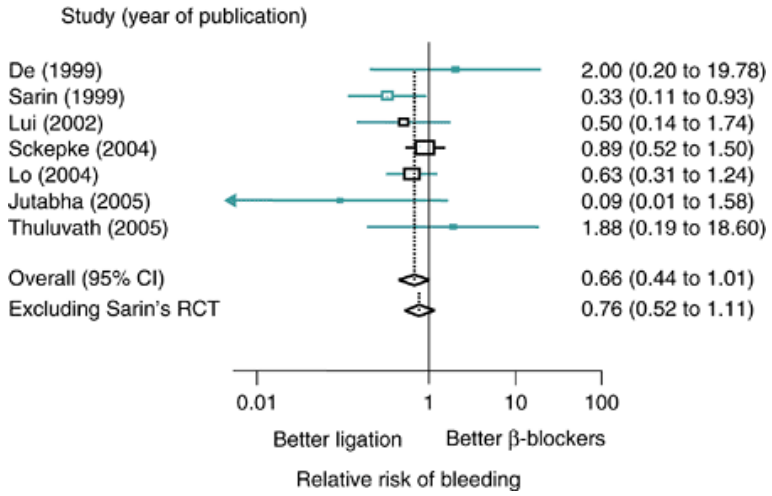
P.461

3 years. They should not receive treatment for prevention of the development of varices.

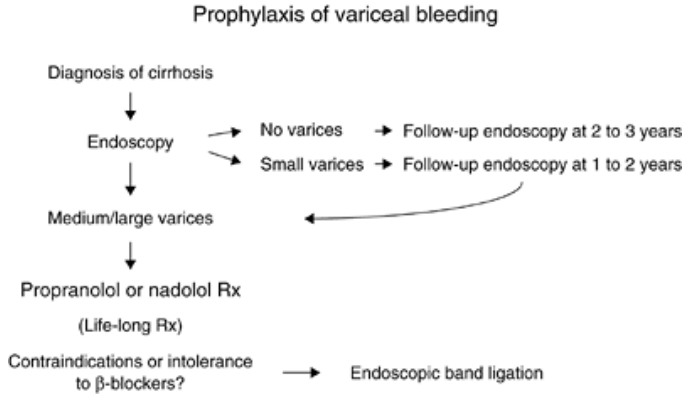


▪ **Figure 15.26** Meta-analysis of randomized clinical trials (RCTs) comparing endoscopic variceal sclerotherapy (EVS) with no treatment to prevent first bleeding in cirrhosis. RCTs are identified by the name of the first author (references in the text) and are sorted according to the baseline risk (the risk of bleeding among untreated controls). *Solid squares* indicate the relative risk for bleeding in the study groups for each RCT; the size of the solid squares varies according to the weight of each study in the meta-analysis. *Horizontal bars* denote the 95% confidence intervals (CIs) of the relative risks. The *vertical dashed line* represents the pooled relative risk of the whole set of RCTs. The *diamond* represents the 95% CI of the pooled relative risk. The *vertical solid line* represents the line of identity of effect of the two treatments (relative risk = 1). A marked and statistically significant difference was observed between RCTs, with a beneficial effect of

sclerotherapy when the baseline risk for bleeding was above 40%.



▪ **Figure 15.27** Meta-analysis of the randomized clinical trials (RCTs) comparing endoscopic band ligation of esophageal varices with β-blockers to prevent first bleeding in cirrhosis. Each RCT is identified by the name of the first author and year of publication (references in the text). *Squares* indicate the relative risk for bleeding with the two treatments for each RCT. The size of the square varies according to the weight of each study in the meta-analysis. *Horizontal bars* denote the 95% confidence intervals (CIs) of the relative risks. The *vertical dashed lines* represent the pooled relative risk of the whole set of RCTs or with exclusion of the RCT of Sarin (225). The *diamonds* represent 95% CIs of the pooled relative risk. The *vertical solid line* represents the line of identity of effect of the two treatments (relative risk = 1). The Sarin study appears to behave as an outlier, probably because of an insufficient dose of β-blocker (see text).



▪ **Figure 15.28** Recommended approach to the prophylaxis of variceal bleeding. All patients with cirrhosis should undergo diagnostic endoscopy. If medium to large varices are present, the patient should receive prophylactic

therapy with propranolol or nadolol unless these are contraindicated or the patient cannot tolerate them. In such cases endoscopic band ligation can be used. Patients with no varices or small varices should undergo follow-up endoscopy to assess the progression of the varices and determine the need for prophylactic treatment. Rx, treatment.

- Patients with small varices should be screened for enlargement of varices every 1 to 2 years. At present, there is no evidence to recommend treatment for the prevention of variceal bleeding in these patients because of their low risk of bleeding, but more studies are required to address this issue because approximately one third of the first episodes of variceal bleeding occur in patients with small varices and because drug therapy is the only applicable treatment in this situation.
- Patients with medium or large varices should be treated with a nonselective β-blocker. The dose should be titrated individually.
- Available evidence does not support the use of IMN alone or in combination with nonselective β-blockers.
- Endoscopic banding ligation appears to be an alternative to nonselective β-blockers. Patients with medium or large varices with contraindications or who are intolerant to β-blockers may be considered for banding ligation of varices. IMN alone does not appear to be a good treatment option for these patients.

Treatment of Acute Bleeding from Esophageal Varices

General management

Variceal bleeding is a medical emergency and its management should be undertaken in an intensive care setting by a team of experienced medical staff, including a clinical hepatologist, endoscopist, and surgeon. It is essential to have well-trained nurses. A specific plan of management should always be used, following a protocol adapted to the particular resources available. This is greatly facilitated by the establishment of gastrointestinal bleeding units. Early referral is warranted if there is a lack of either medical or surgical expertise in techniques to control bleeding (5).

Clinical and laboratory data to assess the severity of hemorrhage and liver disease should be included in the initial assessment because these have prognostic significance. The following should be evaluated: Hemoglobin/hematocrit, white cell count, platelet count, plasma urea and electrolytes, creatinine, prothrombin and partial thromboplastin times, baseline liver function tests, routine blood cultures, urine culture, ascitic fluid culture, chest radiograph, and electrocardiogram. Blood gases (in decompensated patients and in those with chest problems) should also be measured.

The initial therapy is aimed at correcting hypovolemic shock, preventing complications associated with gastrointestinal bleeding, and achieving hemostasis at the bleeding site. The two initial goals, which are independent of the cause of the hemorrhage, demand immediate management. Specific therapy to stop bleeding is usually given after the patient is subjected to the initial resuscitation and following diagnostic endoscopy, with the important exception of pharmacologic therapy, which can be started earlier in the course of the bleeding episode, on arrival to the hospital or even during transfer to hospital.

Replacement of blood volume

Variceal bleeding in cirrhosis is often massive; it is therefore essential to place at least one large-bore intravenous cannula to allow rapid blood transfusion if required. In addition, a central venous line should be inserted for monitoring the central venous pressure. The blood bank should be contacted on admission and four units of blood should be kept cross-matched and ready for transfusion at any time during the first 5 days (232).

Blood volume replacement should be initiated as soon as possible to avoid complications from hypovolemic shock and decreased perfusion of vital organs. It is important to emphasize that replacement of blood volume should be done conservatively and not considered solely in terms of blood transfusion. It is recommended to use plasma proteins or colloid expanders to replace the volume loss (at a sufficient rate to restore the systolic blood pressure to approximately 100 mm Hg, heart rate below 110 beats/minute, and the central venous pressure between 2 to 6 cm H_2O), while whole blood or packed red cells should be used conservatively to maintain the hemoglobin at about 8 g/dL (8). In this approach only a few units of blood may be needed. Frequent (hourly) measurements of blood pressure, heart rate, and central venous pressure during therapy are mandatory. The hematocrit/hemoglobin should be measured every 6 to 8 hours. Overtransfusion should be avoided, not only because of the risks inherent with blood transfusion but also because it may increase portal pressure, with a consequent risk of continued bleeding or rebleeding (233). Experimental studies in rats with portal hypertension have shown an increase in portal pressure beyond basal values when restoring the lost blood volume (233,234,235). Furthermore, hypovolemia and low blood pressure are powerful stimuli for the activation of vasoactive neurohumoral systems aimed at maintaining the arterial pressure within normal limits. This is achieved by a marked systemic vasoconstriction, which is especially accentuated in the splanchnic area, resulting in a reduction in portal–collateral blood flow with a concomitant fall in portal pressure. Therefore, variceal bleeding tends to stop spontaneously during hypovolemia (233) but may continue or start again with overtransfusion of any fluids. Indeed, studies in experimental models of portal hypertensive–related bleeding have shown that restoring 40% of the estimated blood loss using whole blood and polygeline (50:50) is associated with less blood loss and reduced mortality, as compared with strategies aimed at restoring all the blood volume loss. However, it is important to progressively correct anemia on the following days because persistent anemia is associated with worsening of the hyperkinetic syndrome and portal hypertension and may be a risk factor for rebleeding (236).

Prevention of complications

The main complications associated with gastrointestinal bleeding in patients with chronic liver disease are airway aspiration causing pneumonia, hepatic encephalopathy, infections by enteric organisms, hypoxemia, and renal/electrolyte imbalance, with an increase in the incidence of ascites and renal failure. These frequently lead to deterioration of liver function and may be the ultimate cause of death.

Aspiration of blood or gastric secretions is especially frequent in patients with impaired consciousness due to shock or hepatic encephalopathy. Although aspiration may occur at any time during the bleeding episode, the highest risks are during hematemesis, and during emergency endoscopy and placement of balloon tamponade tubes. Suspected or proved aspiration should be treated immediately with antibiotics; monitoring with pulse oximetry is useful. Its prevention is based on the following measures: (a) Close supervision by a well-trained nurse; (b) positioning the patient in a semireclined position, preferably the left lateral decubitus; (c) orotracheal intubation in comatose patients; and (d) aspiration of the gastric contents through an indwelling nasogastric

tube.

Nasogastric aspiration through an indwelling large bore tube is not universally used; however, it allows the enteral administration of drugs in comatose patients and is a useful method of monitoring the activity of bleeding. In addition, removal of blood from the upper gastrointestinal tract may help prevent and correct hepatic encephalopathy, which is a frequent complication of variceal hemorrhage. When present, encephalopathy is usually treated with the administration of lactulose or lactitol through nasogastric tube and cleansing enemas.

Support of vital organ function relies on the maintenance of adequate tissue perfusion and oxygenation. Aspiration of blood, prolonged shock, and multiple blood transfusions may markedly impair pulmonary gas exchange and result in significant hypoxemia and acute respiratory failure. Arterial hypoxemia due to hepatopulmonary syndrome is frequent in patients with cirrhosis who have advanced liver failure. This results from functional abnormalities such as pulmonary vasodilatation, impaired hypoxic vasoconstriction, ventilation/perfusion mismatching, and shunts. Therefore, it is essential to perform close hemodynamic monitoring, measurements of blood gases or pulse oximetry, and serial chest radiographs. Chest physiotherapy and provision of an adequate oxygen supply are integral parts of the therapy.

Renal function should be supported by adequate fluid and electrolyte replacement (saline infusions should be avoided) and should be monitored with strict attention to fluid balance. Close hemodynamic monitoring should prevent hypotension and allow rapid

correction of hypovolemic shock. It is crucial to avoid the administration of nephrotoxic drugs, especially aminoglycosides and nonsteroidal anti-inflammatory agents. Daily measurements of serum creatinine, urea, and electrolyte concentrations and the rate of urinary output are used as markers of renal perfusion. Urine output should be maintained at over 40 mL/hour; an output below 20 mL/hour indicates poor renal perfusion and impending renal failure. Massive or tense ascites should be treated with paracentesis, preferably with albumin replacement. This has been shown to improve the hemodynamic conditions and transiently decrease portal pressure and portal–collateral blood flow (237,238).

Patients with advanced cirrhosis frequently show wasting of muscle and adipose tissue. Malnutrition may contribute to an increased susceptibility to infections and impaired renal function. Suppression of oral intake during the acute bleeding episode significantly worsens the nutritional state; feeding should be resumed as soon as a 24-hour interval free of bleeding has been achieved. There are difficulties in providing a balanced nutrition in patients with cirrhosis. Enteral nutrition is always preferable because parenteral nutrition further complicates fluid balance and leads to an added risk of sepsis.

Alcoholic patients may exhibit withdrawal symptoms when admitted because of bleeding. These patients often require sedation. Close supervision of fluid and electrolyte balance is mandatory.

An area under investigation is whether the coagulation defects of cirrhosis, such as thrombopenia and factor VII deficiency, should be corrected in patients bleeding from esophageal varices. A double-blind RCT has recently shown that the administration of recombinant factor VIIa may significantly decrease the rate of failure to control variceal bleeding in the subgroup of patients with cirrhosis from Child-Pugh B and C classes (239). However the finding needs to be further confirmed before this treatment is recommended.

Prophylactic antibiotics

Up to 20% of patients with bleeding have a bacterial infection at the time of hospital

admission, and the risk of a nosocomial bacterial infection is nearly 50% in these patients compared to 5% to 7% of hospital-acquired infections in the general population (240,241). Furthermore, bacterial infections significantly increase the risk of failure to control bleeding and the hospital mortality rate for patients with cirrhosis and gastrointestinal bleeding (139,241). The most frequent bacterial infections seen in patients with cirrhosis are urinary tract infection (12% to 29%, mostly *Escherichia coli* or *Klebsiella*), spontaneous bacterial peritonitis (7% to 23%, gram-negative bacilli and aerobic gram-positive cocci), respiratory tract infection (6% to 10%), and primary bacteremia (4% to 11%). The risk of infection is higher for patients undergoing invasive procedures, such as endoscopy, which appears to be associated with bacteremia in 5% to 30% of cases (240).

A recent meta-analysis (242) including five RCTs (534 patients) has shown that antibiotic prophylaxis decreases the incidence of bacterial infections and increases the survival rate in patients admitted because of variceal bleeding. An updated meta-analysis of the eight RCTs now available (789 patients) confirms a significant beneficial effect of antibiotic prophylaxis in decreasing both mortality (RR 0.73, 95% CI 0.55 to 0.95) and the incidence of bacterial infections (RR 0.40, 95% CI 0.32 to 0.51) bacteremia, pneumonia, spontaneous bacterial peritonitis, and urinary tract infection (243).

The antibiotics assessed in these studies were fluoroquinolones, amoxicillin + clavulanic acid, ceftriaxone, imipenem + cilastin, and oral nonabsorbable antibiotics (e.g., gentamicin, vancomycin, nystatin).

Following these studies, a recent consensus conference stated that antibiotic prophylaxis should be an integral part of the therapy for acute gastrointestinal bleeding in cirrhosis and should be instituted from admission (8).

Pharmacologic treatment

The drugs assessed for acute bleeding are vasopressin and its analog terlipressin, and somatostatin and its analogs octreotide and vapreotide. Vasopressin and terlipressin have been combined with NTG in some trials.

Vasopressin

Vasopressin causes a marked splanchnic vasoconstriction with a pronounced decrease of portal blood flow and portal pressure. It also reduces portal–collateral blood flow and variceal pressure (182). However, it also causes marked systemic vasoconstriction, which may result in serious adverse events that prompt discontinuation of therapy in approximately 25% of the cases (5,182,184).

Severe arrhythmias, myocardial infarction, respiratory failure, cerebrovascular accidents, bowel necrosis, local tissue necrosis, and hyponatremia due to antidiuresis have been reported as side effects of vasopressin. Fatal complications have been rarely reported. Vasopressin has been abandoned because of these inconveniences and after the development of more effective and safer drugs.

Combination of NTG with vasopressin infusion significantly reduces the side effects, preventing one harmful event in every three treated patients, compared with

vasopressin alone (141). Moreover this combination also improves control of bleeding, although it does not significantly improve survival. The IV vasopressin infusion rate should be 0.4 U/minute. NTG should be simultaneously infused intravenously or, preferably, administered transdermically (20 mg/day) provided the systolic arterial pressure is over 100 mm Hg.

Terlipressin

Terlipressin is a long-acting vasopressin derivative with much less potential for severe side effects. Indeed, clinical studies have consistently shown less frequent and severe side effects with terlipressin than with vasopressin, even when vasopressin is combined with NTG (184). The increase in arterial pressure and the splanchnic vasoconstriction caused by terlipressin is associated with a significant improvement of renal function in patients with hepatorenal syndrome. Therefore, an additional advantage of this drug is that it may protect against the appearance of hepatorenal syndrome in patients with advanced cirrhosis and variceal bleeding (244,245,246,247).

Compared with placebo or nonactive treatment, terlipressin significantly improves the rate of control of bleeding and survival, with one death prevented in every six patients treated (248). This is the only treatment that has been shown to improve the prognosis of variceal bleeding in placebo-controlled RCTs and meta-analysis (249).

Terlipressin is used in bolus IV injections at doses of 2 mg every 4 to 6 hours for up to 48 hours. After achieving an initial control of bleeding (a 24-hour bleeding-free period), the dose can be halved and the treatment maintained for 5 days to prevent early rebleeding. The more frequent side effects are relatively mild: Abdominal cramps, diarrhea, bradycardia, and hypertension. Severe side effects (e.g., arrhythmias, angina, cerebrovascular accident, and limb ischemia) requiring discontinuation of the drug are in the order of 2% to 4% (232,248).

Terlipressin has been compared with vasopressin in five trials. Vasopressin has been combined with transdermal or sublingual NTG in two studies (141). Overall, these studies did not show significant differences between the two drugs in the control of bleeding, rebleeding, or mortality, but side effects were significantly less frequent and less severe with terlipressin. Terlipressin is as effective as somatostatin infusion and endoscopic therapy (see subsequent text). The overall efficacy of terlipressin in controlling acute variceal bleeding is 75% to 80% across trials (248).

Somatostatin

Several RCTs showed that somatostatin compared with placebo or nonactive treatment significantly improves the rate of control of bleeding. Although the results of these studies were heterogeneous, their meta-analysis showed that this heterogeneity was mainly due to one study with an unusually high rate of spontaneous bleeding cessation (83%, the highest ever reported) in the placebo-treated group (141). However, despite the beneficial effect on control of bleeding, somatostatin does not affect mortality.

Compared with vasopressin, somatostatin is equivalent for mortality and control of bleeding but is associated with less frequent and less severe side effects than vasopressin (141).

Somatostatin has been compared with terlipressin in three studies, including a total of 302 patients. The two larger studies were double-blind placebo-controlled RCTs. Overall, no differences were found for failure to control bleeding, rebleeding, and mortality. Total side effects were 21% with somatostatin versus 29% with terlipressin (NS), and major side effects requiring withdrawal of treatment or specific therapy were 4% in both treatment groups (141).

Contrary to what has been shown for vasopressin, addition of NTG to somatostatin does not improve therapeutic efficacy and induces more adverse effects.

Somatostatin is used as a continuous IV infusion of 250 μg/hour following an initial bolus of 250 μg. A recent study suggested that in high-risk patients (with active bleeding at the time of diagnostic endoscopy) it is wise to increase the infusion dose to 500 μg/hour and to provide repeat 250 μg boluses during the initial hours of therapy (187). Treatment may be maintained for up to 5 days. Side effects of somatostatin are usually mild, most frequently bradycardia, hyperglycemia, diarrhea, and abdominal cramps.

Octreotide

Octreotide is a synthetic somatostatin analog with longer half-life. Like somatostatin, bolus injections of octreotide cause a transient increase in mean arterial pressure and systemic vascular resistance, suggesting a systemic effect (250). However, at the doses used empirically to treat variceal hemorrhage, or higher doses, octreotide infusions have not been found to cause a sustained decrease in portal pressure or collateral blood flow. A rapid desensitization of the hemodynamic effects of octreotide has been reported after its intravenous administration (250). Therefore, the hemodynamic effects of octreotide, as well as its best dose and route of administration, remain unclear. In many occasions, its use has been empirical, assuming that it should be similar to somatostatin, which is probably not exact.

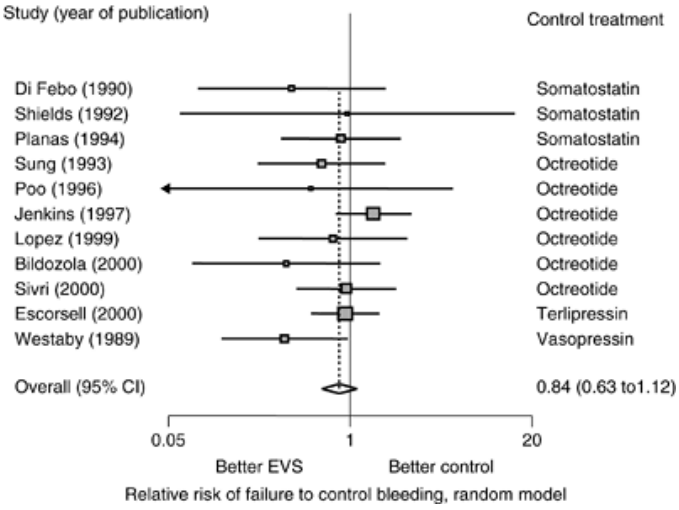
The efficacy of octreotide as a single therapy for variceal bleeding is controversial. Among four RCTs comparing octreotide with placebo, no benefit from

octreotide was found in the only one using octreotide or placebo as initial treatment, whereas in the three using sclerotherapy or ligation before or at the same time of octreotide administration, a significant benefit was found in two studies and nearly significant in the third (141). These results suggest that octreotide may improve the results of endoscopic therapy but has no or little effect if used alone. No effects of octreotide on rebleeding or death were found (141). When compared with other vasoactive drugs, octreotide was better than vasopressin for control of bleeding in two RCTs and similar to terlipressin in other two, again suggesting a clinical value for the use of octreotide. However, the studies were not sized to test for equivalence. Side effects were less frequent and severe with octreotide than with either vasopressin or terlipressin, but the difference was significant only for vasopressin (141).

Octreotide has been used as continuous IV infusions, at empirical dosages of 25 to 50 µg/hour, in some instances after initial IV boluses of 50 µg. Treatment duration was from 1 to 5 days.

Vapreotide

Vapreotide is another somatostatin analog that was shown to improve control of variceal bleeding and transfusion requirements in a double-blind RCT (251). Further studies are required before clinical use of vapreotide can be recommended.



▪ **Figure 15.29** Meta-analysis of the randomized clinical trials (RCTs) comparing emergency endoscopic variceal sclerotherapy (EVS) with vasoactive drugs to

control acute variceal bleeding in cirrhosis. Each RCT is identified by the name of the first author and year of publication; control treatments are listed on the right-hand side of the grid. *Solid squares* indicate the relative risk for failure to control bleeding with the two treatments for each RCT; the size of the *solid squares* varies according to the weight of each study in the meta-analysis. *Horizontal bars* denote the 95% confidence intervals (CIs) of the pooled relative risks. The *vertical dashed line* represents the pooled relative risk of the whole set of RCTs. The *diamond* represents the 95% CI of the pooled relative risk. The *vertical solid line* represents the line of identity of effect of the two treatments (relative risk = 1). The meta-analysis shows that vasoactive drugs are equivalent to emergency sclerotherapy for the control of acute variceal bleeding.

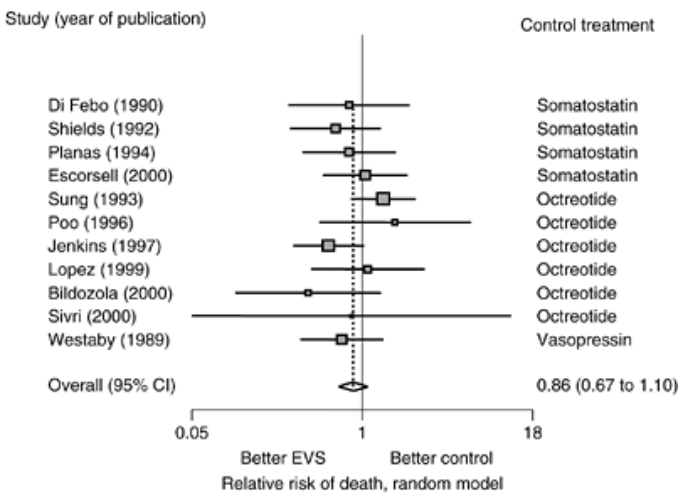
Endoscopic treatment

Emergency endoscopic injection sclerotherapy of esophageal varices is widely used as first-choice treatment because it stops bleeding in about 80% to 90% of patients. Moreover, it allows the start of specific treatment for the prevention of long-term rebleeding at the time of diagnostic endoscopy. However, it requires a skilled endoscopist and is associated with serious complications in 10% to 20% of patients, with an overall mortality of 2% (141).

Emergency sclerotherapy significantly improves control of bleeding and survival when compared with sham therapy (249). However when compared with vasoactive drugs, it is superior only to vasopressin for controlling bleeding, but is similar to terlipressin, somatostatin, or octreotide either for control of bleeding/early rebleeding or for mortality (Figs. 15.29 and 15.30) (252). The equivalence between sclerotherapy and pharmacologic therapy is confirmed also by pooling RCTs irrespective of the vasoactive control therapy (252).

Emergency banding ligation of esophageal varices is probably equivalent to emergency sclerotherapy (218). There is only one RCT specifically designed to compare the two techniques for controlling acute variceal bleeding (253), while eight RCTs for long-term prevention of recurrent variceal bleeding allow for the comparison of the two techniques used

in the emergency situation in the subgroups of patients included with active variceal bleeding (218). The meta-analysis of all these studies, including 288 patients overall, failed to show any significant difference between the two endoscopic techniques either in control of bleeding or in mortality (218). However, it has been reported that emergency banding may be more difficult than sclerotherapy because the field of vision is reduced by approximately 30% with the banding device attached, and blood in the esophagus may further reduce vision and hamper the effective placement of the rubber bands. Sclerotherapy does not have this limitation but carries a greater potential for complications than does banding ligation using multiband devices. The choice of one or another procedure may depend on the expertise with each of these techniques.



▪ **Figure 15.30** Meta-analysis of the randomized clinical trials (RCTs) comparing emergency endoscopic variceal sclerotherapy (EVS) with vasoactive drugs for mortality in patients with acute variceal bleeding in cirrhosis. Each RCT is identified by the name of the first author and year of publication; control treatments are listed on the right-hand side of the grid. *Solid squares* indicate the relative risk for death with the two treatments for each RCT; the size of the *solid squares* varies according to the weight of each study in the meta-analysis. *Horizontal bars* denote the 95% confidence intervals (CIs) of the relative risks. The *vertical dashed line* represents the pooled relative risk of the whole set of RCTs. The *diamond* represents the 95% CI of the pooled relative risk. The *vertical solid line* represents the line of identity of effect of the two treatments (relative risk = 1). The meta-analysis shows that vasoactive drugs are equivalent to emergency sclerotherapy for mortality in patients with acute variceal bleeding. IMN, isosorbide-5-mononitrate.

Endoscopic obturation of esophageal varices by means of the injection of tissue adhesives does not offer advantages compared with sclerotherapy or band ligation (254), and in one study it was associated with a higher incidence of complications than ligation (218). However, the combination of obturation and sclerotherapy may be superior to sclerotherapy alone, suggesting that obturation may be an option in patients in whom bleeding is not controlled by sclerotherapy (218). This treatment has found its best use in patients bleeding from gastric varices (see subsequent text).

Combined endoscopic and pharmacologic therapy

The combination of endoscopic therapy (either sclerotherapy or banding) with pharmacologic therapy significantly improves initial control of bleeding and reduces the 5-day failure rate in terms of control of bleeding or rebleeding (255,256) when compared to endoscopic therapy alone. However, the combination therapy does not improve 5- or 42-day mortality (255,256), while it significantly increases adverse effects (252).

Notably, only two of the RCTs assessing the efficacy of combined endoscopic and pharmacologic therapy used banding ligation, which is nowadays the standard of endoscopic therapy for esophageal varices for clinical practice. Moreover, the advantage of a better initial and 5-day control of bleeding has not translated into survival improvement. Therefore, the advantages of the combination of pharmacologic and endoscopic therapy should be further explored in large RCTs.

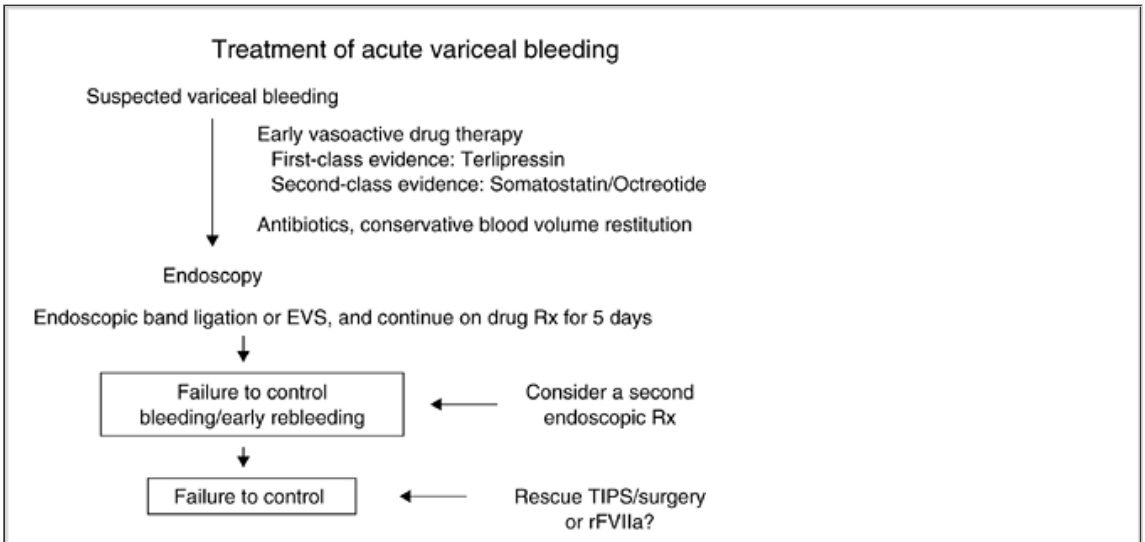
Balloon tamponade

Balloon tamponade stops bleeding by direct compression of the bleeding site at the varices. Control of bleeding is successful in as much as 80% to 90%, but up to 50% of patients will rebleed when the balloon(s) is(are)

deflated. Its efficacy has been confirmed by several RCTs showing that it is more effective than vasopressin and as effective as terlipressin (Glypressin), somatostatin, octreotide, and sclerotherapy (249). Complications are frequent and may be lethal in 6% to 20% of cases. These include aspiration pneumonia, large esophageal ulcers, esophageal rupture, and airways obstruction. Because of the frequency and severity of complications and the high rate of rebleeding, balloon tamponade should be used only by skilled and experienced staff in intensive care units only for temporarily controlling variceal bleeding that is uncontrollable by other treatments, while waiting for definitive therapy.

Transjugular intrahepatic portosystemic shunt

TIPS, when used for acute variceal hemorrhage, stops bleeding in most patients. Some centers use coil embolization of the vessels feeding the varices. However, rebleeding is far more common than after elective TIPS (257). Selection of patients with uncontrolled bleeding, many of them with advanced liver failure, probably accounts for the high 6-week mortality, ranging from 27% to 55% (257). An RCT has recently shown that the best candidates for emergency TIPS for variceal bleeding are those with HVPG ≥20 mm Hg in whom TIPS reduced the 6-week mortality from 38% to 17%, while the corresponding figure was 5% in patients with HVPG less than 20 mm Hg not treated by TIPS (258). Although the applicability of the results of this trial to clinical practice is questionable because it requires HVPG measurement early during the episode of variceal bleeding, it indicates that high-risk patients will benefit from TIPS if they may be treated soon, before clinical conditions deteriorate. Whether other clinical risk indicators may be used in clinical practice instead of HVPG measurement should be assessed in future RCTs. Until such studies are available, given the very high proportion of patients in whom variceal bleeding is controlled by medical and/or endoscopic therapy, TIPS is confined to the rare patients (approximately 10% of cases) with uncontrollable variceal bleeding.



▪ **Figure 15.31** Recommended approach to the treatment of acute variceal bleeding. As soon as possible, patients in whom variceal bleeding is suspected should receive vasoactive drug therapy, even before they arrive at the hospital. At

endoscopy, band ligation or endoscopic variceal sclerotherapy (EVS) should be performed, and drug therapy should be maintained for 5 days to prevent early rebleeding. If bleeding is not arrested or recurs, a second attempt at endoscopic therapy should be considered. If bleeding continues, a rescue transjugular intrahepatic portosystemic shunt (TIPS) or surgical decompression may be indicated. Ancillary therapy with recombinant activated factor VII (rF-VIIa) may be considered in patients with liver failure too advanced to be treated with TIPS. Rx, treatment.

Surgery

Following the introduction of TIPS in clinical practice, shunt surgery and devascularization procedures have almost been abandoned in many centers. However, it is possible that the rare Child-Pugh A or B patient with uncontrollable variceal bleeding may be better managed surgically (using interposition Gore-Tex mesocaval graft shunt) than with TIPS, provided the center still has well-trained surgeons for shunt surgery, which is not frequent at present (see also Chapter 17).

Recommendations for clinical practice

The recommendations for treatment of variceal rebleeding are as follows (Fig. 15.31):

- Blood volume restitution should be done cautiously to maintain hemodynamic stability and hemoglobin at approximately 8 g/dL.

- Antibiotic prophylaxis against gram-negative bacilli and gram-positive cocci should be instituted from admission.
- Pharmacologic treatment should be started immediately when variceal bleeding is suspected, even before endoscopic confirmation of diagnosis.
- Terlipressin (in countries where it is available) is the first choice of treatment because it may reduce mortality. Somatostatin may be considered as an alternative to terlipressin. An increased dose and the administration of extra bolus injections should be considered in patients who actively bleed during endoscopy.
- Octreotide improves the efficacy of emergency endoscopic therapy in controlling variceal bleeding. At present, there is no evidence supporting its use as single therapy.
- If vasopressin is used, it should be combined with nitroglycerin.
- Endoscopic therapy (preferably by banding ligation) is recommended as soon as an experienced endoscopist is available. Pharmacologic therapy should be maintained even after endoscopic therapy for 2 to 5 days.
- TIPS should be used in case of failures of medical and endoscopic therapy.
- Shunt surgery using interposition mesocaval graft shunts or traditional portacaval shunts may be an alternative to TIPS in Child-Pugh A patients (preferably in nontransplantation candidates).

Prevention of Recurrent Bleeding from Esophageal Varices

Patients surviving a first episode of variceal bleeding have a high risk of recurrent bleeding of over 60% within 1 year of the first bleeding. Because of this, all patients surviving a variceal bleeding should receive active treatment for the prevention of rebleeding (8).

Pharmacologic treatment

Pharmacologic treatment for the prevention of rebleeding is based on the use of nonselective β-blockers, which were introduced in the 1980s (179). Recently, their combination with IMN has been proposed (63,190).

Nonselective β-blockers

The hemodynamic basis for the use of nonselective β-blockers in the prevention of rebleeding, as well as their contraindications and side effects, is the same for the prevention of first bleeding and have been discussed earlier in this chapter.

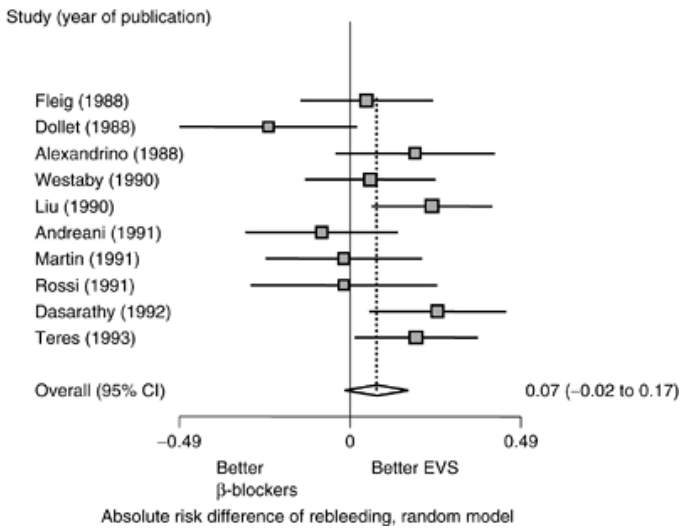
The efficacy of nonselective β-blockers in the prevention of variceal rebleeding has been proved by many RCTs, and these drugs are now widely accepted as the first-line pharmacologic therapy in this setting (8). Twelve RCTs including a total of 809 patients compared nonselective β-blockers with placebo or nonactive treatments. Several meta-analyses of these studies consistently found a marked benefit from β-blockers. The rebleeding rate is reduced from 63% in controls to 42% in treated patients, with an absolute risk reduction (ARD) of -21% (95% CI -30% to -13%) (141). This means that the number of patients needed to treat (NNT) to prevent one rebleeding episode is five. Mortality was significantly reduced, from 27% to 20% (ARD = -7%; 95% CI -12% to -2%; NNT = 14) (141,259). Mortality from bleeding was also significantly reduced by β-blockers (259).

β-Blockers were compared with endoscopic variceal sclerotherapy in ten RCTs including 862 patients. No significant differences were found between the two treatments either for rebleeding (ARD = 7%; 95% CI -2% to 17%) (Fig. 15.32) or for mortality (ARD = 2%; 95% CI -5% to 8%) (Fig. 15.33). Side effects were significantly less frequent and less severe with β-blockers (ARD = -22%; 95% CI -38% to -6%). The number of patients needed to be treated with β-blockers to prevent a harmful event (NNH), compared with sclerotherapy, is four (141).

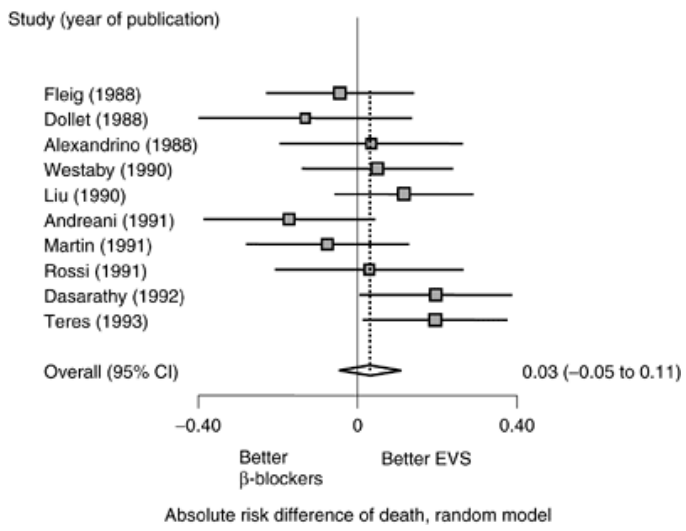
Combined pharmacologic treatment

Nonselective β-blockers plus organic nitrates—the combined administration of propranolol or nadolol plus IMN was introduced after demonstrating that IMN enhanced the portal pressure–reducing effect of nonselective β-blockers (190). There is insufficient information on whether this translates into a clinical advantage because there are only two studies of IMN combined with propranolol (260) or nadolol (261) versus the corresponding β-blocker alone in the prevention of rebleeding. One of the studies showed significant benefit, but not the other (which is still available only in abstract form) (261). However, the combination of IMN with propranolol or nadolol has been found to be superior to either endoscopic sclerotherapy in one study (262) or band ligation in three studies (263,264,265). When all the four studies are pooled (Fig. 15.34), a nonsignificant trend toward a bleeding risk reduction with the combination pharmacologic therapy is found. The results of the four studies are heterogeneous because one trial (265) found an opposite result (benefit with ligation). It is, however, notable that this trial included a significantly higher proportion of patients with large varices in the drug arm than in the endoscopic arm and that the dose of nitrate used was much lower than that in the other studies. These factors may, at least in part explain the heterogeneity. In fact, by removing this study from the meta-analysis, heterogeneity disappears and a significant bleeding risk reduction with drug therapy is

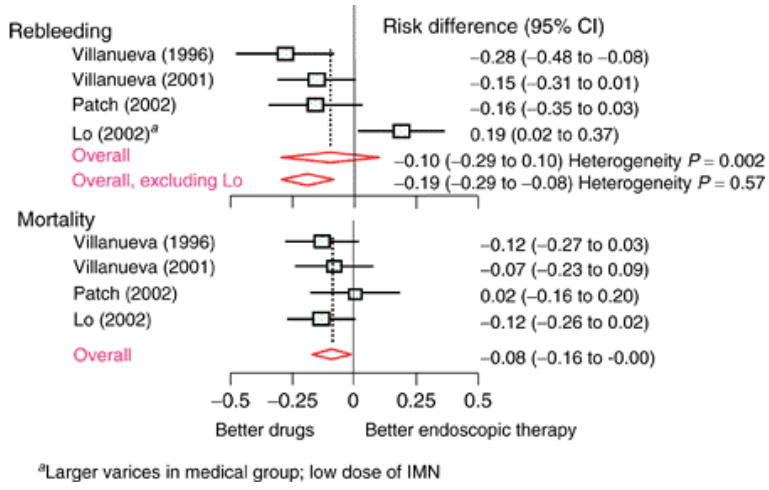
found (ARD = -0.19; 95% CI -0.29 to -0.08), with one bleeding episode prevented out of every five patients treated with the pharmacologic combination. Mortality was nonsignificantly reduced with the pharmacologic combination in three studies (262,264,265) and was the same in one (263). Altogether, mortality was almost significantly less with the combination of β-blocker plus IMN (ARD = -0.08; 95% CI -0.16 to 0.00) (Fig. 15.34). Compared with TIPS, the combination of IMN and propranolol is less effective for the prevention of rebleeding but is associated with significantly less encephalopathy, similar mortality, and much lower cost (266).



▪ **Figure 15.32** Meta-analysis of the randomized clinical trials (RCTs) comparing nonselective β-blockers with endoscopic variceal sclerotherapy (EVS) to prevent recurrent variceal bleeding in patients with cirrhosis. Each RCT is identified by the name of the first author and year of publication. *Solid squares* indicate the absolute difference in risk for recurrent bleeding with the two treatments for each RCT; the size of the *solid squares* varies according to the weight of each study in the meta-analysis. *Horizontal bars* denote the 95% confidence intervals (CIs) of the differences in risk. The *vertical dashed line* represents the pooled absolute difference in risk of the whole set of RCTs. The *diamond* represents the 95% CI of the pooled absolute difference in risk. The *vertical solid line* represents the line of identity of the effect of the two treatments (absolute difference in risk = 0). The meta-analysis shows that β-blockers and sclerotherapy are equivalent for the prevention of recurrent bleeding in cirrhosis.



▪ **Figure 15.33** Meta-analysis of the randomized clinical trials (RCTs) comparing nonselective β-blockers with endoscopic variceal sclerotherapy (EVS) for reducing mortality in patients with cirrhosis who survive an episode of variceal bleeding. Each RCT is identified by the name of the first author and year of publication. *Solid squares* indicate the absolute difference in risk for death with the two treatments for each RCT; the size of the *solid squares* varies according to the weight of each study in the meta-analysis. *Horizontal bars* denote the 95% confidence intervals (CIs) of the differences in risk. The *vertical dashed line* represents the pooled absolute difference in risk of the whole set of RCTs. The *diamond* represents the 95% CI of the pooled absolute difference in risk. The *vertical solid line* represents the line of identity of effect of the two treatments (absolute risk difference = 0). The meta-analysis shows that β-blockers and sclerotherapy are equivalent for mortality after the first episode of variceal bleeding in cirrhosis.



▪ **Figure 15.34** Meta-analysis of the randomized clinical trials (RCTs) comparing β-blockers + isosorbide-5-mononitrate (IMN) with endoscopic band ligation of esophageal varices to prevent recurrent bleeding from esophageal varices in cirrhosis. Each RCT is identified by the name of the first author and year of

publication (references in the text). *Squares* indicate the relative risk for bleeding with the two treatments for each RCT. The size of the *square* varies according to the weight of each study in the meta-analysis. *Horizontal bars* denote the 95% confidence intervals (CIs) of the relative risks. The *vertical dashed lines* represent the pooled relative risk of the whole set of RCTs or with exclusion of the RCT of Lo (265). The *diamonds* represent 95% CIs of the pooled relative risk. The *vertical solid line* represents the line of identity of effect of the two treatments (relative risk = 1). The study of Lo appears to behave as an outlier, probably because of a different distribution of patients with large varices between the two treatment groups and insufficient dose of IMN (see text). *Upper panel*, absolute risk difference for rebleeding; *lower panel*, absolute risk difference for mortality.

Treatment dosage and schedules for propranolol, nadolol, and IMN are the same as those for the prevention of first bleeding.

Monitoring pharmacologic treatment response

Eight studies, either RCTs or prospective consecutive series (143,144,216,262,263,264,267,268), have shown that the pharmacologic (or spontaneous) reduction of HVPG to less than 12 mm Hg or by as much as or more than 20% of the baseline value virtually abolishes the risk of rebleeding. Seven of these studies showed a reduction in bleeding risk in patients achieving at least one of the two hemodynamic targets, and the reduction was significant in six. In only one study was no benefit found from HVPG reduction. When the results of these eight studies are combined in a meta-analysis, the odds ratio for rebleeding in patients achieving one of these hemodynamic targets compared to those not reaching any of them is 0.20 (95% CI 0.08 to 0.47). Therefore, the patients reaching one (or both) of these targets are considered hemodynamic responders to pharmacologic therapy. However, because it is still unclear whether patients with an insufficient hemodynamic response to pharmacologic therapy would benefit from alternative treatments, hemodynamic monitoring of pharmacologic therapy is presently recommended only in the setting of clinical research (8).

Endoscopic treatment

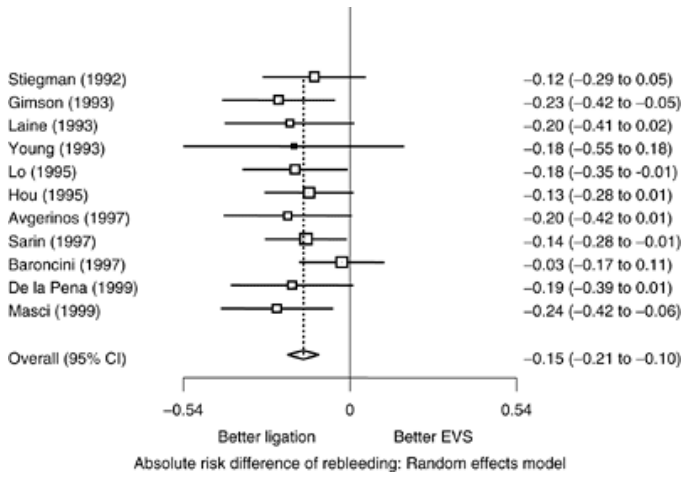
Endoscopic injection sclerotherapy of esophageal varices significantly reduces both the rebleeding and death risk (218), preventing one bleeding episode out of every seven treated patients and one death out of every ten. It takes four to six endoscopic sessions to eradicate varices, but recurrence of varices occurs in nearly 40% of patients within 1 year of eradication. This requires further endoscopic sessions to maintain eradication. It has been estimated that endoscopic sclerotherapy for the prevention of rebleeding may require one endoscopy per month per patient for the first 2 years of treatment. The most serious side effects of therapy are dysphagia, esophageal stenosis, and bleeding from esophageal ulcers, which may account for as much as 14% of all the rebleeding episodes. As commented in the preceding text, sclerotherapy has no advantage over drug therapy and causes more frequent and severe side effects.

Endoscopic banding ligation has been proved superior to sclerotherapy in 20 RCTs (1,634 patients), 11 published as full reports and 9 in abstract form (269) (Fig. 15.35) (270). The meta-analysis of the 11 fully published RCTs shows that the absolute bleeding risk difference is -15% (95% CI -21% to -10%). Complications are significantly less frequent and severe with banding ligation (218). Therefore, banding ligation should be preferred to sclerotherapy (8). Surprisingly, despite decreasing

rebleeding rates, endoscopic ligation does not significantly improve survival compared with sclerotherapy (pooled absolute death risk difference for the 11 fully published RCTs is -2%; 95% CI -7% to +3%), and there is evidence that it is associated with higher recurrence of varices (218).

Combined endoscopic treatment

Banding ligation combined with sclerotherapy—sclerotherapy has been added (either simultaneously or after the reduction of variceal size to small) to endoscopic band ligation and compared to band ligation alone in eight RCTs, yielding contrasting results (218). The meta-analysis of these studies does not show any benefit either for rebleeding (ARD = -0.06; 95% CI -0.17 to 0.05) or for mortality, and importantly, it shows a trend toward an increasing complication rate with combination endoscopic therapy.



▪ **Figure 15.35** Meta-analysis of the randomized clinical trials (RCTs) published as full reports and comparing endoscopic band ligation of esophageal varices with endoscopic variceal sclerotherapy (EVS) for the prevention of recurrent variceal bleeding in patients with cirrhosis. Each RCT is identified by the name of the first author and year of publication (references in the text). *Squares* indicate the absolute difference in risk for recurrent bleeding, with two treatments for each RCT. The size of the *square* varies according to the weight of each study in the meta-analysis. *Horizontal bars* denote the 95% confidence intervals (CIs) of the relative risks. The *vertical dashed line* represents the pooled absolute difference in risk of the whole set of RCTs. The *diamonds* represent 95% CIs of the pooled absolute difference in risk. The *vertical solid line* represents the line of identity of effect of the two treatments (absolute difference in risk = 0). The meta-analysis shows that endoscopic banding ligation of varices significantly reduces the risk for recurrent variceal bleeding.

Combined endoscopic and pharmacologic treatment

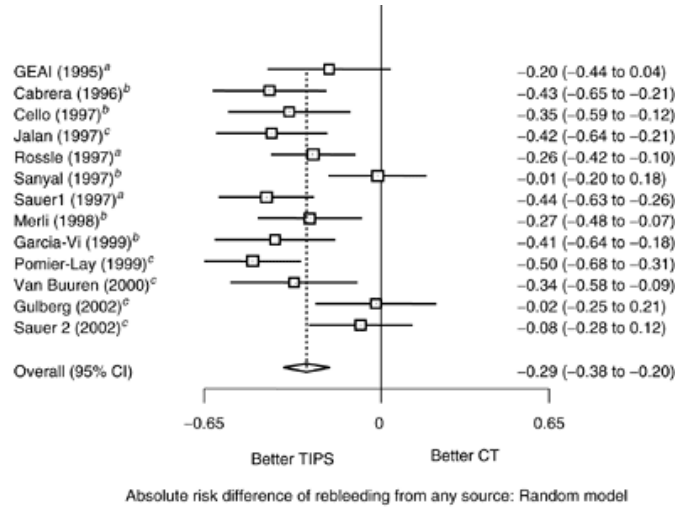
The combination of injection sclerotherapy and β-blockers has been compared with either sclerotherapy or β-blockers alone. The meta-analysis of the ten RCTs comparing combination therapy with sclerotherapy alone showed a significant reduction of the rebleeding risk (pooled odds ratio 0.66, 95% CI 0.46 to 0.93) with combination therapy, but no differences for mortality (pooled odds ratio 0.83, 95% CI 0.52 to 1.33) (249). Also, when compared with β-blockers alone, combination therapy significantly reduced the rebleeding risk without advantage in survival (141).

Two RCTs have shown that the combination of banding ligation plus β-blockers is superior to banding ligation alone in terms of recurrence of varices and recurrence of bleeding (271,272). Therefore, the combination of endoscopic therapy with a nonselective β-blocker is particularly recommended in patients who bleed under either treatment alone. In these patients, the substitution of the failing treatment with the other should not be preferred to their combination.

Transjugular intrahepatic portosystemic shunt

The efficacy of TIPS in the prevention of recurrent bleeding from esophageal varices is not much

different from that of shunt surgery, especially since the introduction of polytetrafluoroethylene (PTFE)-covered stents. It dramatically diminishes the risk of rebleeding (Fig. 15.36), but does not improve mortality and significantly increases the incidence of portosystemic encephalopathy (Fig. 15.37). TIPS has been compared with sclerotherapy in nine RCTs and with banding ligation in four RCTs (273). The 13 trials almost consistently showed that TIPS is superior to either endoscopic therapy for the prevention of rebleeding. When the results of these studies are pooled, the absolute rebleeding risk difference is -29% (95% CI -38% to -20%), indicating that one rebleeding would be prevented in every three patients treated by TIPS instead of endoscopic therapy. Not surprisingly, this impressive efficacy in preventing recurrent bleeding is accompanied by a marked increase in the risk of encephalopathy, with one extra episode of encephalopathy out of every seven patients treated by TIPS (ARD = 14%; 95% CI, 7% to 20%). Overall mortality and mortality from bleeding are similar with TIPS and endoscopic therapy.

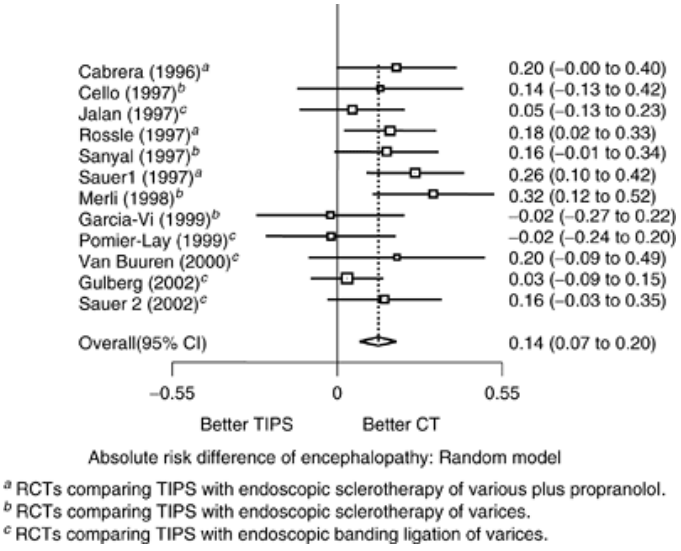


▪ **Figure 15.36** Meta-analysis of the randomized clinical trials (RCTs) of transjugular intrahepatic portosystemic shunt (TIPS) compared with endoscopic control therapy (CT) for the prevention of recurrent variceal bleeding in patients with cirrhosis, published as full report. Each RCT is identified by the name of the first author and year of publication. *Solid squares* indicate the absolute risk difference of recurrent bleeding with the two treatments for each RCT; the size of the *solid squares* varies according to the weight of each study in the meta-analysis. *Horizontal bars* denote the 95% confidence intervals (CI) of risk differences. The *vertical dashed line* represents the pooled absolute risk difference of the whole set of RCTs. The *diamond* represents the 95% CIs of the pooled

absolute risk difference. The *vertical solid line* represents the line of identity of effect of the two treatments (absolute risk difference = 0). The meta-analysis shows that after a variceal bleeding episode TIPS significantly reduces the risk of recurrent bleeding compared with endoscopic therapy.

TIPS has been compared with surgical shunts in two RCTs (274,275). In the first it was compared with 8-mm portacaval H-graft shunt (274). A significantly lower rebleeding rate was found with the surgical shunt. Significantly more patients required liver transplantation in the TIPS group than in the surgical shunt group. There was no difference in mortality. The composite endpoint of "failures," which included rebleeding, shunt thrombosis, deaths, and need for transplant, was significantly higher for TIPS.

In the second trial, TIPS was compared with the DSRS in Child-Pugh class A and B patients (275). The rebleeding rate was 5.5% in the DSRS group and 9% in the TIPS group (P = 0.27). The reintervention rate was significantly higher (P = 0.001) in the TIPS group (82%) than in the DSRS group (11%). At least one episode of encephalopathy was observed in 50% of patients in each group, and cumulative two 2-year survival was over 80% and 5-year survival was over 60% in both groups. Seven patients in each group underwent transplantation.



▪ **Figure 15.37** Meta-analysis of the randomized clinical trials (RCTs) of transjugular intrahepatic portosystemic shunt (TIPS) compared with endoscopic control therapy (CT) for the prevention of recurrent variceal bleeding in patients with cirrhosis. The risk of developing portosystemic encephalopathy is evaluated. Each RCT is identified by the name of the first author and year of publication. *Solid squares* indicate the absolute risk difference of encephalopathy for each RCT; the size of the *solid squares* varies according to the weight of each study in the meta-analysis. *Horizontal bars* denote the 95% confidence intervals (CI) of risk differences. The *vertical dashed line* represents the pooled absolute risk difference of the whole set of RCTs. The *diamond* represents the 95% CIs of the pooled absolute risk difference. The *vertical solid line* represents the line of identity of effect of the two treatments (absolute risk difference = 0). The meta-analysis shows that TIPS significantly increases the risk of encephalopathy compared with

endoscopic therapy.

These two RCTs (274,275) indicate that although variceal rebleeding may be lower with the surgical shunt, in low-risk patients (Child-Pugh class A and B) surgical shunt or TIPS do not significantly differ in the rate or severity of encephalopathy, progression of liver disease, and long-term survival. TIPS needs significantly more surveillance and intervention to maintain patency and achieve these good long-term results.

A major drawback of TIPS is the high rate of occlusion or dysfunction at 2 years, in the order of 60% to 80%. However, one recent multicenter randomized trial (201) and two studies including consecutive patients with Budd-Chiari syndrome (276) or cirrhosis (277) reported much lower obstruction and reintervention rates with PTFE-covered stents and lower rates of recurrent bleeding or ascites, without increased incidence of encephalopathy (201). These results suggest that the small disadvantage of TIPS versus surgical shunt would be overcome by the use of PTFE-covered stents and that uncovered stents will be probably abandoned in the next future.

Recommendations for clinical practice

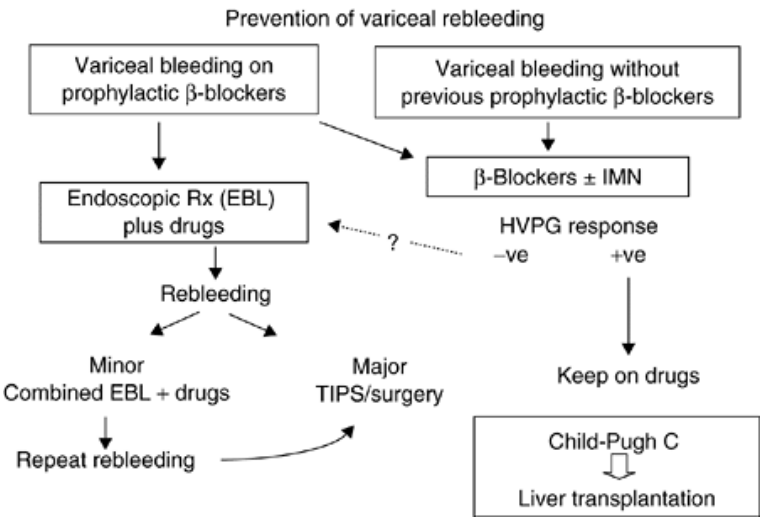
The recommendations for prevention of variceal rebleeding are as follows (Fig. 15.38):

- Patients surviving a bleeding episode should be treated with nonselective β-blockers if they were previously untreated. Those who are intolerant to or have contraindications to β-blockers should be treated with endoscopic therapy. Endoscopic band ligation of esophageal varices is the first choice of endoscopic procedure.
- The combination of β-blockers and endoscopic band ligation is advisable in patients who bleed with β-blockers.
- Whenever possible, the hemodynamic effect of pharmacologic therapy should be monitored. If a reduction of HVPG greater than 20% or below 12 mm Hg is not achieved, IMN or endoscopic therapy may be added.
- In case medical therapy fails, the patients should receive TIPS or derivative surgery. TIPS or surgical shunts (DSRS or 8-mm H-graft shunt) are effective for Child-Pugh class A/B cirrhosis. In nonsurgical candidates TIPS is the only option. PTFE-covered stents improves the results of TIPS.

Treatment of Gastric Varices

There are no specific measures for the prevention of first bleeding from gastric varices. It is conceivable

that the results of pharmacologic therapy are similar as those achieved in the prevention of first bleeding from esophageal varices. Therefore, nonselective β-blockers should be given to patients with large gastric varices to prevent the first bleeding episode.



▪ **Figure 15.38** Schematic representation of the recommended treatment approach to prevent variceal rebleeding. Patients who experience the index bleeding while on prophylactic β-blockers are best treated with a combination of endoscopic band ligation (EBL) and continued drug therapy. Alternatively, as in patients who have not previously taken prophylactic β-blockers, rebleeding can be prevented with pharmacologic therapy alone (β-blockers with or without isosorbide-5-mononitrate [IMN]). In this case, the change in the hepatic vein pressure gradient (HVPG) should be assessed. If it is adequate (reduction in the HVPG by at least 20% of the baseline values or to below 12 mm Hg), continued drug therapy is the best treatment option. Patients failing to show such a response are at higher risk for rebleeding and may benefit from the addition of EBL. Another episode of rebleeding calls for a shift of therapy to TIPS or surgical decompression. All Child-Pugh class C patients should be considered for liver transplantation, irrespective of their response to therapy. Rx, treatment.

The optimal treatment of acute gastric variceal bleeding is not well defined because of the relatively low incidence of this condition. The usual initial treatment is a vasoactive drug(s). Balloon tamponade, with the Linton-Nachlas tube, has been used with limited success (199,278). The tissue adhesive isobutyl-2-cyanoacrylate (Bucrylate), mixed with lipiodol has been found to be efficacious and superior to ethanolamine in nonrandomized studies, achieving hemostasis in 90% of patients (279). In a recent RCT, endoscopic obturation using cyanoacrylate proved more effective and safer than band ligation in the management of bleeding gastric varices (280). However, cerebral embolism has been reported with the tissue adhesives, and interest is therefore focused on thrombin, which provides good hemostasis. Another randomized trial comparing *N*-butyl-2-cyanoacrylate with sclerotherapy in 37 patients had a subset of 17 patients with actively bleeding gastric varices (14). Nonsignificant trends in favor of tissue adhesive were also seen in this small group, and variceal obliteration was significantly more common in the overall group (100% vs. 44%).

Because the rebleeding rate after endoscopic treatment is high, it is recommended that an early decision should be made for TIPS or surgery in patients rebleeding from gastric varices. Salvage TIPS is very effective, with more than 90% success rate for initial hemostasis and an early rebleeding rate below 20%, often from nonvariceal sources, for example, sclerosis ulcers (281).

No specific measures have been studied for the prevention of recurrent bleeding. In clinical practice, nonselective β-blockers are used as first-line therapy. TIPS, shunt

surgery, or variceal obliteration are recommended in failures of pharmacologic treatment (282).

Treatment of Portal Hypertensive Gastropathy and Gastric Antral Vascular Ectasia

There is no indication supporting the primary prophylaxis of bleeding from PHG.

Acute bleeding from PHG should first be treated with the same vasoactive drugs as those for variceal bleeding, although there are no RCTs specifically designed for PHG (283,284,285). Oral propranolol may be used in hemodynamically stable patients (157), starting at 40 mg/day in two divided doses; the dosage may be then titrated up to the maximum tolerated amount.

Recurrent bleeding from PHG should be prevented using nonselective β-blockers, at the same dosage as that used for treating esophageal varices (158). Adequate iron supplementation may be useful to prevent or correct chronic iron-deficient anemia in patients with severe PHG (158). TIPS may be considered as an alternative therapy for the rare patient who has repeated

severe bleeding from PHG despite pharmacologic therapy (282,286). Portal decompressive surgery is reserved for those who are not candidates for orthotopic liver transplantation.

Patients bleeding from *GAVE* may benefit from endoscopic ablation by argon plasma coagulation, neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, or heater probe (282). There is no proof that TIPS and β-blockers are effective for the prevention of recurrent bleeding from GAVE. For select patients with severe recurrent bleeding or uncontrollable acute bleeding from GAVE, an antrectomy with Billroth I anastomosis may be considered (285).

Chapter 16

Surgical Management of Portal Hypertension

J. Michael Henderson

Key Concepts

- Liver transplantation has significantly improved outcome among Child-Pugh class C patients with variceal bleeding.
- Evaluation of patients with portal hypertension being considered for surgery requires endoscopy, vascular imaging, and assessment of the liver disease.
- Primary therapy for variceal bleeding is with endoscopic and pharmacologic modalities.
- Variceal decompression is indicated for patients who fail primary therapy or who cannot undergo primary therapy. Decompression is performed with a transjugular intrahepatic portosystemic or surgical shunt.
- All surgical shunts—total, partial, or selective—control variceal bleeding in more than 90% of patients.
- The occurrence of encephalopathy and liver failure after insertion of a shunt depends on the extent of liver disease and loss of portal perfusion.
- Devascularization procedures are a surgical alternative in the management of variceal bleeding in patients who cannot undergo shunting.

History

Surgical management of portal hypertension was initiated in the late 19th century when Nicolai Eck first performed end-to-side portacaval shunts in dogs (the Eck fistula). Pavlov, more famous for his studies in gastric physiology, used this animal model of shunting all portal flow

away from the liver to describe the portaprival syndrome characterized by meat intoxication (encephalopathy), progressive muscle wasting, and inanition. In the early 1900s, Vidal performed the first portacaval shunt in humans, and Drummond, Morrison, and Talma developed surgeries for portal hypertension in attempts to control variceal bleeding or manage ascites. Banti popularized splenectomy on the basis of his belief that splenomegaly was etiologic in portal hypertension. None had long-term success, but their ideas were the forerunners of much of what followed later (1).

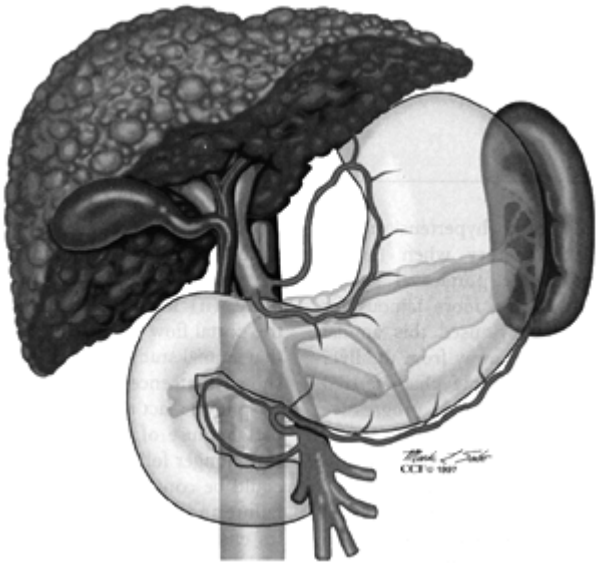
In the 1940s Whipple and the Columbia group reintroduced decompressive shunts for the management of variceal bleeding. His rationale was (i) the recognition that variceal bleeding was not controlled by splenectomy, (ii) that in patients with advanced cirrhosis the portal flow often reduced spontaneously, and (iii) that animal studies with dietary protein restriction had shown that encephalopathy could be controlled (2). Despite the fact that initial results were good, in large part because of the attention to detail and technical skill, longer follow-up showed that although bleeding could be controlled, shunting led to accelerated liver failure and encephalopathy. Randomized clinical studies ensued first with prophylactic shunts in patients with varices that had not bled and subsequently in patients after an initial variceal bleed. These trials in

the 1960s and 1970s showed no significant advantage in patient survival of portosystemic shunts over nonsurgical therapy. The mode of death changed from bleeding to liver failure (3).

In the 1970s and 1980s, surgeons remained active in the field of portal hypertension. Selective variceal decompression was introduced by Warren et al. (4) in the United States and Inokuchi (5) in Japan. They documented that varices could be selectively decompressed with good control of bleeding, maintenance of portal perfusion of the liver, and a lower rate of encephalopathy. Devascularization procedures became more extensive, largely popularized by Sugiura and Futagawa (6) in Japan and Hassab (7) in Egypt. The 1970s also saw the reintroduction of endoscopic sclerotherapy, initially by three surgeons, Johnston, Terblanche, and Paquet. Although initially performed with a rigid esophagoscope, sclerotherapy rapidly moved to flexible endoscopy and was performed by gastroenterologists. In the 1980s the success of sclerotherapy in treating acute bleeding and as first-line treatment to prevent rebleeding diminished the use of shunts (8). Endoscopic therapy evolved with banding replacing injection sclerotherapy in the 1990s (9).

The late 1980s and 1990s saw two other major changes in the treatment of portal hypertension. Liver transplantation became widely used, with excellent outcomes for patients with end-stage liver disease

(10). Second, transjugular intrahepatic portosystemic shunt (TIPS) was introduced in the 1990s (11) and has led to renewed interest in decompressive shunts in the care of patients with adequate liver function who bleed despite endoscopic and pharmacologic therapy but do not need liver transplantation.



▪ **Figure 16.1** Portal venous anatomy. The portal vein is formed by the union of the superior mesenteric and splenic veins behind the neck of the pancreas. The main tributaries are the inferior mesenteric, left and right gastric, and gastroepiploic veins.

Anatomy

Portal venous anatomy is remarkably consistent, considering the complexity of its embryologic development (Fig. 16.1). The portal vein is formed behind the neck of the pancreas by the confluence of the superior mesenteric and splenic veins. The portal vein is normally 10 to 12 mm in diameter but can enlarge up to 20 mm in portal hypertension. It follows a consistent course in the free edge of the gastrohepatic ligament to the porta hepatis, where it divides into right and left branches. The precise sites of entry of other feeding tributaries to this system, which are of clinical relevance in portal hypertension, are more variable. The inferior mesenteric vein enters the splenic vein in approximately two thirds of persons and the superior mesenteric vein in one third. It always serves as an outflow from the portal vein in portal hypertension. The left gastric or coronary vein enters the portal vein in approximately two thirds of persons and the splenic vein in the other one third. The left gastric vein varies considerably in size and may be the major feeding vein of

gastroesophageal varices.

The umbilical vein is constant in its communication with the left branch of the portal vein, and recanalization of this vessel in portal hypertension may open it to a significant size. An understanding of the pattern of tributaries to the portal vein is important to the surgeon both for liver transplantation and for shunts.

The hepatic arterial blood supply is highly variable, and anomalies are of clinical significance to transplantation surgeons, particularly during donor hepatectomy. The normal arterial anatomy is a common hepatic artery arising from the celiac axis and giving rise to right and left hepatic arteries after the gastroduodenal artery leaves the common hepatic trunk. Approximately 20% of persons have an anomalous right accessory or replaced hepatic artery arising from the superior mesenteric artery. The incidence is similar for an accessory or replaced left hepatic artery, which arises from the left gastric artery. These two anomalies can coexist.

The segmental anatomy of the liver subdivides eight segments according to their own major hepatic arterial and portal venous inflow and hepatic venous drainage. This subdivision of the liver is of particular importance in liver resection or for reduced-size liver transplantations. The physiologic functional unit of the liver is the liver lobule, and at this level the hepatic artery and portal venous blood mix, traverse the sinusoids, and drain through the central veins. The hepatic veins are consistent, with the right, middle, and left draining the segmental anatomy of the liver.

The major pathologic changes of the portal venous anatomy in portal hypertension are at the gastroesophageal junction. Reevaluation with radiologic, ultrasound, and corrosion cast studies has shown that the submucosal and periesophageal veins communicate around the gastroesophageal junction through perforating vessels and align in a consistent pattern with the palisades that run in the submucosa in the distal 2 cm portion of the esophagus. This is the most common site of variceal bleeding.

Pathophysiology

Normal portal venous pressure is 5 to 8 mm Hg, with a portal flow of 1 to 1.5 L/minute. The portal vein is a passive conduit that carries blood from the gastrointestinal tract to the liver. Total liver blood flow is regulated by intrinsic and extrinsic mechanisms, with alterations in portal flow causing a reciprocal increase or decrease in hepatic arterial flow.

Portal hypertension is present when portal pressure exceeds 8 mm Hg, and the risk of variceal bleeding occurs at pressures greater than 12

mm Hg. The pathophysiologic sequence of the events in portal hypertension has been defined in animal models (12). The initial resistance to portal venous flow is followed by the development of collateral vessels from the hypertensive bed to the systemic circulation. This is followed by increased plasma volume, development of a hyperdynamic systemic circulation, and marked splanchnic hyperemia, which contributes to the increased portal flow and pressure.

Evaluation

When the surgeon is asked to evaluate a patient with portal hypertension, the focus is on issues pertinent to surgical intervention. A hepatologist has usually evaluated and managed the patient's liver disease and its complications already, and the current status should be defined. The main points of emphasis to the surgeon are the following:

1. Does the patient have decompensated cirrhosis? If this is the case, the only surgical option is liver transplantation.
2. Is the patient bleeding from varices? Have the varices reached a point where they cannot be adequately managed with first-line therapy? First-line management of variceal bleeding is endoscopic and pharmacologic therapy. However, 20% to 30% of patients have rebleeding and need additional therapy. Evaluation is accomplished with endoscopy and vascular imaging. Endoscopy may show varices that cannot be obliterated in the esophagus, gastric varices, or portal gastropathy as the site of bleeding. Doppler ultrasound should be used to show patency of and flow directions in the major veins, but if a decision is being made to perform decompression, angiography is usually needed to obtain details about the site of origin of collateral vessels.
3. Is the patient a suitable candidate for shunt surgery who is likely to survive the surgical procedure? This is primarily assessed by Child-Pugh classification (Table 16.1). Child-Pugh class A patients are surgical candidates. If the patients have no

ascites or encephalopathy, their bilirubin level is less than 3 mg/dL, and the albumin level is greater than 3 g/dL, with an international normalized ratio less than 1.5, the surgeon can operate on them with the expectation of a reasonable outcome. Child-Pugh class B patients may be either class B improving toward class A or class B moving toward class C. In the care of Child-Pugh class C patients, the only realistic surgery is liver transplantation. The role of Model for End-Stage Liver Disease (MELD) scoring (Table 16.2) in assessing patients for shunt surgery has not been fully defined to the same extent as that

used for transplantation.

Table 16.1. Child-Pugh Grading of Severity of Liver Disease

Clinical and laboratory measurement	Patient score for increasing abnormality		
	1	2	3
Encephalopathy (grade)	None	1 or 2	3 or 4
Ascites	None	Mild	Moderate
Bilirubin (mg/dL)	1–2	2.1–3	≥3.1
Albumin (g/dL)	≥3.5	2.8–3.5	≤2.7
Prothrombin time (increase, s)	1–4	4.1–6	≥6.1

Child-Pugh grade is A when total score is 5–6, B when total score is 7–9, and C when total score is 10–15.

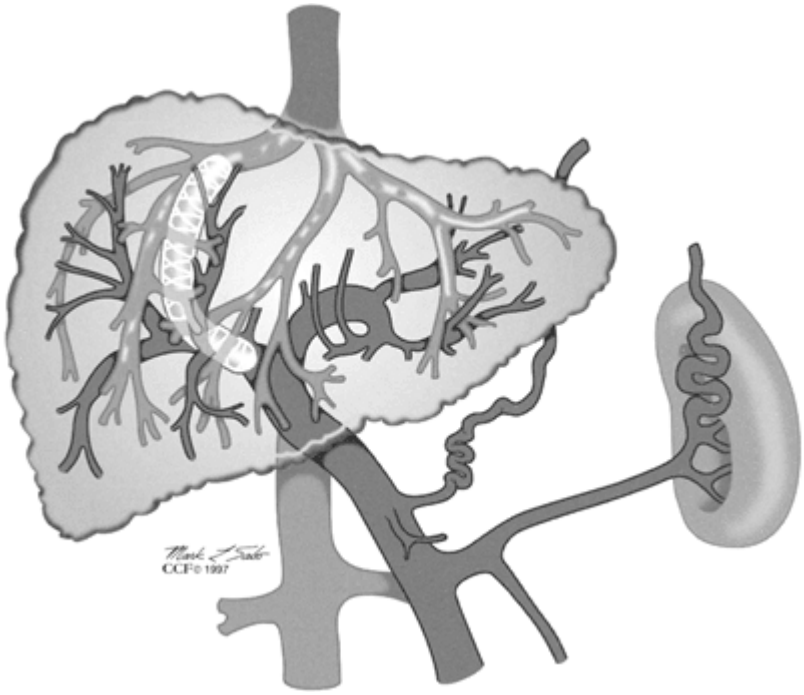
Table 16.2. Model for End-Stage Liver Disease (Meld) Score

Score = 0.957 $\log_e$ creatinine (mg/dL) + 0.378 $\log_e$ bilirubin (mg/dL) + 1.120 $\log_e$ INR
INR, international normalized ratio.

Portal Decompression

Transjugular Intrahepatic Portosystemic Shunt

TIPS emerged in the 1990s as an alternative to surgical decompression (Fig. 16.2) and is currently the most widely used shunt. This shunt, which is addressed in Chapter 15, must, however, also be considered when discussing the site for surgical decompression. Although a TIPS is placed more easily than a surgical shunt, it currently has the disadvantage of high rates of stenosis and thrombosis, leading to rebleeding within 2 years in approximately 20% of patients (13,14). The introduction of polytetrafluoroethylene covered stents has lowered the dysfunction rates, and in a European multicenter trial it reduced rebleeding to 13% at 2 years (15). However, the inability to identify "dysfunction" reliably without repeat shunt catheterization and pressure measurement adds to the complexity of follow-up and cost of TIPS. All patients need an intensive follow-up protocol after TIPS placement. The encephalopathy rate after TIPS appears to be similar to that after total shunt placement (13,16). TIPS is a good treatment for patients with portal hypertension, variceal bleeding, and ascites who are awaiting liver transplantation when bleeding is not controlled with endoscopic therapy (13). The role of TIPS in the care of lower-risk patients who may either have a longer bridge to transplantation or not need transplantation is addressed in subsequent text.



▪ **Figure 16.2** Transjugular intrahepatic portosystemic shunt. A track developed between a major hepatic vein and the portal vein is dilated and stented. This is a side-to-side portal systemic shunt, either total or partial.

Surgical Methods

Three surgical methods are used in the management of portal hypertension:

1. Decompressive shunts
2. Devascularization procedures
3. Liver transplantation

There is a role for each of these operative procedures, and this section discusses the goals and outcome of these procedures.

Decompressive Surgical Shunts

Decompressive surgical shunts fall into three groups:

1. Total portosystemic shunts that decompress all portal hypertension

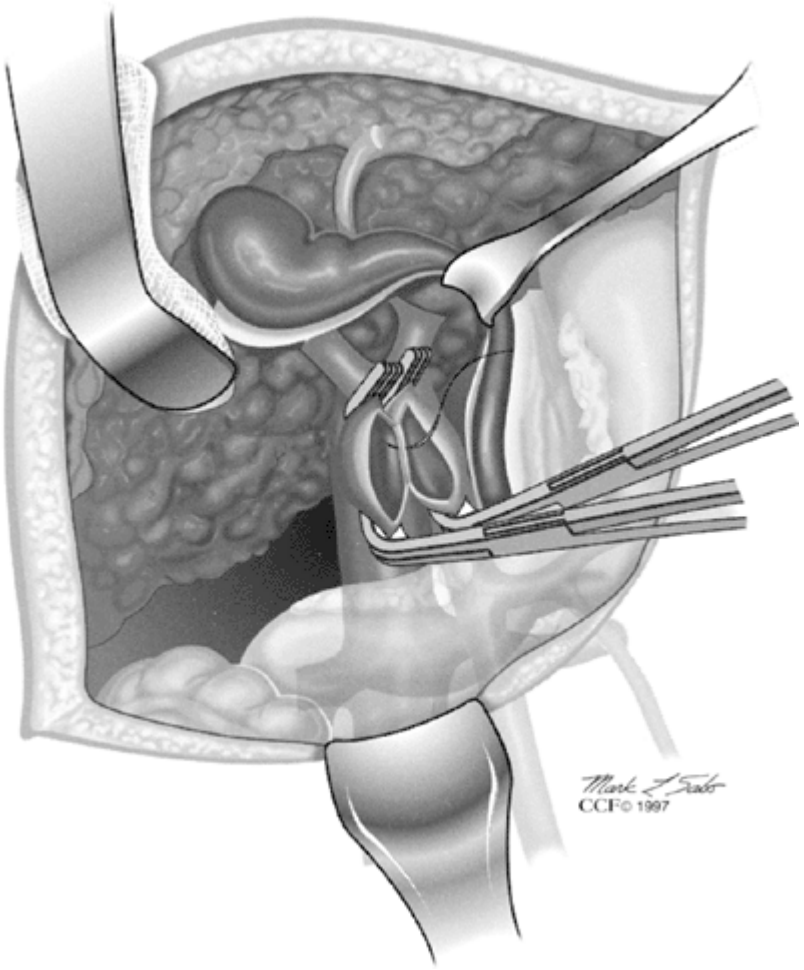
2. Partial portosystemic shunts that reduce portal hypertension to approximately 12 mm Hg
3. Selective shunts that decompress gastroesophageal varices but maintain portal hypertension

Total portosystemic shunts

In the end-to-side portacaval shunt (Eck fistula) procedure, the liver end of the portal vein is ligated and the splanchnic end is anastomosed to the vena cava. With this shunt, the hepatic sinusoids maintain their hypertension; therefore, this surgery does not relieve ascites. Hence, there are currently almost no indications for this surgery at present.

By contrast, the second group of total shunts are side-to-side shunts, all of which decompress the portal hypertension both in the splanchnic bed and in the liver (Fig. 16.3). These procedures still have some proponents. The common factor to these shunts is that they are 10 mm or more in diameter and include side-to-side portacaval, mesocaval, and central splenorenal shunts. They may either be direct vein-to-vein anastomoses or incorporate prosthetic material. The pathophysiology of these shunts is associated with the portal vein acting as an outflow tract from the obstructed sinusoids, with reversal of blood flow in the portal vein to the low-pressure shunt. Side-to-side shunts are excellent for controlling variceal bleeding and ascites but deprive the liver of prograde portal flow and increase the risks of progressive liver failure and encephalopathy (17,18,19). The other major disadvantage of these shunts is that when prosthetic material is used as an interposition graft, there is increased risk of thrombosis (20).

The indications for side-to-side shunts are at present relatively limited. A patient with massive continued bleeding who also has ascites can be treated with a side-to-side shunt, although TIPS achieves the same goal without surgery. The strongest advocates of emergency side-to-side portacaval shunts are Orloff et al. who in 1995 reported an extensive series with excellent outcome in a largely alcoholic group of patients (17). The other indication for this type of side-to-side shunt is acute Budd-Chiari syndrome because it allows decompression of the obstructed sinusoids and halts ongoing hepatocellular necrosis (21).



▪ **Figure 16.3** Side-to-side portacaval shunt. The portal vein and inferior vena cava must be mobilized sufficiently to allow them to be opposed for anastomosis. If the distance between the veins is too great, graft interposition may be needed.

Partial portosystemic shunts

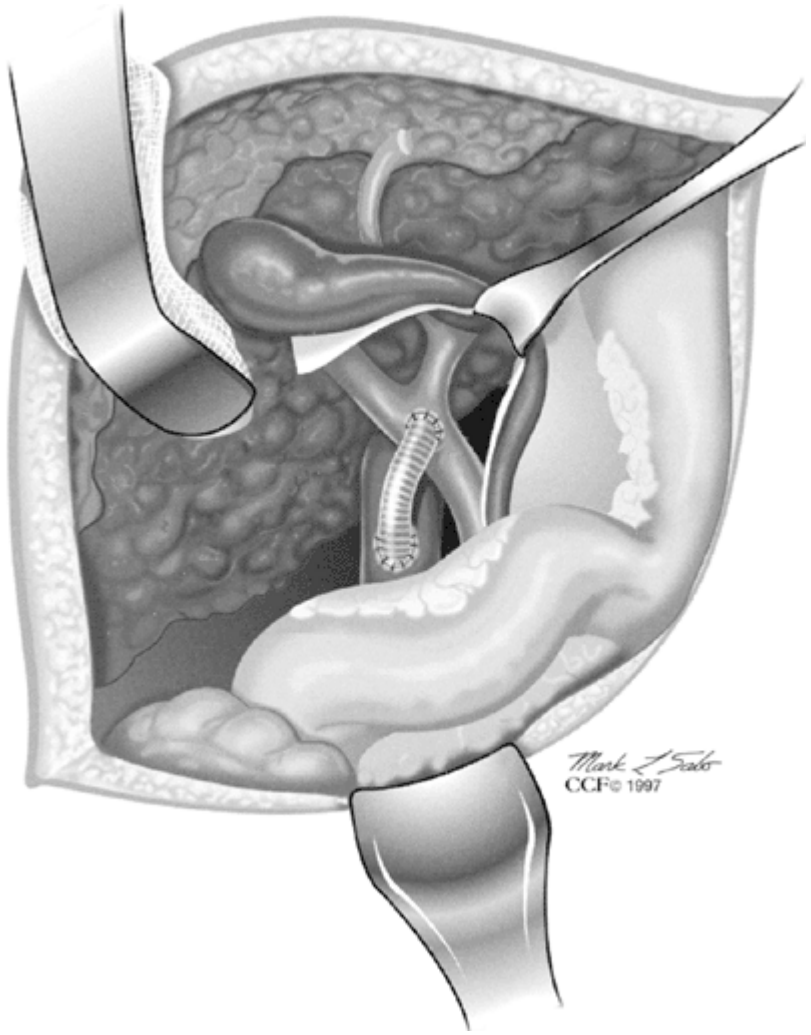
Partial portosystemic shunts can be achieved by reducing side-to-side portosystemic shunt diameter to 8 mm. Data show that at this size portal flow is maintained in 80% of patients, and portal hypertension is reduced to 12 mm Hg (22). This interposition portacaval shunt is illustrated in Figure 16.4. Attention to detail in the execution of this graft is critical to minimize the risk of thrombosis.

Outcomes with partial shunts documented from two prospective, randomized controlled trials indicate control of bleeding in 90% of patients (23,24). The maintenance of some portal flow has been associated with a lower incidence of encephalopathy and liver failure than that with total portosystemic shunting. Other groups have

advocated the use of a limited-size mesocaval shunt in a similar way and have presented data in support of this concept, although not from randomized, controlled studies (25,26).

One randomized trial has compared the 8-mm portacaval surgical shunt to TIPS. In this "all-comers" study, 50% of patients had Child-Pugh C cirrhosis and 63% of the patients had alcoholic liver disease. There was

significantly better control of bleeding and lower need for transplantation in the surgical shunt group compared to the TIPS group—survival was not significantly different (24).



▪ **Figure 16.4** Partial portosystemic shunt. Interposition of an 8-mm expanded polytetrafluoroethylene (Gore-Tex) graft between the portal vein and inferior vena cava reduces portal hypertension to 12 mm Hg and allows continued portal perfusion in 80% of patients.

Selective shunts

In selective variceal decompression, a different pathophysiologic concept is applied for the control of variceal bleeding. Varices are selectively decompressed, usually by a distal splenorenal shunt (DSRS) through the short gastric veins, spleen, and splenic vein to the left renal vein (4). Portal hypertension is maintained in the splanchnic and portal venous system to maintain prograde portal flow to the cirrhotic liver. This surgery is illustrated in Figure 16.5 and has been the most widely used surgical shunt worldwide over the last 20 years. This surgery should be part of the repertoire of liver transplantation surgeons for patients who have refractory bleeding but still have good liver function.

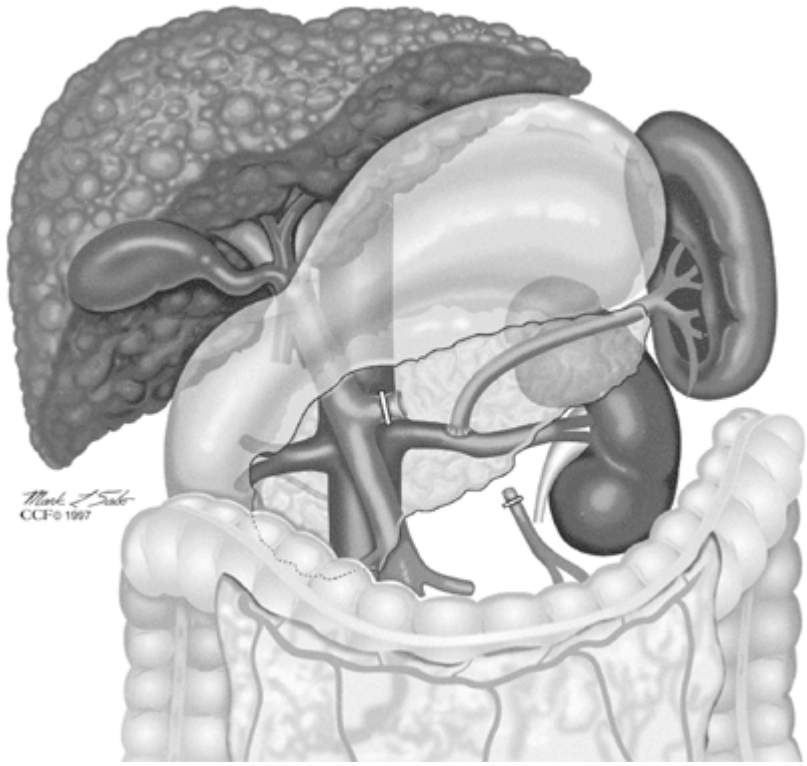
Long-term patency of DSRS is excellent with the vein-to-vein anastomosis, and bleeding is controlled in more than 90% of patients (19,27,28,29,30,31,32,33). The highest risk time for rebleeding is in the first 4 to 6 weeks while the short gastric and renal veins accommodate the increased flow from the enlarged spleen and varices (34). Maintenance of portal perfusion is achieved in 90% of patients in the short term. Long-term maintenance of portal perfusion has proved excellent in nonalcoholic patients, but 50% of alcoholic patients lose portal perfusion unless splenopancreatic disconnection is performed. This has resulted in maintenance of portal flow in 84% of patients with alcoholic cirrhosis (35).

Randomized controlled trials in which DSRS was compared with total shunts have shown equivalent control of bleeding (36). Although three of these six studies have shown lower incidence of encephalopathy after insertion of a DSRS, the others have not. These other studies were conducted with a predominantly alcoholic (83%) population, which may be a factor in the failure to show significant advantage for DSRS.

Four randomized trials have been conducted in which DSRS was compared with endoscopic sclerotherapy (37). In these studies, use of a DSRS resulted in significantly better control of variceal bleeding. The rate of encephalopathy was not significantly different between sclerotherapy and shunt groups. This was the strongest evidence that DSRS does not accelerate the rate of encephalopathy in patients with cirrhosis. One study showed significantly improved outcome among patients initially randomized to sclerotherapy, one third of whom needed subsequent surgical salvage because of recurrent variceal bleeding (38). Another trial showed a significantly better outcome in patients initially randomized to DSRS (39). This difference was predominantly due to the failure to surgically rescue patients in the sclerotherapy group who have rebleeding because they were often geographically remote from the primary managing center. The other

two trials showed no significant difference in survival.

There is much interest in the comparative role of DSRS and TIPS. Several studies have looked at this (a) in a nonrandomized manner (40), in which the superiority of DSRS was demonstrated; (b) in relation to subsequent likely liver transplantation (41); and (c) in a decision analysis evaluation (42), which favored DSRS over TIPS in a cost analysis. A multicenter randomized trial has compared DSRS to TIPS in Child-Pugh class A and B patients who rebled through pharmacologic and endoscopic therapy (43). Sixty percent of the patients entered had alcoholic liver disease. At a median follow-up of 42 months, there was no significant difference in control of bleeding (DSRS 94%, TIPS 89%), time to first encephalopathy event (DSRS, 1 year 20%, 5 years 50%; TIPS, 1 year 22%, 5 years 50%), or survival (DSRS 1 year 85%, 5 years 62%: TIPS 1 year 90%, 5 years 61%). However, the TIPS patients required significantly ($P < 0.001$) more reinterventions (83%) compared to DSRS patients (11%). This emphasizes the need for careful protocol follow-up for TIPS patients—including shunt catheterization and pressure measurements—to achieve these results.



▪ **Figure 16.5** Distal splenorenal shunt. Varices are selectively decompressed through the short gastric veins, spleen, and splenic vein to the left renal vein. Portal hypertension is maintained in the superior mesenteric and portal veins to keep portal flow to the

liver.

Devascularization Procedures

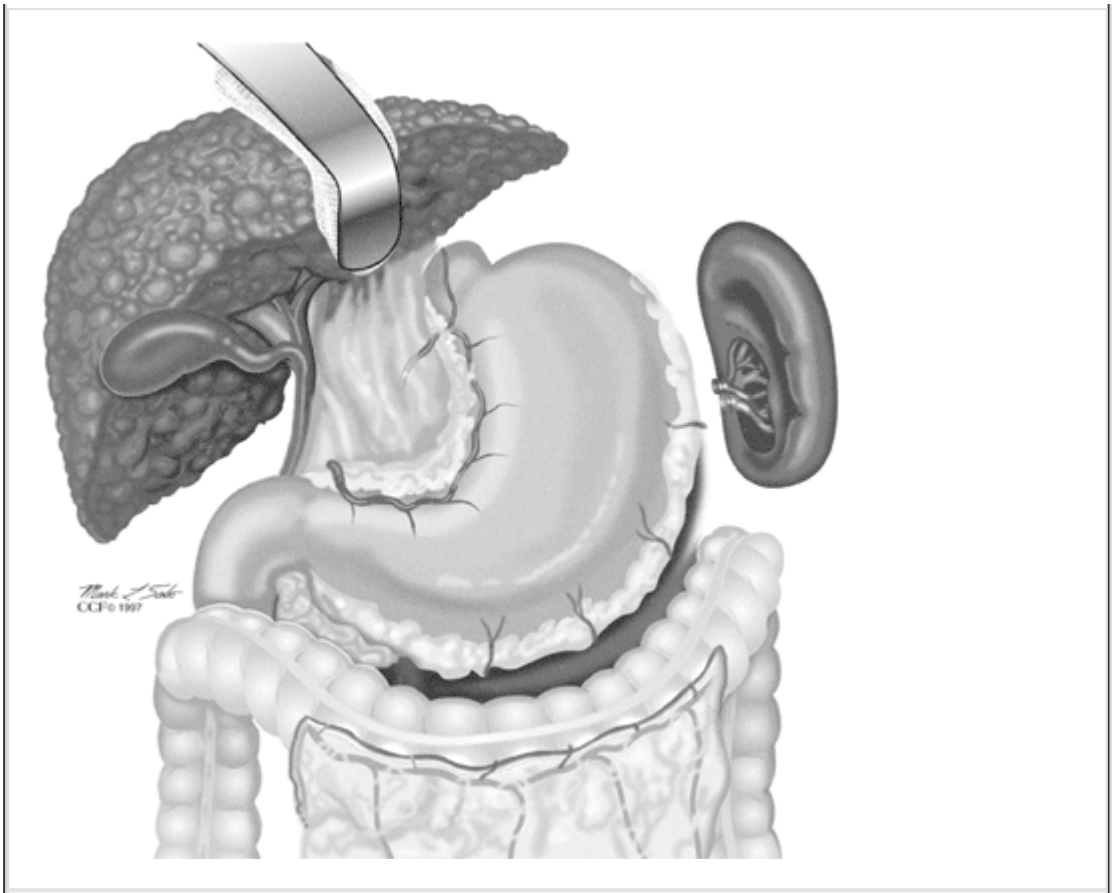
Devascularization procedures have the components of splenectomy, gastric and esophageal devascularization, and in some situations, esophageal transection (Fig. 16.6). The advantage of these procedures is that they maintain portal hypertension and portal flow to the cirrhotic liver and do not accelerate liver failure or encephalopathy. The disadvantage is that they have a higher rate of rebleeding, which probably depends on the extent of the surgical procedure. Sugiura et al. devascularized from the pylorus to the inferior pulmonary veins using both thoracotomy and laparotomy to achieve an extensive procedure with a low rate of rebleeding (6,44). Lesser procedures using only a transabdominal approach, as performed in Europe and the United States, have rebleeding rates in the range of 20% to 40% (45). In patients who have extensive portal venous thrombosis and in whom no vessels can be shunted, devascularization procedures are the only surgical option. When these patients do not have bleeding controlled by pharmacologic and endoscopic therapy, extensive devascularization may significantly reduce the risk of rebleeding. This is the major indication for devascularization procedures.

Liver Transplantation

Liver transplantation has dramatically altered the outcome for patients with advanced liver disease, portal hypertension, and variceal bleeding. It is the one therapy that has significantly improved survival of patients with bleeding varices and Child-Pugh class C cirrhosis. The indication for liver transplantation, however, is end-stage liver disease rather than variceal bleeding.

Liver transplantation both restores hepatic function and relieves portal hypertension, making it the most effective shunt in the management of variceal bleeding. However, supply and demand dictate that transplantation cannot be the therapy for all patients with cirrhosis who have variceal bleeding. The evolution of national organ allocation standards for livers has had an impact on who receives the transplant. The sickest patients from the perspective of the severity of liver disease receive priority, and variceal bleeding per se does not increase priority. This appropriately drives the need

to use the other modalities discussed in this chapter to treat variceal bleeding in patients who still have adequate liver function.



▪ **Figure 16.6** Devascularization procedures have the components of splenectomy and devascularization of the greater and lesser curves of the stomach, as well as the distal 7 cm of the esophagus.

The outcome of liver transplantation has dramatically improved in the last decade. Currently, patients can anticipate an initial 6-month mortality of approximately 10%, with continuing long-term risk of 2% to 5% per year for death or major morbidity. The major risk factors facing transplantation patients are recurrent disease, especially hepatitis, chronic rejection, and immunosuppression-related infection.

In the context of this chapter, for the management of variceal bleeding, liver transplantation is the most viable long-term treatment option for patients with variceal bleeding and end-stage disease. Timing is always a major issue, and with the increasing lengthening of waiting lists it becomes more problematic. Determining the correct "bridge" to transplantation is key, and the least therapy that can be used as a bridge, the better it is for the patient. However, when patients have bleeding refractory to endoscopic therapy, it may be appropriate to decompress the portal hypertension with TIPS. Surgical decompression is also an appropriate bridge for a patient who has a

disease that may not necessitate transplantation for 5 to 10 years.

Management Strategies for Variceal Bleeding

Prophylaxis

There is no indication for surgical intervention as prophylaxis before the first episode of variceal bleeding. Current data indicate that prophylaxis should be with pharmacologic therapy. In some patients at high risk with large varices, endoscopic therapy as prophylaxis against initial variceal bleeding may be indicated. The data on surgical prophylaxis are old, primarily being collected in the 1960s, but still lead to the recommendation of no surgical intervention before an initial episode of bleeding.

Acute Variceal Bleeding

Primary therapy for acute variceal bleeding is endoscopic. Sclerotherapy or banding is done at the time of the initial diagnostic endoscopic procedure. This treatment may be combined with pharmacologic therapy to reduce the risk of early rebleeding. Surgical intervention is rarely indicated for acute variceal bleeding.

More than 90% of patients can be treated with endoscopic therapy. In the small minority of cases in which this therapy fails, balloon tamponade with emergency decompression using TIPS in the next 24 hours is the best approach. The one exception to this view is that of Orloff et al. (17), who continue to advocate emergency portacaval shunting for acute variceal bleeding. The success of their approach is probably based on the patient population they treat and their commitment to early intervention and a program of long-term follow-up evaluation of these patients.

Prevention of Variceal Rebleeding

Surgical intervention is part of an overall program for this group of patients but has been progressively replaced with new options. Initial first-line treatment is with pharmacologic and endoscopic therapies. Seventy percent of patients are successfully treated in this way.

It is for the 30% of patients who have rebleeding through first-line treatment or in whom the varices are not obliterated that decompression should be considered. How should this decompression be achieved? A key decision at this point is whether the patient has end-stage liver disease or a disease that is rapidly approaching this stage. Patients who do have such disease should be fully evaluated for transplantation and moved in this direction. For patients who rebleed through first-line treatment and have adequate and stable liver function, the choice of surgical shunt or TIPS is based on availability,

access to care, and commitment to follow-up. Both are equally efficacious in outcomes.

Reaching decisions in patient care requires early and accurate evaluation. Once a patient's condition has been stabilized after acute variceal bleeding, the patient should undergo full evaluation as outlined earlier. Equally important for patients being treated with first-line therapy is to monitor whether the disease is stable and whether hepatocellular function is deteriorating or improving. Patient education is also key to the care of these patients over the long term so that they understand that there are other treatment options should first-line treatment fail.

New Trends as a Consequence of Improved Control of Variceal Bleeding

The advances and improvements in the control of variceal bleeding in the last two decades have led to the increased recognition of other complications of cirrhosis, which were previously uncommon. Two that are clinically important, and should be considered in long-term management of these patients, are hepatocellular carcinoma (HCC) and the pulmonary complications of chronic liver disease.

HCC is increasing in frequency for many reasons. Improved management of variceal bleeding, with overall improved survival of an "at-risk" population, is one contributing factor. Prospective evaluations of such patients by the Barcelona Group gave a 14% to 21% risk of HCC at 5 years, but their data do not indicate that shunts increase that risk (46).

The pulmonary complications of cirrhosis are the hepatopulmonary syndromes (HPSs) and portopulmonary hypertension (PPH). HPS is seen in up to 15% of patients with cirrhosis (47), whereas PPH is less common. The role of portal–systemic shunting in the development of either of these has been widely debated. The pathophysiology of HPS is a nitric oxide–mediated pulmonary vasculature vasodilatation: How far this is triggered by mediators from the damaged liver or through portal systemic shunting is not fully defined (47). A larger multicenter review of both these complications in patients considered for transplantation did not implicate surgical or radiologic shunts as etiologies in the patients who were identified (48). The current data leaves open the question of the importance of shunting in these syndromes.

Chapter 17

Renal Complications and Hepatorenal Syndrome

Andrés Cárdenas

Pere Ginès

Juan Rodés

Key Concepts

- Renal impairment in most patients with cirrhosis is secondary to functional abnormalities that occur in response to a severe splanchnic arterial vasodilatation which triggers an intense homeostatic neurohumoral response causing sodium retention and solute-free water retention and, finally, severe renal vasoconstriction.
- Sodium retention is the first and most common functional renal abnormality in patients with cirrhosis and plays a fundamental role in the formation of ascites and edema. The total amount of extracellular fluid accumulated as ascites or edema depends on the balance between sodium intake and excretion.
- In the natural history of cirrhosis and ascites, in time, patients develop an impairment in the renal handling of solute-free water and retain water in excess of sodium. Those with a marked impairment in solute-free water excretion develop dilutional hyponatremia, a condition that carries a poor prognosis in patients with cirrhosis and ascites.
- Treatment of spontaneous dilutional hyponatremia with V2 receptor antagonists in patients having cirrhosis and ascites seems to be a promising new therapy that enhances solute-free water excretion and raises serum sodium levels in this condition.
- Hepatorenal syndrome (HRS) is the end of the spectrum of functional renal abnormalities caused by a severe vasoconstriction of the renal circulation. Patients with marked sodium and water retention are at high risk of developing HRS.
- There are two types of HRS; type 1 is an acute and rapidly progressive form with a very poor prognosis and type 2 is a more stable form with a slightly better prognosis.
- The short-term mortality rate in patients with HRS is very high. The type of HRS and the Model for End-stage Liver Disease (MELD) score are predictive factors of survival. Transplantation candidates should undergo transplantation with a high priority.
- HRS that develops in patients with cirrhosis after spontaneous bacterial

peritonitis (SBP) or in the setting of acute alcoholic hepatitis can be prevented effectively. The administration of intravenous albumin together with antibiotic therapy in the former condition, and oral pentoxifylline in the latter prevent HRS.

- The treatment of HRS should be aimed at reversing the intense splanchnic arteriolar vasodilatation with splanchnic vasoconstrictors and plasma expansion as a bridge to liver transplantation. The use of transjugular intrahepatic portosystemic shunt also appears to be effective in select cases.

Table 17.1. Functional Renal Abnormalities in Cirrhosis

Abnormality	Clinical consequence
Sodium retention	Ascites and edema
Solute-free water retention	Spontaneous dilutional hyponatremia
Renal vasoconstriction	Hepatorenal syndrome

In the natural history of cirrhosis, a progressive derangement of renal function, which is functional in nature, leads to an inability to maintain the extracellular fluid volume within normal limits. This abnormal extracellular fluid volume regulation is due to alterations in the splanchnic and systemic arterial circulation that cause functional renal abnormalities, leading to sodium retention. The characteristic and predominant renal function abnormality in cirrhosis is sodium retention and its main clinical consequence is the recurrent accumulation of extracellular fluid as ascites and/or edema. Sodium retention, when severe, is often associated with an impaired ability to eliminate a regular water intake, which may lead to dilutional hyponatremia due to an unbalanced increase in total body water, relative to the total sodium content (i.e., water in excess of sodium). With disease progression a gradual vasoconstriction of the renal circulation usually develops because of circulating vasoconstrictors. This event causes renal hypoperfusion, reduction in glomerular filtration rate (GFR), and eventually renal failure or the so-called hepatorenal syndrome (HRS) (Table 17.1). All these abnormalities of renal function contribute significantly to the high morbidity and mortality, characteristic of cirrhosis.

The mechanisms leading to renal dysfunction in cirrhosis are not completely understood and are still a matter of investigation. Extrarenal and intrarenal vasoactive factors, sodium and water retaining systems, abnormalities in systemic, cardiac and splanchnic hemodynamics, and the diseased liver causing severe portal hypertension and hepatic failure play an important role in the pathophysiology of HRS. This chapter describes the clinical characteristics,

pathogenesis, and treatment of renal complications in patients with cirrhosis.

Clinical Features

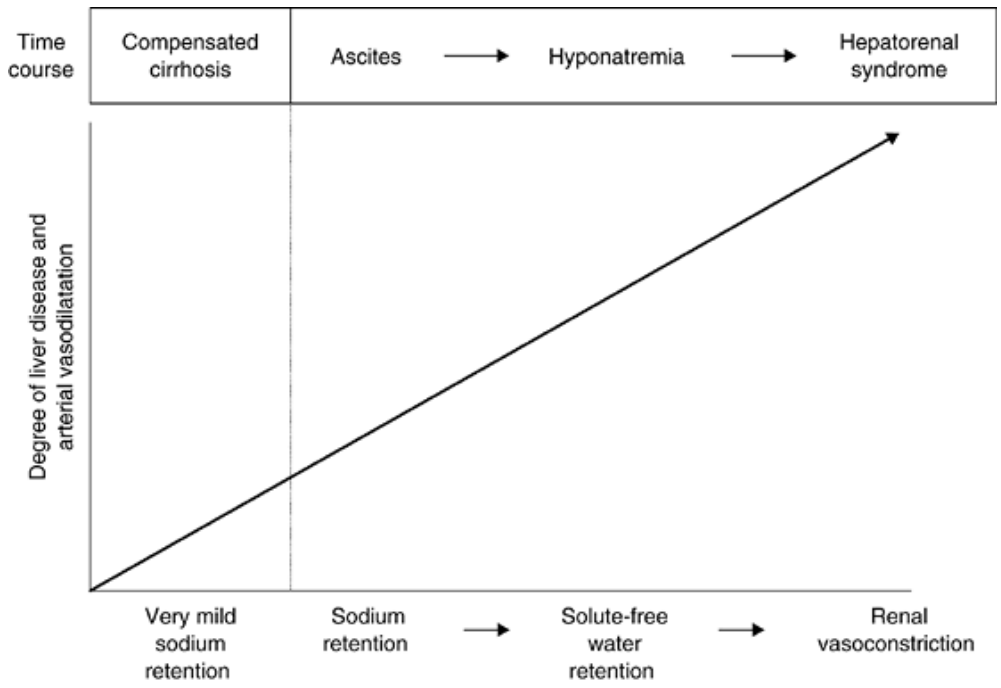
Sodium Retention and Ascites/Edema

Sodium retention is the most common abnormality of renal function in patients with cirrhosis and ascites and plays a key role in the pathophysiology of ascites and edema formation (1,2,3). It is the first manifestation of renal impairment these patients develop (Fig. 17.1). The total amount of sodium retained by patients with cirrhosis and the subsequent gain of extracellular fluid is dependent on the balance between sodium intake and excretion. Patients accumulating ascites and edema invariably have a lower amount of sodium excreted in the urine than their dietary intake. However, if they decrease their sodium intake and use diuretics, sodium excretion increases and they lose extracellular fluid and ascites and/or edema decrease. Compensated patients with cirrhosis (no past history of ascites) usually do not retain sodium while consuming a normal diet, but may develop ascites and/or edema when sodium intake is increased (high-sodium diet or administration of intravenous saline solutions) or when they are treated with drugs that increase sodium reabsorption, such as mineralocorticoids or nonsteroidal anti-inflammatory drugs (NSAIDS) (2,3,4,5).

The intensity of sodium retention varies considerably from patient to patient. In baseline conditions (low-sodium diet and without diuretics) some patients have relatively high urinary sodium excretion, whereas in other patients, urinary sodium excretion is very low (Fig. 17.2) (6). The underlying mechanisms leading to this variability are not well understood; however, it seems that they could be related to the amount of circulating sodium-retaining systems (mainly aldosterone), increased sensitivity to these, or an increase in renal tubular sodium transporters regulated by aldosterone (2,7). Most patients who require hospitalization for the treatment of ascites have marked sodium retention with a very low baseline urinary sodium excretion (usually <10 mEq/day). Patients with moderate sodium retention (≥10 mEq/day) have a better response to diuretic therapy than those with marked sodium retention (8). Although sodium retention in cirrhosis is not a fixed and unalterable disorder, in most patients the intensity of the disorder increases over time. However, a subset of patients with marked sodium retention (particularly abstinent alcoholics with cirrhosis) may improve spontaneously and remain without ascites for prolonged periods of time.

The underlying mechanism responsible for renal sodium retention is an increased renal tubular reabsorption of sodium in the proximal and distal tubules (2,9). This occurs even in the presence of a normal or only moderately reduced GFR (10,11). Although numerous mechanisms have been proposed to explain sodium retention in cirrhosis, the two main sodium-retaining systems responsible are the

renin-angiotensin-aldosterone-system (RAAS) and the sympathetic nervous system (SNS). These are activated as a homeostatic response to a circulatory dysfunction (see later). The two final products of the RAAS system, angiotensin II and aldosterone, induce sodium retention by acting in the proximal tubule (12). The SNS also stimulates sodium reabsorption, particularly in the proximal tubule (13).



▪ **Figure 17.1** Schematic representation of the time course of the functional renal abnormalities and the relationship with the underlying liver disease and arterial vasodilatation in patients with cirrhosis.

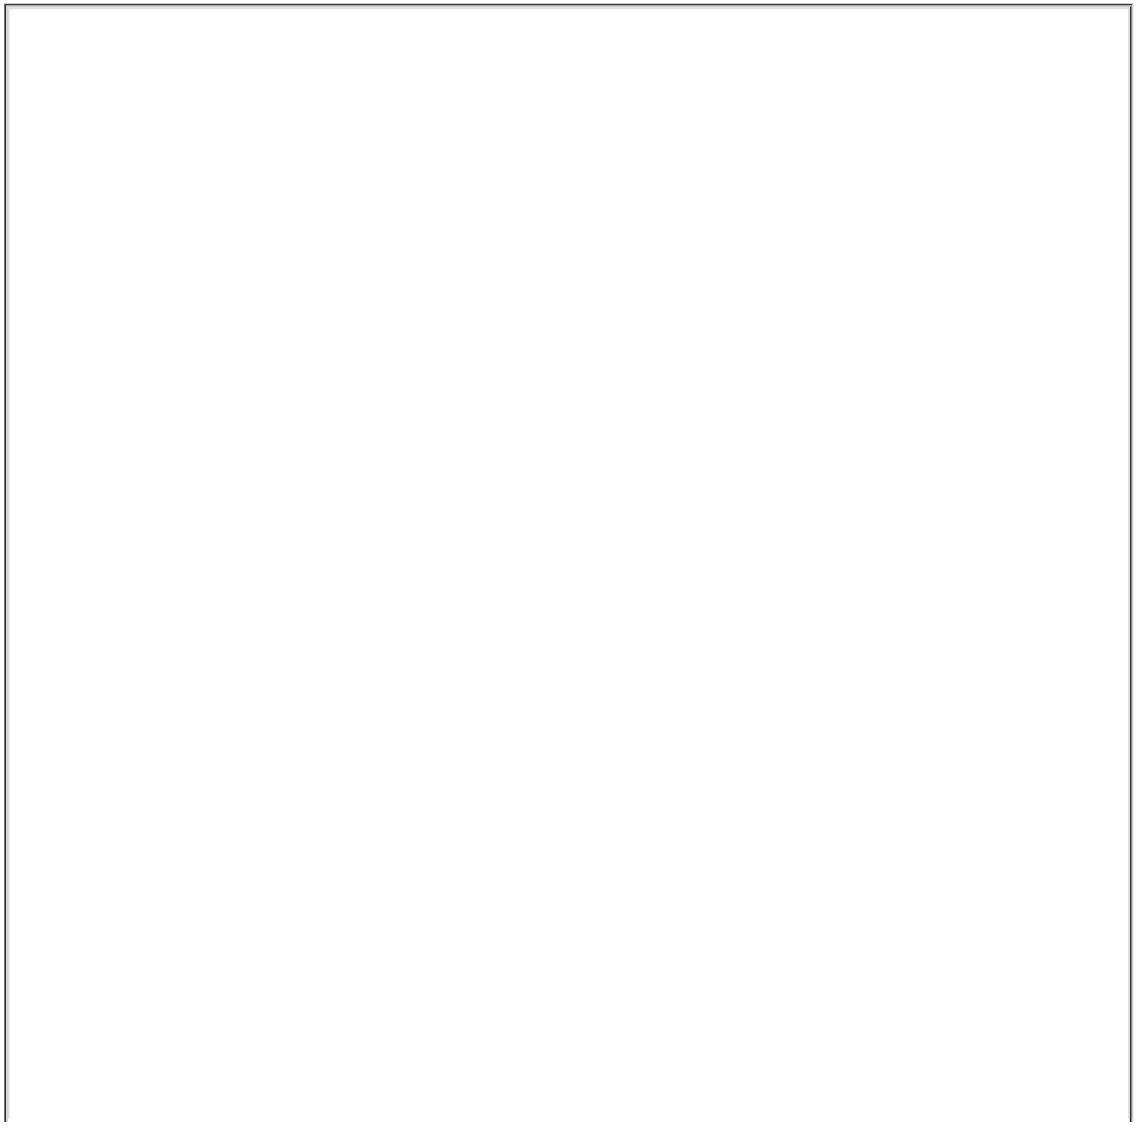
Solute-Free Water Retention and Dilutional Hyponatremia

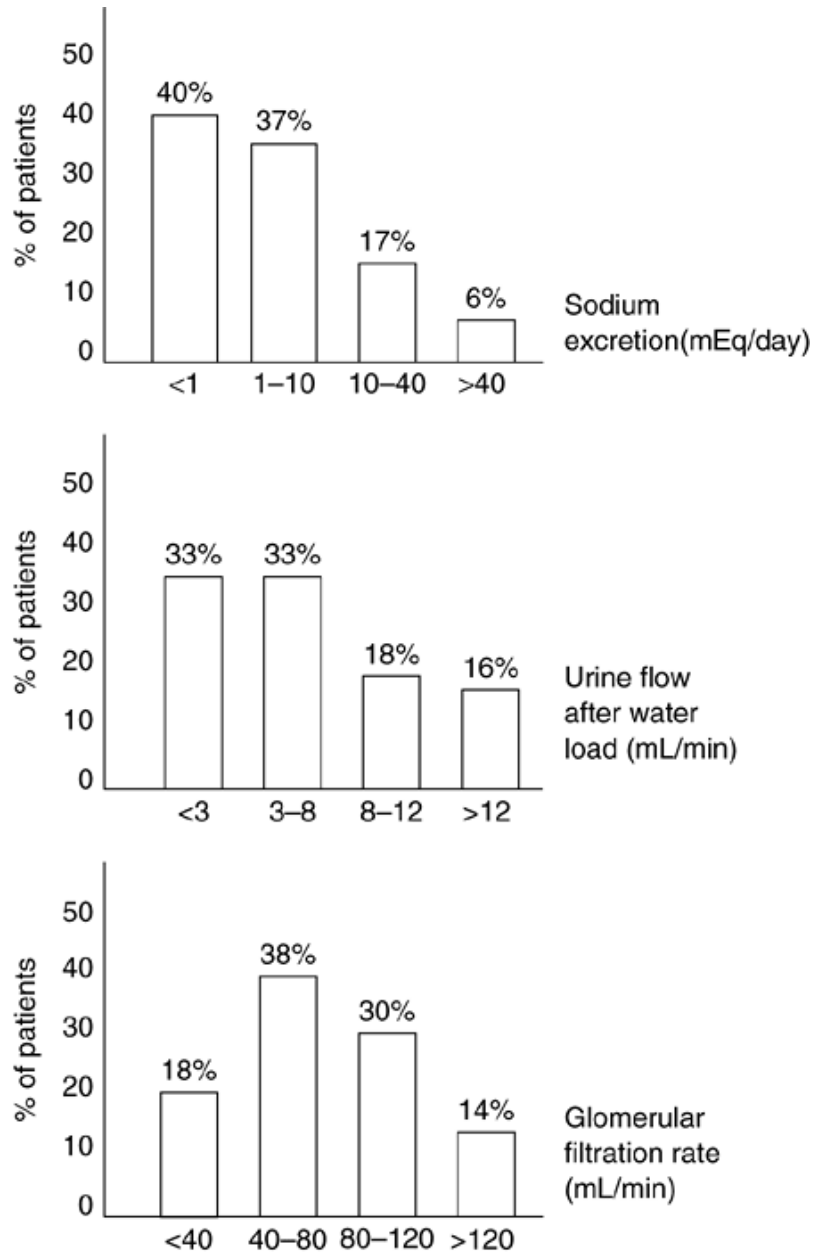
Patients with cirrhosis without ascites usually have normal or only slightly impaired renal water handling. In these patients, total body water, plasma osmolality, and serum sodium concentration are normal and do not develop hyponatremia even in conditions of high fluid intake (3,4,14,15). In contrast, an impairment in the renal capacity to excrete solute-free water is common in patients with cirrhosis and ascites. Approximately 75% of patients with cirrhosis and ascites have an impaired renal water handling, as indicated by an inability to eliminate a water load (20 mL/kg of 5% dextrose)(16). However, the intensity of this disorder is not uniform and varies markedly from patient to patient (Fig. 17.2). In some patients, impaired solute-free water excretion is moderate and can be detected only after the administration of a water load (16). These patients maintain a normal serum sodium concentration as long as their water intake is kept within normal limits. However, they may develop dilutional hyponatremia and hypo-osmolality when water intake is increased (i.e., administration of intravenous fluids in hospitalized patients) (6). Therefore, a normal serum sodium concentration in a patient with cirrhosis and ascites is not synonymous with a normal renal capacity to excrete solute-free water. In other patients, the severity of solute-free water retention is such that they retain most of the water in their diet, causing spontaneous dilutional hyponatremia and hypo-osmolality. Additionally, impairment in solute-free water excretion may be aggravated by administration of diuretics or NSAIDS and large-volume paracentesis without plasma volume expansion (17,18). Dilutional hyponatremia defined as serum sodium level <130 mEq/L in cirrhosis occurs in the presence of marked sodium

retention, with water being retained in excess of sodium, leading to the dilution of body fluids and a fall in serum sodium concentration (19). This indicates that in patients with cirrhosis, sodium retention occurs first and the inability to excrete solute-free water is a later event (Fig. 17.1). Moreover, patients with marked impairment in solute-free water excretion have a high risk of developing HRS during follow-up (20).

The pathogenesis of solute-free water retention in cirrhosis seems to be related to three events: (i) A reduced delivery of filtrate to the ascending limb of the loop of Henle (the diluting segment of the nephron), (ii) a reduced renal synthesis of prostaglandins (PGs), and (iii) an increased secretion of arginine vasopressin (AVP), the antidiuretic hormone (14,21). Among these, AVP is probably the most powerful factor that triggers intense solute-free water retention in cirrhosis with ascites. High levels of AVP in cirrhosis due to nonosmotic hypersecretion of AVP from the neurohypophysis

in response to a reduced effective intravascular volume secondary to vasodilatation in the splanchnic circulation are responsible for water reabsorption in the distal collecting duct of the kidney (see later). The renal synthesis of PGE_2 is increased in patients with cirrhosis to counteract the water-retaining effect of AVP and hence NSAIDs may impair the renal ability to excrete solute-free water in these patients (6,17).





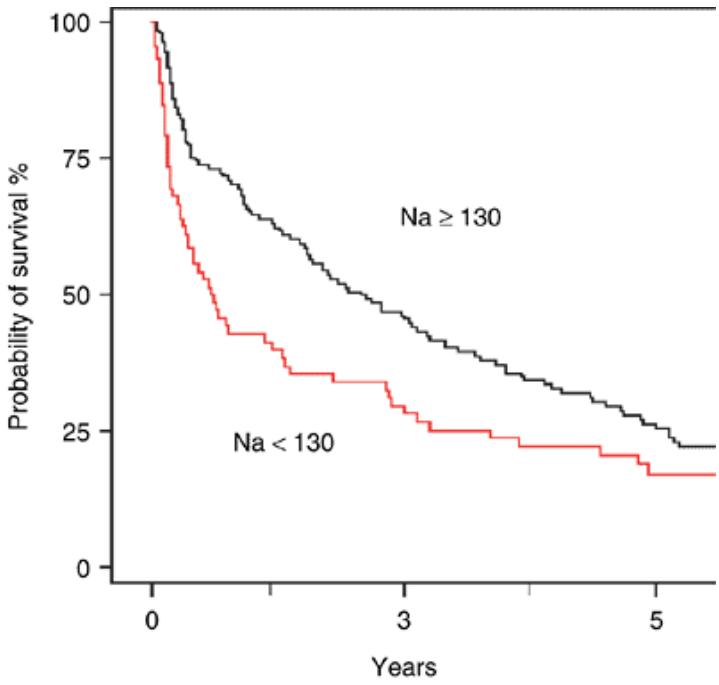
▪ **Figure 17.2** Urinary sodium excretion, diuresis after a water load (20 mL/kg body weight of 5% dextrose IV) and glomerular filtration rate (GFR, insulin clearance) in a series of patients with cirrhosis hospitalized for the treatment of an episode of ascites. All patients were studied after a minimum of 5 days on a 50 mEq/day sodium diet and without diuretic therapy. Values in healthy subjects studied under the same conditions are urine sodium, 40 to 60 mEq/day; diuresis after a water load, 10 to 18 mL/minute; GFR, 110 to 140 mL/minute. Most patients had marked sodium and water retention. Moderate reductions of GFR were present in two thirds of patients, whereas a marked reduction of this parameter was found in 18%. (From Ginès P, Fernández-Esparrach G, Arroyo V, et al. Pathophysiology of ascites. *Semin Liver Dis* 1997;17:175, with permission.)

As stated previously, the clinical consequence of impairment in solute-free water

excretion is the development of hyponatremia. This type of hyponatremia is referred to as *dilutional hyponatremia* because it occurs in the setting of an increased total body water and dilution of extracellular fluid volume. Dilutional hyponatremia associated with sodium retention and increased total body sodium level should be distinguished from true hyponatremia due to sodium depletion that, although less common, may develop in patients with cirrhosis who are maintained on high doses of diuretics causing a negative sodium balance after complete resolution of ascites and edema. The prevalence of spontaneous dilutional hyponatremia in hospitalized patients with cirrhosis and ascites is approximately 30% (22,23). Spontaneous dilutional hyponatremia is also associated with poor survival among patients with cirrhosis and ascites with an estimated 1-year probability of survival of 40% (A. Cárdenas, P. Ginès, unpublished observations, 2003) (Fig. 17.3). Although hyponatremia in cirrhosis and ascites had been recognized as a marker of poor prognosis in the past, it was not considered an important prognostic factor in clinical practice. Only recently it has gained attention as a strong prognostic marker, particularly in patients awaiting liver transplantation, given that several reports indicate that when serum sodium concentration is combined with the Model for End-Stage Liver Disease (MELD) score it improves the prognostic accuracy of MELD in patients listed for orthotopic liver transplantation (24,25,26).

Patients with cirrhosis and ascites usually develop dilutional hyponatremia over several days or weeks. In most patients the degree of hyponatremia is mild, with levels ranging from 125 to 130 mEq/L; nonetheless some patients may have lower values reaching 110 to 125 mEq/L (22). In some patients, hyponatremia is asymptomatic, but in others it may be associated with

clinical symptoms similar to those found in hyponatremia of other etiologies, including nausea, vomiting, apathy, anorexia, headache, difficulty in mental concentration, disorientation, sluggish thinking, and lethargy. Nevertheless, neurologic symptoms related to hyponatremia may be difficult to distinguish from those of hepatic encephalopathy, which may also occur concomitantly with dilutional hyponatremia. Important advances have been made trying to elucidate the role of hyponatremia and its relationship with hepatic encephalopathy. The astrocytes of patients with cirrhosis and hyponatremia have a reduced amount of organic osmolytes (mainly myo-inositol) as measured by magnetic resonance spectroscopy, that may help prevent the development of brain cell edema (27,28). This indicates that organic osmolytes could play a role in cerebral fluid homeostasis in cirrhosis, and in theory they predispose to disturbances in neurologic function. Preliminary studies in patients with cirrhosis and refractory ascites suggest that dilutional hyponatremia is a major predisposing factor to the development of hepatic encephalopathy (29). Further studies in this area are required to establish this possible pathogenic relationship.



▪ **Figure 17.3** Survival of a large group of patients with cirrhosis and ascites with and without dilutional hyponatremia (P. Ginès & A. Cárdenas, *unpublished data*, 2003).

Renal Vasoconstriction and Hepatorenal Syndrome

Renal vasoconstriction leading to decreased renal perfusion is the renal functional abnormality that develops last in patients with cirrhosis and ascites (Fig. 17.1) (2,6). As with the impairment in sodium and solute-free water excretion, the intensity of renal vasoconstriction is variable among patients with ascites (Fig. 17.2). Moderate degrees of renal vasoconstriction are commonly overlooked in clinical practice, because tests used to estimate GFR in the clinical setting have low sensitivity in cirrhosis due to a low endogenous production of creatinine. The existence of a moderate renal vasoconstriction (serum creatinine between 1.2 and 1.5 mg/dL, which corresponds to a median GFR of approximately 50 mL/minute) in patients with cirrhosis and ascites is clinically relevant for several reasons. First, a significant proportion of these patients have refractory ascites, as sodium and water excretion are markedly impaired. Second, moderate renal vasoconstriction predisposes to the development of HRS (20). Finally, mortality is higher in these patients than in those with normal renal perfusion (20,30).

An increased activity of vasoconstrictor factors (mainly plasma renin activity and norepinephrine) and reduced activity of renal vasodilator factors acting on the renal circulation play the most important role in the pathogenesis of HRS because renal vasoconstriction in cirrhosis occurs in the absence of morphologic changes in the kidney (1). The pathogenesis of renal vasoconstriction in cirrhosis is also related to changes in systemic hemodynamics. The most accepted theory considers that renal vasoconstriction is the consequence of the extreme underfilling of the systemic arterial circulation due to marked vasodilatation of the splanchnic circulation, which activates homeostatic vasoconstrictor systems,

whose effect on the kidney vasculature cannot be counterbalanced by either renal or systemic vasodilators (31,32). As a consequence, severe vasoconstriction of renal vessels occurs and HRS ensues. Nonetheless, other reasons causing renal dysfunction in cirrhosis have been suggested. For instance, a role for intrahepatic adenosine causing an increase in portal venous blood flow and triggering a hepatorenal reflex to regulate sodium and water excretion has been recently proposed as a mechanism that may lead to decreased renal perfusion and HRS (33,34). This mechanism by means of increasing sympathetic activity in the kidney probably decreases renal blood flow and GFR (34,35). In humans, the presence of hepatorenal reflex has been suggested with observations of reduced renal blood flow following an increase in portal pressure and renal release of endothelin, suggesting that this vasoconstrictor could perhaps play a role in this reflex (35). Further studies in animals and humans are needed to elucidate the role of hepatorenal reflex in HRS.

The definition of HRS proposed by the International Ascites Club is the most widely accepted and states: "Hepatorenal syndrome is a clinical condition that develops in patients with chronic liver disease and advanced hepatic failure and portal hypertension characterized by impaired renal function and marked abnormalities in the arterial circulation and activity of the endogenous vasoactive systems. In the kidney, there is marked renal vasoconstriction that results in low GFR. There is also vasoconstriction in other vascular territories such as the muscle, spleen and brain. In the splanchnic circulation, there is an intense arteriolar vasodilatation that results in reduction of total systemic vascular resistance and arterial hypotension. A similar syndrome can also develop in the setting of acute liver failure" (32).

The incidence of HRS in patients with cirrhosis hospitalized for ascites is approximately 10% (20). However, the probability of developing HRS in patients with cirrhosis and ascites is 18% at 1 year and increases to 39% at 5 years (20). Two different types of HRS that represent distinct expressions of the same pathogenic mechanism have been defined (Table 17.2) (32). Renal failure in HRS in most cases is associated with oliguria, marked sodium retention, and spontaneous dilutional hyponatremia. Patients with type 1 HRS (serum creatinine >2.5 mg/dL [220 μmol/L]) develop a very rapid and aggressive course of illness, becoming very ill in a matter of days to weeks; these patients usually have signs of advanced liver disease. In nearly half of patients,

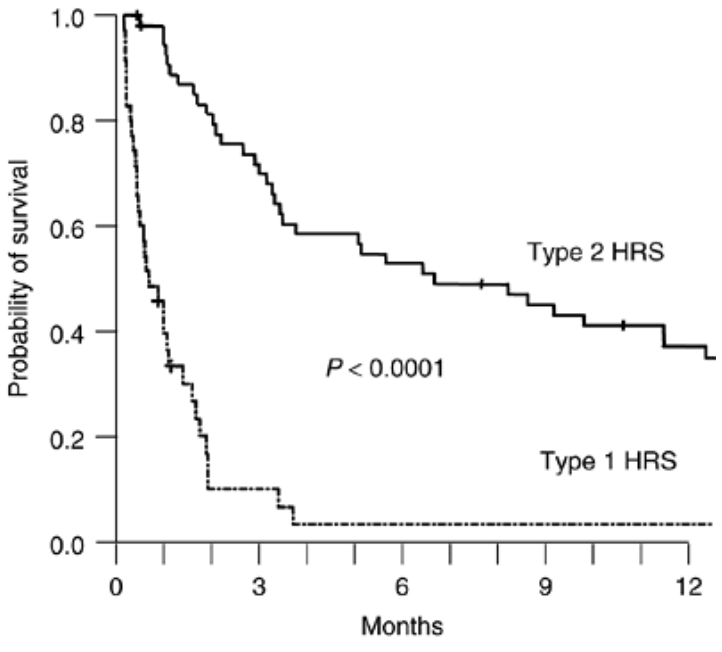
this type of HRS develops spontaneously without any identifiable precipitating factor, whereas in the rest it can occur in close association with systemic bacterial infections such as spontaneous bacterial peritonitis (SBP), surgical operations, and acute alcoholic hepatitis (30,32,36). In addition, large-volume paracentesis (≥5 L) without albumin expansion may precipitate type 1 HRS in approximately 20% of cases (18). This is one of the reasons why intravenous albumin is routinely administered after large-volume paracentesis in patients with cirrhosis and ascites. Bacterial infections in patients with cirrhosis, particularly SBP, are now recognized as the most common precipitating cause of type 1 HRS, which occurs in approximately one third of cases with SBP despite resolution of the infection with intravenous antibiotics (37,38,39). Renal failure occurs in 10% of patients with cirrhosis and gastrointestinal bleeding (40). However, renal failure in this setting occurs mainly in patients who develop hypovolemic shock, suggesting acute tubular necrosis (ATN) and not HRS as the cause of renal failure (40). Although contrast media for radiologic procedures was previously felt to be a frequent precipitant of renal failure in patients with cirrhosis and ascites,

recent data indicates that contrast media in these patients is very infrequently associated with the development of renal failure (41).

Table 17.2. Clinical Types of Hepatorenal Syndrome

Type 1	Rapid and progressive impairment of renal function as defined by a doubling of the initial serum creatinine to a level higher than 2.5 mg/dL (220 μmol/L) or a 50% reduction of the initial 24-h creatinine clearance to a level lower than 20 mL/min in <2 wk
Type 2	Impairment in renal function with serum creatinine >1.5 mg/dL (130μmol/L) that does not meet criteria for type 1

Without treatment, the median survival time of patients with type 1 HRS is approximately 1 month and practically all patients die within 10 to 12 weeks of renal failure onset (20,30,42). The MELD score along with type of HRS have an independent prognostic value for survival (43) (Fig. 17.4). Most patients with type 1 HRS have a MELD score ≥20 (43). In contrast to type 1 HRS, type 2 HRS is characterized by a less severe and stable reduction of GFR (serum creatinine levels are usually <2.0 mg/dL or 177 μmol/L). The main clinical consequence of type 2 HRS is diuretic-resistant ascites due to the combination of intense sodium retention and reduced GFR. As expected, survival is longer in patients with type 2 HRS than in those with type 1 HRS, but is shorter than that of patients with cirrhosis and ascites without renal failure (20,42,43) (Fig 17.4). In patients with type 2 HRS, a MELD score of 20 or more is also associated with a poor outcome (43).



▪ **Figure 17.4** Probability of survival of patients with cirrhosis according to type of hepatorenal syndrome (HRS). (From Alessandria C, Ozdogan O, Guevara M, et al. MELD score and clinical type predict prognosis in hepatorenal syndrome: relevance to liver transplantation. *Hepatology* 2005;41:1282–1289, with permission.)

Predictive factors associated with a greater risk of developing HRS have been described in patients with cirrhosis and ascites (Table 17.3) (20,30). Patients with intense sodium retention (<10 mEq/day), spontaneous dilutional hyponatremia (serum sodium <130 mEq/L), low mean arterial blood pressure (<85 mm Hg), decreased cardiac output (<6.0 L/minute) and increased plasma renin activity, aldosterone, and norepinephrine levels have a high probability of developing HRS (20,30). Other parameters such as the degree of liver failure, as assessed by parameters of liver function (serum bilirubin, albumin, and prothrombin time), the Child-Pugh score, and hepatic venous pressure gradient have not consistently shown to predict the development of type 1 HRS.

There is no specific test or marker for the diagnosis of HRS. The diagnosis of HRS is based on the demonstration of a reduced GFR in the absence of data suggesting other causes of renal failure. The proposed criteria for the diagnosis of HRS are listed in Table 17.4 (32). Low GFR is defined as serum creatinine level greater than 1.5 mg/dL (130 μmol/L) or 24-hour- creatinine clearance lower than 40 mL/minute, without diuretic therapy. Other criteria include the absence of precipitants of renal failure (i.e., volume depletion, shock, bacterial infections, or nephrotoxic drugs), no improvement of renal function following diuretic withdrawal and plasma expansion, no proteinuria, and a normal renal ultrasonogram. Other causes of renal failure in cirrhosis such as prerenal renal failure secondary to volume depletion, ATN, drug-induced nephrotoxicity

(mainly from nonsteroidal anti-inflammatory agents or aminoglycosides), and glomerulonephritis in patients with hepatitis B or C should be excluded before the diagnosis of HRS is made. Most cases of HRS have urine sodium level below 10 mEq/L.

Table 17.3. Parameters Associated with a Higher Risk of Hepatorenal Syndrome Development in Nonazotemic Patients with Cirrhosis and Ascites[a]

Previous episodes of ascites
Poor nutritional status
Moderately increased BUN[b]
Moderately increased serum creatinine[b]
Low serum sodium (serum sodium <130 mEq/L)
Low urinary sodium excretion (urine sodium <10 mEq/L)
High plasma renin activity (>4 ng/mL per h)
Low mean arterial pressure (<85 mm Hg)
Reduced solute-free water excretion after water load (<3 mL/min)
Increased plasma norepinephrine (>500 pg/mL)

Presence of esophageal varices
Model for End-Stage Liver Disease score

[a]All measurements were obtained after a minimum of 5 days on a low-sodium diet and without diuretics.
[b]Blood urea nitrogen and serum creatinine values up to 30 mg/dL and 1.5 mg/dL (130 μmol/L), respectively.

Incidence, predictive factors, and prognosis of hepatorenal syndrome in cirrhosis. *Gastroenterology* 1993;105:229–236; Ruiz del Arbol L, Monescillo A, Arocena C, et al. Circulatory function and hepatorenal syndrome in cirrhosis. *Hepatology* 2005;42:439–447.

Table 17.4. Diagnostic Criteria of Hepatorenal Syndrome According to the International Ascites Club[a]

Major criteria

1. Low glomerular filtration rate, as indicated by serum creatinine >1.5 mg/dL (130 μmol/L) or 24-h creatinine clearance <40 mL/min
2. Absence of shock, on-going bacterial infection, fluid losses, and current treatment with nephrotoxic drugs
3. No sustained improvement in renal function (decrease in serum creatinine to 1.5 mg/dL [130 μmol/L] or less or in crease in creatinine clearance to 40 mL/min or more) following diuretic withdrawal and expansion of plasma volume with 1.5 L of a plasma expander
4. Proteinuria <500 mg/d and no ultrasonographic evidence of obstructive uropathy or parenchymal renal disease

Additional criteria

1. Urine volume <500 mL/d
2. Urine sodium level <10 mEq/L
3. Urine osmolality > plasma osmolality
4. Urine red blood cells <50 per high-power field
5. Serum sodium concentration <130 mEq/L

[a]Only major criteria are necessary for the diagnosis of hepatorenal syndrome.

Other Renal Abnormalities in Cirrhosis

Patients with cirrhosis may also develop nonfunctional abnormalities of renal

function, particularly glomerular diseases, ATN, renal tubular acidosis (RTA), and drug-induced renal diseases.

The development of glomerular diseases occurs mainly in association with hepatitis B and C viruses as well as with alcoholic liver disease. Although there are no studies specifically assessing the incidence of ATN in cirrhosis, it may occur in patients who develop volume depletion in different clinical settings, such as septic or hypovolemic shock or after the administration of nephrotoxic drugs (42,44,45). If renal failure is secondary to volume depletion, renal function may improve after volume repletion and treatment of the precipitating factor. While hypovolemic shock related to gastrointestinal bleeding is easily recognized, the presence of septic shock may be more difficult to diagnose because of the subtle symptoms of bacterial infections in some patients with cirrhosis. Patients with cirrhosis are also at high risk of developing renal failure due to ATN when treated with aminoglycosides (44,45). Because of this high risk of nephrotoxicity and the existence of other effective antibiotics (i.e., third-generation cephalosporins) treatment with aminoglycosides should be avoided in patients with chronic liver disease. RTA may occur in cirrhosis of different etiologies, particularly primary biliary cirrhosis, autoimmune hepatitis, and alcoholic cirrhosis (46). The most common type of RTA in cirrhosis is the incomplete distal RTA. This form is usually subclinical and can be diagnosed only by measuring urinary pH following acid loading.

One of the most common types of renal failure physicians encounter when treating patients with cirrhosis is drug-induced renal dysfunction. Patients with cirrhosis may develop sodium and water retention or renal failure when treated with a variety of drugs, especially NSAIDs, aminoglycosides, diuretics, or vasodilators (45,47,48). Of these, the most important and commonly used in patients with cirrhosis are NSAIDS and diuretics. NSAIDs inhibit the enzymes cyclo-oxygenase 1 (COX-1) and COX-2 that are responsible for PG synthesis. PGs are important renal vasodilators that contribute significantly to maintaining normal renal perfusion. Renal failure has been reported to occur after a short treatment with a variety of NSAIDs, including indomethacin, aspirin, ibuprofen, naproxen, and sulindac (47,48,49,50,51). In these studies, the GFR quickly returned to the pretreatment values after cessation of the drug. However, it is not known whether renal failure may be reversible in patients treated for longer periods. Recent studies in patients with cirrhosis and ascites indicate that

COX-2 enzyme inhibitors do not cause renal failure when administered for a short period (51,52). The incidence of renal impairment during diuretic treatment ranges between 20% and 40% (48,53). This diuretic-induced renal failure is usually moderate and reversible after diuretic withdrawal and is related to an imbalance between the fluid loss from the intravascular space caused by diuretic treatment and the passage of fluid from the peritoneal compartment to the general circulation.

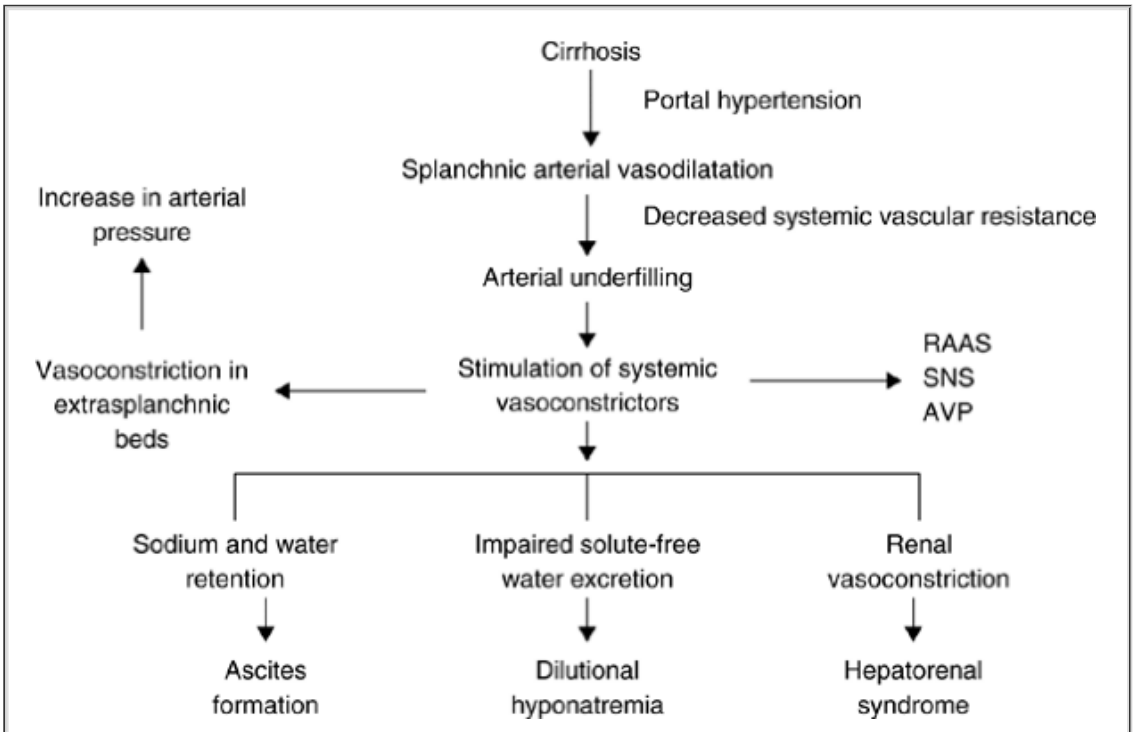
Factors Responsible for the Renal Functional Abnormalities in Cirrhosis

There are several intrarenal and extrarenal factors that have been proposed as potential mediators of functional renal abnormalities in cirrhosis. However, a common pathway for these derangements seems to be the development of an intense splanchnic arterial vasodilatation, which triggers an important compensatory response accounting for the three main renal function

abnormalities described earlier (Fig. 17.5). A concise review of these systems is provided in the subsequent text.

Extrarenal Factors

Most patients with cirrhosis and ascites show an overactivity of the two major vasoconstrictor and antinatriuretic systems, the RAAS and SNS (12,13,31,33). In addition, as described in the preceding text, there is also a nonosmotic hypersecretion of AVP. The activation of these systems is significantly more pronounced, once the patients develop HRS. These systems are activated in response to a reduced effective arterial blood volume, which is due to marked splanchnic vasodilatation. A large body of evidence indicates that the activation of these systems plays a major role in the increased tubular reabsorption of sodium and water in cirrhosis (12,13,31,33). However, in approximately 20% to 30% of patients with cirrhosis and ascites the serum levels of renin, aldosterone, and norepinephrine are normal. This is an unanswered question, but it has been suggested that increased renal tubular sensitivity to aldosterone or catecholamines (15,54), the decreased synthesis of a putative hepatic natriuretic factor (55), or existence of a "hepatorenal reflex" (see preceding text) could explain this phenomenon (33,34,35,54).



▪ **Figure 17.5** The pathogenesis of functional renal abnormalities in cirrhosis according to the arterial vasodilatation theory. RAAS, renin-angiotensin-aldosterone system; SNS, sympathetic nervous system; AVP, arginine vasopressin.

The activation of the RAAS and SNS is very intense in patients with HRS, which suggests that they participate in the pathogenesis of vasoconstriction of the renal circulation (12,13). Increased plasma levels of AVP enhance the solute-free water reabsorption in the collecting ducts and contribute to the water retention and

spontaneous dilutional hyponatremia (21). The pharmacologic interruption or blockade of the effectors of these three major vasoconstrictor systems (angiotensin II, norepinephrine, and AVP) in human or experimental cirrhosis results in marked reduction of total systemic vascular resistance and arterial hypotension, which suggests that these systems are activated as a homeostatic response to maintain arterial pressure within normal limits (56,57). The circulating levels of endothelin-1, an endothelial-derived peptide

with potent vasoconstrictor effect, are also increased in cirrhosis (58,59). These increased levels are probably due to an enhanced release of the peptide from the hepatic and/or splanchnic circulation (60,61). It has been proposed that the increased circulating levels and/or enhanced intrarenal production of endothelin may induce vasoconstriction of the renal circulation and play a role in the pathogenesis of HRS (62,63).

The plasma concentration of major natriuretic hormones, namely, atrial natriuretic peptide and brain natriuretic peptide, is increased in patients with cirrhosis and ascites (64,65,66). These increased plasma levels are due to an enhanced cardiac release and not due to a reduced systemic or hepatic clearance. Because natriuretic peptides have powerful effects on renal function (mainly vasodilator and natriuretic effects) and inhibit renin release, it is possible that increased natriuretic peptide levels may act as a homeostatic mechanism to counteract the effects of antinatriuretic and vasoconstrictor systems in the renal circulation.

Intrarenal Factors

In addition to extrarenal factors, a number of intrarenal factors with powerful effects on the renal circulation and/or tubular transport of sodium and water play an important role in the functional renal abnormalities of cirrhosis. Metabolites of arachidonic acid are the most widely studied metabolites of the intrarenal system. Arachidonic acid is metabolized in the kidney through three separate pathways involving different enzymes, namely, cyclo-oxygenases, lipoxygenases, and microsomal cytochrome P-450. The most important of these three pathways is dependent on cyclo-oxygenases and gives rise to PGs. The renal PGs, namely PGI_2 and PGE_2, by exerting vasodilatation have a protective effect on sodium and water transport and on renal circulation in conditions such as cirrhosis with ascites characterized by a marked activation of vasoconstrictor systems (17,47,67,68). Patients with cirrhosis and ascites without renal failure show increased renal production of vasodilator PGs compared with healthy subjects or patients without ascites (47,67,68). This increased production contributes to the maintenance of renal hemodynamics. This is demonstrated by the fact that PG synthesis inhibition by NSAIDs causes renal failure, particularly in patients with marked activation of vasoconstrictor systems (47,48,49,50,51). By contrast, patients with cirrhosis and HRS have a reduced renal production of PGs: PGE_2 and $PGF_{1\alpha}$ (1,68). These findings have been interpreted as indicative that the regulation of renal circulation in cirrhosis with ascites depends on an adequate balance between vasoconstrictor systems and intrarenal production of PGs. An imbalance between these vasoconstrictor systems and PGs likely contributes to renal vasoconstriction. However, eicosanoids with vasoconstrictor effects, such as cysteinyl leukotrienes or F_2-isoprostanes, may also participate in renal vasoconstriction in cirrhosis (67,68,69). In summary, the regulation of renal circulation in cirrhosis with ascites is a complex process which depends on an adequate balance between vasoconstrictor systems and intrarenal production of

PGs.

Nitric oxide (NO) locally synthesized in different structures within the kidney also participates in the regulation of renal function. Under normal circumstances, NO plays a role in the regulation of glomerular microcirculation by modulating the arteriolar tone and the contractility of mesangial cells. Moreover, NO facilitates natriuresis in response to changes in renal perfusion pressure, and regulates renin release (70). There is limited information on the role of NO in the regulation of renal function in cirrhosis, but it appears likely that NO interacts with PGs to maintain renal hemodynamics in cirrhosis with ascites (71,72,73).

Pathogenesis of Renal Functional Abnormalities

Although several theories have been proposed to explain the renal function abnormalities present in cirrhosis, the arterial vasodilatation theory still seems to be the most rational explanation for these derangements (31) (Fig. 17.5). This theory proposes that ascites formation and renal function abnormalities are the result of the effect of vasoconstrictor systems (RAAS and SNS) on the renal circulation activated as a homeostatic mechanism to improve the underfilling of the arterial circulation. This mechanism is qualitatively similar to what occurs in states of volume depletion. However, in volume depletion the activated mechanisms responsible for sodium retention are turned off as soon as the extracellular fluid volume reaches normal values, thereby preventing the appearance of edema. By contrast, in edematous conditions like cirrhosis, antinatriuretic mechanisms remain activated despite a progressive expansion of the extracellular fluid volume and edema formation.

According to the arterial vasodilatation theory, the initial abnormality causing renal sodium retention would be a sinusoidal portal hypertension leading to a marked arterial vasodilatation located mainly in the splanchnic circulation. Potential substances involved in this vasodilatation include NO and vasodilator peptides. NO seems to be the most important substance mediating vasodilatation in this territory (74). Splanchnic arterial vasodilatation would result in an abnormal distribution of blood volume with reduction of effective

arterial blood volume (i.e., the blood volume in the heart, lungs, and central arterial tree that is sensed by arterial receptors) and subsequent renal sodium and water retention due to the activation of vasoconstrictor and antinatriuretic factors. In the preascitic stage (increased total blood volume without ascites or edema), the retained fluid would suppress sodium and water retention and reset fluid balance at an upper level of blood volume. In addition, there is a homeostatic increase in cardiac output as a result of a decreased afterload. However, as the disease progresses more and more vasodilatation would be produced in the splanchnic circulation and the effective arterial blood volume would no longer be maintained by the increased total blood volume, and leakage of fluid from the splanchnic circulation to the peritoneal cavity is what results as ascites. At this point, a persistent activation of vasoconstrictor and antinatriuretic systems occurs in an attempt to maintain a normal effective arterial blood volume and arterial pressure. Vasodilatation is so intense that the increased cardiac output is not sufficient to maintain circulatory homestasis. The continuous leakage of intravascular fluid to the peritoneal cavity likely explains the paradox of unrelenting activation of antinatriuretic systems in the setting of an increased extracellular fluid volume. In very advanced stages of the disease, the disturbance in the splanchnic circulation is so intense that systemic

hemodynamics can be maintained only at the expense of severe vasoconstriction in most vascular beds, including the renal circulation, and HRS develops. Recent studies suggest that the development of HRS occurs in the setting of a reduction in cardiac output, indicating that the progression of circulatory and renal dysfunction in cirrhosis are not only due to splanchnic vasodilatation but also due to a reduction in cardiac output (30,75). This suggests that HRS may be the consequence of a fall in cardiac output in the setting of marked splanchnic vasodilatation (30).

Management of the Functional Renal Abnormalities in Cirrhosis

Sodium Retention and Ascites

The management of patients with cirrhosis and ascites is discussed in detail in Chapter 19.

Solute-Free Water Retention and Hyponatremia

Although hyponatremia is associated with a poor prognosis, there are no studies indicating that correcting hyponatremia per se is associated with an improved survival. Treating the underlying liver disease is the most important aspect of treatment and therefore evaluation for liver transplantation is mandated in all patients presenting with spontaneous dilutional hyponatremia. At present, no approved pharmacologic therapy exists for dilutional hyponatremia and the only therapeutic measure that may slow the progressive decrease in serum sodium concentration is water restriction to 1 L/day. Fluid restriction in patients with cirrhosis and dilutional hyponatremia is not very effective in raising serum sodium levels. However, in a randomized placebo-controlled study comparing placebo versus a V2 receptor of AVP antagonist, fluid restriction did not increase serum sodium, but it did prevent it from lowering further (76). The administration of hypertonic saline solutions is not recommended because it invariably leads to further expansion of extracellular fluid volume and marked accumulation of ascites and edema (19). Moreover, these patients also have marked sodium retention and therefore their sodium intake must also be restricted. Also, as mentioned earlier, certain circumstances such as the use of NSAIDs and large-volume paracentesis without volume expansion with albumin should be avoided.

Pharmacologic approaches to the management of dilutional hyponatremia in cirrhosis have focused on inhibiting the actions of AVP. The most promising types of drugs are the antagonists of the V2 receptor of AVP which are under clinical investigation (19,76,77,78). These agents selectively antagonize the water-retaining effect of AVP in the cortical collecting duct and increase solute-free water excretion, decrease body weight, and raise serum sodium levels in patients with cirrhosis, ascites, and dilutional hyponatremia (76,78). Results of further large-scale phase III trials will certainly help define the usefulness of V2 receptor antagonists in clinical practice.

Renal Vasoconstriction and Hepatorenal Syndrome

Prevention

HRS can be prevented in two clinical settings. In patients with SBP, the administration of albumin (1.5 g/kg body weight at diagnosis of infection and 1

g/kg body weight 48 hours later) prevents the circulatory dysfunction and subsequent development of HRS (39). Because SBP may trigger HRS by decreasing effective arterial blood volume, the rationale for albumin administration is to prevent arterial underfilling and subsequent activation of vasoconstrictor systems during the infection (39). The incidence of HRS in patients with SBP receiving albumin together with antibiotic therapy is 10%, compared to that of 33% in patients not receiving albumin. Most importantly, hospital mortality was lower in patients receiving albumin (10%) versus those not receiving plasma expansion (29%) (36). In patients

with acute alcoholic hepatitis, the administration of pentoxifylline, an inhibitor of tumor necrosis factor-α (400 mg t.i.d. orally for 28 days) reduces the incidence of HRS and mortality (8% and 24%, respectively) with respect to a control group (35% and 46%, respectively) (36). Although there are no follow-up studies confirming these results, these two approaches are widely used in the clinical setting owing to the wide accessibility of albumin and pentoxifylline in most centers.

Pharmacologic therapy

While considering pharmacologic therapy, all patients with HRS should be evaluated for liver transplantation because it is the best treatment as it removes the diseased liver that causes disturbances in renal function. A variety of pharmacologic interventions have been attempted over the years to treat HRS. Drugs with renal vasodilator activity were used in patients with HRS in an attempt to counteract the effect of vasoconstrictor factors on renal circulation. Dopamine was the first drug used because of its renal vasodilatory effect when given in suppressor doses. Studies specifically assessing the effects of dopamine on renal function in series of patients with HRS showed no or only minor effects on GFR; therefore, there are no data to support its use in clinical practice in patients with HRS (79,80). The second type of renal vasodilators used in patients with HRS are PGs and PG analogs. The rationale for the use of PGs is based on the fact that renal vasoconstriction in HRS is partly related to a reduced intrarenal synthesis of vasodilator PGs. Unfortunately, no consistent beneficial effects on renal function were observed after the intravenous or intra-arterial administration of PGA_1 or PGE_2 (1,15). The oral administration of misoprostol (a PGE_1 analog) was found to improve renal function in one study but this beneficial effect was not confirmed in a subsequent investigation (81,82). The problem with this drug is the high incidence of side effects, especially diarrhea. Other approaches such as the use of endothelin blockers (BQ123) and *N*-acetylcysteine seem to be promising, but larger uncontrolled as well as controlled studies are needed to confirm their role in the therapy of HRS (83,84).

Systemic vasoconstrictors with plasma expansion seem to be the best therapy because several studies have confirmed their beneficial role in HRS, particularly type 1 HRS (80,85,86,87,88,89,90,91,92,93,94,95,96,97,98,99,100,101) Although using vasoconstrictors in a condition characterized by renal vasoconstriction seems paradoxical, the rationale is based on the fact that the initial event in the pathogenesis of HRS is an arterial splanchnic vasodilatation causing activation of endogenous vasoconstrictors. Vasoconstrictors used for treatment of HRS include vasopressin analogs (terlipressin) that have a potent vasoconstrictor effect through the action on V1 receptors with a low V2 receptor agonist activity, somatostatin analogs (octreotide) that act as glucagon inhibitors, and α-adrenergic agonists (midodrine and noradrenaline) that also

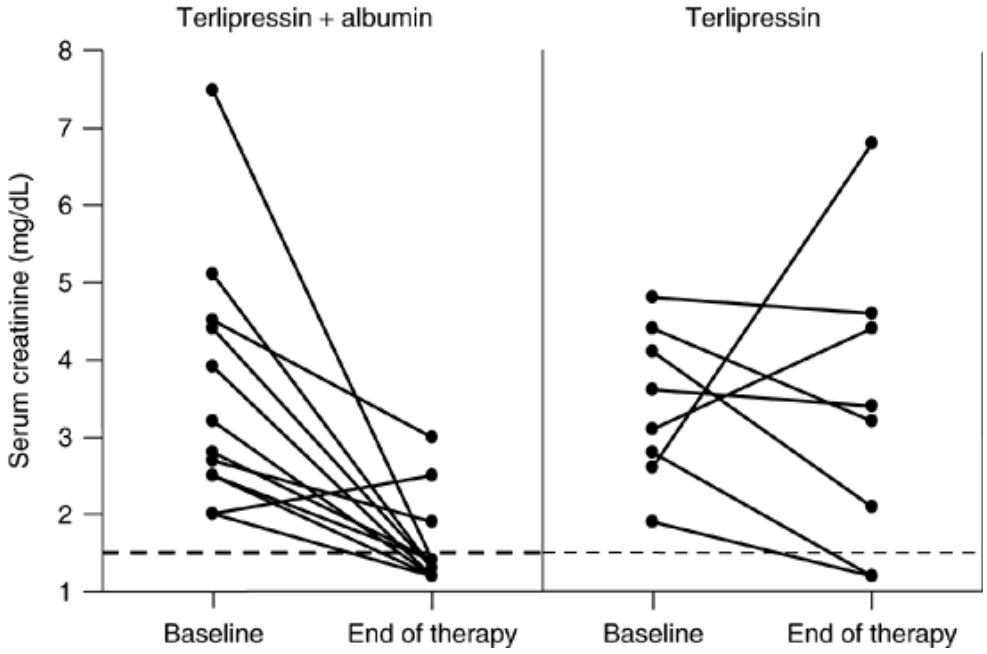
cause vasoconstriction by acting on α_1-adrenergic receptors. In most studies, vasoconstrictors have been given in combination with plasma expansion (albumin), which seems to improve the efficacy of treatment.

Vasopressin analogs have a marked vasoconstrictor effect in the splanchnic circulation and have been used for many years in the management of acute variceal bleeding in patients with cirrhosis. The administration of terlipressin and albumin is associated with a significant improvement in GFR and reduction of serum creatinine level below 1.5 mg/dL in 42% to 92% of patients with type 1 HRS (89,90,91,92,93,94,95,96,97,98,99,102) (Fig. 17.6). Ornipressin and vasopressin, although effective in HRS, caused significant ischemic side effects in approximately 30% to 40% of patients and were abandoned (85,86,87). The incidence of ischemic side effects with terlipressin is lower and occurs only in 5% to 10% of cases (89,90,91,92,93,94,95,96,97,98,99,102). Patients with Child-Pugh scores of 13 or higher and those who do not receive albumin expansion do not seem to respond well to this treatment (90,91). There may be recurrence after stopping treatment and a repeat course of terlipressin with albumin is usually effective (90,91). In addition, survival of responders to terlipressin is better than that of nonresponders (90,91).

Administration of midodrine in association with octreotide, an inhibitor of the release of glucagon and other vasodilator peptides, and albumin also improves renal function in patients with cirrhosis and HRS, although information about this therapeutic approach is limited to only two studies with a total of less than 20 patients (80,100). In all cases there was a marked improvement in renal perfusion and GFR, and a suppression of renin, aldosterone, norepinephrine, and AVP to normal or near normal levels. Interestingly, octreotide is ineffective when administered alone (103). These results require confirmation in a larger group of patients. Finally, the administration of noradrenaline (0.5 to 3 mg/h) for a minimum of 5 days in association with intravenous albumin resulted in a significant improvement of renal function in a small group of 12 patients with cirrhosis and type 1 HRS (101). Reversal of HRS was observed in 10 patients in association with an increase in mean arterial pressure and a marked reduction in renin and aldosterone. There was an episode of reversible myocardial hypokinesia, and no other ischemic side effects (101).

The information about the use of vasoconstrictors in patients with HRS is somewhat limited because there are no large-scale placebo controlled studies showing that they are superior to no treatment. However, on the basis of published studies, some recommendations can

be made while awaiting the results of large randomized controlled trials:



▪ **Figure 17.6** The effects of terlipressin and albumin compared to terlipressin alone on serum creatinine levels in patients with type 1 hepatorenal syndrome. (Reprinted with permission from Ortega R, Ginès P, Uriz J, et al. Terlipressin therapy with and without albumin for patients with hepatorenal syndrome. Results of a prospective, non-randomized study. *Hepatology* 2002;36:941–948.)

1. These drugs should be used for at least 7 to 20 days, because the improvement of renal function usually occurs slowly.
2. Therapy should be aimed at reducing serum creatinine level below 1.5 mg/dL (130 µmol/L).
3. The following are the recommended dosages:
    A. Terlipressin: 0.5 mg intravenously every 4 hours; can increase dose in a stepwise manner (i.e., every 2 days) to 1 mg/4 hours and then up to 2 mg/4 hours in cases where there is no reduction of serum creatinine level.
    B. Midodrine: 7.5 mg orally three times daily with an increase to 12.5 mg three times daily if needed and octreotide: 100 µg subcutaneously three times daily with an increase to 200 µg three times daily, if needed.
    C. Noradrenaline : Titration of 0.5 to 3 mg/hour continuous intravenous infusion.
4. The concomitant administration of albumin (1 g/kg on the first day, followed by 20 to 40 g/day) as a plasma expander is recommended in all cases, although its beneficial effect has not been tested in randomized studies.
5. Contraindications: Patients with coronary artery disease, peripheral vascular

disease, and/or cerebrovascular disease due to the potential risk of ischemic events.

6. Because of limited information and the possibility of side effects, treatment with vasoconstrictors should probably be restricted at present to patients with type 1 HRS.

The most important goal of pharmacologic therapy in HRS is that of successfully reversing renal failure so that potential liver transplantation candidates can undergo transplantation with less morbidity and have survival similar to patients without HRS. Patients treated successfully with terlipressin and albumin before liver transplantation have a good posttransplantation outcome and a survival similar to that of patients without HRS, who underwent transplantation (104).

Transjugular intrahepatic portosystemic shunt

Transjugular intrahepatic portosystemic shunt (TIPS) is a nonsurgical method of portal decompression that has evolved as an alternative therapy for patients with cirrhosis who are bleeding from esophageal or gastric varices and are refractory to endoscopic and medical treatment. Although the use of TIPS has been evaluated for the treatment of refractory ascites, there are very scarce data regarding its use in the management of HRS (100,105,106,107,108). The rationale for using TIPS is based on the fact that reducing portal pressure may improve circulatory function and suppress RAAS and SNS activities. Uncontrolled studies indicate that TIPS may improve renal function and GFR as well as reduce the activities of RAAS and SNS in patients with cirrhosis and type 1 HRS (100,106,107,108). The effects on renal function and the clinical course of patients after TIPS insertion are variable. Improvement in renal function after TIPS placement alone is generally slow with success in approximately 60% of patients (100,105,106,107,108). Studies assessing TIPS for type 1 HRS have included patients with relatively preserved

liver function. Patients with a Child-Pugh score of 12 or more were excluded because of the risk of worsening liver failure and/or hepatic encephalopathy. Unfortunately, most patients with type 1 HRS fall in this category. An approach combining the use of vasoconstrictors with TIPS for treatment of type 1 HRS was reported showing that patients with preserved liver function (Child-Pugh score <12) who responded to midodrine, octreotide, and albumin and then had a TIPS inserted had an excellent outcome with renal function that continued to improve, and completely normalized (100). However, larger studies are needed to confirm these results.

In patients with type 2 HRS, TIPS improves renal function and reduces ascites (107,108,109,110). However, experience from a large series of patients with cirrhosis undergoing TIPS for refractory ascites indicates that those with a Child-Pugh score of 12 or more, hepatic encephalopathy and severe coagulopathy have a worse outcome if TIPS is placed (109,110). Although uncontrolled studies suggest that TIPS alone improves prognosis in patients with type 1 and 2 HRS (108), the impact of this therapy on patient survival remains to be assessed.

Dialysis

Hemodialysis and peritoneal dialysis have been used in the management of patients with HRS, and sporadic cases of improvement of renal function have

been reported. Unfortunately, there are no controlled studies evaluating the effectiveness of dialysis in HRS. Uncontrolled studies suggest that it is hardly effective because most patients die during treatment and there is a high incidence of severe side effects, including arterial hypotension, coagulopathy, and gastrointestinal bleeding. Although hemodialysis is not routinely recommended in HRS, it may be a reasonable option in suitable liver transplantation candidates as a bridge to transplantation when there is no response to vasoconstrictors or TIPS, or in patients who develop severe volume overload, metabolic acidosis, or refractory hyperkalemia (42). Continuous arteriovenous or venovenous hemofiltration have also been used but their efficacy also remains to be determined. Data on the extracorporeal albumin dialysis system, that is molecular adsorbent recirculating system (MARS) seem to be beneficial, but only one study is available. In this study of only 13 patients with Child-Pugh C cirrhosis and type 1 HRS, the authors reported a significant decrease in bilirubin and creatinine levels; an improvement in serum sodium level, urine volume, and mean arterial blood pressure; and decreased mortality (111). Additionally, a study using Prometheus, another extracorporeal liver support system that combines removal of albumin-bound substances and water-soluble substances, was reported to be safe and beneficial in a small group of patients with type 1 HRS (112) However, these results require further evaluation to consider albumin dialysis as a therapy for HRS.

Liver transplantation

Liver transplantation is the best treatment for patients with HRS. This therapy offers a cure to both the diseased liver and the circulatory and renal dysfunction. The long-term outcome of patients with cirrhosis and HRS treated by liver transplantation is good (survival is 85% at 1 year and 73% at 3 years), although the presence of HRS is associated with increased morbidity and early mortality after transplantation (113). Unfortunately, transplantation for type 1 HRS is limited by the fact that a significant proportion of patients die before the surgery because they have a short survival and a prolonged waiting time in most centers (114). Patients with type 1 HRS have a very poor prognosis and this group of patients should be given immediate priority (43,114). Additionally, patients with type 2 HRS and a MELD score of 20 and more also have a poor outcome and should be given high priority for transplantation (43). If patients are successfully treated with pharmacologic therapy, the outcome appears to be similar to that of patients without HRS (104,114).

Chapter 18
Pulmonary Manifestations of Liver Disease

Michael B. Fallon
Miguel R. Arguedas

Key Concepts

- Liver disease, most commonly cirrhosis, is associated with unique pulmonary vascular abnormalities independent of intrinsic cardiopulmonary disease.
- Ten percent to 20% of patients with cirrhosis develop hepatopulmonary syndrome (HPS), which results when vasodilatation in the pulmonary microvasculature leads to hypoxemia. The presence of HPS increases mortality in cirrhosis. Currently, liver transplantation is the only established therapy for HPS. However, when HPS is severe the outcome of liver transplantation is adversely affected.
- Portopulmonary hypertension (POPH) results when vascular remodeling increases pulmonary vascular resistance and elevates mean pulmonary artery pressure. POPH occurs in 4% to 8% of patients with cirrhosis and, when moderate or severe, it prohibitively increases mortality after liver transplantation. Medical therapies can improve pressures, but no studies clearly support that liver transplantation improves POPH.
- Screening for HPS and POPH is important in cirrhosis because the presence of these disorders influence survival and liver transplantation candidacy.

The presence of dyspnea can be elicited in as many as 70% of patients with cirrhosis undergoing evaluation for liver transplantation (1). In addition, abnormalities in pulmonary function and impaired gas exchange may occur in as many as 45% to 50% of patients (2). The most common causes of these abnormalities and of respiratory symptoms in general are disorders that occur in patients independent of the presence or absence of chronic liver disease (i.e., chronic obstructive pulmonary disease and interstitial lung disease). Additionally, symptoms may result from patient deconditioning, muscular wasting, or the presence of tense ascites/hepatic hydrothorax (see Chapter 19). Finally, certain liver diseases may be associated with specific pulmonary abnormalities, such as panacinar emphysema in α_1-antitrypsin deficiency (Chapter 37) and fibrosing alveolitis and granulomas in primary biliary cirrhosis (Chapter 24).

In a subset of patients, however, two distinct disorders, the hepatopulmonary syndrome (HPS) and portopulmonary hypertension (POPH), are observed. This chapter reviews the epidemiology, clinical characteristics, and treatment of these

pulmonary vascular complications of liver disease.

Hepatopulmonary Syndrome

Definition

HPS is commonly defined as a widened age-corrected alveolar–arterial oxygen gradient of room air with or without hypoxemia that occurs as a result of intrapulmonary vasodilatation in the presence of hepatic dysfunction or portal hypertension (3,4). Fluckiger first described the association between pulmonary dysfunction and liver disease over 100 years ago (5), but the term *hepatopulmonary syndrome* was not used until 1977 (6) when the role of intrapulmonary vasodilatation as the major contributor to gas exchange abnormalities was recognized.

Epidemiology and Disease Associations

Although detectable intrapulmonary vasodilatation may be present in 40% of patients with cirrhosis (7), only 8% to 15% will develop impaired oxygenation, leading to significant functional limitations (3). Prior definitions of HPS emphasized the need to exclude intrinsic cardiopulmonary disease to establish the diagnosis (4). However, recent data supports the observation that HPS may occur in the setting of other cardiopulmonary abnormalities (8,9).

Typically, HPS is diagnosed in subjects with cirrhosis and portal hypertension regardless of the underlying etiology of liver disease. Whether the prevalence or severity of HPS correlates with the degree of hepatic synthetic dysfunction and the severity of portal hypertension remains unclear (7,8,10,11,12,13). Cases of HPS have been described in patients with portal hypertension without cirrhosis (e.g., prehepatic portal hypertension, nodular regenerative hyperplasia, congenital hepatic fibrosis, and hepatic venous outflow obstruction) (14,15,16,17) and in patients with hepatic dysfunction in the absence of established portal hypertension (e.g., acute and chronic hepatitis) (18,19). A syndrome similar to HPS has been described in pediatric congenital cardiovascular abnormalities associated with altered hepatic venous drainage to the lungs (20,21) and in a case of metastatic carcinoid tumor (22).

Pathogenesis

The most important alteration in HPS is the dilatation of the precapillary and postcapillary pulmonary vasculature (23), which leads to impaired oxygenation of venous blood as it passes through the lung (24,25).

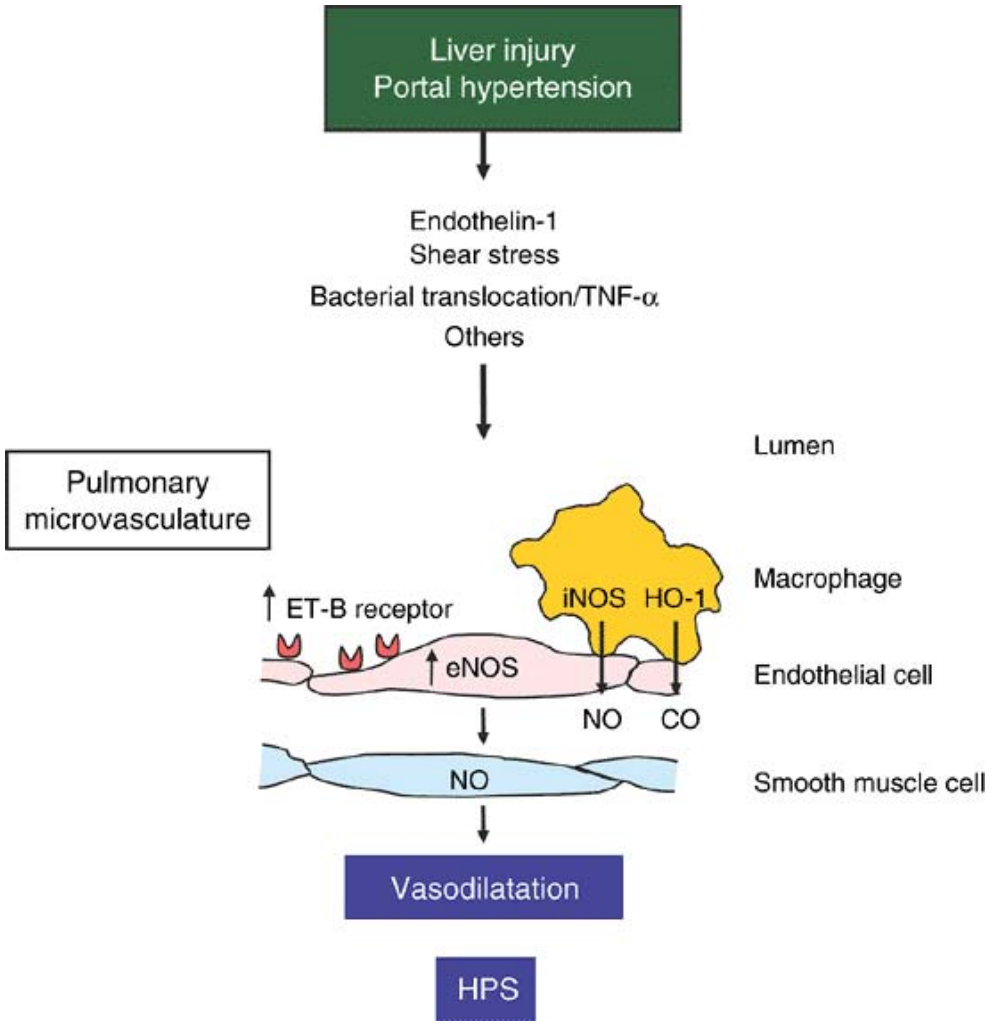
Human studies have demonstrated increased pulmonary production of nitric oxide (NO). Exhaled NO levels are increased in patients with cirrhotic HPS and normalize after liver transplantation (26,27,28) as HPS resolves. In addition, inhibition of the production or action of NO with N^G-nitro-L-arginine methyl ester (L-NAME) or methylene blue, respectively, transiently alleviates HPS (29,30,31). However, the mechanisms of increased NO production in human HPS and its relationship to the degree of liver injury and portal hypertension and/or the hyperdynamic circulation observed in cirrhosis remain unclear. In addition, it is not known whether other vasoactive mediators such as carbon monoxide (CO), the level of which has recently been found to be increased in human HPS, contribute to vasodilatation (32).

Common bile duct ligation (CBDL) in rats (33,34) has been used as an experimental model of HPS because other animal models of cirrhosis and/or portal hypertension (i.e., thioacetamide-induced cirrhosis or partial portal vein ligation) do not result in the development of HPS (35). In this model, increased pulmonary production of NO appears to be a central event in the development of HPS through increased pulmonary vascular expression and activity of endothelial nitric oxide synthase (eNOS) (36,37,38,39). Enhanced hepatic production and release of endothelin-1 (ET-1) and shear stress–mediated increase in pulmonary endothelial endothelin B receptor (ET-B) expression appear to be major contributors to the observed increase in eNOS expression and activity (40,41,42). These events lead to enhanced activation of eNOS by ET-1 through the ET-B receptor and are followed by the accumulation of intravascular macrophages and the production of inducible nitric oxide synthase (iNOS) (36,38,39) and heme oxygenase-1 (HO-1) (38,43), leading to increased NO and CO production, respectively, which result in vasodilatation. Increased tumor necrosis factor-α (TNF-α) production and ET-1 itself appear to contribute to endothelial alterations and macrophage accumulation and activation (42,44) as in CBDL animals. TNF-α inhibition through intestinal decontamination or administration of pentoxifylline and selective ET-B receptor antagonists ameliorate HPS (42,44,45). Figure 18.1 summarizes the current understanding of mechanisms of pulmonary microvascular dilatation in experimental HPS. However, whether similar mechanisms are operative in human disease is unknown.

Clinical Features

The diagnosis of HPS may be overlooked or delayed because many patients with HPS are asymptomatic or their respiratory symptoms may be attributed to intrinsic lung disease; therefore, a high index of suspicion is necessary to establish the diagnosis. In symptomatic patients, the insidious onset of dyspnea (1) is the most frequent complaint. Platypnea (increased dyspnea upon standing) is a "classical" complaint in HPS and is attributed to the predominance of vasodilatation in the lung bases and the increased "shunting" through these regions in the upright position, leading to hypoxemia (46). However, the prevalence, sensitivity, and specificity of platypnea remain undefined. Spider angiomata, digital clubbing, and cyanosis are also commonly described in subjects with HPS but have not been prospectively evaluated as diagnostic indicators. Chest x-rays are most commonly normal but may reveal lower lobe interstitial changes that may be confused with interstitial lung disease (47). Pulmonary function tests typically demonstrate well-preserved spirometry and lung volumes; however, the diffusing capacity of lung for carbon monoxide (DLCO) is often significantly reduced. However, the DLCO is also commonly decreased in cirrhosis in the absence of

HPS, and the diagnostic utility of a reduced value has not been established (48).



▪ **Figure 18.1** Proposed mechanisms of hepatopulmonary syndrome (HPS) based on findings in experimental models. Liver injury and/or portal hypertension trigger the production of cytokines and vasoactive mediators that increase vascular shear stress. Pulmonary microvascular dilatation is initiated by hepatic endothelin-1 production and release and endothelial nitric oxide synthase (eNOS)-derived nitric oxide (NO) production through an increased number of endothelial endothelin B receptors. Macrophages that accumulate in the microvasculature also contribute to vasodilatation by producing NO from inducible nitric oxide synthase (iNOS) and carbon monoxide (CO) from heme oxygenase-1 (HO-1).

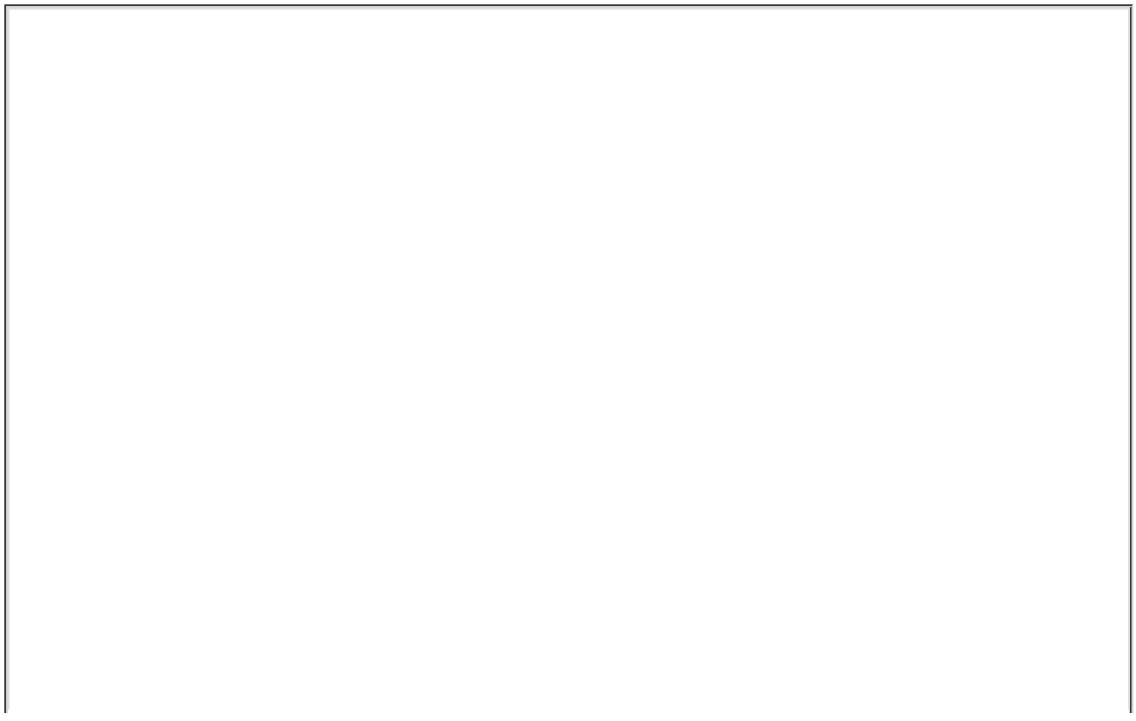
Evaluation for Hepatopulmonary Syndrome

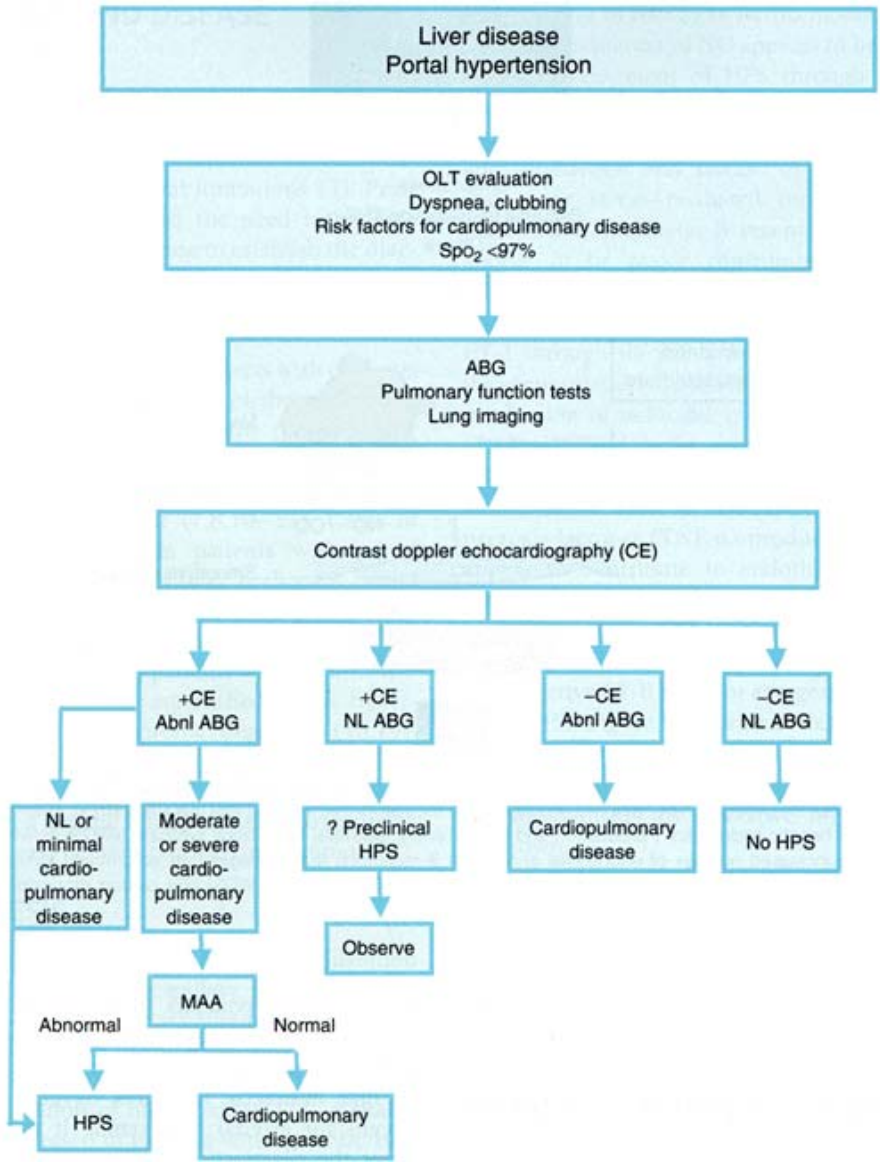
Pursuing the diagnosis of HPS is appropriate in patients complaining of dyspnea and/or in those who display digital clubbing or cyanosis. In patients being considered for liver transplantation, regardless of the presence of symptoms, screening is important because the presence of HPS may influence transplant candidacy and priority. Figure 18.2 summarizes one approach to the diagnosis of HPS.

The diagnosis of HPS is established by (i) the presence of arterial gas exchange

abnormalities and (ii) documenting intrapulmonary vasodilatation. Gas exchange abnormalities, detected by arterial blood gas measurements, are defined as a widened age-corrected alveolar–arterial oxygen gradient ([PAO_2 – PAO_2] >15 to 20 mm Hg) with or without hypoxemia (PaO_2 < 70 mm Hg) (4). Obtaining arterial blood gases in the sitting position may enhance the likelihood of detection of hypoxemia in HPS because of the predominance of vasodilatation in the lower lung fields. Pulse oximetry is a noninvasive screening modality that indirectly measures oxygen saturation and screens for arterial hypoxemia. It may be useful to target the diagnostic evaluation for HPS at patients who have a higher likelihood of advanced disease (PaO_2 <70 mm Hg) (49). However, the threshold oximetry value for detecting hypoxemia in cirrhosis is higher than that typically expected (≤97%), and it is not possible to detect less-advanced disease with oximetry alone (normal PaO_2, widened PAO_2 – PaO_2) (49,50). The clinical significance of these latter gas exchange abnormalities is not well defined (51). Contrast echocardiography, lung perfusion scanning, pulmonary angiography, and high-resolution chest computed tomography (CT) scanning are modalities available to detect intrapulmonary vasodilatation. Two-dimensional transthoracic contrast echocardiography is the most sensitive and most commonly employed screening technique. The contrast agent utilized is agitated saline that creates microbubbles visible on echocardiography. Visualization of intravenously

administered saline microbubbles in the left cardiac chambers after three cardiac cycles is considered a positive test (52,53) (Fig. 18.3). Normally, microbubbles should not be visualized in the left side of the heart, whereas immediate visualization of injected contrast indicates intracardiac shunting. Transesophageal contrast echocardiography may increase the sensitivity of detecting intrapulmonary vasodilatation compared to transthoracic echocardiography but the former is a more invasive and expensive modality (52,53). Echocardiography can also assess cardiac function and estimate pulmonary arterial systolic pressure and is useful for screening for cardiac dysfunction and pulmonary hypertension. As many as 40% of patients with cirrhosis and normal arterial blood gases may have a positive contrast echocardiogram, suggesting that mild intrapulmonary vasodilatation insufficient to alter gas exchange and cause HPS is common (7).



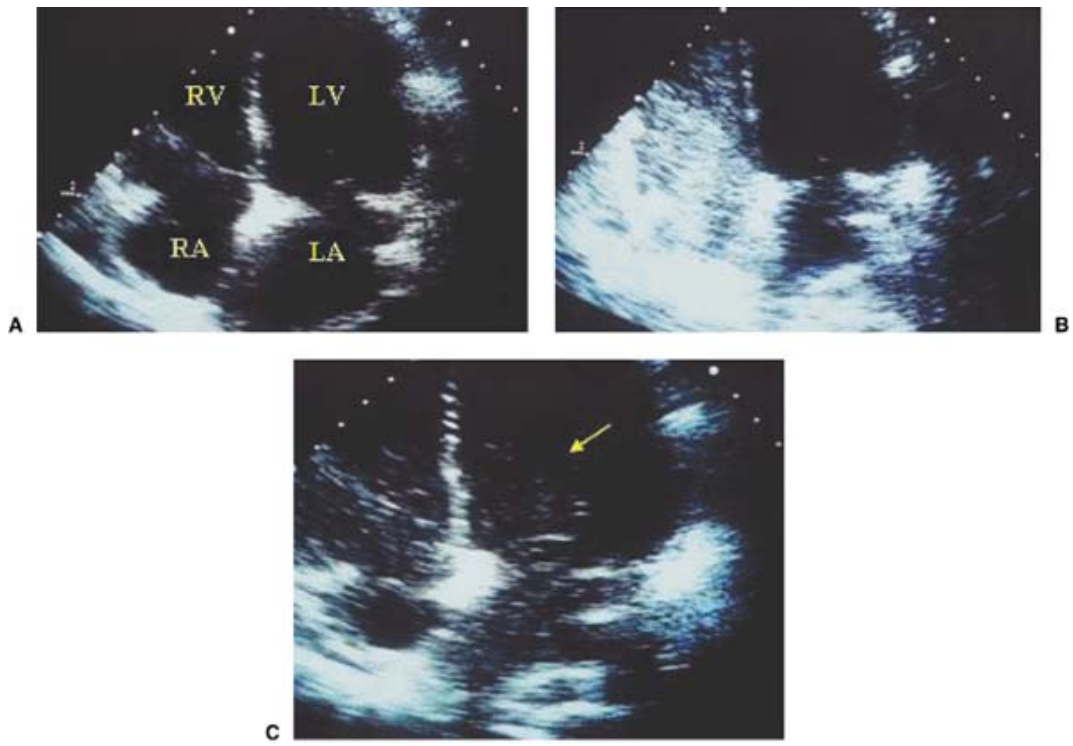


▪ **Figure 18.2** Diagnostic approach to hepatopulmonary syndrome (HPS). See text for details. OLT, orthotopic liver transplantation; Spo_2, pulse oximetry oxygen saturation; ABG, arterial blood gas; CE, contrast echocardiography; Abnl, abnormal; NL, normal; ^{99m}Tc MAA, technetium- 99m–labeled macroaggregated albumin scan.

Radionuclide lung perfusion scanning, using technetium-99m–labeled macroaggregated albumin particles (^{99m}Tc MAA scan), is another method for detecting intrapulmonary vasodilatation (Fig. 18.4). In this test, macroaggregated albumin particles 50 to 100 μm in size are injected intravenously. Normally, all particles are

trapped in the lung microvasculature. In HPS, some particles escape through dilated pulmonary capillaries and lodge in beds supplied by systemic arteries. Quantitative imaging of the lung and brain using a standardized methodology allows calculation of a shunt fraction (8). The ^{99m}Tc MAA scan offers one

significant advantage over contrast echocardiography; a positive scan (shunt fraction >6%) is specific for the presence of HPS even in the setting of coexistent intrinsic lung disease (8) and is valuable in determining the relative importance of intrapulmonary vasodilatation or the underlying pulmonary process as the major contributor for observed gas exchange abnormalities. However, as a screening test for intrapulmonary vasodilatation, ^{99m}Tc MAA scanning is less sensitive than contrast echocardiography.



▪ **Figure 18.3** Contrast echocardiogram for detecting intrapulmonary vasodilatation. **A:** Parasternal four-chamber view of the heart before the administration of agitated saline contrast. RA, right atrium; RV, right ventricle; LA, left atrium; LV, left ventricle. **B:** Four-chamber view immediately after the administration of agitated saline contrast into the antecubital vein, leading to the demonstration of the presence of echogenic microbubbles in the right atrium and ventricle. **C:** Visualization of echogenic microbubbles in the left atrium (*arrow*) and ventricle three cardiac cycles after visualization on the right due to intrapulmonary vasodilatation in a patient with hepatopulmonary syndrome. Intracardiac shunting results in immediate passage of microbubbles from the right to left chambers without a three-cycle delay and can be excluded using this technique.

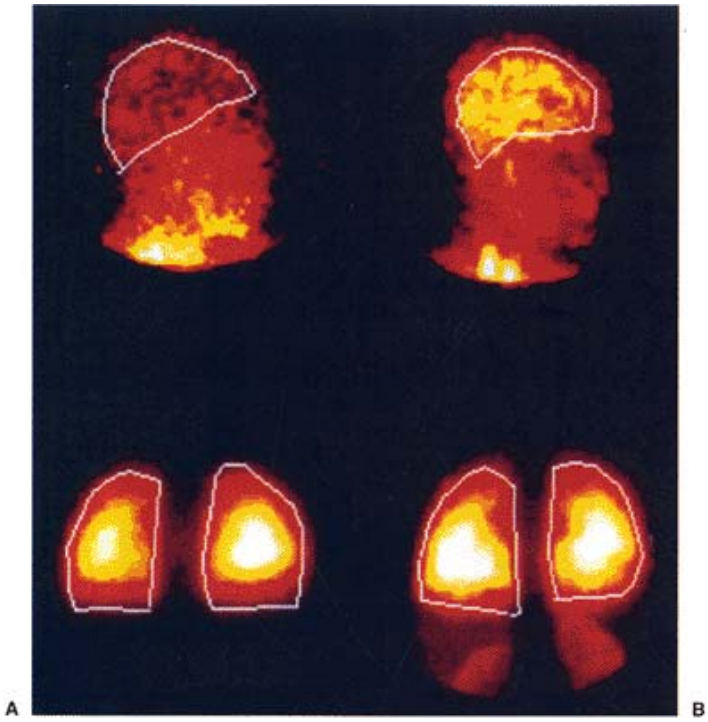
Two types of angiographic findings have been reported in HPS: Type 1—diffuse "spongiform" appearance of pulmonary vessels during the arterial phase—and type 2—small discrete arteriovenous communications. However, many patients with documented HPS have normal angiograms and the test is invasive. Therefore, pulmonary angiography is not a useful screening test.

High-resolution chest CT scan has been recently demonstrated to be a useful modality to detect dilated pulmonary vessels in HPS (54). The degree of

dilatation observed on CT scan can be correlated with the severity of gas exchange abnormalities in patients with HPS, suggesting that quantitation of intrapulmonary vasodilatation may be possible, but further studies are warranted to define the role of CT scan in assessing the presence and severity of HPS.

Prognosis and Natural History

The natural history of HPS is incompletely characterized, but available data indicates that most patients develop progressive intrapulmonary vasodilatation and worsening gas exchange (55) over time. Mortality is significant in patients with HPS (55) and may be due in part to causes directly related to intrapulmonary vasodilatation.



▪ **Figure 18.4** Technetium-99m–labeled macroaggregated albumin (^{99m}Tc MAA) scanning. **A:** A normal ^{99m}Tc MAA scan from a patient without hepatopulmonary syndrome (HPS) with regions of interest drawn around the lungs and cerebrum. In the absence of intrapulmonary vasodilatation, there is minimal passage of intravenously administered labeled albumin through the lungs and signal intensity is low in the cerebrum. Shunting is quantified by comparing the relative signal intensity in the lung and the brain. **B:** An ^{99m}Tc MAA scan in HPS demonstrates significant cerebral uptake because of passage of labeled albumin through the dilated pulmonary microvasculature. (Reproduced from Abrams GA, Nanda N, DubovskyE, et al. Use of macroaggregated albumin lung perfusion scan to diagnose hepatopulmonary syndrome: a new approach. *Gastroenterology* 1998;114:308 with permission.)

A recent prospective study has evaluated the natural history of HPS in a cohort of

111 patients with cirrhosis among whom 24% had HPS (10). The median survival among patients with HPS was significantly shorter (10.6 months) compared to those without HPS (40.8 months). Mortality remained higher in patients with HPS after adjusting for severity of underlying liver disease and after excluding patients who underwent liver transplantation during follow-up. The causes of death in patients with HPS were mainly due to complications of hepatocellular dysfunction and portal hypertension and correlated with the severity of hypoxemia in HPS. Analysis of data from an HPS registry has confirmed higher mortality in patients with HPS, although median survival in HPS was longer than that in the study mentioned earlier (56).

Therapy

A number of agents including somatostatin, almitrine, indomethacin, intravenous L-NAME, and plasma exchange have been tried unsuccessfully to treat HPS (15). Aspirin increased arterial oxygenation in two children with HPS (57), and a case report (58) and a subsequent open-label trial of 15 patients (59) reported that using garlic powder administered for a minimum of 6 months led to significant improvement in PaO_2 (>10 mm Hg) in 6 patients (40%). Infusion of methylene blue, which inhibits the effect of NO on soluble guanylate cyclase, was also found to transiently improved oxygenation in two reports comprising a total of eight patients (30,31). In addition, the inhibition of NO production with inhaled L-NAME also transiently improved oxygenation in one patient (29). Finally, a case report found that norfloxacin use contributed to improvement in oxygen saturation (60). None of these agents is clearly effective as medical therapy for HPS and randomized multicenter trials are needed. On the basis of our current understanding of experimental HPS, agents that modulate endothelin signaling, TNF-α production and action, and shear stress (Figure 18.1) are appropriate candidates for study in human disease.

The role of transjugular intrahepatic portosystemic shunts (TIPS) as a therapeutic option for HPS remains undefined and should be considered an experimental treatment. Case reports have documented improved oxygenation in patients with HPS but interpretation of the results of TIPS placement are limited because of the short duration of follow-up, coexistence of other potential explanations of hypoxemia (i.e., hydrothorax), persistent post-TIPS intrapulmonary shunting, and small numbers of patients (61,62,63,64,65).

Liver transplantation is the only proved therapy for HPS based on the total resolution or significant improvement in gas exchange postoperatively in more than 85% of reported patients (66). However, the length of time for arterial hypoxemia to normalize after transplantation varies and may be delayed for over 1 year (67). In addition, mortality is increased after transplantation in patients with HPS compared to subjects without HPS, especially in those with severe HPS (66,68), and unique postoperative complications including pulmonary hypertension (69), cerebral embolic hemorrhages (70), and immediate postoperative deoxygenation requiring prolonged mechanical ventilation (71) have been reported. Prospective evaluation of the utility of the severity of HPS as a predictor of outcome after liver transplantation revealed that a preoperative Pao_2 of 50 mm Hg or less alone or in combination with a macroaggregated albumin shunt fraction of 20% or less were the strongest predictors of postoperative mortality (68). Innovative approaches such as frequent body repositioning (72) or inhaled NO (73,74) have been used to improve

postoperative gas exchange. Further research focused on the perioperative medical management of patients with HPS is needed to optimize survival.

Portopulmonary Hypertension

Definition

POPH is defined as a mean pulmonary artery pressure greater than 25 mm Hg and a pulmonary capillary wedge pressure less than 15 mm Hg occurring in the setting of portal hypertension (75). An elevated transpulmonary gradient (mean pulmonary artery pressure–pulmonary capillary wedge pressure >10 mm Hg) and/or pulmonary vascular resistance (>240 dyne sec/cm^{-5}) are additional criteria included in the definition of this syndrome.

Epidemiology

Changes consistent with pulmonary hypertension were found in 0.73% of patients with cirrhosis compared to a prevalence of 0.13% in subjects without chronic liver disease in a series of 17,901 autopsies (76). A subsequent prospective study of 507 patients who underwent right-sided heart catheterization (RHC) revealed a 2% prevalence of POPH (77). More recently, retrospective studies in liver transplantation candidates have found a prevalence ranging from 3.5% to 16% (78,79,80,81). The prevalence and severity of POPH do not appear to correlate with the degree of hepatic dysfunction or the severity of portal hypertension (77); however, the severity of cardiopulmonary symptoms worsens with increasing pulmonary hypertension (82). POPH has been described most commonly in patients with cirrhosis and portal hypertension, regardless of etiology, but has also been observed in disorders characterized by portal hypertension without cirrhosis (25).

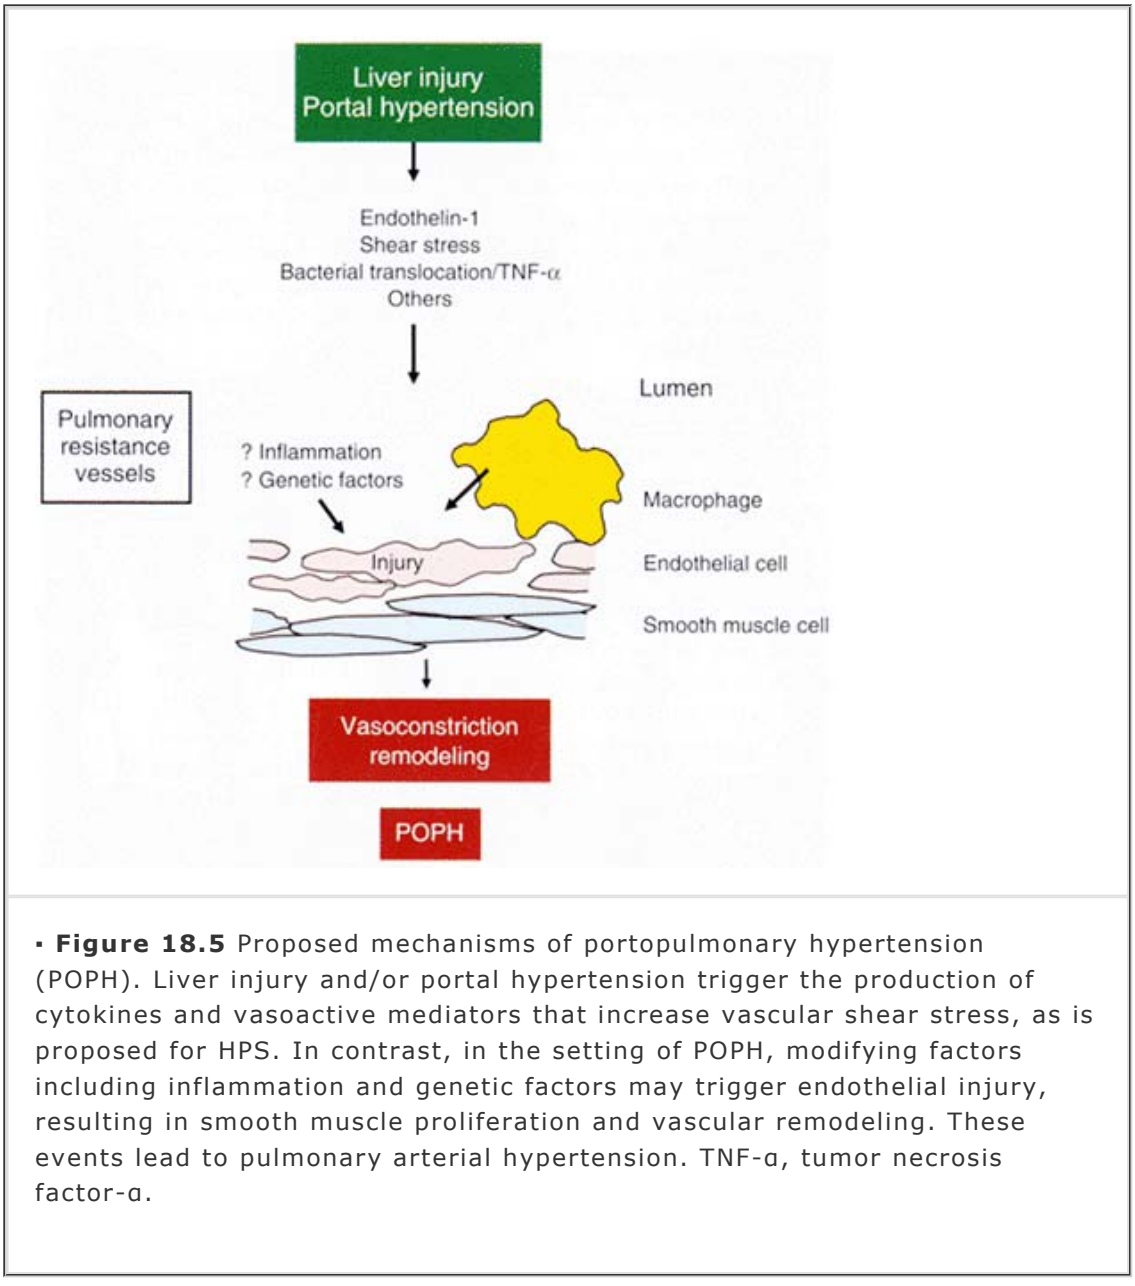
Pathology and Pathogenesis

The histologic features of POPH are similar to those seen in primary pulmonary hypertension. These include smooth muscle hypertrophy and hyperplasia, concentric intimal fibrosis, plexogenic arteriopathy, and necrotizing vasculitis (23,76,83,84,85). The underlying mechanisms in POPH remains incompletely understood and no animal models have been developed. Elevated portal pressure is critical for the development of pulmonary hypertension (77). The hyperdynamic circulatory state, causing increased vascular shear stress, and portosystemic shunting, causing altered production or metabolism of vasoactive substances, have been hypothesized to contribute to vascular changes in POPH (25). Endothelial and circulating factors (e.g., prostacyclin, thromboxane, serotonin, and ET-1) and polymorphisms in genes regulating vascular proliferation (e.g., serotonin and transforming growth factor-β [TGF-β] receptor superfamily) might contribute to POPH. One hypothesis suggests that endothelial injury or dysfunction may be a key early event that contributes to vascular proliferation and inflammation, leading to POPH (Fig. 18.5). In addition, HPS may coexist with POPH, suggesting that these two entities may share underlying pathogenetic mechanisms. One unifying concept is that the degree of endothelial dysfunction or injury may determine whether vascular proliferation and inflammation or vasodilatation occurs, with more severe injury leading to POPH, whereas less severe disease leads to HPS.

Clinical Features

Symptoms of POPH are nonspecific. Most patients may be asymptomatic (81). The most common symptom described in POPH is dyspnea on exertion, with the development of progressive fatigue, dyspnea at rest, peripheral edema, syncope, and chest pain as severity increases (86). Physical examination reveals jugular

venous distention, a loud pulmonary component of the second heart sound, and a systolic murmur resulting from tricuspid regurgitation. Lower extremity edema is commonly noted. Electrocardiographic abnormalities are similar to those seen in primary pulmonary hypertension and include evidence of right atrial enlargement, right ventricular hypertrophy, right-axis deviation, and/or right bundle branch block. Radiographic findings are generally subtle, but in advanced cases, a prominent main pulmonary artery or cardiomegaly due to prominent right cardiac chambers may occur. Gas exchange abnormalities are generally mild and less severe than those in HPS. An increased PAO_2–PaO_2 with mild hypoxemia and hypocarbia may be seen, particularly in more severe disease (25,87).



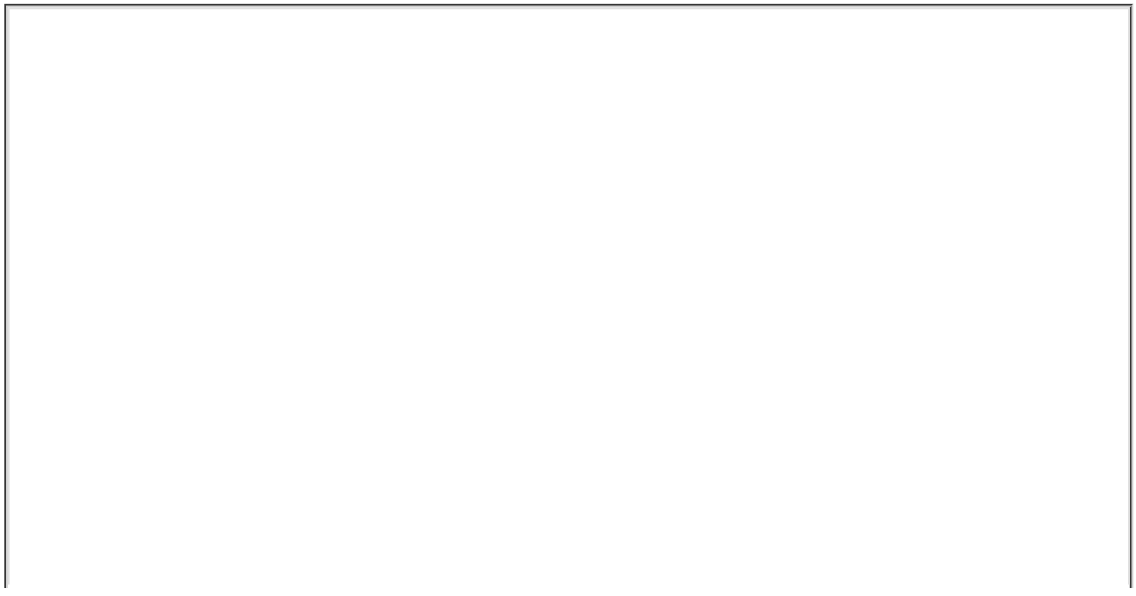
▪ **Figure 18.5** Proposed mechanisms of portopulmonary hypertension (POPH). Liver injury and/or portal hypertension trigger the production of cytokines and vasoactive mediators that increase vascular shear stress, as is proposed for HPS. In contrast, in the setting of POPH, modifying factors including inflammation and genetic factors may trigger endothelial injury, resulting in smooth muscle proliferation and vascular remodeling. These events lead to pulmonary arterial hypertension. TNF-α, tumor necrosis factor-α.

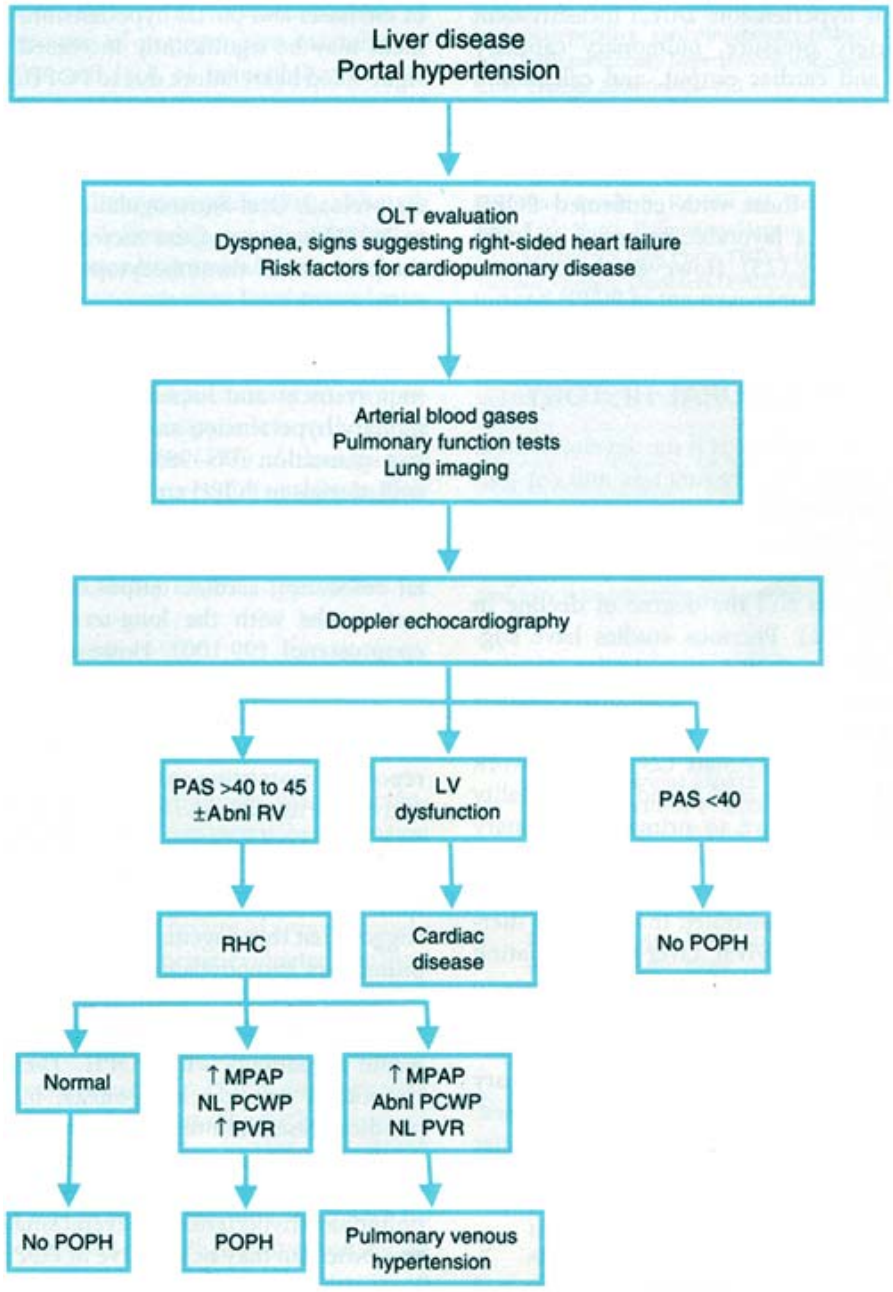
Evaluation for Portopulmonary Hypertension

Patients with POPH are often asymptomatic and the diagnostic utility of various clinical features is low (79,88). Therefore, the diagnosis of POPH requires a high index of suspicion (Fig. 18.6). Other causes of elevated pulmonary pressures and/or right-sided heart failure including left ventricular dysfunction, volume overload, and chronic obstructive lung disease have to be excluded. In general, in patients not being evaluated for liver transplantation, the presence of suggestive symptoms and signs and screening for POPH after exclusion of other cardiopulmonary diseases are reasonable. In all patients being evaluated for liver transplantation, regardless of signs or symptoms, screening is warranted because the presence of POPH may influence transplantation candidacy (89).

Transthoracic Doppler echocardiography is the best noninvasive screening study. If combined with intravenous contrast injection, screening for HPS and POPH can be accomplished at the same time. The presence of pulmonary hypertension is suggested by an increased estimated pulmonary artery systolic (PAS) pressure (derived from measuring the velocity of the tricuspid regurgitant jet), pulmonary valve insufficiency, right atrial enlargement, and/or right ventricular hypertrophy or dilatation. Several recent studies have evaluated the utility of estimated pulmonary arterial systolic pressure measurements in the diagnosis of POPH (81,88,90). In these studies, estimated PAS pressures used to define an elevated value ranged from 30 to 50 mm Hg. According to these studies, between 10% and 15% of patients had elevated estimated PAS

pressures by echocardiography, and roughly half of these patients were confirmed to have POPH. In a recent prospective study, Doppler echocardiography had positive and negative predictive values of 59% and 100%, respectively, in detecting POPH (81). However, the precise methods for estimating PAS pressures have not been standardized between studies and may have influenced the operating characteristics of echocardiographic screening. From a practical perspective, using an estimated PAS pressure of greater than 40 to 45 mm Hg to trigger further evaluation, particularly if right atrial and/or right ventricular abnormalities are also present, is likely to detect almost all cases of POPH. Most false-positive results occur commonly in the setting of elevated pulmonary venous pressures because of the hyperdynamic circulatory state and volume overload in cirrhosis (81).





▪ **Figure 18.6** Diagnostic approach to portopulmonary hypertension (POPH). See text for details. OLT, orthotopic liver transplantation; PAS, estimated pulmonary artery systolic pressure; Abnl, abnormal; RV, right ventricle; LV, left ventricle; RHC, right-heart catheterization; MPAP, mean pulmonary artery pressure; NL, normal; PCWP, pulmonary capillary wedge pressure; PVR, pulmonary vascular resistance.

If echocardiographic findings suggest POPH, right-sided heart catheterization is indicated to confirm elevated pulmonary artery pressures and exclude

pulmonary venous hypertension. Direct measurement of pulmonary artery pressure, pulmonary capillary wedge pressure, and cardiac output, and

calculation of systemic and pulmonary vascular resistance, are included. Vasodilator responsiveness with a number of agents, most frequently NO and/or epoprostenol, may be undertaken in those with confirmed POPH in an effort to predict a favorable response to long-term vasodilator therapy (25). However, the utility of vasodilator testing in the management of POPH has not been studied.

Prognosis and Natural History

The major complication of POPH is the development of progressive right ventricular dysfunction and cor pulmonale. Survival in pulmonary hypertension correlates with the severity of right-sided cardiac dysfunction, as assessed by the degree of elevation in the right-sided cardiac pressures and the degree of decline in the cardiac output (91). Previous studies have suggested that survival in POPH was similar or even prolonged compared to primary pulmonary hypertension, possibly related to the beneficial effects of the hyperdynamic circulatory state (24). Recent work has challenged this concept and found that mortality was higher in POPH relative to primary pulmonary hypertension despite a higher cardiac index and lower systemic and pulmonary vascular resistance (92). To date, no studies have demonstrated that medical therapy for POPH improves survival. Liver transplantation in patients with mild POPH (<35 mm Hg) appears to have comparable outcomes relative to patients without pulmonary hypertension, although long-term follow-up has not been reported. At higher mean pulmonary artery pressures, perioperative mortality is increased, particularly in those with higher pulmonary vascular resistance values or lower cardiac output (89).

Therapy

Medical treatment for POPH improves symptoms and is largely based on experience with primary pulmonary hypertension. Treatment with vasodilators is the mainstay of therapy and can reverse the vasoconstriction associated with POPH, but it has little or no effect on the fibrotic and proliferative remodeling changes. In primary pulmonary hypertension, administration of calcium channel blockers prolongs survival (93), but these agents have not been studied in POPH because of the possibility that they may increase portal pressure (94). A single case has found short- and long-term beneficial pulmonary hemodynamic effects with the use of isosorbide-5’-mononitrate (95). The use of β-adrenergic blockers in patients with POPH is controversial on the basis of the potential risk for cardiac depression. Diuretics are often required to control fluid retention in cirrhosis and portal hypertension, and this requirement may be significantly increased in the setting of right-sided heart failure due to POPH. However, diuretics should be used with particular caution in POPH because intravascular volume depletion may critically reduce the cardiac output by decreasing right ventricle preload. Oral anticoagulation is not recommended in POPH because of the increased risk of bleeding in the presence of thrombocytopenia, coagulopathy, and gastroesophageal varices.

Prostacyclin (epoprostenol) is a potent vasodilator and platelet aggregation inhibitor that results in clinical improvement and increased survival in primary pulmonary hypertension and is useful as a bridge to lung transplantation (96,97,98). Although randomized, controlled trials in POPH are not available, two small series and a case report have also demonstrated improved mean pulmonary artery pressures, pulmonary vascular resistance, cardiac output, and 6-minute walking test results with the long-term use of intravenous epoprostenol (99,100).

However, epoprostenol does not appear to improve survival in POPH and whether it might provide a bridge to liver transplantation has not been clearly defined (101). In addition, there have been reports of worsening splenomegaly and hypersplenism and concerns related to worsening ascites with the long-term use of epoprostenol (102). Preliminary reports of the use of other prostacyclin analogs including treprostinil (subcutaneous injection) and iloprost (inhaled) suggest that these agents may also be useful to improve pulmonary hemodynamics in POPH.

Newer agents developed or under study for the treatment of primary pulmonary hypertension may also be useful in patients with POPH. These agents include endothelin receptor antagonists, inhaled NO, phosphodiesterase inhibitors, and L-arginine. Bosentan is an orally available dual ET receptor antagonist (A and B) that improves pulmonary hemodynamics in primary pulmonary hypertension. Several small studies support that bosentan may be effective in POPH (87,103,104,105). However, this agent has been associated with increases in hepatic enzymes (106), possibly because of inhibition of hepatocyte bile acid transport (107), and may lower systemic blood pressure. The safety of this agent in cirrhosis, particularly if advanced, is unknown. Sitaxsentan, a selective ET-A receptor blocker, has been associated with severe cases of acute hepatitis and should be avoided in POPH (108). Finally, two recent reports have shown beneficial hemodynamic effects of sildenafil in POPH without detrimental effects on systemic hemodynamics (109,110). The safety and efficacy of newer agents for POPH need to be established.

The efficacy of liver transplantation as a mode of treatment of POPH also remains controversial. On the basis of retrospective data and clinical experience, moderate to severe POPH (mean pulmonary artery

pressure >50 mm Hg) is a contraindication to transplantation because of perioperative mortality of approximately 40% and lack of reversibility of pulmonary hypertension (111,112). Patients with mild POPH (mean pulmonary artery pressure <35 mm Hg) appear to have no increase in perioperative cardiopulmonary mortality after liver transplantation, although the results of long-term follow-up and documentation of resolution of pulmonary hypertension has not been undertaken (89). The outcome after liver transplantation in patients with intermediate-severity POPH (mean pulmonary artery pressure 35 to 50 mm Hg) and in those who have improvement in pulmonary artery pressures on long-term medical therapy is less well defined and requires further evaluation (111). Although case reports have demonstrated successful outcomes after combination lung–liver or heart–lung–liver transplantation, limited organ availability and technical challenges limit the feasibility of such approaches for POPH (113).

Summary and Conclusions

HPS and POPH are unique pulmonary vascular complications of liver disease and/or portal hypertension that may cause significant morbidity and influence survival and liver transplantation candidacy. HPS occurs in approximately 20% and POPH occurs in approximately 6% of patients with cirrhosis being evaluated for liver transplantation. Dilatation in the pulmonary microvasculature is an important event that leads to hypoxemia and symptoms in HPS. Vasoconstriction and remodeling in resistance vessels occur in POPH and may lead to right-sided cardiac dysfunction. The pathogenesis of pulmonary vascular abnormalities in HPS and POPH is an area of ongoing investigation, and similar mechanisms may

play a role in each syndrome. There are no effective medical therapies for HPS, but liver transplantation can reverse the syndrome in most patients. In contrast, there are symptomatic medical therapies for POPH, but for many patients liver transplantation is currently contraindicated or controversial. Transplantation carries increased mortality in both severe HPS and POPH, underscoring the importance of screening for these disorders in patients undergoing liver transplantation evaluation.

Annotated References

Arguedas M, Abrams GA, Krowka MJ, et al. Prospective evaluation of outcomes and predictors of mortality in patients with hepatopulmonary syndrome undergoing liver transplantation. *Hepatology* 2003;37:192–197.

The first prospective study that demonstrates that the outcome after liver transplantation in HPS is influenced by the severity of hypoxemia and intrapulmonary vasodilatation.

Krowka M, Plevak D, Findlay J, et al. Pulmonary hemodynamics and perioperative cardiopulmonary-related mortality in patients with portopulmonary hypertension undergoing liver transplantation. *Liver Transpl* 2000;6:443–450.

This retrospective study analyzes the outcomes of liver transplantation relative to the severity of POPH. It forms the basis for the practice of avoiding liver transplantation in moderate to severe POPH.

Rodriguez-Roisin R, Krowka MJ, Herve P, et al. On behalf of the ERS Task Force Pulmonary-Hepatic Vascular Disorders Scientific Committee ERS Task Force PHD Scientific Committee. Pulmonary-Hepatic vascular Disorders (PHD). *Eur Respir J* 2004;24:861–880.

Recent comprehensive review of HPS and POPH, outlining epidemiology, pathogenesis, diagnosis, and current therapies.

Schenk P, Schoniger-Hekele M, Fuhrmann V, et al. Prognostic significance of the hepatopulmonary syndrome in patients with cirrhosis. *Gastroenterology*. 2003;125:1042–1052.

Swanson K, Wiesner R, Krowka M. Natural history of hepatopulmonary syndrome: impact of liver transplantation. *Hepatology* 2005;41:1122–1129.

These two studies support that the presence of HPS increases mortality in patients with cirrhosis. The second study also supports that liver transplantation improves survival in patients with HPS and cirrhosis.

Chapter 19

Ascites and Spontaneous Bacterial Peritonitis

Vicente Arroyo

Miguel Navasa

Key Concepts

- The most common cause of ascites in humans is cirrhosis followed by congestive heart failure, malignant ascites, and tuberculous peritonitis. Measurement of serum to ascitic fluid gradient of albumin and the concentration of leukocytes, standard cytologic examination for malignant cells, measurement of the concentration of adenosine deaminase, and the detection of deoxyribonucleic acid of *Mycobacterium* organisms by means of polymerase chain reaction of ascitic fluid are the specific tests for the differential diagnosis of the causes of ascites. However, investigation of physical and exploratory findings characteristic of these entities are also important in making the diagnosis.
- In cirrhosis the ascitic fluid protein concentration is considerably lower than the plasma protein concentration. This is due to the capillarization of the hepatic sinusoids, which reduces their permeability to plasma proteins, and to a major contribution of the splanchnic microcirculation (with low permeability to proteins) to the formation of ascites. The concentration of proteins in ascitic fluid in cirrhosis correlates inversely with the degree of portal hypertension.
- Lymph formation within the liver and the splanchnic circulation is markedly increased in patients with nonascitic cirrhosis who have portal hypertension. Lymph is effectively transported into the systemic circulation through the splanchnic lymphatic system and thoracic duct. Ascites develops when lymph formation overcomes the transport capacity of the lymphatic system. In the splanchnic organs (e.g., intestines, stomach, peritoneum) the increased lymph formation is more related to an increased blood inflow into the splanchnic microcirculation secondary to an arterial vasodilatation, which leads to an increase in capillary pressure and permeability, than to a backward transmission of the increased portal venous pressure into the splanchnic capillaries. The mechanism of the splanchnic arterial vasodilatation in cirrhosis is related to portal hypertension, which increases local production of vasodilatory substances, particularly nitric oxide.
- Splanchnic arterial vasodilatation is the key mechanism of ascites formation (forward theory of ascites). In addition to increasing lymph formation in the splanchnic microcirculation, splanchnic arterial vasodilatation impairs arterial circulatory function and leads to the activation of the renin–

aldosterone system, sympathetic nervous system, and antidiuretic hormone and renal sodium and water retention. The simultaneous occurrence of excessive lymph formation and renal retention of fluid lead to continuous ascites formation.

- There is an alteration in cardiac function in cirrhosis that could also contribute to the pathogenesis of the circulatory and renal dysfunction and to the formation of ascites. Although higher than normal in most patients, cardiac output decreases during the course of decompensated cirrhosis despite the reduction in peripheral vascular resistance. On the other hand, the heart rate does not increase in response to the progressive stimulation of the sympathetic nervous system, indicating impairment of cardiac chronotropic function.
- Moderate sodium restriction (90 mmol/day), spironolactone, and furosemide are the basis of the medical management of ascites. Spironolactone is the principal drug. Furosemide can be added to spironolactone to increase diuretic response. Medical treatment is indicated in patients with moderate ascites.
- Therapeutic paracentesis with intravenous administration of albumin (8 g/L of ascitic fluid removed) is the treatment of choice for tense ascites in cirrhosis. Sodium restriction and diuretics should be used to prevent the reaccumulation of ascitic fluid. Large-volume paracentesis without plasma volume expansion frequently impairs circulatory function, which although asymptomatic can adversely influence the clinical course.
- Peritoneovenous shunting and transjugular intrahepatic portacaval shunting are effective therapies for refractory ascites in cirrhosis. They are, however, associated with a high rate of complications, particularly shunt obstruction, and do not improve the overall results of paracentesis in relation to the duration of hospitalization and survival. The recent introduction of covered stents with less rate of shunt obstruction will probably increase the indication of transjugular intrahepatic portacaval shunting in patients with refractory ascites.
- Spontaneous infection of the ascitic fluid (spontaneous bacterial peritonitis) is a frequent event in cirrhosis (10% to 30% prevalence in patients admitted to hospital with ascites). Its pathogenesis is multifactorial, including translocation of bacteria from the intestinal lumen into the circulation, impaired reticuloendothelial system phagocytic activity leading to sustained bacteremia, and decreased antibacterial activity of the ascitic fluid. The most important predictive factor of spontaneous bacterial peritonitis is a low ascitic fluid protein concentration (<10 g/L). The protein concentration in ascitic fluid correlates closely with the antibacterial activity of ascites.
- The gold standard method for the diagnosis of spontaneous bacterial peritonitis is the measurement of the concentration of polymorphonuclear leukocytes in ascitic fluid (diagnosis is made when it is >250 cells/mm^3). Leukocyte esterase reagent strips are useful for a rapid bedside diagnosis of spontaneous bacterial peritonitis. Cultures of ascitic fluid and/or blood cultures are positive in approximately 50% of cases. The organism most commonly isolated in spontaneous bacterial peritonitis is *Escherichia coli*.
- Third-generation cephalosporins are the best antibiotics for the empiric management of spontaneous bacterial peritonitis. The rate of resolution of the infection is more than 90%. However, despite rapid resolution of the infection, 30% of patients die during hospitalization.

- The most common cause of death in patients with spontaneous bacterial peritonitis is a multiorgan failure secondary to severe impairment of circulatory function. It is characterized by intense reduction of the cardiac output; aggravation of splanchnic arterial vasodilatation and portal hypertension; severe impairment of renal, hepatic and cerebral function; and a relative adrenal insufficiency. Circulatory support with intravenous administration of albumin at the time of diagnosis of infection reduces hospital mortality by 60%.
- The probability of recurrence of spontaneous bacterial peritonitis is extremely high (>60% at 1 year). Antibiotic prophylaxis with oral norfloxacin drastically reduces the rate of recurrence of spontaneous bacterial peritonitis. Norfloxacin is also used for primary prophylaxis of bacterial infection in the care of patients with cirrhosis and gastrointestinal hemorrhage and of those with ascites who are at high risk for a first episode of spontaneous bacterial peritonitis (patients with advanced liver disease and low ascitic fluid protein concentration).
- Spontaneous bacterial peritonitis caused by quinolone-resistant bacteria is emerging as a clinical problem.

P.529

Ascites is the most common complication in patients with cirrhosis. It develops as a consequence of a severe impairment of liver function and portal hypertension, and, not surprisingly, it is associated with a poor prognosis. Great advances have been made in the pathogenesis and management of cirrhotic ascites. It is now evident that ascites formation in cirrhosis cannot be considered as a consequence of "backward" transmission of the increased intrahepatic hydrostatic pressure into the hepatic and splanchnic microcirculation and a decrease in intravascular oncotic pressure because of the impaired hepatic synthesis of albumin. Ascites formation is related more to events occurring in the arterial vascular compartment and in the kidneys than to those occurring in the portal venous system. The central event of ascites formation in cirrhosis is a splanchnic arterial vasodilatation secondary to portal hypertension. It simultaneously induces two different types of events: (a) A "forward" increase in capillary pressure because of a great inflow of blood at high pressure into the splanchnic microcirculation, which favors the leakage of fluid into the peritoneal cavity (1,2), and (b) impairment of systemic hemodynamics and renal function, which leads to sodium and water retention. The recent demonstration that cardiac output decreases during the course of cirrhosis in parallel with the progression of the splanchnic arterial vasodilatation (3) adds a new dimension to the complexity of the pathogenesis of circulatory dysfunction and ascites in chronic liver diseases.

These new concepts in the pathogenesis of ascites are important for a better understanding of several events occurring in patients with cirrhosis and ascites. Most important, they are the basis for the design of new treatments in these patients. For example, it is now well known that the systemic circulation is extremely unstable in patients with decompensated cirrhosis because of the resistance of the splanchnic arterial vascular compartment to the effect of endogenous vasoconstrictors (e.g., norepinephrine or angiotensin II). Therefore, the regulation of arterial blood pressure largely depends on the effect of these substances on the renal circulation. This explains why patients with cirrhosis and ascites are predisposed to the development of renal vasoconstriction and

hepatorenal syndrome (HRS) (4). HRS may develop spontaneously; however, it most commonly occurs in close chronologic relationship with an event that increases arterial vasodilatation and decreases cardiac function (e.g., therapeutic paracentesis or spontaneous bacterial peritonitis [SBP]) (5). The recent demonstration that HRS in cirrhosis can be successfully treated by the administration of vasoconstrictor agents associated with plasma volume expansion is the most outstanding consequence of the new concept of the circulatory dysfunction associated with ascites (6,7).

The introduction of the transjugular intrahepatic portacaval shunt (TIPS) and the progressive abandonment of the peritoneovenous shunting for the treatment of refractory ascites are the most relevant changes in therapy during the last decade (8,9). During this period, the important role of paracentesis in the management of patients with cirrhosis and tense ascites was clearly established (10). Also, the initial studies on a new family of drugs, the aquaretic V2 antagonists, was performed in patients with cirrhosis and ascites (11,12). These agents, by inhibiting the renal tubular effect of antidiuretic hormone, increase diuresis without affecting sodium excretion. The net effect is an increase in free water excretion and, in patients with hyponatremia, normalization of serum sodium concentration.

SBP, the spontaneous infection of ascitic fluid, is the clinical condition in hepatology with the most impressive improvement in prognosis. The hospital mortality rate has decreased from 80% in the early 1970s to 10% in the last randomized controlled trial published in 2000 (13). An early diagnosis and the use of effective non-nephrotoxic antibiotics were the initial factors improving prognosis. In this regard, the recent observation that leukocyte esterase reagent strips are

very sensitive and specific for the diagnosis of SBP will facilitate its rapid diagnosis at the bedside and an earlier treatment (14,15,16,17). For many years the hospital mortality rate associated with SBP ranged between 30% and 40% despite the resolution of the infection in more than 90% of the patients. Studies showing that SBP induces a deterioration of circulatory function, which may not be reversible after resolution of the infection and causes multiorgan failure, are essential to the understanding that circulatory support is important in patients with SBP (3,5,18,19). Subsequently, a randomized controlled trial clearly demonstrated that energetic plasma volume expansion with albumin at the time of diagnosis of the infection markedly reduces the incidence of circulatory and renal dysfunction and hospital mortality in patients with SBP (13). This positive finding, however, is counterbalanced by recent observations of patients with quinolone and trimethoprim–sulfamethoxazole–resistant SBP suggesting that these antibiotics are at present not as effective in the prophylaxis of SBP as it was reported in the past.

The aim of the current chapter is to review the pathogenesis, diagnosis, and treatment of ascites and SBP. Particular attention has been paid to these new advances in the field. Classical well-established concepts are more briefly summarized. The reader is referred to Chapter 17 for a better understanding of some aspects of the current chapter.

Ascites

Clinical Aspects

Etiology

Many diseases can lead to the accumulation of fluid within the peritoneal cavity. They can be grouped into two major categories depending on whether they directly affect the peritoneum (Table 19.1). In the first category, ascites forms as a consequence of primary or secondary peritoneal disease (e.g., tuberculous, fungal, parasitic, and granulomatous peritonitis; vasculitis; eosinophilic gastroenteritis; Whipple's disease; and primary or metastatic peritoneal tumor). The second category includes diseases causing sinusoidal portal hypertension (e.g., cirrhosis, acute alcoholic hepatitis, fulminant or subacute viral or toxic hepatitis, Budd-Chiari syndrome, hepatic veno-occlusive disease, congestive heart failure, constrictive pericarditis, and inferior vena caval obstruction over the liver) and hypoalbuminemia (e.g., nephrotic syndrome, protein-losing enteropathy, and malnutrition), and a variety of disorders that may cause ascites by different mechanisms (e.g., myxedema, benign and malignant ovarian tumors, ovarian hyperstimulation syndrome, pancreatitis, biliary tract leakage, chronic renal failure, and diseases affecting the lymphatic system of the splanchnic area). The common feature of all these diseases is that the peritoneum is not affected. By far the most

frequent cause of ascites is hepatic cirrhosis followed by neoplasm. Other relatively frequent causes are congestive heart failure and tuberculous peritonitis. These four conditions account for more than 90% of ascites in Europe and North America.

Detection of ascites

The diagnosis of ascites is simple when large amounts of fluid accumulate in the abdominal cavity. However, diagnosis can be difficult when the volume of ascitic fluid is small or if the patient is obese. In these circumstances, ultrasonography is the best method for the detection of ascites because it is not expensive and gives information about the liver and other intra-abdominal organs. Ascites due to portal hypertension characteristically appears as homogeneous, echo-free areas surrounding and interposed between the loops of bowel and viscera in a relatively uniform manner. When the amount of ascites is small, the fluid tends to collect in the flanks and the superior right paracolic gutter, around the liver, and in the lower peritoneal reflection in the pelvis. Atypical sonographic characteristics, such as the presence of multiple echoes, septations or fibrous strands within the ascitic fluid, and loculation of fluid, are highly suggestive of an ascites unrelated to portal hypertension. The sonographic characteristics of the liver, suprahepatic veins, portal venous system, peritoneum, spleen, stomach, intestine, and intra-abdominal lymphatic nodes, are of great help in assessing the etiology of ascites.

Characteristics of cirrhotic ascites

The biochemical and cytologic characteristics of the ascitic fluid provide important information for the differential diagnosis. The ascitic fluid in cirrhosis

is characteristically transparent and yellow/amber in color. In most patients (70%) the total protein concentration is lower than 2.5 g/dL and approximately 50% correspond to albumin. The total protein concentration in ascitic fluid correlates inversely with portal pressure. It decreases during the course of the disease as portal hypertension increases (20,21). SBP characteristically develops in patients with a low total protein concentration in ascitic fluid (<1 g/dL) (22). Although it has been suggested that this may be due to a low concentration of proteins with antibacterial activity in the ascitic fluid, an alternative explanation is that patients with low total ascitic protein concentration are those with higher portal hypertension and greater liver insufficiency and, therefore, at higher risk for developing bacterial infections.

The ascitic fluid in most patients with cirrhosis without SBP has a concentration of leukocytes lower than 300 to 500 μL/mm^3 (usually <100 μL/mm^3). In some cases, however, it can be higher than 500 μL and even more than 1,000 μL. More than 70% of these white blood cells are mononuclear leukocytes. In contrast, in patients with SBP the ascitic fluid concentration of polymorphonuclear neutrophils (PMNs) is more than 250 μL (usually >2,000 μL). The ascitic fluid of patients with uncomplicated cirrhosis also has a high concentration of macrophages. The absolute concentration of leukocytes in ascitic fluid but not that of PMNs increases during diuretic treatment.

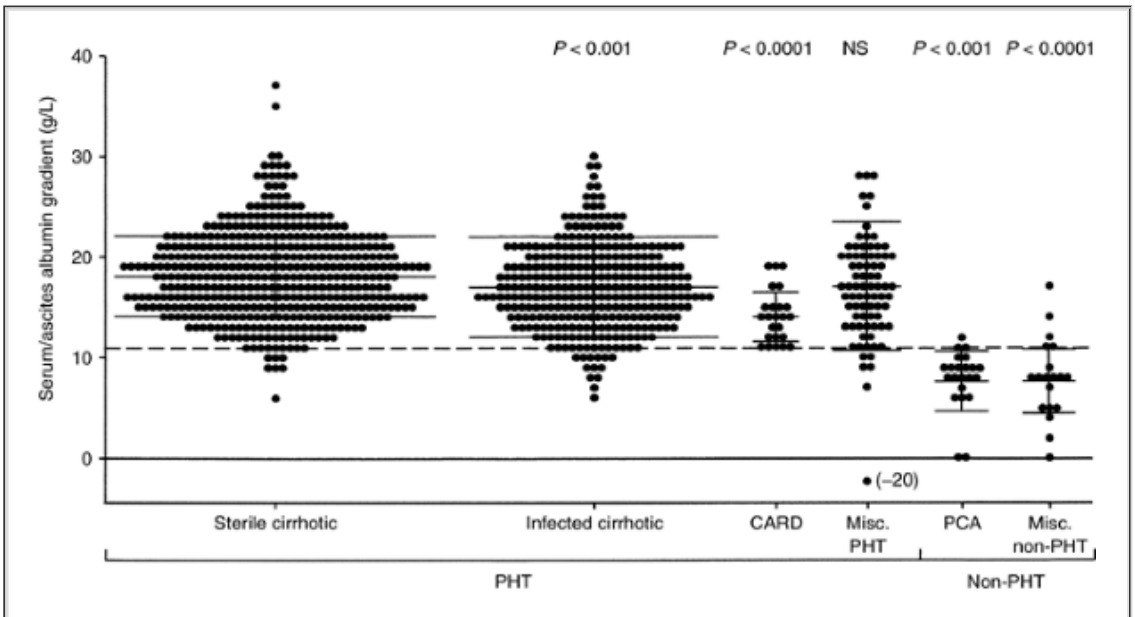
The concentration of red blood cells in cirrhotic ascites is usually less than 1,000 μL, although it can be higher. Bloody ascites (hematocrit >0.50) occurs in 2% of patients. In some cases, bloody ascites is secondary to a superimposed superficial hepatocellular carcinoma bleeding into the peritoneal cavity. In most cases no apparent cause can be detected. Because hepatic and thoracic lymph is often bloody in cirrhosis, bloody ascites can be caused by leakage of bloody lymph into the abdominal cavity.

Ascites in cirrhosis has traditionally been considered an inert fluid mainly composed of water, electrolytes, and proteins that transudates passively from the microvascular compartment into the peritoneal cavity. At present, there is evidence that many metabolic reactions and synthetic processes occur within the ascitic fluid. For example, in patients with cirrhosis a complex coagulation process within the ascitic fluid results in intraperitoneal coagulation and primary and secondary fibrinolysis. The macrophages of ascitic fluid synthesize vasodilatatory substances (e.g., nitric oxide, adrenomedullin, vascular endothelial growth factor), a feature not observed in their precursors, the circulating monocytes (23). The pathophysiologic significance of this finding is unknown. It is also unknown whether this reflects a generalized activation of the peritoneal macrophages or a local activation by some factor within the ascitic fluid (e.g., an endotoxin). The concentration of interleukin-6 and tumor necrosis factor is higher in ascites than in plasma, indicating a local production of cytokines (19). Also, the concentration of leptin and vascular endothelial growth factor is higher in ascitic fluid than in plasma (24,25). The angiogenic activity of the ascitic fluid of patients with cirrhosis may be related to this feature (26). Finally, the ascitic fluid has antibacterial activity, which correlates directly with the total ascitic fluid protein concentration (21). Substances such as complement, fibronectin, cytokines, and nitric oxide are implicated in this effect, which may be an important defensive mechanism against SBP. Not surprisingly, the infusion of ascitic fluid within the general circulation is associated with important biologic effects, the most important being intravascular coagulation and fever.

Differential diagnosis of cirrhotic ascites and other types of ascites

Malignant ascites is macroscopically bloody in only 10% of patients.
Differentiation from cirrhotic ascites

is based mainly on the characteristics of the ascitic fluid and on additional diagnostic findings. The total ascitic protein concentration is over 3.0 g/dL in most patients with malignant ascites. The serum to ascitic fluid gradient of albumin (usually <1.1 in malignant ascites and higher in cirrhotic ascites) is more accurate than total protein concentration in ascitic fluid for the differentiation of cirrhotic versus malignant ascites (18) (Fig. 19.1). The concentration of lactate dehydrogenase and of cholesterol in malignant ascites is higher than the corresponding values in plasma and than values observed in cirrhotic ascites. However, these values do not improve the diagnostic sensitivity of the serum to ascitic fluid albumin gradient. Conventional cytologic examination is 60% to 90% accurate in the diagnosis of malignant ascites if adequate volumes of fluid (several hundred milliliters) and concentration techniques are used. Immunocytochemical techniques with monoclonal or polyclonal antibodies against tumor markers may help differentiate malignant cells from atypical mesothelial cells. Laparoscopy and direct biopsy of peritoneal lesions may be necessary to confirm the diagnosis in the patients with negative cytologic results.



▪ **Figure 19.1** Serum/ascites albumin gradient in patients with portal hypertension (PHT) (sterile cirrhotic, infected cirrhotic, cardiac failure [CARD], and miscellaneous [Misc. PHT]) and in nonportal hypertensive (non-PHT) patients (peritoneal carcinomatosis [PCA] and miscellaneous nonportal hypertension [Misc. non-PHT]). (From Runyon BA, Montano AA, Akriviadis EA, et al. The serum-ascites albumin gradient is superior to the exudate-transudate concept in the differential diagnosis of ascites. *Ann Intern Med* 1992;117:218, with permission.)

Patients with ascites secondary to postsinusoidal portal hypertension (e.g.,

congestive heart failure, constrictive pericarditis, obstruction of the inferior vena cava, Budd-Chiari syndrome) also have a high total ascitic fluid albumin ratio less than 1.1. Lactate dehydrogenase and cholesterol concentrations, however, are not increased. The diagnosis of congestive heart failure and acute Budd-Chiari syndrome is easy from a clinical point of view. However, differentiation between cirrhotic ascites and that secondary to constrictive pericarditis or chronic Budd-Chiari syndrome can be difficult. Patients with ascites due to constrictive pericarditis often lack symptoms of congestive heart failure. On the other hand, in patients with chronic Budd-Chiari syndrome, the protein concentration in ascitic fluid may be low because of capillarization of the hepatic sinusoids (see later) and hepatic stigmata, abnormal liver function test results, splenomegaly, and esophageal varices. It is, therefore, essential to seek physical and additional diagnostic findings characteristics of these entities. This often requires the performance of standard radiologic examination, electrocardiography, and cardiac echography for pericarditis and hepatic ultrasonography or computed tomography to visualize the major hepatic veins in Budd-Chiari syndrome. In many cases, however, diagnosis can only be achieved after cardiac or hepatic venous catheterization and liver biopsy. Ascites due to postsinusoidal portal hypertension secondary to deficient venous drainage is occasionally seen in the postoperative period of liver transplantation (27).

The differential diagnosis between cirrhotic ascites and ascites secondary to tuberculous peritonitis is important because alcoholic cirrhosis can predispose

to peritoneal tuberculosis. Tuberculous peritonitis is frequent among patients with cirrhosis and acquired immunodeficiency syndrome. Ascites due to tuberculous peritonitis is characterized by an increased concentration of proteins (>3 g/dL) and lymphocytes. However, in cirrhosis with ascites and tuberculous peritonitis the ascitic fluid may be a transudate. The concentration of adenosine deaminase, an enzyme that participates in the proliferation and differentiation of lymphocytes, is increased in tuberculous pleural effusions and ascitic fluid in tuberculous peritonitis. It has been reported, however, that the percentage of false-negative results in tuberculous peritonitis is high in the presence of cirrhosis (28). The diagnosis of tuberculous peritonitis cannot be based on cultures of ascitic fluid because the usual techniques of culturing acid-fast bacilli requires several weeks of incubation and frequently gives false-negative results (21). On the other hand, although it has been suggested that the proportion of positive culture results may be as high as 80% when 1L of ascitic fluid is concentrated by means of centrifugation, the proportion reported in most studies is much lower. The detection of deoxyribonucleic acid (DNA) of *Mycobacterium tuberculosis* by means of polymerase chain reaction (PCR) assay of ascitic fluid is rapid and appears to be as sensitive as culture. False-negative results, however, have been reported, justifying the administration of antituberculosis treatment in patients with clinical and histologic features characteristic of peritoneal tuberculosis, even in cases with negative results from culture and PCR analysis. Laparoscopy and direct biopsy of the affected areas is required for the diagnostic confirmation and differentiation from other conditions causing granulomatous peritonitis (e.g., sarcoidosis, Crohn's disease).

Chylous ascites consists of a macroscopically turbid and milky ascites caused by a high concentration of chylomicrons rich in triglycerides (29). The principal causes of chylous ascites in adults are primary abnormalities of the lymphatic vessels (lymphangiectasia) and obstruction of the lymphatic system by neoplasms, particularly lymphoma. Chylous ascites should be differentiated from

pseudochylous ascites, in which, although the macroscopic appearance is identical, the triglyceride concentration is less than 110 mg/dL (the diagnostic cutoff for chylous ascites). Cirrhosis is an infrequent cause of chylous ascites that is usually related to hydrostatic hypertension within the splanchnic lymph vessels, which can lead to spontaneous rupture of some of these vessels into the abdominal cavity. Other causes of chylous ascites are surgical procedures involving the retroperitoneal region (including splenorenal shunt), pancreatitis, sarcoidosis, tuberculosis, and abdominal trauma.

Biliary and pancreatic ascites are caused by leakage of bile and pancreatic fluid, respectively, into the abdominal cavity. In biliary ascites, paracentesis yields a green ascitic fluid with a concentration of bilirubin considerably higher than that in plasma. Although bile leakage into the abdominal cavity can induce signs and symptoms of biliary peritonitis, some patients have no symptoms other than the accumulation of a large amount of biliary ascitic fluid. Therefore, biliary ascites should be considered a possible diagnosis when any patient accumulates intra-abdominal fluid after liver biopsy or biliary surgery (30). Pancreatic ascitic fluid is usually an exudate (ascitic fluid protein concentration is generally >3 g/dL), contains very high concentrations of pancreatic enzymes, and is mainly secondary to chronic pancreatitis. Because most patients with this disorder have alcoholism and may have massive ascites with little or no abdominal pain, the differential diagnosis of pancreatic from cirrhotic ascites can be difficult on clinical grounds (24).

Peripheral edema and cirrhotic hydrothorax

Edema in the lower extremities is frequent in patients with cirrhosis. In many cases it precedes the development of ascites by weeks or months. It can also appear simultaneously with the onset of ascites, or weeks or months thereafter. Hypoalbuminemia and increased venous pressure in the lower extremities due to constriction of the intrahepatic segment of the inferior vena cava or due to the high intra-abdominal pressure caused by the presence of ascites have been proposed as possible mechanisms. Massive peripheral edema with minimal or no ascites is found in patients with cirrhosis having severe hepatic insufficiency and low portal hypertension from TIPS insertion.

Five percent patients with cirrhosis have pleural effusion in the absence of pulmonary or pleural diseases or any other potential cause of hydrothorax. Clinical ascites is almost always evident, and the pleural effusion is usually right sided. The mechanism of this cirrhotic hydrothorax in most cases is the direct passage of ascites through defects in the diaphragm into the pleural space. The driving force is the hydrostatic gradient between the positive intra-abdominal pressure and the negative intrathoracic pressure. In cases of cirrhotic hydrothorax without detectable abdominal ascites (thoracic ascites) the passage of fluid into the pleural cavity probably equals the rate of ascites formation. Because ascites and the pleural fluid of cirrhotic hydrothorax have the same origin, a different cause of pleural effusion should be suspected if marked differences in biochemical and cytologic characteristics are observed between both fluids. Because cirrhotic hydrothorax occurs with abdominal ascites, patients with this condition may

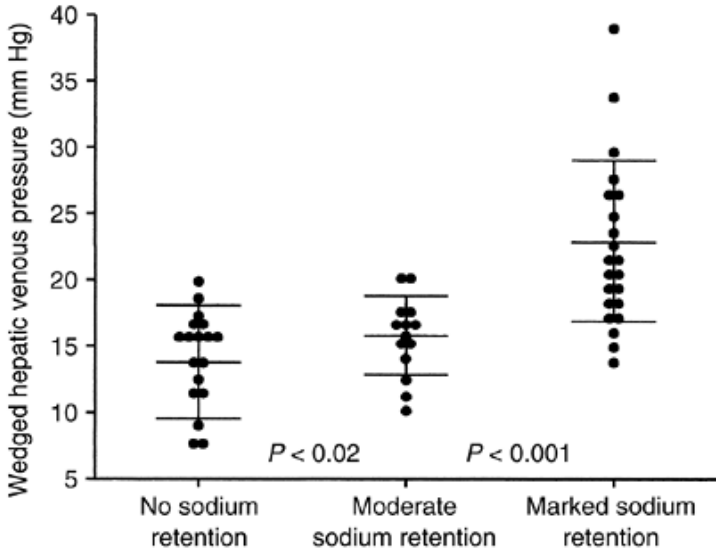
contract spontaneous infection of the pleural fluid (spontaneous bacterial empyema) (31).

Local Intra-Abdominal Factors in the Formation of Ascites

Portal hypertension and leakage of fluid from the intravascular compartment to the peritoneal cavity

There is substantial evidence that severe portal hypertension is the main disorder in the formation of ascites in cirrhosis. Patients have significantly higher portal pressure than those without ascites (Fig. 19.2). Ascites develops only when the hepatic venous pressure gradient (an estimation of the intrahepatic vascular resistance) is more than 12 mm Hg. Ascites is unusual in patients treated with a surgical side-to-side or end-to-side portacaval shunt for bleeding varices. In patients treated by TIPS, ascites frequently disappears after insertion of the stent and reappears if there is malfunction of the shunt.

Ascites is a frequent complication of diseases associated with increased hydrostatic pressure in the hepatic sinusoids (diseases that cause postsinusoidal blockage of the hepatic blood flow such as pericarditis, congestive heart failure, suprahepatic vena caval obstruction, Budd-Chiari syndrome, and hepatic veno-occlusive disease) and of those in which the blockade of the hepatic blood flow occurs mainly at the sinusoidal level (e.g., cirrhosis, severe acute alcoholic hepatitis, and fulminant or subacute toxic or viral hepatitis). Ascites is unusual in diseases associated with intrahepatic or extrahepatic presinusoidal portal hypertension. On the basis of these features and the results of early experimental studies, it has been traditionally considered that ascites is derived mainly from the hepatic microcirculation. Although differences in permeability characteristics between the hepatic and the splanchnic peritoneal (gastric and intestinal) microcirculation also support this concept, recent data suggest that ascites in cirrhosis is derived from both the hepatic and the splanchnic microcirculation (1).

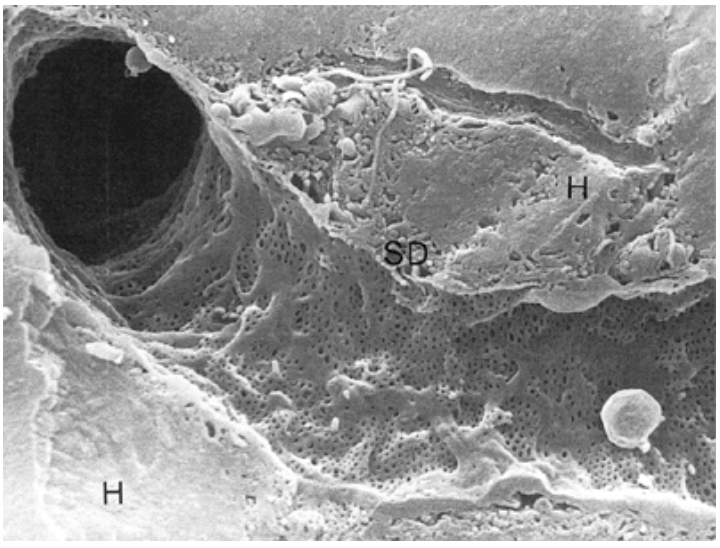


▪ **Figure 19.2** Wedged hepatic venous pressure in patients with compensated cirrhosis (no ascites) and in those with ascites and moderated and marked sodium retention. (From Bosch J, Arroyo V, Betriu A, et al. Hepatic hemodynamics and the renin-angiotensin system in cirrhosis. *Gastroenterology* 1980;78:92–99, with permission.)

Transmicrovascular fluid exchange in postsinusoidal and prehepatic portal hypertension

The hepatic sinusoids do not have basement membranes. They are lined only by endothelial cells, Kupffer cells, and stellate (fat-storing or Ito) cells. The endothelial cells are by far the main component of the sinusoidal wall. Kupffer cells also contribute to the sinusoidal wall, although they are most often within the sinusoidal lumen attached by processes to the endothelial cells. The endothelial cells form a porous sinusoidal wall, with apertures ranging between 100 and 500 nm in radius (Fig. 19.3). Microvilli from the hepatocytes cross the space of Disse and pass through these pores to reach the sinusoidal lumen. Stellate cells, together with few collagen fibers and other particles, are mainly located in the space of Disse. Under normal conditions this is an inconspicuous space in free communication with the interstitial space of the portal and central venous area, where there are terminal lymphatic vessels. The characteristics of the sinusoidal wall explain why, in the normal liver, the concentration of proteins in the hepatic lymph is approximately 90% of that in plasma.

The trans-sinusoidal oncotic gradient in the microcirculation of a normal liver, therefore, is very low. In contrast, the splanchnic capillaries are much less porous (the estimated pore size is 50 to 100 times less than that of the hepatic sinusoids) and have a basement membrane. Not surprisingly, the concentration of protein is lower in the splanchnic than in the hepatic lymph (lymph to plasma ratio of proteins is 0.50 in the intestinal lymph vs. 0.85 in the hepatic lymph) (1,32,33).



▪ **Figure 19.3** Normal hepatic sinusoid in rat liver. The fenestrae are regularly distributed in the sieve plates, which are separated by intervening cytoplasmic processes. *H*, hepatocyte; SD, space of Disse. (From MacSween RNM, Scothorne RJ. Developmental anatomy and normal structure. In: MacSween RNM, Anthony PP, Scheuer PJ, et al. eds. *Pathology of the liver*,

3rd Ed. New York: Churchill Livingstone, 2002:1–66, with permission.)

There are other marked differences between the hepatic and the splanchnic microcirculation. First, capillary pressure is autoregulated in the splanchnic circulation but not in the liver. The acute increase in pressure in the hepatic veins (e.g., after the constriction of the suprahepatic vena cava or the hepatic veins) is almost completely transmitted back into the hepatic sinusoids. In addition, the increase in pressure is associated with an increase in filtration coefficient in the sinusoids and, therefore, in the permeability to proteins (1,32,33). In contrast, only 60% of the acute increase in portal venous pressure is transmitted back to the capillary bed of the small and large intestines and is associated with a decreased filtration coefficient. These effects represent a myogenic constriction of the arteriolar resistance and precapillary sphincters, which reduces microvascular pressure and the number of perfused capillaries. Second, the compliance (relation between interstitial pressure and interstitial volume) is much lower in the liver than in the intestine. Finally, the intestines, but not the liver, have an efficient lymphatic system for removing interstitial edema (1,32,33).

These differences between the hepatic and splanchnic microcirculation explain the findings observed in experimental animals after constriction of the suprahepatic vena cava or hepatic veins and partial ligation of the portal vein. Elevation of hepatic venous pressure is associated with a dramatic increase in the passage of fluid, with a protein concentration similar to that in the plasma from the sinusoidal lumen to the space of Disse. The macroscopic consequence of this is a marked enlargement of the liver. Because the compliance of the liver is low and the ability of the lymphatic system to remove the interstitial fluid insufficient, a marked increase in interstitial pressure ensues. This leads to leakage of hepatic lymph with very high protein concentration from the liver surface into the peritoneal cavity. This sequence of events probably occurs in Budd-Chiari syndrome and other clinical forms of suprahepatic portal hypertension, in which there is hepatomegaly as well as protein-rich ascites formation.

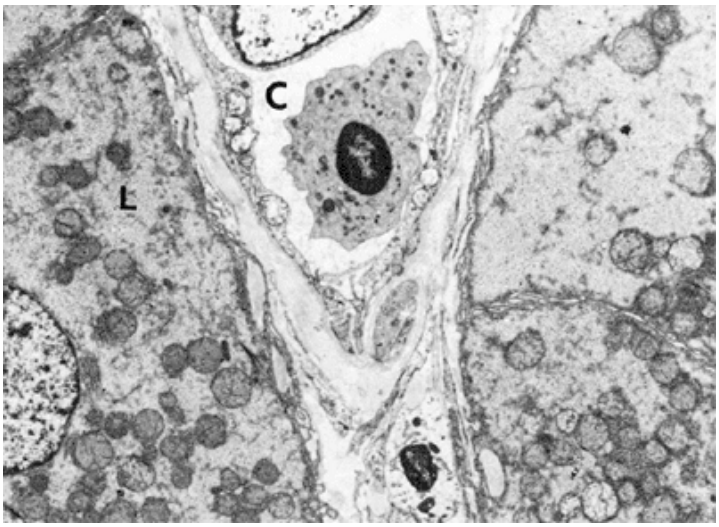
The elevation in portal venous pressure (e.g., after partial ligation of the portal vein) increases the formation of lymph with low protein concentration from the stomach, small intestine, and colon and is associated with local edema in these organs. However, there is no leakage of fluid into the abdominal cavity probably because of two factors. First, the acute increase in filtration is rapidly counterbalanced by an increase in the oncotic pressure difference between the capillary lumen and interstitial space, which limits the exit of fluid from the intravascular compartment. Second, the splanchnic lymphatic system is able to return most of the excess of lymph produced in the stomach and intestines to systemic circulation. Interestingly enough, and contrary to the process occurring in the normal liver in which an increase in hepatic venous pressure is associated with an increase in the lymph to plasma protein ratio to almost 1, in the intestine the increase in portal pressure decreases the lymph to plasma protein ratio to 0.20 (34,35).

Transvascular exchange of fluid and source of ascites in cirrhosis

The hepatic and the splanchnic transvascular exchange of fluid in cirrhosis differs

considerably from that in postsinusoidal and prehepatic portal hypertension. This is due to anatomic and functional changes occurring in the hepatic and splanchnic microcirculation during the course of cirrhosis. In the hepatic microcirculation there is a "capillarization" of the sinusoids, which means that the normal sinusoids become microvessels with continuous endothelial lining, lacking fenestra and supported by a basement membrane and collagenous tissue (33) (Fig. 19.4). This capillary-like structure and the sinusoidal structures are encountered in sequence in the same vascular pathway, the

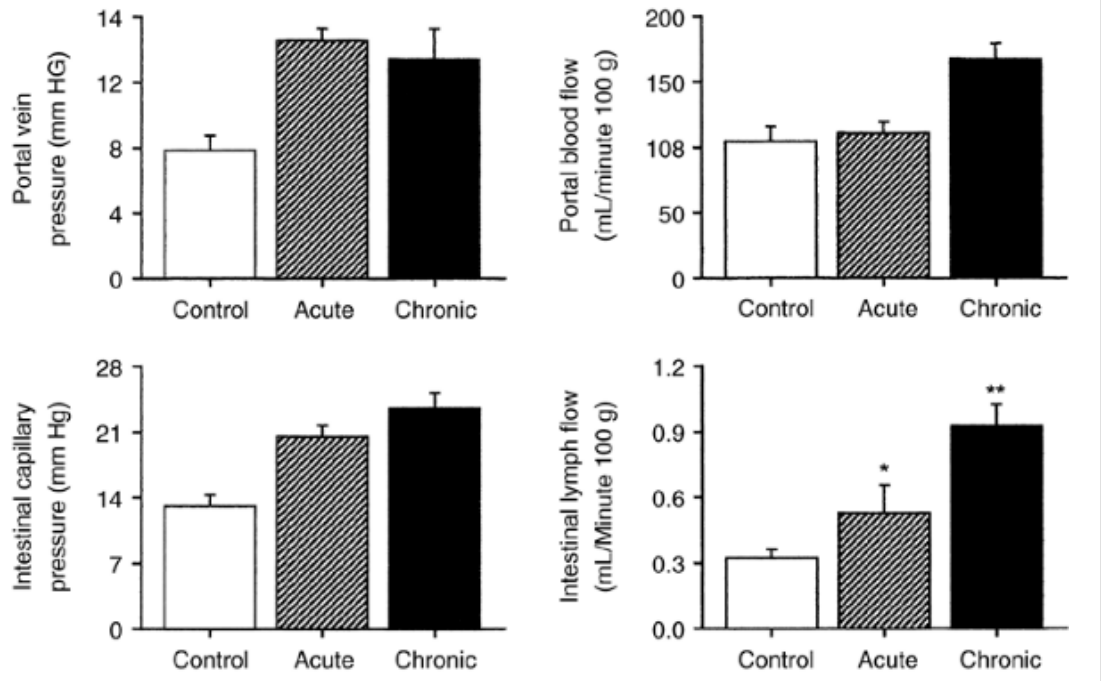
former being more commonly found at the periphery of the regenerative nodules. The degree of capillarization of the hepatic sinusoids, and, therefore, the permeability to albumin in the hepatic microcirculation, varies greatly from patient to patient. For example, whereas the volume of distribution of albumin in the normal liver exceeds that of red blood cells by 60% because of the passage of albumin but not cells into the space of Disse, in cirrhotic livers it may be as low as 5%, indicating a microcirculation almost totally impermeable to albumin (33). In some cirrhotic livers, however, this percentage may approach that found in normal livers. Not surprisingly, the hepatic lymph to plasma ratio for total proteins in cirrhosis ranges between 0.07 and 0.60 (mean value 0.50).



▪ **Figure 19.4** Capillarization of sinusoids in hepatic cirrhosis. An electron micrograph in which a capillary is seen between regenerative liver parenchymal cells. The capillary lumen (*C*) is separated from the liver cells (*L*) by the nonfenestrated endothelial cell, a basement membrane, and a layer of fibrillary collagen. (From Huet P-M, Goresky CA, Villeneuve JP, et al. Assessment of liver microcirculation in human cirrhosis. *J Clin Invest* 1982;70:1234–1244, with permission.)

In cirrhotic portal hypertension there is no autoregulation of capillary pressure and filtration coefficient in the splanchnic microcirculation. Instead of inducing a splanchnic vasoconstriction, portal hypertension in cirrhosis is associated with generalized splanchnic arterial vasodilatation (32). The increase in hydrostatic pressure in the splanchnic capillaries in cirrhosis is due to both a "backward" transmission of the increased portal pressure into the splanchnic microcirculation and a "forward" transmission of the high pressure in the arterial vascular

compartment to the splanchnic capillaries due to the decreased arterial vascular resistance (1). Results of experimental studies indicate that by far the most important mechanism of the increased hydrostatic pressure in the splanchnic microcirculation in portal hypertension is the reduction in arterial vascular resistance and, consequently, the increased inflow of blood at high pressure to this compartment (Fig. 19.5). This increase in hydrostatic pressure leads to a fall in lymph to plasma ratio of protein (0.20 vs. 0.50 to 0.60 in normal conditions). Not surprisingly, interstitial edema in the intestinal mucosal, muscular, and serosal layers is prominent in cirrhosis among humans.



▪ **Figure 19.5** Portal vein pressure, portal blood flow, intestinal capillary pressure and intestinal lymph flow in control and in acute and chronic portal hypertensive rats. *, $P < 0.05$ versus control; **, $P < 0.01$ versus 0.04. (From Korthuis RJ, Kinden DA, Brimer GE, et al. Intestinal capillary filtration in acute and chronic portal hypertension, *Am J Physiol* 1988;254:G339–G345, with permission.)

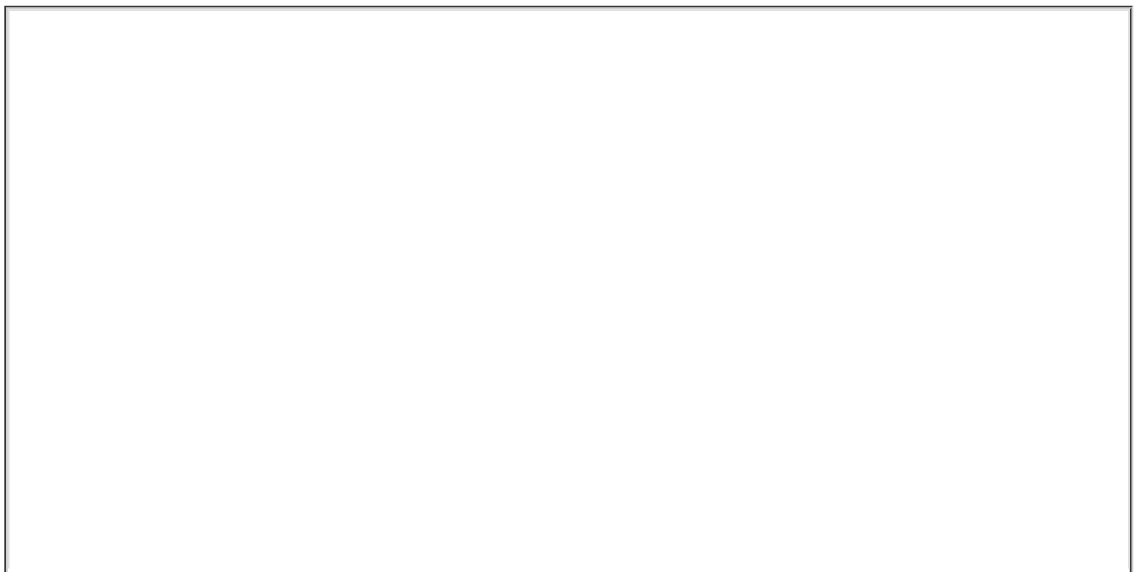
Vessels leaving the liver by the hilum principally drain liver lymph. Liver lymph, as well as that derived from other intra-abdominal organs (e.g., pancreas, spleen, stomach, large and small intestines and mesentery), drains into the thoracic duct. The thoracic duct is a 35- to 45-cm long lymphatic channel that begins in the upper lumbar region, passes through the diaphragm, ascends in the posterior mediastinum, and drains into the left subclavian or internal jugular vein. In healthy humans, thoracic duct lymph flow is approximately 1L/day. In cirrhosis it averages 8 to 9 L/day, and may be higher than 20 L/day, indicating a high filtration of fluid from the hepatic and splanchnic intravascular compartment into the interstitial space (35). There is evidence that the lymphatic system is efficient in returning most of this fluid into the intravascular compartment in patients with cirrhosis and ascites. Less than 5% of the albumin leaving the intravascular compartment (an estimation of the dynamic of fluid through the

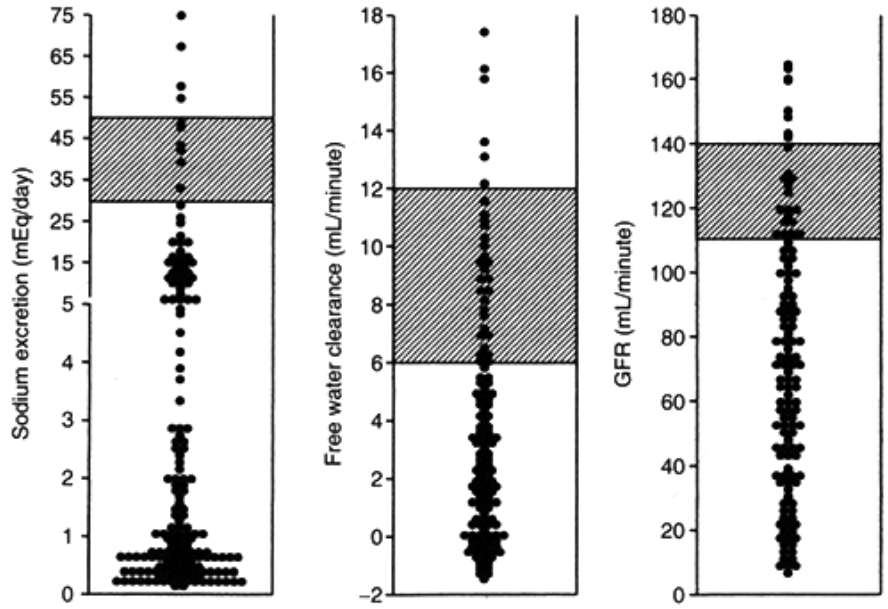
sinusoids and splanchnic capillaries) escapes into the peritoneal cavity (34). Ascites formation in cirrhosis is therefore the consequence of a small spillover of the increased hepatic and splanchnic lymph formation, most of which is returned directly to the circulation through the lymphatic system.

The source of ascites in cirrhosis has never been specifically investigated. The traditional concept that ascites in cirrhosis is derived mainly from the hepatic vascular compartment is not in agreement with the data presented earlier. The total concentration of protein in ascitic fluid and thoracic duct lymph in most patients with cirrhosis is lower than that in the hepatic lymph. This finding indicates a significant contribution of the splanchnic organs to the formation of ascites. In patients with advanced decompensated cirrhosis, severe portal hypertension, intense splanchnic arterial vasodilatation, and very low total protein concentration in ascitic fluid, most cases of ascites are probably the result of intestinal (and filtration by other splanchnic organs) filtration.

Reabsorption of ascitic fluid

The volume of ascites depends not only on the amount of hepatic and splanchnic interstitial fluid leaking into the peritoneal cavity but also on the rate of reabsorption of ascitic fluid into the intravascular compartment. The lymphatic vessels on the undersurface of the diaphragm play an important role in this latter process. These vessels and the diaphragmatic peritoneum are especially prepared for this function. A single layer of mesothelial cells covers the peritoneal surface of the diaphragm over a connective tissue matrix with a very rich plexus of terminal lymphatic vessels (lymphatic lacunae) (36,37,38). The submesothelial connective tissue over the lymphatic lacunae is almost absent and wide gaps, large enough to allow the passage of erythrocytes, connect the peritoneal cavity with the lumen of the terminal lymphatics. The submesothelial lymphatic plexus drains into a deeper plexus of valved collecting vessels, which penetrates connecting tissue septa between the muscular fibers of the diaphragm and drain into parasternal trunks on the ventral thoracic wall, right lymphatic duct, and right subclavian or internal jugular vein. During inspiration, intercellular gaps close, intraperitoneal pressure increases, and the lacunae are emptied through the combined effects of local compression, increased intra-abdominal pressure, and reduced intrathoracic pressure. During expiration, the gaps open and free communication is reestablished.





▪ **Figure 19.6** Sodium excretion, free water clearance, and glomerular filtration rate (GFR) in a large series of patients with cirrhosis and ascites. Shadowed areas indicate normal values in healthy subjects. Measurements of sodium excretion in healthy subjects and patients with cirrhosis were done under conditions of sodium restriction (50 mEq/day). Free water clearance was measured after an intravenous water load of 20 mg/kg body weight (5% dextrose solution).

Reabsorption of ascites in cirrhosis is a rate-limited process. The estimated mean rate of ascitic fluid reabsorption is 1.4 L/day, ranging from less than 0.5L to more than 4L. The low rates of ascites formation and reabsorption do not mean that the intraperitoneal cavity is almost isolated from the rest of the body. The transperitoneal exchange of water and water-soluble substances (e.g., antibiotics not bound to proteins) by diffusion is rapid in patients with cirrhosis and ascites.

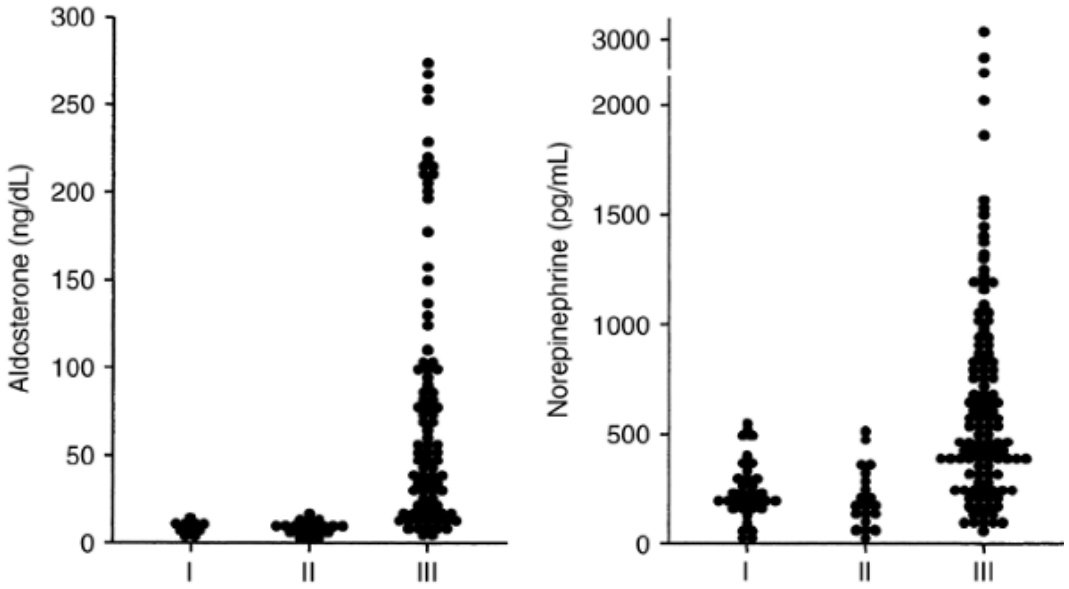
Renal and Circulatory Dysfunction: Role in the Formation of Ascites

Renal dysfunction in cirrhosis

Renal sodium retention, as well as the secondary retention of water, is the second important factor in the formation of ascites (Fig. 19.6). The mechanism of

this abnormality is multifactorial. The renin–angiotensin–aldosterone system, which stimulates sodium reabsorption in the distal nephron, and the sympathetic nervous system, which increases sodium reabsorption in the proximal tubule, loop of Henle, and distal tubule, are stimulated in a significant number of patients with cirrhosis and ascites but not in those with compensated cirrhosis (Fig. 19.7). Glomerular filtration rate (GFR) is markedly reduced in some patients with decompensated cirrhosis and may contribute to sodium retention. However, 30% of patients with cirrhosis, sodium retention, and ascites show plasma concentration of aldosterone and norepinephrine (a sensitive marker of the

sympathetic nervous activity) and GFR within normal limits. This finding indicates that other, still unknown mechanisms participate in the pathogenesis of sodium retention in cirrhosis. The circulating plasma levels of natriuretic peptides (i.e., atrial natriuretic peptide, brain natriuretic peptide) (39) are markedly increased in patients with decompensated cirrhosis. Therefore, sodium retention occurs despite an increased synthesis of these endogenous natriuretic hormones.



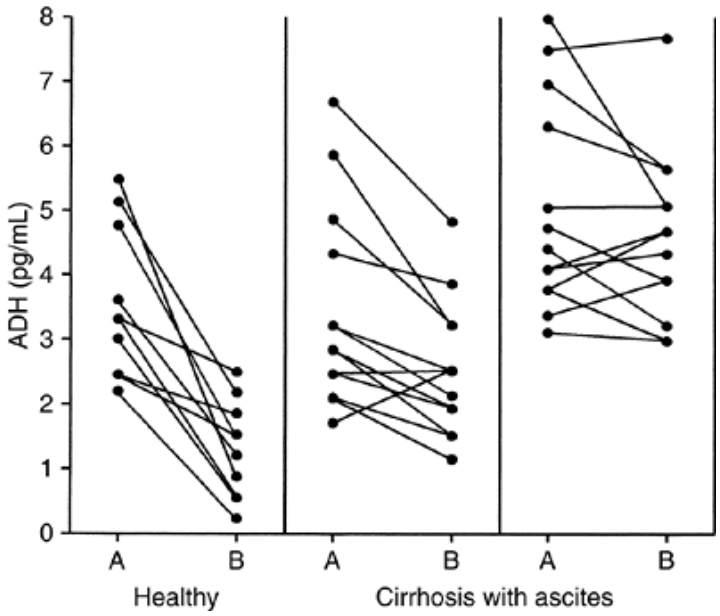
▪ **Figure 19.7** Aldosterone and norepinephrine levels in healthy subjects (*I*), compensated patients with cirrhosis (*II*), and patients with cirrhosis and ascites (*III*). (From Arroyo V, Planas R, Gaya J, et al. Sympathetic nervous activity, renin-angiotensin system and excretion of prostaglandin E2 in cirrhosis. Relationship to functional renal failure and sodium and water excretion. *Eur J Clin Invest* 1983;13;271–278, with permission.)

As decompensated liver diseases progresses, patients develop a decreased renal ability to excrete free water. When this function is severely depressed, patients become unable to excrete the excess of water ingested with the diet. This water dilutes the interior milieu and produces hyponatremia and hypo-osmolality. Water retention and dilutional hyponatremia develop months after the onset of sodium retention and ascites and are secondary to a nonosmotic hypersecretion of antidiuretic hormone (Fig. 19.8). Water retention in patients with dilutional hyponatremia is a part of the positive fluid balance and contributes to the formation of ascites.

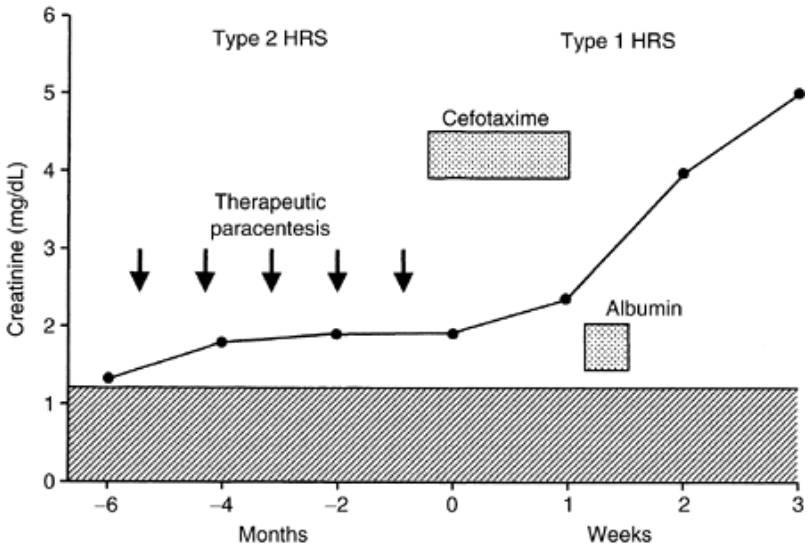
At the terminal stage of the disease patients have HRS (4). This is a functional renal failure due to an intense vasoconstriction of the renal arteries, which causes a decrease in renal perfusion and GFR. Two types of HRS have been identified (Fig. 19.9). Type 2 HRS involves a moderate renal failure (serum creatinine between 1.5 and 2.5 mg/dL; upper normal level 1.2 mg/dL) that

remains steady during relatively long periods (months). Type 1 HRS is a rapidly progressive renal failure. It usually develops in patients who already have type 2 HRS in close chronologic relation to a precipitating event, such as bacterial

infection, gastrointestinal hemorrhage, or major surgical procedure. In type 1 HRS, the serum creatinine level can become very high (>4 to 5 mg/dL) in a short period (days or weeks). The prognosis of patients with type 1 HRS is extremely poor (80% of patients die within 1 month of the onset of the syndrome).



▪ **Figure 19.8** Antidiuretic hormone (ADH) levels in healthy subjects and in patients with cirrhosis and ascites after water restriction (*A*) and after water loading (*B*). Patients with cirrhosis and ascites are divided into two groups: Those with positive free water clearance after a water load (20 mL/kg of body weight) (*middle graph*) and those with negative free water clearance and dilutional hyponatremia. There was an inverse relationship between free water clearance and ADH. (From Pérez-Ayuso RM, Arroyo V, Camps J, et al. Evidence that renal prostaglandins are involved in renal water metabolism in cirrhosis. *Kidney Int* 1984;26:72–80, with permission.)



▪ **Figure 19.9** A typical patient with type 2 hepatorenal syndrome (HRS) and refractory ascites who developed type 1 HRS in close chronologic relationship with spontaneous bacterial peritonitis. Despite the rapid resolution of the infection, the patient developed a rapidly progressive renal failure and died.

Circulatory dysfunction and peripheral arterial vasodilatation in cirrhosis: Relationship with renal dysfunction and intrahepatic hemodynamics

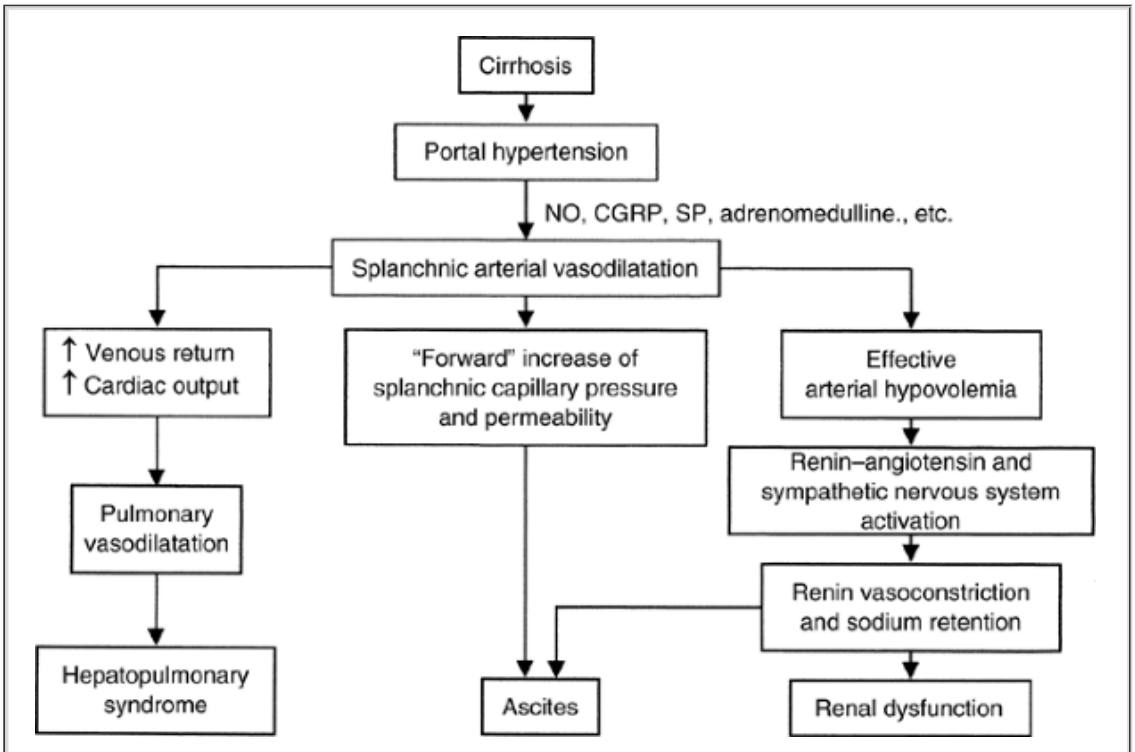
Renal dysfunction in patients with cirrhosis occurs in the setting of a circulatory dysfunction characterized by a marked arterial vasodilatation (40,41). There is evidence that the splanchnic circulation is the site of this arterial vasodilatation because there is vasoconstriction in all the other major vascular territories such as the kidneys, muscle, skin, and brain (42,43,44). In contrast, in the splanchnic circulation there is vasodilatation, which increases the inflow of blood into the portal venous system (26). Indirect evidence suggests that the degree of splanchnic arterial vasodilatation in cirrhosis with ascites is intense because the hepatic blood flow is normal although 60% to 80% of the portal flow is shunted through collateral circulation. The splanchnic arterial blood flow in cirrhosis, therefore, may be double that in healthy subjects. The splanchnic circulation is also the predominant site where arterial vasodilatation occurs in patients with compensated cirrhosis.

It is well established that splanchnic arterial vasodilatation in cirrhosis is related to portal hypertension. It plays a major role in the maintenance of increased portal pressure despite the development of collateral circulation. The mechanism by which increased portal pressure decreases splanchnic arterial vascular resistance is not well understood. For many years arterial vasodilatation in cirrhosis has been attributed to increased circulating plasma levels of vasodilators such as glucagon, prostaglandins, adrenomedullin, and natriuretic peptide. However, because the site of arterial vasodilatation is the splanchnic circulation, a local mechanism (increased release of a vasodilator substance within the splanchnic area) is a more likely hypothesis. Results of recent studies suggesting that nitric oxide, a vasodilator substance that acts in a paracrine manner, is important in the pathogenesis of splanchnic arterial vasodilatation in cirrhosis is consistent with this hypothesis. Increased activity of nitric oxide synthase in the splanchnic circulation has been reported in experimental cirrhosis (45,46,47). On the other hand, inhibition of nitric oxide normalizes circulatory function in experimental cirrhosis (47). Two hypotheses have been proposed to explain the mechanism of the increased production of nitric oxide in the splanchnic circulation. The first is that it occurs secondary to bacterial translocation from the intestinal lumen to the interstitial intestinal space. Endotoxin and the increased cytokine production stimulate the activity of nitric oxide synthase in the endothelial and vascular smooth muscle cells (46,48). The second hypothesis

considers that there is a stimulation of the nonadrenergic, noncholinergic nervous system secondary to portal hypertension (46,49). This is a sensitive system that, when activated, releases numerous vasodilatory neurotransmitters, including nitric oxide, calcitonin gene–related peptide, substance P, and vasoactive intestinal peptide (50,51). Nonadrenergic, noncholinergic terminals are abundant

not only in the gastrointestinal smooth muscle but also in the vascular smooth muscle cells. It may be possible that portal hypertension induces changes in the intestinal wall (increase in interstitial pressure and interstitial edema) that stimulate this system and cause an inhibitory effect on the gastrointestinal smooth muscle cells. The gastrointestinal transit time is greatly prolonged in patients with cirrhosis; this finding indicates inhibition of gastrointestinal motility (52).

The circulatory dysfunction induced by the splanchnic arterial vasodilatation is the primary mechanism implicated in the pathogenesis of complications in patients with cirrhosis. The impairment of renal function is the most characteristic complication induced by the circulatory dysfunction (Fig. 19.10). It is also the mechanism of hepatopulmonary syndrome, which is characterized by mild to severe hypoxemia in the absence of associated cardiopulmonary disease. The hypoxemia is caused by vasodilatation in the intrapulmonary circulation. Finally, although the distortion of the liver vascular architecture caused by fibrosis and nodule formation is the most important mechanism of the increased intrahepatic vascular resistance in cirrhosis, there is a functional component of portal hypertension because of an increase in the intrahepatic vascular tone. The contractile intrahepatic vascular elements include the vascular smooth muscle cells from the small venules and the hepatic stellate cells that surround the sinusoids. In cirrhosis these stellate cells undergo a phenotypic transformation, acquiring receptors for numerous endogenous vasoactive substances, including angiotensin II, norepinephrine, antidiuretic hormone, and endothelin, and contractile properties. Therefore, the circulatory dysfunction in cirrhosis and the secondary activation of these endogenous vasoactive substances may affect the functional component of the intrahepatic resistance to the portal venous flow and increase portal pressure.

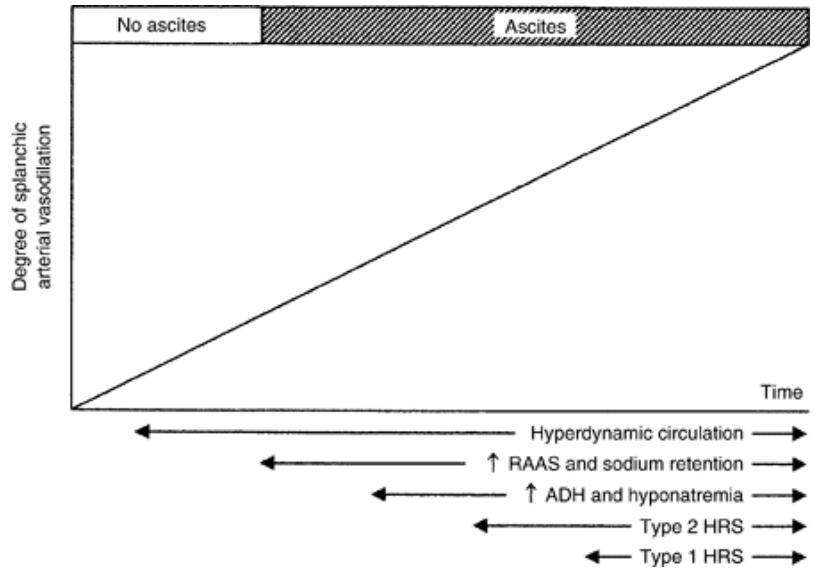


▪ **Figure 19.10** Peripheral arterial vasodilatation hypothesis. NO, nitric

oxide; CGRP, calcitonin gene–related peptide; SP, substance P.

In the initial stages of cirrhosis, circulatory dysfunction is compensated by a hyperdynamic circulation (Fig. 19.11). Plasma volume, cardiac output, and heart rate increase and the circulatory transit time decreases. The splanchnic circulation behaves functionally as an arteriovenous fistula. The incidence of arterial hypertension in patients with cirrhosis and portal hypertension is very low because of this circulatory abnormality. With the progression of the liver disease and the accentuation of portal hypertension and splanchnic arterial vasodilatation, patients develop sodium retention and ascites. In the initial phases of ascites, the renin–angiotensin and the sympathetic nervous systems are not stimulated, and the mechanism of sodium retention in this period is unknown. Later during the course of the disease, the renin–angiotensin–aldosterone system and the sympathetic nervous system become progressively activated in parallel with more intense reduction in urine sodium excretion. Patients with ascites and normal plasma

renin activity and aldosterone concentration, in general, have urinary sodium excretion over 10 mEq/day, and they respond easily to low diuretic dosage. In contrast, most patients with high renin and aldosterone concentration show a urinary sodium excretion lower than 5 mEq/day (in many cases, almost zero) and need high diuretic dosage to achieve a natriuretic response. Hypersecretion of antidiuretic hormone occurs at later stages of the disease. This explains why hyponatremia is a late event in decompensated cirrhosis. This is probably related to the fact that antidiuretic hormone is less sensitive than the sympathetic nervous system and the renin–angiotensin system to changes in the effective circulating blood volume. HRS develops at the very late stages of the disease, always in the setting of an intense activation of the renin–angiotensin and sympathetic nervous systems and antidiuretic hormone.



▪ **Figure 19.11** Temporal relationship between the degree of splanchnic

arterial vasodilatation and the appearance of the various disorders of renal function in cirrhosis. RAAS, renin–angiotensin–aldosterone system; ADH, antidiuretic hormone; HRS, hepatorenal syndrome. (From Arroyo V, Jimenez W. Complications of cirrhosis II. Renal and circulatory dysfunction. Lights and shadows in an important clinical problem. *J Hepatol* 2000;32(suppl 1):157–170, with permission.)

The administration of specific antagonists of the vascular effect of angiotensin II or antidiuretic hormone (V1 antagonists) to experimental animals or patients with cirrhosis and ascites is associated with a profound hypotensive response secondary to a decrease in peripheral vascular resistance. This effect, which is not observed in healthy persons or in patients with compensated cirrhosis (patients who have never had ascites), indicates that activation of the renin–angiotensin system, sympathetic nervous system, and antidiuretic hormone in cirrhosis with ascites is a homeostatic response to maintain arterial pressure at normal or nearly normal levels. Arterial vasodilatation and the secondary arterial hypotension are therefore stimuli leading to the activation of these systems.

The different phases of cirrhosis in the development of ascites and abnormalities of renal function parallel the progression of portal hypertension and splanchnic arterial vasodilatation. In patients with cirrhosis there is a strong direct relationship between the degree of portal hypertension; plasma level of renin, aldosterone, and norepinephrine; and the intensity of sodium retention. Arterial pressure is lower in patients with cirrhosis and ascites than in those with compensated cirrhosis. Finally, among patients with ascites, those with HRS present with the lowest arterial pressure and the highest plasma levels of renin, norepinephrine, and antidiuretic hormone.

Renal and other extrasplanchnic regional circulations in cirrhosis

Traditional studies with para-aminohippurate clearance and recent investigations with echo-Doppler technique have shown increased intrarenal vascular resistance in patients with cirrhosis and ascites before the development of HRS. Therefore, HRS is the extreme expression of an impairment of renal circulatory function that starts at earlier stages. Renal plasma flow, intrarenal vascular resistance, and GFR in cirrhosis with ascites closely correlate with the degree of stimulation of the renin–angiotensin system and the

sympathetic nervous system (53). Patients with normal or moderately increased plasma levels of renin and norepinephrine usually show normal renal perfusion and GFR, whereas the levels of these substances are markedly increased in patients with HRS (Table 19.2). These data have led to the contention that HRS in cirrhosis is caused by renal vasoconstriction related to the activation of these systems (3). However, this hypothesis is too simple, and at present, there is evidence that intrarenal mechanisms may also participate in the regulation of renal perfusion.

Table 19.2. Mean Arterial Pressure, Plasma Volume, Cardiac Index, Plasma Renin Activity, and Norepinephrine Levels in Patients with

Cirrhosis with and without Hepatorenal Syndrome and in Healthy Subjects

		Cirrhosis with ascites	
	Healthy subjects	**No HRS**	**HRS**
MAP (mm Hg)	87 ± 3	82 ± 2	69 ± 5
Plasma volume (mL/kg)	44 ± 2	66 ± 2	59 ± 4
Cardiac index (L/min m^2)	3.0 ± 0.2	5.7 ± 0.2	5.5 ± 0.5
Plasma renin activity (ng/mL h)	0.5 ± 0.1	8.2 ± 2	31.7 ± 10.4
Norepinephrine (pg/mL)	200 ± 22	512 ± 39	1,141 ± 134

P < 0.001 for all values (analysis of variance [ANOVA]).
HRS, hepatorenal syndrome; MAP, mean arterial pressure.

The kidneys synthesize vasodilator substances, the most important of which are prostaglandins, particularly prostaglandin E_2, and prostacyclin. The renal synthesis of prostaglandins increases whenever there is an increased activity of the renin–angiotensin and sympathetic nervous systems (45). Prostaglandins antagonize the vasoconstrictor effect of angiotensin II and norepinephrine and, by this mechanism, play an essential role in the maintenance of renal perfusion and GFR in conditions such as decompensated cirrhosis or congestive heart failure, in which there is circulatory dysfunction. A syndrome similar to HRS can be produced in patients with nonazotemic cirrhosis and ascites by the administration of nonsteroidal anti-inflammatory drugs, which inhibit prostaglandin synthesis (53,54). Investigations in experimental animals with cirrhosis and ascites have shown that the renal production of nitric oxide also participates in the maintenance of renal perfusion (55). Finally, the administration of antagonists of the vascular receptors of natriuretic peptides in animals with cirrhosis and ascites induces an impairment of renal function that mimics HRS (56). Therefore, intrarenal and circulating vasodilatory substances contribute to the maintenance of renal perfusion in cirrhosis with ascites. HRS develops when the renal production of these substances is insufficient to antagonize the renal effects of the endogenous vasoconstrictor systems. This can occur when there is a stimulation of the vasoconstrictor systems, a reduction in the synthesis of vasodilators, or both.

Prostaglandin synthesis is initiated by the transformation of membrane

phospholipids to arachidonic acid, a process mediated by phospholipase A_2. Subsequently, arachidonic acid is converted into the endoperoxides prostaglandin G_2 and prostaglandin H_2 by the action of the enzyme cyclo-oxygenase (COX). Two types of COX exist, COX-1, which plays an important role in many physiologic processes including the protection of the gastric mucosa and the regulation of renal perfusion, and COX-2, which is involved in the inflammatory process. Aspirin and the traditional nonsteroidal anti-inflammatory drugs (e.g., indomethacin, ibuprofen, and diclofenac) inhibit both COX-1 and COX-2. Therefore, in addition to their anti-inflammatory effect, they may produce lesions in the gastric mucosa and, in edematous patients, renal failure. Recently, specific inhibitors of COX-2 have been developed. Studies in experimental animals with cirrhosis and ascites and a recent investigation in patients with cirrhosis and ascites who have an increased activity of the renin–angiotensin system suggest that COX-2 inhibitors do not impair renal function in decompensated cirrhosis (57).

The kidney produces vasoconstrictor substances, such as angiotensin II, endothelin, and adenosine. The production of these substances is stimulated in conditions of renal hypoperfusion. Therefore, these substances could also participate in the pathogenesis of HRS. If fact, it has been proposed that when severe renal hypoperfusion develops in cirrhosis with ascites, there could be a reduction of the intrarenal synthesis of vasodilators and a stimulation of the renal synthesis of vasoconstrictors secondary to renal ischemia, thereby creating vicious circles that lead to a rapidly progressive impairment of renal perfusion and GFR (type 1 HRS). This could explain why type 1 HRS usually occurs in patients with type 2 HRS, who already have a precarious equilibrium between vasoconstrictor and vasodilator mechanisms, and after a precipitating event (e.g., paracentesis, hemorrhage, and bacterial infection) that produces a further deterioration in circulatory function and renal perfusion. Once type 1 HRS develops, it progresses by the intrarenal mechanisms, independent of the correction of the precipitating event. Only the normalization of circulatory function can reverse these intrarenal vicious circles and improve renal perfusion and GFR in patients with type 1 HRS.

Doppler studies of the brachial and femoral arteries, which supply blood mainly to the skin and muscles, and the middle cerebral artery, which supplies

approximately 75% of the blood in the cerebral hemispheres, in patients with cirrhosis and ascites have also shown the presence of vasoconstriction in these vascular territories (42,43,44). Because cutaneous, muscular, and cerebral vascular resistance in patients with cirrhosis and ascites parallels renal vascular resistance and correlates closely with the degree of activity of the renin–angiotensin and the sympathetic nervous systems, it is clear that changes in these regional circulations in decompensated cirrhosis represent a homeostatic response to maintain the arterial pressure.

An important point is that splanchnic arterial vasodilatation persists in decompensated cirrhosis despite the marked stimulation of the renin–angiotensin and the sympathetic nervous systems and the nonosmotic hypersecretion of antidiuretic hormone. This phenomenon is caused by marked resistance of the splanchnic arterioles to the vasoconstrictor effect of angiotensin II, noradrenaline, and vasopressin. Data on experimental cirrhosis suggest the resistance is caused by increased local synthesis of nitric oxide because inhibition of nitric oxide synthase normalizes the response of the splanchnic circulation to

these vasoconstrictors. Therefore, splanchnic arterial vasodilatation in cirrhosis progresses with the increase in portal hypertension, induces the activation of the endogenous vasoconstrictor systems, and leads to vasoconstriction in the extrasplanchnic vascular territories. Because the splanchnic circulation in cirrhosis has little capacity to participate in the homeostasis of arterial pressure owing to the lack of response to vasoconstrictors, muscular and cutaneous blood flow is very low under rest conditions, and the cerebral circulation is regulated by effective mechanisms, the maintenance of circulatory function in cirrhosis relies mainly on the renal circulation. This explains why patients with cirrhosis and ascites are highly prone to the development of renal impairment and HRS in conditions associated with an impairment of circulatory function, such as bacterial infections, paracentesis, hemorrhage, and diuretic treatment.

Cardiac dysfunction in cirrhosis: A second important mechanism of circulatory and renal dysfunction and ascites

Research on circulatory function in cirrhosis has focused for many years on the peripheral arterial circulation. Recent studies, however, suggest that in cirrhosis cardiac dysfunction is also present, which could be of major importance in the deterioration of circulatory and renal function and the pathogenesis of ascites and HRS (3,5). As indicated previously, arterial vasodilatation in the splanchnic circulation increases during the course of the disease, leading to homeostatic activation of the renin–angiotensin and sympathetic nervous systems to maintain arterial pressure. This progressive decrease in cardiac afterload should be followed by an increase in cardiac output and heart rate. However, this is not the case (Table 19.3). Heart rate in patients with nonazotemic cirrhosis, ascites, and normal or slightly increased activity of the renin–angiotensin and sympathetic nervous systems is similar to that in nonazotemic patients with increased activity of these systems or with HRS, indicating a severe impairment of cardiac chronotropic function. On the other hand, the cardiac output, although higher than normal in most cases, decreases progressively during the course of the disease. The mechanisms of circulatory dysfunction in cirrhosis may be, therefore, more complex than that proposed by the peripheral arterial vasodilatation hypothesis (Fig. 19.12). In patients with compensated cirrhosis, the splanchnic arterial vasodilatation is compensated by an appropriated cardiac response, with increased heart rate, left ventricular systolic ejection fraction, and cardiac output. However, with the progression of liver failure and portal hypertension this compensatory mechanism fails. The increase in arterial vasodilatation is not followed by an increase in heart rate. On the other hand, the cardiac output decreases rather than increases. Arterial pressure homeostasis is, therefore, solely dependent on the stimulation of the endogenous vasoconstrictor systems (i.e., renin–angiotensin system, sympathetic nervous system, and antidiuretic hormone), which has deleterious effects on renal perfusion and on the perfusion of other organs and produces sodium retention and leads to ascites formation.

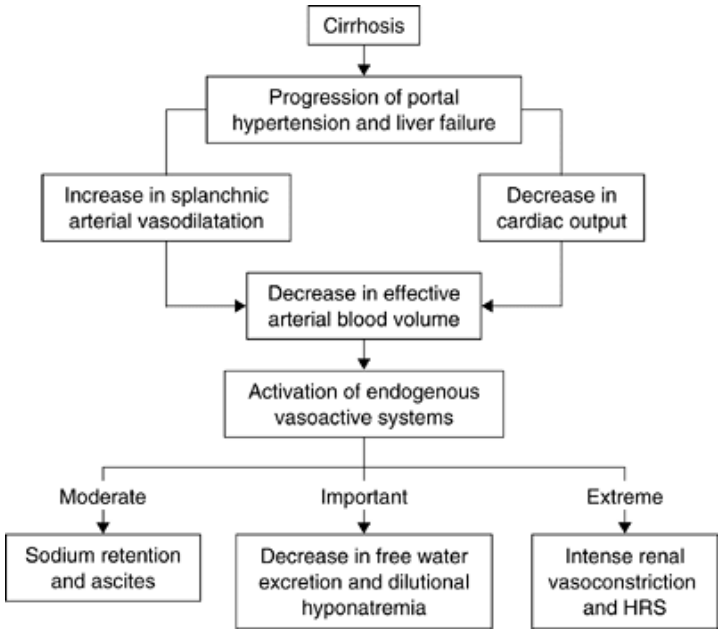
Table 19.3. Chronologic Changes of Vasoactive Systems and Cardiovascular Function from Nonazotemic Cirrhosis with Ascites to Hepatorenal Syndrome

	NA-1	NA-2	HRS
MAP (mm Hg)	88 ± 9	83 ± 9	75 ± 7
PRA (mg/mL h)	3 ± 2	10 ± 5	17 ± 14
NE (pg/mL)	221 ± 68	571 ± 241	965 ± 502
SVR (dyne s/cm^5)	962 ± 256	1,058 ± 265	1,096 ± 327
CO (L/min)	7.2 ± 1.8	6.0 ± 1.2	5.4 ± 1.5
HR (beats/min)	87 ± 15	85 ± 13	82 ± 14

Changes in plasma renin activity, norepinephrine concentration, and cardiac output were statistically significant ($P < 0.01$).
NA, patients with nonazotemic cirrhosis and ascites; NA-1, patients with normal or slightly increased plasma renin activity and norepinephrine concentration; NA-2, patients with high plasma renin activity and norepinephrine concentration; HRS, hepatorenal syndrome; MAP, mean arterial pressure; PRA, plasma renin activity; NE, norepinephrine concentration; SVR, systemic vascular resistance; CO, cardiac output; HR, heart rate.
From Ruiz del Arbol L, Urman J, Fernández J, et al. Systemic, renal and hepatic hemodynamic derangement in cirrhotic patients with spontaneous bacterial peritonitis. *Hepatology* 2003;38:1210–1218, with permission.

Cardiac chronotropic dysfunction in cirrhosis is probably related to the downregulation of β-adrenergic

receptors owing to the overactivity of the sympathetic nervous system. The decrease in cardiac output is probably related to a reduction in cardiac preload (3). There is a cirrhotic cardiomyopathy characterized by an impaired left ventricular diastolic function and cardiac hypertrophy (58,59). It is, however, unlikely that it plays a significant role in the decrease in cardiac function because in decompensated cirrhosis cardiac output increases after maneuvers that expand the central blood volume (e.g., head-out water immersion, plasma volume expansion, therapeutic paracentesis, and insertion of a peritoneovenous or a TIPS), indicating a preserved cardiac reserve. Cardiac dysfunction in cirrhosis, therefore, appears to be a functional disorder unrelated to the structural changes in the heart.



▪ **Figure 19.12** The new hypothesis of circulatory dysfunction in cirrhosis. HRS, hepatorenal syndrome.

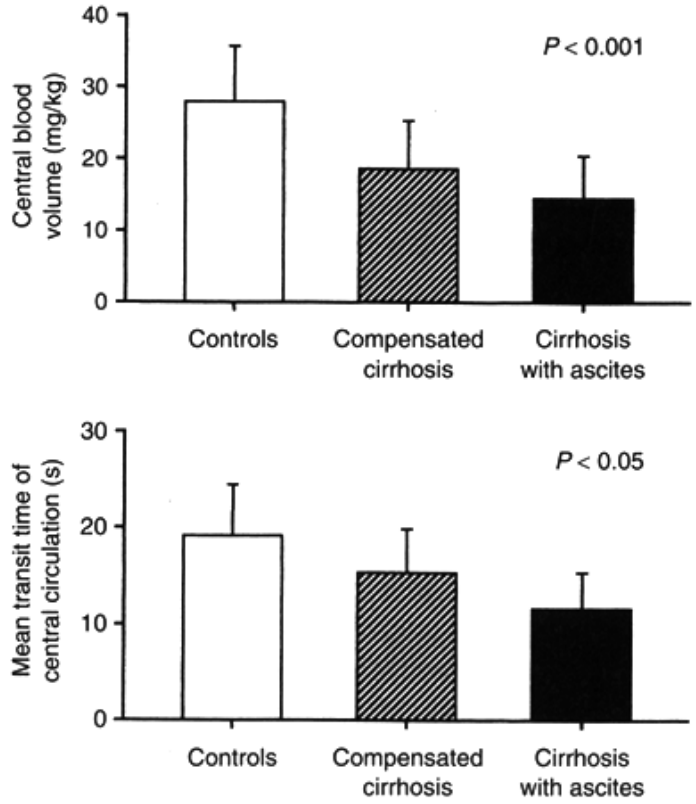
Pathogenesis of Ascites in Cirrhosis: The Forward Theory of Ascites

The previous discussion shows that our concept on ascites formation is moving from the portal venous system to the splanchnic arterial vascular compartment. Ascites formation in cirrhosis was traditionally considered to be due to a rupture of the Starling equilibrium within the splanchnic microcirculation secondary to a backward transmission of the increased intrahepatic and portal pressure to the sinusoids and splanchnic capillaries, respectively, and to hypoalbuminemia. According to this traditional theory, renal dysfunction is the consequence of a reduction in circulating blood volume secondary to the leakage of intravascular fluid to the peritoneal cavity. The fact that plasma volume and cardiac output are not reduced, but rather increased, in most patients with cirrhosis and ascites, however, invalidates this hypothesis. The low peripheral vascular resistance in decompensated cirrhosis is also evidence against this theory because circulating hypovolemia is associated with arterial vasoconstriction rather than with arterial vasodilatation.

The concept of effective hypovolemia was later proposed. Although circulating blood volume is increased in cirrhosis with ascites, the effective blood volume (the fraction of the blood volume present at a particular instant within the intrathoracic circulation that is able to influence low-pressure and high-pressure baroreceptors and, therefore, the sympathetic nervous activity, the renin–angiotensin system, and antidiuretic hormone) is actually reduced. This promotes sodium and water retention, which contributes to the formation of ascites. Results of subsequent studies confirmed this hypothesis. The transit time of blood within the intrathoracic vascular compartment is very short in patients with cirrhosis and ascites because of extremely rapid circulation as a consequence of the arterial vasodilatation. On the other hand, the intrathoracic blood volume is

reduced in patients with cirrhosis and ascites compared with that in patients with compensated cirrhosis and in healthy persons (Fig. 19.13). Therefore, although the blood volume circulating per unit time (i.e., per minute) throughout the intrathoracic vascular compartment is increased in patients with ascites, the intrathoracic blood volume present at a particular moment

is reduced owing to the hyperdynamic circulation. The splanchnic circulation, therefore, behaves as an arteriovenous fistula in decompensated cirrhosis (60). A large volume of blood enters into and leaves the portal venous system rapidly owing to the reduced splanchnic vascular resistance and the existence of portocollateral circulation. The hyperdynamic circulation leads to a vasodilatation in the pulmonary circulation to allocate the increased venous return, and this effect may be associated with an abnormal ventilation/perfusion ratio and low arterial oxygen saturation. Finally, increased venous return and arterial hypotension in the systemic circulation lead to increased stroke volume, tachycardia and, consequently, increased cardiac output. This closes the circle of the hyperdynamic circulation in decompensated cirrhosis.



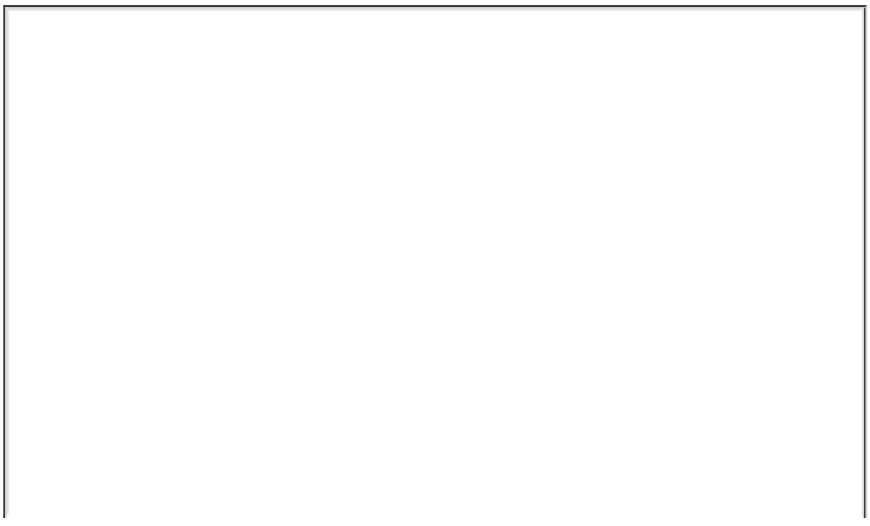
▪ **Figure 19.13** Central blood volume and mean transit time of central circulation in controls, in compensated cirrhosis, and in cirrhosis with ascites. (From Henriksen JH, Bendstsen F, Sorensen TI, et al. Reduced central blood volume in cirrhosis, *Gastroenterology* 1989;97:1506–1513, with permission.)

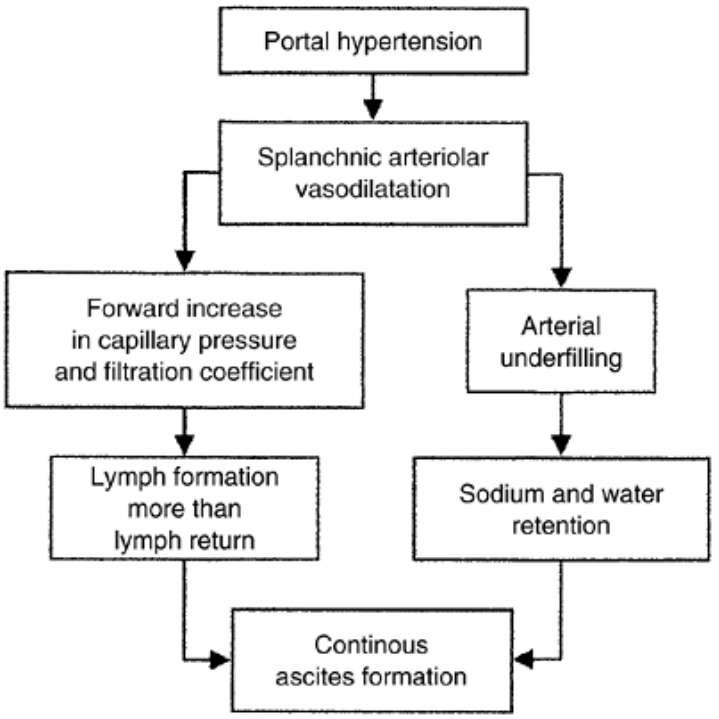
The recent demonstration that the hyperdynamic circulation diminishes during the course of the disease because of a decrease in the cardiac output adds a new

dimension to the pathogenesis of circulatory dysfunction and ascites formation in cirrhosis (3). As the disease progresses, the hyperdynamic circulation, which is intense before and soon after the development of ascites, decreases, contributing to the stimulation of the endogenous vasoconstrictor systems. Angiotensin II, vasopressin, and the overactivity of the sympathetic nervous system produce significant vasoconstriction in the extrasplanchnic organs, including the kidneys, but not in the splanchnic circulation, which is resistant to these vasoconstrictor stimuli owing to an increase in the local synthesis of vasodilators. The circulatory profile of a patient with decompensated cirrhosis, therefore, consists of a progressive decrease of effective arterial blood volume because of both an increase in splanchnic arterial vasodilatation and a decrease in cardiac output; a progressive compensatory activation of the rennin–angiotensin system, sympathetic nervous system, and antidiuretic hormone; and a progressive impairment of the perfusion of extrasplanchnic organs.

Because splanchnic arterial vasodilatation is the predominant mechanism by which splanchnic lymph formation is increased in cirrhosis, the pathogenesis of ascites can be satisfactorily explained on the basis of the changes in the arterial circulation induced by portal hypertension. This "forward" hypothesis considers that the accumulation of fluid within the peritoneal cavity is the consequence of the splanchnic arterial vasodilatation, which simultaneously produces a reduced effective arterial blood volume and a "forward" increase in splanchnic capillary pressure (Fig. 19.14). In patients with compensated cirrhosis or presinusoidal portal hypertension, the degree of portal hypertension and splanchnic arterial vasodilatation is moderate, the lymphatic system is able to return the excess of lymph produced in the hepatic and splanchnic area to the systemic circulation, and the arterial vascular underfilling is compensated by transient periods of sodium and water retention that increase the plasma volume and cardiac index and refill the dilated vascular bed. As cirrhosis progresses, however, portal hypertension and the secondary splanchnic arterial vasodilatation become progressively more intense and a critical point is

reached at which the consequences of splanchnic arterial vasodilatation can no longer be compensated by increasing lymph return, plasma volume, and cardiac output. The patients have effective hypovolemia and sodium and water retention, but this fluid is ineffective in compensating this impairment of circulatory function because it escapes from the intravascular compartment because of an imbalance between the formation and the reabsorption of lymph. The final consequence of both disorders is the continuous formation of ascites.





▪ **Figure 19.14** The "forward" theory of ascites formation.

During the initial stages of decompensated cirrhosis, sodium retention occurs despite normal levels of renin, aldosterone, and norepinephrine. It has been proposed that sodium retention at this period may be caused by mechanisms unrelated to a reduction in effective blood volume (reduced hepatic metabolism of some endogenous substance with sodium-retaining effect or a direct hepatorenal reflex) and may promote sodium retention. This is highly unlikely because these patients have hemodynamic characteristics identical to those of patients with ascites and high renin levels. The most likely explanation is that a still unknown mechanism extremely sensitive to changes in effective blood volume induces sodium retention at these early stages of decompensated cirrhosis. This mechanism would be more sensitive than that of the sympathetic nervous system and renin–angiotensin–aldosterone system and, consequently, would be stimulated earlier. Activation of the sympathetic nervous system and the renin–angiotensin–aldosterone system represents a further step and indicates more severe impairment of circulatory function as a consequence of the progression of the disease. Finally, the level of plasma antidiuretic hormone, the secretion of which is highly sensitive to small changes in serum osmolality but requires greater changes in effective blood volume, increases at later stages of the disease. This phenomenon explains why dilutional hyponatremia is a late event in the course of decompensated cirrhosis.

Management of Ascites in Cirrhosis

Bed rest, low sodium diet, and diuretics

The assumption of an upright posture associated with moderate physical exercise by patients with cirrhosis and ascites induces a marked stimulation of the renin–

angiotensin–aldosterone system and sympathetic nervous system (61). Therefore, from a theoretic point of view, bed rest may be useful in patients with poor response to diuretics. Because the natriuretic action of loop diuretics starts soon after administration and disappears approximately 3 hours later, bed rest should be adjusted to this time schedule. The effect of spironolactone lasts for more than 1 day and, therefore, is not important in planning bed rest.

Mobilization of ascites occurs when a negative sodium balance is achieved. In 10% to 20% of patients, those spontaneously excreting relatively high amounts of sodium in the urine, this can be obtained simply by reducing the sodium intake to 40 to 70 mEq/day (i.e., no salted food, no salt during cooking, no salt on the table). A greater reduction in sodium intake interferes with the nutrition of the patients and is not advisable (62). In most instances, a negative sodium balance cannot be achieved unless urinary sodium excretion is increased with diuretics. Even in these patients, sodium restriction is important because it reduces diuretic requirements. Patients responding satisfactorily to diuretics may be allowed to increase the sodium intake up to 70 to 100 mEq/day if they do not tolerate the standard low sodium diet. However, sodium restriction is essential in the care of patients responding poorly to diuretics. A frequent cause of "apparently" refractory ascites is inadequate sodium restriction. This should be suspected whenever ascites does not decrease despite a good natriuretic response to diuretics. Once ascites is mobilized, it is better to reduce the diuretic dosage than to increase sodium intake.

Furosemide and spironolactone are the diuretics most commonly used in the treatment of ascites in patients with cirrhosis. Furosemide, as do other loop diuretics (torsemide, ethacrynic acid, bumetanide), inhibits chloride and sodium reabsorption in the thick ascending limb of the loop of Henle but has no effect on the distal nephron (distal and collecting tubules). Furosemide is rapidly absorbed from the intestine, is highly bound to plasma proteins, and is actively secreted from the blood into the urine through the organic acid transport pathway in the proximal tubule. Once in the luminal compartment, furosemide is carried in the luminal fluid to the loop of Henle, where it inhibits the Na^+-$2Cl^-$-K^+ cotransport system located in the luminal membrane of the ascending limb cells, and sodium reabsorption occurs in this segment of the nephron. Because between 30% and 50% of the filtered sodium is reabsorbed in the loop of Henle, it is not surprising that furosemide has a high natriuretic potency. At high dosage, it can increase sodium excretion by up to 30% of the filtered sodium in healthy subjects. Furosemide also increases the synthesis of prostaglandin E_2 by the ascending limb cells. This effect is related to the natriuretic effect because nonsteroidal anti-inflammatory drugs reduce its natriuretic activity. The onset of action of furosemide is extremely rapid (within 30 minutes of oral administration), with the peak effect occurring within 1 to 2 hours and most natriuretic activity stopping 3 to 4 hours after administration.

Spironolactone undergoes extensive metabolism that produces numerous biologically active compounds, the

most important one being canrenone. These aldosterone metabolites are tightly bound to plasma proteins from which they are released slowly to the kidney and other organs. Spironolactone metabolites act by competitively inhibiting the tubular effect of aldosterone on the distal nephron. This hormone enters the collecting tubule through the basolateral membrane and interacts with a cytosolic receptor. The aldosterone receptor complex is translocated to the nuclei and

interacts with specific DNA sequences, stimulating the release of messenger ribonucleic acid and the synthesis of sodium channels, which are inserted into the luminal membrane, and the transporter Na^+/K^+-adenosine triphosphatase (ATPase), which activates the extrusion of sodium from the intracellular space into the peritubular interstitial space. The effect of this transporter together with the activation of potassium channels in the luminal membrane is the predominant mechanism of the kaliuretic effect of aldosterone. Spironolactone metabolites also enter the basolateral membrane in the collecting tubule and interact with the cytosolic receptor, but the complex spironolactone metabolite receptor is unable to interact with DNA. Therefore, spironolactone acts as a specific antagonist of aldosterone. The half-life of the aldosterone-induced proteins and of spironolactone metabolites is relatively prolonged, explaining the lag of 2 to 3 days between the initiation or the discontinuation of spironolactone treatment and the onset or the end of the natriuretic effect, respectively. Spironolactone metabolism is impaired in cirrhosis, such that the terminal half-life of spironolactone metabolites is increased in this condition. Because the amount of sodium reabsorbed in the collecting tubule is low, spironolactone and other distal diuretics (e.g., triamterene, amiloride) have a much lower natriuretic potency than furosemide. They are able to increase sodium excretion by up to 2% of the filtered sodium.

The administration of furosemide at relatively high doses (80 to 160 mg/day) to nonazotemic patients with cirrhosis and ascites gives rise to a satisfactory natriuretic response in only 50% of cases. In contrast, most of these patients respond to spironolactone at doses of 150 to 300 mg/day (55) (Table 19.4). The mechanism of this resistance to the natriuretic effect of furosemide is mainly pharmacodynamic. Most of the sodium not reabsorbed in the loop of Henle by the action of furosemide is subsequently reabsorbed in the distal nephron by the action of aldosterone. Patients responding to furosemide are those with normal or only moderately increased plasma aldosterone levels. Patients with marked hyperaldosteronism usually do not respond to this drug. The response to spironolactone depends on the degree of hyperaldosteronism. Patients with a normal or slightly increased plasma concentration of aldosterone usually respond to low doses of spironolactone (100 to 150 mg/day), but as much as 300 to 400 mg/day may be needed to antagonize the tubular effect of aldosterone in patients with marked hyperaldosteronism. The basic drug for the treatment of ascites, therefore, is spironolactone. Simultaneous administration of furosemide and spironolactone increases the natriuretic effect of both agents and reduces the incidence of hypo- or hyperkalemia that can occur when these drugs are given alone.

Table 19.4. Comparison of the Efficacy of Furosemide and Spironolactone in Nonazotemic Cirrhosis with Ascites

	Positive response	Negative response	Total
Furosemide	11	10[a]	21
Spironolactone	18	1[b]	19

χ^2=6.97; P < 0.01.
[a]Nine cases responded later to spironolactone.
[b]This case did not respond later to furosemide.
From (63) Pérez-Ayuso RM, Arroyo V, Planas R, et al. Randomized comparative study of efficacy of furosemide versus spironolactone in nonazotemic cirrhosis with ascites. *Gastroenterology* 1984;84:961–968, with permission.

Two different diuretic approaches can be used in patients with cirrhosis and ascites. The step-care approach (64) consists of the progressive implementation of the therapeutic measures currently available, starting with sodium restriction. If ascitic volume does not decrease (as measured by loss of body weight), spironolactone is given at increasing doses (starting with 100 mg/day; if no response is seen within 4 days, increasing to 200 mg/day; and if no response is seen, further increasing to 400 mg/day). When there is no response to the highest dose of spironolactone, furosemide is added, also by increasing the dosage every 2 days (40 to 160 mg/day). The second approach is the combined treatment. It begins with the simultaneous administration of sodium restriction, spironolactone 100 mg/day, and furosemide 40 mg/day. If the diuretic response is insufficient after 4 days, the dose is increased to 200 mg/day and 80 mg/day, respectively. For patients who do not respond despite the increase in dosage, spironolactone and furosemide are increased to 400 mg/day and 160 mg/day, respectively. A recent randomized controlled trial has shown that the step-care and the combined treatment approaches are similar in terms of response rate, rapidity of ascites mobilization, and incidence of complications (65). There is a general agreement that patients not responding to 160 mg/day of furosemide and 400 mg/day of spironolactone will not respond to higher doses of these diuretics. For patients receiving the combined treatment with an exaggerated response,

diuretic administration should be adjusted with a reduction in the dose of furosemide. The goal of diuretic treatment should be to achieve a weight loss of 300 to 500 g/day in patients without peripheral edema and 500 to 1,000 g/day in patients with peripheral edema. Once ascites is mobilized, diuretic treatment should be reduced to keep the patients free of ascites. The most important predictor of diuretic response in patients with cirrhosis and ascites is the degree of impairment of circulatory and renal function. Patients with increased serum creatinine levels (>1.2 mg/dL; upper normal limit), dilutional hyponatremia (serum sodium concentration <130 mEq/L), or intense hyperaldosteronism need a high diuretic dosage or do not respond to the highest doses of furosemide and spironolactone.

The major complications associated with diuretic management of cirrhosis with ascites are renal failure, hyponatremia, and hepatic encephalopathy (55). Approximately 20% of patients with cirrhosis and ascites have marked renal impairment (increased blood urea nitrogen and serum creatinine levels), which is usually moderate and always reversible after diuretic withdrawal. It is caused by

a reduction in intravascular volume caused by an imbalance between the fluid loss induced by the diuretic treatment and the reabsorption of ascitic fluid into the general circulation, which varies greatly from patient to patient. The incidence of diuretic-induced renal failure is lower among patients with ascites and peripheral edema than among those without edema because there is no limitation in the reabsorption of peripheral edema into the general circulation; therefore, it compensates any insufficient reabsorption of ascites.

Hyponatremia secondary to impairment of the renal ability to excrete free water also occurs in 20% of patients with cirrhosis and ascites managed with diuretics. Two mechanisms are involved in this complication. The first is related to the reduction in intravascular volume, which stimulates baroreceptors and the secretion of antidiuretic hormone. The second is related to the action of furosemide. Free water (water free of solutes) is generated within the kidney by the active reabsorption of chloride and sodium without the concomitant reabsorption of water from the water-impermeable ascending limb of the loop of Henle. The hypotonic urine generated by this process is maintained throughout the distal nephron if antidiuretic hormone secretion is inhibited, for example, after a water load. Furosemide interferes with the generation of free water because it inhibits chloride and sodium reabsorption in the ascending limb of the loop of Henle. In patients with advanced cirrhosis, who have a spontaneous severe reduction in free water excretion caused by homeostatic nonosmotic hypersecretion of antidiuretic hormone, any additional impairment of renal water metabolism, because of either further stimulation of antidiuretic hormone secretion or interference with the diluting process of the urine in the loop of Henle, can precipitate the development of severe hyponatremia.

The most severe complication of diuretic therapy for cirrhosis with ascites is hepatic encephalopathy, which has been reported to occur in 25% of cases (55). The mechanism is unknown. It has been suggested that it may be caused by an increase in renal production of ammonia. Accentuation of the cerebral vasoconstriction already present in these patients secondary to the reduction in intravascular volume may be a contributory event.

Other complications of use of diuretics to manage cirrhosis include hyperkalemia and metabolic acidosis in patients with renal failure treated with high doses of spironolactone, hypokalemia in patients treated with high doses of furosemide and no or low doses of spironolactone, gynecomastia in patients receiving spironolactone, and muscle cramps. Muscle cramps are clearly related to the reduction in intravascular volume because they occur in patients with severe baseline circulatory dysfunction and can be prevented by means of plasma volume expansion with albumin. Oral administration of quinine also reduces the frequency of diuretic-induced muscle cramps (57).

Therapeutic paracentesis

Treatment with low sodium diet and diuretics is effective in mobilizing ascites in cirrhosis. However, it has several limitations. First, approximately 10% to 20% of patients do not respond to diuretics (diuretic-resistant ascites). Second, diuretic treatment is frequently associated with complications, particularly when high doses of diuretics have to be used. Finally, the mobilization of ascites with diuretics is a slow process. This problem is not relevant to the care of patients with moderate ascites, who are usually treated as outpatients.

In 1987 the demonstration that large-volume paracentesis associated with

plasma volume expansion is a rapid, effective, and safe treatment of ascites in cirrhosis has considerably simplified the treatment of patients admitted to the hospital with tense ascites (66). Therapeutic paracentesis is considered the best therapy for tense ascites in cirrhosis (62). It considerably shortens hospital stay and, therefore, the cost of treatment, and the incidence of complications during hospitalization is significantly lower among patients undergoing paracentesis than among those treated with diuretics (66,67,68).

Although paracentesis is a simple procedure, several precautions should be taken to avoid complications. Therapeutic paracentesis can be performed either as repeated large-volume paracentesis (4 to 6 L/day until complete disappearance of ascites) or as total

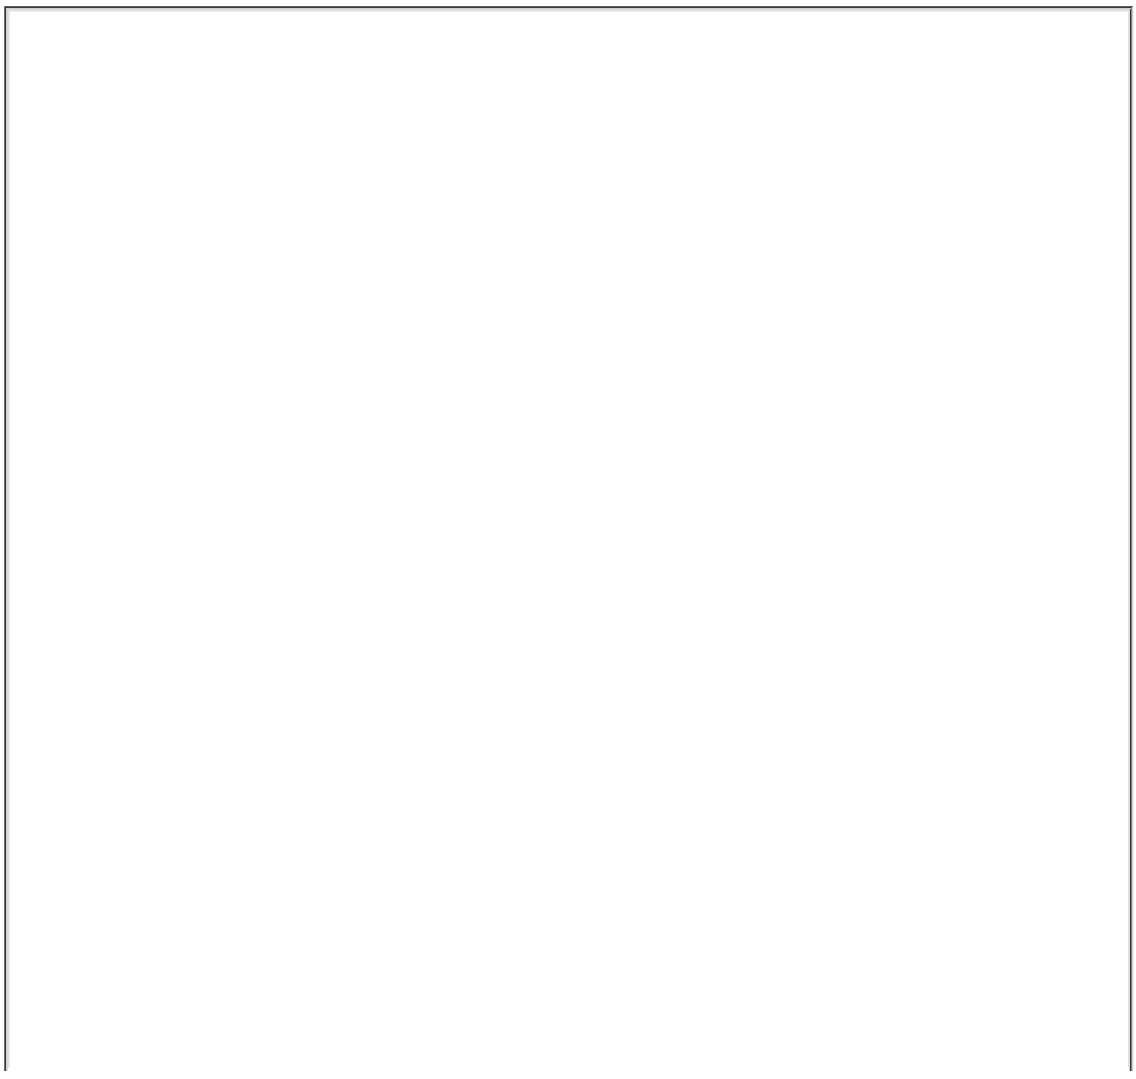
paracentesis (complete removal of ascites in only one paracentesis session). Total paracentesis is the best method because it is faster and associated with lower incidence of local complications (49,57,58). Ascites leakage through the skin or within the abdominal wall is relatively frequent after partial paracentesis because a significant volume of ascites remains in the peritoneal cavity after the procedure. On the other hand, although complications related to the insertion of the needle are exceptional, the incidence increases with the number of taps. Paracentesis should be performed under strictly sterile conditions with specially designed needles. We use a modified Küss needle, which is a sharp, pointed, blind, metal needle within a 7-cm long, 17-gauge, metal, blunt-edged cannula with side holes. With the patient under local anesthesia, the needle is inserted into the left lower abdominal quadrant. The inner part is removed, and the cannula is connected to a large-capacity suction pump. The physician should remain at the bedside throughout the procedure. With this technique, the duration of treatment ranges from 30 to 60 minutes, depending on the amount of ascitic fluid removed. Total paracentesis procedures are finished when the flow from the cannula becomes intermittent despite gentle mobilization of the cannula within the peritoneal cavity and turning the patient to the left side. Peripheral edema is rapidly reabsorbed after the mobilization of ascites in most patients and usually disappears within the first 2 days of treatment. Most of the fluid goes to the abdominal cavity as ascites. It is therefore not infrequent for patients with marked peripheral edema to need a second procedure after complete mobilization of ascites at the initial paracentesis. Patients treated by means of repeated large-volume paracentesis should recline for 2 hours on the side opposite the paracentesis site to prevent the leakage of ascitic fluid. The modified Küss needle and specific kits for paracentesis that include the needle are now available commercially.

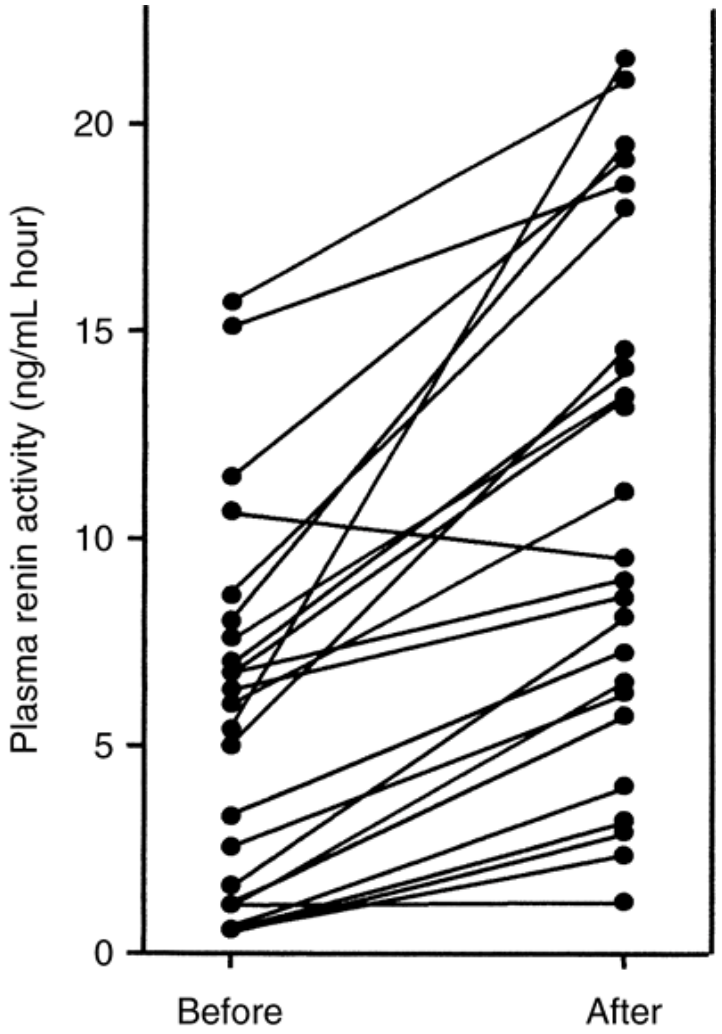
When paracentesis is performed without plasma volume expansion, there are no apparent major changes in circulatory function. Arterial pressure decreases slightly, but this also occurs when paracentesis is performed with plasma volume expansion. The pulse rate does not increase, and the patient does not experience any symptoms other than those related to the disappearance of ascites (67,69). In addition, if serum creatinine and serum electrolytes are measured within the first days of performance of paracentesis, no changes are observed in most patients. For this reason, some investigators consider that therapeutic paracentesis does not adversely affect circulatory function and that, consequently, plasma volume expansion is not necessary in the care of patients with cirrhosis and ascites treated with this procedure.

Many studies indicate that marked changes in circulatory function occur after

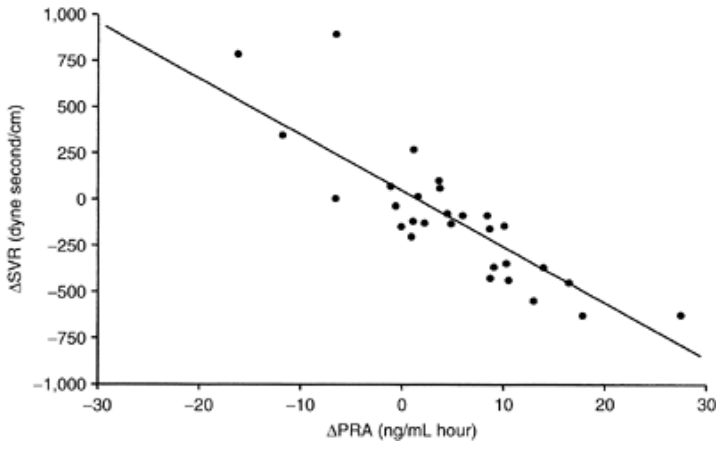
therapeutic paracentesis (59). Immediately after paracentesis, circulatory function improves, with a marked increase in cardiac output and stroke volume, a reduction in cardiopulmonary pressure, and a suppression of the renin–angiotensin and sympathetic nervous systems (59). These effects, which persist for approximately 12 hours and have been attributed to mechanical factors (i.e., reduction in intrathoracic pressure and increase in venous return), are followed by opposing hemodynamic changes, including a reduction in cardiac output to baseline value and marked activation of the renin–angiotensin (Fig. 19.15) and sympathetic nervous systems over the corresponding levels before paracentesis (69). Renal function also improves during the first hours after paracentesis and may worsen 24 to 48 hours after the procedure. The impairment of circulatory function induced by paracentesis is not related, as proposed initially, to a decrease in circulating blood volume secondary to a rapid reaccumulation of ascites, but rather to an accentuation of the arterial vasodilatation already present in these patients (Fig. 19.16). The mechanism by which paracentesis induces reduction of peripheral vascular resistance and the site where this vasodilatation occurs are unknown, although it is probably in the splanchnic circulation. An important observation is that the circulatory dysfunction induced by paracentesis is not

spontaneously reversed (68). Once plasma renin activity and plasma norepinephrine concentration increase, they remain elevated throughout the course of the disease. The cause of this phenomenon is unknown.





• **Figure 19.15** Plasma renin activity before and after therapeutic paracentesis without albumin infusion. (From Ginès P, Tito L, Arroyo V, et al. Randomized comparative study of therapeutic paracentesis with and without intravenous albumin in cirrhosis. *Gastroenterology* 1988;94:1493–1502, with permission.)

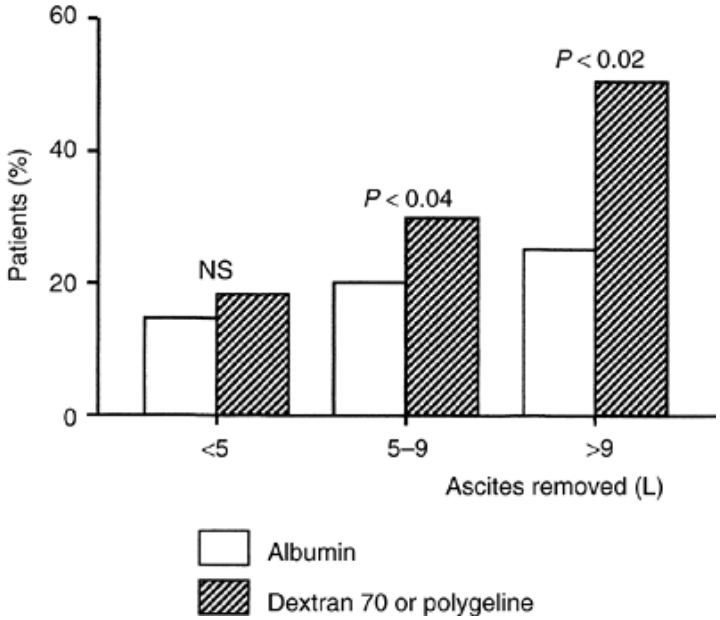


▪ **Figure 19.16** Direct negative correlation between the increase in plasma renin activity (ΔPRA) and the decrease in systemic vascular resistance (ΔSVR) after therapeutic paracentesis in cirrhosis. (From Ruiz del Arbol L, Monescillo A, Jimenez W, et al. Paracentesis-induced circulatory dysfunction: mechanism and effect on hepatic hemodynamics in cirrhosis. *Gastroenterology* 1997;113:579–586, with permission.)

Plasma renin activity is a sensitive marker of circulatory function and is the parameter used to detect impairment of circulatory function after paracentesis in most studies. Paracentesis-induced circulatory dysfunction has been defined as a 50% increase in plasma renin activity over baseline on the sixth day after treatment up to a value greater than 4 ng/mL hour (upper normal limit) (50, 59, 60). According to this criterion, the incidence of spontaneous circulatory dysfunction among patients with cirrhosis admitted to hospital because of tense ascites and not receiving any treatment during 1 week of hospitalization was 16% (unpublished observations obtained in 56 patients). The incidence of paracentesis-induced circulatory dysfunction has been estimated to be 75% among patients not undergoing plasma volume expansion, 33% to 38% in patients receiving polygeline (saline solution, 8 g/L of ascitic fluid removed), dextran 70 (dextrose solution, 8 g/L of ascitic fluid removed, or saline), and 11% to 18% among patients receiving albumin (salt-poor solution, 8 g/L of ascitic fluid removed) (68). Similar findings have been reported in a recent trial comparing albumin versus saline in patients with ascites treated by total paracentesis (70). The incidence of paracentesis-induced circulatory dysfunction was 33.3% in patients receiving saline and 11.4% in those receiving albumin.

In the care of patients undergoing plasma volume expansion and treated by total paracentesis, the amount of ascitic fluid volume removed is a predictor of paracentesis-induced circulatory dysfunction (Fig. 19.17). When the amount of ascitic fluid removed is less than 5 L, the

incidence of circulatory dysfunction is similar among patients treated with albumin and those treated with synthetic plasma expanders (16% vs. 18%). However, when the amount is between 5 and 9 L, the incidence of circulatory dysfunction is higher among patients receiving synthetic plasma expanders (19% vs. 30%). Differences are particularly marked when the volume of the paracentesis is greater than 9 L. In the latter case, the incidence of paracentesis-induced circulatory dysfunction is 52% among patients receiving synthetic plasma expanders (68).



▪ **Figure 19.17** Relationship between the rate of circulatory dysfunction following paracentesis, the volume of ascites removed, and the type of plasma expander used. NS, not significant. (From Ginès A, Fernandez-Esparrach G, Monescillo A, et al. Randomized trial comparing albumin, dextran 70, and polygeline in cirrhotic patients with ascites treated by paracentesis, *Gastroenterology* 1996;111:1002–1010, with permission.)

These data indicate the following: (a) Paracentesis-induced circulatory dysfunction is frequent when the plasma volume is not expanded, (b) plasma volume expansion with synthetic colloids is effective in reducing the incidence of circulatory dysfunction after paracentesis, (c) plasma volume expansion with albumin almost totally prevents paracentesis-induced circulatory dysfunction, (d) among patients with an ascitic fluid volume of less than 5 L, the incidence of paracentesis-induced circulatory dysfunction is low and independent of the type of the plasma expander used, (e) when the amount of ascitic fluid volume removed is over 5 L, the incidence of circulatory dysfunction increases with the volume of paracentesis in patients receiving synthetic plasma expanders but not in those receiving albumin.

Despite being asymptomatic, paracentesis-induced circulatory dysfunction adversely affects the clinical course of the disease. The incidence of hyponatremia (3.8% vs. 17%) and renal impairment (0% vs. 11%) within few days of paracentesis is significantly lower among patients receiving albumin infusions than among those not receiving plasma expanders. The time to first readmission to hospital is significantly shorter for patients with circulatory dysfunction after paracentesis than among those who do not have this complication. Finally, the probability of survival is also lower among patients with circulatory dysfunction after paracentesis (68).

The mechanism by which deterioration in circulatory function impairs the clinical course and the prognosis for patients with cirrhosis and ascites is probably multifactorial. Circulatory dysfunction is associated with an increase in the

circulating levels of vasoconstrictors, which impairs renal hemodynamics and the renal response to diuretics. Angiotensin II and norepinephrine are important mediators of HRS, which are associated with a poor survival. These substances also induce vasoconstriction of intrahepatic vascular resistance, which may reduce liver perfusion, impair hepatic function, and increase portal pressure. These changes may further deteriorate circulatory function and create vicious circles that accelerate the course of the disease. One study has shown that the hepatic venous pressure gradient (an estimation of the intrahepatic vascular resistance) increases after paracentesis in patients with circulatory dysfunction but not in patients who do not have this complication (69).

There is substantial evidence indicating that paracentesis-induced circulatory dysfunction is a relevant complication that should be prevented. The best way to do this is to expand the plasma volume with albumin when the volume of ascitic fluid removed is more than 5 L. When the volume is less than 5 L, less expensive synthetic plasma expanders can be used. The amount of albumin given in most centers is 8 g/L of ascitic fluid removed, which represents the approximate amount of albumin removed with the paracentesis. Fifty percent of the dose is infused immediately after paracentesis and 50% after 6 hours. The patient may then leave the hospital with diuretics to prevent the reaccumulation of ascites. Patients with normal blood urea nitrogen and serum creatinine levels require a standard diuretic dosage (200 mg/day of spironolactone or 40 mg/day of furosemide plus 100 mg/day of spironolactone). Higher diuretic dosages, however, are required in patients with abnormal blood urea nitrogen or serum creatinine concentration, or in patients with ascites that is refractory before treatment.

Management of refractory ascites

According to the International Ascites Club, the term *refractory ascites* applies to the ascites that cannot be mobilized or the early recurrence of which (i.e., after therapeutic paracentesis) cannot be prevented by medical therapy (70). There are two subtypes of refractory ascites. Diuretic-resistant ascites is the type that cannot be mobilized (loss of body weight less than <200 g/day after 4 days) or the early recurrence of which cannot be prevented because of a lack of response to dietary sodium restriction (approximately 50 mEq/day) and intensive diuretic treatment (spironolactone 400 mg/day plus furosemide 160 mg/day). Diuretic-intractable ascites is the type that cannot be mobilized or the early recurrence of which cannot be prevented because of the development of diuretic-induced complications that precludes the use of an effective diuretic dosage (e.g., hepatic encephalopathy in the absence of any other precipitating cause, increase in serum creatinine by >100% to a value >2 mg/dL, decrease in serum sodium level by >10 mEq/L to a concentration <125 mEq/L, and decrease of serum potassium level to <3 mEq/L or an increase to >6 mEq/L despite appropriate measures to normalize potassium concentration). Recidivant ascites is the type that recurs frequently (on three or more occasions within a 12-month period) despite dietary sodium restriction and adequate diuretic dosage. This condition should not be considered as refractory ascites.

Most patients with cirrhosis who have diuretic-resistant ascites have type 2 HRS (serum creatinine level >1.5 mg/dL) or lesser despite marked degrees of impairment of renal perfusion and GFR (serum creatinine level between 1.2 and 1.5 mg/dL). It has

been estimated that a serum creatinine level greater than 1.2 mg/dL in patients with cirrhosis and ascites reflects a decrease of renal blood flow and GFR greater than 50% with respect to values in healthy persons. The most important mechanisms of refractory ascites are (a) impairment of the access of diuretics to the effective sites on the tubular cells due to the renal hypoperfusion and (b) reduced delivery of sodium to the ascending limb of the loop of Henle and the distal nephron secondary to the low GFR and an excessive sodium reabsorption in the proximal tubule. Inadequate sodium restriction or the use of nonsteroidal anti-inflammatory drugs should be ruled out in the evaluation of any patient with the presumptive diagnosis of diuretic-resistant ascites.

Three different treatments can be used for the management of patients with cirrhosis and refractory ascites: Peritoneovenous shunting, TIPS, and therapeutic paracentesis (71,72). Peritoneovenous shunting was the first treatment specifically designed for patients with refractory ascites. LeVeen et al. introduced the first prosthesis in 1974. It consists of a perforated intra-abdominal tube connected through a one-way pressure-sensitive valve to a second tube that traverses the subcutaneous tissue up to the neck, where it enters the internal jugular vein. The tip of the intravenous tube is located in the superior vena cava near the right atrium. Insertion of a LeVeen shunt is technically simple and can be performed under local anesthesia. It is advisable to remove most of the ascitic fluid before the insertion of the prosthesis to avoid early complications related to the massive passage of ascites to the general circulation (e.g., pulmonary edema, variceal hemorrhage, and severe intravascular coagulation). Prophylactic administration of antistaphylococcal antibiotics before and after surgery is also recommended. Although the LeVeen shunt is the most widely used, other types, such as the Denver shunt, are available. However, they do not improve the results obtained with the initial prosthesis.

The shunt produces a sustained expansion of the circulating blood volume by the continuous passage of ascitic fluid from the abdominal cavity to the systemic circulation; a marked suppression of the plasma levels of renin, norepinephrine, and antidiuretic hormone; and an increased response to diuretics. Therefore, it is a rational therapy for refractory ascites (10). Unfortunately, obstruction of the shunt is common and occurs in approximately 40% of patients within the first postoperative year; it is usually due to the deposition of fibrin either in the valve or around the intravenous catheter, thrombotic obstruction of the venous limb of the prosthesis, or thrombosis of the superior vena cava. Although thrombosis of the vena cava is usually incomplete, total occlusion can occur, resulting in the development of a superior vena cava syndrome. Shunt occlusion requires reoperation, removal of the obstructed shunt, and insertion of a new prosthesis. Another long-term complication of peritoneovenous shunting is small-bowel obstruction, which occurs in approximately 10% of patients. Small intestinal obstruction is caused by marked intraperitoneal fibrosis and can make further intra-abdominal procedures, such as liver transplantation, impossible.

The reintroduction of therapeutic paracentesis has markedly reduced the use of peritoneovenous shunting in patients with refractory ascites. Results of two randomized controlled trials have been published in which paracentesis was compared with use of a LeVeen shunt in the care of these patients. Although shunting was clearly superior in the long-term control of ascites, it had no effect on the course of the disease. Patients from both therapeutic groups did not differ in the time to first readmission to the hospital during the follow-up and survival (Table 19.5). Furthermore, frequent reoperations were needed because of shunt

obstruction (10). These data led the International Ascites Club to propose that paracentesis is preferred to peritoneovenous shunting for the management of refractory ascites.

TIPS is the most recent treatment introduced for the management of refractory ascites. It works as a side-to-side portacaval shunt and, from a theoretic point of view, it should correct the two principal mechanisms in the pathogenesis of ascites (71). By doing so, it should suppress the endogenous vasoconstrictor system, improve renal perfusion and GFR, and increase the response to diuretics. On the other hand, by decompressing both the splanchnic and the hepatic microcirculation, TIPS should decrease the formation of lymph both in the liver and in the other splanchnic organs.

A review of the records of the first 358 reported patients with refractory ascites treated with TIPS clearly indicated that this therapeutic procedure is extremely effective in improving circulatory and renal function and in managing ascites in these patients (71). TIPS induces a marked increase in cardiac output, a decrease in systemic vascular resistance, and an elevation in right atrial pressure, pulmonary artery pressure, and pulmonary wedge pressure (59,60). These changes, which

are similar to those after peritoneovenous shunting, are probably caused by an increase in venous return resulting from the presence of portacaval fistula. The decrease in systemic vascular resistance, which is also a constant feature in patients treated by peritoneovenous shunting, is probably a physiologic response to accommodate the increase in cardiac output.

Table 19.5. Peritoneovenous Leveen Shunt Versus Therapeutic Paracentesis in the Management of Refractory Ascites: Efficacy, Associated Complications, and Survival

	Paracentesis (*n* = 38)	LVS (*n* = 42)
Ascites episodes	125	38
LVS obstruction[a]	—	40%
Time in hospital (days)	48 ± 8	44 ± 6
Survival[a]	57%	44%

[a]1-year probability.
LVS, LeVeen shunt.

Because it increases the hyperdynamic circulation, it has been suggested that TIPS impairs the systemic hemodynamics in cirrhosis. However, results of studies of the effects of TIPS on the endogenous vasoactive systems do not support this concept. The results indicate that effective arterial blood volume is markedly improved after TIPS insertion in patients with cirrhosis and ascites. As indicated

earlier, the maintenance of arterial pressure in patients with advanced cirrhosis and ascites is critically dependent on a marked overactivity of the renin–angiotensin system, sympathetic nervous system, and antidiuretic hormone. If TIPS enhances arterial vasodilatation, a further increase in the degree of stimulation of these vasoconstrictor systems should occur. In contrast, TIPS insertion is associated with marked suppression of the plasma levels of renin, aldosterone, norepinephrine, and antidiuretic hormone (59,60). Suppression of the renin–angiotensin–aldosterone system occurs within the first week of TIPS insertion and persists during the follow-up period. Suppression of norepinephrine and antidiuretic hormone seems to require a longer period of time.

Deterioration in circulatory function should also be associated with a further impairment of renal function after TIPS insertion; however, this process induces a rapid increase in urinary sodium excretion, which is already observed within the first 1 to 2 weeks and persists during the follow-up period (59,60). A significant increase in serum sodium concentration and GFR is also observed, indicating an improvement in renal perfusion and free water clearance. However, these latter changes require 1 to 3 months to occur.

TIPS induces a marked decrease in the portacaval gradient. In the aforementioned review of the care of 358 patients with refractory ascites treated by TIPS, the mean decrease was from 20.9 to 10 mm Hg (60). Portal venous pressure also decreased markedly, from 29.4 to 21.8 mm Hg. However, TIPS only partially decompresses the portal venous system; portal venous pressure in most healthy subjects is less than 5 mm Hg. Although suppression of the renin–aldosterone system is evident, the plasma levels of renin and aldosterone do not decrease to normal levels. Improvement in splanchnic and systemic hemodynamics is associated with the disappearance of ascites or partial response (no need for paracentesis) in most patients. Only 10% of cases do not respond to TIPS. Ascites characteristically resolves slowly (within 1 to 3 months). Continuous diuretic treatment is required in more than 95% of cases, either for the management of ascites or to reduce the peripheral edema that frequently occurs in patients treated with TIPS. The persistence of portal hypertension and hyperaldosteronism may be the explanation for this phenomenon.

Hepatic encephalopathy is the most important complication among patients with cirrhosis and refractory ascites managed with TIPS (60). More than 40% of patients have this complication. In most cases hepatic encephalopathy responds to standard therapy. However, it occasionally requires a decrease in stent size. Although hepatic encephalopathy before insertion of TIPS is a predictor of encephalopathy after its insertion, new or worsening hepatic encephalopathy develops in approximately 30% of cases. Shunt dysfunction is also a major problem, occurring in approximately 40% of cases within the first year. This is an important limitation of TIPS that necessitates frequent retreatments. The 1-year probability of survival among patients with cirrhosis and refractory ascites treated with TIPS is extremely poor. Early mortality (within 30 days of insertion of TIPS) is approximately 12% and late mortality is 40%. Predictors of survival are the Child-Pugh score, age, and the presence of HRS before TIPS insertion (60).

Five randomized controlled trials have been reported comparing TIPS and therapeutic paracentesis (73,74,75,76,77). Two included patients with recidivant and refractory ascites, and three included patients with only refractory ascites. The five trials clearly showed that TIPS was better than paracentesis in the long-term control of ascites. Three trials showed significantly higher incidence of

hepatic encephalopathy in patients treated with TIPS. An improvement in survival in the TIPS group was observed only in the trials including patients with recidivant ascites. The total time in hospital during follow-up was similar in both groups owing to the high incidence of shunt obstruction requiring new hospitalization for treatment of complications related to portal hypertension and/or restenting (Table 19.6). In one of these trials the quality of life was assessed and changes were similar in the two therapeutic groups (78). These results indicate that TIPS changes the course of cirrhosis from ascites to hepatic encephalopathy without improving the overall results of paracentesis in relation to length of hospitalization and survival.

Treatment of Patients with Cirrhosis, Ascites, and Hyponatremia or Hepatorenal Syndrome

Hyponatremia in patients with cirrhosis and ascites is usually asymptomatic, even in those with markedly reduced serum sodium concentration. On the other hand, it does not contraindicate diuretic treatment

because most patients respond to treatment without a further reduction in serum sodium concentration. Therefore, the use of aggressive procedures (e.g., peritoneovenous shunting, TIPS) for the treatment of hyponatremia is not justified. The intravenous administration of sodium chloride may produce a transient increase in serum sodium concentration but at the expense of increasing the rate of ascites formation. Finally, water restriction is difficult to carry out and is rarely effective. Therefore, at present there is no treatment for dilutional hyponatremia in cirrhosis. However, the future is very promising. Several specific antagonists of the renal effect of antidiuretic hormone (V2 antagonists) have been developed by different pharmaceutical companies and tested for treatment of patients with cirrhosis, ascites, and dilutional hyponatremia (11,12,79,80). These agents produce a marked increase in urine volume without a concomitant increase in urine sodium and solute excretion; this effect is associated with a significant increase in serum sodium concentration and serum osmolality in most patients. There are, however, patients in whom hyponatremia is refractory to aquaretic drugs (11), indicating that mechanisms other than antidiuretic drugs play an important role in the pathogenesis of free water retention in cirrhosis. The aquaretic drugs, therefore, will be important for the management of patients with cirrhosis. Potential indications would be not only the treatment of spontaneous dilutional hyponatremia but also the prevention and treatment of diuretic-induced hyponatremia.

Table 19.6. Transjugular Intrahepatic Portacaval Shunt Versus Paracentesis for Refractory Ascites—Summary of Studies

	Type of ascites	Control of ascites	Hepatic encephalopathy	Survival
Lebrec et al. (73)	Refractory	Better with TIPS	No difference	Worse with TIPS

Rössle et al. (74)	Refractory and recidivant	Better with TIPS	No difference	Better with TIPS
Ginès et al. (76)	Refractory	Better with TIPS	Worse with TIPS	No difference
Sanyal et al. (77)	Refractory	Better with TIPS	Worse with TIPS	No difference
Salerno et al. (75)	Refractory and recidivant	Better with TIPS	Worse with TIPS	Better with TIPS

TIPS, transjugular intrahepatic portacaval shunt.

Table 19.7. Effects of 1- to 2-Week Treatment with Ornipressin or Terlipressin Plus Albumin on Mean Arterial Pressure, Plasma Renin Activity, Norepinephrine, and Serum Creatinine Levels in Type 1 Hepatorenal Syndrome

	Baseline (*n* = 15)	**Day 7 (*n* = 9)**	**Day 14 (*n* = 7)**
MAP (mm Hg)	70 ± 8	77 ± 9	79 ± 12
PRA (ng/mL h)	15 ± 15	2 ± 3	1 ± 1
NE (pg/mL)	1,257 ± 938	550 ± 410	316 ± 161
Creatinine (mg/dL)	3 ± 1	2 ± 1	1 ± 1

Normal values: Plasma renin activity <1.4 ng/mL h; NE <250 pg/mL.
P < 0.001 for all values (analysis of variance [ANOVA]).
MAP, mean arterial pressure; PRA, plasma renin activity; NE, norepinephrine concentration.

Ginès P, Cordenas A, et al. Terlipressin plus albumin infusion: an effective and safe therapy of hepatorenal syndrome. *J Hepatol* 2000;33:43–48, with permission.

For many years there has been no effective therapy for HRS, a severe complication. Expansion of plasma volume, administration of renal vasodilatory drugs (e.g., dopamine, prostaglandins), and insertion of a peritoneovenous shunt fail to produce a sustained increase in renal perfusion and GFR in these patients. However, the situation has changed completely during the last few years. Results of several studies show that long-term (1 to 2 weeks) simultaneous administration of albumin and vasoconstrictors (e.g., ornipressin, terlipressin, octreotide plus midodrine, or norepinephrine) to patients with severe type 1 HRS induces a normalization of plasma renin activity and a marked suppression of the plasma level of norepinephrine. These findings

indicate improvement in circulatory function (Table 19.7) (6,7) associated with normalization in serum creatinine and serum sodium concentration and a marked increase in GFR. The results of these studies also strongly suggest that reversal of HRS is associated with an increased survival (Table 19.8). TIPS is also effective in the treatment of patients with type 1 HRS (81,82). Improvement in renal function with TIPS occurs in approximately 75% of cases. Most important, survival rate also improves.

Table 19.8. Treatment of Hepatorenal Syndrome with Vasoconstrictors and Albumin and with Standard Medical Therapy: Review of 19 Studies (6,7,83,84,85,86,87,88,89,90,91,92,93,94,95,96)

	Group 1 (*n* = 155)	Group 2 (*n* = 137)	MCFS (*n* = 99)
Reversal of HRS	61.7%	2.9%	58%
HRS recurrence	20%	—	—
Survival 1 mo	41.6%	3%	40%
Survival 3 mo	30%	0%	22%

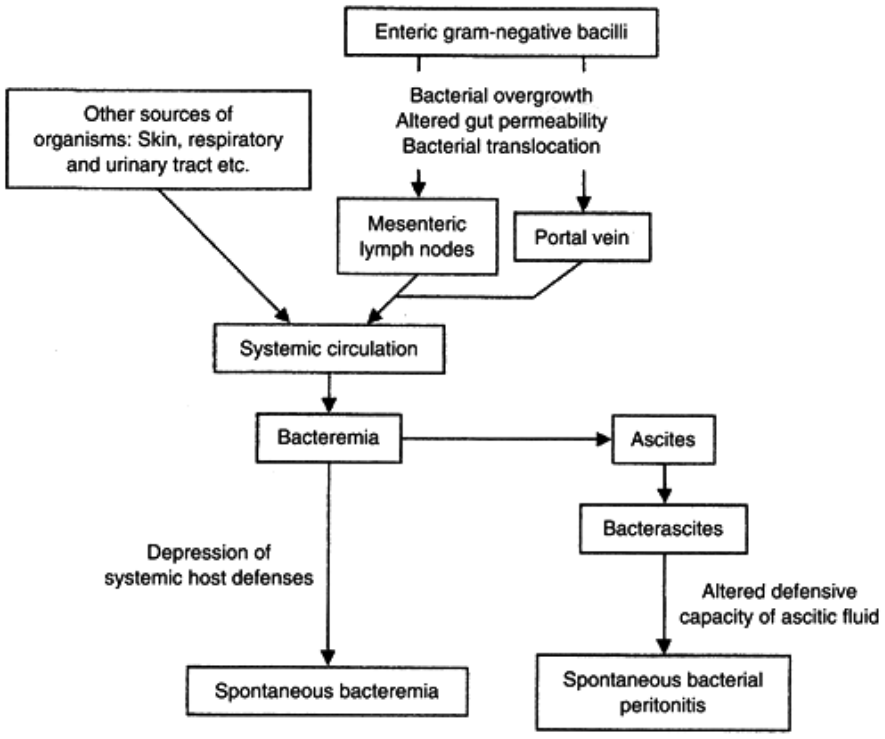
Liver transplantation	12.3%	—	13%

Group 1: It includes 12 pilot studies assessing treatment with vasoconstrictors (e.g., ornipressin, terlipressin, amidodrine, or noradrenaline) associated with the infusion of albumin in patients with hepatorenal syndrome (most with type 1 HRS).
Group 2: It includes six studies in patients with HRS (most with type 1 HRS) treated with standard medical therapy (volume expansion alone or associated with dopamine).
MCFS: Multicenter French Study reviewing 99 patients with type 1 HRS treated with terlipressin plus albumin in 22 hospitals (84). It represents the results obtained in daily clinical practice, outside pilot or randomized studies.
HRS, hepatorenal syndrome; MCFS, Multicenter French Study.

Ginès and Rodés give a detailed description of the treatment of dilutional hyponatremia and HRS in Chapter 17.

Spontaneous Bacterial Peritonitis

SBP is defined as the infection of a previously sterile ascitic fluid without an apparent intra-abdominal source of infection. The prevalence of SBP in unselected patients with cirrhosis and ascites admitted to a hospital ranges between 10% and 30% (97). Most patients with SBP present with complicated ascites (i.e., ascites plus fever, abdominal pain, diarrhea or ileus, encephalopathy, or renal failure). The incidence of SBP in patients with uncomplicated ascites (i.e., patients admitted only for the treatment of ascites with paracentesis) ranges between 0% and 3.6% (98,99). The diagnosis of SBP is established with a PMN count in ascitic fluid higher than 250 cells/mm^3. In approximately 50% to 60% of the cases, the organism responsible is isolated in ascitic fluid culture or in blood cultures. The remaining cases are considered as a variant of SBP (neutrocytic ascites) and are managed in the same way as those with a positive culture (100). The outcome among patients with cirrhosis and SBP has dramatically improved during the last 20 years. In the last randomized controlled trial comparing cefotaxime versus cefotaxime plus intravenous albumin infusion at the time of diagnosis of infection, the hospital mortality among patients receiving albumin was only of 10% (13). An early diagnosis of SBP, the use of third-generation cephalosporins, and the expansion of plasma volume at the time of diagnosis of infection to prevent the impairment of circulatory function induced by SBP are the most likely reasons for the improvement in SBP prognosis. Mortality associated with SBP is due to the development of a severe impairment of circulatory function leading to multiorgan failure (3,5). Patients with cirrhosis recovering from an episode of SBP should be considered potential candidates for liver transplantation because the survival expectancy after this bacterial infection is very poor.



▪ **Figure 19.18** Pathogenesis of spontaneous bacterial peritonitis.

Pathogenesis

Colonization of the ascitic fluid from an episode of bacteremia is the most accepted hypothesis of the pathogenesis of SBP (Fig. 19.18). Although the passage of microorganisms from the bloodstream to ascitic fluid

has never been documented, it can be assumed that bacteria present in the circulation can easily pass to the ascitic fluid and exchange between these two compartments. Once bacteria have reached the ascitic fluid, the development of SBP depends on the antimicrobial capacity of the ascitic fluid. Patients with a decreased defensive capacity of ascitic fluid develop SBP.

The most common organisms isolated from patients with SBP in cirrhosis are bacteria normally present in the intestinal flora. Gram-negative aerobic bacteria from the family of *Enterobacteriaceae*, and individually *Escherichia coli*, are the most common causative organisms. Nonenterococcal streptococcal organisms cause most of the other cases (66). Several pathogenic mechanisms have been proposed to explain the passage of enteric organisms from the intestinal lumen to the systemic circulation. Bacterial translocation is the process by which enteric bacteria normally present in the gastrointestinal lumen cross the mucosa, colonize the mesenteric lymph nodes, and reach the bloodstream through the intestinal lymphatic circulation. Bacterial translocation could be the consequence of the intestinal bacterial overgrowth that leads to an increase in aerobic gram-negative bacilli in the jejunal flora in cirrhosis and of the possible alteration in gut permeability caused by portal hypertension or by circumstances that decrease mucosal blood flow (e.g., acute hypovolemia or splanchnic vasoconstrictor

drugs). Depression of the hepatic reticuloendothelial system allows free passage of microorganisms from the intestinal lumen to the systemic circulation through the portal vein and prolongs bacteremia. The skin, the urinary tract, and the upper respiratory tract may be the sites through which nonenteric bacteria enter the circulation and cause SBP. This pathogenic mechanism is favored in many cases by diagnostic or therapeutic procedures, which break the natural mucocutaneous barriers. Whatever the source of the bacteria that reach the bloodstream, a bacteremic event is more prolonged and, therefore, can more readily become clinically significant in patients with cirrhosis than in those without this disease because of the marked depression of the reticuloendothelial system associated with cirrhosis.

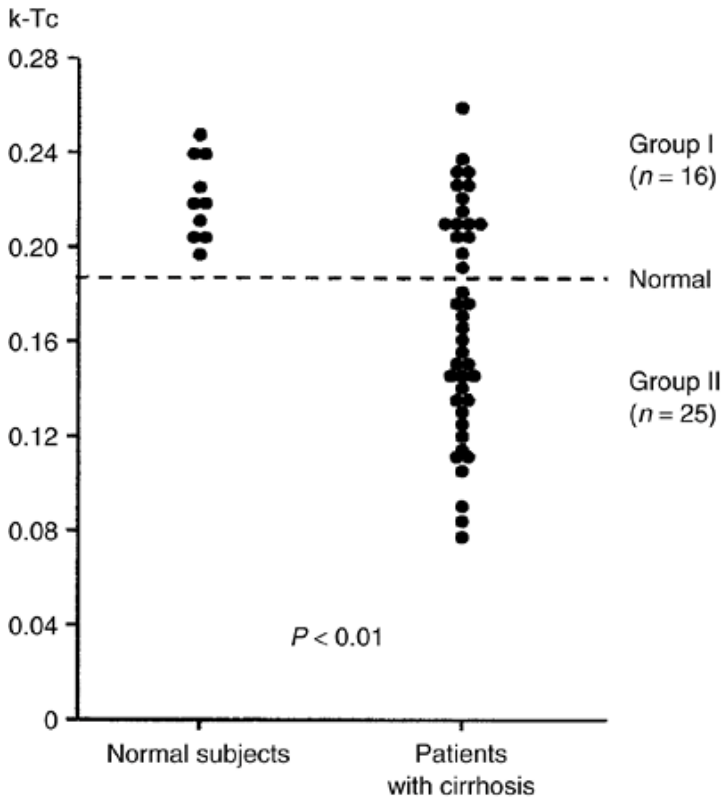
Bacterial translocation

Most studies on bacterial translocation have been performed in rats with cirrhosis induced by carbon tetrachloride. It is shown that in these animals there is an increased passage of bacteria from the intestinal lumen to extraintestinal sites, including regional lymph nodes and the systemic circulation. Causes for bacterial translocation are a disruption of the intestinal permeability barrier, bacterial overgrowth, and a decrease in host immune defenses. The simultaneous presence of intestinal bacterial overgrowth and a severe disturbance in the intestinal barrier seem to be required for bacterial translocation to mesenteric lymph nodes. The alteration in intestinal permeability could be partially caused by portal hypertension that causes marked edema and inflammation in the submucosa of the cecum, thereby favoring bacterial translocation. Changed permeability of the intestinal mucosa also occurs in hemorrhagic shock, sepsis, or injury, or on administration of endotoxin. Results of experiments on portal hypertension have shown that hemorrhagic shock is followed by increased bacterial translocation to mesenteric lymph nodes. This finding suggests that hemorrhagic shock, a not-infrequent event in patients with cirrhosis, can alter the intestinal barrier in these animals. Overgrowth of gram-negative bacteria is found in the jejunal flora of patients with cirrhosis. The intestinal hypomotility in patients with cirrhosis who have sympathetic overactivity may, at least partly, explain this fact. The change in the intestinal flora may increase the chance that aerobic gram-negative bacteria will invade the bloodstream and cause infection of enteric origin in patients with cirrhosis. In these patients, bacterial translocation to mesenteric lymph nodes seems to be related to the presence of ascites and to the degree of hepatic insufficiency because both are markedly increased in Child-Pugh C patients (101).

Depression of activity of the reticuloendothelial system

Although the reticuloendothelial system is widely distributed throughout the body, approximately 90% of this defensive system is in the liver, where Kupffer cells and endothelial sinusoidal cells are the major components. Patients with cirrhosis may have marked depression of the reticuloendothelial system (Fig. 19.19). The risk of acquiring bacteremia and SBP in cirrhosis is directly related to the degree of dysfunction of the reticuloendothelial system (102). Reticuloendothelial cell function in cirrhosis is also a predictor of survival (Fig. 19.20). The mechanism of the impairment of the phagocytic activity of the reticuloendothelial system in cirrhosis is probably multifactorial. It likely includes intrahepatic shunting, which leads to a lack of contact between the reticuloendothelial cells and the blood; impairment of the intrinsic phagocytic

capacity of the reticuloendothelial cells (103,104); and a reduction in the serum opsonic activity, probably as a consequence of a decreased serum concentration of complement and fibronectin. These substances normally stimulate the phagocytosis of microorganisms by enhancing their adhesiveness to the reticuloendothelial cell surface.



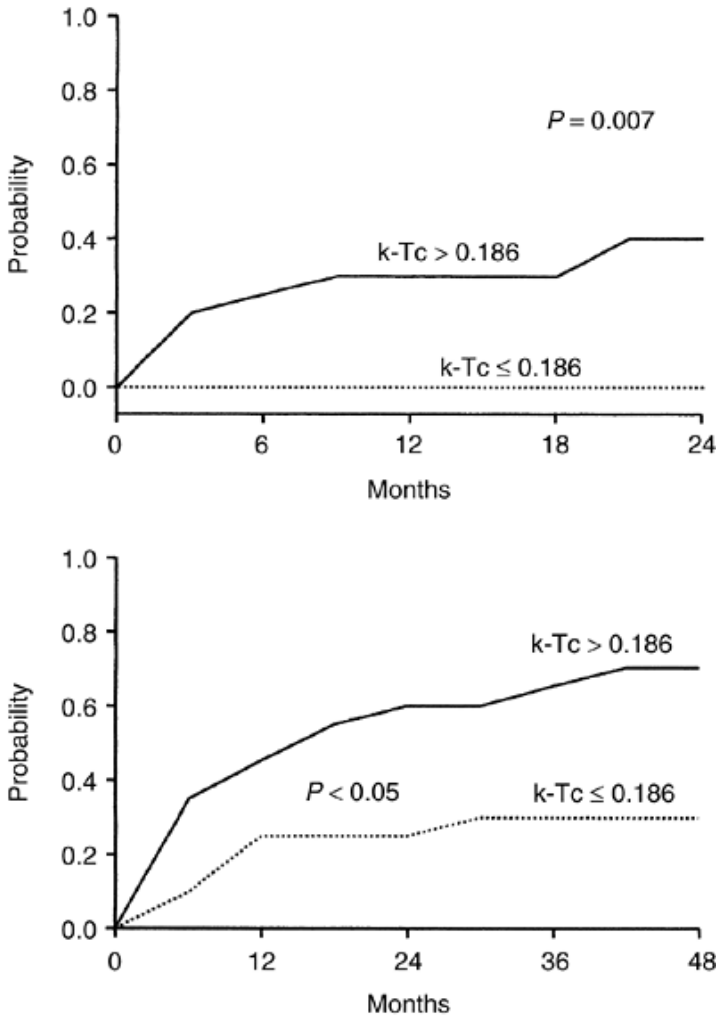
▪ **Figure 19.19** Phagocytic activity of the reticuloendothelial system estimated by the constant elimination rate of albumin labeled with technetium Tc 99m in healthy subjects and in patients with cirrhosis (normal phagocytic activity—group I—and impaired phagocytic activity—group II). (From Rimola A, Soto R, Bury F, et al. Reticuloendothelial system phagocytic activity in cirrhosis and its relation to bacterial infections and prognosis. *Hepatology* 1984;4:53–58, with permission.)

Decreased opsonic activity of the ascitic fluid

The nonspecific antimicrobial capacity of ascitic fluid in cirrhosis varies greatly from patient to patient, and this variability may be involved in the pathogenesis of SBP. There is a highly significant inverse correlation between the opsonic activity of ascitic fluid and the risk of development of SBP among patients admitted to the hospital with ascites (105).

The opsonic activity of ascitic fluid in cirrhosis correlates directly with the total protein level in ascites and with the concentration of defensive substances, such as immunoglobulins, complement, and fibronectin (21,22,106,107,108). It is, therefore, not surprising that the concentration of total protein in ascitic fluid, an

easy measurement in clinical practice, correlates directly with the risk of SBP in cirrhosis with ascites (Fig. 19.21). Patients with protein concentration in ascitic fluid less than 10 g/L contract peritonitis during hospital stay with a significantly higher frequency than do those with a higher protein content in ascites (15% vs. 2%) (22). The cumulative 1-year probability of developing peritonitis is significantly greater in this subgroup of patients with cirrhosis than among those with an ascitic protein concentration greater than 10 g/L (20% vs. 2%) (107). Finally, the probability of the first episode of SBP among patients with cirrhosis and ascites is significantly related to ascitic fluid protein and serum bilirubin levels (108).

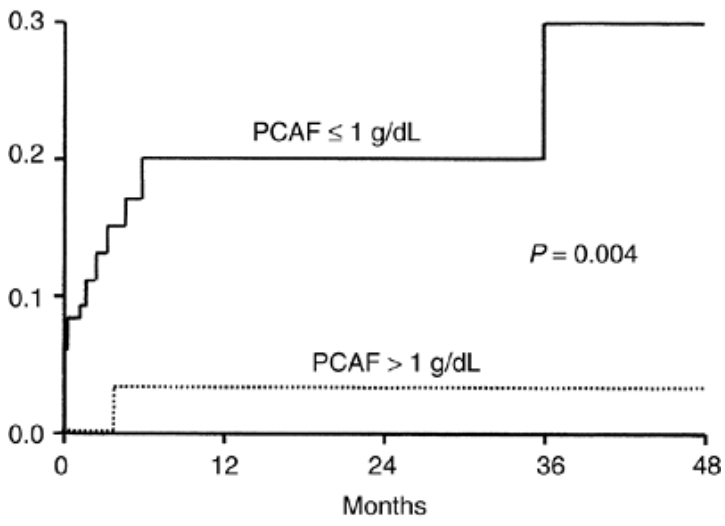


▪ **Figure 19.20** Probability of developing spontaneous bacterial peritonitis or bacteremia (*top*) and probability of survival (*bottom*) according to the phagocytic activity of the reticuloendothelial system (k-Tc ≤ 0.186: Normal phagocytic activity). (From Rimola A, Soto R, Bory F, et al. Reticuloendothelial system phagocytic activity in cirrhosis and its relation to bacterial infections and prognosis. *Hepatology* 1984;4:53–58, with permission.)

Neutrophil leukocyte dysfunction

A high proportion of patients with cirrhosis have altered neutrophil leukocyte function. The most frequent disturbance is a marked reduction of chemotaxis, probably caused by the presence of chemotactic inhibitory substances in the serum. The nature of these substances has not yet been determined. Furthermore, the phagocytic and bacterial killing capacity of neutrophils is reduced in cirrhosis. However, because the type of infection in patients with congenital or acquired abnormalities in neutrophil function (mainly chronic granulomatous diseases and recurrent staphylococcal and fungal infections) is very different from that in patients with cirrhosis, it seems unlikely that leukocyte dysfunction

plays a major role in the susceptibility of patients with cirrhosis to bacterial infection.



▪ **Figure 19.21** Probability of developing the first episode of spontaneous bacterial peritonitis in patients with cirrhosis and ascites according to the protein concentration of the ascitic fluid (PCAF). (From Llach J, Rimola A, Navasa M, et al. Incidence and predictive factors of first episode of spontaneous bacterial peritonitis in cirrhosis: relevance of ascitic fluid protein concentration, *Hepatology* 1992;16:724–727, with permission.)

Iatrogenic factors

Patients with cirrhosis frequently undergo diagnostic or therapeutic maneuvers that can alter the natural defense barriers and, therefore, increase the risk of bacterial infection. Endoscopic sclerotherapy for bleeding esophageal varices, particularly emergency sclerotherapy, is associated with bacteremia in 5% to 30% of cases. Although in some patients sclerotherapy is implicated in the development of serious infections such as purulent meningitis and bacterial peritonitis, bacteremia is usually a transient phenomenon and the use of prophylactic antibiotics is not recommended. The insertion of a TIPS for the management of bleeding esophageal varices is not associated with the development of significant bacterial infections. However, patients with cirrhosis with a peritoneovenous shunt (LeVeen shunt) frequently have infections, particularly bacteremia and peritonitis. In several series the incidence of

bacterial infection after the insertion of a LeVeen shunt for the management of ascites was approximately 20%. The risk of clinically relevant infection with other invasive techniques often performed in these patients, such as diagnostic or therapeutic paracentesis and endoscopy, is low.

Diagnosis

Clinical characteristics

The clinical presentation of SBP depends on the stage at which the infection is diagnosed. When the infection is well developed, most patients have signs or symptoms clearly suggestive of peritoneal infection. However, SBP can be minimally symptomatic or asymptomatic in the initial stages. Abdominal pain and fever are the most characteristic symptoms. Other signs and symptoms, such as alterations in gastrointestinal motility (i.e., vomiting, ileus, diarrhea), hepatic encephalopathy, gastrointestinal bleeding, renal impairment, septic shock, and hypothermia, may be present in many patients. Diagnostic paracentesis should be performed at hospital admission on all patients with cirrhosis and ascites to ascertain the presence of SBP, and on hospitalized patients with ascites whenever they have any of the following: (a) Abdominal pain, vomiting, diarrhea, ileus, or rebound tenderness; (b) systemic signs of infection such as fever, leukocytosis, or septic shock; and (c) hepatic encephalopathy or impairment of renal function.

Laboratory and microbiologic data

The diagnosis of SBP is based on clinical suspicion and on the results of analysis of ascitic fluid. A PMN count of 250 cells/mm^3 in the ascitic fluid is considered the gold standard for the diagnosis of SBP and constitutes an indication to initiate empiric antibiotic treatment. In patients with hemorrhagic ascites a subtraction of one PMN per 250 red blood cells should be made to adjust for the presence of blood in ascites. Leukocyte esterase reagent strips are useful for a rapid bedside diagnosis of SBP. Sensitivity in different series ranged from 83% to 100% and specificity from 89% and 100% (14,15,16,17). Measurement of lactate dehydrogenase concentration, glucose level, and total protein concentration in ascitic fluid is important to establish a differential diagnosis between spontaneous and secondary peritonitis. Secondary peritonitis should be suspected when at least two of the following conditions are present in the ascitic fluid: Glucose levels less than 50 mg/dL, protein concentration greater than 10 g/L, and lactate dehydrogenase concentration greater than normal serum level. Results of Gram stain of a smear of sediment obtained after centrifugation of ascitic fluid are frequently negative for SBP because the concentration of bacteria is usually low (one organism per milliliter or less). Nevertheless, Gram stain may be helpful in identifying intestinal perforation when several types of bacteria are present.

Results of culture of ascitic fluid drawn directly into blood culture bottles (aerobic and anaerobic media) at the bedside are positive in 50% to 80% of cases. Results of blood cultures are also positive in a large proportion of patients with SBP. Other alterations in systemic laboratory values such as leukocytosis, azotemia, and acidosis occur in patients with cirrhosis and SBP.

Treatment

Antibiotic therapy must be started once the diagnosis of SBP is established.

Empiric treatment should cover all potential organisms responsible for SBP without causing adverse effects. At present, third-generation cephalosporins are considered the standard in the management of SBP associated with cirrhosis. Other antibiotics are also effective.

Cefotaxime

Results of the first investigation of the efficacy of cefotaxime in the treatment of patients with SBP were published in 1985 (109). The study was a randomized controlled trial comparing cefotaxime with the combination of ampicillin plus tobramycin in the treatment of a large series of patients with cirrhosis and SBP or other severe bacterial infection. Cefotaxime was more effective in achieving SBP resolution than ampicillin plus tobramycin. Whereas no patient treated with cefotaxime had nephrotoxicity and superinfection, these two adverse effects occurred in more than 10% of the patients treated with ampicillin plus tobramycin. After this study, cefotaxime was considered the first-choice antibiotic in the empiric therapy for SBP in patients with cirrhosis.

Two randomized controlled trials were conducted to assess the optimal dosage of cefotaxime and duration of therapy in the treatment of patients with cirrhosis and SBP (110,111). Ninety patients with SBP were randomized to receive cefotaxime (2 g intravenously every 8 hours) for 10 or 5 days. Resolution of the infection (93.1% vs. 91.2%), recurrence of SBP during hospitalization (11.6% vs. 12.8%), and hospital mortality (32.6% vs. 42.5%) were comparable in the two groups. In a second study 143 patients with SBP were randomized to receive two different dosages of cefotaxime: 2g every 6 hours or 2 g every 12 hours. Rates of SBP resolution (77% vs. 79%) and patient survival (69% vs. 79%) were similar in both groups. Therefore, in patients with SBP, cefotaxime should be used at a dose of 2 g every 12 hours and for a minimum of 5 days.

Other parenteral antibiotics

Ceftriaxone (2 g intravenously every 24 hours) is highly effective in the treatment of SBP. The resolution rate is 90% to 100% and the hospital mortality rate is 30%. Cefonicid (2 g intravenously every 12 hours) is also effective in the treatment of SBP, with a resolution rate of 94% and a hospital mortality rate of 37%. Aztreonam has been evaluated in SBP in a single pilot study. The overall mortality during hospitalization was 62%. Superinfections due to resistant organisms were detected in three cases (19%). These results, together with the fact that aztreonam is only capable of covering approximately 75% of the potential organisms causing SBP, clearly establish that this antibiotic is not adequate for the empiric treatment of patients with cirrhosis and SBP. Finally, two studies have shown that the parenteral administration of amoxicillin–clavulanic acid is effective and safe in the treatment of SBP. The lower cost of this antibiotic regimen in comparison with third-generation cephalosporins is an important advantage.

Oral antibiotics

Patients with SBP may be in relatively good clinical condition and could be treated orally. Two studies have been conducted to assess the effectiveness of oral antibiotics in the management of SBP. In both studies wide-spectrum quinolones were used; these agents are almost completely absorbed after oral administration and rapidly diffuse to the ascitic fluid. In the first study, oral pefloxacin alone (one case) or in combination with other oral antibiotics

(cotrimoxazole, nine cases; amoxicillin, three cases; cefadroxil, one case; and cotrimoxazole–metronidazole, one case) was administered in 15 episodes of SBP. The rate of resolution of infection was 87%. Two patients had superinfections, and the survival rate at the end of hospitalization was 60%. The second study was a randomized controlled trial in patients with nonsevere complications of SBP (i.e., no septic shock, ileus, or serum creatinine concentration >3 mg/dL). Treatment with oral ofloxacin (400 mg every 12 hours) was compared with intravenous administration of cefotaxime (2 g every 6 hours). The study showed a similar rate of infection resolution and patient survival in the two groups. The incidence of superinfection and the length of antibiotic treatment were also similar in two groups. These findings suggested that oral ofloxacin is as effective as intravenous cefotaxime in the management of uncomplicated SBP associated with cirrhosis. Quinolones should not be empirically used in the treatment of patients in whom SBP develops while they are undergoing selective intestinal decontamination with norfloxacin. Third-generation cephalosporins are the best therapeutic option in these patients because they can develop infection from quinolone-resistant bacteria.

Intravenous albumin infusion in spontaneous bacterial peritonitis

For many years the hospital mortality rate associated with SBP (30% to 50%) has been relatively high despite a significant improvement in the rate of resolution of the infection (80% to 90%). Therefore, 20% to 30% of patients with SBP died during hospitalization despite being cured of the infection. Initial studies showed that development of type 1 HRS and not resolution of the infection was the principal predictor

of hospital mortality (112). Subsequent investigations showed that type 1 HRS in patients with SBP occurs in the setting of a rapid deterioration of systemic hemodynamics, with a marked increase in the degree of activity of the renin–angiotensin system and sympathetic nervous system (18,19). SBP-induced circulatory dysfunction develops in patients with marked inflammatory response to the infection (very high ascitic fluid concentration of leukocytes and cytokines) and is associated with an increased production of vasodilatory substances such as nitric oxide and carbon monoxide (113,114). Finally, two recent studies have presented data indicating that impairment of circulatory function in SBP is due to both an accentuation of the arterial vasodilatation already present in these patients and a marked decrease in cardiac output (3,5). These studies also showed that in addition to an impairment of renal perfusion, there is a severe reduction in hepatic blood flow and a marked increase in the intrahepatic resistance to the portal venous flow and portal pressure. The frequent deterioration of hepatic function, the development of hepatic encephalopathy, and the relatively high frequency of variceal bleeding in patients with SBP are probably related to these features.

A recent randomized controlled trial showing that circulatory support with intravenous albumin reduces the incidence of renal impairment and improves hospital survival in SBP has been important in the process of decreasing hospital mortality associated with this infection (13). The study included 126 patients with SBP who were treated with intravenous cefotaxime (63 patients) or with cefotaxime and intravenous albumin (63 patients). Albumin was given at a dose of 1.5 g/kg body weight at the time of diagnosis, followed by 1 g/kg body weight on day 3. Plasma renin activity increased significantly in patients treated with

cefotaxime and decreased in patients receiving cefotaxime plus albumin, indicating that albumin prevents the deterioration of the effective arterial blood volume induced by SBP. Renal impairment developed in 21 patients in the cefotaxime group (33%) and in 6 patients in the cefotaxime plus albumin group (10%). The hospital mortality rate was 29% in the cefotaxime group in comparison with 10% in the cefotaxime plus albumin group. Renal impairment and hospital mortality were extremely low in patients with serum creatinine and/or serum bilirubin levels at time of diagnosis of infection equal to or lower than 1 mg/dL and 4 mg/dL, respectively, in the two therapeutic groups. The results of this study, therefore, indicate that patients with cirrhosis and SBP, particularly those with high serum creatinine or bilirubin levels over 4 mg/dL, should be treated with albumin for volume expansion.

The mechanism by which albumin prevents circulatory dysfunction and type 1 HRS and improves survival has recently been explored in a randomized pilot study comparing the hemodynamic effects of albumin and the synthetic plasma expander hydroxyethyl starch in patients with SBP (115). Albumin but not hydroxyethyl starch improved the effective arterial blood volume, as estimated by the mean arterial pressure and plasma renin activity. This was due both to a greater expansion in central blood volume and an increase in systemic vascular resistance. In patients with SBP, therefore, albumin acts not only as a plasma volume expander but also in the arterial circulation, reducing the degree of arterial vasodilatation. Because the levels of nitric oxide metabolites increased in patients receiving hydroxyethyl starch but not in those treated with albumin and the plasma concentration of the von Willebrand's factor, which is released from the vascular endothelium in parallel with nitric oxide, decreased in patients receiving albumin but not in those treated with hydroxyethyl starch, it was suggested that albumin improves the systemic vascular resistance in SBP by inhibiting the increased activity of nitric oxide synthase by the vascular endothelium.

Predictors of Resolution of Spontaneous Bacterial Peritonitis and of Survival

Several studies have been performed to identify the predictors of resolution of infection and hospital survival in SBP. The results have shown that parameters related to kidney function are the most important predictors of survival. In a retrospective analysis of 213 consecutive episodes of SBP empirically managed with cefotaxime in 185 patients with cirrhosis, multivariate analysis identified 4 out of 51 clinical and laboratory variables obtained at the time of diagnosis of infection (i.e., band neutrophils in white blood cell count, community-acquired versus hospital-acquired SBP, blood urea nitrogen level, and serum aspartate aminotransferase level) as independent predictors of resolution infection and 6 (i.e., blood urea nitrogen level, serum aspartate aminotransferase level, community-acquired vs. hospital-acquired SBP, age, Child-Pugh score, and ileus) as independent predictors of survival (112). In another study of 252 consecutive episodes of SBP, the development of renal impairment after the diagnosis of SBP was the strongest independent predictor of patient mortality in episodes responding to cefotaxime (18). Renal impairment occurred in 83 episodes (33%), and in every instance it fulfilled the criteria of functional renal failure. Renal impairment was progressive in 35 episodes, steady in 27, and transient in 21. The mortality rate was 100% in episodes associated with progressive renal impairment, 31% in episodes associated with steady renal impairment, 5% in episodes with transient renal impairment, and 7% in episodes without renal

impairment. Other independent predictors of mortality

in this series were age, blood urea nitrogen level at diagnosis, isolation of the responsible organism in the ascitic fluid culture, and peak serum bilirubin during antibiotic treatment. Plasma and ascitic fluid cytokine levels also have prognostic value in patients with SBP (19). Renal impairment in SBP occurs in patients with the highest concentration of cytokines in plasma and in ascitic fluid and is associated with marked activation of the renin–angiotensin system. It is likely that renal impairment in SBP occurs as a result of a cytokine-induced impairment of effective arterial blood volume. This is the rationale for the use of plasma expanders in SBP. The recommendation of avoiding diuretics and large-volume paracentesis is also based on this concept.

The development of SBP is associated with poor survival in patients with cirrhosis ascites. The 1-year probability of survival is lower than 40%. Therefore, SBP is considered an important criterion for the indication of liver transplantation.

Prophylaxis

Current indications of intestinal decontamination in SBP prevention are summarized in Table 19.9. Patients with cirrhosis and gastrointestinal hemorrhage are predisposed to develop severe bacterial infections during or immediately after the bleeding episode. Two studies have shown that short-term intestinal decontamination with oral nonabsorbable or poorly absorbable (norfloxacin) antibiotics is effective in preventing bacterial infections and SBP in patients with cirrhosis and gastrointestinal hemorrhage (116,117). The usefulness of systemic administration of prophylactic antibiotic agents to patients with cirrhosis and gastrointestinal hemorrhage was investigated in three controlled studies. In these studies the treated groups received ofloxacin (initially intravenously and then orally) plus amoxicillin–clavulanic acid (before each endoscopy examination), ciprofloxacin plus amoxicillin–clavulanic acid (first intravenously and then orally once the bleeding was controlled), and oral ciprofloxacin (118,119,120,121). The incidence of bacterial infections was significantly lower in the treated groups (10% to 20%) than in the corresponding control groups (45% to 66%). In these studies, the effect of systemic antibiotics on SBP was not specifically studied. However, because improvement in survival in the groups receiving antibiotic prophylaxis was also observed, the use of prophylactic antibiotics in the care of patients with cirrhosis and gastrointestinal hemorrhage, independent of their specific risk of SBP was highly recommended. A meta-analysis including all the aforementioned studies, showed a significant benefit in the subgroup of patients with cirrhosis with and gastrointestinal hemorrhage: 95% of patients in the treated group were free of SBP as opposed to 87% in the control group (121).

Table 19.9. Current Indications and Proposed Duration of Selective Intestinal Decontamination in Cirrhosis

Indications	Duration of prophylaxis
Patients with cirrhosis recovering from a previous episode of SBP (secondary	Indefinitely or until liver transplantation

prophylaxis)	
Patients with cirrhosis and gastrointestinal bleeding	7 d
Patients with cirrhosis and ascites and low ascitic fluid protein levels (≤10 g/L)	During hospitalization (no consensus)

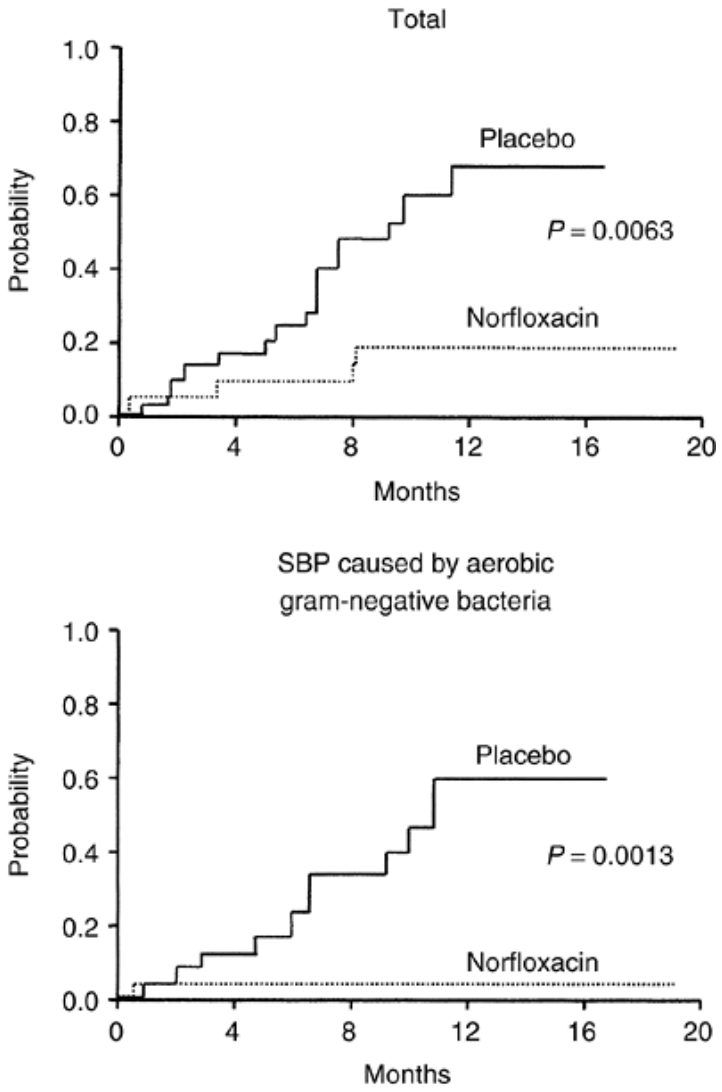
SBP, spontaneous bacterial peritonitis.

Patients with low total protein concentration in ascitic fluid may be a second group of patients with cirrhosis who may benefit from selective intestinal decontamination. Four randomized controlled trials showed that oral antibiotics reduced the incidence of bacterial infections and SBP in this type of patients. In the care of 63 patients admitted to hospital for management of an episode of ascites associated with a low total protein concentration in ascitic fluid (some with previous episodes of SBP), continuous administration of norfloxacin (400 mg/day) throughout the hospitalization decreased the in-hospital incidence of SBP from 22% (control group) to 0% (treated group) (122). In another study in patients with cirrhosis, low ascitic fluid protein concentration, and no previous episodes of SBP, the 6-month incidence of SBP was 0% for the group of patients prophylactically treated with norfloxacin (400 mg/day) and 9% for those treated with placebo (123). A third placebo-controlled study in patients with and without previous episodes of SBP showed that 6-month prophylaxis with ciprofloxacin (750 mg once a week) was effective in reducing the incidence of SBP (4% for the treated group, 22% in the placebo-controlled group) (124). A fourth investigation showed that trimethoprim–sulfamethoxazole (one double-strength tablet 5 days a week) is effective in the prevention of SBP in patients with cirrhosis and ascites (125). The medium follow-up period was only 90 days. However, the incidence of SBP was 26.7% in the control group and 3.3% in the treated group. In this study, patients who were at different levels of risk for SBP (patients with low and high ascitic fluid protein levels and those who did or did not have previous SBP episodes) were included.

Patients recovering from an episode of SBP represent a unique population for assessing the effect of long-term intestinal decontamination in the prophylaxis of SBP because the rate of recurrence of SBP 1 year after treatment may be as high as 70%. In a double-blind placebo-controlled trial including 80 patients with cirrhosis who had recovered from an episode of SBP, the

overall probability of recurrence of SBP after 1 year of follow-up study was 20% in the norfloxacin group and 68% in the placebo group. The probability of SBP caused by aerobic gram-negative bacilli after 1 year of follow-up evaluation was 3% and 60% in the norfloxacin and the placebo group, respectively (Fig. 19.22). Only one patient treated with norfloxacin had side effects related to treatment (oral and esophageal candidiasis) (126). Long-term selective intestinal decontamination, therefore, dramatically decreases the rate of recurrence among patients with SBP. In three economic analyses, investigators calculated that long-

term antibiotic prophylaxis in the care of patients with cirrhosis is associated with reduced cost compared with the "diagnose and treat" strategy. This finding suggests that prophylaxis is cost effective in the treatment of patients at high risk of the development of SBP.

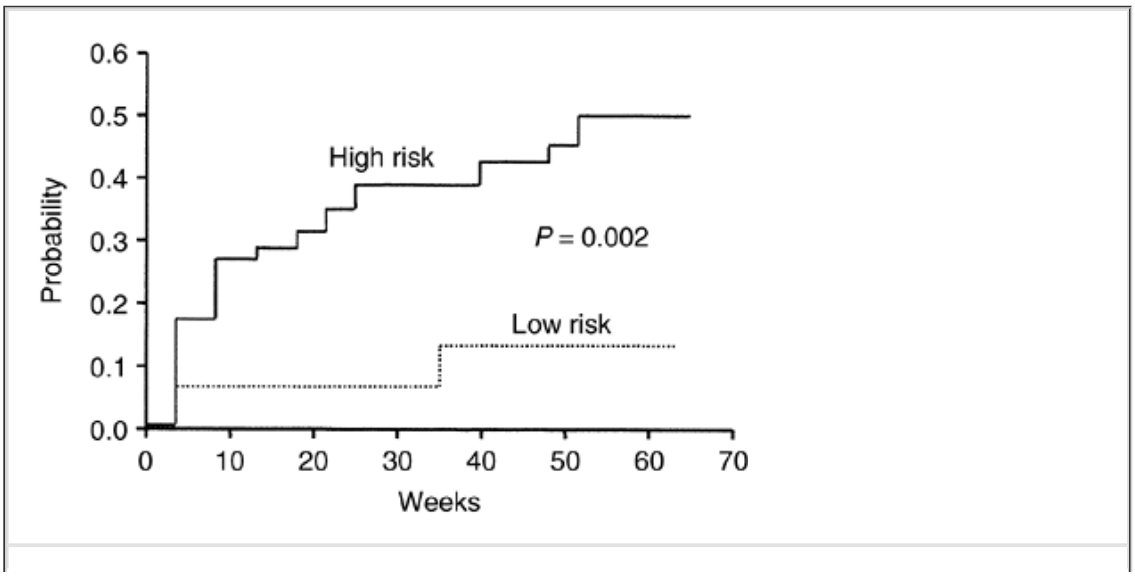


▪ **Figure 19.22** Probability of spontaneous bacterial peritonitis (SBP) recurrence caused by all types of bacteria (*top*) and by gram-negative bacteria alone (*bottom*) in patients receiving norfloxacin prophylaxis or placebo. (From Ginès P, Rimola A, Planas R, et al, Norfloxacin prevents spontaneous bacterial peritonitis recurrence in cirrhosis: results of a double blind, placebo-controlled trial, by Ginès P, *Hepatology* 1990;12:716–724, with permission.)

Antibiotic prophylaxis, therefore, is indicated in the care of patients with cirrhosis who have had a previous episode of SBP because they are at high risk of SBP and because prophylaxis is cost effective. It is also clearly indicated in the care of patients with gastrointestinal hemorrhage independent of the presence of ascites. However, in the care of patients with low protein content in ascitic fluid who have never had SBP, the recommendation is difficult to establish because of the

heterogeneity of the published studies, which also included patients with previous episodes of SBP. Three studies to assess the incidence of and predictive factors for the first episode of SBP in patients with cirrhosis and ascites may be of help in antibiotic prophylaxis. In a series of 127 patients admitted for the treatment of an episode of ascites, the probability of the appearance of the first episode of SBP was 11% at 1 year and 15% at 3 years of follow-up (105). Five variables obtained at admission were significantly associated with a higher risk of SBP during the follow-up (i.e., poor nutritional status, increased serum bilirubin levels, decreased prothrombin activity, increased serum aspartate aminotransferase level, and low protein concentration in the ascitic fluid), but only one (i.e., low protein concentration in the ascitic fluid) had independent predictive value. The 1- and 3-year probabilities of the first episode of SBP in patients with ascitic fluid protein content less than 10 g/L were 20% and 24%, respectively. Among those with ascitic fluid protein content of 10 g/L or greater, the 1- and 3-year probabilities were 0% and 4%, respectively. A clear conclusion from this study is that long-term prophylactic administration of antibiotic is not necessary in the care of patients without previous episodes of SBP and with protein content in ascitic fluid greater than 10 g/L because the risk of development of SBP is negligible. In a similar study performed in 110 patients with cirrhosis consecutively hospitalized for the management of an episode of ascites (107), six variables associated with a higher risk of first appearance of SBP during the follow-up period were identified. These included serum bilirubin level greater than 2.5 mg/dL, prothrombin activity less than 60%, total protein concentration in ascitic fluid less than 10 g/L, serum sodium concentration less than 130 mEq/L, platelet count less than 116,000/mm^3, and serum albumin concentration less than 26 g/L. Only two of these variables (protein concentration in the ascitic fluid and serum bilirubin level) had an independent predictive value (Fig. 19.23). Finally, in one study, patients with cirrhosis, low ascitic fluid protein levels (≤ 10 g/L), and high serum bilirubin levels (>3.2 mg/dL) or low platelet count (<98,000/mm^3) had a 1-year probability of 55% for the development of a first episode of SBP in comparison with 24% among patients with only low ascitic fluid protein levels (108). The results of these studies indicate that routine determination of biochemical values may help identify patients with ascites who are at high risk for developing a first episode of SBP and the

patients, therefore, may benefit from primary antibiotic prophylaxis. This contention, however, requires confirmation by prospective randomized trials.



▪ **Figure 19.23** Probability of the development of the first episode of spontaneous bacterial peritonitis (SBP) in patients with cirrhosis and ascites classified into low-risk and high-risk groups according to the concentration of protein in ascitic fluid and serum bilirubin and/or platelet count. (From Andreu M, Sola R, Sitges-Sarra A, et al. Risk factors for spontaneous bacterial peritonitis, *Gastroenterology* 1993;104:1133–1138, with permission.)

Problem of the Development of Quinolone-Resistant Bacteria

Our concept about infections caused by quinolone-resistant bacteria in patients undergoing long-term prophylactic treatment with norfloxacin has moved from an exceptional event to a relatively frequent phenomenon. Results of initial studies suggested that the risk of development of SBP or other infections caused by quinolone-resistant strains of gram-negative bacilli was low because most recurrences of SBP in patients taking norfloxacin prophylaxis were caused by gram-positive cocci, mainly streptococci (127,128,129) Thereafter, a high incidence of quinolone-resistant strains of *E. coli* in stools of patients with cirrhosis undergoing long-term quinolone prophylaxis was described in several studies. None, however, reported any clinical infection caused by quinolone-resistant *E. coli*. In 1997, the first study involving patients with cirrhosis undergoing long-term norfloxacin prophylaxis for SBP showed a relevant increased incidence of infection, mainly mild urinary infection, caused by gram-negative bacilli resistant to quinolones (90% of *E. coli* isolated were resistant to quinolones) (129). More recently it was shown that 39 out of 106 infections caused by *E. coli* among hospitalized patients with cirrhosis were quinolone-resistant. This finding suggested that the long-term norfloxacin prophylaxis was significantly associated with these types of infections (mainly urinary tract infections). However, the rate of development of SBP caused by quinolone-resistant *E. coli* in decontaminated patients was exceptional (130). Data from the latest study, however, clearly indicates that SBP due to quinolone-resistant bacteria will probably be an important clinical problem in the near future. All cases of bacterial infection diagnosed within a 2-year period among patients with cirrhosis were prospectively evaluated (131). In patients undergoing long-term norfloxacin prophylaxis, quinolone-resistant gram-negative bacilli caused 50% of culture-positive SBP. This finding occurred only among 16% of patients with culture-positive SBP not receiving norfloxacin. Although in this study SBP caused by quinolone-resistant gram-negative bacilli represented only 26% of the cases of culture-positive SBP, quinolone-resistant SBP seems to have emerged as a real problem. This study also showed a high rate of culture-positive SBP caused by trimethoprim–sulfamethoxazole–resistant gram-negative bacteria in patients undergoing long-term treatment with norfloxacin (44%). This finding suggested that this antibiotic is not an alternative to norfloxacin. The effectiveness of norfloxacin in the prevention of SBP is lower than that found in the initial studies. This situation is not surprising because all patients undergoing long-term norfloxacin prophylaxis have quinolone-resistant bacteria in the fecal flora. Despite this observation, the incidence of SBP caused by quinolone-resistant bacteria in patients undergoing long-term norfloxacin prophylaxis is still low. Different explanations have been proposed for this phenomenon, including a

reduction in the intestinal overgrowth or a favorable effect of quinolones on nonspecific immune defenses. Results also suggest that quinolone-resistant bacteria are less invasive than wild-type bacteria.

Chapter 20
Hepatic Encephalopathy

Juan Córdoba
Andrés T. Blei

Key Concepts

- Hepatic encephalopathy is a neuropsychiatric syndrome that encompasses multiple manifestations resulting from liver failure and/or portosystemic shunting.
- The neurologic abnormalities are potentially reversible with correction of the liver disease and/or the abnormal portal collateral circulation.
- The pathogenesis of hepatic encephalopathy is multifactorial and relates to the exposure of the brain to toxins that arise mostly from the gut.
- Several neurotoxic substances have been implicated in the development of hepatic encephalopathy; ammonia is an important factor in its pathogenesis.
- The most characteristic manifestation is confusional syndrome in patients with cirrhosis, precipitated by a factor that enhances the toxin's effect or load.
- Treatment is based on the identification and correction of the precipitating factor, provision of supportive measures, and the administration of drugs that decrease the production of toxins or antagonize their effects on the brain.
- Management of patients with hepatic encephalopathy, in addition to the assessment of neurologic manifestations, should include the treatment of the underlying liver disease and/or the abnormal portal collateral circulation.

Hepatic encephalopathy (HE) can be defined as a disturbance in central nervous system (CNS) function due to hepatic insufficiency or portosystemic shunting. This vague definition reflects the existence of a spectrum of neurologic manifestations that develop in association with different liver diseases (1). A common link is the potential reversibility of the neurologic manifestations once the abnormality of liver function is corrected, as well as the importance of shunting of blood arising from the portal venous bed into the systemic circulation. HE must be differentiated from the concurrence of neurologic symptoms and liver disease secondary to a common pathogenetic mechanism such as brain and liver damage caused by alcohol or copper (Wilson disease). HE must also be differentiated from neurologic disturbances directly caused by bilirubin accumulation, hypoglycemia, disorders of blood coagulation, or other well-defined abnormalities that are secondary to liver failure.

The nomenclature of HE is confusing. Some terms are used with different meanings by different authors. Some efforts have been made to reach a consensus, especially for the design of clinical trials (2). Despite this limitation, from a clinical perspective HE is generally classified according to the underlying liver disease and the evolution of the neurologic manifestations (Table 20.1). The most frequent liver disease is cirrhosis, usually accompanied by extrahepatic portosystemic shunts (spontaneous or surgical). HE can also be seen in acute liver failure, in which it constitutes a clinical hallmark of the disorder. In rare cases, HE develops in the absence of any sign of parenchymal liver disease and is

caused solely by portosystemic shunting of congenital or surgically induced origin.

Table 20.1. Classification of Hepatic Encephalopathy

Hepatic encephalopathy	Liver disease	Extrahepatic portosystemic shunting	Neurologic manifestations	Specific features
Acute episode				
In cirrhosis	Cirrhosis	Variable	Acute confusional state to coma	Usually precipitated
In acute liver failure	Acute liver failure	Absent	Acute confusional state to coma	Frequently complicated by brain edema and intracranial hypertension
Chronic				
Relapsing	Cirrhosis	Severe	Relapsing episodes of encephalopathy	Usually without precipitating factors
Persistent	Cirrhosis	Severe	Persistent cognitive or motor abnormalities	Generally related to surgically induced shunts
Minimal hepatic	Cirrhosis	Variable	Asymptomatic	Abnormalities revealed by

encephalopathy				neuropsychological or neurophysiologic tests
In patients with portosystemic bypass with no intrinsic liver disease	No signs of parenchymal disease	Large shunts	Relapsing episodes and persistent abnormalities	Rare disorder, secondary to congenital abnormalities or surgical shunts

Along the lines of Ferenci P, Lockwood A, Mullen K, et al. Hepatic encephalopathy–definition, nomenclature, diagnosis, and quantification: final report of the working party at the 11th World Congresses of Gastroenterology, Vienna, 1998. *Hepatology* 2002;35:716–721.

The neurologic manifestations of HE are variable. The most distinctive presentation is an acute episode characterized by the sudden onset of an acute confusional state that can evolve into coma. Neuromuscular abnormalities are common, the most characteristic being the presence of asterixis; pyramidal signs may also be present. The term *chronic HE* is reserved for patients who have frequent episodes of encephalopathy or persistent cognitive (e.g., memory loss, confusion, and disorientation) or neuromuscular (e.g., tremor, apraxia, and rarely paraplegia) disturbances. Minimal HE (previously termed *subclinical HE*) corresponds to those neurologic manifestations not obvious at clinical examination but detected with neuropsychological or neurophysiologic tests (3).

Pathogenesis

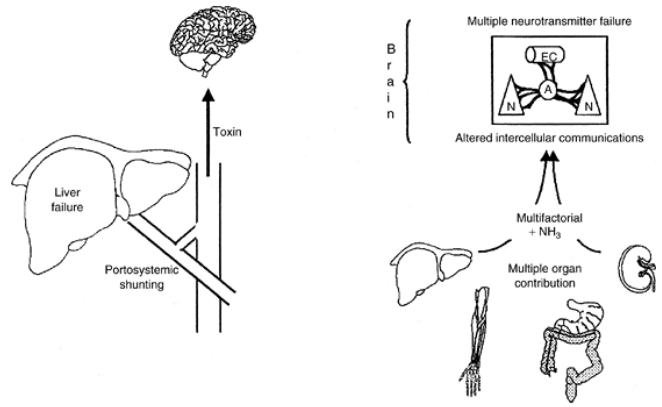
General Aspects

Different hypotheses have been proposed to explain the changes in mental state that occur in HE. Ideally, such a theory should explain the relation between liver abnormalities, neurologic disturbances, and clinical manifestations. However, establishing such relations is difficult, in part because of limitations in the methods available to study brain function in humans in vivo and limitations in knowledge of the neurobiologic basis of behavior. For these reasons, any hypothesis on the pathogenesis of HE should be able to explain the improvement with a specific treatment or account for the mechanism of action of a precipitating factor.

A common pathogenetic notion is that HE is caused by substances that under normal circumstances are efficiently metabolized by the liver, rather than by an insufficient production of substrates that could be essential for neurologic function (Fig. 20.1). In light of this notion, portosystemic shunting plays a critical role because the main impact of this circulatory disturbance is on the concentration of gut-derived substances that are highly cleared by the liver. Studies of crossperfusion in animals with experimental HE and of liver support systems in humans have shown that clearance of toxic substances present in the blood is more important to improve mental function than the synthetic capacity of the support system. In patients with liver disease, these toxic substances reach the systemic circulation through portosystemic shunting or reduced hepatic clearance and produce deleterious effects on brain function. Once the toxic substances are in neural tissues, a large number of neurochemical changes occur that affect multiple neurochemical pathways, each affected to a variable extent.

Historical hypotheses have ranged from single *unifying theories* (4) to the notion of HE as a *multifactorial process* (5). As in other metabolic encephalopathies, general neuronal dysfunction results

in abnormalities of consciousness. However, in contrast to other conditions that affect consciousness (such as hypoglycemia), in which neuronal function is primarily affected, a unique feature of HE is the abnormality of astrocyte morphology and function (See "Abnormalities in the Central Nervous System"). This feature has led to a view that in HE the abnormality in consciousness is the consequence of altered astrocyte–neuronal communications, resulting in changes of multiple neurotransmitter systems (6). Alternative views, such as the γ-aminobutyric acid (GABA) theory, explain the spectrum of HE through the direct effect of a toxin on a key aspect of neurologic function (7). Other paradigms arise from the experimental observation that different toxins (e.g., fatty acids or mercaptans) enhance the negative effects of ammonia on consciousness (*synergistic theory*) (8). More recently, the concept of synergism has been expanded to include the contribution of systemic inflammation to the encephalopathic process (9). Finally, current views also emphasize differing effects of different toxins at various neurologic levels. For example, manganese appears to be involved in parkinsonian manifestations but not in decreasing arousal. In addition, the relative importance of each toxin (See "Putative Toxins") and the site where they cause their main effect (See "Abnormalities in the Central Nervous System") is modulated by different factors (See "Factors that Favor the Effects of Toxins").



▪ **Figure 20.1** A traditional paradigm of the pathogenesis of encephalopathy emphasizing the interplay between liver failure and portosystemic shunting for the availability of toxins in the systemic circulation. A current paradigm includes a multiorgan abnormality in the "periphery." Several factors potentiate the effects of ammonia on the brain, where the presence of multiple neurotransmitter abnormalities can be explained by altered intercellular communications between astrocytes (*A*), neurons (*N*),

and endothelial cells (*EC*).

Putative Toxins

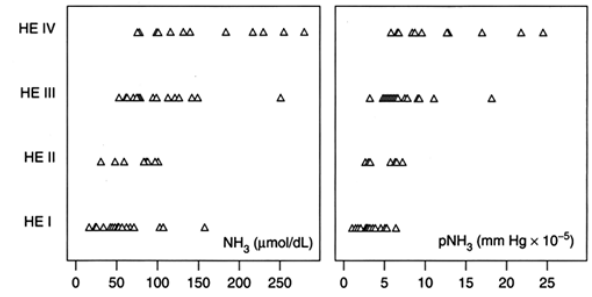
Ammonia

Ammonia has historically been viewed as the most important factor in the genesis of HE. The importance of ammonia in the pathogenesis of HE is highlighted by the following five sets of observations: (a) Ammonia is produced by the gut and a significant amount is of bacterial origin (10), (b) the concentration of ammonia in portal blood is high and a high degree of extraction occurs in the liver (11), (c) concentrations of ammonia are high in the systemic circulation and the cerebrospinal fluid (CSF) of patients with HE (12), (d) precipitating factors cause elevations in the blood level of ammonia or result in the exposure of brain tissue to ammonia (13), (e) treatment strategies of clinical benefit decrease the blood level of ammonia (14).

Ammonia is generated in different tissues by the breakdown of amino acids and other nitrogenous substances (10). Under normal physiologic conditions, ammonia enters the portal circulation from the gastrointestinal tract, where it is derived from colonic bacteria and from the deamidation of glutamine in the small bowel. Traditionally, absorption was viewed as the result of passive diffusion; more recent studies indicate the presence of specific ammonia transporters (15). Regardless of the mechanism of absorption, ammonia reaches high concentration in the portal blood and

undergoes a high first-pass hepatic extraction (80%). In the liver, ammonia is transformed in the periportal hepatocytes into urea (a high-capacity and low-affinity system) and in the centrovenular hepatocytes into glutamine (a low-capacity and high-affinity system). Urea is quantitatively the most important product of ammonia metabolism and elimination. Circulating urea diffuses into the intestine (40%), where it undergoes hydrolysis into ammonia through ureases present in the colonic bacteria. Urinary elimination of nitrogen in the form of urea is a route of ammonia disposal from the organism.

In addition to the intestine and the liver, kidney and muscle contribute to regulate the arterial ammonia level (16). In muscle, ammonia is transformed into glutamine through the action of glutamine synthetase. Experiments in normal volunteers showed that 50% of injected ^{15}N-ammonia is removed by the muscles (17). The ability of the muscle to "fix" appreciable amounts of blood-borne ammonia becomes important for regulating arterial ammonia in case of liver failure and highlights the importance of maintaining an adequate muscular mass by patients with HE. It is generally accepted that at rest skeletal muscle is an ammonia-consuming organ. However, during moderate to heavy exercise, the muscle releases ammonia (18). The kidneys generate ammonia from the deamination of glutamine, a step involved in the regulation of arterial and urinary pH. A small fraction of renal ammonia is released into the systemic circulation; urinary ammonia excretion may be affected by dehydration and increases in conditions of hyperammonemia (19). Notwithstanding the role of peripheral organs, the main factors resulting in the increase in blood levels of ammonia in liver failure are a decrease in the capability of the liver to generate urea and glutamine and the bypass of first-pass hepatic metabolism through portosystemic shunts.



▪ **Figure 20.2** Relationship between venous levels of ammonia and clinical stage of hepatic encephalopathy (HE)—NH_3 (*left graph*, $r = 0.69$, $P < 0.001$) or pNH_3 (*right graph*, $r = 0.79$, $P < 0.001$). (From Kramer L, Tribl B, Gendo A, et al. Partial pressure of ammonia versus ammonia in hepatic encephalopathy. *Hepatology* 2000;31:30–34.)

Patients with HE have an increased diffusion of ammonia into the brain (12), although recent studies using sophisticated positron emission tomography techniques have questioned this tenet (20). Variations in the passage of ammonia across the blood–brain barrier may explain the poor relationship between the level of arterial ammonia and the degree of HE, which nonetheless can be seen when large groups of patients are compared (Fig. 20.2; (21)). Glutamine in brain tissue, which is the product of ammonia metabolism and can be estimated by ^{1}H-magnetic resonance spectroscopy, and glutamine level in CSF is more related to HE than the blood level of ammonia (22).

Ammonia has many deleterious effects on brain function and affects multiple neurotransmitter systems (Table 20.2). However, the clinical manifestations of pure ammonia intoxication differ from the usual manifestations of HE. Patients with urea cycle disorders have symptoms at much higher levels of blood ammonia than those with liver failure. They may also exhibit mental retardation, seizures, and agitation, which are not common in HE. Brain edema leading to intracranial hypertension, a common feature of acute ammonia intoxication, is not clinically relevant in patients with cirrhosis and HE. Additional studies are required to determine whether the differences between these two situations relate to the presence of additional toxins, rate of exposure of the brain, activation of compensatory mechanisms, or other time-dependent factors.

γ-Aminobutyric acid agonists

Several lines of evidence support the presence of activated GABAergic tone in HE (23). One of the postulated mechanisms for this effect is the increased availability of agonist ligands of the GABA receptor complex, a

key inhibitory neurotransmitter in the brain. The term *natural benzodiazepines* has been coined for a group of substances of nonpharmacologic origin that bind to the benzodiazepine site of the GABA receptor, where they can act as an agonist or antagonist. These substances, which are poorly characterized from a chemical and functional perspective, have been reported to be present in a variety of human tissues in normal conditions and to purportedly accumulate in the brain of patients with HE (24). It has been

proposed that natural benzodiazepines with agonistic effects on the GABA receptor induce a decrease of consciousness in HE. However, not all the benzodiazepine ligands found in HE have agonistic effects on the GABA receptor (e.g., diazepam-binding inhibitor). Furthermore, alternative routes of activation of GABA neurotransmission may be present. These include direct and indirect effects of ammonia on the affinity of GABA receptors to its natural ligand (7). Ammonia may also lead to an increased density of peripheral-type benzodiazepine receptors (PTBRs) present in astrocytic mitochondria and whose activation results in the synthesis of neurosteroids, powerful ligands of neuronal GABA receptors (25,26).

Table 20.2. Effects of Ammonia on Nervous Tissue

Effects	Possible consequences
Blocking of chloride channels	Impairment of postsynaptic inhibition
Increase in the transport of neutral amino acids and cerebral tryptophan	Interaction with serotonin-related neurotransmission
Decrease in the activity of α-ketoglutarate dehydrogenase	Decrease in cerebral energy metabolism
Enhancement of the synthesis of neurosteroids	Agonistic effects on GABA neurotransmission
Modulation of GABA receptor	Agonistic effects on GABA neurotransmission
Upregulation of peripheral benzodiazepine receptors	Agonistic effects on GABA neurotransmission
Downregulation of glutamatergic synaptic uptake	Interaction with glutamate-related neurotransmission
Increase in brain glutamine	Interaction with glutamatergic neurotransmission Brain edema
Increase in nitric oxide synthesis	Interaction with glutamatergic neurotransmission

GABA, γ-aminobutyric acid.
Butterworth RF. The neurobiology of hepatic encephalopathy. *Semin Liver Dis* 1996;16:235–244.

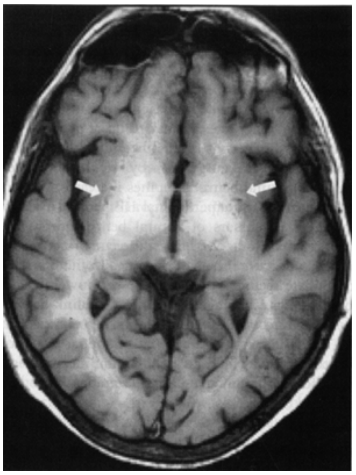
Several arguments have been proposed in favor of a role for natural benzodiazepines in HE. The most relevant is the observation of an improvement of mental state after the administration of flumazenil (a benzodiazepine receptor antagonist) in some patients with advanced stages of HE who have not consumed benzodiazepines of pharmacologic source (27). However, the beneficial effects of flumazenil, usually mild and transient, are only seen in a subgroup of patients. One of the main limitations of this theory is the lack of an explanation of the mechanism by which the concentration of natural benzodiazepines increases in HE. A study in rats with experimental HE showed the generation of precursors of natural benzodiazepines in the intestinal flora (28). These precursors are transformed into natural benzodiazepines in the brain and accumulate secondary to liver failure. However, additional studies in humans to confirm the link between intestinal flora, liver function, natural benzodiazepines, and HE are lacking. An alternative source of natural benzodiazepines could be hemoglobin; metabolites of hemoglobin that mimic benzodiazepines have been described (29).

Manganese

Manganese is probably involved in the development of parkinsonian manifestations in HE, but its role in other neurologic manifestations is uncertain (30). The concentration of manganese is elevated in the plasma of patients with cirrhosis and in the brain of patients who die with HE. Hypermanganesemia is the result of portosystemic shunting and a reduction in biliary excretion (31). Patients with cirrhosis typically exhibit a hyperintense signal in the globus pallidum (Fig. 20.3) that has been attributed to the preferential accumulation of manganese in the basal ganglia. However, some studies have failed to show a good association between the intensity of the signal in basal ganglia and neurologic manifestations of HE (32). Nevertheless, its similarities to the clinical and radiologic features of manganese intoxication suggest that the increase in manganese level in cirrhosis causes the extrapyramidal signs of chronic HE through mechanisms that impair dopaminergic neurotransmission. The effect of manganese removal on the neurologic signs and symptoms of chronic HE has not been evaluated.

Other compounds

A group of potentially neurotoxic compounds of colonic origin has been postulated to affect neurologic function. These include GABA (23), mercaptans, and short-chain fatty acids (8). The concentration of these compounds have been found to be elevated in the plasma of patients and in experimental models of HE, but controversial results and lack of confirmatory data do not support a primary role in HE (Table 20.3).



▪ **Figure 20.3** T1-weighted magnetic resonance image of the brain of a patient with cirrhosis. The patient exhibits a symmetrical hyperintensity of the globus pallidus (*arrows*).

Patients with liver failure show an increase in aromatic amino acid levels (e.g., tyrosine, phenylalanine, or tryptophan) and a decrease in branched-chain amino acid levels (e.g., valine, leucine, or isoleucine). It was proposed that this imbalance would enhance the passage of aromatic amino acids through a neutral amino acid carrier into the brain in exchange for glutamine generated from ammonia detoxification (4). The excess of aromatic amino acids would then be channeled in the brain into the synthesis of *false neurotransmitters* (e.g., octopamine, phenylethanolamine) and serotonin, an inhibitory neurotransmitter. However, this hypothesis, which was the basis for the treatment of HE with branched-chain amino acids, has not been supported by the result of in vivo and postmortem studies. If there is any beneficial effect of the therapy for HE with branched-chain amino acids, it may be through alternative mechanisms (See "Principles of Treatment").

Table 20.3. Other Compounds that Have Been Involved in the Pathogenesis of Hepatic Encephalopathy

Substance	Pros	Cons
GABA	Increase in plasma levels (33) Disturbance in GABAergic neurotransmission (23)	GABA not increased in central nervous system (34)
Short-chain fatty acids	Synergistic effects with ammonia (8) Lactulose decreases the genesis (35)	Lack of correlation between plasma levels and grade of HE (36)
Mercaptans	Synergistic effects with ammonia (37)	Plasma levels found in HE are not neurotoxic (38) Lack of correlation between plasma levels and grade of HE (39)
Aromatic amino acids	Increase in plasma levels (40)	Lack of correlation between plasma levels and grade of HE (41) Normal blood–brain barrier permeability to amino acids (42) False neurotransmitters not found in human brain (43)

GABA, γ-aminobutyric acid; HE, hepatic encephalopathy.

Abnormalities in the Central Nervous System

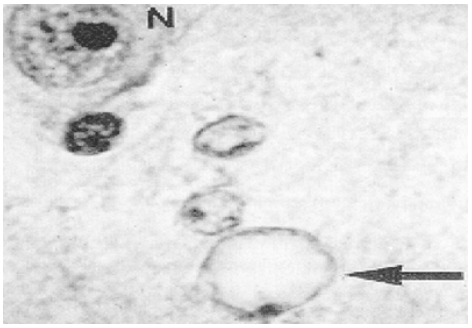
Astrocytes

Experimental and pathologic evidence points at astrocytes as the prominent cells affected in HE (44). No significant or consistent morphologic changes have been identified in neurons or other cells of the CNS. The distinctive morphologic alteration is the Alzheimer type II astrocytic change, which is characterized by a cell with enlarged, pale nuclei with peripheral margination of chromatin and often prominent nucleoli (Fig. 20.4). Results of microscopic studies of specimens from humans and of experimental preparations suggest that the astrocytic changes can be explained by the existence of cellular swelling.

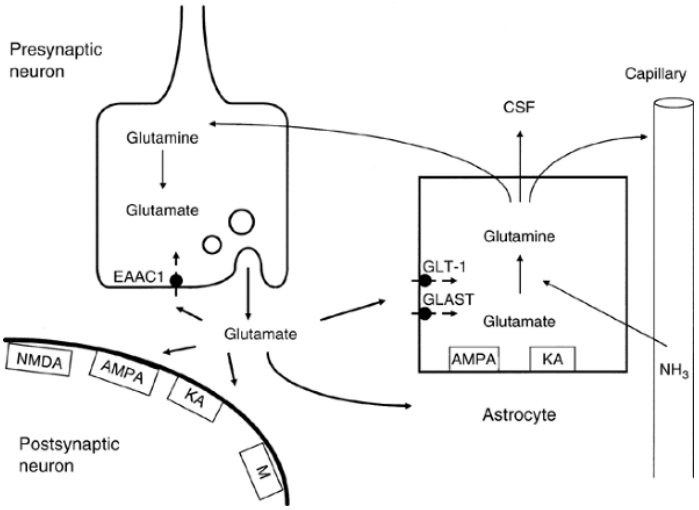
Astrocytes occupy one third of the volume of the cerebral cortex. Their foot processes surround brain capillaries, where they contribute to blood–brain barrier function, and neurons. This anatomic organization forms a syncytium, where critical metabolic supportive functions involved in the maintenance and regulation of the extracellular microenvironment, such as uptake of ions and neurotransmitters, influence neuronal excitability and neurotransmission. A specific

astrocyte function is the detoxification of ammonia through the amidation of glutamate to glutamine. An increase in intracellular

osmolality as a result of glutamine accumulation underlies the genesis of astrocytic swelling in HE (46). These findings have led to the proposal of HE being the clinical manifestation of a gliopathy, in which neuronal dysfunction develops as the result of astrocytic abnormalities (6). Several mechanisms by which abnormal glial cells could influence neuronal function have been postulated:



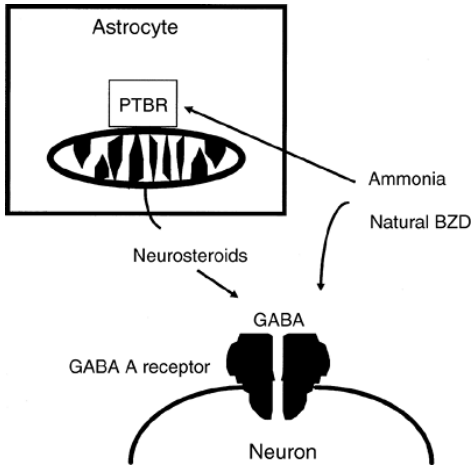
▪ **Figure 20.4** Alzheimer type II astrocyte showing nuclear enlargement and clearing (*arrow*), with the chromatin displaced to the periphery. Two adjacent relatively normal astrocytes are also present. A nearby neuron (*N*) is normal (45). (From Norenberg MD. Hepatic encephalopathy. In: Kettenmann H, Ransom BR, eds. *Neuroglia*. New York: Oxford University Press, 1995:950–963, with permission.)



▪ **Figure 20.5** Abnormalities of glutamate neurotransmission in hepatic encephalopathy. Glutamate released from the presynaptic neuron is again taken up into the perineuronal astrocyte through the glutamate transporter (GLT-1) and glutamate–aspartate transporter (GLAST). Glutamate receptors are expressed in neurons (*N*-methyl-D-aspartate [NMDA], α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid [AMPA], kainic acid [KA], or metabotropic subtypes [M]) and astrocytes (AMPA, KA). CSF, cerebrospinal fluid; EAAC1, excitatory amino acid carrier 1. (Adapted from Butterworth RF. The neurobiology of hepatic encephalopathy. *Semin Liver Dis* 1996;16:235–244.)

1. Interaction with glutamate reuptake (Fig. 20.5) (47). In experimental models, glial reuptake of the glutamate released from presynaptic neurons is likely to be decreased. Downregulation of glutamate transporters located in the plasma membrane of astrocytes (i.e., glutamate transporter-1, glutamate-aspartate transporter) can be reproduced in astrocyte cultures exposed to ammonia. A decrease in reuptake will result in an increase in brain extracellular glutamate levels, with subsequent effects on glutamatergic neurotransmission.
2. Activation of the PTBRs (Fig. 20.6) (44). An increase in the number of PTBRs has been observed in the brain of patients who died with HE and can be reproduced experimentally after administration of ammonia. Activation of PTBRs by different ligands, such as ammonia and diazepam-binding inhibitor, results in an increase in the synthesis of neurosteroids (e.g., pregnenolone, dehydroepiandrosterone), powerful ligands of the neuronal GABA A receptor, thereby affecting GABAergic neurotransmission.
3. Metabolic consequences of cellular swelling (6). The cellular hydration state regulates cell function and gene expression. Swelling of astrocytes

activates extracellular regulated protein kinases, elevates calcium concentration, and affects multiple ion channels and amino acid transport. Oxidative stress can be detected in vitro and in vivo (48). All these abnormalities may affect the ability of astrocytes to efficiently uptake or release extracellular ions and neurotransmitters, secondarily affecting glial–neuronal communication.



▪ **Figure 20.6** Abnormalities of γ-aminobutyric acid (GABA) neurotransmission in hepatic encephalopathy. The activation of "peripheral-type" benzodiazepine receptor (PTBR) by ammonia enhances the synthesis of neurosteroids in the mitochondria of astrocytes. Neurosteroids and ammonia may modulate the GABA A receptor and thus contribute to hepatic encephalopathy. BZD, benzodiazepine. (Adapted from Butterworth RF. The neurobiology of hepatic encephalopathy. *Semin Liver Dis* 1996;16:235–244.)

Table 20.4. Main Abnormalities of Neurotransmission Described in Hepatic Encephalopathy and Their Possible Consequences

System	Findings	Possible consequences
Glutamate	Decrease in total brain glutamate level (50) Increase in extracellular glutamate level (49) Decrease in glutamate transporter levels (51) Decrease in glutamate receptor levels (49)	Impaired mental function Brain edema Convulsions
GABA	Signs of increased GABAergic tone (23) Positive response to flumazenil (27) Increase in benzodiazepine receptor ligand levels (23) Activation of peripheral-type benzodiazepine receptor (44) Increase in neurosteroid levels (44)	Decrease of consciousness
Serotonin	Increase in the metabolism of serotonin (52)	Behavioral abnormalities
Dopamine	Decrease of dopamine receptor levels (53) Increase in degradation of dopa (54) Improvement of extrapyramidal signs with dopa (55)	Extrapyramidal manifestations
Opioid	Increase in the sensitivity to morphine (56) Increase in endogenous opioids (57)	Behavioral abnormalities
Histamine	Increase in histamine receptors (58)	Circadian rhythm abnormalities
Nitric Oxide	Decrease in cerebellar cyclic guanosine monophosphate (59)	Learning impairment

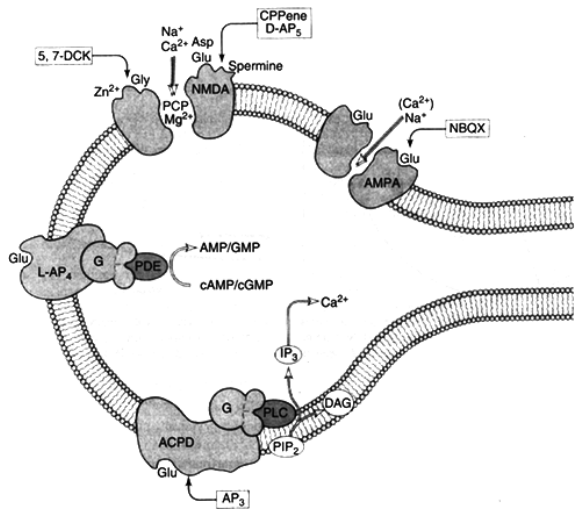
GABA, γ-aminobutyric acid.

Neurotransmitter systems

HE, as other forms of metabolic encephalopathy, appears to occur as a result of abnormalities in neurotransmission (5). This hypothesis is supported by its potential reversibility and by the lack of neuronal damage. Multiple abnormalities of neurotransmitter systems have been described (Table 20.4). Glutamate neurotransmission is clearly disturbed in animal models of HE (49), where it appears to have a role in the pathogenesis of HE (Fig. 20.7). However, supportive human data arise mostly from autopsied samples (50), and pharmacologic manipulation of glutamatergic neurotransmission has not been attempted.

The improvement of neurologic manifestations after the administration of a drug that interacts with an individual transmitter system is an important argument to support a pathogenic role for that system. The first attempt to normalize the abnormalities of neurotransmission arose from the false neurotransmitter hypothesis. The notion was to restore the abnormalities in the profile of plasma amino acids and the transport of amino acids across the blood–brain barrier by administering branched-chain amino acids. Subsequent therapeutic attempts have been focused on the brain itself and include stimulation of dopaminergic transmission with

bromocriptine or levodopa (55) and blockage of GABA-inhibitory neurotransmission with flumazenil (27). The results have not been remarkable, highlighting the complexity of a paradigm in which several neurotransmitter systems are simultaneously affected. Still, these attempts indicate it may be possible to treat HE using drugs that act in the brain in addition to measures that decrease the plasma level of a putative toxin.



▪ **Figure 20.7** Molecular views of four types of glutamate receptors. Two heteromeric receptors are shown, the *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors, and two metabotropic receptors, the L-AP_4 and trans-(±)-1-amino-cyclopentane-1,3-dicarboxylate (ACPD) receptors. Competitive antagonists of each receptor are boxed. AMP, adenosine monophosphate; cAMP, cyclic adenosine monophosphate; GMP, guanosine monophosphate; cGMP, cyclic guanosine monophosphate; PLC, phospholipase C; PIP_2, phosphatidylinositol-4,5-bisphosphate; PCP, purine-cytosine permease; DAG, diacyl glycerol; IP_3, inositol triphosphate; Glu, glutamine; PDE, phosphodiesterase; DCK, 5,7-di-chlorokynurenic acid; Gly, glycine (60). Energy abnormalities

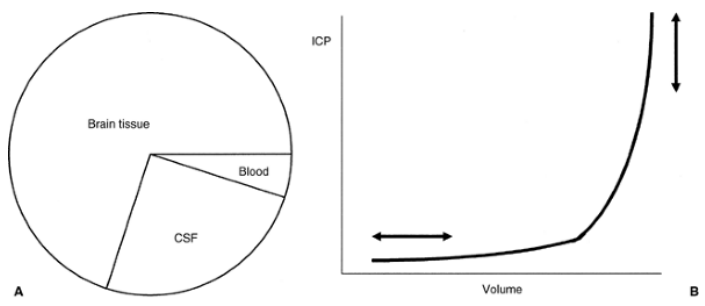
The brain is the tissue with the highest energy requirements of the body and depends entirely on the process of glycolysis and respiration within its own cells to fulfill its energy demands. In HE in humans, a decrease in consumption of oxygen and glucose is accompanied by a parallel decrease in cerebral blood flow (61). These energy abnormalities are not homogeneous across the brain, with basal ganglia exhibiting a different pattern from the cortex (20). Some studies with humans have shown focal reductions of glucose utilization that are related to specific neurologic manifestations (62). However, the findings cannot separate whether the decrease is the cause or the consequence of the encephalopathy. The current interpretation is that, as in other metabolic encephalopathies, the decrease in energy consumption is secondary to the decrease in demand. As observed in some patients with high cerebral blood flow, especially among those with fulminant hepatic failure, an increase in supply does not improve the mental state (63). Ammonia may impair glycolysis because it inhibits α-ketoglutarate dehydrogenase, the rate-limiting enzyme of the tricarboxylic acid cycle (22). However, the histologic features are different from those observed in hypoglycemia or hypoxia. In experimental preparations, energy deficits are only observed after prolonged periods of coma. Results of magnetic resonance spectroscopy performed on humans suggest that there are no significant deficits in the generation of high-energy compounds in the brain (64).

Brain edema

Brain edema is a complication of fulminant hepatic failure, which can progress to intracranial hypertension and death (Fig. 20.8). Brain edema has been frequently regarded as a distinct entity, dissociated from the neurologic features of HE. However, several lines of evidence relate brain edema to HE (46). Although intracranial

hypertension is a common problem in patients with fulminant hepatic failure in coma, the development of high intracranial pressure (ICP) in patients with cirrhosis in deep coma is only occasionally documented (65).



▪ **Figure 20.8 A:** A pie chart separating the three compartments in the brain according to their relative volume: Brain tissue (70%), cerebrospinal fluid (CSF) (25%) and blood volume (5%). **B:** In an early stage of increase in brain volume, large

changes in volume result in small changes in intracranial pressure (ICP); at a later stage, brain compliance is reduced, and small changes in volume cause large changes in pressure.

One important limitation is the assessment of brain edema in these circumstances. Standard neuroimaging techniques are insensitive to detect increases in brain water even when intracranial hypertension is already present. MRI provides multiple indirect evidences of an increase in brain water (66). Magnetization transfer imaging is a technique based on the transfer of magnetization between free protons in water and bound protons associated with macromolecules that allows an estimation of the amount of free water through the calculation of the magnetization transfer ratio (MTR). Brain edema causes a decrease in MTR, a result that is well documented in cirrhosis (67). In addition, the development of low-grade brain edema in cirrhosis is supported by diffusion weighted imaging (68) and magnetic resonance spectroscopy (69). The corticospinal tract, which corresponds to the first neuron of the voluntary motor pathway, appears more vulnerable to edema and functional impairment (70). The parallel improvement of magnetic resonance abnormalities and neurophysiologic disturbances after liver transplantation supports the hypothesis that astrocytic edema may cause secondary neuronal dysfunction (6).

Brain edema appears to originate from the accumulation of glutamine, the product of ammonia metabolism in astrocytes (46). The osmotic effects of an acute increase in glutamine concentration appear to overcome the compensatory capacity of astrocytes, cells that are swollen in neuropathologic preparations. Brain edema has been described in all situations of acute hyperammonemia and has been associated with plasma levels of ammonia in fulminant hepatic failure (71). In the experimental setting, brain swelling secondary to ammonia infusion can be prevented with the administration of an inhibitor of the synthesis of glutamine. Other factors, such as hyponatremia, may enhance the effects of ammonia on brain swelling (72). In fulminant hepatic failure, an additional factor that plays an important role in the development of intracranial hypertension is the presence of abnormalities of cerebral circulation. Cerebral vasodilatation and loss of autoregulation are characteristic findings in fulminant hepatic failure (63). The mechanism that causes the abnormalities of cerebral circulation has not been fully elucidated. They appear to arise from a signal generated in the brain. Indeed, measures that decrease cerebral vasodilatation are of clinical benefit for patients with severe intracranial hypertension (73). In addition to differences in the cerebral circulation and in the rate of exposure of the brain to ammonia, patients with cirrhosis may activate compensatory mechanisms that counteract osmotic changes in the brain (46). Those with hyponatremia are at higher risk for the development of intracranial hypertension.

Factors that Favor the Effects of Toxins

Precipitating factors

Several factors are known to precipitate an episode of HE in stable patients with cirrhosis (Table 20.5). They exert their effects through an increase in the generation of putative toxins, impairment in liver function (resulting in enhanced portosystemic shunting and

larger delivery of toxins to the brain), or enhancement of the effects of the toxins on the CNS. In some cases the mechanisms that explain the action of the precipitating factor seem obvious (i.e., worsening liver function in acute hepatitis). In other cases, there are multiple factors acting as coprecipitants.

Table 20.5. Precipitating Factors for Hepatic Encephalopathy

Precipitating factor	Possible effects	Mechanism of action	Associated coprecipitant
Sepsis	Increase in blood ammonia level Enhancement of the effects of putative toxins on the CNS	Protein catabolism Activation of cytokines	Azotemia Arterial hypotension
Gastrointestinal bleeding	Impairment in liver function Increase in blood ammonia level	Hepatic hypoperfusion Nitrogen load Disturbances of plasma amino acids	Infection Anemia Arterial hypotension
Hypokalemia	Increase in blood ammonia level	Ammonia generation	—
Azotemia	Increase in blood ammonia level	Ammonia generation	—
Dehydration	Increase in blood ammonia	Hepatic hypoperfusion	Hypokalemia Azotemia
Diuretics	Increase in blood ammonia	Hypokalemia Azotemia Dehydration	—
Acute hepatitis	Impairment in liver function Enhancement of effects on the CNS	Liver injury Activation of cytokines	
Surgery	Impairment in liver function	Hepatic hypoperfusion	Anesthetics
Constipation	Increase in blood ammonia	Ammonia generation by enteric flora	—

Large protein intake	Increase in blood ammonia	Nitrogen load	—
Psychoactive drugs	Enhancement of effects on the CNS	Activation of inhibitory neurotransmission	—

CNS, central nervous system.

Infection and inflammation have been postulated to play an important synergistic role in the pathogenesis of HE (9). Possible mechanisms by which such effects may be mediated include activation of vagal afferents at the site of inflammation, binding of cytokines and/or inflammatory cells to receptors in cerebral endothelial cells with subsequent transduction of signals into brain, and direct access of cytokines into brain tissue to sites lacking blood–brain barrier (such as the circumventricular organs). Cytokines may increase blood–brain barrier permeability to ammonia, resulting in the generation of intracerebral mediators, such as nitric oxide and prostanoids, and cause astrocytic swelling (6,74). A systemic infection will also impair renal function, increasing circulatory urea levels, with subsequent colonic generation of ammonia through urease-containing bacteria. Treatment of infection has been shown to have a direct impact on neuropsychological function in patients with cirrhosis (75).

Portosystemic shunts

Portosystemic shunting allows the access of gut-derived toxins into the systemic circulation. There are three different types of portosystemic shunts: (a) Congenital shunts without significant liver disease, (b) large spontaneous shunts in cirrhosis, and (c) procedural shunts.

Congenital shunts are rare conditions that connect the portal with the systemic circulation and may cause neurologic manifestations compatible with HE without abnormalities in the liver parenchyma (76). Different morphologic types have been described. They may be single or multiple and be located intrahepatic or extrahepatic. Congenital shunts may be associated with hypoplastic portal vein branches or even the absence of portal vein (patent ductus venosus or Abernethy malformation). Associated abnormalities in the portal branches may lead to some degree of parenchymal atrophy. Clinical manifestations present very early in life or in the sixth or seventh decades, suggesting an age-dependent sensitivity of the CNS to develop HE.

Large portosystemic shunts may develop in some patients with cirrhosis and favor the development of persistent HE (77). These spontaneous shunts can decrease portal pressure, and the patients seldom have significant portal hypertension. These shunts may have different extrahepatic locations. Among the different shunts, large splenorenal shunts are those more commonly associated with chronic HE because they lead to marked portal flow steal (78).

Procedural shunts are secondary to transjugular intrahepatic portosystemic shunt (TIPS) or other surgical intervention (79). The frequency of postshunt encephalopathy depends on the type of shunt and the susceptibility of the individual. Approximately, one third of patients subjected to a TIPS procedure will

develop encephalopathy. Nonselective portosystemic shunts (i.e., portocaval, mesocaval) produce more encephalopathy than do selective shunts (i.e., distal splenorenal) in patients with nonalcoholic cirrhosis. However, selectivity of splenorenal shunts is lost in the long term. Elderly patients and those with poor liver function are at higher risk for postshunt encephalopathy. However, there is no hepatic functional test that confidently identifies individuals who will develop HE. Closure of TIPS is associated with improvement of HE (80).

Increased brain susceptibility

Patients with cirrhosis prone to HE have an increased susceptibility to the effects of different psychoactive drugs, such as morphine, antidepressants, or benzodiazepines. This increased susceptibility is not explained simply by pharmacokinetic changes induced by liver failure (81). Hypersensitivity to psychoactive drugs may be mediated by changes in neurotransmission secondary to the disease of the liver, such as underlying abnormalities in benzodiazepine receptors. Additional factors could be the presence of abnormalities at the level of the blood–brain barrier and/or cerebral blood flow. General derangements of blood–brain barrier permeability do not appear to be present in HE (46). However, selective increments in permeability may occur, as has been shown for ammonia in patients with minimal HE (12). Comorbid conditions, which are common in patients with cirrhosis, such as alcoholism or dilutional hyponatremia, as well as advanced age, may facilitate the development of HE because of their direct effects on brain function.

Clinical Features

The Acute Episode of Encephalopathy

An acute episode of HE is characterized by the development of an acute confusional syndrome that includes impaired mental state, neuromuscular abnormalities, fetor hepaticus, and hyperventilation (1). Variability is an important feature; the clinical manifestations may fluctuate rapidly and oscillate from mild confusion to deep coma. The onset is usually abrupt; HE develops over hours to days. Most patients do not have significant neurologic manifestations before the onset of the acute episode of HE, unless they had persistent HE. The evolution of an acute episode of HE tends to parallel the course of liver function or the removal of the precipitating factor. Prolonged episodes of HE occur among patients with terminal liver failure. Patients usually recover from HE without major neurologic deficits and are able to return to previous activities.

Impairment of consciousness initially manifests as subtle changes of personality or disturbances in the circadian rhythm of sleep and wakefulness (i.e., insomnia during the night, somnolence during the day). As HE progresses, the manifestations include inappropriate behavior, disorientation, confusion, slurred speech, stupor, and coma. Some patients may experience nausea and vomiting, especially if there is rapid evolution into coma.

Asterixis is a characteristic feature of HE that represents the failure to actively maintain posture or position (1). Asterixis is caused by abnormal function of diencephalic motor centers that regulate the tone of the agonist and antagonist muscles normally involved in maintaining posture (82). The classic method of eliciting asterixis is by dorsiflexion of the patient's hand, with the arms outstretched and fingers separated. The postural lapse that occurs consists of a series of rapid, involuntary, flexion–extension movements of the wrist. Asterixis may be observed during any sustained posture: Tongue protrusion, dorsiflexion of the foot, or fist

clenching. Asterixis is not exclusive to HE and can occur in other metabolic or structural encephalopathies (e.g., renal failure, hypercapnia, stroke affecting basal ganglia). Asterixis does not occur in early or advanced HE. In coma, asterixis disappears, but the patient may exhibit signs of pyramidal involvement, such as exaggerated deep tendon reflexes, hypertonia, or extensor plantar responses. Transient decerebrate posturing and abnormal ocular movements may occur in deep coma.

Fetor hepaticus is a peculiar pungent odor of the breath that is often regarded as a component of HE. This odor is attributed to dimethylsulfide, a volatile sulfur compound, that can be identified in the breath and serum of patients with cirrhosis (39). The presence of fetor hepaticus is not constant; patients with cirrhosis but not HE can have this condition. Hyperventilation is also frequent, especially among patients with advanced HE, and has been interpreted as a compensatory mechanism that decreases the entrance of ammonia into the brain through a decrease in arterial pH. It has also been related to elevated levels of estrogens and progestogens (83).

The Patient with Chronic Encephalopathy

Chronic encephalopathy encompasses two different situations: (a) The patient with relapsing episodes of HE and (b) the patient with persistent neurologic manifestations. This differentiation highlights the more prominent clinical presentation, but in practice both situations are difficult to separate. Some patients initially

have relapsing episodes and later have persistent symptoms. A patient with purely relapsing HE or purely persistent HE is rare. Furthermore, symptoms tend to fluctuate after the institution of therapeutic measures or the occurrence of precipitating events.

Relapsing episodes may be due to precipitating factors, but in most cases are spontaneous or related to the discontinuation of medication. A history of constipation is commonly elicited. The course of the acute episode does not differ from the one previously described, except a tendency for an abrupt onset and resolution. Between episodes, the patient can be perfectly alert and not show any sign of cognitive dysfunction. However, a careful neurologic examination and neuropsychological tests may reveal abnormalities. Mild parkinsonian signs, characterized mostly by bradykinesia without tremor (84), are probably the most common manifestation between episodes.

Persistent HE refers to those manifestations that do not reverse despite adequate treatment. In most patients with cirrhosis and prior episodes of acute HE and advanced liver failure, a careful neurologic examination will reveal multiple mental and motor abnormalities. Most of these abnormalities are subtle, such as increased muscle tone, reduced mental or motor speed, dysarthria, hypomimia, lack of attention, or apraxia. Psychometric tests may be helpful in describing and quantifying the degree of impaired mental function.

Persistent HE is considered severe when it impairs daily activities. The most characteristic manifestations of severe chronic HE are dementia, severe parkinsonism, or myelopathy in combination with other manifestations of neurologic involvement (e.g., ataxia, dysarthria, gait abnormalities, or tremor). This clinical picture is seldom seen nowadays because of the availability of liver transplantation and the limited number of patients who undergo surgical portosystemic shunts. Patients with *hepatic dementia* tend to have fluctuating symptoms with periods of improvement and a subcortical pattern. The initial manifestations are attentional deficits, visuopractic abnormalities, dysarthria, and apraxia. Those with *hepatic parkinsonism* may resemble Parkinson's disease, except for a symmetrical presentation and lack of significant tremor. *Hepatic myelopathy* (85) is characterized by a progressive spastic paraparesis accompanied by hyper-reflexia and extensor plantar responses. Only a few patients have sensory symptoms or incontinence. The pathogenetic mechanisms of these complications are obscure. They have associated neuronal loss—in case of dementia—and demyelination along the pyramidal tract—in case of myelopathy. Although these lesions are difficult to reverse, there are descriptions of improvements after liver transplantation (86), a challenge to the notion of irreversibility. The term *hepatocerebral degeneration* has been occasionally used to describe such patients. However, this is a neuropathologic diagnosis applied to those patients whose brains exhibit substantial and irreversible loss of gray matter in the cortex and basal ganglia. It is preferable not to use it to describe the clinical picture.

The Brain in Fulminant Hepatic Failure

The clinical picture of HE in acute liver failure parallels that of an acute episode of HE: An acute confusional syndrome that evolves into coma. However, in acute liver failure, brain edema leading to intracranial hypertension and abnormalities of brain perfusion is critical (87).

Brain edema does not result in clinical manifestations unless intracranial hypertension is present because the displacement of brain tissue is the factor that results in neurologic symptoms. Intracranial hypertension may manifest as decerebrate rigidity, myoclonus, seizures, mydriasis, bradycardia, or arterial hypertension (Cushing's reflex). However, the diagnosis of intracranial hypertension based on clinical signs is unreliable because they can be absent with pressures as high as 60 mm Hg (88) and are difficult to monitor because these patients are intubated and paralyzed when they are in coma.

A major consequence of intracranial hypertension is the effect on cerebral perfusion. The maintenance of cerebral blood flow is critical to ensure an adequate supply of oxygen. The driving force in maintaining a stable blood flow is the cerebral perfusion pressure, the arithmetical difference between mean arterial pressure and ICP. When cerebral perfusion pressure is less than 40 mm Hg, structural tissue damage from brain ischemia may ensue. In spite of low cerebral blood flow, an occasional patient may recover from this situation without irreversible brain damage. Another consequence of intracranial hypertension is the mechanical compression of neighboring structures. The increase in pressure causes displacement of brain tissue, resulting in herniation and direct compression of the temporal lobe or the cerebellum. Brain stem compression can result in sudden respiratory arrest and circulatory collapse.

Minimal Hepatic Encephalopathy

Minimal HE, also referred by the terms *latent* or *subclinical*, is a mild dysfunction of brain function that cannot be detected by standard clinical examination (3,89). This label was originally applied to a group of individuals who performed abnormally on psychometric tests but had essentially normal findings on clinical examination. Psychometric tests are more sensitive than clinical observation, as shown in other neuropsychiatric diseases, such as dementia.

Other techniques (e.g., electroencephalogram [EEG]), evoked potentials, or neuroimaging) that are more sensitive than clinical examination to reveal neurologic impairment have also shown a stage of minimal dysfunction, which is understood as part of a continuous disorder that has several levels of severity, minimal HE being the mildest expression of HE. This interpretation is supported by the observation of amelioration of minimal HE after using the same therapeutic measures as those used against *overt* HE (90) and the relationship between minimal HE, ammonia levels, and liver function (91).

The diagnosis of minimal HE is arbitrary and can be performed with neuropsychological or neurophysiologic tests. The most characteristic deficits are in motor and attentional skills (92). Learning impairment, which has also been described in experimental models (59), appears to be the consequence of attention deficits (93). The depth of the psychometric and the clinical examination necessary to diagnose minimal HE is not defined. The frequency of the diagnosis is variable (30% to 84% of patients), depending

on the characteristics of the population being studied and the extent of the psychometric evaluation. Some attempts have been made to develop practical tools on the basis of the design of short batteries of neuropsychological tests, such as the Psychometric Hepatic Encephalopathy Score (PHES) (94). However, these batteries have not been fully standardized and their use is still investigational. Critical flicker frequency, a neurophysiologic tool, has been proposed as a practical test to assess low-grade encephalopathy (95).

The importance of establishing the diagnosis of minimal HE is unknown. Some studies have highlighted that minimal HE may have an adverse impact on the ability to perform daily activities and on health-related quality of life (96). However, many subjects are able to compensate for these deficits (89). From a practical point of view, a psychometric evaluation may be adequate in those individuals whose occupations demand attentional and motor abilities. A report of impaired driving in patients with minimal HE (97) suggests the need to develop a therapeutic program for such individuals. Benefits of treatment, as assessed by monitoring the neuropsychological response, should be weighed against secondary side effects. There are no data on the effects of therapy on health-related quality of life. Patients with cirrhosis and minimal HE have a clear tendency to develop overt HE (98). Whether the institution of preventive measures would decrease the risk of the progression to overt encephalopathy has not been evaluated. The presence of minimal HE indicates worse prognosis, especially if associated with high levels of blood ammonia after the administration of glutamine (99). For this reason, liver transplantation should be considered in patients with minimal HE.

Methods for the Assessment of Hepatic Encephalopathy

Grading Hepatic Encephalopathy

Grading of HE is necessary to assess the evolution of the condition and the response to the effects of therapy. Several methods are based on clinical findings or the combination of neurophysiologic and neuropsychological tests, but the simplest grading of HE is based on clinical findings. The West Haven index is widely used (13). It is based on changes in consciousness, intellectual function, and behavior (Table 20.6). The Glasgow Coma Scale offers a system that monitors consciousness according to simple and more objective parameters. This scale was initially developed for traumatic coma but has gained widespread use for all forms of coma. It is probably more reliable than the West Haven criteria but has the limitation that it is less sensitive in quantifying the mildest forms of HE and is better suited for advanced HE.

The portosystemic encephalopathy (PSE) index has been used in many studies to assess the effects of therapeutic measures. This index combines the assessment for mental state, arterial ammonia level, EEG, the number connection test, and estimation of the degree of asterixis. An arbitrary weight of 3 is assigned to the mental state and the other parameters are weighted. Concerns have been raised about the arbitrary scoring system, the inclusion of ammonia (a putative toxin), the feasibility of an arterial puncture, and the assessment of the number connection test in the evaluation of advanced HE. It is generally considered that blood levels of ammonia, although separating groups according to mean values (21), show wide dispersion in individual values and are not useful to predict the severity of HE and monitor the response to therapy (100). A

consensus has been reached indicating that the PSE index is not adequate for clinical follow-up and is not recommended for clinical trials.

Table 20.6. Grading Scale of Hepatic Encephalopathy Based on Change in Mental Status

Grade	Neurologic manifestations
0	No alteration in consciousness, intellectual function, personality, or behavior
1	Trivial lack of awareness, euphoria or anxiety; short attention span
2	Lethargy, disorientation, personality change, inappropriate behavior
3	Somnolence to semistupor, confusion; responds to noxious stimuli
4	Coma, no response to noxious stimuli

From Conn H. & Bircher J. with mild modifications Conn HO. The hepatic encephalopathies. In: Conn HO, Bircher J, eds. *Hepatic encephalopathy. Syndromes and therapies*. Bloomington, IL: Medi-Ed Press, 1994:1–12.

Neuropsychological Tests

The main role of neuropsychological tests is the diagnosis of minimal HE and the assessment of cognitive function in patients with persistent HE. On the basis of the most frequently found abnormalities, several psychometric tests have been proposed to be the most adequate for diagnosing HE (89,92). Neuropsychological tests can be affected by multiple factors. It is important that the neuropsychological assessment takes into consideration these factors. Patients with clear signs of decreased arousal cannot undergo testing. Care is needed to control for comorbidities, visual impairment, or cultural barriers. The test should be adapted to the cultural characteristics of the population being evaluated. Nomograms to compare the results should take into consideration age and, ideally, the degree of education. The patient undergoing testing should be seated in a quiet room with sufficient light. An important limitation of the neuropsychological tests is the practice effect in follow-up evaluation. Results of psychometric tests are affected by learning. Use of parallel versions can lessen this effect, but only few tests have well-standardized versions.

Some short batteries specifically developed for HE may be useful for the detection of abnormal cognition. However, they do not substitute a formal neuropsychological evaluation performed by an experienced neuropsychologist. The *PHES* is a battery of tests specifically developed for the diagnosis of minimal HE (94). Similar to the Mini-Mental State Examination for dementia, PHES can be useful for screening minimal HE. The PHES combines five paper–pencil tests (i.e., line tracing tests, digit symbol test, serial dotting test, number connection test A, and number connection test B) that examine motor speed and accuracy, visual perception, visual–spatial orientation, visual construction, concentration, attention, and, to a lesser extent, memory. The results of the battery are scored according to normograms from a group of healthy controls. Each one of the test scores 0 points when it falls in the ±1 standard deviation (SD) range. A test that falls in the range more than 1 SD is scored +1 point and for less than -1 SD, -2 SD, -3 SD range, the tests are scored with -1, -2, or -3 points, respectively. Thereby, the subjects could achieve between +6 and -18

points. A pathologic test result (diagnosis of minimal HE) is set at -4 points.

Neurophysiologic Tests

A large number of different neurophysiologic tests have been proposed for the diagnosis and quantification of HE. Reports for and against the specificity of electrophysiologic changes have been published (101,102). These tests are most useful in documenting cerebral dysfunction in difficult cases and possibly in monitoring response to therapy. They have the advantage of not being influenced by learning effects. Therefore, they may be better suited for assessing effects of treatment than neuropsychological tests, especially for advanced stages of HE. For minimal–mild HE, neurophysiologic tests do not give information about behavioral consequences, in contrast to the insight provided by neuropsychological tests.

The standard EEG shows slowing of the frequency from the normal 8 to 13 Hz to the delta range below 4 Hz. The change usually commences in the frontal or central regions and progresses posteriorly. High-voltage, low-frequency (1.5 to 3 Hz) waves with triphasic appearance have been considered characteristic of HE. However, they have been described in a variety of forms of metabolic encephalopathy and are not specific for HE. Several stages of evolution of EEG changes have been described in HE, and a fair correlation with clinical stages and ammonia levels has been observed. The simplest EEG assessment is to grade the degree of abnormality of the conventional tracing. Computer-assisted frequency analysis of the EEG includes evaluation of the mean dominant frequency and the power of a particular EEG rhythm. Minor changes in the dominant frequency occurs in patients with minimal HE (91).

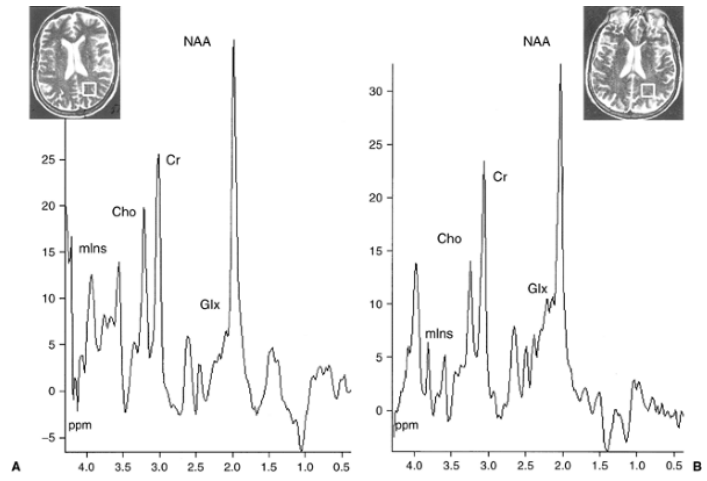
Evoked responses are externally recorded potentials reflecting discharges through neuronal networks after exposure to specific stimuli (102). Depending on the type of stimulus and the pathway analyzed, they could be visual, somatosensory, or acoustic-evoked potentials. Event-related potentials using different stimuli represent an endogenously task-related cortical response reflecting the neural pathway involved in awareness, learning, and decision-making processes. Event-related potentials, such as the P300-evoked potential, requires patient cooperation and well-trained operators. Evoked potentials and event-related potentials are considered more sensitive than the conventional EEG for the diagnosis of mild forms of HE. They may be useful for assessing the presence of minimal or mild HE in patients with cirrhosis who have memory loss or other mental symptoms.

Neuroimaging

At autopsy, the brains of patients with cirrhosis who have died from HE do not show major anatomic abnormalities, except for various degrees of atrophy. Therefore, neuroimaging studies that exclusively assess the morphologic structure of the brain, such as computed tomography (CT) scan, do not detect specific abnormalities in HE. Brain atrophy, which is depicted with CT scan, is more common in patients with

long-standing cirrhosis and chronic HE (103). However, brain atrophy is not a specific abnormality of HE and may be related to factors other than HE (e.g., alcoholism, age, or comorbid conditions). Furthermore, as in other neurodegenerative diseases, brain atrophy is not associated with neuropsychological performance (104). Conventional neuroimaging techniques are insensitive to the detection of brain swelling that may develop in some patients with cirrhosis and frequently complicates HE in acute liver failure (105). No studies have been able to find a neuroimaging correlate of hepatocerebral degeneration (cortical laminar necrosis and polymicrocavitation at the corticomedullary junctions and in the striatum).

Magnetic resonance imaging (MRI) and spectroscopy allow the acquisition of data on cerebral metabolic function that are otherwise not available (64). Proton MRI shows a typical pallidal hyperintensity on T1-weighted images (Fig. 20.3). This abnormality is most frequently seen in patients with cirrhosis and severe liver failure or long-standing portosystemic shunts and is absent or only minimally present in patients with well-compensated cirrhosis and unimpaired neuropsychiatric function. It can be also present in patients with congenital shunts or portal thrombosis and normal liver function (106). No direct correlation between the magnitude of pallidal hyperintensity and the grade of HE have been found, but some studies have related pallidal hyperintensity to parkinsonian manifestations (107). Because of radiologic similarities to manganese intoxication, it has been proposed that pallidal hyperintensity is the consequence of the preferential deposition of manganese in the basal ganglia. The deposition of manganese in brain tissue would be secondary to portosystemic shunting and might be involved in the parkinsonian symptoms found in persistent HE.



▪ **Figure 20.9** Proton magnetic resonance spectroscopy. White matter spectrum representation from a healthy control **(A)** and a cirrhotic patient with chronic HE and mild neuropsychological impairment at the time of the study **(B)**. The most significant peaks correspond to *myo*inositol (mIns, 3.55 ppm), choline (Cho, 3.2 ppm), creatine (Cr, 3.0 ppm), glutamine/glutamate (Glx, 2.15 to 2.50 ppm), and *N*-acetyl aspartate (NAA, 2.0 ppm). The spectrum of the patient with cirrhosis shows a marked decrease in mIns and an increase in Glx. (From Cordoba J, Hinojosa C, Sanpedro F, et al. Usefulness of magnetic resonance spectroscopy for diagnosis of hepatic encephalopathy in a patient with relapsing confusional syndrome. *Dig Dis Sci* 2001;46:2451–2455, with permission.)

Proton magnetic resonance spectroscopy allows the assessment of several brain metabolites (e.g., glutamine, glutamate, *myo*inositol) that may be related to the pathogenesis of HE. The level of glutamine, the product of ammonia metabolism in astrocytes, is characteristically increased in brain tissue. Although glutamine is considered neuronally inactive, changes in its concentration may affect neuronal–astrocytic trafficking and affect glutamate neurotransmission (44). The concentration of

glutamine in CSF, an indicator of its level in brain tissue, has been correlated to the stage of HE. Unfortunately, the standard available systems in which magnetic fields of 1.5 T are used do not allow a separation between the peaks of glutamine (moderately high increase in HE) and glutamate (mild decrease in HE). *Myo*inositol has an important role in osmotic regulation in astrocytes. The decrease in brain *myo*inositol content found by spectroscopy has been corroborated in experimental preparations and has been attributed to a compensatory response to the increase in intracellular osmolality caused by the increased concentration of glutamine (46). Although the technique is insensitive to mild changes in the concentration of metabolites, the abnormalities found with spectroscopy (Fig. 20.9) have been related to neuropsychological impairment and liver function (69). The role of proton magnetic resonance in the diagnosis of HE has not been investigated. Nevertheless, a completely normal study in a patient suspected to suffer from HE is a strong argument against this diagnosis.

Regional distribution of radionuclides in the brain has been used to study cerebral blood flow, oxygen and glucose consumption, neurotransmitter utilization, and availability of neuronal receptors. The results of some of these studies are controversial (64). Although they may help in understanding the pathogenesis of HE, radionuclide studies are not adequate for diagnostic purposes.

Principles of Treatment

HE is a manifestation of severe liver failure; its treatment cannot be separated from the treatment of liver failure. Nevertheless, several measures specifically designed to manage HE appear to be beneficial. The effects have not been evaluated by well-designed randomized clinical trials including a large number of patients. Study design is especially complex in this condition because the clinical course of HE tends to resolve and relapse spontaneously in many cases. The concurrence of other disorders (e.g., anemia, electrolytic disturbances, fever, severe infection, or alcoholic injury) are confounding factors that complicates the assessment of the neurologic manifestations. For these reasons, almost all modalities of therapy have been criticized. In fact reexamination of the results obtained in available trials have questioned the evidence base for current therapies (108). Despite these limitations, critical reappraisal of available data and the clinical experience render it possible to devise a rational approach to the management of HE.

Nutrition

Classically, the recommendation for patients with HE has been to restrict dietary protein intake. The extent of the restriction will depend on the degree of HE, being more marked for severe HE. Many investigators have recommended withholding all protein intake and subsequently increasing intake in increments to maximal clinical tolerance (109). This recommendation has been criticized (110). Only one randomized study has investigated the effects of protein restriction on the outcome of HE (111). In this study 30 patients admitted for an episode of HE received progressive amounts of proteins (from 0 to 1.2 g/kg per day) or normal protein amounts (1.2 g/kg per day) from the beginning. The diet was administered through nasogastric tube for 2 weeks and HE was assessed, blinded for the group of treatment. The main result of the study was that there were no differences in the outcome of HE; the normal protein diet was metabolically more adequate. Therefore, restriction of proteins in the diet does not appear to have any beneficial effect for episodic HE.

Protracted nitrogen restriction may be harmful, as witnessed in patients with acute alcoholic hepatitis (112). Severe malnutrition, which is common among patients with cirrhosis, is associated with a poor short-term prognosis. Although avoiding intake of large amounts of protein may be advantageous for reducing the levels of toxins involved in HE, restriction may worsen liver function and increase the risk of death. A positive nitrogenous balance may improve encephalopathy by promoting hepatic regeneration and increasing the capacity of the muscle to detoxify ammonia. For these reasons the current recommendation is to avoid restrictions of dietary protein (110).

Improvement in nutritional status in patients with cirrhosis and encephalopathy is difficult. A high protein intake (1.2 g/kg per day) may be necessary to maintain nitrogen balance. However, in a classical study (109) the investigators related the intake of increasing quantities of protein to the precipitation of HE. Modifying the composition of the diet and increasing its calorie/nitrogen ratio may improve tolerance to protein. At isonitrogenous levels, vegetable and dairy products cause less encephalopathy than does meat (113). Differences in amino acid composition and in the ratio of carbohydrates to total protein could explain these effects. A high calorie to nitrogen ratio, which is characteristic of casein-based and vegetable-based diets, reduces gluconeogenesis and has anabolic effects on the utilization of dietary proteins. The benefits of vegetable-based diets are also related to the presence of nonabsorbable fiber that is metabolized by colonic bacteria. Fiber increases the elimination of nitrogen products in stool, probably through a similar mechanism to that of nonabsorbable disaccharides.

Branched-chain amino acids were promoted as a means of correcting the imbalance in the plasma amino acid profile, which was thought to be involved in the pathogenesis of HE. However, clinical trials using

branched-chain amino acids have not shown major beneficial effects for episodes of HE and only mild effects for chronic HE (Table 20.7). Branched-chain amino acids do not show significant effects on survival. Critical reviews of the published studies highlight the inadequate design of most studies. Considerations of cost-effectiveness indicate that branched-chain amino acids should not be used outside clinical trials (114). They show anticatabolic effects in patients with chronic liver diseases, probably because of their ability to serve as an energy substitute for muscle and because of their actions on muscle protein synthesis and degradation. This nutritional effect may result in an improvement of liver function and a better clinical outcome, as shown in a multicenter trial performed in Italy that included patients with advanced cirrhosis, most of them without prior HE (115).

Table 20.7. Overview of Randomized Controlled Trials of Branched-Chain Amino Acids for Hepatic Encephalopathy

Treatment	Control	Type of hepatic encephalopathy	Trial	*N*	Design	Duration	Effects on encephalopathy
BCAA IV + glucose 20%	Lactulose + glucose 20%	Acute	Rossi-Fanelli et al. 1982 (116)	34	Multicenter	2–4 d	=
BCAA IV + glucose 50%	Lactulose + glucose 50%	Acute	Vilstrup et al. 1990	65	Multicenter double-	<16 d	=

+ lactulose			(117)		blind		
BCAA IV. + glucose 50% + lipid 20%	Glucose 5% + glucose 50% + lipid 20%	Acute	Wahren et al. 1983 (118)	50	Multicenter double-blind	<5 d	=
BCAA IV + glucose 25%	Neomycin + glucose 25%	Acute	Cerra et al. 1985 (119)	75	Multicenter double-blind	14 d	+
BCAA IV + hypertonic glucose	Neomycin + glucose 50%	Acute	Strauss et al. 1986 (120)	29	Two-center	5 d	=

BCAA IV + glucose 30% + lipid 20%	Conventional amino acid mixture + glucose 30% + lipid 20%	Acute	Michel et al. 1985 (122)	70	Multicenter double-blind	5 d	=
BCAA oral 20-g increments + diet 20 g protein	Dietary protein 20-g increments + diet 20 g protein	Chronic	Horst et al. 1984 (109)	26	Multicenter double-blind	30 d	+
BCAA oral 0.3 g/kg + diet 0.5–0.8 g/kg protein	Lactulose + diet 0.5–0.8 g/kg protein	Chronic	Riggio et al. 1984 (123)	90	Single-center	90 d	=
BCAA 0.24 g/kg + usual diet	Casein 0.18 g/kg + usual diet	Chronic	Marchesini et al. 1990 (124)	64	Multicenter double-blind	90 d	+
BCAA oral 0.25 g/kg + diet 1 g/kg protein	Casein 0.25 g/kg + diet 1 g/kg	Latent	Egberts 1985 (125)	22	Single-center crossover	7 d	+

BCAA, branched-chain amino acids; +, some beneficial effect on encephalopathy with treatment; =, no differences between treatment and control.

Nonabsorbable Disaccharides

Lactulose (β-galactosidofructose) was first introduced with the aim of promoting the growth of *Lactobacillus bifidus*, which contains some urease activity, and, through urease, decreasing the production of ammonia in the colon. This is, however, not its mechanism of action, which is still complex and not fully understood. The bulk of evidence links the efficacy of lactulose to an interaction with the enteric flora and to a decrease in the generation of nitrogenous compounds in the intestine (126). Administered orally, lactulose is not broken down by intestinal disaccharidases and reaches the cecum, where it is metabolized by enteric bacteria to lactate and acetate (127), causing a drop in cecal pH. The decrease in pH appears to be necessary for lactulose to be active. Measurement of

stool pH can be used to monitor the dose, but is not practical. As a result of the changes induced in nitrogen metabolism in the colonic flora, lactulose increases fecal nitrogen excretion and decreases the amount of nitrogen that reaches portal blood (128). Subsequently, plasma levels of ammonia (the putative toxin) decrease (129). A similar mechanism of action is shared by other nonabsorbable disaccharides that are metabolized by the colonic flora, such as lactitol (β-galactosidosorbitol).

Lactulose is considered the "gold standard" in the treatment of HE, and drugs introduced for the management of HE are invariably compared with lactulose. However, the effectiveness of lactulose has never been validated by well-designed trials including a large number of patients (108). Few randomized studies have compared lactulose against placebo (Table 20.8). Nevertheless, the clinical experience with lactulose is large, and it is considered that clinical improvements should be expected in 70% of treated patients (130). Comparisons of lactitol to lactulose in randomized trials show a similar efficacy but better palatability for the former compound (131).

Table 20.8. Controlled Trials of Nonabsorbable Disaccharides and Neomycin for Hepatic Encephalopathy in Patients with Cirrhosis

Treatment	Control	Type of hepatic encephalopathy	Trial	*N*	Design	Duration	Effects on encephalopathy
Lactulose	Placebo (glucose)	Acute	Simmons et al. 1970 (132)	21	Parallel	10 d	+

[a]Analysis of the first 20 patients of the study.
+, some beneficial effect on encephalopathy with treatment; =, no differences between treatment and control.

Neomycin

Neomycin is considered an alternative drug to nonabsorbable disaccharides. It may be prescribed for patients who do not tolerate nonabsorbable disaccharides or when it is difficult to monitor their effects, for example, when a patient has diarrhea caused by an associated disorder or drug. Like lactulose, neomycin was introduced

to affect the intestinal flora that generates ammonia (138). However, the mechanism of action of neomycin may be through a nonbacterial effect (145). Neomycin has many effects on the intestinal mucosa and may even result in intestinal malabsorption. Because neomycin is an aminoglycoside, the major concern with its use is the potential for renal or auditory toxicity. Absorption of neomycin is poor (<4%), and the drug is considered potentially toxic only after long-term use. Toxicity may be minimized by tapering the dose after clinical response (i.e., neomycin 3 to 6 g/day during 2 to 3 days followed by 1 to 2 g/day thereafter) and avoiding prolonged use. The effect of long-term therapy is unclear. Periodic assessment of auditory and renal function, special nutritional care, and dose adjustment of additional drugs are recommended.

Clinical studies have demonstrated that neomycin exhibits efficacy similar to lactulose (Table 20.8). In acute episodes of HE, the efficacy of neomycin and lactulose is difficult to evaluate because the correct identification and treatment of the precipitating factor is the most important therapeutic measure. In a double-blind randomized study (137) comparing neomycin to placebo in patients with acute, but mild encephalopathy (approximately 70% stage I to II encephalopathy), neomycin did not significantly shorten the time to regression to a normal mental state. However, the duration of this period was variable, highlighting the difficulties in performing clinical trials in such patients because the course of the precipitant event cannot be fully controlled during randomization.

Flumazenil

The proposal that HE was related to an enhanced GABAergic tone was followed by the introduction of flumazenil, a highly selective antagonist of the central benzodiazepine receptor. Flumazenil is easy to administer and has few secondary effects. An arousal effect has been demonstrated in clinical trials (Table 20.9) and in experimental models (23). However, its clinical benefits are questionable because the drug causes only transient improvements of the mental state and is efficacious only for a subset of patients (146). When there is a response to flumazenil, it occurs within few minutes of administration of the bolus. However, in clinical studies no differences between placebo and flumazenil were seen 24 hours after the start of therapy (147). New antagonists, chemically related to flumazenil but with slightly different pharmacokinetic and pharmacodynamic properties, may be more effective for the management of encephalopathy.

Table 20.9. Controlled Trials of Flumazenil for Acute Hepatic Encephalopathy

	Flumazenil		Placebo		
Trial	***N***	**Responses (%)**	***N***	**Responses (%)**	**Effects on encephalopathy**
Cadranel et al. 1995 (146)	18	55	12	16	+
Pomier-Layrargues et al. 1994 (147)	13	46	15	0	+
Gyr et al. 1996 (148)	14	35	11	0	+
Barbaro et al. 1998 (27)	265	32	262	5	+

+, some beneficial effect on encephalopathy with treatment; =, no differences between treatment and control.

A source of controversy is whether the benefits of flumazenil reflect a potential antidote of the effects of exogenous benzodiazepines. In clinical trials the response to flumazenil was not related to detectable levels of benzodiazepines in plasma. Antagonists of the GABA receptor complex have resulted in amelioration of HE in animal models that were not given pharmaceutical benzodiazepines (23). Possible nonspecific effects of flumazenil must be evaluated in the management of other forms of metabolic encephalopathies.

Other Measures

Several additional treatments have been reported to be beneficial for HE. However, the use of these drugs is not widespread, probably because they do not present major advantages over nonabsorbable disaccharides. These drugs may be classified according to the main site of action (Table 20.10).

Decreasing the production of toxins

Several antibiotics have been used to treat patients with HE. They are aimed at reducing the intestinal flora, thereby decreasing the

source of intestinal toxins. It is intriguing that metronidazole, rifaximin, and vancomycin, antibiotics that affect bacterial populations different from those affected by neomycin, have been reported to improve encephalopathy (149,150,163). An important limitation of antibiotics is the risk for toxicity and the possible selection of multiresistant strains. For these reasons, antibiotics are not usually recommended for prolonged periods. Dose adjustments may be necessary for drugs that undergo hepatic elimination, such as metronidazole (250 mg twice a day).

Modification of intestinal flora with the aim of reducing ammonia production can also be achieved with agents that are not antibiotics, but experience with these agents is scant. Acarbose is a hypoglycemic agent

acting through the inhibition of glucose absorption that results in the promotion of intestinal saccharolytic bacterial flora at the expense of proteolytic flora. A randomized study found that acarbose significantly decreased ammonia blood levels and improved an intellectual score (154). The administration of probiotics (non–urease-producing *Lactobacillus* species) or fiber modifies the intestinal flora. Improvements in response to minimal HE (155) and chronic HE (156) have been observed with this approach, which may be related to a decrease in endotoxemia and secondary to an improvement in liver function.

Table 20.10. Drugs with Possible Beneficial Effects for Hepatic Encephalopathy

Drug	Mechanism of action	Trials	Patients (*N*)	Control	Effect
Metronidazole	Decreasing the production of toxins	Morgan et al. 1982 (149)	36	Neomycin	=
Vancomycin	Decreasing the production of toxins	Tarao et al. 1990 (150)	24	Lactulose	=

Fixation of ammonia

An increase in the capacity of a diseased liver to clear putative toxins is a desirable goal, but is difficult to attain. Activation of the urea cycle has been pursued as a measure to reduce blood ammonia levels. *Ornithine–aspartate* provides substrates both for ureagenesis and synthesis of glutamine, the two hepatic mechanisms that remove ammonia from the portal blood. The drug appears to prevent the increase in blood ammonia levels after a nitrogenous load and has been shown to be better than placebo in a study of episodes of HE in patients with cirrhosis (157). *Zinc*—a cofactor of urea cycle enzymes—is frequently deficient in cirrhosis, as a result of increased urinary excretion and malnutrition. Zinc supplementation (600 mg/day) has been proposed as a measure to reduce blood levels of ammonia and manage HE. The clinical results have been conflicting (159,160). Alternative pathways for nitrogen excretion, such as drugs used in children with urea cycle enzyme deficiencies (e.g., *benzoate* and *phenylbutyrate*), have been examined in cirrhosis. In the liver, benzoate is conjugated with glycine to form hippuric acid and phenylacetate (derived from phenylbutyrate) is conjugated with glutamine to form phenylacetylglutamine. Urinary excretion of these conjugates results in the removal of one and two nitrogen atoms per molecule of drug. Benzoate has been reported to be as efficacious as lactulose for the treatment of acute episodes of encephalopathy (161).

Drugs that act on the central nervous system

Drugs that enhance dopaminergic neurotransmission were introduced to restore the proposed displacement of central neurotransmitters caused by the putative false neurotransmitters. Although the hypothesis was contested in subsequent experimental observations, recent evidence supports the existence of dopaminergic dysfunction that may arise from the accumulation of manganese in the basal ganglia (164). When targeted to improve consciousness, dopaminergic drugs (e.g., levodopa, bromocriptine) did not yield satisfactory results (162). However, they may have a role in the treatment of extrapyramidal manifestations in patients with chronic encephalopathy. In these subjects, improvements of extrapyramidal signs have been reported when bromocriptine is added to conventional

therapy (55). The constipation caused by bromocriptine may be counteracted by an increased dose of nonabsorbable disaccharides.

Management of the Acute Episode of Hepatic Encephalopathy

Diagnosis

The diagnosis of HE is clinical and relies on the development of compatible neurologic manifestations in a patient who has severe liver failure and/or portosystemic shunting. The development of any neurologic abnormality in patients with cirrhosis should raise the possibility of HE. However, there is no diagnostic test that confirms the clinical suspicion. The diagnosis is supported by the presence of a time-related precipitating factor and by a history of similar episodes. However, the neurologic manifestations may vary from the first to subsequent episodes (165).

The neurologic manifestations of HE are not specific and can be present in many other metabolic or structural types of encephalopathy. Patients with alcoholic cirrhosis may have alcohol-induced complications, such as Wernicke-Korsakoff encephalopathy, seizures, alcoholic intoxication, or deprivation. For these reasons, the first step is to exclude alternative diagnoses. Usually, the clinical history, the physical examination, and routine blood tests are enough to exclude other neurologic diseases. Additional tests are indicated according to the clinical situation (Table 20.11). A common pitfall is not to diagnose thiamine deficiency, as emphasized by results of a neuropathologic study of patients with cirrhosis who died in coma (166). The determination of the activity of pyruvate transketolase in blood and the routine administration of thiamine may help in these circumstances. A CT scan is recommended to exclude structural abnormalities in patients with focal neurologic signs, severe encephalopathy, or lack of precipitating factors or in those who do not recover after adequate treatment is initiated. EEG is not helpful for establishing the diagnosis of HE because slowing of the normal rhythm is common in other forms of encephalopathy. Occasionally, the results of the EEG may suggest other diseases, such as status epilepticus or the development of herpetic encephalitis. Examination of the CSF may be helpful in select cases to rule out infectious meningoencephalitis, but lumbar puncture is complicated by concomitant coagulopathy. It is important to emphasize that the clinical course may fluctuate and that frequent observation of the patient is necessary. Assessment of the stage of HE is helpful to follow the evolution.

Table 20.11. Differential Diagnosis of Hepatic Encephalopathy

Alternative diagnosis	Clinical clues
METABOLIC ENCEPHALOPATHIES	
Hypoxia or hypercapnia	Cyanosis, respiratory signs, blood gas
Hypoglycemia	Hepatocarcinoma, diabetic therapy, clinical chemistry
Hyponatremia or hypernatremia	Diuretic therapy, body weight changes, blood chemistry
Azotemia	Diuretic therapy, vomiting, blood chemistry, urinalysis
Diabetic coma	Diabetes, blood chemistry
INTRACRANIAL STRUCTURAL DISORDERS	
Stroke	Focal neurologic signs, neurologic imaging (e.g., CT scan, MRI)
Subarachnoid hemorrhage	Sudden headache, arterial hypertension, lumbar puncture, neurologic imaging (e.g., CT scan, MRI)
Intracranial tumors	Focal neurologic signs, neurologic imaging (e.g., CT scan, MRI)

Subdural hematoma	Alcoholism, cranial trauma, focal neurologic sings, neurologic imaging (CT scan, MRI)
DRUG OR TOXINS	
Alcohol	Drug abuse, urine and blood toxin screen
Hypnotics	Drug abuse, urine and blood toxin screen
MISCELLANEOUS	
Meningitis, encephalitis, cerebral abscess	Fever, meningeal signs, lumbar puncture, neurologic imaging (e.g., CT scan, MRI)
Seizures	Prior history, bitten tongue, urinary incontinence, EEG
Wernicke's encephalopathy	Alcoholism, pyruvate transketolase activity, response to thiamine, compatible MRI signs
Alcohol withdrawal	Prior history, visual hallucinations, history

CT, computed tomography; MRI, magnetic resonance imaging; EEG, electroencephalography.

The diagnosis of HE requires the appreciation that the patient has underlying hepatic dysfunction. Usually, this conclusion can be reached with a clinical history, physical examination, and laboratory testing. However, some patients with normal or nearly normal liver test results may have fully established cirrhosis and/or large portosystemic shunts. The finding of spider nevi or mild thrombocytopenia may indicate the presence of underlying cirrhosis. CT scan or ultrasonography shows prominent venous collateral vessels or an irregular liver. Arterial ammonia levels add nothing in terms of diagnosis of typical cases, but,

occasionally, may be the clue for diagnosing a congenital portosystemic shunt, an acquired urea cycle enzyme defect presenting in adults or significant liver disease. Care to avoid false-positive values requires proper handling of samples and adequate performance of assays.

Supportive Measures

The supportive measures include the general management of a patient with change in mental status. Intravenous catheters are usually necessary to provide fluid and electrolytes. Hydration is important; patients should receive adequate fluid replacement, even if they present with ascites or edema. Replacement of intravenous fluid with albumin infusion appears to be superior to the use of other volume expanders for patients with diuretic-induced encephalopathy (19). In general, diuretics should be avoided, unless pulmonary edema is present. Urinary and nasogastric tubes may be necessary. Special care should be taken to avoid line sepsis. In deep coma, the prevention of aspiration pneumonia may require tracheal intubation and ventilatory support. In immobile patients, pressure sore prevention is necessary.

It is important to provide an adequate nutritional support. The current recommendation is to provide 25 to 35 kcal/kg per day or 0.5 to 1.2 g/kg per day of proteins or amino acids, respectively (110). In most cases during the initial period of decreased arousal (2 to 3 days), the patient is initially treated exclusively with glucose supplements as intravenous fluids. Usually, after this period the patient recovers the ability to tolerate an oral diet. The administration of diet with a normal content of protein has been shown to be safe (111). Therefore, patients should receive standard diets with 60 to 80 g/day of proteins. Patients with prolonged coma (>2 to 3 days) should receive nitrogen supplements as solutions of amino acids—up to 70 g/day—preferably through the enteral route (167).

Table 20.12. Management of Precipitating Factors

Precipitating factor	Diagnostic approach	Management
Gastrointestinal bleeding	Examination of rectal and gastric content Endoscopy	Specific treatment according to site of hemorrhage Bowel cleansing
Constipation	Clinical history	Bowel cleansing
Large protein meal	Clinical history	Bowel cleansing
Psychoactive drugs	Clinical history Drug screen	Antidotes (i.e., flumazenil, naltrexone)
Renal failure	Renal function tests Ultrasonography	Withhold diuretics and nephrotoxic drugs Specific treatment of the cause

Electrolyte imbalance	Blood electrolytes	Withhold diuretics Correct electrolyte disturbances
Infection	Cultures of blood and body fluids Tap of ascites and pleural effusion	If suspicious, broad-spectrum antibiotics (avoid aminoglycosides) Adjust antibiotics to microbiologic studies
Superimposed acute hepatic injury	Clinical history Liver chemistries, ultrasonography Liver biopsy	Specific measures may be helpful according to cause

The table is conceived as a guide for the recognition and management of the most common precipitating factors; it does not include an exhaustive description of the diagnostic and therapeutic procedures.

Elimination of Precipitating Factors

The clinical course of HE can be interrupted in the most patients through control of precipitating factors (Table 20.5). Effective methods exist to control most of these factors. The key is identifying their presence. Multiple precipitating factors may be present and some may be occult and difficult to demonstrate. Systematic exclusion of all the precipitating factors is recommended (Table 20.12) but can be difficult because of the situation of the patient. A practical approach is to initiate several therapeutic measures against putative precipitating factors while additional information and the results of the complementary tests become available.

A common pitfall is to not exclude an ongoing infection. Cultures of blood and body fluids and cell count of ascitic fluid are recommended even in the absence of clear signs of infection. It is wise to assume that a patient with cirrhosis and a major change in mental status is infected until proved otherwise. If a patient does not have a clear precipitating factor, broad-spectrum antibiotics may be initiated until the results of the cultures become available.

Constipation and a large oral protein load are common precipitating factors that may be difficult to recognize. HE may be associated with a slow intestinal transit and, through this mechanism, amplify the generation of encephalopathic substances from the intestine (168). Colonic cleansing reduces the luminal content of ammonia, decreases bacterial counts, lowers blood ammonia, and prevents encephalopathy after a gastrointestinal hemorrhage (169). It is common to include bowel cleansing as part of the initial therapy. Various laxatives can be used, but nonabsorbable disaccharides are preferred because they result in additional effects that enhance the elimination or reduce the formation of nitrogenous compounds. Precipitation of HE by major gastrointestinal hemorrhage is generally recognized easily. However, it is sometimes not evident until intestinal cleansing is commenced. It is important to remember in such cases that treatment includes not only arrest of hemorrhage but also the administration of broad-spectrum antibiotics to prevent superimposed infection.

Administration of Drugs

Lactulose has become the standard drug for the treatment of acute episodes of encephalopathy. We have reviewed the uncertainty of its benefits in this setting (108). Initially, patients should receive a large dose of lactulose or another nonabsorbable disaccharide (142) orally (50 mL of lactulose syrup every 1 to 2 hours) or as an enema (300 mL lactulose in 1 to 3 L of water). After catharsis begins, the oral dose (15 to 30 mL lactulose four times a day) or dose of the enema (i.e., every 8 to 12 hours) should be adjusted. Patients in coma or with small bowel ileus can receive lactulose by enema (135). The administration of lactulose in enema shortens the time to achieve catharsis. However, the major limitation of enema is the difficulty in administering it correctly, especially in semiconscious patients. The patient should be placed in Trendelenburg left lateral decubitus position, then right decubitus, and finally a position in which the upper part of the body is elevated to maximize the exposure of the entire colon. The dose of nonabsorbable disaccharides—orally or through a nasogastric tube—is titrated to produce two to three soft bowel movements daily. If diarrhea develops, the drug should be stopped and reinstituted later at a lower dose. Protracted diarrhea can result in hypertonic dehydration with hypernatremia (170).

Although the use of flumazenil in HE is not well standardized, a therapeutic trial of flumazenil can be attempted. This is justified by the prescription of pharmaceutical benzodiazepines to hospitalized patients with cirrhosis and the impossibility to identify a priori those patients who may respond. Flumazenil seems not to dramatically modify the course of HE because in clinical trials there were no differences with placebo 24 hours after its administration. However, it may be useful to improve consciousness and avoid orotracheal intubation in patients in deep coma. Flumazenil is available as an intravenous preparation that is administered as a bolus (0.4 to 2.0 mg). If a favorable response occurs, additional doses can be given, but the effects of multiple doses of flumazenil have not been evaluated. Dose adjustments may be necessary because elimination half-life (normal individuals approximately 45 minute) may be doubled in patients with cirrhosis. Overdose of flumazenil may have proconvulsant effects.

Management of the Patient with Chronic Hepatic Encephalopathy

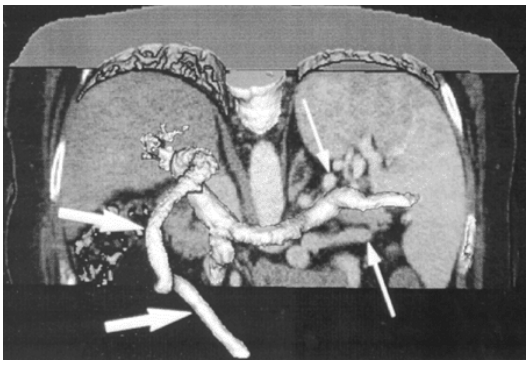
Diagnostic Problems

One of the most difficult diagnostic problems is to differentiate chronic HE from other chronic degenerative diseases of the CNS in patients with chronic liver failure. A fluctuating course with relapsing episodes of encephalopathy is characteristic of chronic relapsing HE. However, patients with chronic persistent HE may show neither a fluctuating course nor superimposed relapsing episodes. The differential diagnosis with neurodegenerative diseases is difficult because most of them are diagnosed on clinical grounds. Although a therapeutic trial may be attempted, the lack of response is not necessarily an argument against HE. MRI of the brain may be helpful in select cases (171). The absence of hyperintensity of the basal ganglia on T_1-weighted imaging and the characteristic pattern of decreased *myo*inositol and increased glutamine/glutamate concentrations in spectroscopy are arguments against the diagnosis of HE.

In the care of patients with chronic relapsing HE, it is important to differentiate those with precipitated and those with spontaneous events. Several covert precipitating factors, such as over-the-counter medications or diuretic overdose, may not have been recognized. In patients with apparent spontaneous encephalopathy and those with chronic persistent HE it is reasonable to presume that they have associated large portosystemic shunts before assuming that HE is the irreversible manifestation of terminal liver disease. In this setting, ultrasonography and abdominal CT scan may be helpful in revealing a large portosystemic shunt that may be amenable to radiologic occlusion (Fig. 20.10).

Among the additional factors that underlie the relapsing episodes of HE, it is important to consider the nutritional state, especially in the care of patients with alcoholism. Trials with zinc administration have not shown impressive results on the course of HE. However, it may be worthwhile to assess plasma

zinc levels and administer zinc supplements to patients with low levels. Colonization of the stomach with *Helicobacter pylori* is frequent in patients with cirrhosis. Because it is a urease-containing organism, it has emerged as a possible source of hyperammonemia and HE. Treatment of *H. pylori* infection may be attempted in chronic cases. However, results of several studies suggest that eradication of *H. pylori* is not associated with improvements in HE or a decrease in plasma levels of ammonia (172).



▪ **Figure 20.10** Three-dimensional reconstruction of the portosplenic venous circulation and a patent umbilical vein combined with a coronal reconstruction of a helical CT scan. The figure shows a small liver, an enlarged spleen and a patent portal vein that is mildly dilated. Large portosystemic shunts are seen at the level of the umbilical vein (*thick arrows*) and perisplenic collateral veins (*thin arrows*). (From Cordoba J, Hinojosa C, Sanpedro F, et al. Usefulness of magnetic resonance spectroscopy for diagnosis of hepatic encephalopathy in a patient with relapsing confusional syndrome. *Dig Dis Sci* 2001;46:2451–2455, with permission.)

Design of a Therapeutic Program

Patients with chronic HE usually exhibit severe malnutrition. Therefore, the routine prescription of protein-restricted diets may worsen the nutritional status (173). Patients are better off with multiple small feedings (five to six per day). Evening snacks are recommended, and the importance of breakfast should be stressed. The amount of protein in the diet should be individually adapted. Progressive increments on the total amount of proteins should be tried. Tolerance to protein may be improved by feeding dairy products and vegetable-based diets. Oral branched-chain amino acids are reserved for the protein-intolerant patient. In one study including 64 patients with cirrhosis with mild forms of chronic encephalopathy (124), treatment with oral branched-chain amino acids was associated with a decreased number of acute exacerbations and nutritional improvement. Treatment was maintained for 3 months and complemented with lactulose and a limited protein intake (45 to 65 g/day). However, other studies—with a smaller sample size and a shorter duration—have not yielded consistent results (114).

Nonabsorbable disaccharides should be prescribed and the patient should be instructed to adjust the dose to obtain two to three bowel movements per day. The oral dose should be frequently augmented during chronic treatment because of individual variability and changes in the bacterial metabolism of disaccharides (127). Care is needed to avoid excessive diarrhea and dehydration-precipitated HE. Some patients complain of an excessively sweet taste, flatulence, or abdominal cramping and find treatment with nonabsorbable disaccharides difficult to follow. Neomycin or other antibiotics may be an alternative for these patients. Tests to monitor toxicity should be periodically performed and periods of more than 6 months under the same antibiotic should be discouraged.

Management of problems associated with chronic liver dysfunction are of special relevance for patients with chronic HE. Ascites is better treated with paracentesis than diuretics. Nevertheless, low-dose diuretics may be prescribed. Plotting the patient's increase in body weight can be helpful. It is important for the patient to understand that some mild degree of water retention is not harmful and it is better to have some degree of edema than to suffer an episode of HE. Among different alternatives to prevent variceal bleeding, pharmacologic or endoscopic treatments are less likely to cause HE as compared to decompressive options (e.g., TIPS, surgical shunting).

The development of HE carries important prognostic implications (174). All patients who have suffered an episode of HE should be considered liver transplantation candidates. In patients with chronic encephalopathy, the decision to proceed to liver transplantation can be difficult. Severe chronic

neuropsychological abnormalities are usually considered a contraindication for liver transplantation. However, improvement of such manifestations have been reported after transplantation (175). Neuropsychological abnormalities are well documented after liver transplantation. The controversy is whether they correspond to sequelae of HE or are the neurologic consequences of perioperative complications (176). The surgical exclusion of the colon was proposed for chronic severe HE (177). However, this measure has been abandoned because of a high surgical mortality.

The Patient with Portosystemic Shunts

A common subset of patients with chronic HE are those with *postshunt encephalopathy*, secondary to a previous surgically created portosystemic shunt or TIPS. Persistent and intractable encephalopathy may be treated by occluding the shunt (80,178). In patients who have undergone a TIPS, a prudent waiting time is warranted. Most episodes of encephalopathy are concentrated during the first 2 months after the procedure and usually respond to treatment with lactulose; subsequent narrowing of the stent—an untoward hemodynamic effect—may afford protection from encephalopathy (179). The prophylactic administration of drugs to prevent the development of encephalopathy after the insertion of TIPS has not been shown to be effective (180). If encephalopathy becomes problematic, the stent diameter can be reduced (80,181). The risks of reintervention and rebleeding after shunt reversal should be weighed against the severity of the neurologic symptoms. Newer, coated stents with a decreased incidence of narrowing may result in more problems with HE in the future.

Occlusion of portosystemic shunts should be also considered in the rare patient with cirrhosis and large spontaneous shunts or in

the exceptional patient with congenital shunts (182). In patients with cirrhosis it is preferred to occlude large shunts with angioradiologic techniques because they have lower operative risk. Several reports suggest that it is a safe and effective treatment in select patients. Treatment of congenital shunts depends on the characteristics of the portal vein and may be performed with surgical or angioradiologic approaches. Closure of the shunts associated with marked hypoplasia of the portal vein can cause portal hypertension and gastrointestinal bleeding. Slow closure of the shunt may be more adequate (183).

Chapter 21
Fulminant Hepatic Failure

Stephen M. Riordan
Jelica Kurtovic
Roger Williams

Key Concepts

- Fulminant hepatic failure (FHF) is defined by the presence of hepatic encephalopathy occurring as the consequence of severe liver damage in patients without previous, clinically overt liver disease.
- Components of the clinical syndrome include cerebral edema, hemodynamic instability, renal failure, coagulopathy, metabolic disturbances, and susceptibility to bacterial and fungal infection.
- The nature of the causative factor or initiating event is an important factor influencing both the rate of progression of the clinical syndrome and its prognosis. Establishing the cause is also important because for certain etiologies specific therapies can be effective.
- Relative prevalences vary according to geographic location, with hepatotoxicity due to acetaminophen and idiosyncratic drug hepatotoxicity being the most common cause in many western countries and single or dual infection with the hepatitis viruses predominating in the East. The cause is not established in 10% to 20% of patients, in whom non–A to E viral hepatitis or an undetected hepatotoxin is presumed to be responsible.
- Supportive management, based on an understanding of underlying pathophysiology, is aimed at maintaining hemodynamic, cerebral, and renal function, reversing metabolic derangements, preventing or treating complicating infection, minimizing stress ulceration of gastric mucosa, and, where appropriate, treating coagulopathy.
- In its most severe form, FHF carries a high mortality rate unless urgent liver transplantation is performed. Lack of fulfillment of current selection criteria cannot be taken to reliably predict spontaneous survival, making it difficult to identify those patients who can confidently be managed by medical means alone.
- The efficacy of temporary liver support based on the use of artificial or bioartificial devices, either as a bridge to emergency transplantation or to allow time for the regeneration of the native liver, upon which spontaneous survival ultimately depends, remains to be proved in controlled clinical trials.

The original description of fulminant hepatic failure (FHF) in 1970 was based on the occurrence of hepatic encephalopathy as a consequence of severe liver injury developing within 8 weeks of the onset of symptoms in patients without preexisting liver disease (1). More recent terminologies taking into account the interval between the onset of jaundice, rather than often nonspecific symptoms at onset, and the development of encephalopathy have alternatively been proposed (Table 21.1) in recognition of the fact that the jaundice-to-encephalopathy time is an important prognostic index (2,3,4). In contrast to the original description,

these other classifications allow for the inclusion of cases with previously asymptomatic

chronic liver conditions, such as fulminant presentations of Wilson disease and underlying chronic hepatitis B. In this chapter, FHF is applied as a generic term encompassing this range of definitions.

Table 21.1. Definitions of Fulminant Hepatic Failure Based on the Time Interval Between the Onset of Jaundice and the Development of Hepatic Encephalopathy, an Important Prognostic Guide

Authors	Classification	Jaundice-to-encephalopathy time
Bernuau et al. Paris (2)	"Fulminant liver failure"	Within 2 wk
	"Subfulminant liver failure"	Between 2 and 12 wk
O'Grady et al. London (3)	"Hyperacute liver failure"	Within 1 wk
	"Acute liver failure"	Between 1 and 4 wk
	"Subacute liver failure"	Between 5 and 12 wk

FHF is a potentially devastating syndrome that may include as components cerebral edema, hemodynamic instability, renal failure, coagulopathy, profound metabolic disturbances, and a particular susceptibility to bacterial and fungal infection. The severity of the clinical syndrome in individual patients depends on the degree of impairment of metabolic and endotoxin-scavenging activity consequent to the loss of functioning liver tissue, together with the systemic effects of various cytokines released by activated nonparenchymal cells, and the extent to which these abnormalities are reversed by liver regeneration, upon which the prospect of spontaneous survival ultimately depends. The nature of the initiating event is an important factor influencing both the histologic pattern of liver injury and the rate of progression of the clinical syndrome. Although advances in supportive medical care have improved survival, FHF, in its most severe form, continues to carry a high mortality rate unless emergency orthotopic liver transplantation (OLT) is performed. Nonetheless, the rapidity with which the clinical syndrome often progresses, along with a worldwide shortage of cadaveric donor organs, is such that many patients die or develop contraindications to the transplantation before a donor liver becomes available, even with priority listing, thereby limiting the number that can be treated in this way. The increasing use of living-donor liver transplantation in recent years is another option that needs to be considered for adults and children with FHF. The risk of serious side effects from long-term pharmacologic immunosuppression means that conventional OLT cannot be considered a panacea in this setting, and there is considerable ongoing interest in the provision of temporary liver support by auxiliary partial liver transplantation, extracorporeal artificial or bioartificial devices, or hepatocyte transplantation, with the ultimate aim of allowing time for or even actively promoting native liver regeneration, thereby decreasing the need for OLT.

This chapter focuses on the range of etiologies of FHF and their influence on both clinical manifestations and prognosis, the spectrum of liver damage along with factors influencing liver regeneration, and the pathophysiology of the resultant clinical syndrome. Management issues are discussed, including specific and supportive medical measures of proved value, indications for OLT, and the current status of evolving strategies for temporary liver support.

Etiology and Related Clinical Implications

The prevalences of the various etiologies of FHF vary according to geographic location. The natural history of FHF is influenced by its cause (5,6,7). In addition to carrying prognostic significance, establishing the cause whenever possible is important so that specific therapies can be instituted, at least in a proportion of cases (Table 21.2). Experience in the United Kingdom, other European countries, and the United States has shown that the rate of progression of the clinical syndrome varies according to the etiology and, somewhat paradoxically, that spontaneous survival with medical management alone is inversely related to the rapidity of onset of encephalopathy (5,6,7). In a nontransplantation

series, survival was 36% when encephalopathy was hyperacute in onset, occurring within 1 week of the development of jaundice, but no more than 14% with longer jaundice-to-encephalopathy times. FHF due to acetaminophen hepatotoxicity is nearly always hyperacute in onset, as are most cases related to infection with hepatitis A virus (HAV) and hepatitis B virus (HBV) and a lower proportion of patients with the other etiologies discussed in the subsequent text (3). Owing to the rapidity of progression of encephalopathy in the hyperacute category, patients may become comatose before clinical jaundice is even apparent. Within the acetaminophen hepatotoxicity group, survival with medical management is inversely correlated with the admission grade of encephalopathy, at least in nonacidotic patients, highlighting the potential benefit of early referral (4,6,8).

Table 21.2. Etiology-Specific Therapies to be Considered in Patients with Fulminant Hepatic Failure

Etiology	Therapy
Acetaminophen	*N*-acetylcysteine
Hepatitis B virus	Lamivudine, famciclovir
Herpes simplex virus	Acyclovir
Cytomegalovirus	Ganciclovir
Autoimmune hepatitis	Trial of corticosteroids, cyclosporine
Pregnancy associated	Urgent delivery
Budd-Chiari syndrome	Decompressive vascular shunt
	Thrombolysis
	Hepatic venous angioplasty
	Stenting of inferior vena cava
	Treatment of any underlying procoagulant state
Veno-occlusive disease	Decompressive vascular shunt
	Thrombolysis

Cardiac failure	Inotropes
Septic shock	Antibiotics, vasopressor agents
Wilson disease	D-penicillamine
Amanita phalloides	Penicillin, silibinin
Lymphoma	Chemotherapy

Acetaminophen

Hepatotoxicity due to acetaminophen accounted for 60% to 70% of cases in a recent series from the United Kingdom (9,10). Acetaminophen has also been reported to be the most common cause of FHF in recent series from Denmark, the United States, and many other western countries (6,11,12), reflecting the fact that acetaminophen remains the most commonly used substance causing self-poisoning in these countries (13,14,15,16). There is no evidence that increasing general awareness of the serious toxicity of acetaminophen leads to any reduced frequency of overdose (17). Indeed, the opposite may pertain. In the United Kingdom, rates of acetaminophen overdose with deliberate intent have increased in both men and women in comparison to the late 1980s, with rates in men showing a relatively larger increase and now approaching those in women (13,14,15,16,18,19). Recent legislative change in packaging and the introduction of measures designed to limit the quantity of acetaminophen that can be purchased without a prescription have had some impact in reducing the number of overdoses and also the number of patients with severe liver damage (20,21). An estimated 100,000 cases of intentional acetaminophen overdose are reported annually in the United States (22). Increasing numbers of overdose cases are also being recorded in Australia and many other parts of the world (23,24,25,26).

Most instances of acetaminophen-induced hepatotoxicity in the United Kingdom and Australia are the consequence of an overdose of the drug taken at a single time point with suicidal or parasuicidal intent (25,26,27,28,29,30,31). Cases of severe hepatotoxicity after ingestion of recommended (or near-recommended) doses of acetaminophen, mostly over several days to weeks, have also been reported, including those in patients with long-term exposure to alcohol or enzyme-inducing drugs, such as antituberculous chemotherapy (e.g., rifampicin and isoniazid) and anticonvulsants (e.g., phenytoin, carbamazepine, and phenobarbital) (12,32,33,34). Considerable emphasis has been placed on this in the United States, with the combination of alcohol and acetaminophen accounting for up to two thirds of all cases of FHF admitted to one center in a recent report (12).

A true effect of long-term alcohol use in predisposing to acetaminophen-related hepatotoxicity at low doses or in exacerbating liver injury in the overdose situation would be of great clinical significance, given the increased incidence of depression among patients with long-term, heavy alcohol intake (35) and the well-documented association between alcohol use and suicidal behavior. Up to 62% of patients hospitalized after a nonfatal suicide or parasuicide attempt in the United Kingdom, including 40% to 75% of men and 12% to 50% of women, have consumed alcohol at the time of the event or in the 6 hours before it (36,37,38,39). An association with recent alcohol use is also apparent in substantial proportions of patients presenting to Australian centers after deliberate acetaminophen overdose (25,26). Alcohol and acetaminophen are also frequently used together in the general community in the absence of suicidal or parasuicidal intent. Ten percent of long-term alcoholics admitted to a detoxification program in the United States were found to have recently consumed acetaminophen for pain relief (40).

Our experience in the United Kingdom, and that of others, is that most instances of FHF related to acetaminophen in alcoholics, as in nonalcoholic patients, are the direct

consequence of having ingested a large overdose of the drug at a single time (25,26,27,28,29,30,31). Most cases of severe hepatotoxicity occurring in association with therapeutic acetaminophen use, rather than suicidal or parasuicidal intent, are also caused by ingestion of large doses, generally over several days (41). A recent prospective analysis of patients presenting to centers in the United States with acetaminophen-related FHF found that the mean dose ingested by those taking acetaminophen for therapeutic purposes (30 g) was significantly higher than that taken by those with suicidal intent (15 g) (42). Large retrospective series to date have provided little evidence that long-term alcohol exposure exacerbates acetaminophen-related hepatotoxicity or worsens outcome when doses markedly in excess of the recommended daily maximum for acetaminophen have been ingested. In the United States, Rumack et al. (43) found no difference in the severity of hepatotoxicity in patients with and without chronic alcohol abuse among a national cohort of 662 consecutive patients presenting with "at risk" blood acetaminophen levels. Neither was a history of long-term alcohol consumption in excess of 80 g daily

associated with a significantly worse prognosis in a series of 247 patients managed at King's College Hospital, London, in 1982 and 1983, most of whom had allegedly ingested 25 to 50 g at a single time (31). A subsequent study of 79 patients presenting to the same unit in 1987 and 1988 with hepatotoxicity related to similarly large doses of acetaminophen (30) examined markers of severity of liver damage and outcome in relation to alcohol intake above or within the guidelines recommended by the Royal College of Physicians, namely 21 units per week for men and 14 units per week for women. Rates of development of cerebral edema and requirement for dialysis or ventilation were not significantly more prevalent in the high–alcohol intake group. The finding of an increased mortality rate in those with an alcohol intake above that recommended by the Royal College of Physicians than in those with more modest alcohol intake (67% vs. 34%, respectively) was not confirmed when these patients were included in a larger series of 553 patients with hepatotoxicity related to acetaminophen overdose who presented between 1987 and 1993 (27). Despite the large sample size, no association could be detected between long-term alcohol consumption and severity of hepatotoxicity, as reflected by rates of requirement for inotropic support or renal dialysis, development of grade III or IV encephalopathy, or fulfillment of transplantation criteria. Similarly, Denison et al. (41) failed to identify an association between long-term alcohol use and severity of liver injury after acetaminophen overdose in a series of 38 consecutive patients in Sweden. On the other hand, Smilkstein and Rumack (44) more recently reported higher serum levels of liver transaminases after paracetamol overdose in patients with a history of long-term alcohol intake than in those without.

The possibility that FHF may occur in long-term alcoholics after ingestion of acetaminophen at recommended or near-recommended daily doses, taken for therapeutic reasons, has been raised mainly in case reports from the United States (12,32,33,34). Zimmerman and Maddrey (45) retrospectively identified from a United States registry a cohort of 27 patients with acetaminophen-related hepatotoxicity after the ingestion of 4 g or less of paracetamol daily, mostly for periods in excess of 1 day and up to 1 week. All were regular users of alcohol, mostly in excess of 60 g daily. Schiodt et al. (46) retrospectively identified 21 patients who had accidentally poisoned themselves while taking acetaminophen for analgesia, generally using recommended or near-recommended doses repeatedly over days to weeks, among a total of 71 patients hospitalized for acetaminophen-related toxicity at an urban county hospital in the United States over a 3-year period to 1995. Patients in the "accidental" category had significantly higher rates of severe liver disease and death than their suicidal counterparts, despite consuming substantially lower amounts of acetaminophen, which the authors postulated was due to a greater proportion of long-term alcohol abusers in the former group (63% vs. 25%, respectively). Delays in recognition of the etiologic connection between acetaminophen use and hepatotoxicity contribute to a poor prognosis.

Cases of "accidental" or "therapeutic dosage" acet aminophen hepatotoxicity have also been reported in the absence of long-term alcohol use, mostly in the context of prior starvation or malnutrition (27,47,48,49). Indeed, in a study of 10 patients, identified over a 5.5-year period at hospitals of the University of Pittsburgh Medical Center, who had developed hepatotoxicity with paracetamol doses less than 10 g daily, Whitcomb and Block (49) found that liver injury correlated more closely with recent fasting than with long-term alcohol use. Most of these patients had ingested acetaminophen for more than 1 week before the onset of

symptomatic hepatotoxicity.

The development of FHF due to acetaminophen may be prevented if the antidote, *N*-acetylcysteine, is given within 15 hours of exposure. Furthermore, the later use of this agent, after signs of liver necrosis have developed, has been shown in one controlled trial to ameliorate associated multiorgan failure and improve survival (50).

Hepatitis Viruses

Any virus that can cause acute hepatitis may potentially give rise to FHF. Such viruses can be broadly categorized as those that primarily affect the liver, such as the hepatitis viruses A to E, and those in which liver involvement may occur as part of disseminated infection, as with Epstein-Barr virus, Cytomegalovirus (CMV), varicella-zoster virus, enteroviruses, parvovirus B19, adenovirus, and herpes simplex virus (HSV). The latter occur mainly, although not exclusively, in the immunosuppressed and in children (10,51). FHF due to HSV may respond to high-dose acyclovir (52), while treatment with ganciclovir is instituted in cases of CMV infection. FHF has also been reported in cases of infection with Toga virus–like particles, papilloma virus, paramyxoviruses, and hemorrhagic fever viruses (10,53). Although decreasing as a cause of FHF in the West, viral hepatitis remains the major etiologic factor in a large part of the world, including Asia, the western Pacific region, the Middle East, Africa, South America, and some European countries.

In general, the frequency with which the different hepatitis viruses cause FHF in a particular geographic location is a reflection of their underlying prevalence. Accounting for less than 10% of cases of FHF in most series, the risk of FHF due to HAV increases markedly in those older than 40 years and in the setting of preexisting chronic liver disease (54). HAV superinfection in

patients with chronic hepatitis C virus (HCV) infection resulting in FHF in one series from Italy was attributed to the HAV in view of a reduced rate of HCV replication observed during acute HAV infection (55). The implication of this finding is that those with chronic HCV infection should be vaccinated against HAV, although its cost-effectiveness is yet to be established (56).

HBV infection is highly endemic in the southeast Asian and western Pacific regions, along with parts of the Mediterranean Littoral, the Middle East, and sub-Saharan Africa (57) and, accordingly, is the major cause of FHF in such areas. Reactivation of HBV, such as after withdrawal of immunosuppressive or cytotoxic chemotherapy for various hematologic and other malignancies (58), is a well-recognized cause of FHF. Reactivation occurring in the context of chronic HBV carriage, unrelated to immunosuppression withdrawal, is more common than de novo HBV infection as a cause of FHF in Taiwan and other countries of the Far East. Antiviral agents, such as lamivudine, is usually given in patients with detectable circulating HBV deoxyribonucleic acid (DNA) levels, although viral replication is characteristically low or absent at the time of clinical presentation with FHF and reports are conflicting as to their value.

In fulminant HBV infection, there appears to be an exaggerated host immune response so that one half to two thirds of cases have lost hepatitis B surface antigen (HBsAg) within a few days of clinical presentation. The diagnosis of acute HBV infection in such cases rests on the presence in serum of immunoglobulin M antibody to hepatitis B core antigen (anti-HBc IgM). However, a recent Japanese study of patients with FHF found that anti-HBc IgM was not measurable in serum in approximately 50% of cases in whom HBV was detected by a sensitive polymerase chain reaction technique (59). Evidence of HBV infection in seronegative individuals with FHF, the so-called occult HBV infection, was first reported in San Francisco, where HBV DNA was detected in serum or liver tissue of 6 out of 17 (35%) such patients (60). HBV DNA was found in the liver, but not serum, in 50% of those for whom both serum and the liver were available for analysis. HBV viral sequences may even be evident in liver tissue when immunohistochemical staining for HBsAg and hepatitis B core antigen (HBcAg) is negative (61). Nonetheless, evidence of "occult" HBV infection was not found in any patient with FHF of otherwise "indeterminant" etiology in a more recent multicenter series of 22 such patients from the United States (62).

An association between FHF and the precore mutant HBV strain, which has a point mutation

at nucleotide 1896 in the precore region that results in a translational stop codon, preventing the secretion of hepatitis e antigen (HBeAg), has been described (63,64). This mutant is highly prevalent in Asia, Africa, and the Middle East (65), especially in relation to HBV genotype D (66,67). Interestingly, recent data from Taiwan suggest that acute superinfection of chronic HBV carriers with HCV suppresses the development of the precore stop mutant, in marked contrast to the progressive increase that occurs during the natural history of chronic HBV infection alone (68). Cases of FHF due to mutant HBV appear to be caused by transmission of the mutant virus rather than by a subsequent mutation of an infecting wild-type strain. The precore mutation has been found in all patients of a series of seven Japanese patients with HBV-related FHF (63) and in all five such patients in a study from Israel (64). Conversely, studies from the United States, France, and India, where the prevalence of the precore mutant is low, have demonstrated that this mutation is not necessary for the development of fulminant hepatitis B (69,70,71). Additional HBV mutations involving nucleotides 1762 and 1764 within the precore promoter region, resulting in increased viral replication but similarly impaired HBeAg synthesis, were subsequently described (72,73). An association between such mutations and FHF has been reported in Japanese patients (74). More recently, Aritomi et al. (65) demonstrated a correlation between mutations in the core promoter and precore regions of the HBV genome and severity of HBV infection in Japan, with at least one such mutation present in all 7 patients with HBV-related FHF compared with 4 of 41 (9.8%) patients with self-limited, acute hepatitis B.

Both coinfection with HBV and hepatitis D virus (HDV) and superinfection of chronic HBV carriers with HDV have been associated with development of FHF (75). Seropositivity for anti-HBc IgM was apparent in only 5 of 28 (18%) cases of FHF in Taiwan in which HBV and HDV were implicated as causes (76), suggesting that most patients had superinfection rather than coinfection with HDV. Investigations among Yucpa Indians in Venezuela were the first to disclose the importance of HDV superinfection in an open community as the cause of large outbreaks of FHF in populations with a high preexisting HBV endemicity (77,78). A similar association has been be recognized for previous epidemics of FHF in Brazil and Colombia (78,79,80). Cases of FHF due to dual HBV and HDV infection are becoming less common in southern Europe, consequent to the decreasing prevalence of HDV in recent years (81). Evidence from India suggests a worse outcome in dual HBV- and HDV-infected patients with FHF compared to those having infection with HBV alone (82). Coinfection with HAV and HBV and superinfection with HAV of chronic HBV carriers leading to FHF have also been reported (61,83).

Hepatitis E virus (HEV), an enterally transmitted ribonucleic acid(RNA) virus of the calicivirus group (84) for which no specific antiviral treatment is available, is the most common cause of epidemic hepatitis and FHF in tropical countries such as India and other

developing countries of southeast Asia, accounting for 50% of cases of FHF in a recent series (85,86,87,88). A particularly high prevalence of infection with HEV, along with a high mortality rate, has been documented in pregnant women, especially during the second and third trimesters (85,87). HEV infection has also occasionally been implicated in a relatively small number of sporadic cases of FHF in the West (89).

There is also a striking geographical difference in the prevalence of FHF due to HCV infection. In Japan and Taiwan, HCV positivity has been found in up to 59% of patients with FHF of presumed viral origin and in whom markers for HAV and HBV were negative (90,91,92). Conversely, infection with HCV alone is an uncommon cause of FHF in the West (61,89,93,94,95) and in India (85,87). An exception is the 60% positivity rate for HCV RNA reported in patients of low socioeconomic status and Hispanic ethnicity in Los Angeles (96). There is also evidence of direct hepatitis C transmission to a chimpanzee using serum obtained from an HCV RNA–positive patient with FHF, who developed recurrent disease after OLT (97). Instances of FHF related to HCV have also been reported in Italian patients with chronic HCV infection after the withdrawal of chemotherapy (98), a situation analogous to that seen with chronic HBV infection, as discussed earlier. As in the latter circumstance, levels of HCV viremia were typically low at the time of the fulminant illness. Risk of FHF is increased in HCV and human immunodeficiency virus–coinfected patients treated with highly active antiretroviral therapy (99).

Feray et al. (95) found in a study in France that 8 of 17 (47%) individuals with HBV-related

FHF also had evidence of HCV infection, with the combination of HCV RNA in the liver or serum (including negative-stranded replicative intermediates) but negative anti-HCV indicating acute, replicative HCV infection. Among the eight HCV RNA– and HBsAg-positive cases, five (63%) were anti-HBc IgM–positive, suggesting coinfection with HBV and HCV, while the remaining three individuals (37%) had no detectable anti-HBc IgM and were probably chronic HBV carriers superinfected with HCV. Superinfection with HCV was also apparent in 9/46 (20%) chronic HBsAg carriers with FHF in Taiwan (92). Up to 43% of patients with FHF in India also show dual infection with HEV and HCV (86,87).

A non–A to E presumed hepatitis virus is thought to currently account for 19% of otherwise indeterminant cases of FHF in the United States (100), 14% to 18% in India (85,87), and 16% in Taiwan (101). In this context, the potential of three recently described viruses to cause non–A to E FHF, namely GB virus-C (GBV-C)/hepatitis G virus (HGV), transfusion transmitted virus (TTV), and the SEN virus, warrants consideration. GBV-C/HGV is a globally distributed RNA virus of the Flaviviridae family that is transmitted predominantly by the parenteral route (102,103). Although GBV-C/HGV was found in up to 50% of patients with FHF in earlier series (104,105), more recent data from both the East and West suggest that it is neither a hepatotropic virus nor responsible for FHF, either by itself or in concert with other known hepatitis viruses (101,106,107). TTV, a widely and highly prevalent DNA virus belonging to the circovirus family (108), was initially discovered by representational difference analysis of serum obtained from Japanese patients with posttransfusion non–A to G hepatitis (109). TTV is transmitted by both parenteral and enteral routes (110,111). Recent studies suggest that TTV plays no causal role in the development of FHF (112,113). SEN-V is a novel DNA virus isolated from the plasma of injecting drug users with human immunodeficiency virus infection and is termed after the initials of the patient from whom it was first isolated (114). Testing of patients with FHF of indeterminant etiology in the United States has not revealed an association with this virus (115).

Bone marrow suppression and aplastic anemia are uncommon but well-recognized complications of FHF due to viral hepatitis, especially in children. Recognized associations are with parvovirus B19 and hepatitis viruses A, B, and C. However, the presumed viral infection remains undiagnosed in most cases (116,117,118,119). Bone marrow failure was reported to occur in 8 out of 75 (10.7%) children with FHF admitted to a single center in a recent retrospective series, with the etiology of FHF being parvovirus B19 infection in 2 and non-A, non-B, and non-C hepatitis in 6 (116). Four children with aplastic anemia were treated with antithymocyte globulin (ATG) or antilymphocyte globulin (ALG). Two of these children recovered fully, whereas one developed myelodysplasia and the other, with unresponsive disease, died of septic complications. Of the four patients who did not receive ATG or ALG, three underwent liver transplantation. All four resumed satisfactory granulopoiesis after a median time of 99 days (range 20 to 153 days).

Other Causes

Documentation of cases of FHF due to ingestion of food contaminated with the *Bacillus cereus* emetic toxin, which inhibits hepatic mitochondrial fatty-acid oxidation, raises the possibility that other hitherto poorly categorized mitochondrial toxins may be responsible for many cases currently considered cryptogenic or indeterminant in etiology (6,9,10,11,120,121). Nonacetaminophen drug reactions, mostly idiosyncratic, account for approximately 10% to 15% of cases of FHF in western countries (10). "Ecstasy" (3,4-methylene-dioxymethamphetamine) and other illicit drugs are increasingly recognized causes in our experience (122).

Instances of severe liver damage with the use of antiretroviral agents in patients with human immunodeficiency virus infection are also recognized, either as a direct drug effect or in relation to immune reconstitution in the setting of associated chronic hepatitis B or C viral infections (123,124). Hepatotoxicity due to Chinese herbs is also increasingly seen in western patients.

Other uncommon etiologies of FHF include autoimmune hepatitis, pregnancy-related disorders such as acute fatty liver and the hemolysis elevated liver enzymes and low platelet count (HELLP) syndrome, *Amanita phalloides* poisoning, veno-occlusive disease, acute Budd-Chiari syndrome, hepatic ischemia related to heart failure or septic shock, heatstroke, and Wilson

disease. Specific therapies and interventions to be considered in these disorders include a therapeutic trial of corticosteroid or cyclosporine in autoimmune hepatitis, urgent delivery of the fetus in pregnancy-related etiologies, the use of penicillin and silibinin as antidotes in *Amanita* poisoning, and decompressive vascular shunting (surgical or radiologically achieved) in select patients with veno-occlusive disease and acute Budd-Chiari syndrome. Investigation for an underlying procoagulant disorder is mandatory in this latter disorder. Interventional radiology including not only placement of a transjugular intrahepatic portosystemic shunt (TIPS) but also hepatic venous angioplasty and stenting of the inferior vena cava may have a role in patients with hepatic venous outflow block, depending on the exact clinical context. Treatment of precipitating cardiac dysfunction is necessary in ischemic FHF due to left ventricular failure, along with appropriate antibiotics and vasopressor agents in septic shock. Circulatory collapse with resultant ischemic liver injury also contributes to the pathogenesis of FHF associated with heatstroke.

Recognition of the rare fulminant presentation of Wilson disease, suggested clinically by the presence of hemolysis, splenomegaly, and Kayser-Fleischer rings, is crucial because mortality in those with severe encephalopathy is virtually 100% without urgent OLT. By contrast, survival without transplantation can be achieved with early D-penicillamine treatment in most patients with nonencephalopathic Wilson disease who present acutely with other manifestations of severe hepatic insufficiency, highlighting the importance of early recognition of this disorder (125). Lymphomatous infiltration of the liver is another rare but potentially treatable cause of FHF. Making a specific diagnosis is also important in view of the potential for recurrence of the lymphoma post-OLT (126). Many of the etiologies for which specific therapies may be applied can be established only by liver biopsy, using a transjugular approach in cases with uncontrollable coagulopathy or more than minimal ascites.

Spectrum of Liver Damage

Severe damage to the liver generally has already occurred by the time of presentation (Table 21.3). Histologic examination at this time typically demonstrates confluent necrosis with cell dropout and parenchymal collapse in either a zonal or a nonzonal distribution, especially in cases related to acetaminophen, other drugs and toxins, viruses, and ischemia (127). A considerable number of activated sinusoidal-lining cells, including Kupffer cells, stellate cells, and endothelial cells, may be seen, particularly when cell dropout has commenced in the perivenular region. Increasing evidence suggests that hepatocyte necrosis in FHF results both as a direct consequence of the initiating drug, toxin, viral, or other causes and from the subsequent activation of these various nonparenchymal cells with the release of cytokines (128,129,130). Marked cholestasis, limited to areas of surviving parenchyma, may occur and is not necessarily a poor prognostic sign. Features of venous outflow block, namely sinusoidal dilatation and congestion, are additionally found in cases of FHF due to Budd-Chiari syndrome. Most patients presenting with FHF due to Wilson disease are already cirrhotic (131), although also displaying superimposed parenchymal necrosis and/or collapse, steatosis, moderate portoseptal and parenchymal inflammation, and typically florid ductular proliferation with cholestasis. The presence of orcein-positive granules in a patchy distribution within hepatocytes and macrophages is a distinctive feature. Evidence of CD95-mediated apoptosis has also been reported (132).

Less commonly, microvesicular steatosis in the absence of substantial hepatocyte necrosis or parenchymal loss dominates the histologic picture in FHF, as in cases due to acute fatty liver of pregnancy and with hepatotoxicity related to various mitochondrial toxins, valproic acid, and the tetracyclines. Malignant infiltration of the liver, most often with lymphomatous, leukemic, or metastatic carcinomatous deposits, represents yet

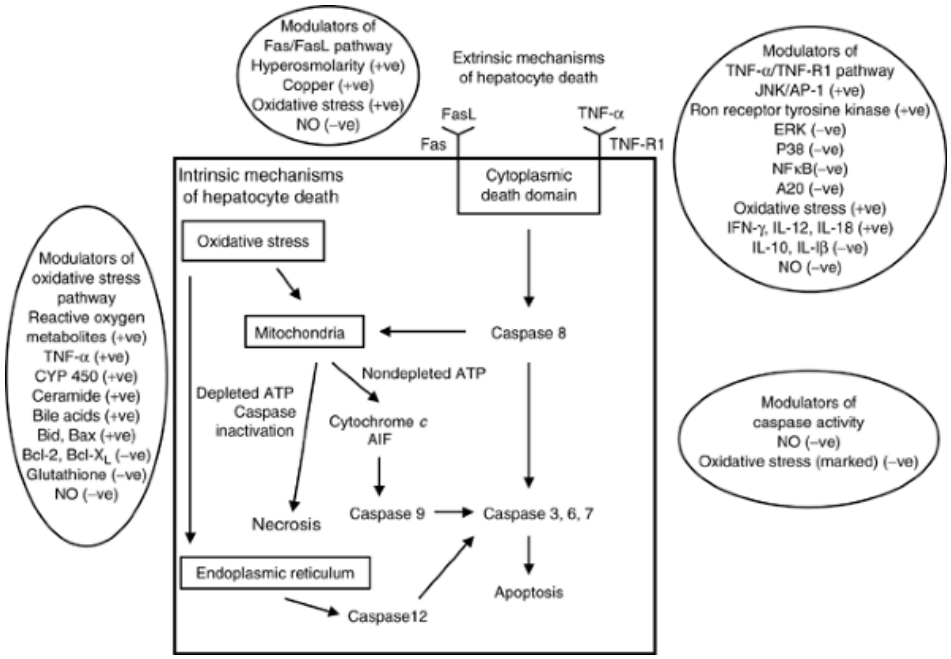
another pathologic process occasionally evident in case of FHF.

Table 21.3. Spectrum of Liver Damage Related to the Etiology of Fulminant Hepatic Failure

Pathology	Etiology
Confluent necrosis (+ activation of nonparenchymal cells)	Drugs (e.g., acetaminophen) Toxins
	Viruses
	Ischemia
Microvesicular steatosis	Acute fatty liver of pregnancy
	Mitochondrial toxins
	Drugs (e.g., valproic acid, tetracyclines)
Malignant infiltration	Lymphoma
	Leukemia
	Metastases

Molecular Mechanisms of Hepatocyte Injury in Fulminant Hepatic Failure

A critical degree of liver cell death, not adequately compensated for by sufficient regeneration of hepatocytes expressing differentiated hepatic functions, is fundamental to the development of FHF. Two pathways of liver cell death exist, namely apoptosis and necrosis. Apoptosis is manifest by nuclear and cytoplasmic shrinkage, without disturbance of cell membrane integrity or liberation of intracellular content. Consequently, secondary inflammation is not a feature. The other pathway of cell death, necrosis, involves depletion of adenosine triphosphate (ATP), with resultant cell swelling and lysis leading to release of cellular content and secondary inflammation (133). At a molecular level, apoptosis occurs as a result of the sequential activation of a series of cysteine proteases, known as caspases. Apoptosis can be triggered by extrinsic or intrinsic mechanisms, the former involving activation of death receptors located on cell membranes and the latter oxidative stress of mitochondria and endoplasmic reticulum (133, 134, 135, 136, 137). The specific caspases involved vary according to the type of proapoptotic stimulus. For example, caspase 8 mediates proapoptotic signal transduction downstream of activated cell surface death receptors, whereas caspase 9 mediates signals that follow oxidative mitochondrial damage. These latter signals augment cell death initiated by activation of death receptors, illustrating important interactions between extrinsic and intrinsic pathways of cell death (133) (Fig. 21.1).



▪ **Figure 21.1** Extrinsic and intrinsic pathways of hepatocellular apoptosis, illustrating interactions of relevance to the development of fulminant hepatic failure. In particular, oxidative stress of mitochondria and endoplasmic reticulum may amplify the apoptotic signals originating from the binding of tumor necrosis factor-α (TNF-α) or Fas ligand (FasL) to their respective "death receptors." TNF-R1, tumor necrosis factor receptor 1; NO, nitric oxide; ATP, adenosine triphosphate; AIF, apoptosis-inducing factor; ERK, extracellular signal-regulated kinase; P38, P38 mitogen activated protein kinase; NFκB, nuclear factor κB; A20, a TNF-inducible protein; IR, ischaemia-reperfusion; IFN-γ, interferon-γ; IL, interleukin; JNK, c-Jun *N*-terminal kinase; AP-1, activating protein-1; Bcl2, Bcl-X_L: members of the Bcl protein family; CYP450, the microsomal cytochrome P450 enzyme system. (Reproduced from Riordan SM, Williams R. Mechanisms of hepatocyte injury, multiorgan failure and prognostic criteria in acute liver failure. *Semin Liver Dis* 2003;23:203–215, with permission.)

A number of causes of FHF have been shown, predominantly in experimental animal models, to induce predominantly one or the other form of liver cell death, such as necrosis in the case of severe

acetaminophen overdose and apoptosis in the case of ischaemia—reperfusion injury and, as alluded to earlier, fulminant Wilson disease (133, 138, 139, 140, 141). Nonetheless, an insult capable of inducing apoptosis may cause cell death by necrosis, particularly if the degree of mitochondrial damage is sufficient to exhaust ATP stores. Processes leading to marked oxidative stress typically cause cell death by necrosis rather than apoptosis, as a consequence of not only the severity of mitochondrial damage but also inhibition of the proapoptotic caspase cascade (133, 142, 143, 144) (Fig. 21.1). Cellular content of the antioxidant, glutathione, and nitric oxide (NO), along with osmolarity and an increasingly recognized number of tyrosine kinases, adapter molecules, transcription factors, cytokines, and chemokines act as important factors that modulate pathways of liver cell death (145). In the clinical setting, intrahepatic expression of interferon-γ (IFN-γ), interleukin-2 (IL-12), and IL-10 has recently been assessed in the explants of 11 patients undergoing transplantation for fulminant hepatitis B (146). A marked induction of the proinflammatory mediators IFN-γ and IL-12 was apparent at both the protein and messenger RNA (mRNA) levels and not counterbalanced by the anti-inflammatory IL-10. A similar pattern was found in five patients with FHF due to other etiologies, including autoimmune hepatitis, ecstasy-related hepatotoxicity, and cryptogenic, implying that imbalance between pro- and anti-inflammatory

cytokine mediators may contribute to the pathogenesis of FHF due to a range of etiologies. Increased circulating levels of IL-6 and IL-8 (147) along with tumor necrosis factor-α (TNF-α), soluble TNF-R1, and IL-10 (148) have also been reported.

Mechanisms Impacting Hepatocellular Regeneration

A variable degree of liver regeneration is evident histologically in most cases of FHF, with the extent of regenerative activity typically more pronounced in hyperacute than subacute categories. Factors responsible for the adequacy, or otherwise, of regeneration in the setting of such severe liver cell loss remain incompletely understood. Nonetheless, increasing evidence points to key roles for a number of cytokines, including TNF-α and IL-6, and growth factors, especially hepatocyte growth factor (HGF). Increased circulating levels of TNF-α and IL-6 have each been described (147,148). These cytokines are key initiators of liver regeneration after partial hepatectomy, although TNF-α–related cell death rather than regeneration predominates in the presence of oxidative stress (149), as discussed in the preceding text. The importance of the IL-6 system in hepatocellular regeneration in FHF has been suggested in a murine model of d-galactosamine—induced liver injury, in which gene therapy with hyper-IL-6, a chimeric protein formed by the fusion of human IL-6 and a truncated form of its soluble receptor that acts as a superagonist, was associated with markedly increased regenerative activity and improved survival (150,151).

Plasma levels of stimulatory HGF and inhibitory transforming growth factor-β (TGF-β) are also elevated in FHF, presumably because of their release from the damaged extracellular matrix (152,153). Increased activity of the fibrinolytic system, responsible for activation of both HGF and TGF-β (154,155), is also evident (156). Nonetheless, toxins that impair HGF-induced DNA synthesis by hepatocytes have been described in plasma of FHF patients (157). Studies of liver tissue from experimental animals and patients with FHF have shown reduced hepatic expression of c-MET, the receptor for HGF (158), raising the possibility that HGF-mediated intracellular signaling may be impaired. Despite this, increased regeneration has been observed in rats with carbon tetrachloride—related FHF treated with exogenous human recombinant HGF (159). Regeneration was also augmented following treatment with anti-TGF-β antibody in such a model (160). The antimicrobial agent, ciprofloxacin, also significantly enhanced hepatic regenerative activity in a rat model of FHF, most likely by blocking hepatocyte membrane receptors for inhibitory γ-aminobutyric acid (161,162).

Impaired regeneration after partial hepatectomy, along with increased susceptibility to acetaminophen-related hepatotoxicity, has recently been documented in peroxisome proliferator—activated receptor-α null mice, possibly as a consequence of altered expression of the genes responsible for cell cycle control, cytokine signaling, and fat metabolism (163,164). The latter may be particularly important because replicating hepatocytes require β-oxidation of fatty acids in the mitochondria for energy (165). Supplementation with free fatty acids and carnitine, the carrier responsible for the transport of fatty acids into mitochondria, augments the rate of regeneration after partial hepatectomy in the rat (166). The role of such supplementation in the FHF setting, in which mitochondria may be profoundly damaged and unable to oxidize fatty acid supplements, has not been assessed but is of potential importance because rapid depletion of fat stores is often seen in this condition, as discussed in the preceding text.

Studies performed in experimental animals after partial hepatectomy demonstrate that hepatic regeneration is also a phosphate-consuming process. Several processes contribute to this, including protein phosphorylation (167), a rapid turnover of intracellular high-energy phosphate (168), and requirement for increased synthesis of phospholipids (169). A substantial fall in serum phosphate values is often seen clinically in patients after partial hepatectomy, presumably

as a result of substrate utilization due to a high degree of regenerative activity (170). Hypophosphatemia is also seen in a substantial proportion of patients with FHF and correlates with a favorable outcome. Conversely, hyperphosphatemia, possibly reflecting impaired hepatocellular regenerative activity, has been identified as a poor prognostic marker (171).

In addition to strategies that enhance liver regeneration to improve outcome in FHF, recent data suggest that strategies to augment the function of surviving hepatocytes may also be of

value. In particular, treatment with lovastatin, a drug that inhibits the p21-Ras—mediated signaling pathway (172), shown in rat hepatocytes to downregulate several liver-specific functions (173), has been reported to improve ammonia metabolism, glucose production, and clotting factor synthesis and substantially reduce the mortality rate in rats subjected to 90% partial hepatectomy (174). Such beneficial effects preceded the initiation of hepatic regeneration, implying that they resulted from an improvement in the functional status of surviving hepatocytes. Notably, the dose of lovastatin used was in the order of 13-fold higher than that recommended in humans for the treatment of hypercholesterolemia, and any impact of such intervention in the clinical setting remains to be evaluated.

Pathophysiology of the Resultant Clinical Syndrome

Hemodynamic Changes

Hemodynamic studies have shown that FHF is characterized by marked splanchnic and systemic arteriolar vasodilatation along with a hyperdynamic circulation and low arteriovenous oxygen content difference. Recent clinical data suggest that elevated levels of IL-6 and IL-8 may contribute to this splanchnic and systemic vasodilatation and the systemic hypotension commonly evident in this syndrome (147). Adrenal insufficiency may contribute to the propensity for systemic hypotension (175), as has been demonstrated in patients with severe sepsis. Studies using the Fick method to determine oxygen transport parameters have suggested that, as in patients with severe sepsis, the ability to extract oxygen at the cellular level is impaired in those with FHF. Consequently, tissue oxygen consumption becomes dependent on oxygen delivery over a wider range of delivery rates than in health (pathologic oxygen supply dependency) (176). The pathogenesis of the microcirculatory disorder leading to impaired tissue oxygen extraction is poorly understood, but production of vasoactive cytokines and endothelial damage caused by generation of oxygen-free radicals may be important. Microcirculatory plugging due to formation of microthrombi as a consequence of activation and consumption of platelets, together with increased adhesion of leukocytes to endothelium, may also be contributory, with blood being shunted through non-nutritive arteriovenous channels (176). Increased activity of the vasodilatory NO–cyclic 3′, 5′-guanosine monophosphate (cGMP) pathway is also evident in FHF (177). However, plasma levels of cGMP were found to have no significant correlation with any hemodynamic or oxygen transport parameter, such that the possible role of this system in the pathogenesis of tissue hypoxia is unclear. Relative hypovolemia secondary to reduced vascular resistance would exacerbate any microcirculatory disturbance unless corrected.

The validity of the concept that tissue oxygen extraction is globally impaired in FHF has recently been called into question by the results of a study in which oxygen consumption was simultaneously calculated by the Fick method and indirect calorimetry (178). Only a poor agreement between the two methods was apparent, with the former consistently underestimating oxygen extraction in comparison to the gas exchange technique. The reproducibility of Fick-derived calculations was less than that of those measured from indirect calorimetry, indicating that in patients with a high cardiac output and small arteriovenous oxygen content difference the dispersion of data attributable to measurement error was greater with the Fick method. Indeed, delivery-dependent global tissue oxygen extraction was reported in less than one third of patients with FHF, reaching the level denoting pathologic oxygen supply dependency in none, when indirect calorimetry is used to derive such data (179).

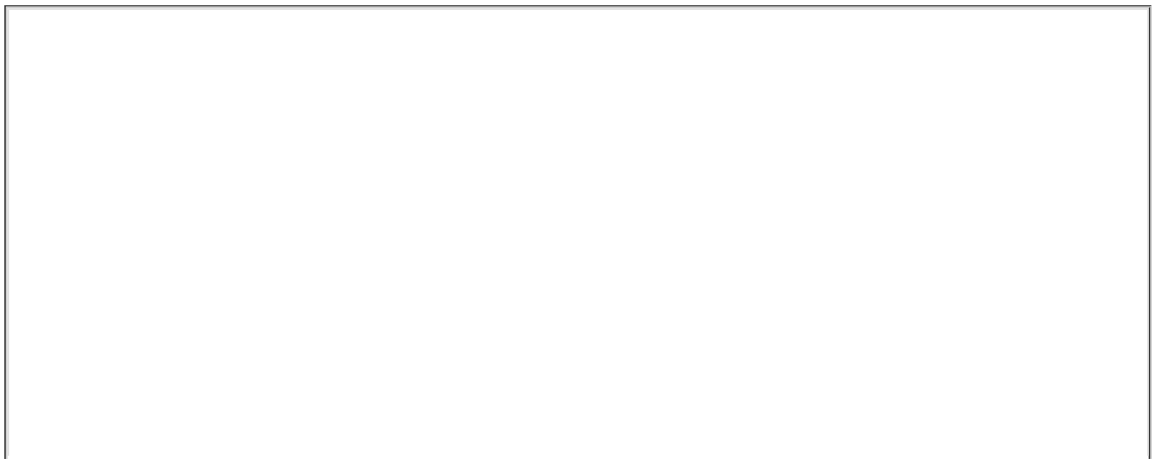
Hepatic Encephalopathy and Cerebral Edema

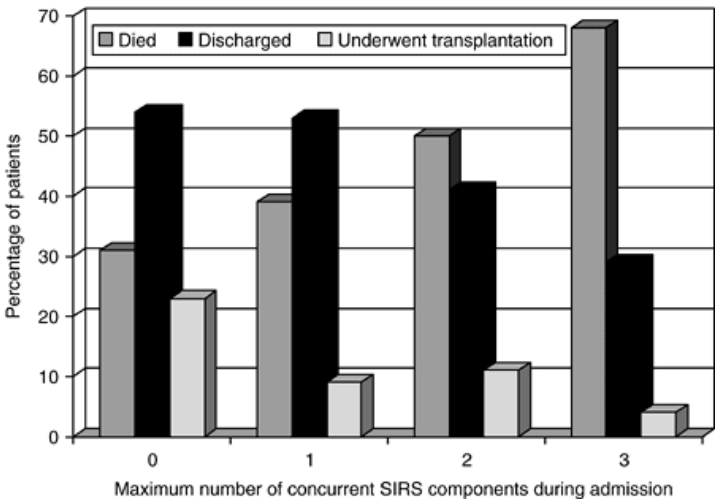
The pathophysiologic mechanisms responsible for encephalopathy in FHF, which is so characteristically rapid in onset and progression, have not been fully elucidated. Accumulation of unmetabolized ammonia; disturbance of central glutamatergic, serotoninergic, and noradrenergic pathways; production of false neurotransmitters; activation of central γ-aminobutyric acid/benzodiazepine receptors; and altered cerebral energy metabolism may be important (180,181,182,183,184,185,186,187). Autoregulation of cerebral blood flow (CBF), through which cerebral perfusion is maintained as a result of reactive dilatation or constriction of cerebral resistance vessels in response to changes in systemic arterial pressure, is impaired or absent in patients with FHF and advanced

encephalopathy grade (188).

The prevalence of severe encephalopathy has fallen in recent years, possibly as a consequence of the recognition that, in those requiring renal support,

continuous hemodiafiltration is preferable to intermittent dialysis, as discussed in the subsequent text. Better control of infection, as discussed later, is probably also an important contributory factor (189). Subclinical epileptiform activity, detectable by continuous electroencephalographic monitoring, is common in patients with FHF and grade III or IV encephalopathy in our experience and this would exacerbate any imbalance between cerebral oxygen demand and supply and precipitate or exacerbate cerebral edema (190). CBF is often increased in FHF, especially at the stage when cerebral edema develops (191). It has been postulated that ammonia is central to the development of cerebral edema in patients with FHF (192), and recent data support an association between arterial ammonia levels and cerebral herniation in this group (193). Ammonia is detoxified in astrocytes to glutamine, the accumulation of which may lead to increased intracellular osmolarity and, in turn, cerebral edema (194,195). Studies performed in the setting of induced hyperammonemia in patients with cirrhosis suggest that the neuropsychiatric effects of ammonia are blunted by the compensatory ability of astrocytes to lose osmolytes such as *myoinositol*, thereby countering the osmotic effects of raised intracellular glutamine levels and reducing the potential for cell swelling (196). This compensatory mechanism may also be important in limiting cerebral edema in patients with FHF. Certainly, increased brain glutamine concentrations have been detected by proton magnetic resonance spectroscopy in this group (197). The local generation of glutamine and glutamate from ammonia, leading to increased neuronal-derived NO levels, has additionally been postulated to be a critical step for the developmente of cerebral edema through the promotion of cerebral hyperemia (198). Nonetheless, the pathogenesis of cerebral hyperemia in FHF remains uncertain, with the recent finding in a rodent model that NO synthase inhibition fails to prevent a rise in CBF associated with hyperammonemia, implying that NO is not the mediator of cerebral hyperemia in this setting (199). Oxidative stress may be important, given preliminary evidence suggesting that zinc protoporphyrin, an inhibitor of oxidative stress—induced activation of heme oxygenase, can prevent increases in CBF and cerebral edema in an experimental hyperammonemic model (200). Exposure to ammonia has been shown to contribute to the propensity for oxidative stress in isolated hepatocytes as a consequence of the production of reactive oxygen species (201), possibly as a result of glutamine-related induction of the mitochondrial permeability transition (202). Accumulation of lactate has also been implicated in the pathogenesis of cerebral edema in FHF (203). Ammonia-induced inhibition of α-ketoglutarate dehydrogenase, resulting in decreased entry of pyruvate into the tricarboxylic acid cycle, likely contributes to the increased lactate production in FHF. The recent finding of a normal hepatic venous pyruvate to lactate ratio suggests that accelerated glycolysis, but not tissue hypoxia, also contributes to the elevated lactate levels (204,205). Increased glycolysis is a known consequence of the systemic inflammatory response syndrome (SIRS) and may be an important mechanism underlying the observation of a significant association between the severity of the SIRS and grade of hepatic encephalopathy in FHF (189). Increased CBF mediated by proinflammatory cytokines such as TNF-α, important mediators of the SIRS, may also be contributory (206).





▪ **Figure 21.2** Outcomes for 887 patients with fulminant hepatic failure and maximum number of concurrent systemic inflammatory response syndrome (SIRS) components during admission. (Reproduced from Rolando N, Wade J, Davalos M, et al. The systemic inflammatory response syndrome in acute liver failure. *Hepatology* 2000;32:734–739, with permission.)

Renal Impairment

Renal failure occurs in approximately 70% of patients with FHF due to acetaminophen and 30% of those with other etiologies (5). Relative hypovolemia due to vasodilatation, microcirculatory disturbance, and acute tubular necrosis related to complicating sepsis are important contributing factors. Direct nephrotoxicity may also play a role in those with FHF related to acetaminophen, especially when the degree of renal impairment is disproportionately severe. The use of nephrotoxic antibiotics may also be a contributory factor.

Susceptibility to Bacterial and Fungal Infection

Patients with FHF are susceptible to infection as a consequence of impaired neutrophil and Kupffer cell phagocytic function, reduced hepatic production of complement, and the requirement for invasive procedures (207). Increased bacterial translocation of gut flora may also be important (208). Culture-proved bacterial infection, most often pneumonia, septicemia, and urinary tract sepsis, occurs in up to 80% of patients (209). The infecting organisms are gram-positive in over 50% of cases. Fungal infection, predominantly with *Candida species*, occurs in over 30%, particularly in the later stages of the clinical syndrome and almost always in association with concurrent bacterial sepsis. Approximately one third of patients with sepsis remain afebrile with a normal white cell count, highlighting the need for close vigilance and a high index of suspicion.

An analysis of 887 patients with FHF admitted to a single center over an 11-year period found significant associations between infection, severity of SIRS (temperature >38°C or <36°C, heart rate >90 beats/minute, tachypnea >20 breaths/minute or Paco2 <4.3 kPa, white cell count >12 × 109/L or <4 × 109/L, or the presence of >10% immature neutrophils), and progressive encephalopathy, reducing the chance of OLT and conferring a poor prognosis (189) (Fig. 21.2). Sepsis is a major cause of the SIRS in FHF, and sepsis-related oxidative stress (210) has been shown in rodents to both promote hepatocellular necrosis and inhibit liver cell regeneration (211), upon which spontaneous recovery ultimately depends.

Nutritional Disturbance

Energy requirements in FHF are increased by up to 60% and are further elevated by complicating infection. Mean energy expenditure has been estimated to be 4.05 kJ/kg per hour. Despite the reduction in functioning liver mass, the metabolic rate is substantially increased (212), in keeping with the marked SIRS that typically accompanies this syndrome. Harris-Benedict predictions are unreliable for estimating energy expenditure in the FHF setting (212). Rapid deterioration in nutritional status, with depletion of muscle and fat stores, is often seen. Impairment of glycogen storage and reduced capacity for gluconeogenesis result in increased breakdown of adipose tissue and muscle consequent to the use of fat and protein as alternative fuel sources (213). However, the predominant factor responsible for the exaggerated whole body protein degradation is likely reduced hepatic synthesis of insulin-like growth factor-1 (214). Hypoglycemia occurs early in the course of FHF; hypophosphatemia, hypokalemia, and hypomagnesemia are also common, especially in patients who maintain an adequate urine output. As is well described in chronic liver disease, impaired peripheral uptake of glucose consequent to insulin resistance has been documented early in the course of FHF, with insulin sensitivity typically being restored by 2 weeks in patients who survive (215).

Coagulopathy and Bleeding Diathesis

Several mechanisms contribute to the coagulopathy associated with FHF, including reduced hepatic synthesis of clotting and anticlotting factors together with consumption of clotting factors and platelets due to disseminated intravascular coagulation (DIC) (216). Although evidence of the latter may be obtained from moderately raised levels of fibrinogen degradation products in a substantial proportion of patients, as has been well demonstrated in experimental animal models, DIC is usually not severe except in acute fatty liver and other pregnancy-related etiologies. The platelet count generally falls progressively day-by-day and is a good marker of disease stage and prognosis. In addition to thrombocytopenia, qualitative platelet defects including increased adhesiveness and impaired aggregation have been described. The degree of prolongation of the prothrombin time is closely related to the severity of liver damage, whereas factor V has the shortest half-life and is, theoretically, the most sensitive index of impaired clotting factor synthesis. Deficiencies of anticlotting factors, such as protein C and antithrombin III, may result in thrombosis of dialysis circuits, despite other manifestations of a bleeding diathesis.

Supportive Management

Management in a specialized liver intensive care unit is mandatory for all patients with FHF and more than grade I hepatic encephalopathy. Supportive medical interventions, based on an understanding of underlying pathophysiology, are aimed at maintaining

hemodynamic, cerebral, and renal function; reversing metabolic derangements; preventing or treating complicating bacterial and/or fungal infection; preventing stress ulceration of gastric mucosa; and, where appropriate, treating coagulopathy.

Hemodynamic

Interventions to achieve or maintain hemodynamic stability are aimed at optimizing tissue oxygen delivery and consumption parameters. Substantial volumes of colloid, as well as crystalloid, may be required to attain an adequate cardiovascular filling pressure (i.e., pulmonary capillary wedge pressure 8 to 14 mm Hg), given the often profound vasodilatation. In studies performed at King's College Hospital using the Fick method and reported in 1991, *N-acetylcysteine infusion* was shown to facilitate improved hemodynamic stability in association with mean 46% and 29% increases in global tissue oxygen consumption after 30 minutes of its administration in patients with acetaminophen and other etiologies of FHF, respectively; prostacyclin infusion also improved oxygen delivery and consumption, whereas combined infusions led to a significant increase in oxygen delivery but not consumption compared to infusion of N-acetylcysteine alone (217). A more variable systemic hemodynamic response to N-acetylcysteine was subsequently reported, with clear separation of responders and nonresponders. Overall, a small (6%) early improvement in tissue oxygen consumption that was not sustained throughout a 5-hour period of monitoring was recorded (179). Results of a multicenter study currently under way in the United States are awaited with interest.

Vasopressor agents are indicated if the mean arterial pressure (MAP) is <60 mm Hg despite adequate intravascular volume. Most experience is with the use of epinephrine and norepinephrine. Oxygen consumption may fall with the use of these agents despite the increased arterial pressure, as a result of reduction in oxygen delivery and extraction rates. The latter may be prevented by concurrent use of prostacyclin (218). Recent data supporting the use of vasopressin in severe vasodilatory shock syndromes (219,220), in which baroreflex-mediated secretion of this agent becomes impaired (221), raise the possibility that vasopressin infusion may also be of value as an alternative to epinephrine or norepinephrine for patients with marked vasodilatation and refractory hypotension. The vasopressin prodrug, terlipressin, is less likely to cause myocardial ischemia than vasopressin but should be used with caution in those with grade IV hepatic encephalopathy and raised intracranial pressure (ICP) in view of recent evidence that it may exacerbate cerebral hyperemia and intracranial hypertension (222).

Hepatic Encephalopathy and Cerebral Edema

Neurologic support is aimed at optimizing CBF, cerebral perfusion pressure (CPP) and oxygen consumption, along with preventing or treating cerebral edema. Patients should be nursed in the 20- to 30-degrees head-up position. Elective mechanical ventilation, with sedation and paralysis using agents such as propofol and atracurium, along with minimization of endotracheal suctioning, patient turning, and other tactile stimulation, prevents surges in ICP, which may provoke or exacerbate cerebral edema. Treatment with N-acetylcysteine has been reported in one study to increase CBF and cerebral oxygen consumption, with a fall in anaerobic metabolism; infusion of prostacyclin also improves CBF (223). Extradural pressure monitoring, with sufficient clotting factor support to achieve an international normalized ratio of 2 or less and platelet transfusions to achieve a count of 50 × 109/L or more at the time of insertion of the transducer, is of value in guiding further therapy in ventilated patients with grade III or IV encephalopathy. It is particularly valuable during OLT because the increase in CBF that occurs with reperfusion may be deleterious, especially in those with defective autoregulation (224). Such monitoring does carry some risk of hemorrhage at the time of insertion of the transducer or later, and the transducer should be removed no longer than 5 days after insertion in view of the risk of infection. A fall in CPP, the difference between MAP and ICP, to less than 50 mm Hg because of arterial hypotension should be managed with vasopressor agents, provided intravascular volume status is adequate. When CPP is reduced as a consequence of an increase in ICP, or when the latter exceeds 25 mm Hg, bolus intravenous injection of mannitol (0.5 g/kg body weight) is first-line treatment (223). Renal replacement therapy, aiming to remove two to three times the volume of infused mannitol, is required in patients in oliguric renal failure. Repeated doses may be given as necessary, provided the plasma osmolarity does not exceed 320 mOsmol/L. Thiopentone may be beneficial in cases of intractable cerebral edema, although it may result in further hemodynamic instability.

Considerable interest at present centers on the relatively simple procedure of induction of moderate hypothermia (32°C to 33°C), which, as in experimental animals, may be beneficial in both adults and infants with uncontrolled increases in ICP through reductions in CBF, cerebral metabolism, and glutamine synthesis (225,226,227,228,229). Lowering of core body temperature to 32°C to 33°C using cooling blankets for periods ranging from 10 to 118 hours led to a significant reduction in CBF in 14 patients with FHF awaiting OLT and with increased ICP refractory to standard medical therapy in several recent reports (225,228,229). Significant

reduction in ICP and improved CPP were documented, along with reduced requirement for norepinephrine support (225,229) (Table 21.4). Thirteen of 14 liver transplantation candidates were successfully maintained until the time of OLT (229). Stimulation of the detoxification of ammonia in skeletal muscle with ornithine aspartate (230,231) and antagonism of postsynaptic glutamate-*N*-methyl-D-aspartate (NMDA) receptors with memantine (232) may also have therapeutic potential, either alone or in combination.

Table 21.4. Changes in Systemic and Cerebral Hemodynamics with Induction of Moderate Hypothermia (32°C To 33°C) in Patients with Fulminant Hepatic Failure

Having Raised Intracranial Pressure Unresponsive to Mannitol and Hemofiltration

	Before cooling mean (SEM)	4 hour after cooling mean (SEM)	10–24 hour after cooling mean (SEM)
Systemic vascular resistance (dyne s/cm^5)	503.8 ± 41	671 ± 48.4[a]	716.8 ± 43.3[b]
Mean arterial pressure (mm Hg)	76 ± 3.6	82.8 ± 2.2[b]	77 ± 1.8[c]
Intracerebral pressure (mm Hg)	36.5 ± 2.7	16.3 ± 0.7[c]	16.8 ± 1.5[c]
Cerebral blood flow (mL/100 g min)	78.2 ± 9.7	46.5 ± 3.8[c]	44.0 ± 1.9[c]
Cerebral perfusion pressure (mm Hg)	40.1 ± 2.9	66.4 ± 2.8[c]	67.2 ± 2.8[c]

[a]*P* <0.05 compared to precooling.

Prophylactic phenytoin has been found in one study to reduce the incidence of subclinical epilepsy and associated cerebral edema, with evidence of the latter at autopsy in 22% of treated patients compared to 70% of untreated counterparts (190). Seizure activity despite phenytoin treatment may respond to diazepam, although hypotension related to the use of this drug must be quickly reversed, and benzodiazepines should otherwise be avoided in view of the possible role of activation of central γ-aminobutyric acid/benzodiazepine receptors in the pathogenesis of encephalopathy. The somewhat dramatic procedure of total hepatectomy with temporary portocaval shunt is worth considering during the period between organ retrieval and transplantation in those awaiting OLT. In cases with refractory intracranial hypertension, both cerebral and systemic hemodynamics can be substantially improved (233). Hyperventilation reduces CBF and is appropriate in the subgroup with cerebral hyperemia, as reflected by increased reverse jugular venous oxygen saturation and elevated ICP. A reverse jugular venous oxygen saturation of 55% to 75% and an arteriojugular venous lactate difference of 35 mmol/L or less suggest an adequate CPP.

Renal Failure

Ensuring adequate intravascular volume status and treatment of any complicating infection are important measures to prevent or treat established renal impairment. In patients with FHF related to acetaminophen, the incidence of renal failure requiring dialysis was reported to be reduced by *N*-acetylcysteine infusion in one study, even after severe liver damage had occurred (50). Indications for renal replacement therapy in FHF include uncontrolled acidosis, hyperkalemia, fluid overload, and oliguria associated with either a serum creatinine level >300 μmol/L or cerebral edema requiring treatment with mannitol. Continuous veno–veno hemodiafiltration is preferable to intermittent hemodialysis because complicating hypotension

with the latter results in a fall in CPP that may exacerbate or precipitate cerebral edema (234).

Susceptibility to Infection

Prophylactic parenteral broad-spectrum antibiotic regimens, such as ceftazidime plus flucloxacillin or piperacillin plus tazobactam, combined with enteral amphotericin B and vaginal clotrimazole in one study reduced the incidence of infection from 80% to 20%. The latter approach was as effective as the more intensive enteral decontamination regimens (235). Proved bacterial infection should be treated according to in vitro sensitivities, whereas invasive fungal infection requires parenteral treatment with an appropriate antifungal agent. In the absence of a positive isolate, the possibility of fungal infection should be considered in the settings of a fever unresponsive to broad-spectrum antibiotics, leukocytosis, or deterioration in neurologic status after initial improvement, especially in the presence of renal failure. Granulocyte colony-stimulating factor improves neutrophil function both in vitro and in vivo in FHF (236,237) and may have a future role in preventing or treating infection in this group.

Nutrition

Caloric requirements in the order of 35 to 50 kcal/kg daily are required to meet the resting metabolic demand. Protein intakes in excess of 1g/kg daily are necessary to maintain nitrogen balance (238). Up to

50% of nonprotein calories should be delivered as lipid. Hypoglycemia, hypophosphatemia, hypokalemia, and hypomagnesemia require aggressive replacement. Enteral nutrition is considered preferable to parenteral in view of reports of maintained integrity of gut mucosa and reduced rates of bacterial translocation and sepsis in experimental animals (208).

Coagulopathy and Bleeding Diathesis

Because the prothrombin time is an important prognostic variable, infusion of fresh frozen plasma is indicated only for bleeding or at the time of invasive procedures, such as insertion of ICP monitors, as discussed earlier. Platelet transfusions are required in the latter circumstances if the count is less than 50×10^9/L and if less than 20×10^9/L platelets should be given prophylactically. Recent data in a small number of patients with FHF suggest that plasma infusion in combination with recombinant activated factor VII may be advantageous (239). The risk of bleeding from stress ulceration of gastric mucosa is reduced by the prophylactic use of sucralfate. This agent is preferable to antisecretory drugs, which predispose to gastric bacterial overgrowth and nosocomial pneumonia. Endoscopic treatment of bleeding varices, which can develop acutely in FHF, or of uncontrolled hemorrhage from stress ulceration may be required. Use of low-dose heparin or prostacyclin is generally required to prevent thrombosis of dialysis circuits, despite other manifestations of a bleeding diathesis.

Selection Criteria for Liver Transplantation

Reliable, clinically applicable, early markers of prognosis are required to accurately stratify risk in individual patients and ensure that those who are highly likely to die without OLT are listed as early as possible, thereby maximizing the time for a donor organ to be procured, while at the same time sparing unnecessary transplantation in other patients, in whom spontaneous recovery will otherwise occur.

Table 21.5. King's College Selection Criteria for Orthotopic Liver Transplantation According to Etiology of Fulminant Hepatic Failure

Etiology	Selection criteria for OLT
Acetaminophen	Arterial pH <7.30 despite normal intravascular filling

	pressures (irrespective of grade of encephalopathy)
	OR
	Prothrombin time >100 s + serum creatinine level >300 μmol/L in patients with grade III or IV encephalopathy
Nonacetaminophen	Prothrombin time >100 s (irrespective of grade of encephalopathy)
	OR
	Any three of the following (irrespective of grade of encephalopathy): Non-A, non-B hepatitis (cryptogenic), halothane hepatitis, or other drug toxicity Age <10 y or >40 y Jaundice-to-encephalopathy interval >7 d Prothrombin time >50 s Serum bilirubin >300 μmol/L

OLT, orthotopic liver transplantation.

King's College Criteria

Selection criteria for OLT in the setting of FHF are not currently standardized worldwide. Nonetheless, those formulated at the King's College Hospital, following retrospective, multivariate analysis of possible prognostic factors in 588 patients treated medically between 1973 and 1985 (4), are widely applied (Table 21.5). The original assessment of the accuracy of these indicators was based on the consideration of outcome, again retrospective, in a further consecutive series of patients managed during 1986 and 1987, including 121 with FHF due to acetaminophen and 54 with other etiologies. Positive predictive values for death (the proportion of patients fulfilling criteria who died) in the acetaminophen and nonacetaminophen groups were 84% and 98%, respectively, whereas negative predictive values (NPVs) (the proportion of patients not fulfilling criteria who survived) were 86% and 82%, respectively. Predictive accuracies (the proportions of all patients in whom outcome was correctly predicted) were 85% and 94%, respectively.

Several subsequent reports from other centers using the King's College criteria indicated that, although fulfillment of criteria carries a poor prognosis for spontaneous survival, lack of fulfillment carries a less favorable outlook than originally suggested (7,9), leading to much uncertainty about which patients can be managed without listing for urgent transplantation (Table 21.6). Shakil et al. (7) reported retrospectively on the Pittsburgh experience with these criteria in 177 patients over a 13-year period up to 1995, the first such assessment to be performed in the United States, adding

to two previously published validation studies from the United Kingdom and Europe (9,240). Approximately 50% of the patients in the Pittsburgh series underwent OLT a median 3 days after admission. The spontaneous survival rate was 14%, while almost three times as many patients died a median 6 days after admission without undergoing OLT. Patients who died

without OLT were significantly more likely than those who survived spontaneously to have grade III or IV encephalopathy at the time of admission, in keeping with previous reports from the United Kingdom and United States (4,7,9). Most patients who died without OLT had been considered transplantation candidates, at least early in their clinical course, compatible with the experience in the United Kingdom, where approximately 35% of those initially suitable for OLT rapidly developed contraindications such as uncontrolled cerebral edema, sepsis, severe hemodynamic disturbance, and multiorgan failure and became unsuited for transplantation (241).

Table 21.6. Validation of the King's College Prognostic Criteria in Patients with Fulminant Hepatic Failure

Criteria	PPV (%)	NPV (%)	PA (%)
FULMINANT HEPATIC FAILURE DUE TO ACETAMINOPHEN

[a]PT >50 s; jaundice-to-encephalopathy time >7 d; non-A, non-B hepatitis or drug-induced etiology; age <10 y or >40 y; serum bilirubin >300 μmol/L.
PPV, positive predictive value; NPV, negative predictive value; PA, predictive accuracy; PT, prothrombin time; INR, international normalized ratio. From Riordan SM, Williams R. Use and validation of selection criteria for liver transplantation in acute liver failure. *Liver Transpl* 2000;6:70–173, with permission.

The Pittsburgh analysis found that the King's College prognostic criteria carry acceptably high positive predictive values for death in patients with FHF due to both acetaminophen and other causes. NPVs in the acetaminophen group were also acceptably high in the Pittsburgh series, comparable to those documented in the original report. However, the NPV in

the nonacetaminophen group was found to be seriously lacking, especially in the case of those in the nonacetaminophen group, a finding in accord with that reported previously in 81 patients managed at Hôpital Saint-Antoine, Paris, between 1978 and 1988, and in 145 patients treated at Queen Elizabeth Hospital, Birmingham, between 1990 and 1994 (9,240). Overall predictive accuracies were somewhat reduced in each of these series in comparison to the original assessment (Table 21.6).

There is a need, therefore, to include other factors in the King's College criteria of prognostic significance. Anand et al. (9) identified peak white cell count and hyperkalemia as additional, independent indicators of poor prognosis in acetaminophen-related FHF. Any practical significance in terms of identifying patients whose prognosis would be improved by emergency OLT would likely be limited by the fact that such abnormalities often occur relatively late in the clinical course and in the setting of contraindications such as sepsis and hemodynamic disturbance. In the nonacetaminophen group, NPV was marginally improved without compromising positive predictive value by reducing the cutoff for prothrombin time from 100 to 75 seconds.

The King's College criteria were recently reevaluated in another cohort of patients with FHF due to acetaminophen managed at that center (242). The positive predictive value was 80% compared to 84% in the original series, whereas the NPV was 94%, even higher than the 86% found in the original series, and in keeping with the figure of 93% in a recent series from Denmark (171). With additional consideration of blood lactate levels (a postresuscitation arterial blood lactate level >3.0 mmol/L or either a postresuscitation or an "early" value >3.5 mmol/L), NPVs were 97% and 99%, respectively. Positive predictive values fell to 79% and 74%, respectively. Additional consideration of blood lactate levels modestly improved the NPV, but positive predictive value remained higher with the initial King's College criteria alone (Table 21.6). Patients with a poor outcome were identified earlier when blood lactate levels were taken into consideration (242).

Other Prognostic Criteria

Alternate prognostic indices have been proposed. In a series of 58 patients with acute viral hepatitis, mostly due to HBV infection, who did not undergo transplantation, managed between 1986 and 1990, Bernuau et al. (243) in Clichy found that criteria based on the presence of coma or confusion in association with reduced factor V levels carried positive predictive values and NPVs for death of 82% and 98%, respectively. Clinically apparent encephalopathy was present on admission or subsequently in most, but not all, patients. However, a subsequently reported French study of 81 patients with encephalopathy and nonacetaminophen-related FHF, mostly due to acute viral hepatitis B as in the Clichy series, found a substantially lower ability of the Clichy criteria to correctly identify patients who will survive without OLT (240). Furthermore, the Clichy criteria performed less well in this regard than the King's College criteria when both sets of indicators were applied to the same nonacetaminophen study population, with NPV of 28% and 50%, respectively, on admission, and 36% and 47%, respectively, when reevaluated 48 hours before death (240), a time chosen to approximate the mean waiting time for a donor liver in some contemporary European transplantation series. By contrast, positive predictive values of the two sets of criteria were comparably high (240).

Nevens et al. (244), in a Belgian series of 28 patients with nonacetaminophen-related FHF, found that the overall predictive accuracy was modestly increased when both sets of criteria were considered in combination, although the ability to identify patients who will recover spontaneously remained low even in this circumstance. In the only reported comparative assessment of the two sets of criteria in acetaminophen-related FHF, Izumi et al. (245) in a series of 81 patients found that the Clichy criteria performed less well, with lower positive predictive value (49% vs. 92%) and predictive accuracy (56% vs. 83%). The NPV was, however, acceptably high.

Taken together, these findings suggest that patients with either acetaminophen- or nonacetaminophen-related FHF who fulfill the King's College criteria and those with nonacetaminophen etiologies meeting the Clichy criteria should be listed for urgent OLT, with the exception of nonacidotic acetaminophen patients, when the encephalopathy grade is not

advanced. Patients not fulfilling prognostic criteria, especially with FHF unrelated to acetaminophen, should still be considered for OLT and excluded only if serial assessments indicate spontaneous recovery. This issue will likely become even more difficult if the use of temporary liver support based on extracorporeal perfusion or transplantation of hepatocytes or stem cells, as discussed in the subsequent text, is proved to be of benefit.

Factor VIII/V ratios; serial prothrombin times; assessment of liver size on computed tomography scanning; liver histology; the Acute Physiology and Chronic Health Evaluation (APACHE) score; sensory-evoked potentials; serum levels of Gc-globulin (vitamin D–binding protein), which is an important liver-derived component of the extracellular actin-scavenging system; and the severity of the SIRS have alternatively been proposed as possible prognostic indices in FHF, with varying degrees of applicability and reports of efficacy (246). In the tropical population

of India, in which viral hepatitis is the most common cause of FHF, older age, cerebral edema, and degree of prolongation of prothrombin time have been identified as factors indicative of poor prognosis. As already referred to, fulminant presentations (with encephalopathy) of Wilson disease and Budd-Chiari syndrome in association with extensive hepatocellular necrosis are generally considered to represent indications for urgent OLT. Primary myeloproliferative disorders responsible for the Budd-Chiari syndrome should not be considered a contraindication to this intervention (246).

The possible prognostic value of circulating and intrahepatic cytokine levels has been the subject of several recent reports. In a report from the United Kingdom, circulating levels of both IL-6 and IL-8, but not TNF-α, were found to be significantly higher in patients who subsequently died than in those who survived (147). Lack of correlation with degree of liver failure, as reflected by prothrombin time, serum bilirubin level, or degree of hepatic encephalopathy, suggested that these parameters reflected not the severity of FHF per se but rather complications such as circulatory disturbance and resultant extrahepatic multiorgan failure. Indeed, the hemodynamic instability of which they are reflective would preclude OLT. A Japanese study found that, at hospital admission, circulating levels of TNF-α and IL-10, but not IL-6, were significantly higher in patients who died than in those who survived. In keeping with the United Kingdom experience, circulating levels of these cytokines did not correlate significantly with the degree of liver injury, as reflected by serum transaminase values (148). A German series found no significant correlations between intrahepatic levels of IL-12, IFN-γ, or IL-10, at either protein or mRNA levels, and jaundice-to-encephalopathy time, encephalopathy grade, requirement for inotrope support, serum bilirubin level, prothrombin time, or APACHE II score (146).

As alluded to earlier, hyperphosphatemia, possibly as a consequence of renal impairment and lack of substrate utilization due to blunted hepatic regenerative activity, has recently been reported to be an early predictor of poor outcome in severe acetaminophen-related liver injury (171). In a series of 125 patients, including 30 with hepatic encephalopathy, a threshold phosphate concentration of 1.2 mmol/L or above at 48 to 96 hours after overdose had higher sensitivity, predictive accuracy, and positive predictive values and NPVs for death than the King's College criteria (89% vs. 67%, 98% vs. 92%, 100% vs. 80%, and 98% vs. 93%, respectively). Specificity was 100%. Consideration of the King's College criteria in combination with the phosphate level led to improvement in sensitivity to 94%. As with consideration of blood lactate levels (242), patients with a poor outcome were identified substantially earlier using the phosphate criteria (median 1 hour after referral) than with the King's College guidelines (median 12 hours).

Adrenal insufficiency has also recently been shown to correlate with outcome. Patients who did not survive to discharge from the intensive care unit or underwent liver transplantation had significantly lower increment and peak cortisol levels after stimulation with tetracosactide (Synacthen) than those who survived. Higher incidences of subnormal increment and peak cortisol levels were found in nonsurvivors (55%) than in survivors (21%) (175). Nonetheless, the relative lack of both sensitivity and specificity limits the usefulness of these parameters for prognostic modeling.

Trends in Transplantation Activity

Data from the National Transplant Database of the United Kingdom and Ireland indicate that the number of patients with acetaminophen-induced FHF who were listed for super-urgent OLT increased by more than 75% during the period from 1995 to 1998, accounting for 40% of all super-urgent listings and 38% of all super-urgent transplantations in the 12 months to August 1998. In more recent years, however, the numbers have fallen progressively with the proportion of patients listed and undergoing transplantation in 2001/2002 reducing to 53% and 56% of their 1997/1998 values, respectively. As a corollary, the number of patients listed and undergoing transplantation for FHF of other etiologies has increased, including a more than 50% increase over the last few years in the number of patients listed for acute graft dysfunction after transplantation (247), presumably reflecting a greater use of marginal liver grafts. The number of patients undergoing transplantation for FHF because of non–A to E hepatitis has also increased over this time (247) as a direct consequence of greater organ availability for super-urgent transplantation consequent to the reduction in acetaminophen-related procedures rather than an increase in the prevalence of FHF due to seronegative hepatitis. Priority listing within the super-urgent category in the United Kingdom and Ireland offers the possibility of ABO-matched grafts being available within 24 to 72 hours.

Recent experience from the United States is that 66% of patients with FHF listed for transplantation received a graft after a median waiting time of 3 days and 18% on the waiting list died after a median 5 days. These findings indicate that lack of early donor organ availability remains a crucial factor limiting survival (248). As in the United Kingdom, a relatively low percentage of acetaminophen-related cases compared to those with FHF due to other etiologies underwent transplantation because of the relatively high spontaneous survival rate (248).

Outcome of Transplantation

The most recent analysis from the European Liver Transplant Registry (ELTR) (Hôpital Paul Brousse, Villejuif, France) documents 1-, 5-, and 10-year survival rates of 63%, 59%, and 54%, respectively, after cadaveric OLT for FHF. The plateau in mortality rate after the first 3 months reflects the fact that patients undergoing transplantation are critically ill before the procedure and often undergo a complicated early postoperative period. Survival is substantially reduced in patients with sepsis and multiorgan failure before OLT (249). Nonetheless, ELTR data indicate that those patients who survive beyond the first 3 months follow a survival curve comparable to that seen after elective OLT performed for cirrhosis. A center workload of fewer than 25 transplantations per year and fewer than 20 split liver grafts per year were among the risk factors for poor outcome after liver transplantation (250). In the best centers, outcome with split liver grafts is comparable to that after the use of full-size organs (251).

An important issue is the potential for viral-related cases of FHF to recur post-transplantation, especially under the influence of immunosuppression. Patients undergoing transplantation for fulminant HBV infection have a significantly reduced rate of hepatitis B recurrence than those undergoing transplantation for HBV-related cirrhosis (252). This presumably relates to the high prevalence of viral clearance before the procedure. Recurrent HBV-related FHF is distinctly uncommon. Graft damage due to recurrent HAV and other viral infections, including those described with Toga-like particles, is occasionally seen after OLT for fulminant disease (253). Although some degree of hepatitis C recurrence is almost universal after OLT for cirrhosis, there are little data in the FHF setting. Recurrence of hepatitis E has not been observed in the small number of patients undergoing transplantation for fulminant HEV infection to date.

A retrospective comparison of costs and cost-effectiveness of OLT performed for FHF and cirrhosis was recently reported (254). Costs up to 1 year were estimated to be 107,675 for the cirrhosis cases and 90,792 for those undergoing transplantation for FHF. OLT was considered less cost-effective when performed for FHF than for cirrhosis on account of the lower 1-year post-OLT survival in the former group.

Auxiliary Partial Transplantation

The use of auxiliary partial OLT is based on the undoubted potential for spontaneous liver

regeneration in FHF. This technique involves the removal of the left- or right-lobe segments of the diseased liver and their replacement by the equivalent segments of the donor organ. Right-lobe transplantation is generally used in adults, while a left lobe harvested from an adult graft may suffice for a child. Results published from the European Auxiliary Liver Transplant (EURALT) co-operative Study (255) show a survival rate comparable to that of conventional OLT and that immunosuppressive therapy could be withdrawn, leading to graft atrophy, in 65% of patients surviving at 1 year, in whom adequate regeneration of the native liver had occurred. Similarly, full regeneration of the native liver was documented in 8 of 11 (74%) surviving patients in a series of 17 auxiliary partial OLT recipients from two French centers (256). Immunosuppressive treatment was subsequently withdrawn or the dosage tapered in seven of these eight patients.

Differing results have been reported by Azoulay et al. (257), who recently compared auxiliary partial OLT with standard whole-liver transplantation in a consecutive series of 49 patients undergoing transplantation for fulminant or subfulminant hepatitis at another French center. OLT was performed in 37 patients and auxiliary partial OLT in 12. Each patient treated with auxiliary partial OLT was matched to two patients undergoing OLT according to age, coma grade, etiology of liver failure, and clinical course. Although 1-year patient survival was identical (66%) in the two groups, the complication rate was higher in the auxiliary partial OLT recipients. In particular, patients undergoing the auxiliary procedure experienced significantly more technical complications (1 ± 1.3 vs. 0.3 ± 0.5), episodes of bacteremia, requirement for retransplantation (3/12 vs. 0/24), and neurologic sequelae or brain death (4/12 vs. 2/24). Only in 2 of 12 auxiliary partial OLT recipients (17%) was the procedure a complete success, as reflected by the ability to withdraw immunosuppression and patient survival.

Living-Related Transplantation

In parts of the world where cadaveric organ donation is not widely accepted, recourse has been made to the living-related donor procedure, especially in children. The 1-year survival rates after living-related OLT for FHF in a total of 35 pediatric cases in three reported series (258,259,260), using left lobe and left lateral segments, ranged from 59% to 90%. Living-related left lobe, right lobe, and extended right lobe OLT has also recently been used successfully in cases of adults with FHF. The 1-year survival rate in the largest reported series of 53 adult patients in Japan was 75% (261). Pioneering work in Hong Kong has demonstrated that a graft in excess of 40% of standard liver volume is often required to reverse the severe metabolic derangements that occur in FHF (262,263). This can translate to the requirement for an extended right lobe graft for adult recipients, although

few centers go as far as this. At least some degree of live donor graft injury is common in small-for-size adult recipients. In particular, patients receiving a right lobe graft less than 40% of standard liver weight often develop transient portal hypertension after reperfusion, accompanied by intragraft upregulation of endothelin-1 and ultrastructural evidence of sinusoidal damage (264). Reduction in portal blood flow by portocaval shunting and splenic artery ligation may alleviate this "small-for-size" phenomenon and even allow the use of the left lobe for transplantation (265,266). Low-dose treatment with the NO donor, FK409, has recently been shown to attenuate small-for-size liver graft injury in rats (267). A relatively high rate of biliary complications ranging from 15% to 64% has also been reported with living-related liver transplantation (268). Nonetheless, availability of right lobe living-related transplantation has been shown to substantially improve the survival rate of adults with FHF, with 50% of patients enrolled in such a program surviving compared to only 6% managed medically while awaiting a cadaveric graft in a recent series from Hong Kong (269).

Rigorous donor selection criteria, both physical and psychological, along with expert postoperative care are required if the safety of the donor is not to be compromised. The reported incidence of donor death in the United States is in the order of 0.2% overall (270), substantially higher than that for kidney donation, which carries a risk of death in the order of 0.03%. Cases of donor death have also been reported from Asia and Europe. Concern has been expressed about the ability to properly assess potential donors on an emergency basis, as is necessary when dealing with FHF. Although in the pediatric setting parents approach the possibility of living-related liver transplantation with enthusiasm, a recent analysis found that

almost two thirds of potential donors were ultimately considered unsuitable for organ donation, with both parents deemed unsuitable in over 20% of cases (271). Living-related transplantation from adult to adult is being increasingly performed in the United States and Europe.

Extracorporeal Liver Support

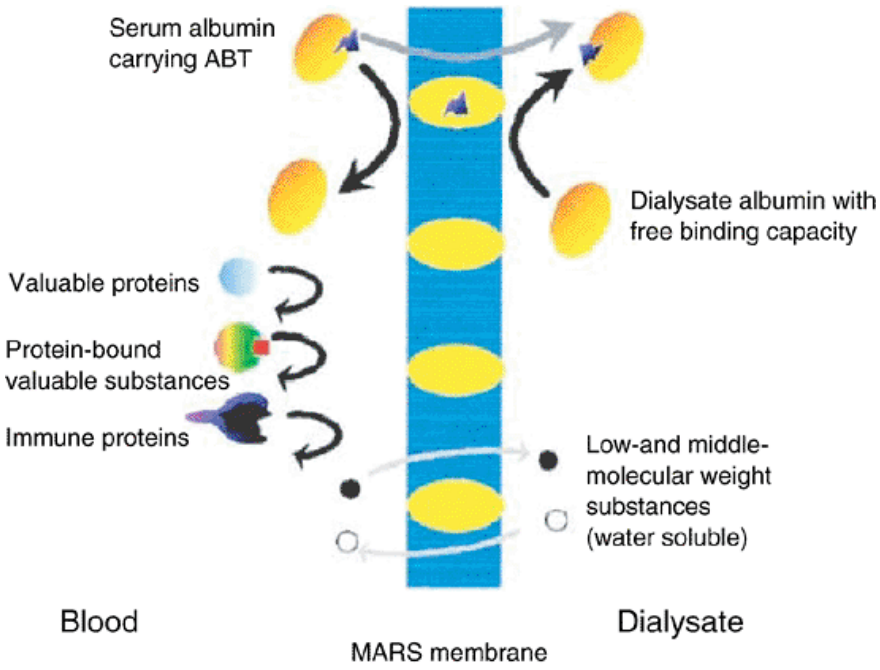
An ever-increasing number of extracorporeal devices of varying complexity are being developed as potential alternatives to auxiliary partial OLT for providing temporary liver support in FHF. Approaches to extracorporeal liver support may be broadly categorized as *artificial*, which contain no biologic component, or *bioartificial*, which include viable liver cells in culture within bioreactors or involve perfusion of the patient's blood through an isolated human or porcine whole liver.

Artificial Liver Support

Early attempts at extracorporeal support based on purely artificial modalities, such as exchange blood transfusion, conventional plasmapheresis, hemodialysis, and hemoperfusion over charcoal or resins (272,273,274,275,276,277,278), were based on the premise that removal of water-soluble and albumin-bound toxins was of paramount importance. The best studied of these artificial modalities is charcoal hemoperfusion. Charcoal is an effective adsorbent for a range of water-soluble molecules in the low-to-middle molecular weight range (up to 5 kDa) and many purported toxins that accumulate in the serum of patients with FHF, such as mercaptans, γ-aminobutyric acid, aromatic amino acids, and fatty acids, but not ammonia (which is heavily ionized at physiologic pH), can be removed or at least reduced in concentration by charcoal hemoperfusion. By contrast, compounds tightly bound to plasma proteins are, in comparison, poorly adsorbed to charcoal (277,278). A number of experimental studies performed in both small and large animal models of FHF reporting a survival benefit with charcoal hemoperfusion, especially with earlier intervention (279,280,281,282), led to initial clinical assessment in patients with FHF and advanced encephalopathy grade (283,284,285). These studies found improved metabolic profiles, including an increased branched-chain amino acid to aromatic amino acid ratio, and at least a transient recovery of consciousness in most treated patients. However, no survival benefit was demonstrated in the only randomized clinical trial performed, even when confounding influences such as etiology of FHF and the jaundice-to-encephalopathy time were taken into account (5). Neither has improved survival in FHF been convincingly demonstrated with any of the other artificial systems listed in the preceding text.

Recent interest has centered on the possible value of large-volume plasmapheresis in FHF, with uncontrolled reports mainly of neurologic improvement and significant reduction in arterial ammonia levels (286,287). Two hemodiadsorption systems that variously combine the processes of hemodialysis and adsorption to charcoal, resins, or albumin, namely the BioLogic-DT device and the molecular adsorbent recirculating system (MARS), are also currently undergoing assessment. As compared to charcoal hemoperfusion alone, removal of tightly protein-bound compounds is enhanced by perfusion over resins or albumin, while reduction in ammonia levels is achieved by dialysis or perfusion over resins (288,289,290,291). The BioLogic-DT system utilizes a flat-bed cellulose membrane for hemodialysis against a suspension of powdered charcoal (with surface area substantially greater than that of granules or beads in a column) and cation exchange resin (292). Nonetheless, clearance of solutes is limited to those that are permeable through the cellulose

membrane, such that removal of highly protein-bound compounds including unconjugated bilirubin remains limited (293). Preliminary experience in a small number of patients with acute on chronic liver disease has demonstrated instances of improvement in neurologic status after daily, 6-hour treatments (292), although no substantial impact on either encephalopathy grade or overall survival was demonstrated in the setting of FHF (294).



▪ **Figure 21.3** Schematic representation of exchange of albumin-bound toxin (ABT) from serum albumin of the patient through the molecular adsorbent recirculating system (MARS) membrane to the dialysate albumin. (Reproduced with permission from Mitzner SR, Stange J, Klammt S, et al. Improvement of hepatorenal syndrome with extracorporeal albumin dialysis MARS: results of a prospective, randomized, controlled clinical trial. *Liver Transplant* 2000;6:277–286.)

The MARS enables albumin-bound toxins to be removed by dialysis, along with other conventionally dialyzable compounds, as a consequence of the use of a double-sided, albumin-impregnated polysulfone or a hollow-fiber dialysis membrane as a molecular adsorbent in a closed-loop dialysis circuit (295) (Figs. 21.3 and 21.4). Such an approach is based on the long-recognized principle that albumin molecules with free binding sites compete for toxins bound to carrier proteins in perfused blood (284). Incorporation of 5% human albumin in the dialysate results in the transfer of adsorbed toxins in turn from the membrane to the dialysate. The dialysate is then perfused over charcoal and resin adsorbents to remove albumin-bound toxins from the

dialysate albumin and finally dialyzed to remove water-soluble toxins, including ammonia, in readiness for the next cycle. Most experience with MARS to date has been obtained in patients with acute on chronic liver disease. A survival benefit has been suggested in small case series (296) and one controlled study (297). Results of a large, multicenter randomized trial under way in the United Kingdom and Europe are awaited. A recent report documents the successful treatment of fulminant Wilson disease with albumin dialysis, which resulted in the removal of substantial quantities of albumin-bound copper and bilirubin and reversal of multiorgan failure before OLT was performed (298). Other successful experiences have been reported, including spontaneous survival without OLT in cases of acetaminophen overdose and bridging to retransplantation in cases of primary nonfunction of a liver graft (299), although, despite all the difficulties, only with a controlled clinical trial will a definite answer about efficacy be obtained.

Improvement of hepatorenal syndrome with extracorporeal albumin dialysis MARS: results of a prospective, randomised, controlled clinical trial. *Liver Transplant* 2000;6:277–286.)

Table 21.7. Various Bioartificial Liver Devices Designed as Alternatives to the Hepatassist and Extracorporeal Liver Assist Device, for which Preliminary Clinical Experience is Available

Name of device	Site of development	Cell type	Additional detoxification components	Comments
TECA Hybrid Artificial Liver Support System	Beijing, China	1–2 × 10^{10} freshly isolated porcine hepatocytes	Charcoal column	Assessed in three patients with FHF; improvement in neurologic status and blood ammonia levels reported (310)
Bioartificial Liver Support System	Pittsburgh, United States	70–120 g freshly isolated porcine hepatocytes mixed with 20% collagen	Nil	Assessed in two patients with FHF; improvement in blood ammonia but not neurologic status

				reported (311)
Radial Flow Bioreactor	Ferrara, Italy	200–230 g freshly isolated porcine hepatocytes	Nil	Assessed in four patients with FHF and three with primary nonfunction; six of seven bridged to OLT; mean reduction in blood ammonia 33% (312)
Hybrid Liver Support System	Berlin, Germany	500–600 g freshly isolated porcine hepatocytes	Nil	Assessed in seven patients with FHF; all bridged to OLT; elevated blood ammonia levels not corrected (313)
Modular Extracorporeal Liver Support	Berlin, Germany	500–600 g freshly isolated human hepatocytes	Albumin dialysis	Assessed in two patients with FHF; both bridged to OLT; improvement in neurologic status in both cases (314)
AMC-Biaortificial Liver	Amsterdam, The Netherlands	1×10^{10} freshly isolated porcine hepatocytes	Nil	Assessed in 12 patients with FHF; 11 of 12 bridged to OLT; 1 patient recovered without OLT; mean reduction in blood ammonia 44% (315)

Bioartificial Hepatic Support System	Udine, Italy	1.5×10^{10} cryopreserved porcine hepatocytes	Nil	Assessed to date in only one patient (with acute on chronic rather than FHF); Neurologic status and blood ammonia levels improved (316)
Hybrid-Bioartificial Liver	Nanjing, China	1×10^{10} freshly isolated porcine hepatocytes	Charcoal column or bilirubin absorption column or plasma exchange	Assessed in 12 patients; clinical data limited—9 patients said to have improved (317)

FHF, fulminant hepatic failure; OLT, orthotopic liver transplantation.

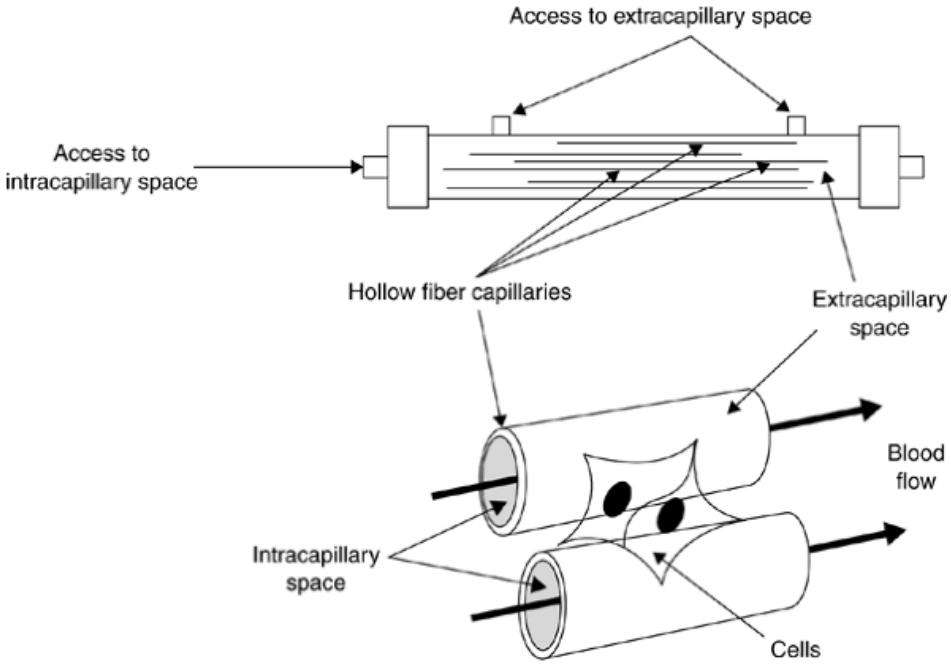
An important consideration in assessing liver support strategies is whether the treatment can reduce the elevated plasma levels of proinflammatory cytokines, which, among other influences, are associated with the development of multiorgan failure and a poor prognosis (300,301). In vitro experiments suggest that perfusion

of plasma over resins or charcoal achieves this aim to varying extents, depending on the adsorbent used and the cytokine in question, whereas hemodialysis using either polysulfone or polyacrylonitrile membranes is ineffective (302). Plasma exchange has been shown to reduce plasma concentrations of TNF-α and IL-6 in patients with FHF and primary nonfunction of hepatic grafts (303,304), although this has not always been the reported experience in other disorders associated with increased circulating cytokine levels (305). Treatment with the BioLogic-DT system results in further elevations in plasma levels of TNF-α and IL-8, possibly as a result of activation of peripheral blood mononuclear cells when passing through the extracorporeal circuit (306). A plasma separation system has recently been incorporated into the circuit, and a preliminary report has indicated a reduction in IL-1β levels with its use (307). An additional, although unproven, concern with some artificial systems is that the treatment may remove hepatotropic factors essential for liver regeneration, such as HGF and TGF-α.

Bioartificial Liver Support

Several bioartificial liver devices, containing viable hepatocytes as a component with the aim of providing additional synthetic and biotransformatory liver functions but differing substantially in both the hepatocyte component and bioreactor design, are currently being assessed either experimentally or clinically (308,309,310,311,312,313,314,315,316,317) (Table 21.7). The simplest design consists of cartridges containing hollow fiber membranes, with perfusion of the patient's blood or plasma through the hollow fiber lumen and culture of the hepatocyte component in the extrafiber space (Fig. 21.5). Although the additional incorporation of nonparenchymal cells may be advantageous for maintaining hepatocyte viability and function in culture as a result of secretion of extracellular matrix (318,319),

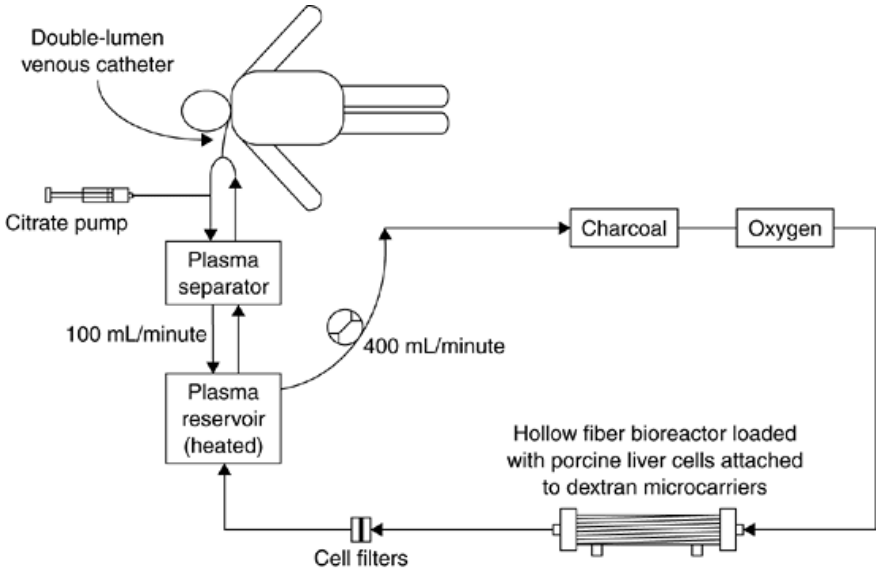
their inclusion might also have deleterious effects if these cells become activated in culture or during clinical application and produce cytokines such as TGF-β associated with the apoptosis of hepatocytes and inhibition of liver regeneration.



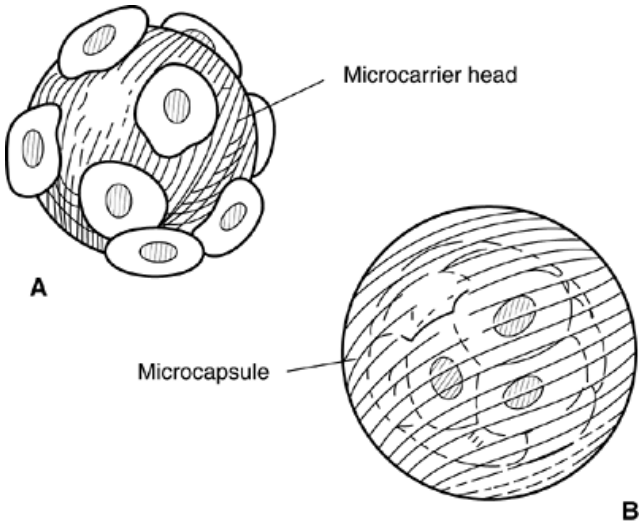
▪ **Figure 21.5** Diagram of a hollow fiber cartridge, on which the bioartificial liver (BAL) and extracorporeal liver assist device (ELAD) are based. The close-up view shows cells attached to the external surface of the hollow fibers. (Reproduced with Permission from: Ellis AJ, Sussman NL, Kelly JH, Williams R. Clinical experience with an extracorporeal liver assist device. In: Lee WM, Williams R, eds. *Acute liver failure*. Cambridge, Cambridge University Press, 1997:255–265.)

Of the devices that have so far undergone preliminary clinical evaluation, most experience is with the "HepatAssist" bioartificial liver support system, which contains porcine hepatocytes as the cellular component, the number approximating 2% of the normal adult hepatocyte mass, and a charcoal column (308) (Fig. 21.6). The hepatocyte component is attached to dextran microcarriers, thereby promoting cell growth and maintenance of cell function in culture (Fig. 21.7). Uncontrolled data suggested more impressive improvement in neurologic rather than metabolic parameters. A prospective, randomized, multicenter controlled trial of the HepatAssist device has recently been completed in the United States and Europe. A significant survival advantage was demonstrated in patients with FHF treated with the device, excluding those with primary graft nonfunction post-transplantation, compared

with controls managed with full medical supportive measures alone (44% reduction in mortality) (308). Although a porcine endogenous retrovirus resistant to lysis by human complement and capable of infecting human cells in vitro has been reported (320), no instances of transmission of this infection on using porcine hepatocytes in the HepatAssist device or others incorporating these cells have yet been documented (321).



▪ **Figure 21.6** Schematic representation of extracorporeal perfusion with the HepatAssist bioartificial liver. (Modified with permission from Rozga J, Podesta L, LePage E, et al. A bioartificial liver to treat severe acute liver failure. *Ann Surg* 1994;218:538–546.)



▪ **Figure 21.7** Attachment of hepatocytes to microcarrier beads is a commonly used technique to promote cell growth and maintain differentiated function in culture **(A)**. Encapsulation of cells within semipermeable microcapsules, such as with alginate–polylysine **(B)** is an alternative technique. (Modified with permission from Gerlach JC. Hepatocyte culture and bioreactor design for liver support systems. In: Lee WM, Williams R, eds. *Acute liver failure*. Cambridge, Cambridge University Press, 1997:245–254.)

In the only other controlled experience with a bioartificial liver device so far reported, a pilot but controlled clinical trial of the "extracorporeal liver assist device" (ELAD), which contains a human hepatoblastoma cell line in numbers in the order of 15% of the normal adult hepatocyte mass (309) (Fig. 21.8), demonstrated no statistically significant clinical or metabolic effect in treated patients. Several alternative designs to the HepatAssist and ELAD have been developed and at least preliminarily assessed clinically

(310,311,312,313,314,315,316,317,322). The design characteristics and preliminary clinical experiences with these devices are summarized in Table 21.7. No controlled data are available. Only one device currently undergoing assessment incorporates scarcely available primary human hepatocytes as the cellular component. The functional capacity and suitability or otherwise of immortalized or reversibly immortalized human hepatocytes (323) for use in bioartificial liver support devices represents another area of important investigation.

The use of human, as well as porcine, whole livers for extracorporeal perfusion is also the subject of ongoing interest. Although uncontrolled, metabolic and neurologic improvement was documented in a cohort of 14 patients treated with continuous perfusion until liver transplantation or withdrawal of support. Arterial ammonia levels fell from a median 146 to 83 µmol/L over the first 12 hours, and this reduction persisted for at least 48 hours. Whether pig or human livers were perfused was associated with comparable reductions in

blood ammonia levels. Nine patients were successfully bridged to transplantation (324)

A treatment system for implementing an extracorporeal liver assist device. *Artif Organs* 1994;18:385–389.)

Hepatocyte and Stem Cell Transplantation

The feasibility of isolated hepatocyte transplantation as a therapeutic tool has been demonstrated in studies performed in animals with liver-based metabolic defects, such as analbuminemic and Gunn rats, hypercholesterolemic rabbits, and dogs with impaired purine metabolism (325,326,327,328,329). These studies, in which syngeneic or allogeneic primary hepatocytes in quantities ranging from approximately 2% to 15% of the animal's normal liver cell mass were delivered by intraperitoneal, intrasplenic, or intraportal injection, generally demonstrated satisfactory, if incomplete, correction of the metabolic defect for periods, on occasion, of over 150 days. Approximately 50% to 95% of hepatocytes transplanted in this way are incorporated into liver parenchyma after their deposition in hepatic sinusoids, the remainder sequestrating in other sites, including an estimated 2% to 3% in the pulmonary circulation (330,331,332). The latter are rapidly destroyed in pulmonary capillaries, and the clinical relevance of pulmonary translocation has been considered limited (333). Transient respiratory insufficiency was described in a proportion of treated patients in a recent series (334), while other potential complications include portal vein thrombosis and splenic infarction (335). Successful hepatic engraftment of transplanted hepatocytes is associated with a transient five- to sixfold increase in transaminase levels, along with other evidence of

microcirculatory damage to the host liver (336). The development of portal hypertension precludes the transplantation of larger quantities of hepatocytes, at least as given in one session.

Experience with hepatocyte transplantation in experimental animals with FHF due to chemically induced hepatic necrosis or surgical models of hepatic ischemia or resection has generally demonstrated improved survival, even when small numbers of cells, in the order of only 0.5% to 3% of normal hepatocyte mass, are used (322,327,328,329,330,331,332,333,334,335,336,337,338,339,340). Evidence of enhanced regeneration of the native liver has been reported, possibly as a result of reduction in levels of transforming growth factor β (341). However, transplantation was performed before the induction of FHF in some surgical models, a scenario clearly incongruous to the clinical setting. Furthermore, the relevance of animal models in which the liver is removed to the clinical situation of FHF is uncertain.

Transplantation of freshly isolated or cryopreserved human hepatocytes has, to date, been performed in only a small number of pediatric and adult patients with FHF (342,343,344,345,346,347,348). Instances of mostly short-term improvement in encephalopathy and some metabolic parameters have been recorded both in OLT and

non-OLT candidates, generally after a lag period of several days, possibly reflecting the time necessary for effective engraftment, as in experimental animals (Table 21.8). No randomized, controlled data are currently available. Light microscopic and fluorescent in situ hybridization evidence of persistence of hepatocytes for up to 52 days post-transplantation has been recorded (334). On the basis of experimental evidence that transplanted allogeneic hepatocytes stimulate a weak humoral but strong cell-mediated host immune response (349,350), systemic immunosuppression has been instituted in the clinical applications so far. Alternative strategies for preventing rejection without the need for immunosuppressive drugs, including the transplantation of encapsulated hepatocytes (351), are currently under investigation in animal models.

Table 21.8. Clinical Experiences with Hepatocyte Transplantation in Fulminant Hepatic Failure in Adults and Children

Recipients	N	Transplanted hepatocytes	Assessment of efficacy
Adults			
Bilir et al. (342)	1	1×10^9 cryopreserved human hepatocytes delivered by injection into splenic artery	Improvement in encephalopathy and reduction in prothrombin time; subsequent deterioration precipitated by sepsis
Bilir et al. (343)	6	Cryopreserved human hepatocytes (number not stated) delivered by percutaneous injection	One patient withdrawn because of anaphylactoid reaction; of the remaining five patients, three (60%) survived >72 h (12–52 d), with transient improvement in encephalopathy, blood ammonia levels, and prothrombin times (no patient was considered an OLT candidate)
Bilir et al. (344)	1	3×10^{10} cryopreserved human hepatocytes	No clinical benefit observed and patient died within 18 h.

		delivered through transjugular intraportal injection	
Habibullah et al. (345)	6	6×10^7 ABO-matched fetal hepatocytes per kilogram body weight delivered by intraperitoneal injection	Blood ammonia level reduced in 80% of those in whom serial levels available; survival rate 30% compared with 33% in patients not consenting to hepatocyte transplantation; OLT not available
Strom et al. (346)	2	3×10^7 to 2×10^8 ABO-matched human hepatocytes (depending on availability; ≤0.1% adult hepatocyte mass); cryopreserved hepatocytes used in one case, freshly isolated cells in the other; cells delivered by injection into splenic artery	Each patient with grade III or IV hepatic encephalopathy at time of transplantation; reduction in blood ammonia level in both patients, who underwent OLT after 3 and 10 d; none of three patients for whom no hepatocytes were available for transplantation survived for >3 d
Strom et al. (347)	5	Human hepatocytes delivered by injection into splenic artery as in the preceding entry	Four patients with grade III or IV hepatic encephalopathy at time of transplantation; three bridged to OLT 1–5 d later; one died on day 5 before OLT could be performed; the other patient, with grade I hepatic encephalopathy before hepatocyte transplantation, survived without OLT
Children			
Strom et al. (346,347), Soriano et al. (348)	6	ABO-matched human hepatocytes delivered by injection into splenic artery	Five children with grade IV hepatic encephalopathy at time of hepatocyte transplantation; four of these patients (80%) died within 7 d, despite instances of reduction in serum ammonia levels and requirement for inotropicx support; one of these children recovered without OLT, having received multiple infusions of hepatocytes over a 3-d period; the other child, with grade I hepatic encephalopathy at the time of hepatocyte transplantation, underwent OLT 2 d after the procedure

OLT, orthotopic liver transplantation.

The limited availability of primary human hepatocytes for transplantation represents a major difficulty. Isolation of hepatocytes from livers rejected for liver transplantation is the standard approach, with reported yields in the order of 7 million cells per gram of digested tissue and a mean cell viability of 73% (352). With the source of such hepatocytes in increasingly short supply, the feasibility of harvesting tumor-free hepatocytes from macroscopically normal liver unavoidably removed during hepatic resection for malignancy has recently been demonstrated using an immunomagnetic filtration technique (353). In addition to the potential

new sources of primary human hepatocytes, recent data suggesting that cell viability and function after cryopreservation can be substantially improved with the use of University of Wisconsin solution as a cryopreservation medium (354,355) may enhance the future applicability of hepatocyte transplantation in the FHF setting. Transplantation of hepatocytes with fibrin or other biomatrix, shown in both mice and pigs to result in enhanced hepatocyte engraftment and in maintaining differentiated cell function (356,357), is another technical advance yet to be clinically trialled. The possible benefit to hepatocyte survival of cotransplantation with nonparenchymal cells, as suggested in rats (358), also remains to be established clinically.

In experimental models, repopulation of the whole liver can be obtained with infusion of relatively small numbers of purified hepatic stem cells that are able to replicate at least 100 times without loss of function or malignant transformation, as identified in adult rodent liver (359,360). Repopulation experiments using purified fractions of total liver cell suspensions will be required to identify any such cells in the adult human liver (361). Of note, a bone marrow–derived stem cell capable of repopulating the liver with mature hepatocytes after hepatic injury has recently been described in rodents. In the order of 1.0×10^6 hepatocytes (approximately 0.1% of the total hepatocyte mass) originated from transplanted bone marrow cells by day 13 after liver injury (362). If extrapolated from the animal to the human situation, the time required for engraftment and cell differentiation would be problematic in the acute setting.

On the premise that the fetal liver contains epithelial cells that are in different stages of lineage progression, some of which may exhibit the full regenerative potential of stem cells, transplantation of fetal hepatocytes, rather than the use of adult cells, has been suggested (347). Clinical data so far are limited, and the range of ethical issues pertaining to the use of fetal cells is currently the subject of much debate.

As with approaches to providing extracorporeal support, controlled trials on a multicenter basis in well-defined patient groups and with standardized outcome measures will be essential to properly evaluate the clinical value of hepatocyte transplantation in FHF. A better understanding of mechanisms responsible for the development of liver cell death and complicating multiorgan failure, along with strategies to enhance liver regeneration, may in future enable a more targeted approach to extracorporeal and cell-based therapies for this disorder.

Chapter 22

Gallstone Disease: Pathogenesis and Treatment

Joanne M. Donovan

Fred M. Konikoff

Key Concepts

- Gallstones affect approximately 10% of the population in the western world. Common risk factors for stones include age, female sex, obesity, pregnancy, ethnic origin (i.e., American Indian > European > African and Asian), rapid weight loss, chronic hemolytic states, and cirrhosis.
- Gallstones are divided into three types on the basis of their composition. *Cholesterol* gallstone formation involves hepatic cholesterol hypersecretion, gallbladder hypomotility, mucin hypersecretion, and intestinal metabolism of bile salts. *Black pigment* gallstone formation is associated with hypersecretion of conjugated bilirubin, which undergoes conversion to the insoluble unconjugated form, which then precipitates as the calcium salt. *Brown pigment* stones form within the bile ducts as a consequence of biliary stasis and infection, causing degradation and precipitation of biliary components.
- Most gallbladder stones are asymptomatic and do not require treatment. Stones most often present with biliary colic before the development of complications that include acute cholecystitis, biliary obstruction, or pancreatitis. The natural history of bile duct stones is less clear, but because of potentially severe consequences, choledocholithiasis is usually treated, even when asymptomatic.
- Laparoscopic cholecystectomy is the mainstay of treatment of gallbladder stones. Endoscopic therapy is an important tool for common bile duct (CBD) stones, either in addition to surgery or instead of surgery in high-risk patients.

Gallstone disease is one of the most common gastrointestinal afflictions, affecting 10% or more of the population in western countries. Although stones are most often silent, once symptomatic, their management is a major cause of morbidity, with some mortality and major costs to the health care system (1,2,3,4,5,6).

Gallstones are divided into three types on the basis of their composition: Cholesterol, black pigment, and brown pigment. Normally, bile functions as a detergent, facilitating hepatic excretion of otherwise insoluble compounds, as well as intestinal absorption of dietary lipids. Distinct pathophysiologic

mechanisms lead to incomplete solubilization of biliary components such as cholesterol and unconjugated bilirubin (UCB), with formation of either cholesterol or black pigment stones within the gallbladder (Fig. 22.1). Cholesterol stones constitute approximately 80% of stones in patients in western countries and may be composed of almost pure crystalline cholesterol, with minor amounts of UCB, calcium phosphate, mucin, and proteins. The predominant element of black pigment stones is polymerized calcium bilirubinate, with minor quantities of calcium. Their calcium content renders black pigment stones relatively radiopaque on plain radiographs in contrast to cholesterol stones. In addition to the precipitation of these constituents within the gallbladder, pathophysiologic mechanisms in the liver and intestine contribute to cholesterol and black pigment stone formation. In

contrast, brown pigment stones form when bile duct obstruction and bile stasis lead to bacterial infection and degradation of biliary lipids to insoluble compounds, including calcium bilirubinate, along with cholesterol and calcium salts of fatty acids. Epidemiologic risk factors differ for each type of stone and are discussed in the context of their pathophysiology.

Note that individual cholesterol monohydrate crystals can be seen radiating from a pigmented core. **B:** Black pigment stone composed of polymerized calcium bilirubinate. **C:** Microscopic view of cholesterol monohydrate crystals from human bile. **D:** Microscopic view of calcium bilirubinate granules from human bile.

Pathophysiology of Gallstone Formation

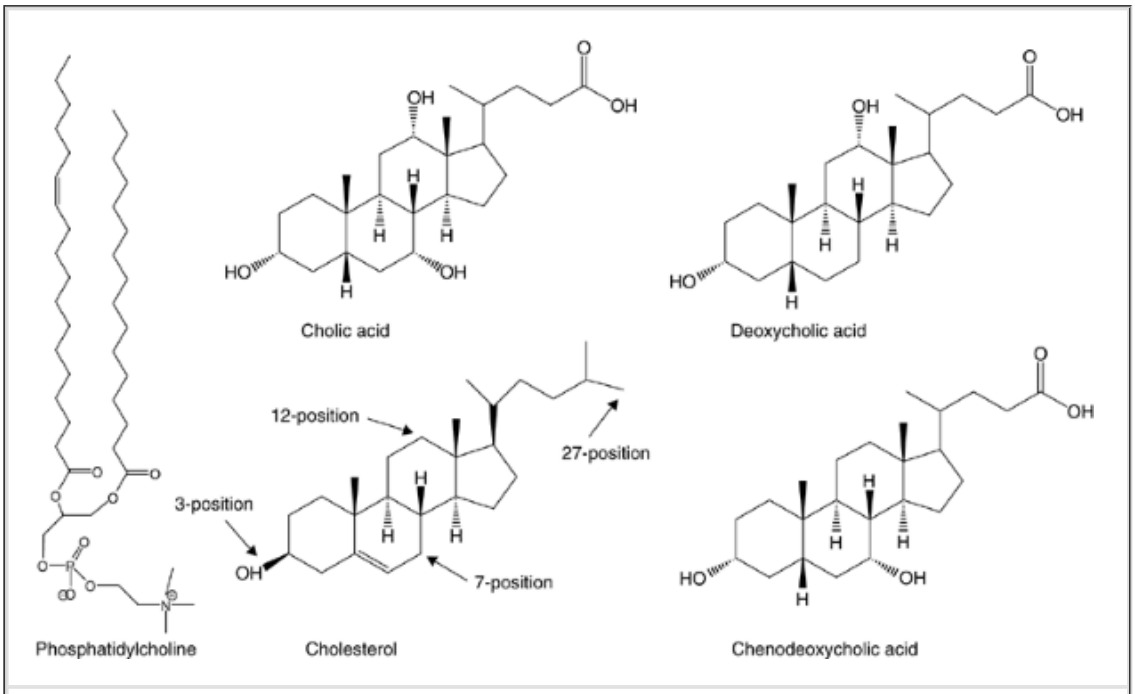
Biliary Lipid Secretion

The principal physiologic functions of bile, absorption of lipids and facilitation of excretion of relatively insoluble compounds, are mediated through the synthesis and secretion of lipid molecules that are either detergents or can cooperatively facilitate solubilization. Major components of bile include bile salts, phosphatidylcholine, and cholesterol, the chemical structures of which are shown in Figure 22.2. (7).

Components of bile

Although bile salts are derived from cholesterol, they are quite water soluble, as compared to the insolubility of cholesterol (approximately 10^{-7} mol/L) (8). The chemical transformation from the parent molecule includes truncation of the hydrocarbon side chain with addition of a carboxylic acid and either two

or three hydroxyl groups. The orientation of the hydroxyl groups allows interaction of the molecule with an air–water or oil–water interface, such that the hydrophilic hydroxyl groups and carboxylic acid can interact with water while the hydrophobic sterol nucleus remains protected from interaction with water. At concentrations above a critical value, denoted by the critical micellar concentration, bile salts self-aggregate to form micelles, with their hydrophobic surfaces on the interior to allow solubilization of otherwise insoluble molecules such as cholesterol (8). Approximately two thirds of secreted bile salts are conjugated with glycine and the other one third with taurine. Conjugation renders bile salts resistant to precipitation at physiologic pH values: Free bile salts precipitate at a pH value less than 7, whereas glycine conjugates precipitate at pH values less than 4.5 and taurine conjugates only below a pH value of 1. Therefore, conjugated bile salts, but not unconjugated bile salts, remain active as detergents throughout the intestine.



▪ **Figure 22.2** Chemical structures of typical biliary lipids. Phosphatidylcholine (lecithin) has varying chain lengths, the most common of which is the 1-palmitoyl, 2-oleyl shown here. Cholic acid and chenodeoxycholic acid are the predominant bile salts synthesized by the liver and are secreted as the glycine or taurine conjugate of the carboxylic acid side chain. Cholesterol is secreted as such and contributes the steroid nucleus for bile salt synthesis. Deoxycholic acid is derived from dehydroxylation of cholic acid by intestinal microflora. Ursodeoxycholic acid differs from chenodeoxycholic acid only in the orientation of the hydroxyl group in the seventh position.

Phosphatidylcholine and cholesterol are insoluble membrane components. Both are amphipathic—phosphatidylcholine with a hydrophilic zwitterionic choline head group and hydrophobic acyl chains and cholesterol with a single hydrophilic hydroxyl group and a hydrophobic sterol nucleus. Bile salts interact with phosphatidylcholine and cholesterol to form spontaneous lipid aggregates, micelles, or vesicles (8). Formation of bile salts into simple micelles enhances the

solubility of cholesterol by approximately 10,000-fold, whereas in the presence of phosphatidylcholine, bile salts form mixed micelles that increase cholesterol solubility by an additional severalfold (9). Exceeding the micellar solubility of cholesterol triggers the formation of unilamellar vesicles composed of a single bilayer of phosphatidylcholine and cholesterol with minor amounts of bile salts (10). Unilamellar vesicles aggregate, fuse, and transform to multilamellar vesicles containing multiple concentric bilayers that can spawn cholesterol crystals (11).

Bile salt synthesis is a highly regulated process that occurs principally in the liver (12,13). Distinct pathways are initiated by hydroxylation at either the 7- or 27-position, mediated by cholesterol 7α-hydroxylase (Cyp7A1) or sterol-27-hydroxylase (Cyp27), respectively (Fig. 22.2). The "classical" pathway of bile acid synthesis is initiated through Cyp7A1 and leads to cholic acid after further hydroxylation at the 12th position. Whereas Cyp7A1 is expressed only in the liver, Cyp27 is expressed widely, including the vascular endothelium. The "alternative" pathway of bile acid synthesis initated by Cyp27 leads to chenodeoxycholic acid, after further 7-hydroxylation by oxysterol-7α-hydroxylase (Cyp7B1) (14). The trihydroxy bile

salt cholate and the dihydroxy bile salt chenodeoxycholate are termed *primary bile salts*. The deoxycholates, ursodeoxycholates, and the monohydroxy lithocholates (with only the 3-hydroxyl group) are the products of intestinal bacterial transformation of primary bile salts: 12-dehydroxylation of cholate, epimerization of the 7-hydroxyl group of chenodeoxycholate, and 7-dehydroxylation of chenodeoxycholate, respectively. The deoxycholates are more powerful detergents and, as discussed later, can play a role in the pathogenesis of cholesterol gallstones (15). Ursodeoxycholate differs from chenodeoxycholate only in the orientation of a single hydroxyl group but does not solubilize cholesterol as well (16). After resorption of more than 95% of bile acids in the ileum by the apical sodium-dependent bile acid transporter (SLC10A2), bile acids are efficiently taken up at the hepatocyte basolateral membrane by the sodium-taurocholate cotransporting polypeptide (NTCP, SLC10A1) (17) and by multiple sodium-independent multispecific organic anion transporters (OATP-A and OATP-C; SLC21A3 and SLC 21A6, respectively) (17). Enterohepatic circulation of bile acids allows efficient conservation of the bile acid pool.

Bile secretion

The sterol nucleus of cholesterol can be excreted only as free cholesterol or after transformation to bile acids. The free cholesterol pool is a major determinant of biliary cholesterol saturation. Cholesterol is stored within the hepatocyte either in intracellular membranes, principally the endoplasmic reticulum, or as cholesteryl esters after esterification by acyl cholesterol acyltransferase-2 (ACAT-2) (18). Cholesterol, free and esterified, enters the hepatocyte through lipoprotein uptake in the form of low-density lipoprotein (LDL), high-density lipoprotein (HDL), or chylomicrons carrying dietary cholesterol. Each process is mediated by apical membrane receptors: The LDL receptor (LDLR) and the LDL-related protein (LRP) receptor for LDL and chylomicrons, and scavenger receptor B type 1 (SR-B1) for HDL. Esterified cholesterol can be stored, hydrolyzed by cholesterol esterases, or exported as newly synthesized very low density lipoprotein (VLDL). Newly synthesized cholesterol can be transformed into bile salts, although the major source of cholesterol for bile salt synthesis is HDL cholesterol, as evidenced by impaired biliary cholesterol excretion in mice with decreased levels of SR-B1

(19).

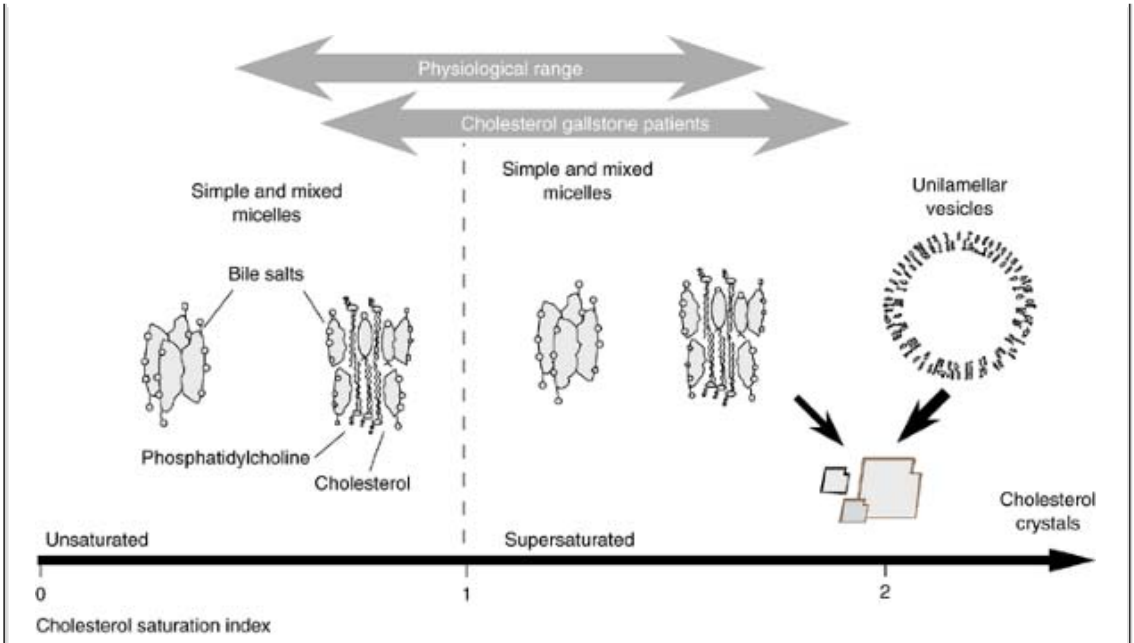
Biliary lipid secretion occurs through the coordinated expression of multiple transporters at the canalicular membrane (17,20). Unconjugated bile salt secretion occurs predominantly through the bile salt export protein (Bsep, ABCB11), a member of the adenosine triphosphate–binding cassette superfamily (21), whereas glucuronidated and sulfated bile salts are excreted by the canalicular multispecific organic anion transporter multidrug resistance protein (MRP2) (22). Phosphatidylcholine is transported from the inner to the outer canalicular membrane by a transmembrane transferase, or flippase, encoded by the murine gene product mdr2 and the human gene product MDR3 (ABCB4), the absence of which is associated with almost total ablation of phosphatidylcholine and cholesterol secretion in bile (23). Cholesterol transport at the canalicular membrane is mediated by two gene products (ABCG5 and ABCG8), which form a heterodimer transport protein (24). However, residual cholesterol excretion is observed in patients with sitosterolemia, in whom both gene products are defective (25); this suggests that cholesterol excretion into bile may occur by alternative mechanisms such as spontaneous transmembrane movement ("flip-flop") (26). Multiple monogenetic defects in canalicular transporter genes, as well as those of the enzymes of bile acid biosynthesis, have been identified with phenotypes ranging from cholesterol gallstone disease to severe early childhood cholestasis (27).

Once in the canalicular lumen, bile salts initiate vesiculation of phosphatidylcholine and cholesterol, culminating in the release of unilamellar vesicles (28). Despite the presence of other phospholipids in the canalicular membrane, phosphatidylcholine is virtually the sole phospholipid secreted in bile, consistent with the higher affinity of bile salts for phosphatidylcholine as compared with sphingomyelin (29). The mechanism for the selectivity for phosphatidylcholine versus sphingomyelin is likely to be physicochemical in part, given the greater susceptibility of phosphatidylcholine to bile salt solubilization (29,30). As bile is concentrated, bile salt concentration increases above the critical micellar concentration and solubilizes phosphatidylcholine and cholesterol as mixed micelles (31). The cholesterol content of bile in part depends on the detergent capability of the bile salt species present. More highly detergent hydrophobic bile salts more effectively extract cholesterol from the canalicular membrane to produce bile with relatively higher cholesterol content (32).

The relative cholesterol content of bile is most often expressed as the cholesterol saturation index (CSI), which is the amount of cholesterol present divided by the maximum micellar solubility of cholesterol by the bile salts and phosphatidylcholine present. This can be expressed on a ternary phase diagram showing the relative quantities of bile salts, phosphatidylcholine, and cholesterol, where the apices of the triangle represent systems with 100% of each component in aqueous solution or suspension (9).

The concentration of cholesterol in human bile fluctuates around the limit of cholesterol solubilization (Fig. 22.3). At lower bile salt secretion rates, such as during fasting when less bile salts are being returned in

the portal circulation, the relative cholesterol content increases (33). Patients with gallstones have somewhat higher CSI values; however, there is great overlap in the distribution of CSI values in bile between healthy individuals and patients with cholesterol gallstones (34).



▪ **Figure 22.3** Cholesterol saturation in bile typically fluctuates around a value of unity for the cholesterol saturation index (CSI). Below a CSI of 1, cholesterol is solubilized in simple and mixed micelles, whereas above a CSI of 1, unilamellar and, ultimately, multilamellar vesicles are formed, from which cholesterol crystallization can occur. (Adapted from Donovan JM. Pathogenesis of gallstones. In: Feldman M, LaRusso NF, eds. *Gastroenterology and hepatology: The comprehensive visual reference, vol 6, gallbladder and bile ducts*. St. Louis: Mosby, 1997:7.1–7.22.)

Bile acid and cholesterol homeostasis is tightly regulated. The liver X receptor (LXR), which forms heterodimers with the retinoid X receptor (RXR), appears to be the major mediator of cholesterol homeostasis (35). The major ligands of LXR are oxysterols; activation by elevated levels of intracellular cholesterol stores triggers coordinated changes that serve to decrease body cholesterol stores. Among the target enzymes whose activity is enhanced are Cyp7A1 effecting conversion of cholesterol to bile acids, ABCG5/ABCG8 effecting biliary cholesterol excretion, and ABCA1 serving to decrease intestinal cholesterol absorption (36) while downregulating the ileal bile acid transporter to enhance bile acid excretion (35). Similarly, the farnesoid X receptor (FXR), which also forms RXR heterodimers, acts as the major mediator of bile salt homeostasis. The major ligands of FXR are the hydrophobic bile acids, particularly chenodeoxycholate. Elevated intrahepatocyte bile acid levels trigger several homeostatic mechanisms: Cyp7A1 is downregulated, decreasing bile acid synthesis; whereas ABCB4 and ABCB11 are upregulated, increasing phosphatidylcholine and bile acid excretion at the canalicular membrane. The critical importance of FXR is illustrated by the observations that FXR-null mice display a phenotype of cholesterol-supersaturated bile, whereas treatment with an FXR agonist prevents the development of cholesterol gallstones (37).

Cholesterol Gallstones

Overview of factors in cholesterol gallstone pathogenesis

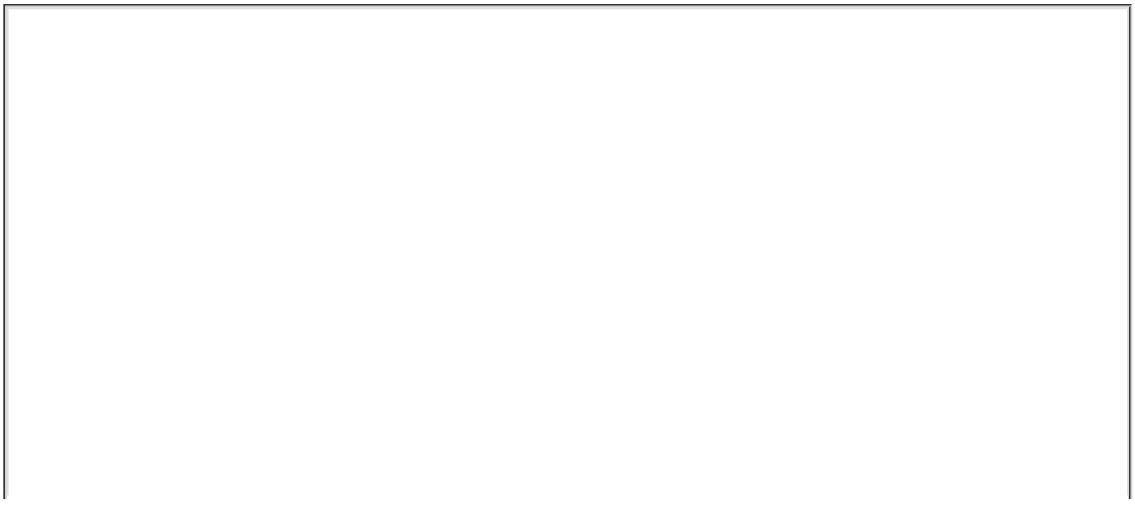
Although cholesterol supersaturation is absolutely required for cholesterol stone formation, multiple factors interact during the formation of stones. As discussed later, cholesterol supersaturation of bile also depresses gallbladder motility. Consequently, the impaired storage capacity of the gallbladder allows a larger fraction of newly secreted bile to be directed to the intestine, where bile salts undergo bacterial transformation to more hydrophobic bile salts such as deoxycholate and lithocholates. Enterohepatic recycling of deoxycholic acid and more efficient extraction of cholesterol at the canalicular membrane can lead to more cholesterol-supersaturated bile. Moreover, cholesterol-supersaturated bile triggers mucin hypersecretion, which accelerates cholesterol crystal

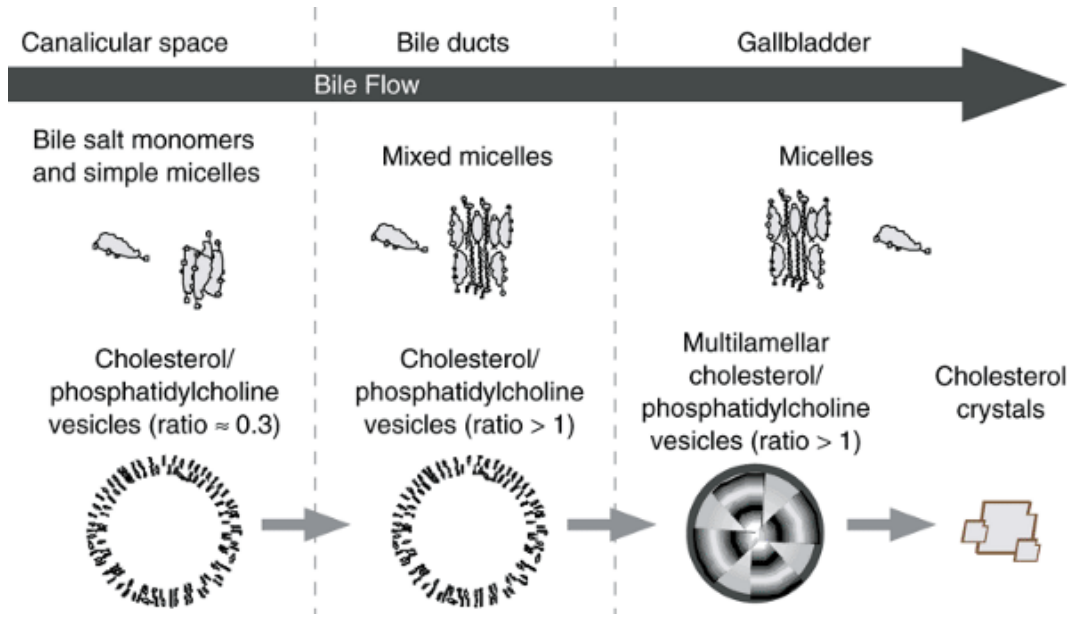
formation and forms a mucous gel layer that impairs biliary clearance of cholesterol crystals and incipient stones (38). Additional factors, such as pro- and antinucleating substances and possibly bacteria, are also thought to play a role in the processes leading to cholesterol crystallization and gallstone formation.

Cholesterol crystallization

When bile is supersaturated with cholesterol, dissolution of vesicles to micelles is incomplete (Fig. 22.4). The remaining vesicles become highly enriched with cholesterol, reaching cholesterol to phosphatidylcholine ratios of 2 or more, which are thermodynamically unstable and cause fusion to produce multilamellar vesicles (10). The similarity of the molecular arrangement of cholesterol in bilayers with that of the crystal structure of cholesterol monohydrate suggests that multilamellar vesicles are crucial in spawning cholesterol crystal formation, as has been observed microscopically (39).

Cholesterol exists in gallstones as the thermodynamically favored cholesterol monohydrate form (40). These are rhomboid, platelike microcrystals that aggregate to form the macroscopic stones (41). Under conditions when the driving force for cholesterol nucleation is high, initial crystallization can also occur in other crystal forms, including cholesterol filaments, helices, and ribbons (42). Some of the earliest crystal forms are intermediate polymorphs of cholesterol monohydrate, with a shift in the water molecules in relation to the cholesterol (43,44). As crystallization proceeds, these structures disappear in favor of the more stable cholesterol monohydrate crystals (45).





▪ **Figure 22.4** Cholesterol is secreted in the form of cholesterol/phosphatidylcholine vesicles that are unsaturated with cholesterol in the proximal biliary tree. As bile becomes more concentrated distally, bile salt concentrations rise, causing preferential extraction of phosphatidylcholine from unilamellar vesicles. Consequently, cholesterol-enriched vesicles are formed that are thermodynamically unstable. In the gallbladder, vesicles aggregate and fuse and ultimately spawn crystalline cholesterol. (Adapted from Donovan JM. Physical and metabolic factors in gallstone pathogenesis. *Gastroenterol Clin North Am* 1999;28:75–98.)

The rate of cholesterol crystal formation is higher in bile from patients with cholesterol gallstones than in bile from healthy controls (46). When determined in vitro, cholesterol crystals form within a few days when bile from patients with cholesterol gallstones are incubated at 37°C but may not form in several weeks in bile from control patients. Numerous pronucleating and antinucleating proteins have been identified (47). Proteins that promote nucleation include mucin, fibronectin, α_1-glycoprotein, *N*-aminopeptidase, haptoglobin, and immunoglobulins, whereas antinucleating proteins include apolipoproteins A-I and A-II and certain immunoglobulins. The consensus view is that differences in concentrations of these proteins do not distinguish a subgroup of patients destined to develop gallstones (48). The exception may be the pronucleating agent mucin, which plays a crucial role in inhibiting cholesterol crystal clearance from the gallbladder and in internally scaffolding mature cholesterol gallstones (49). Additionally, the process of cholesterol crystal formation can be accelerated by increased cholesterol content, total lipid concentration, and relative bile salt content and hydrophobicity (1).

Role of the gallbladder

Gallbladder motor function and mucosal function play critical roles in the formation of gallstones (38,50). Gallbladder filling is a dynamic process characterized by interdigestive partial contractions allowing significant turnover

of bile during its residence in the gallbladder (51). Impaired gallbladder contractility in patients with cholesterol gallstones prevents complete clearance of nascent crystals, presumably facilitating their

growth to mature gallstones (52). The increased cholesterol content of bile alters the cholesterol content of the sarcolemmal membrane and impairs contractility (53).

Hypersecretion of mucin, a heavily glycosylated protein that binds hydrophobic biliary lipids and accelerates cholesterol crystal formation (49), is a central event in both cholesterol and black pigment gallstone formation that can be inhibited by prostaglandin inhibitors (54). Further, this highly viscous gel entraps cholesterol crystals and is a component of biliary sludge (55). The biochemical composition (i.e., lipids, proteins, and bilirubin) of bile is also modified during residence in the gallbladder, contributing to sludge formation (50).

The process by which cholesterol gallstones grow is not well characterized but presumably involves both accretion of cholesterol monohydrate crystals and, to a lesser degree, the enlargement of existing crystals (56). Cross-sections of cholesterol stones show a radial arrangement of cholesterol monohydrate crystals, cemented together by a mucin matrix. Frequently, cholesterol stones have pigmented rings, containing small amounts of calcium bilirubinate (57), possibly caused by fluctuations in bile composition during stone formation. In general, stones from a single gallbladder are of a single type (cholesterol or black pigment), with similar compositions. However, a single gallbladder can contain a single large stone or dozens of tiny stones, possibly through different mechanisms (58).

Role of intestinal transit

Bacteria may influence gallstone formation not only directly in bile but also indirectly within the intestines (59). Intestinal bacteria can increase deoxycholate production in the gut. Elevated levels of deoxycholate are associated with cholesterol gallstone formation (60). This hydrophobic bile acid has been shown to increase biliary cholesterol secretion, and thereby cholesterol saturation and bile lithogenicity. The observation that cholesterol gallstones are prevalent in patients with acromegaly treated with octreotide led to a series of studies demonstrating that these patients have impaired gallbladder contractility and prolonged intestinal transit times, with increased intestinal production of deoxycholate and increased relative amounts of biliary deoxycholate and cholesterol (61,62). The central mediator appears to be increased conversion of the primary bile salt cholate to the secondary bile salt deoxycholate. Enhanced enterohepatic circulation of deoxycholate leads to cholesterol hypersecretion because deoxycholate is a more potent detergent at the canalicular membrane. Additionally, increased biliary deoxycholate levels accelerate cholesterol crystal formation (63). Further, interventions that increase intestinal transit time also trigger cholesterol stone formation in animal models, a process that can be prevented by agents that enhance intestinal transit (64). Although not all patients with cholesterol gallstones have elevations in biliary deoxycholate levels (65), it is likely that prolonged intestinal transit time and increased deoxycholate levels together are contributing factors in a subgroup of patients without other obvious risk factors (66). Patients with gallstones have been shown to harbor an increased mass of bacteria (mainly *Clostridium* spp) capable of 7α-dehydroxylation and deoxycholate production (61). Moreover, antibacterial

treatment has been shown to decrease biliary deoxycholate concentration and bile lithogenicity (67)

Genetics

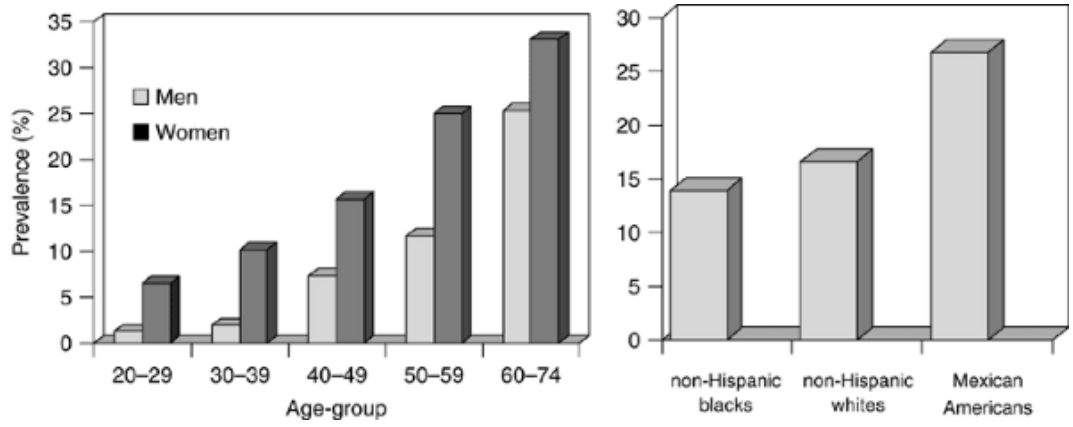
A genetic component of gallstones was initially suggested by a host of epidemiologic data (68). In particular, the strikingly high prevalence of gallstones in specific populations such as American Indians strongly supports a genetic background of gallstone disease (69). This clustering of gallstones does not necessarily prove the genetic basis of the disease but could also reflect environmental factors. However, additional data from family studies with spouses, as well as mono- and dizygotic twins, have provided more firm evidence that gallstone formation is indeed genetically determined (70,71). In this background, a series of studies in the mouse model have looked for underlying genetic defects leading to gallstone formation. By using the genetic tool of Quantitative Trait Locus (QTL) analysis with inbred mice, a number of gallstone susceptibility genes, have been identified, which they have termed *Lith genes* (72,73). To date 16 Lith gene candidates have been identified on 12 different mouse chromosomes, among which several seem to be of greatest potential relevance to cholesterol gallstone formation: Lith 1 on chromosome 2, Lith 2 on chromosome 19, and Lith 9 on chromosome 17. Likely candidate genes include ABCB11 (encoding for the bile salt export pump), ABCC1 (an organic anion transporter), ABCG5/G8 (the cholesterol transporter), and FXR (modulating bile acid metabolism), respectively (74). Absolute confirmation of the relevance of these findings, however, requires verification by experiments with knockout and knock-in animals (75).

Epidemiologic studies in humans have revealed several genetic associations with gallstone disease. The ApoE4 genotype has been shown to predispose to gallstone formation in some studies, but not in others (76,77). Patients with progressive familial intrahepatic cholestasis (PFIC) type 3 have defects in *ABCB4*, which encodes for the phophatidylcholine flippase (ABCB4) (78). Consequent decreases in the phosphatidylcholine to cholesterol ratio in bile result

in decreased cholesterol solubility and accelerated cholesterol crystallization (79). Patients with benign recurrent intrahepatic cholestasis (BRIC) type 2 have mutations in ABCB11, the main canalicular bile salt transporter (80). However, the phenotype of mice strains susceptible to cholesterol gallstone formation has been reported to be that of increased activity of the bile acid transporter with cholesterol gallstone formation (81); hence, it is unclear in humans whether this mutation is associated with gain or loss of function. Patients having defects in the rate limiting enzyme of bile acid synthesis (CYP7A1) have hypercholesterolemia and gallstones and evidence of disproportionate bile acid synthesis through the alternative pathway (82). Observed increases in hepatic cholesterol content and the chenodeoxycholic acid to cholic acid ratio could lead to cholesterol-supersaturated bile, the former by enhancing cholesterol secretion and the latter by augmenting cholesterol solubilization from the canalicular membrane by the more hydrophobic bile acid chenodeoxycholate. Polymorphisms in the promoter region of the gene for the cholecystokinin (CCK) receptor have been identified in patients with gallstones (83). Presumably, impaired gallbladder contractility could increase the risk for gallstones. In general, genetic mutations associated with gallstones tend to present as cholelithasis at a young age.

Bacteria and gallstones

Although traditionally bacteria were not believed to be involved in the pathogenesis of cholesterol gallstones as opposed to brown pigment stones, this concept has been challenged in recent years. Using molecular biology techniques, bacterial deoxyribonucleic acid (DNA) can be found in most cholesterol gallstones (84). Bacteria may form a biofilm that serves as a matrix for crystals and stones (85). They can influence bile lithogenicity by phospholipase activity or the production of mucin, prostaglandins, or oxysterols (86). Recently, several *Helicobacter* species have been found in the intestines, bile, and even gallstones of laboratory animals and humans (87,88). Moreover, pathogen-free C57L mice failed to develop gallstones on a lithogenic diet (88) Although mounting data suggest that gallstone formation may be significantly influenced by bacteria and bacterial products, the exact role of bacteria in cholesterol gallstone pathogenesis still remains to be determined.



▪ **Figure 22.5** Prevalence of gallstones in the US population as determined by ultrasonography. With increasing age, gallstone prevalence increases, and in each age-group, women more commonly have gallstones than men. Mexican Americans have a higher prevalence than non-Hispanic whites or non-Hispanic African Americans. (Data from Everhart JE, Khare M, Hill M, et al. Prevalence and ethnic differences in gallbladder disease in the United States. *Gastroenterology* 1999;117:632–639.)

Epidemiology and clinical risk factors

Clinical risk factors for cholesterol gallstones are most often associated with biliary hypersecretion of cholesterol. Large epidemiologic surveys performed in countries where cholesterol stones are most prevalent have demonstrated that gallstones are common and most frequent in women and occur with increasing frequency at older ages (89,90). Results are similar in studies using abdominal ultrasonography as a screening tool to identify both asymptomatic and symptomatic stones and in studies examining the prevalence of previously diagnosed gallstone disease. The prevalence of gallstones increases with age (Fig. 22.5), apparently as a result of a decrease in bile salt synthesis, leading to an increase in biliary cholesterol saturation (91).

The propensity for the development of gallstones varies widely among populations (92). The highest prevalence is found among populations of American Indian ancestry, such as the Pima Indians, but extending to North and South American populations with significant genetic contributions from American Indian populations (93). Northern Europeans have a higher prevalence of stones than southern Europeans (5), whereas gallstones are less common among populations of Asian and African ancestry (90). Ancestral

exposure to adverse climates with selection for efficiency of nutrient use has been suggested as a common factor (94). An increased risk occurs within kindreds but does not appear to be mediated by a single gene in most patients.

Both endogenous and exogenous estrogens are associated with increases in gallstone prevalence. At every age, women are more likely than men to harbor stones, with the greatest excess prevalence occurring in the premenopausal years when estrogen levels are highest in women (90). Oral contraceptives (95) and estrogen replacement therapy (96) are associated with modest increases (relative risk <1.8) in gallstone prevalence; because of the much lower prevalence of gallstones in younger women, the effect is of more potential consequence for postmenopausal women. Pharmacologic estrogen administration accelerates stone formation in men as well (97). The common mechanism appears to be upregulation of the LDL receptor (98), with consequent increases in the biliary cholesterol pool and biliary cholesterol saturation (99). In the Pima Indians, puberty in girls but not in boys is accompanied by an increase in biliary cholesterol saturation (100).

Pregnancy is a particularly high-risk period for gallstone formation (101,102). In addition to the association of elevated estrogen levels with cholesterol hypersecretion, elevated progesterone levels impair gallbladder contractility (103). The prevalence of biliary sludge rises throughout pregnancy, reaching more than 30% at delivery (101,102). Although in most women sludge disappears over the postpartum period, stones form in up to 10%.

Obesity and weight loss appear to be independently associated with gallstone disease (104,105). The activity of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase is increased in obesity. The increased synthesis of cholesterol enriches the hepatic pool and hence canalicular cholesterol secretion (106). During rapid weight loss, gallbladder contraction is impaired and bile cholesterol saturation increases (107), leading to high prevalence rates of cholesterol gallstones in patients after extremely hypocaloric diets or in those who have undergone antiobesity surgery (108,109).

Dietary factors associated with gallstone disease include a modest negative correlation with vegetable protein intake (110) and a positive correlation with consumption of legumes (111) and trans-fatty acids (112). Increased physical activity is associated with decreases in clinical gallstone disease (113). Increase in carbohydrate intake seem to be associated with gallstones (114)

Hypertriglyceridemia has been associated with biliary hypersecretion and gallstone disease (115), apparently mediated through the effect of bile salt malabsorption (116) with decreased activation of FXR-dependent pathways that decrease serum triglycerides (117). Decreased activation of FXR in animal models is associated with cholesterol supersaturation (37). Plasma cholesterol levels have been negatively correlated with gallstone disease, whereas reduced HDL cholesterol levels have been associated with an increased risk (118), consistent

with the role of HDL in supplying biliary cholesterol. Fibric acid derivatives and, to a lesser extent, nicotinic acid increase biliary cholesterol saturation as a consequence of decreasing serum cholesterol level. In contrast, the effect of HMG-CoA reductase inhibitors on decreasing hepatic cholesterol has been associated with decreased biliary cholesterol saturation and even dissolution of gallstones in animal models (119). Apolipoprotein E-4 genotype has been associated with increased biliary cholesterol saturation, cholesterol stones, and rapid recurrence after lithotripsy treatment, leaving the gallbladder in situ (76), although not in all populations (77).

Gallstones have been associated with diabetes mellitus and insulin resistance (120,121). A large part of this association reflects the relation of obesity to type 2 diabetes, but there is an independent effect of diabetes, likely mediated through impaired gallbladder emptying (122) or a direct effect of insulin to increase biliary cholesterol saturation (123). Of note, there are strong correlations among risk factors for gallstone disease associated with syndrome X such as obesity, insulin resistance (120), and hypertriglyceridemia, as well as negative associations with physical activity (124). Both high carbohydrate intake and diets with high glycemic indices are also associated with an increased risk of gallstone formation (114,125). The recent appreciation that FXR has effects on glucose metabolism suggests that the association between diabetes and gallstone formation is based on metabolic cross-talk between lipid and glucose homeostasis rather than common epidemiologic risk factors (126)

Patients who have spinal cord injuries have a high prevalence of gallstone disease, which may present atypically because of impaired sensory innervation (127).

Intestinal hypomotility has been suggested to be a major etiologic factor in a subset of patients with gallstones (128). As discussed in the preceding text, patients with acromegaly treated with the somatostatin analog octreotide are at substantial risk for the development of cholesterol gallstones (129).

Black Pigment Gallstones

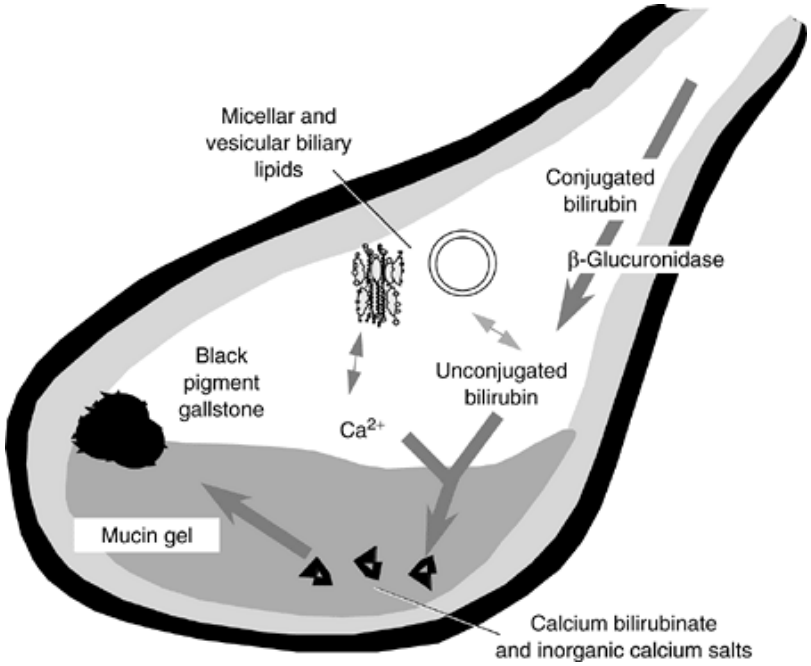
Black pigment gallstones predominantly contain the calcium salt of UCB, with minor amounts of calcium phosphate in a mucin matrix (130). Conjugated bilirubin, the degradation product of heme, is the predominant form secreted in bile after its synthesis in the hepatocyte by conjugating two glucuronide residues

with the tetrapyrrole rings of UCB (131,132). Small amounts of nonenzymatic degradation (133), along with tissue-derived β-glucuronidase, transform conjugated bilirubin to UCB. Bile salt micelles can solubilize minor amounts of UCB (131), but in the presence of calcium, UCB precipitates as the calcium salt (Fig. 22.6). After precipitation, calcium bilirubinate undergoes a free-radical–induced polymerization to an insoluble polymer (134,135). As is the case for cholesterol stones, mucin glycoproteins also form a structural matrix of black pigment stones.

The major determinant of the amount of conjugated bilirubin secreted is the requirement for degradation of heme to bilirubin for excretion. Therefore, conditions in which heme degradation is increased predispose to black pigment gallstone formation (1). An increased prevalence is observed in chronic hemolytic anemias such as sickle cell anemia and β-thalassemia. Patients with chronic liver disease have a substantially increased risk of gallstones (136), most of which are

of the black pigment type. In addition to increased hemolysis in the presence of portal hypertension and splenomegaly, in cirrhosis, secretion of bile salts is diminished, reducing the capacity of bile to solubilize UCB in bile salt micelles (137).

Although patients with Crohn's disease have been observed to have a twofold to threefold increase in the prevalence of gallstones compared with the general population (138), the mechanism has only recently been elucidated (139). Contrary to previous belief that bile acid malabsorption could contribute to biliary cholesterol supersaturation, patients with Crohn's disease have decreased biliary cholesterol saturations (140). Under normal conditions, conjugated bilirubin undergoes bacterial deconjugation in the colon, with further metabolism of bilirubin to urobilinogens. However, in Crohn's disease, ileal disease can lead to impaired bile salt reabsorption and spillover of bile salts into the colon, where they mediate absorption of UCB (139) This enhanced enterohepatic circulation produces an increase in hepatic conjugated bilirubin secretion, which initiates the cascade leading to UCB precipitation and black pigment stone formation.



▪ **Figure 22.6** Formation of black pigment gallstones. A relative increase in conjugated bilirubin secretion results in an increase in unconjugated bilirubin level. Deconjugation occurs by tissue β-glucuronidases or nonenzymatically. Biliary lipid aggregates can only partially solubilize calcium bilirubinate and precipitation ensues, along with inorganic (carbonate and phosphate) calcium salts. As for cholesterol stones, mucin provides a scaffolding for the formation of mature black pigment gallstones. (Adapted from Donovan JM. Physical and metabolic factors in gallstone pathogenesis. *Gastroenterol Clin North Am* 1999;28:75–98.)

Patients on total parenteral nutrition (TPN) have gallbladder stasis secondary to decreased stimulation of CCK release. Additionally, intestinal hypomotility may allow increased resorption of UCB, contributing to increases in biliary secretion of

conjugated bilirubin, as has been observed in animal models (141). These factors contribute to the nearly universal presence of biliary sludge and frequent development of black pigment gallstones observed in patients receiving TPN (142).

Brown Pigment Gallstones

The pathogenesis of brown pigment stones appears to differ in various parts of the world. In general, brown pigment stones form when bile duct obstruction and

bile stasis lead to bacterial infection and degradation of biliary lipids to insoluble compounds including calcium bilirubinate, along with cholesterol and calcium salts of fatty acids (85,143). In countries with a western, high-fat diet, brown pigment stones most often form in the common bile duct (CBD) after cholecystectomy. The initiating event is the presence of a foreign body, typically a retained stone and occasionally suture material. Transient bacterial colonization in the presence of a foreign body can trigger the formation of bacterial superinfection, followed by formation of a biofilm that prevents eradication of infection. Bacterial degradation of biliary lipids then leads to precipitation of calcium bilirubinate and calcium fatty acid salts (144), which further obstructs the bile duct, causing biliary stasis and perpetuating infection. The presence of periampullary diverticula or biliary strictures is also a clinical risk factor, presumably because of bile stasis with bacterial overgrowth leading to CBD colonization (145).

In the Far East, brown pigment stones are common, often the sequelae of parasitic infection with *Clonorchis*. The major components of Eastern and Western brown pigment stones are derived from the products of bacterial degradation of biliary lipids: Calcium bilirubinate and calcium palmitate or stearate (134,146). Bilirubin is secreted as the highly water-soluble diglucuronide conjugate but can undergo degradation by bacterial β-glucuronidase to form UCB. Lacking the solubilizing hydrophilic glucuronides, UCB internally bonds to hydrogen and is extremely insoluble, precipitating as the calcium salt. The calcium bilirubinate in brown pigment stones is not polymerized as in black pigment stones. Bacterial degradation of biliary phosphatidylcholine by phospholipases produces lysolecithin and fatty acids. The latter, predominantly palmitic and stearic acid, precipitate as their calcium salts. Additionally, a protein matrix is composed of both mucin and bacterially derived glycoproteins. Scanning electron micrographs demonstrate bacteria in the core of brown pigment gallstones (147), and bacterial DNA is consistently present, attesting to the etiologic role of bacterial infection of bile.

Rarely, cholesterol stones can form as a primary event in the bile ducts (148). Abnormalities in cholesterol and bile duct metabolism may play a role in brown pigment stone formation (149). Patients with almost pure intrahepatic cholesterol stones have been reported to have impaired phosphatidylcholine secretion (143) and a mutation in MDR3, the phosphatidylcholine flippase (78).

Biliary Sludge

Biliary sludge, or microlithiasis, is thought to be a key intermediate step in both cholesterol and black pigment stone formation, although a minority of patients with sludge go on to develop stones (150). Sludge can be composed of either cholesterol crystals or bilirubin granules in a mucin matrix. The clinical outcome ranges from spontaneous dissolution and development of asymptomatic or

symptomatic stones to complications such as pancreatitis and biliary obstruction (151,152). Sludge formation has also been observed in patients receiving high doses of ceftriaxone, causing precipitation of the calcium salt (55), but resolution is rapid after discontinuation of the drug. In patients with cholesterol microlithiasis, cholesterol supersaturation was found to be due to phospholipid deficiency as opposed to an increased percentage of cholesterol in patients with gallstones (153), suggesting that at least in some cases microlithiasis may represent a disease process different than that typically leading to cholesterol cholelithiasis.

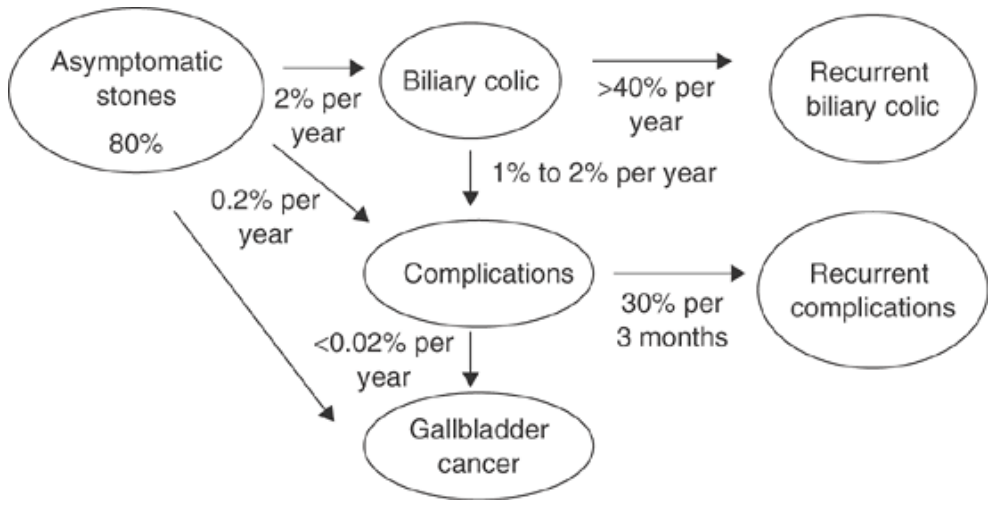
Clinical Spectrum of Gallstone Disease

Natural History of Gallstones

The clinical spectrum of gallstones may be divided into three stages: Asymptomatic, symptomatic, and complicated gallstone disease. Most gallstones are asymptomatic and remain so throughout the lifetime of the patient. Only between 15% and 20% of stones become symptomatic, between 1% and 3% per year (154,155) (Fig. 22.7). The most common initial symptom is biliary colic because gallstone disease rarely presents initially with complications. In some populations, such as the Pima Indians and South American natives, the rate of conversion to symptomatic disease appears to be higher (69). Once symptoms occur, the risk of recurrent symptoms is considerably higher: In one study, 70% of patients with symptoms in the previous year had recurrent symptoms within 2 years (156). In symptomatic patients, the risk of developing biliary complications is 1% to 2% per year, although symptomatic disease has a tendency to continue to remain so (154,155,156,157,158). Therefore, the natural history of asymptomatic stones is generally benign, whereas that of symptomatic stones follows a more aggressive course (156,159). These aspects are crucial in making clinical decisions about treatment of patients with gallstones (3,160).

The symptomatic stage of gallstone disease manifests itself primarily as attacks of biliary colic and episodes of pain, mainly in the epigastrium or right hypochondrium and often radiating to the back or the right shoulder or scapula (161,162,163). Biliary colic is believed to be caused by stone impaction in the cystic duct or gallbladder neck and produces a steady rather than a cramping pain, making the term biliary "colic" a misnomer. The pain correlates with gallbladder contractility (164). Lasting from 30 minutes to 6 hours, it arises and disappears slowly and may be associated

with nausea and vomiting. The pain typically occurs 15 minutes to 2 hours after eating but may be unrelated to food ingestion. Other features of dyspepsia, such as belching, bloating, bitter taste, or chronic pain should not be attributed to gallstones. Fatty food intolerance, commonly believed to be a characteristic of gallstones, is actually not more common in patients with gallstones than in others. The severity of biliary colic is sufficient to awaken the patient from sleep and often bring him or her to medical attention. Less commonly, this symptom complex may be associated with bile duct stones.



▪ **Figure 22.7** Natural history of gallstones. The 80% of stones that are asymptomatic tend to remain so. Most often their initial manifestation is biliary colic, rather than complications. However, once either biliary colic or complications occur, further symptoms are frequent. Gallbladder cancer is a rare complication.

The complicated stage of gallstone disease includes acute and chronic cholecystitis, acute pancreatitis, choledocholithiasis, ascending cholangitis, cholecystoenteric fistula, and gallbladder cancer. In acute cholecystitis, persistent cystic duct obstruction triggers an inflammatory process. The clinical picture resembles that of biliary colic, but with increased duration and severity, fever, leukocytosis, and often nausea and vomiting (165). On physical examination, right subcostal tenderness is characteristic, and pain and inspiratory arrest during palpation of the right subcostal area is relatively specific—Murphy's sign. Further complications include localized perforation, uncommonly, and free perforation and peritonitis, rarely.

Chronic cholecystitis is actually a pathologic condition and not clearly linked to a specific clinical entity. It is believed to be the result of recurrent episodes of biliary colic or acute cholecystitis, although a preceding history of attacks cannot always be obtained. The recurrent attacks or the presence of stones may contribute to local injury or ischemia and lead to a chronic inflammatory response with fibrosis, atrophy, and loss of gallbladder function.

Choledocholithiasis, or the presence of stones in the CBD, may be asymptomatic, but the likelihood of symptoms is held to be higher than that for gallbladder stones. In western countries these are typically secondary to stones in the gallbladder and occur in approximately 15% of patients with gallbladder stones (166). Their composition reflects that of the primary gallbladder stones, being composed mainly of cholesterol stones in the West (144). Primary stones in the biliary tree are more commonly seen in the Far East, particularly in the context of parasitic or bacterial infections in the bile ducts and are mainly of the mixed (brown stone) type (148). The natural history of choledocholithiasis is not well defined, but complications appear to be more frequent and severe than those with gallbladder stones (167). In contrast to gallbladder stones, the clinical presentation of choledocholithiasis is more likely to be extrahepatic biliary

obstruction or cholangitis. Elevation of alkaline phosphatase and γ-glutamyl transpeptidase levels is characteristic, as is mild jaundice with hyperbilirubinemia between 2 and 5 mg/dL but rarely more than 10 mg/dL (168,169). Although alkaline phosphatase and γ-glutamyl transpeptidase are the classic liver enzymes whose levels rise during cholestasis, in acute obstruction the transaminase levels may be significantly elevated (170). Choledocholithiasis may result in dilatation of the extrahepatic and intrahepatic bile ducts, although the lack of dilatation does not dissuade one from the diagnosis. Prolonged choledocholithiasis may lead to bile duct strictures and even secondary biliary cirrhosis (171).

Acute bacterial cholangitis is a medical emergency that is most often caused by a stone impacted in the distal common duct. The classic clinical presentation consists of biliary pain, jaundice, and fever (Charcot's triad). Chills and rigors are often seen, and, particularly in elderly patients, mental confusion, lethargy, and delirium may develop. Leukocytosis and jaundice with a bilirubin concentration of 2 mg/dL is seen in more than 80% of cases. The biliary tract becomes contaminated by bacteria, mainly *Escherichia coli*, *Klebsiella*, *Pseudomonas*, enterococci, or *Proteus*. Less commonly

anaerobes (e.g., *Bacteroides fragilis* and *Clostridium perfringens*) are involved. Bacterial translocation from the biliary tree to the bloodstream may lead to septicemia and septic shock. If untreated, bacterial cholangitis has a high mortality.

Biliary pancreatitis is believed to occur when a stone is impacted at the papilla of Vater, obstructing the outflow of the pancreatic duct (172). The obstruction may be transient, particularly during the spontaneous passage of a stone or of microcrystalline matter originating from the gallbladder. Often a direct association cannot be demonstrated, although systematic examination has demonstrated the presence of stones in the feces of up to 95% of patients after an episode of biliary pancreatitis (173). Microscopic examination of bile aspirated from the duodenum or CBD has been shown to reveal cholesterol monohydrate or calcium bilirubinate crystals in more than 60% of patients presumed to have idiopathic pancreatitis (152). The presence of sludge or small stones rather than larger stones may actually place patients at higher risk for pancreatitis (174). The clinical presentation and course of biliary pancreatitis is often indistinguishable from acute pancreatitis of any other cause. It is, however, crucial to identify those patients who have a stone impacted in the papilla because outcome in this condition is improved when they are treated by prompt endoscopic sphincterotomy and extraction of the stone (175,176).

Mirizzi's syndrome is a rare condition in which a stone becomes impacted in the cystic duct, causing external compression of the CBD with ensuing cholestasis (177). The clinical presentation may be indistinguishable from choledocholithiasis.

Gallbladder cancer is an uncommon complication of gallstone disease (178). In some populations, particularly in South Americans or Pima Indians, the frequency may be increased, but in most western countries, it is lower than the mortality during cholecystectomy and, therefore, does not constitute an indication for prophylactic surgical treatment of stones. Because the risk is highest for stones larger than 3 cm in diameter (179), cholecystectomy should be considered in such cases. Porcelain gallbladder is another rare condition defined by intramural calcification of the gallbladder wall. It is not necessarily associated with gallstones but has such a high predisposition for gallbladder cancer that it should

be considered an indication for prophylactic cholecystectomy.

Rarely, stones in the gallbladder may cause local injury and erode through the gallbladder wall into the intestines. The resulting cholecystenteric fistula most often communicates to the duodenum, although fistulization into the colon, stomach, and jejunum have been reported. If the stone is large (>25 mm in diameter), it may cause intestinal obstruction, in particular, at the level of the ileocecal valve. Gastric outlet obstruction due to a gallstone impacted in the distal stomach or duodenum is known as *Bouveret's syndrome* (180).

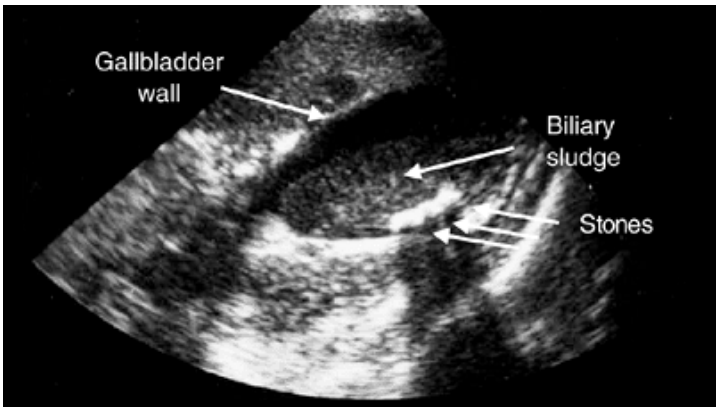
Diagnostic Modalities in Gallstone Disease

Imaging studies can reliably diagnose the presence and location of gallstones. Because gallstones are common in an older population, it is crucial for the clinician to decide whether abdominal symptoms are referable to the biliary tract before performing diagnostic studies. Otherwise, the incidental discovery of gallstones can lead to unnecessary intervention that is unlikely to relieve symptoms.

A plain abdominal radiograph rarely detects gallstones because most stones are radiolucent: Less than 25% contain enough calcium to be detected by radiographs. Only on rare occasions of air in the biliary tree (caused by surgery, endoscopic sphincterotomy, or spontaneous biliary enteric fistulation) can the plain abdominal radiograph be of assistance to the clinician.

Ultrasonography, on the other hand, has become the primary imaging modality in gallstone disease (Fig. 22.8). It is widely available, inexpensive, and completely noninvasive. Most gallstones these days are detected by ultrasonography, often as an incidental finding when evaluating the patient for an unrelated condition. Abdominal gas and obesity are limiting factors for the use of ultrasonography. Although operator dependent, the accuracy for detecting gallbladder stones, which appear as mobile echogenic foci casting an acoustic shadow, is in general more than 90%. The sensitivity of detecting stones larger than 2 mm in diameter exceeds 95%, with a specificity on the same order of magnitude (181). Ultrasonography can also detect sludge in the gallbladder. A sonographic Murphy's sign

(gallbladder tenderness under transducer pressure) is of value in diagnosing acute cholecystitis. Pericholecystic fluid is an additional quite specific indicator of this diagnosis. Despite its significant use in detecting gallbladder stones, ultrasonography even in the best hands has limited value in choledocholithiasis. Only approximately 25% to 40% of CBD stones are detected by transabdominal ultrasonography (182). This drawback is somewhat balanced by the ability of ultrasonography to recognize dilatation of the biliary tree beyond 7 mm, a value generally considered the upper limit of the normal choledochus.



▪ **Figure 22.8** Ultrasonographic demonstration of several gallbladder stones. A dependent layer of echogenic biliary sludge can be distinguished from the (*black*) echolucent bile above it. The stones cast a characteristic shadow, preventing further penetration of the ultrasound into the liver parenchyma.

Computed tomography (CT) scan has limited value in the diagnosis of gallstones for the same reasons as plain radiographs. However, CT scan improves the patient's evaluation by its capability of detecting or excluding complications, such as pancreatitis, pericholecystic fluid, perforation, or abscess formation. More recently, computerized analysis of CT scan data has been used to reconstruct bile duct images to provide a CT cholangiography (183).

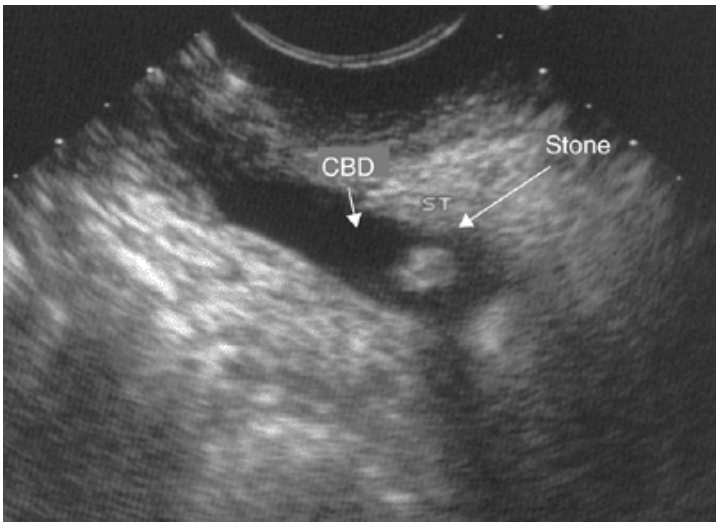
Oral cholecystography (OCG) was formerly used widely for diagnosing gallstones but has been largely superseded by ultrasonography. It is currently used for patients considered for oral dissolution therapy of gallstones because OCG can assess cystic duct patency and the cholesterol content of the stones. These two characteristics are prerequisites for this form of treatment.

Radionuclide scanning or cholescintigraphy after intravenous administration of a technetium-99m– labeled iminodiacetic acid derivative is valuable in assessing cystic duct obstruction in the diagnosis of acute cholecystitis and postoperative bile leaks (184). Nonvisualization of the gallbladder in the appropriate clinical setting is considered 95% sensitive and 80% to 90% specific for acute cholecystitis (181,185).

Magnetic resonance imaging (MRI) in its conventional form has little use in gallstone disease. However, magnetic resonance cholangiopancreatography (MRCP), a three-dimensional computer-generated reconstruction of the biliary system, is rapidly evolving as the most useful alternative for other methods of cholangiography (186). The method is noninvasive, does not require contrast agents, and can be done with an imaging time of only a few minutes (187). Moreover, the resolution is rapidly approaching a quality comparable to that of direct cholangiography (188). In the diagnosis of choledocholithiasis, MRCP has been reported to reach a sensitivity of around 95% (189,190). Hence, MRCP, where available, is turning into an increasingly important tool in the diagnosis of choledocholithiasis.

Endoscopic ultrasonography (EUS) is also becoming increasingly helpful in the

assessment of choledocholithiasis (Fig. 22.9), with a sensitivity and specificity of more than 95% (191,192). It is highly efficient in decreasing unnecessary endoscopic retrograde cholangiopancreatographys (ERCPs) (see subsequent text) (193). Moreover, it is superior to transabdominal ultrasonography in diagnosing small gallbladder stones, particularly in obese patients. It is also sensitive for detecting sludge and microcrystals in the gallbladder (194,195). EUS is, however, significantly operator dependent and unfortunately not routinely available in many centers.



▪ **Figure 22.9** Endoscopic ultrasonography of the common bile duct (CBD) demonstrating choledocholithiasis.

ERCP has been the gold standard for diagnosing choledocholithiasis for the last two decades (Fig. 22.10) (196). It is an invasive procedure associated with an inherent risk of pancreatitis. The current practice is shifting to MRCP and EUS as diagnostic tools, although ERCP remains the primary modality in managing choledocholithiasis, as discussed in subsequent text.

When gallstone disease is suspected but cannot be identified by other means, microscopic examination of duodenal contents aspirated after administration of CCK or bile obtained through an ERCP catheter may be employed to detect microcrystals. Cholesterol monohydrate crystals or calcium bilirubinate granules are readily recognized when the bile sediment is inspected under light microscopy, preferentially using polarized light (152,197). The presence of crystals is indicative of the presence of gallstone disease with sludge or small stones whose size may be below the limits of resolution of the imaging modalities (approximately 1 to 2 mm). The combination of EUS and bile analysis has been shown to be particularly sensitive (194).

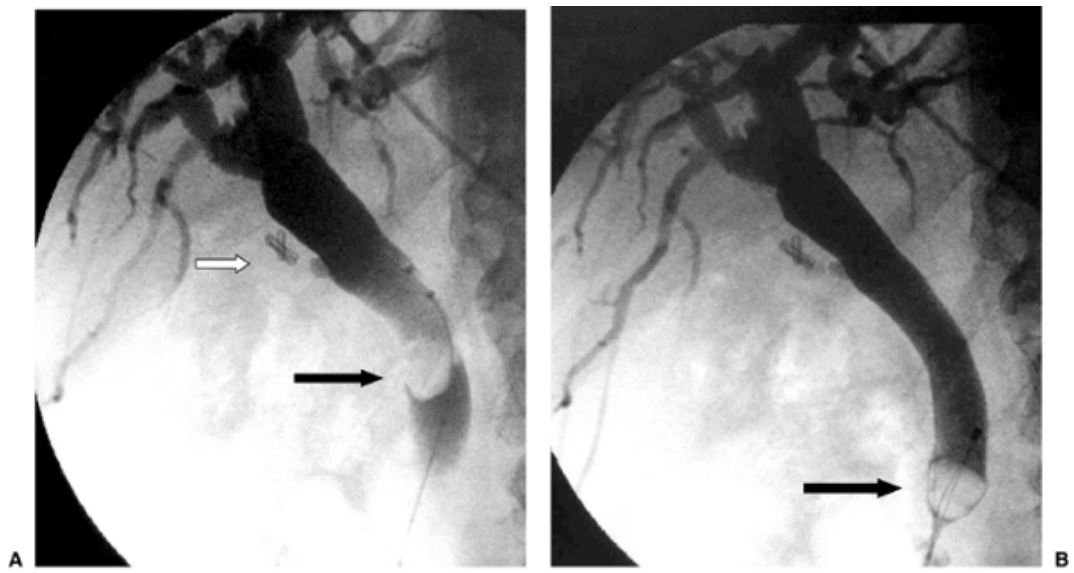
Management of Gallstones

Management of gallstones is guided by the natural history of the disease (Figs. 22.7 and 22.11) (2). Because

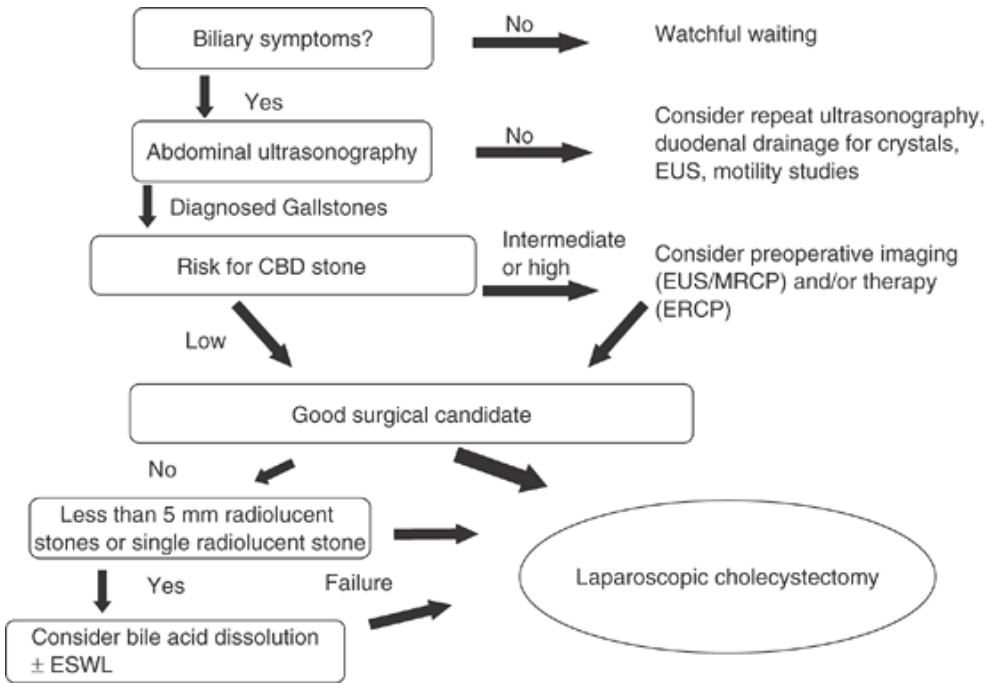
most stones are asymptomatic and will remain so indefinitely, the principal means of dealing with gallstones is expectant management, as supported by

decision analysis (198). However, the identification of patients with symptomatic stones rests on the clinical history rather than any diagnostic test. Patients with symptomatic stones, including biliary colic, should be offered therapy. Given the low likelihood of complications in patients with just pain, treatment is nonurgent (199). The mainstay of gallstone treatment is cholecystectomy. Removal of the gallbladder with the stones will cure the disease and prevent recurrence. In

circumstances in which surgery is too risky or rejected by the patient, alternative therapeutic options may be considered. Once a complication has occurred, the stones should be dealt with promptly.



▪ **Figure 22.10 A:** Endoscopic retrograde cholangiopancreatography of common bile duct stone (*black arrow*) identified after cholecystectomy (*white arrow* identifies surgical clips on the cystic duct). **B:** Endoscopic placement of a basket (*black arrow*) allows extraction of the stone.



▪ **Figure 22.11** Approach to diagnosis and treatment of gallstones. Details of management of complications of gallstones are described in the text. CBD, common bile duct; EUS, endoscopic ultrasonography; MRCP, magnetic resonance cholangiopancreatography; ERCP, endoscopic retrograde cholangiopancreatography; ESWL, extracorporeal shock wave lithotripsy.

Patients with classic symptoms of severe right–upper quadrant or epigastric pain are most likely to gain relief with cholecystectomy (161,162). The conditions of those with nonspecific symptoms such as dyspepsia, bloating, or flatulence are unlikely to be improved with cholecystectomy (200).

Surgical Treatment of Gallbladder Stones

The standard treatment for gallstones since 1892 has been cholecystectomy. Removal of the gallbladder under elective circumstances is associated with very low morbidity and mortality (201,202). In the early 1990s, the field underwent a revolution, when the conventional procedure was replaced by laparoscopic cholecystectomy. First introduced in 1987, the laparoscopic approach reduced postoperative pain, allowing patients to be discharged within 1 to 2 days of surgery and rapidly return to their normal activities (203). Less than 5% of laparoscopic cholecystectomies are converted to open procedures in the operating room because of excessive inflammation, adhesions, unexpected findings, or anatomic variations (204,205). Laparoscopic cholecystectomy is associated with a decreased risk of mortality, cardiopulmonary complications, and wound infections, but an increased risk of bile duct injuries (204,206). Initially believed to be part of the learning curve, it has become evident that the rate of bile duct injury remains between 0.2% and 0.5%, even in the most experienced hands (207). Because the advent of laparoscopy has also increased the rate of cholecystectomies performed by 20% to 30% (208), bile duct injuries are not an uncommon complication seen by gastroenterologists or hepatologists.

The most common immediate problem is bile leak, often manifested by postoperative pain and fever, and is treated easily by prompt endoscopy (209). At ERCP a stent is placed with or without sphincterotomy to decrease outflow resistance and enable spontaneous closure of the leak, usually within a few days. Late complications may be more severe and usually result from bile duct stricturing. Patients may develop asymptomatic cholestasis or jaundice and cholangitis with a risk of secondary biliary cirrhosis if untreated. Endoscopic treatment with balloon dilatation and stent placement is usually effective (210), but specialized surgical repair may be required, particularly in proximal injuries. Although most bile duct injuries are treated efficiently by endoscopy or surgery, they were shown to have a negative effect on overall patient survival (211). Intraoperative cholangiography has been suggested to reduce the risk of bile duct injury, with variable results (211,212). Minilaparotomy has been advocated by some to reduce the risks while retaining the benefits of laparoscopic surgery (213).

Timing of surgery in the context of acute cholecystitis has been debated. It was thought that surgery would increase surgical mortality during the acute episode and should, therefore, be deferred to 6 to 8 weeks after recovery from the event. However, when studied prospectively, it appeared that early cholecystectomy within days of presentation is actually associated with less morbidity and mortality and can also be performed safely through laparoscopy (214). Prompt cholecystectomy is particularly indicated in patients with diabetes and elderly patients, who are more likely to develop serious complications from the acute episode. Patients with acute cholecystitis who are too unstable to tolerate general anesthesia and full cholecystectomy will improve if the gallbladder is decompressed by way of a percutaneous or surgical cholecystostomy (215).

Removal of the gallbladder typically does not alter digestive function measurably. Approximately 5% of patients will experience increased stool frequency or diarrhea postcholecystectomy, possibly related to increased enterohepatic cycling of the bile salt pool (216). Administration of bile acid binding resins such as cholestyramine is often sufficient to control diarrhea, which usually improves over time (217). Recently, some concern has been raised about an increased risk of intestinal cancer after cholecystectomy (218,219). At most, the risk is only modestly elevated, predominantly in women (220).

Nonsurgical Treatment of Gallbladder Stones

Despite the efficient removal of gallbladder stones by surgery, approximately 20% of patients continue to suffer from pain after cholecystectomy (221). Moreover, because nonsurgical expectant management carries a low risk of complications, it can be a reasonable option for mildly symptomatic patients (222).

Oral bile acids can dissolve cholesterol gallstones (223,224). Initial efforts employed chenodeoxycholic acid (chenodiol), a primary bile acid of humans. Chenodiol is a strong detergent whose primary mechanism of action is enhancing the micellar lipid solubilizing capacity of bile. Side effects related to its detergency included diarrhea and hepatocellular injury. Subsequently ursodeoxycholic acid (UDCA), a primary bile acid of bears and normally present only in minute amounts in human bile, was found to have equal efficacy for gallstone dissolution, with virtually no toxicity. UDCA also reduces biliary cholesterol secretion, mainly through its inhibitory effect on intestinal cholesterol absorption (225). Although UDCA is not

a good detergent in allowing true cholesterol solubilization, cholesterol is effectively dispersed in bile as vesicles, thereby preventing and reversing cholesterol crystallization (226).

The main limitation of oral dissolution therapy is that its efficacy is limited to a fraction of patients with cholesterol stones (15% or less) (227). Only small cholesterol stones (preferably <5 mm in diameter) in a functioning gallbladder are amenable to bile acid dissolution. The OCG is the best tool for diagnostic evaluation and patient selection. Small stones that form a floating layer in the gallbladder are composed of almost pure cholesterol and have approximately a 75% likelihood of dissolution (228). If OCG is unavailable, CT scan can be used to select stones that have high cholesterol content (isodense with bile or less than 100 Hounsfield units), whereas gallbladder function may be verified by ultrasonography (before and after gallbladder stimulation) or radionuclide scanning.

Desaturation of bile is obtained with UDCA at a dose of 8 to 12 mg/kg per day. The entire dose may be given at bedtime to optimize desaturation of bile during sleep. Treatment typically requires between 12 and 24 months and should be continued 6 months beyond successful dissolution. Response should be assessed after 6 months, and treatment of nonresponders, that is, those with no decrease in gallstone size, should be discontinued because of the high likelihood of further failure. After successful dissolution, gallstones recur in approximately 50% of individuals over a period of 5 to 10 years (229).

Oral gallstone dissolution therapy is a reasonable option only for symptomatic patients with gallbladder sludge or small cholesterol stones that have not caused complications. UDCA therapy has been associated with a reduction in the occurrence of biliary colic in asymptomatic and symptomatic patients (230). Dissolution of cholesterol crystals within biliary sludge has been suggested as a possible mechanism for this effect. Other oral agents, such as monoterpenes, or HMG-CoA reductase inhibitors, have limited efficacy, mainly in combination with UDCA (231). Recently, fatty acid bile acid conjugates have been shown to dissolve cholesterol gallstones in an animal model (232). These and other comparable agents may prove useful in humans.

A complementary nonsurgical option is extracorporeal shock wave lithotripsy (ESWL) (233), which is actually an extension of oral gallstone dissolution therapy. By fragmenting stones with external shock waves by the same principles as urinary lithotripsy, larger cholesterol stones can be brought into the size range (<5 mm in diameter) ideal for bile acid dissolution. Some fragments are expelled from the gallbladder even without dissolution. ESWL works best with solitary cholesterol gallstones smaller than 2 cm in diameter. The major complications of ESWL are biliary colic and acute pancreatitis resulting from expulsion of gallstone fragments. Because of the inclusion limitations (larger single cholesterol stones in a functioning gallbladder), only 16% of symptomatic patients with gallstones are candidates for this form of therapy (227). The recurrence rate (around 30% within 5 years) seems to be somewhat lower than that with dissolution therapy alone (234). ESWL has been approved for general use in the United States but has been used more frequently in Europe.

A third nonsurgical option employs detergents or organic solvents instilled directly into the gallbladder. Methyl-*t*-butyl ether (MTBE) has been instilled through a percutaneously placed transhepatic catheter curled in the fundus of the

gallbladder to achieve dissolution of cholesterol gallstones within hours in more than 90% of cases (235). The major risks of the procedure are hemorrhage after liver puncture, persistent bile fistula, or inadvertent spilling of solvent into the duodenum (leading to nausea and vomiting) or blood (leading to renal failure or death) (235). Because of the relative invasiveness and high recurrence rate, contact solvent dissolution is performed in only a handful of centers worldwide.

Treatment of Bile Duct Stones

Gallstones in the CBD may be identified preoperatively or postoperatively when imaging is indicated by symptomatology or at the time of surgery through intraoperative cholangiography or cholangioscopy. They should be treated for the reasons mentioned earlier. CBD stones were traditionally removed by opening and exploring the CBD at the time of cholecystectomy, after which a T tube is left in place for 3 to 7 days to facilitate healing. Open common duct exploration prolongs surgery and convalescence and increases surgical morbidity and mortality substantially, whereas laparoscopic bile duct exploration although feasible is technically demanding and performed only in a minority of centers (236,237). Hence, endoscopic management is preferred in most clinical situations.

Endoscopic treatment is usually done under conscious sedation as an outpatient procedure (238). During ERCP the papilla is cannulated and stones are extracted with a balloon or a Dormia basket (Fig. 22.9). A sphincterotomy is usually performed to facilitate stone removal, although for small stones this may be unnecessary or substituted by sphincteroplasty (transient balloon dilatation) to conserve sphincter function (239). Endoscopic sphincterotomy is associated with a 5% to 10% risk of complications such as pancreatitis, hemorrhage, or perforation and occasional late stenosis (240). Conventional ERCP is successful in removing most (>85%) CBD stones. Large (>18 mm in diameter) stones may require fragmentation before removal. This is routinely done by a mechanical lithotriptor

through the endoscope. More sophisticated tools, such as contact lithotripsy by pulse laser or shock waves or ESWL, increase the success rate to approximately 90% (241). Temporary or long-term endoscopic stenting may be offered for difficult cases or in high-risk patients. Urgent endoscopic drainage is the treatment of choice and is often lifesaving for patients with ascending bacterial cholangitis (242).

Since the advent of laparoscopic cholecystectomy, the timing and means of treating concomitant gallbladder and bile duct stones have been debated extensively (243). Theoretically, there are several possible advantages of the laparoscopic one-stage procedure, but this is often unavailable and there are no concrete data to support the advantages (244). Therefore, choledocholithiasis is usually treated endoscopically to avoid open surgery and the associated morbidity (245). However, extensive use of preoperative ERCP may lead to unnecessary endoscopies and cases of pancreatitis, whereas postoperative ERCP may fail and require reoperation. Intraoperative ERCP is possible, but usually impractical. A reasonable strategy is for patients with a high risk of choledocholithiasis to undergo preoperative ERCP while those with moderate risk can have intraoperative cholangiography and laparoscopic CBD exploration (246). Although the approach should be based on local expertise and preferences, most centers perform a preoperative ERCP when the likelihood of choledocholithiasis is high. A

dilated CBD with a stone seen on ultrasonography, persistent jaundice, and elevated alkaline phosphatase levels are good predictors of choledocholithiasis (247,248). In less clear cases, MRCP and EUS can be used to guide therapeutic decisions. A recent decision analysis in patients with acute biliary pancreatitis found MRCP and EUS to be most useful for patients with an intermediate probability of choledocholithiasis (249). When the likelihood of choledocholithiasis is low, preoperative ERCP is best avoided (250). When unexpected choledocholithiasis is revealed intraoperatively, a transpapillary guidewire, catheter, or endoprosthesis may be left in place by the surgeon to increase the postoperative success rate of ERCP (251). Occasionally, small stones will pass spontaneously and uneventfully, rendering ERCP unnecessary (252).

Percutaneous transhepatic cholangiography (PTC) has limited use in the diagnosis or management of gallstones, except as rescue therapy for patients with choledocholithiasis in whom ERCP has failed. PTC provides effective biliary drainage in the setting of acute cholangitis and enables subsequent successful ERCP by the combined percutaneous and endoscopic approaches (253). A guidewire is introduced percutaneously through the bile ducts into the duodenum and is used to cannulate the bile duct to facilitate sphincterotomy and stone extraction by standard means. If ERCP is unavailable, the more invasive transhepatic route may be used for stone extraction.

If patients are at high surgical risks and stones in the common duct can be cleared by endoscopy, it may be reasonable to defer cholecystectomy. Several retrospective and prospective nonrandomized studies have shown that less than 15% of patients develop biliary complications during follow-up (254). Patients with a patent cystic duct at surgery seem to fare particularly well (255). However, a more recent prospective randomized trial has shown that up to 47% of patients may develop biliary symptoms (256). Therefore, whenever possible, surgery should be considered the definitive therapy to minimize recurrent biliary symptoms (257).

Treatment of Microlithiasis

Patients with microlithiasis or biliary sludge comprise a special subgroup of patients who may also develop attacks of biliary pain, acute pancreatitis (152), or cholecystitis (55). Microlithiasis is believed to represent an early stage of gallstone disease because, when left untreated, approximately 8% will develop overt gallstones (150). Most often, the sludge will disappear spontaneously, particularly in circumstances of transient lithogenicity such as pregnancy, parenteral nutrition, or rapid weight loss (101,258). Persistent microlithiasis can be treated by oral bile acid therapy, although significant symptoms and complications should be treated by cholecystectomy or endoscopic sphincterotomy, similar to the approach for macroscopic stones (55).

Prevention of Gallstones

Because of the high prevalence of gallstones and the high costs involved in their management, the ultimate approach should be prevention. Unfortunately, most attempts to effectively prevent gallstone formation in the general population have failed. The increased recognition of risk factors for gallstone formation has unfortunately not resulted in better means of prevention. Despite recommendations for low-fat, low-calorie diets and moderate alcohol intake with regular physical activity, the prevalence of gallstones has not declined.

There are, however, some high-risk situations in which prevention is possible. During rapid weight loss, in particular, after bariatric surgery, prophylactic administration of UDCA will reduce the likelihood of gallstone formation from approximately 30% to almost nil (108). In patients receiving TPN, the administration of CCK (259) or early limited enteral feeding to induce gallbladder contraction may prevent the formation of biliary sludge and stones. More widespread preventive measures will hopefully be available as our understanding of the pathophysiology of gallstones progresses and more effective therapeutic agents are discovered.

Chapter 23
Primary Sclerosing Cholangitis

Konstantinos N. Lazaridis

Nicholas F. Larusso

Key Concepts

- Primary sclerosing cholangitis (PSC) is a progressive, cholestatic liver disease that is characterized by diffuse chronic inflammation and fibrosis of the biliary tree.
- PSC affects primarily young to middle-aged men and frequently is associated with inflammatory bowel disease (IBD), most often chronic ulcerative colitis (CUC).
- The cause of PSC remains unknown, although the interaction of exogenous factors with the genetically predisposed individual is likely critical in disease pathogenesis.
- Cholangiocarcinoma is the most feared complication of PSC; however, colon cancer complicating CUC in a patient with PSC is important as well.
- The prognosis of PSC is variable, but in general the disease process is progressive.
- To date, no medical therapy is available benefit although a variety of pharmacologic agents have been tested; nevertheless, high-dose ursodeoxycholic acid deserves further study in the context of randomized controlled trials.
- Liver transplantation is the best available treatment option for patients with advanced PSC; however, the disease can recur in 20% of recipients after successful transplantation.

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease of unknown causation that is frequently associated with inflammatory bowel disease (IBD). The disorder is characterized by diffuse inflammation and fibrosis of the biliary tree and usually leads to biliary cirrhosis, which can be complicated by portal hypertension and hepatic failure.

PSC was first described by Delbet in 1924 (1). Before the widespread availability of endoscopic retrograde cholangiopancreatography (ERCP) in mid-1970s, PSC was considered a rare disease (2). At present, PSC is seen as an important cause of chronic cholestasis in adults. However, it is still unclear whether the prevalence of the disease has increased in recent decades. The greater availability of ERCP and magnetic resonance cholangiopancreatography (MRCP) as well as the recognized association of PSC with IBD along with screening of these

patients with liver tests have probably enhanced the frequency of PSC diagnosis. To date, we have better understanding of the natural course of PSC, although the cause and identification of specific beneficial therapies have eluded investigators so far.

Epidemiology

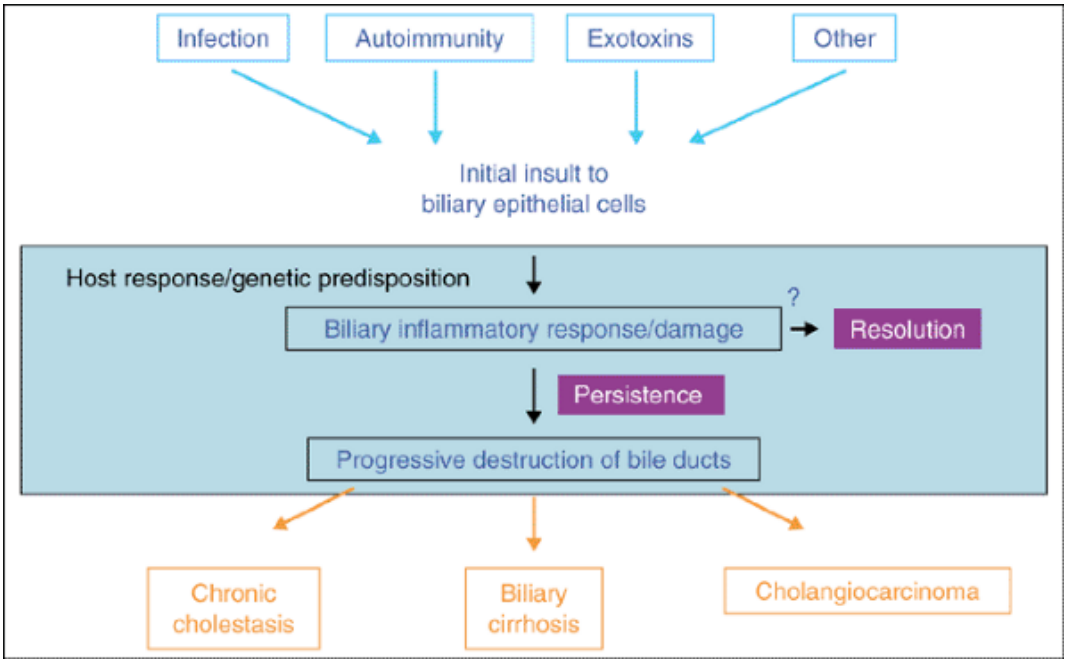
Two recent epidemiologic studies from the United States and United Kingdom described the incidence and prevalence of PSC in the community setting. The first study from Olmsted county, Minnesota, estimated the age-adjusted incidence of PSC to be 0.9 per 100,000 individuals with point prevalence of 13.6 per 100,000 persons in 2000 (3). Specifically, the age-adjusted incidence was 1.25 and 0.54 per 100,000 men and women, respectively (3). The estimated prevalence was 20.9 per 100,000 for men and 6.3 per 100,000 women (3). On the basis of this study, it was projected that

approximately 29,000 cases of PSC exist in the white USA population. Moreover, the median age at PSC diagnosis was 40 years, 68% (15 of 22) of the patients were men and 73% (16 of 22) of the patients had concurrent IBD (3).

The second study from the city and county of Swansea, Wales, UK reported an annual incidence of 0.91 per 100,000 and a point prevalence of 12.7 per 100,000 individuals (July 1, 2003) (4). The median age at PSC onset was 52 years, 62% (33 of 53) of the patients were men, and 62% (33 of 53) of the patients had coexisting IBD (4). Although these two studies have shed light on the epidemiology of the disease, additional population-based studies are required to better define the prevalence and natural history of PSC, a chronic cholestatic liver disease that leads not only to hepatic failure but also predisposes to malignancies of the colon and liver.

Pathogenesis

To date, the exact pathogenesis of PSC remains unknown, although a number of avenues have been explored over the past three decades. A consensus pathogenesis postulates that PSC develops as the result of acquired exotoxins, infectious agents or autoimmunity interacting with predisposing host factors (Fig. 23.1). It is proposed that this interplay leads to an initial damage of cholangiocyte, the target epithelial cell that lines the bile ducts. Subsequently, a biliary inflammatory response takes place but most individuals likely recover (i.e., resolution) without consequences. However, it is the genetic predisposition of the host and probably other unknown mechanisms that contribute to persistance of inflammation of the bile ducts resulting in progressive biliary destruction and complications of PSC such as chronic cholestasis, biliary cirrhosis, and cholangiocarcinoma (Fig. 23.1).



▪ **Figure 23.1** Proposed pathogenesis of primary sclerosing cholangitis.

Genetic Factors

Several observations are consistent with an important role for genetic factors. First, familial PSC cases have been reported (5). Second, a recent report indicated the increased prevalence of PSC among first-degree relatives of patients who are affected (6). These authors calculated an almost 100-fold relative risk of developing PSC in families with an affected member, thereby supporting the presence of inherited elements in disease pathogenesis. In addition, several case control studies have demonstrated the genetic predisposition to PSC development by identifying genetic variants associated with patients compared to controls. To this extent, Chapman first reported the HLA B8 frequency to be significantly higher in patients with PSC (60%) compared with controls (25%) ($P < 0.001$) (7). Subsequently, Donaldson demonstrated an association of PSC with the HLA-A1, B8, DR3 haplotype (40% in cases vs. 12% in controls, $P < 0.0005$) (8).

Moreover, in the past 5 years, genetic polymorphisms (i.e., DNA variants) associated with susceptibility to PSC have been reported including (i) the promoter region of the tumor necrosis factor-α (TNF-α) receptor (9); (ii) stromelysin (i.e., matrix metalloproteinase 3) (10); (iii) major histocompatibility complex class I related-MIC gene family (MICA) gene (i.e.,

MICA) (11); (iv) CCR5-Delta 32 mutation (12); and (v) intracellular adhesion molecule-1 ICAM-1 (i.e., intracellular adhesion molecule-1) (13) (Table 23.1). From a theoretical standpoint, the variety of susceptible genes interacting with environmental factors likely explain the heterogeneity of PSC phenotype as this relates to disease development, progression and complications. It is expected that many genetic variants (i.e., susceptible alleles) predispose to disease, each contributing a small effect on the PSC phenotype. To this end, large association

(i.e., case-control) and familial studies are needed to better dissect the genetic susceptibility of PSC before we develop novel diagnostic tools and intervening therapies.

Table 23.1. Susceptibility Genes in Primary Sclerosing Cholangitis

Gene	Type	Variation	Reference
TNF-α	Cytokine	G/A, substitution	(9)
Stromelysin	Matrix metalloproteinase	5A/6A alleles	(10)
MICA	MHC molecule	*002/*008 alleles	(11)
CCR5-Delta 32	Chemokine	32 base pair deletion	(12)
ICAM-1	Adhesion molecule	K469E	13

TNF-α, tumor necrosis factor α; MICA, major histocompatibility complex class I related-MIC gene family; MHC, major histocompatibility complex; CCR5-Delta 32, chemokine, CC motif receptor 5; ICAM-1, intracellular adhesion molecule-1.

Other Proposed Hypotheses of Primary Sclerosing Cholangitis Pathogenesis

Because of the finding that IBD coexists in approximately 75% of patients with PSC, much interest has been paid to the potential role of an inflamed colon in causing the liver disease (14). For long it was believed that inflammation of the colon may increase the colonic permeability to various intraluminal products leading to liver injury. To this extent, bacteria or bacterial toxins have been considered but have not been convincingly demonstrated to play a pathogenetic role in PSC (15,16). In addition, abnormal bile acids generated by bacterial action in the diseased colon and directly absorbed through the colonic mucosa into the portal system have been suggested as a possible etiology of PSC. Nevertheless, no direct evidence in support of this theory has been forthcoming (17).

In an animal model, inflammatory bacterial peptides led to portal inflammation and histologic changes suggestive of PSC (18,19). In this model, a variety of agents were useful in blocking this response, including an inhibitor of tumor necrosis factor (TNF). However, when pentoxifylline, a TNF inhibitor, was used in patients with PSC, no beneficial effect was found, and doubt was cast on the value of this model in understanding the disease in humans (20). Furthermore,

the finding that PSC can develop in approximately 25% of patients without concurrent IBD, the lack of association between the severity of the colonic inflammation and the likelihood of PSC development and the fact that proctocolectomy for chronic ulcerative colitis (CUC) does not affect the natural history of PSC (21) speak against an essential role of the inflamed colon in development of the cholestatic liver disease.

At present, there is no convincing evidence of a virus or other microorganism causing PSC. The usual hepatotrophic viruses (i.e., hepatitis A virus [HAV], hepatitis B virus [HBV], and hepatitis C virus [HCV]) have been excluded. Cytomegalovirus can produce changes suggestive of PSC in patients with acquired immunodeficiency states, but in patients with competent immune function, no evidence of cytomegalovirus infection has been found (22). Reovirus type 3 was considered a possible causative agent but further work excluded it as an etiology for PSC (23).

Table 23.2. Diseases Associated with Primary Sclerosing Cholangitis

Inflammatory bowel disease
Autoimmune hepatitis
Chronic pancreatitis
Celiac disease
Rheumatoid arthritis
Retroperitoneal fibrosis
Peyronie's disease
Riedel's thyroiditis
Bronchiectasis
Sjögren's disease
Glomerulonephritis
Systemic lupus erythematosus
Pseudotumor of the orbit
Vasculitis
Autoimmune hemolytic anemia
Immune thrombocytopenic purpura
Angioimmunoblastic lymphadenopathy
Histiocytosis X
Cystic fibrosis
Sarcoidosis
Systemic mastocytosis
Polymyositis
Alopecia universalis
Thymoma
Ankylosing spondylitis

Immune-mediated damage of bile ducts seems a plausible mechanism leading to PSC. Abnormalities of the humoral immune system in PSC include the presence of (i) hypergammaglobulinemia, particularly elevated immunoglobulin M levels, (ii) circulating immune complexes; and (iii) activated complement (24). Moreover, patients with PSC have serum positivity for several auto-antibodies including antineutrophil cytoplasmic antibodies (ANCA), anticardiolipin antibodies and

antinuclear antibodies (53%) (25). In addition, the cellular immune system in PSC can be abnormal as indicated by the decrease in the total number of circulating T cells caused due to a decline in CD8 (suppressor/cytotoxic cells) and an increase in circulating B-cells. On the other hand, the documented aberrant expression of HLA class II antigens on the biliary epithelial cells may serve to target an immune response against the biliary cells; (26,27) Although the presence of ICAM-1, which serves as a ligand for the leukocyte function-associated antigen (LFA-1), may help form connections between T-lymphocytes and antigen-presenting cells. Indeed, increased levels of ICAM-1 have been found in both the bile duct epithelial cells and serum (27,28,29). LFA-1 also appears to be overexpressed by intrahepatic lymphocytes, but this expression may simply be induced by proinflammatory cytokines (30). Despite all these observations, the documented altered immune status may simply be an epiphenomenon and yet not linked directly to PSC pathogenesis.

Clinical Features

PSC affects men almost twice as commonly as it does women and the average age at diagnosis is the early 40s (3). In the past two decades, a frequent clinical scenario of diagnosis includes patients who are asymptomatic and come to medical attention solely because of abnormal liver tests. Contrary symptoms of advanced stages of PSC such as jaundice, pruritus, fever, or manifestations of portal hypertension are less common as initial presentation. Physical examination may be unrevealing. Hepatomegaly, splenomegaly, hyperpigmentation, and skin excoriation can be found. Health-related quality of life is significantly impaired among patients with PSC similar to that found in other chronic liver diseases, such as primary biliary cirrhosis (PBC) and chronic viral hepatitis. (31,32).

PSC usually affects the entire biliary tree. Approximately 20% of patients have involvement of the intrahepatic bile ducts alone and approximately 5% of patients have disease involving the interlobular and septal bile ducts (i.e., *small-duct PSC*) seen only in liver biopsy specimens while ERCP is normal (33,34,35,36). Another clinical entity is the *overlap syndrome* in which PSC and autoimmune hepatitis coexist and occurs in approximately 5% of patients (33,34,35).

PSC afflicts children rarely (37). In this population, the disease seems to have more frequent features of autoimmune hepatitis (38,39).

Laboratory Findings

Biochemical Testing

The biochemical findings of patients with PSC are nonspecific. Neverthelesss, chronic biochemical cholestasis is apparent. Alkaline phosphatase is the most commonly elevated liver enzyme; however, the occasional patient with well-documented PSC but normal alkaline phosphatase levels has been described (40). Aminotransferase levels frequently are elevated and the degree of elevation is usually only modest except in patients with *overlap syndrome* in whom these levels could be markedly increased. Serum bilirubin is typically normal but in patients with advanced disease can reach very high levels.

Immunologic Testing

Overall, there are no immunologic or autoantibody profiles specific for PSC.

Hypergammaglobulinemia occurs in approximately 25% of patients with PSC and immunoglobulin M is the most commonly elevated component. PSC patients have serum positivity for several auto-antibodies including ANCA (84%), anticardialipin antibodies (66%) and antinuclear antibodies (53%) (25). Antimitochondrial antibodies are rare in patients with PSC.

Imaging Studies

Visualization of the biliary tree is essential for establishing the diagnosis of PSC. ERCP has been the diagnostic procedure of choice, although MRCP is almost equally sensitive and specific for detection of the disease. Additionally, MRCP is more cost-effective for establishing the diagnosis in patients with suspected PSC (41,42,43). Percutaneous transhepatic cholangiogram (PTC) can be used to evaluate the bile ducts for PSC but because of the frequently sclerotic intrahepatic biliary system gaining access through the percutaneous route could be challenging.

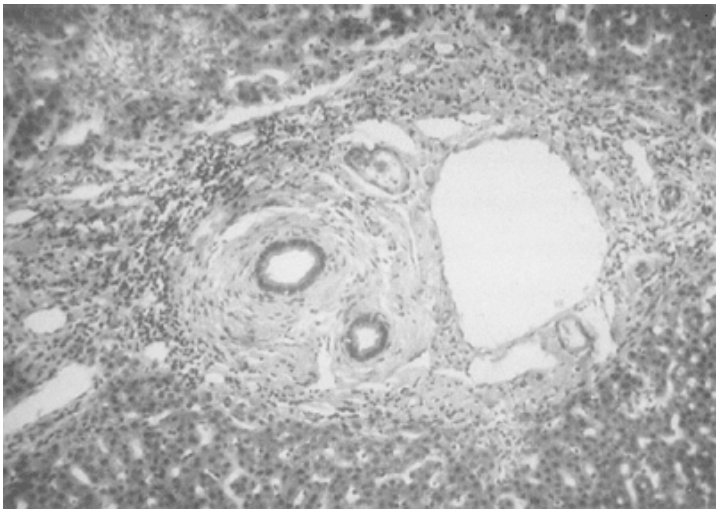
Typical cholangiographic findings of PSC include multifocal stricturing and beading, usually involving both the intrahepatic and extrahepatic biliary system (Fig. 23.2). Involvement of the intrahepatic tree alone can be found in as many as 20% of patients (44,45). Often the strictures are diffusely distributed, short

in length and annular. Cystic duct and gallbladder involvement are present in as many as 15% of patients (46). During cholangiography, the presence of polypoid masses should raise the suspicion of cholangiocarcinoma, although the diagnosis of the latter can be very difficult to establish.

▪ **Figure 23.2** ERCP of a patient with primary sclerosing cholangitis. Extensive extrahepatic and intrahepatic biliary disease is evident.

Histology

Liver biopsy findings are usually not enough to establish the diagnosis of PSC. The classic *onion-skin* fibrosis is present in fewer than 10% of biopsy specimens obtained from patients with PSC, but when seen is almost pathognomonic (Fig. 23.3) (47). The histologic grading system, proposed by Ludwig et al. (47), has four stages: Stage 1, portal; stage 2, periportal; stage 3, septal; and stage 4, cirrhosis (Table 23.3). Of interest, in patients with PSC, the histologic changes seem to be quite varied in different segments of the same liver at any given point in time. To this end, histologic staging has been avoided as a component of the most recent survival model of PSC (48).



▪ **Figure 23.3** The "onion-skin fibrosis" lesion is characteristic of primary sclerosing cholangitis but is not typically found in liver biopsy specimens from patients.

Table 23.3. Histologic Staging of Primary Sclerosing Cholangitis

Portal stage (stage 1)	Portal edema, inflammation, ductal proliferation; abnormalities do not extend beyond the limiting plate.
Periportal stage (stage 2)	Periportal fibrosis, inflammation with or without ductular proliferation; piecemeal necrosis may be present.
Septal stage (stage 3)	Septal fibrosis or bridging necrosis can be identified.
Cirrhotic stage	Biliary cirrhosis.

(stage 4)	

Diagnostic Criteria and Differential Diagnosis

The diagnostic criteria for PSC were first formulated nearly 40 years ago (49). These criteria included (i) absence of previous surgical trauma to the biliary tree; (ii) lack of stones in the gallbladder and common bile duct; (iii) stenosis/stricturing involving most of the biliary system; and (iv) exclusion of biliary malignant disease. Because of the advent of ERCP in the mid-1970s, the diagnosis can be made without surgery. More recently, the availability of MRCP as a screening test for patients with suspected PSC made noninvasive diagnosis possible (41,42,43).

At present, the diagnostic criteria for PSC include (i) typical cholangiographic abnormalities involving any part of the biliary tree; (ii) compatible clinical and biochemical findings (i.e., cholestasis for more than 6 months); and (iii) exclusion of other causes of secondary sclerosing cholangitis (Table 23.4). Liver biopsy has been used in the past to help confirm the diagnosis, although the specificity and sensitivity of the biopsy have come under question. Histologic findings are not always found of value in the most recently developed prognostic scoring systems for patients with PSC (48,50,51,52). However, liver biopsy is useful in the care of a patient with suspected PSC but normal cholangiographic findings (i.e., *small-duct PSC*) and in the setting of a patient with *overlap syndrome*. The differential diagnosis of PSC is outlined in Table 23.4.

Table 23.4. Diagnostic Criteria for Primary Sclerosing Cholangitis

Typical cholangiographic abnormalities involving any part of the biliary tree
Compatible clinical (cholestatic symptoms, history of inflammatory bowel disease) and biochemical findings (twofold to threefold increase in serum alkaline phosphatase level for longer than 6 m)
Exclusion of identifiable causes of secondary sclerosing cholangitis:
AIDS cholangiopathy
Bile duct neoplasm (unless diagnosis of PSC previously established)
Biliary tract surgery, trauma

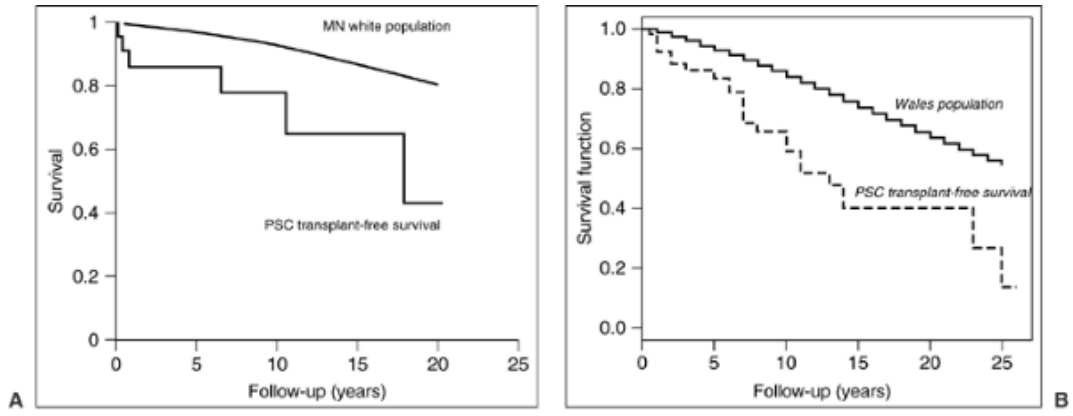
Choledocholithiasis Congenital abnormalities of biliary tract Caustic sclerosing cholangitis Ischemic stricturing of bile ducts Toxicity or stricturing of bile ducts related to intra-arterial infusion of floxuridine

AIDS, acquired immunodeficiency syndrome, PSC, primary sclerosing cholangitis.

Natural History

PSC is usually a progressive disease. In a retrospective study with 174 patients with PSC from the United States, the median survival rate from the time of diagnosis was approximately 12 years, which was less than that for an age-matched population (53). In another study from Norway, investigators estimated the median survival time of patients with PSC to be 17 years (51,54).

Recent population-based epidemiologic data also reported that PSC is a progressive disease and shortens life expectancy. Indeed, studies from Olmsted county, Minnesota, USA and Swansea county, Wales, UK that the liver transplantation free-survival was 65% at 10 years after the diagnosis of PSC and significantly less than the age- and sex-matched populations (Fig. 23.4) (3,4) This information further suggests that PSC is a progressive disease, and if suitable therapy were available, treatment early in the course of the disease would seem warranted.



▪ **Figure 23.4** Transplant-free survival of Olmsted, Minnesota, USA **(A)** and Swansea, Wales, UK **(B)** patients with primary sclerosing cholangitis compared with age- and sex-mathed population controls from the corresponding counties. PSC, primary sclerosing cholangitis. (Reprinted with permission from Bambha, et al. *Gastroenterology* 2003;125:1364–1369; and

Kingham, et al. *Gastroenterology* 2004;126:1929–30.)

Given the natural history studies, prognostic models have been developed to more accurately forecast an individual patient's disease progression, and thereby, define the best timing for liver transplantation. Using the Cox multivariable regression analysis the variables for these prognostic models were detected (48,50,51,52). To this end, the revised Mayo PSC natural history model employs five independent and reproducible parameters (i.e., age, total bilirubin, albumin, aspartate aminotransferase, and history of variceal bleeding) to estimate the survival of patients (48). Recently, the Model of End-stage Liver Disease (MELD) score has been widely used to prioritize PSC patients with end-stage liver disease before undergoing liver transplantation (55).

The natural history of patients with *small-duct* PSC is usually better compared to those suffering from classic PSC (56). Nevertheless, in some patients with *small-duct* PSC the disease can progress to classic PSC with typical cholangiographic features if these cases are followed up for several years (56). Finally, secondary sclerosing cholangitis has worse outcome compared to PSC (57). Finally, PSC predisposes to development of colon cancer and cholangiocarcinoma (see subsequent text). Indeed, patients with PSC and CUC have a significantly greater risk of developing colon cancer compared with patients having CUC only (58). Therefore, patients with PSC should undergo surveillance colonoscopies annually.

Associated Diseases

A variety of diseases aside from IBD have been associated with PSC (Table 23.2). It is unclear however, whether these associations are true, and therefore share a pathogenetic mechanism, or occur by chance and represent the reporting of two uncommon diseases.

The close association of PSC with IBD, particularly CUC, is now widely recognized. This association is found in 70% to 80% of patients with PSC. Crohn's disease has been reported as the cause of colitis in 10% to 15% of patients with PSC (14,59). However, Crohn's disease involving only the small intestine has not yet been described in patients with PSC. There is no clear temporal association between the diagnosis of PSC and IBD, although in general, the diagnosis of the latter is usually established before the liver disease is clinically apparent. Nevertheless, there are well-documented cases of IBD occurring years after the diagnosis of PSC. Similarly, patients can acquire PSC many years after proctocolectomy for colitis (21). In patients with PSC and colitis, the bowel disorder is one of relatively quiescent disease. However, the risk of development of colon cancer in patients with coexisting PSC and CUC seems to be substantially greater than if patients did not have PSC. There has been no association between the severity of bowel disease and the severity of liver disease, and therapy for the bowel disease does not affect the liver disease. Moreover, the most aggressive therapy for the bowel disease, proctocolectomy, has had no effect on PSC (21). Finally, there are no convincing differences in the liver disease of PSC patients with IBD compared to those without the latter.

Management

The complications of PSC can be due to (i) advanced-stage liver disease (i.e., portal hypertension, decompensated cirrhosis, and hepatic failure); (ii) chronic cholestasis; (iii) the underlying disease (i.e., specific for PSC). The management of complications of portal hypertension, decompensated cirrhosis, and hepatic failure is discussed in Chapters 11, 12, and 33. The management of complications related to chronic cholestasis and those specific for PSC are discussed in subsequent text. Chronic cholestasis can lead to pruritus, fat-soluble vitamin deficiency, metabolic bone disease, and steatorrhea. Specific PSC complications include gallstones and choledocholithiasis, dominant biliary strictures, cholangiocarcinoma and peristomal varices.

Table 23.5. Medications Used for the Management of Pruritus

Medication	Dosage
Ursodeoxycholic acid	15–30 mg/kg/d orally
Cholestyramine	4 g three to four times/d orally
Naltrexone	50 mg/d orally
Rifampin	150 to 300 mg two times/d

Management of Complications of Chronic Cholestasis

Pruritus

Although not common, pruritus can be disabling and associated with a diminished quality of life. The pathogenesis of pruritus in cholestasis is unknown, although endogenous opioids and retention of substances usually excreted in the bile have been considered (60,61,62). The intensity of the pruritus does not seem to parallel the severity of the liver disease, and pruritus may diminish as the disease progresses. Ursodeoxycholic acid (UDCA), cholestyramine, antihistamines and rifampin as well as opiate receptor antagonists have been used to treat patients with cholestatic pruritus (63,64). The usual doses of these medications are shown in Table 23.5. It is important to remember that rifampin, which can relieve pruritus in 3 to 5 days, can be associated with a reversible hepatotoxicity in approximately 15% of cases. Therefore, it is important to monitor the liver tests closely if this drug is used.

Fat-soluble vitamin deficiency

Fat-soluble vitamin deficiency is relatively common among patients with PSC, particularly as the patient progresses toward liver transplantation (65). As many as 40% of patients in some series have vitamin A deficiency; vitamin D and vitamin E deficiencies have been found among 14% and 2% of patients respectively (65). Vitamin K deficiency is uncommon. If this condition is suspected, a short trial of 10 mg water-soluble vitamin K can be considered. If

the prothrombin time responds after a few doses, long-term therapy should be recommended. Vitamin E deficiency is rare and unfortunately once established can be very difficult to correct with replacement therapy. The usual fat-soluble doses of vitamin replacement therapy are shown in Table 23.6.

Metabolic bone disease

Metabolic bone disease, usually caused by osteoporosis rather than osteomalacia, is relatively common and an important complication among patients with PSC (66). Glucocorticoids used to treat accompanying IBD aggravate the osteoporosis. Unfortunately, there is no proven therapy that can help these patients. Use of estrogen

replacement therapy by women should be considered. Calcitonin does not appear to be useful to patients with osteoporosis associated with PBC but it has not been tested in the treatment of patients with PSC. Bisphosphonates have been used with varying results to treat patients with PBC but have not been tested in PSC (67,68). Patients with PSC and IBD undergoing long-term glucocorticoid therapy for the latter, may benefit from oral administration of vitamin D and calcium, particularly those with bone density in the range of osteopenia (T score <1) or osteoporosis (T score <2.5).

Table 23.6. Vitamin Replacement Therapy for Primary Sclerosing Cholangitis

Vitamin A	25–50,000 units two to three times per wk, orally
Vitamin D	25–50,000 units two to three times per wk, orally
Vitamin E	100 units/d, orally
Vitamin K	5–10 mg/d, orally

Steatorrhea

Steatorrhea can occur in patients with PSC owing to diminished delivery of bile acids to the intestine either from coexisting chronic pancreatitis or celiac disease. All of these conditions should be considered in the evaluation of patients with steatorrhea in the setting of PSC (69) before treatment is recommended. If steatorrhea in patients with PSC is primary, low fat diet and substitution of medium-chain triglycerides for long-chain ones can improve the steatorrhea.

Management of Specific PSC Complications

Specific complications of PSC include cholelithiasis, choledocholithiasis, dominant biliary stricture along with recurrent cholangitis, cholangiocarcinoma, and peristomal varices in patients with an ileostomy after colectomy for colitis.

Gallstones and choledocholithiasis

Stones involving the gallbladder or bile ducts (i.e., choledocholithiasis) occur in approximately one third of patients with PSC. Chronic cholestasis predisposes to the formation of cholesterol gallstones and bile stasis with bacterial cholangitis leads to the formation of pigment stones of the bile ducts. Patients with PSC and choledocholithiasis may present with acute deterioration of liver tests if the bile duct becomes obstructed. This possibility should be considered if a patient with PSC has evidence of rapidly developing jaundice or bacterial cholangitis. Choledocholithiasis frequently can be treated endoscopically once the diagnosis is made.

Biliary strictures

In the largest series reported to date, dominant biliary stricture(s) occurred in only 7% of patients whose cases were followed up for up to 10 years. These strictures usually are in the extrahepatic biliary system and may be associated with jaundice, pruritus or relapsing bacterial cholangitis. If any of these symptoms occurs in patients with PSC, cholangiography should be considered. Evidence of dominant stricture(s) requires brush cytologic specimens for standard cytology studies as well as fluorescence in situ hybridization (FISH) and digitized image analysis (DIA) to exclude cholangiocarcinoma (see subsequent text). Often, bile duct strictures can be dilated endoscopically with a balloon catheter. Some authors have suggested that short-term biliary stenting is of value in improving the prognosis of liver disease, whereas others have shown that patients with biliary stents are at increased risk of complications (70). Direct surgical intervention for biliary strictures is seldom used and may predispose patients to recurrent bacterial cholangitis, because of the widely patent surgical anastomosis, and make future liver transplantation more technically demanding.

Prophylaxis for bacterial cholangitis should be considered in the care of patients with PSC undergoing biliary manipulation such as diagnostic or therapeutic ERCP. Ciprofloxacin or other broad-spectrum antibiotics are frequently administered both immediately before and for a short period of 1 or 2 days after the procedure because of the high biliary excretion.

Cholangiocarcinoma

Cholangiocarcinoma (CCA) is the most feared complication among patients with PSC. CCA may occur in 7% to 15% of patients with PSC at an annual incidence of 0.5% to 1% (71,72,73,74). Of interest, development of CCA does not correlate with severity of PSC. Chronic inflammation of bile ducts and cholestasis are likely predisposing factors associated with the development of CCA in PSC. Smoking and the presence of IBD have been suggested as predisposing conditions although they remain controversial. The diagnosis of CCA in the patient with PSC can be difficult to establish. The patient may have dominant biliary stricture(s), which is not easy to differentiate between benign and malignant lesion (i.e., CCA).

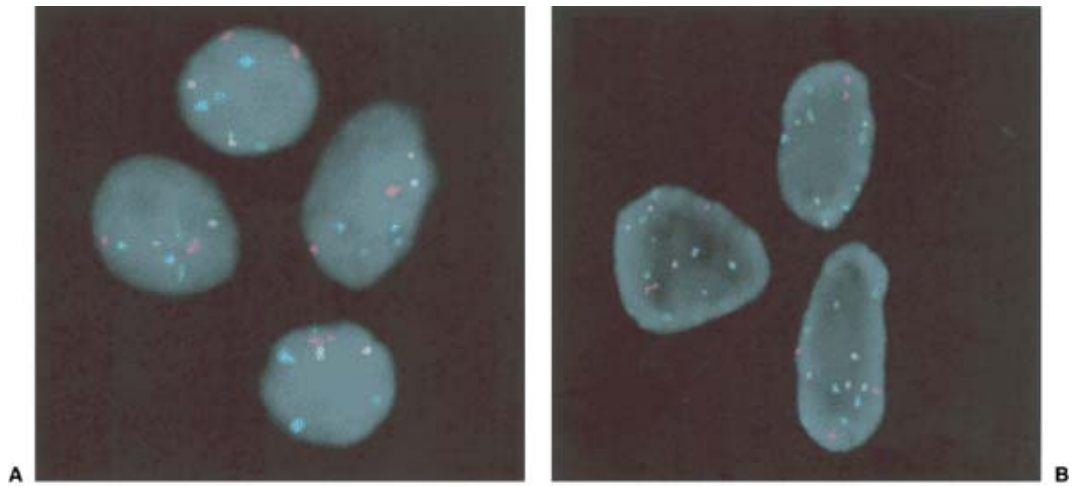
Serum markers for early detection of CCA in PSC have not been helpful. As a screening test, CA 19-9 does not appear to be sensitive enough, and the specificity is limited. For instance, CA 19-9 levels may be elevated due to bacterial cholangitis secondary to benign

strictures therefore limiting the specificity of the test (75,76,77). Nevertheless,

in a patient with PSC, sudden and unexpected clinical deterioration, which is associated with progressive elevation of alkaline phosphatase and serum CA 19-9 (>100 U/mL), in the absence of bacterial cholangitis indicates probable development of CCA.

New diagnostic methods such as DIA and FISH offer promise to evaluate bile duct lesions for cellular aneuploidy and chromosomal aberrations (77). To perform DIA and FISH assays, bile duct brushings are collected at the time of ERCP. DIA allows deoxyribonucleic acid (DNA) content quantificaion, assessment of chromatin distribution and nuclear morphology. In a recent study, DIA was compared to routine brush cytology for cancer detection in suspicious bile duct strictures (78). These authors reported that DIA was significantly more sensitive (39.3%) than standard cytology (17.9%, P = 0.014). Moreover, the accuracy of DIA was comparable to cytology (56% vs. 53%) (78).

The biliary FISH assay uses fluorescently labeled DNA-based probes to detect chromosomal aberrations in brushings of bile duct cells. A FISH assay is declared positive when five or more cells display gains of two or more chromosomes, or ten or more cells demonstrate a gain of a single chromosome (Fig. 23.5) (77). A recent study compared FISH to standard cytology for detection of malignant bile duct strictures. In this study, the sensitivity of FISH and cytology were 34% and 15%, respectively (P < 0.01). Additionally, the specificity of FISH and cytology was 91% and 98% (P = 0.06), respectively (79). Therefore, biliary FISH is more sensitive and virtually as specific as standard cytology for detection of malignant bile duct strictures (79).



▪ **Figure 23.5** Fluorescence in situ hybridization of normal **(A)** and maligant **(B)** bile duct cells. Normal cells display duplicate color for each chromosomal probe whereas malignant cells reveal multiple gains of chromosomes (i.e., polysomy). (Reprinted with permission from Lazaridis, et al. *Gastroenterology* 2005;218:1655–1667.)

Overall, in a patient with PSC, the diagnosis of CCA is usually made by combining the clinical exam, biochemical results, and imaging procedures (i.e., ERCP, MRCP). In medical practice, it is not uncommon to make the diagnosis of CCA based on clinical grounds and imaging studies without tissue proven evidence of tumor. To this end, physicians who evaluate and follow-up patients with PSC

should suspect development of CCA when these patients present with sudden clinical deterioration. Because we lack methods of early CCA detection in PSC the outcome for these patients is poor. Nevertheless, early diagnosis of CCA in PSC can be treated by liver transplantation in selected medical centers (80).

Peristomal varices

Peristomal varices can occur in patients with ileostomy after proctocolectomy for underlying IBD (81). The bleeding of peristomal varices can be severe and refractory to local measures, including ileostomy revision and injection of sclerosants. A transjugular intrahepatic portosystemic shunt or portacaval shunt can be considered, although many of these patients with bleeding peristomal varices have severe liver disease and portal hypertension and therefore, they should be considered for liver transplantation.

Management of PSC

Medical therapy

A variety of drugs have been tested as therapeutic agents for PSC (Table 23.7), but so far none has been found useful to treat the underlying disease. Penicillamine was the first drug tested on patients with PSC in a randomized trial but proved ineffective (82). Colchicine, methotrexate, and UDCA (13 to 15 mg/kg per day) have been unsuccessful to treat or delay PSC progression in randomized controlled trials (83,84,85,86). Other drugs that have been tested in small-scale studies, sometimes in open-label trials, have included nicotine, pirfenidone, pentoxifylline, and budesonide (20,87,88,89,90). The combination of colchicine and glucocorticoids led to some transient biochemical improvement (91). The combination of UDCA and methotrexate was not successful in an open-label trial (92). UDCA in higher doses (20 to 30 mg/kg per day) has appeared most promising in pilot studies (93,94) and large-scale randomized trials are being undertaken. At present, although high-dose UDCA seems promising, we do not recommend this agent in PSC patients except within the context of therapeutic trials. Of interest, UDCA has been shown to decrease the prevalence of colonic dysplasia in patients with PSC and CUC (95). Nevertheless, we need prospective studies to confirm the chemopreventive effect of UDCA in patients with coexisting PSC and CUC before implementation of prophylactic therapy.

Surgical therapy

Surgical therapy other than liver transplantation is seldom warranted for PSC. Biliary reconstruction has been suggested (96) but this aggressive approach has not been validated in prospective controlled studies.

Liver transplantation

The most pressing need of patients with PSC is for effective medical therapy for the underlying disease. Until this therapy is found, liver transplantation is the only option for patients with advanced PSC. The results of liver transplantation on patients with PSC have steadily improved; the 1- and 5-year survival rates are now reported to be 90% to 97% and 85% to 88% respectively (97,98). Nevertheless, PSC can recur after liver transplantation and as the follow-up period lengthens, the risk of recurrence seems to increase, although, the recurrent disease has been mild (99,100). Patients with PSC and CUC who have

undergone liver transplantation seem to be at high-risk of colon cancer. These patients need screening with annual colonoscopy and surveillance biopsies (101).

Table 23.7. Medical Therapy for Primary Sclerosing Cholangitis Tested to Date

D-Penicillamine
Cyclosporine
Pentoxifylline
Nicotine
Colchicine
Methotrexate
Budesonide
Pirfenidone
Azathioprine
Ursodeoxycholic acid

Conclusions

PSC is a chronic cholestatic liver disease of unknown causation. The course of the disease is typically one of slow progression. Various survival models provide individualized prognostic estimates. A number of complications can occur and should be considered in the treatment of these patients, the most important of which is the development of CCA. Unfortunately, no medical therapy is currently available for the underlying liver disease. Liver transplantation is an effective, life-extending option for patients with advanced PSC.

Additional research is necessary to understand the pathogenesis of PSC in order to develop better therapies for this devastating disease.

Chapter 24
Primary Biliary Cirrhosis

Stephen P. James

Key Concepts

- Primary biliary cirrhosis (PBC) is an uncommon condition found throughout the world that primarily affects middle-aged women.
- Most patients are identified in an asymptomatic phase, but gradually they develop symptoms of pruritus, fatigue, and symptoms of associated syndromes or end-stage liver disease.
- Typical laboratory findings are elevations of alkaline phosphatase levels, modest elevations of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels, total cholesterol level, and positive antimitochondrial antibody test results.
- The characteristic pathologic features of PBC are destruction and drop-out of intrahepatic bile ducts, chronic portal tract inflammation, cholestasis, and progressive fibrosis, cirrhosis, and portal hypertension.
- About one half of patients have associated autoimmune syndromes, most commonly sicca syndrome, thyroid disease, arthritis, and scleroderma or calcinosis, Raynaud's phenomenon, esophageal motility disorders, sclerodactyly, and telangiectasia (CREST) syndrome.
- Treatment options include ursodeoxycholic acid (UDCA), cholestyramine, replacement of fat-soluble vitamins, management of complications of portal hypertension, and liver transplantation for end-stage disease.

Primary biliary cirrhosis (PBC) is a chronic, progressive disease of unknown etiology characterized by necrosis of intrahepatic bile ducts that leads to chronic cholestasis, portal fibrosis, and cirrhosis. The disease is characterized by female predominance, characteristic antimitochondrial antibodies (AMAs), associated autoimmune syndromes, and chronic inflammatory histologic features that have led to its classification as an autoimmune syndrome. Although the first descriptions of PBC appeared in the 19th century (1), wider recognition of the disease did not occur until the publication of reviews in the 20th century that clarified the clinical characteristics of this distinct syndrome (2,3). Other important developments were the discovery of AMAs (4), which led not only to an important diagnostic test but also to research into the pathogenesis of PBC that continues to the present time. Another advance was the introduction of cholestyramine to treat intractable pruritus and, more recently, ursodeoxycholic acid (UDCA) treatment to improve the biochemical features and retard the progression of disease. PBC is now frequently recognized in asymptomatic

patients, who may have a slow and insidious disease course. Nonetheless, most patients ultimately develop symptoms and have progressive disease. For those who develop end-stage liver disease, liver transplantation is the only therapeutic option.

Epidemiology

PBC appears to occur throughout the world and in all races; however, there is uneven geographic distribution (Table 24.1). Studies of the epidemiology of PBC are hampered by methodological problems, including variation in case definition and ascertainment and absence of noninvasive markers of high sensitivity and specificity. The estimates of incidence and prevalence vary widely, from 2 to 24 per million and 19 to 240 per million population, respectively, with the highest incidence and prevalence reported in northern Europe (5,6,7,8), where the prevalence appears to be increasing, although the relative contributions of methodological differences, increased awareness, or a true increase in prevalence are uncertain. The median age of diagnosis is approximately 50 years, with a broad range of diagnosis from approximately 20 to 90 years, and 90% of patients are women. Within regions of high prevalence, clustering of cases has been observed, suggesting a contribution of environmental factors to the pathogenesis (7). Two case–control studies have searched for risk factors with inconsistent results: In the United Kingdom an association with smoking was found, while in the United States an association with non-PBC autoimmune disease, genitourinary tract infections, and previous tonsillectomy was identified (9,10).

Genetics

There are multiple lines of evidence indicating that genetic susceptibility plays a role in the pathogenesis of PBC (Table 24.1). This evidence includes striking female predominance, familial clustering, association with other autoimmune syndromes, and concordance in twin studies (11,12,13). The striking female predominance of PBC obviously links the pathogenesis of the disease to the genetic basis of sex determination, as for many other autoimmune diseases. However, the specific causal mechanisms are currently unclear. Among candidate mechanisms are direct effects of female hormones, immunologic differences between males and females, and increased monosomy X in women with PBC (12). A commonly recognized feature of diseases that are thought to have an autoimmune basis is that different autoimmune diseases tend to occur with increased frequency within families, which forms the basis for the hypothesis that the tendency to autoimmunity is based in part on shared genetic traits. Numerous animal studies in models of lupus erythematosus, for example, support the concept of multigenic pathogenesis of complex autoimmune diseases. PBC has long been associated with a variety of autoimmune syndromes both in individual patients and within families of patients with PBC (see subsequent text). One recent population-based study confirmed that autoimmune conditions are found in approximately one half of patients and that the prevalence of autoimmune disease in first-degree family members is 14% (14), consistent with the thesis that PBC shares common genetic susceptibility traits with other autoimmune conditions. Many case series and epidemiologic studies have noted the familial tendency of PBC, which although uncommon, appears to be increased compared to the general population (12). The estimates of the familial prevalence has ranged from approximately 1% to a high of 6.4%, with estimates in the largest studies being in the 1% to 2% range. These estimates are similar in different

ethnic backgrounds, including England, the United States, Sweden, Italy, and Japan. Therefore, the familial occurrence of PBC also supports a genetic basis, although, of course, environmental etiologies also cause familial clustering. One of the important traditional methods to evaluate the heritability of disease is to determine concordance rates in twins. In two older reports of single twin pairs, one was reported to be concordant and the other discordant. More recently, an international study evaluated 16 twin pairs with PBC, of whom 8 were confirmed to be monozygotic (13). The concordance rate was 0.63 in monozygotic twins and 0.0 in dizygotic twins. The concordance rates were potentially subject to bias because cases were collected from referral centers and the Internet, which differs from traditional population-based twin registry studies. Nonetheless, the high concordance rate for monozygotic twins suggests an important contribution of genetic susceptibility to PBC.

Table 24.1. Epidemiology and Genetics

Incidence	2–24/1,000,000
Prevalence	19–240/1,000,000
Median age (y) (range)	50 (20–90)
Female	90%
Environmental risk factors	Unknown
Associated autoimmune syndromes	50%
Familial clustering	1%–2%
Twin concordance rate	Monozygotic 0.63/Dizygotic 0.0
MHC class II	Weak, variable associations

MHC, major histocompatibility complex.

Because PBC is a relatively rare disease and familial cases are uncommon, genome-wide linkage studies to identify novel genetic regions have not been possible. Therefore, the search for specific genetic susceptibility loci in PBC has been limited to association studies involving specific candidate genes. As for other autoimmune conditions, the major histocompatibility complex (MHC) region has been the subject of the most intense study. To date, no significant associations have been identified with MHC class I polymorphisms.

Numerous studies have reported both increased risk and protection associated

with specific MHC class II alleles. Recent reviews of these studies have concluded that there are different MHC class II associations in different ethnic populations, and furthermore, the associations have been relatively weak compared to other autoimmune diseases (12). To date no unifying hypothesis has emerged to explain the role of MHC class II alleles, as it has for other diseases such as celiac disease that are strongly associated with specific MHC class II alleles. A relatively short list of other candidate genes has been examined in PBC, with variable and inconclusive results. Future research using genome-wide single nucleotide polymorphism (SNP) markers for association studies offers promise to identify clues to the genetic basis of PBC.

Symptoms

In the past, patients were frequently diagnosed with initial symptoms of fatigue, pruritus, and jaundice, and physical findings such as hepatomegaly. However, currently, most patients are diagnosed with PBC before the onset of any specific symptoms or physical findings at an early stage of disease (Table 24.2). The reasons for the shift to early, asymptomatic diagnosis include the widespread use of screening laboratory studies including serum alkaline phosphatase, increased physician awareness of the features of the disease, the ready availability of AMA tests, and, finally, recognition that the disease does in fact have a long, presymptomatic phase in which a specific diagnosis is readily accomplished (15,16). Most patients, if followed up long enough, eventually develop symptoms that are attributed to the disease.

In order of frequency, the most common symptoms of PBC are fatigue, pruritus, and jaundice. Occasionally, patients have right upper quadrant abdominal pain. Many other symptoms may be present, including that of associated syndromes, such as dry mouth and eyes, Raynaud's phenomenon, and arthralgias. Occasionally, patients are brought to attention because of xanthoma, xanthelasma, increasing skin pigmentation, or fracture. Much less commonly, the presenting symptoms may be due to decompensated liver disease, including ascites, edema, bleeding, or encephalopathy.

Table 24.2. Symptoms and Physical Findings

Symptoms
Asymptomatic (most common)
Fatigue
Pruritus
Symptoms of associated syndromes (e.g., sicca, arthritis, Raynaud's)
Physical findings
Hepatomegaly
Splenomegaly
Jaundice
Xanthoma
Increased skin pigmentation, excoriations
End stage: Ascites, edema, wasting, encephalopathy

Fatigue may have an insidious onset and is often the dominant symptom, significantly diminishing the quality of life of patients (17). It is not uncommon

for patients to be initially misdiagnosed with other conditions in which fatigue is prominent, including depression, chronic fatigue syndrome, fibromyalgia, or thyroid disease, which may be associated with PBC. The cause of fatigue in PBC is unclear, but it has been suggested to have a central etiology (18), although other causes might exist, such as mechanisms related to chronic inflammation. Pruritus is also a significant, sometimes debilitating symptom in PBC, occurring much earlier in the course of the disease than in other more common forms of liver disease, in which it is commonly associated with hepatic decompensation. As in other cholestatic liver diseases, the pathogenic mechanisms of pruritus are unknown (19).

Physical Findings

Early in the course of the disease, physical abnormalities are often completely absent. As the disease progresses, the most common physical findings are hepatomegaly, splenomegaly, excoriations, skin hyperpigmentation, jaundice, and xanthelasma (20). Late in the course of the disease, physical findings of decompensated liver disease may be present, including ascites, edema, palmar erythema, spider nevi, muscle wasting, and signs of encephalopathy. Uncommonly, patients have physical findings of associated syndromes such as xerophthalmia and xerostomia. Very rarely, patients have Kayser-Fleischer rings because of copper retention.

Routine Laboratory Tests

The routine laboratory abnormalities in PBC are typical of chronic cholestatic syndromes and chronic liver disease (Table 24.3). Almost invariably, the serum alkaline phosphatase and γ-glutamyltransferase levels are elevated, typically two times to two-and-a- half times the upper limit of normal at the time of diagnosis (21). Serum alkaline phosphatase levels often remain relatively stable and do not correlate with the stage or progression of disease. Rarely, patients have been

identified with normal alkaline phosphatase levels on the basis of positive serum AMAs and typical liver histologic abnormalities, presumably at a very early stage of disease (22). Serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels are only modestly elevated, usually less than five times the upper limit of normal, and their levels also do not correlate with stage of disease. Serum bilirubin level is typically normal early in disease and rises with disease progression; therefore, serum bilirubin is a component of the prognostic indices for end-stage PBC (23). In common with other cholestatic syndromes, serum lipid levels are abnormal in PBC. Patients may have striking hypercholesterolemia that may correlate with the physical finding of xanthomas. However, there is a corresponding increase in high-density lipoprotein cholesterol, which may explain why patients with PBC seem to have only an average risk for cardiovascular complications (24). In addition, although low-density lipoprotein (LDL) levels are also increased, a subfraction, lipoprotein X, is present that may inhibit the atherogenic properties of LDL lipoproteins (25). Late in the course of disease serum cholesterol levels may decline along with other synthetic functions during end-stage liver failure, including a fall in serum albumin level and rise in prothrombin time, which may be exacerbated by malabsorption of fat-soluble vitamins such as vitamin K. Because of the overwhelming fatigue experienced by some patients, concern may arise because of anemia in patients with PBC, which is usually due to anemia of chronic disease. Rarely patients are identified with autoimmune Coombs'-positive hemolytic

anemia (26), which may confound the interpretation of serum bilirubin levels, or pernicious anemia (27). Thrombocytopenia, if present, is usually a manifestation of portal hypertension, although rare cases of idiopathic thrombocytopenic purpura are associated with PBC. PBC, like other cholestatic syndromes, is associated with copper retention, resulting in raised urinary copper and serum ceruloplasmin levels (28). Other laboratory abnormalities may be present as a result of associated autoimmune syndromes. Patients with PBC typically have elevated serum IgM, sometimes to striking levels (3), some of which may be monomeric rather than pentameric (29).

Table 24.3. Characteristic Laboratory Abnormalities

Alkaline phosphatase	2 to 2.5 times upper limit of normal
AST, ALT	<5 times upper limit of normal
Bilirubin	Normal in early phase, progressive rise late phase
Cholesterol, HDL cholesterol	Elevated
Serum IgM	Elevated
Antimitochondrial antibodies	Present titer >1:40 in 95% of patients
Other autoantibodies	ANA, RF, SMA, and others commonly found

AST, aspartate aminotransferase; ALT, alanine aminotransferase; HDL, high-density lipoprotein; IgM, immunoglobulin M; ANA, antinuclear antibodies; RF, rheumatoid factor; SMA, smooth muscle antibody.

Autoantibodies

The presence of autoantibodies, particularly AMAs, is a clinical hallmark and important diagnostic feature of PBC, first reported as a distinguishing characteristic compared to other forms of chronic cholestasis by Doniach et al. in 1965 (4). Since this time, extensive studies have refined diagnostic testing for AMAs, which are found in up to 95% of patients (30). Furthermore, AMAs have been a major theme in research on pathogenesis of PBC. Initial studies defined AMAs by indirect tissue immunofluorescence, a test still used for clinical diagnosis. Subsequent studies showed that serum autoantibodies reacted with trypsin-sensitive components of the inner mitochondrial membrane, the so-called M2 antigen, in a non–tissue specific manner with broad cross-reactivity to antigens present in many species, including both eukaryotes and prokaryotes such as *Escherichia coli* (31,32). Other mitochondrial antigens, arbitrarily

designated M1 to M9 (33), have been previously described as the target of PBC autoantibodies. Some, such as M1, represent anticardiolipin of syphilis and are unrelated to PBC. Others, such as M4, M8, and M9, were previously described as being PBC specific; however, the specificity of these antigens has been questioned and they are not routinely used for diagnosis (34).

Cloning and characterization of the M2 autoantigens recognized by PBC sera have led to the identification of four major components of a family of mitochondrial antigens that contain lipoic acid and are members of the 2-oxoacid dehydrogenase (2-OAD) multimeric enzyme complexes (35,36). These include pyruvate dehydrogenase complex (PDC), 2-oxoglutarate dehydrogenase complex (OGDC), and branched-chain 2-oxoacid dehydrogenase complex (BCOADC). All the members of this family play important roles in cellular metabolism. Approximately 95% of sera of patients with PBC reacts with both the PDC core dihydrolipoamide acetyl transferase (E2) structure and the E3-binding protein (E3BP) by immunoblot or enzyme-linked immunosorbent assay (ELISA), these two subunits being completely cross-reactive. PBC sera also react, at a much lower frequency, with other components of PDC, including the E1α and E1β subunits. Sera also react with the E2 subunits of OGDC and BCOADC with a frequency of 90% and 50%, respectively. Considerable information is available on the B-cell epitopes, and they all appear to be defined by conformational

structures contained within the lipoic acid–binding domains. AMAs block the enzymatic activity of 2-OAD complexes in vitro (37,38); however, it is not known whether PBC autoantibodies have in vivo activity against these enzymes.

Although serum IgM may be elevated to striking levels, AMAs are present in all three immunoglobulin classes, including secretory IgA, and no consistent clinical correlations have been reported with different immunoglobulin classes of reactivity.

Although there has been considerable progress in the definition of AMAs in PBC, the literature consistently contains patients who are negative for AMAs but have otherwise the same typical clinical, biochemical, and liver histologic features of the disease (39,40). Some patients are found to be positive for AMAs when more sensitive and specific tests available in research laboratories are used (41). Some studies have reported a high frequency of antinuclear antibodies (ANAs) in this group of patients and have referred to this condition as autoimmune cholangiopathy (39,42). However, because the clinical features of the two conditions overlap considerably (43), it is unclear whether these are separate conditions or variants of the same condition with differing autoantibody patterns. The views on these conditions are more than semantic: The absence of AMAs in patients with PBC-like syndromes has been used as an argument that AMAs are only an epiphenomenon, rather than pathogenic, but this argument would be dismissed if future research on "autoimmune cholangiopathy" identifies a different etiologic basis compared to AMA-positive PBC.

Other autoantibodies are frequently found in patients with PBC. Approximately 25% of patients have ANAs with a "nuclear rim" and "multiple nuclear dots," which correlate with autoantibodies recognizing gp210, nucleoporin 62, and nuclear body protein sp100. These ANAs are relatively specific for PBC (44). Other autoantibodies that have been reported in patients with PBC include those connected with associated autoimmune syndromes (see subsequent text) such as antithyroid autoantibodies, rheumatoid factor, and antibodies found in Sjögren's syndrome, as well as a long list of other antibodies of unknown significance,

including antilymphocytotoxic antibodies, anti–acetylcholine receptor antibodies, antiplatelet antibodies, antihistone antibodies, anticentromere antibodies, and antibodies against carbonic anhydrase II, α-enolase, lactoferrin, and smooth muscles.

For clinical testing, historically, AMA is detected by indirect immunofluorescence on rat tissue sections. Reactivity is detected by the appearance of a cytoplasmic granular pattern of the mitochondria. False-positive reactions may occur because of the presence of other serologic cross-reactions, such as those with anticardiolipin (45). In addition, AMAs may be detected by immunoblot of submitochondrial particle preparations such as antigens or by ELISA using recombinant antigens for PDC-E2, BCOADC-E2, and OADC-E2. It appears that immunoblot and ELISA methods have higher sensitivity and specificity for PBC than immunofluorescence tests. AMAs may be found in patients with other syndromes, particularly overlap syndromes and autoimmune hepatitis (AIH), but also occasionally in primary sclerosing cholangitis (PSC) and drug-induced liver disease.

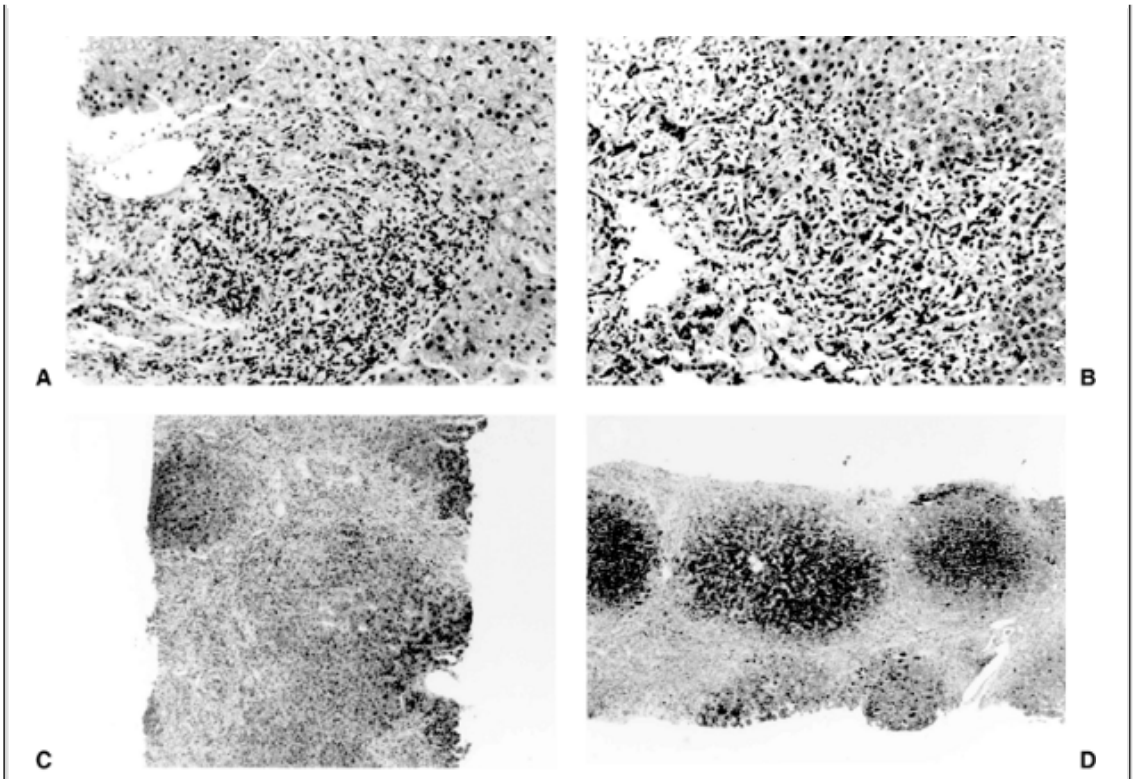
Pathology

The gross pathologic features of PBC are not specific for the disease and include bile staining of the liver, enlargement, fine nodularity, and, eventually, a grossly cirrhotic appearance. The extrahepatic biliary system is normal, with the exception of increased prevalence of gallstones. Enlarged lymph nodes may be found in the porta hepatis, along with other intra-abdominal sites, and these do not have any characteristic features other than the occasional appearance of granulomas. Enlargement of the spleen, along with other pathologic features of portal hypertension, appear later in the course of the disease.

The characteristic microscopic hepatic abnormalities include portal inflammation with destruction and disappearance of intrahepatic bile ducts, abnormal bile duct proliferation, fibrosis, and cirrhosis (Fig. 24.1). Although, overall, the disease is characterized by progressive destruction and loss of bile ducts with portal fibrosis progressing to cirrhosis, in the early and intermediate stages of the disease, the process is not uniformly distributed throughout the liver, and therefore, there is potential for significant sampling error when performing needle biopsy of the liver. Two similar staging systems, as proposed by Ludwig et al. (46) and Scheuer (47), have been widely adopted to describe the liver histologic lesions. Because of the focal nature of the lesions, occasionally multiple, and even all four histologic, stages of lesions have been identified in the same liver.

In stage 1, which is thought to represent the earliest pathologic lesions of the disease, there is destruction of intrahepatic septal and interlobular bile ducts, which can range in size up to 100 μm in diameter. This stage has been called the *portal stage* in the Ludwig system and the *florid duct lesion stage* in the Scheuer system. Portal lesions are characterized by damage to bile ducts, which may be associated with vacuolated or pyknotic biliary epithelial cells and even frank rupture or disappearance of portions of the duct. The duct is typically surrounded by a dense lymphocytic infiltrate, which may also include histiocytes, plasma cells, eosinophils, and, occasionally, true epithelioid giant cells. Neutrophils

are absent or infrequent, and periductular fibrosis, as found in PSC and biliary obstruction, is absent. Inflammation does not extend beyond the portal tracts, and hepatocyte injury is minimal.



▪ **Figure 24.1** Liver histologic abnormalities in PBC. **A:** Stage 1—a damaged bile duct is surrounded by chronic inflammatory cells. **B:** Stage 2—proliferation of abnormal bile ductules; chronic inflammation of portal tract. **C:** Stage 3—portal fibrosis. **D:** Stage 4—cirrhosis.

The second stage of the disease is characterized by the appearance of abnormal proliferating bile ductules without duct lumens, disappearance of normal bile ducts, and extension of the portal inflammation into the hepatic parenchyma. Typically, there is limited piecemeal necrosis of periportal hepatocytes with surrounding foamy macrophages and limited fibrosis confined to the portal tract.

In stage 3, there is a substantial increase in fibrosis, and fibrous septa may link portal tracts. Lymphocytic infiltrates remain in portal tracts, but bile ducts may be difficult to identify or completely absent.

Stage 4 is characterized by frank cirrhosis with regenerative nodules.

Other histologic abnormalities may be found that are not specific for PBC, including Mallory bodies and deposition of copper, which are found in other cholestatic liver diseases.

Immunologic techniques have been used to further define the histologic lesions of PBC (35,48,49). The lymphocytic portal infiltrates primarily contain $CD4^+$ T cells, although $CD8^+$ T cells predominate in areas of piecemeal necrosis, and their levels may be increased in early stages of the disease. The infiltrating $CD4^+$ T cells have a CD45RO high phenotype characteristic of memory T cells. The bile duct epithelium contains small numbers of intraepithelial lymphocytes, potentially analogous to those found in the intestinal epithelium, that are predominantly $CD8^+$ T cells and are found in PBC bile duct lesions. Natural killer T (NKT) cells represent only approximately 5% of lymphoid cells in liver infiltrates. Infiltrates

also contain B cells, plasma cells, eosinophils, macrophages, and dendritic cells. The cytokine profile of PBC tissue is predominantly characterized by expression of interferon-γ, but interleukin (IL)-2, IL-5, IL-6, and transforming growth factor-β (TGF-β) are also expressed, so that PBC does not have a clear T_H1 or T_H2 profile.

A number of bile duct abnormalities have been defined using immunologic techniques. Bile ducts in patients with PBC have aberrant expression of the AMA antigen PDC-E2 on the cell surface (50). In addition, MHC class II antigens, which are usually not expressed on normal bile ducts, have increased expression on bile ducts in PBC. Other molecules have also been noted to have increased expression on bile duct cells in PBC, including intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and the cytokines IL-6 and TNF-α (tumor necrosis factor-α), and the chemotactic molecule fractalkine (51).

Associated Syndromes

Numerous case reports and descriptions of patient cohorts have noted the association of PBC with other diseases, particularly autoimmune syndromes (Table 24.4). There are no extensive epidemiologic studies with case controls to evaluate the true prevalence of autoimmune syndromes in PBC, and many of the reports are likely subject to referral and reporting bias. In one study of a geographically based PBC cohort, the most commonly identified associated conditions were Sjögren's syndrome (25%); Raynaud's phenomenon (24%); autoimmune thyroid disease (23%); rheumatoid arthritis (17%); scleroderma and calcinosis, Raynaud's phenomenon, esophageal motility disorders, sclerodactyly, and telangiectasia (CREST) syndrome (8%); and pernicious anemia (4%) (52). The overall prevalence of autoimmune conditions in patients with PBC was 53% in this study. The association with Sjögren's syndrome, arthritis, Raynaud's phenomenon, and autoimmune thyroid disease is the most commonly reported associated syndrome in other reports on autoimmunity in PBC (53,54,55,56). The most common thyroid disease is Hashimoto's thyroiditis, but rarely Graves' disease or hyperthyroidism is found. Antithyroid antibodies are frequently found in patients with PBC without clinical evidence of thyroid dysfunction. Sicca symptoms are relatively common in PBC, but only a minority of patients have anti-Ro or anti-La antibodies typical of primary Sjögren's syndrome. Similarly, although arthralgia is common in PBC patients, only a minority fulfill American Rheumatism Association criteria for definite or probable rheumatoid arthritis. Patients having manifestations of scleroderma most often have the limited CREST variant of this disease. Among patients with PBC having one autoimmune condition, most also have a second condition.

Table 24.4. Associated Syndromes

Sjögren's syndrome[a]
Raynaud's phenomenon
Thyroid disease
Rheumatoid arthritis
Scleroderma and CREST
Systemic lupus erythematosus
Glomerulonephritis

Type 1 diabetes Polymyositis Myasthenia gravis Autoimmune thrombocytopenic purpura Pernicious anemia Addison's disease Celiac disease Skin diseases (e.g., lichen planus, pemphigoid, dermatomyositis)

[a]Listed in approximate order of decreasing frequency.
CREST, calcinosis, Raynaud's phenomenon, esophageal motility disorders, sclerodactyly, and telangiectasia.

Overlap Syndromes

Patients with PBC may have features that overlap significantly with those of AIH (57,58). Positive AMAs, high serum alkaline phosphatase levels, and histologic bile duct lesions are sometimes found in patients with otherwise typical features of AIH. Conversely, patients with PBC may have significant hepatocyte injury and high–titer positive ANAs. Additional heterogeneity is represented by patients with typical clinical features of PBC except for the absence of AMAs, and some of these patients have high ANA levels. This latter syndrome has been called *autoimmune cholangiopathy* and is otherwise indistinguishable from PBC. There are no specific diagnostic criteria for overlap syndrome, so its prevalence in patients with PBC is unknown. Individual reports have indicated the presence of features of AIH in 2% to 19% of patients with PBC. Further, definition of the overlap syndrome will depend on new specific information on the etiopathogenesis of both conditions to differentiate whether overlap represents a spectrum of one disease or the simultaneous presence of two different conditions. The diagnosis of overlap syndrome is not purely academic because there are different treatment recommendations for AIH and PBC. In patients with significant features of AIH in addition to PBC, a treatment trial with corticosteroids and/or azathioprine should be entertained in addition to treatment with UDCA (59) (see subsequent text).

Complications

The early course of most patients with PBC who are not asymptomatic is marked by fatigue, pruritus, and, occasionally, symptoms or complications of associated conditions; however, patients often continue to have a good functional status. Sometimes, the symptoms of pruritus and fatigue may be quite disabling and emotionally disturbing to patients. Interestingly, depression does not seem to be a common diagnosis in PBC because there are alternative explanations for mood alterations. One small trial of an antidepressant in patients with fatigue found no benefit (60). Late in the course of the disease, the major complications are related to chronic cholestasis, portal hypertension, and cirrhosis (Table 24.5). Chronic cholestasis is associated with metabolic bone disease (61), which may cause painful fractures. The etiology of bone disease appears to be primarily the direct effects of cholestasis on bone, rather

than malabsorption of vitamin D. The full spectrum of complications of portal hypertension is found in patients with PBC, often before the appearance of stage IV cirrhosis on liver biopsy specimens (62). Historically, complications due to portal hypertension were common either as presenting symptoms or shortly after diagnosis, but these are now uncommon. There do not seem to be any unique features related to variceal bleeding, ascites, edema, encephalopathy, or wasting due to end-stage liver disease, with the possible exception of the additional contribution of malabsorption due to chronic cholestasis. Hyperlipidemia is a manifestation of chronic cholestasis, although the specific lipid abnormalities do not provide independent additional risk factors for cardiovascular disease. Although hepatocellular carcinoma has been reported in PBC, it may not be as common as other forms of cirrhosis (63,64). There have been reports of an increase in breast cancer in women with PBC, but this has not been confirmed by others. An increased frequency of asymptomatic urinary tract infection has been reported in PBC; however, the significance of this finding is unclear. Distal renal tubular acidosis has been reported in 30% to 60% of patients with PBC.

Table 24.5. Complications

Emotional disturbance: Debilitating pruritus and fatigue
Metabolic bone disease
Portal hypertension: Ascites, edema, encephalopathy, varices
Malabsorption: Fat-soluble vitamins
Hyperlipidemia
Hepatocellular carcinoma
Asymptomatic urinary tract infection
Distal renal tubular acidosis

Pathogenesis

The etiology and pathogenesis of PBC are unknown. A variety of etiologies have been postulated, including infectious causes; however, the most common view is that the disease falls within the category of autoimmune diseases (35). The rationale for this thesis is that multiple features of PBC support a primary autoimmune pathogenesis, including the histologic features of the liver bile duct lesions; characteristic autoantibodies; strong female predominance; an association, although weak, with MHC class II genes; the frequent association with other autoimmune syndromes; and the presence of similar bile duct lesions in other immunologically mediated diseases, namely, graft versus host disease (GVHD), both in humans and animal models, and the recurrence of PBC in liver allografts. One feature that unfortunately sets PBC apart from other autoimmune diseases is the apparent lack of benefit of immunosuppressive therapies. The lack of robust animal models for the disease has impaired rapid exploration of novel hypotheses, and patient-based research is hindered by the indolent and slowly progressive nature of the disease. Much current research into the pathogenesis of PBC parallels that of other autoimmune disease, including a search for environmental triggers, the genetic basis of susceptibility, and details about the

effector mechanisms responsible for the primary bile duct lesions that will hopefully lead to the identification of new therapeutic targets.

AMAs are the most distinctive specific immunologic characteristic of PBC and, not surprisingly, have been the focus of numerous studies. As noted in the preceding text, AMAs can inhibit the enzymatic activity of their target antigens in vitro; however, it is not known whether this occurs in vivo. Autoantibodies may potentially cause tissue injury, regardless of whether they alter the function of their target antigen; therefore, this particular issue does not resolve the question of the pathogenicity of AMAs. AMAs do fix complement; however, remarkably little attention has been directed at determining whether there is specific deposition of AMAs at sites of tissue injury in the liver. A number of attempts to induce biliary disease in animal models have met with limited success. In one study, immunization of mice with PDC-E2 resulted in an antibody response, however, without evidence of biliary disease (65). This result is not surprising because immunization with an autoantigen alone often does not lead to disease in animal models. In other model systems, the presence of multiple positive and negative genetic susceptibility genes is necessary in addition to environmental triggers to produce autoimmune disease (66); therefore, identification of a permissive genetic background is likely to be necessary to create animals with human disease, as has been demonstrated recently for dermatitis herpetiformis (67). One of the most intriguing pieces of evidence suggesting a potential pathogenic role for AMAs in liver disease is the association of neonatal hepatitis in two cases with the presence of AMAs of maternal origin, which resolved on disappearance of the AMAs (68).

Considerable information has emerged to define the nature of both the B-cell and T-cell responses to the autoantigens recognized by AMAs. There is overlap between epitopes recognized by B cells and both $CD4^+$ T cells and $CD8^+$ T cells, and there is enrichment for specific antigen-reactive clones within the liver (69). Cytokines produced in liver infiltrates are dominated by T_H1 cytokines but also contain T_H2 cytokines, providing a mixed picture. Furthermore, expression of adhesion molecules and chemokines, such as fractalkine, by biliary epithelial cells provide further details on potential mediators involved in the formation of inflammatory lesions within the liver. However, the precise sequence of events and specific effector mechanisms

contributing to bile duct injury are as yet undefined, and the possibility that the inflammatory lesions are entirely secondary in nature has not been eliminated.

Other animal models have been examined that might contribute insights into the pathogenesis of PBC. In an interesting example of serendipity, elimination of a specific diabetes-determining locus in the nonobese diabetic (NOD) mouse eliminates diabetes but results in a mouse with a characteristic spontaneous development of a unique liver phenotype consisting of peribiliary infiltrates, autoantibodies, and cystic biliary lesions (70). Another approach is based on the observation that patients with GVHD have histologic lesions of chronic nonsuppurative destructive cholangitis (71) that has features similar to those of PBC. This disease is mediated by the recognition of alloantigens by T cells, and the disease can be recapitulated in animal models, including the production of bile duct lesions (72). Although this model is useful in elucidating the specific immunologic mechanisms present in GVHD, it is as yet unknown whether the lessons learned extend to PBC.

The mechanisms that trigger the immunologic abnormalities observed in PBC

remain a matter of speculation. The highly conserved sequences in antigens are recognized by AMAs across species, including prokaryotes, suggesting that molecular mimicry could play a role in triggering autoimmune responses. Multiple microbes have been identified with sequence homology, including *E. coli*, *Neurospora crassa*, *Pseudomonas putida*, *Novosphingobium aromaticivorans*, and others (73). It has also suggested that xenobiotics might trigger immune recognition of self-antigens; however, no specific candidates have emerged in PBC.

Another theory for pathogenesis of PBC is that it is the direct result of an infection. In the search for a transmissible agent, filtrates of lymph nodes from patients with PBC were shown to induce the expression of PDC-E2 in biliary epithelial cell cultures (74). Further studies identified viral particles in biliary epithelial cultures and tissues from patients with PBC and cloning of exogenous retroviral sequences from cultured biliary cells, which were identified as a betaretrovirus related to murine mammary tumor virus (MMTV) (75). However, others have not been able to verify the presence of MMTV-related retrovirus in PBC (76). In an uncontrolled pilot study, combination therapy using lamivudine and zidovudine in a small number of patients showed improvement in liver histology and biochemical abnormalities, suggesting the possibility that antiviral therapy might be of benefit, but validation of this approach would require further controlled trials (77).

It is well accepted that PBC may recur (78) in approximately 20% to 30% of patients within 10 years of orthotopic liver transplantation, characterized by typical bile duct lesions and persistence of AMAs. Although recurrent PBC potentially affords an opportunity to study pathogenic mechanisms in the liver prospectively from the onset of disease, the mechanisms of recurrence per se are no less complicated to dissect than the primary disease itself, and as yet no new insights into pathogenesis have emerged from studies of recurrent PBC.

Diagnosis

The diagnosis of PBC is based on the presence of typical clinical features, routine laboratory tests, AMAs, liver biopsy specimen abnormalities, and absence of other conditions that could resemble PBC (20,79). PBC should be suspected in patients with symptoms such as profound fatigue, pruritus, abdominal pain, or hepatomegaly and routine laboratory test results consistent with cholestasis, that is, an elevated alkaline phosphatase levels with minimal or modest elevation of serum transaminase levels (less than five times the upper limit of normal). Other typical features are hypercholesterolemia and high serum IgM level. As noted in the preceding text, most patients are now diagnosed because of abnormal liver biochemical test results obtained on screening examinations in the absence of any symptoms. Occasionally, patients come to attention during the evaluation of symptoms of an associated syndrome, such as sicca syndrome, thyroid disease, or arthritis. The most important confirmatory laboratory test is serum AMA levels. The sensitivity and specificity of AMAs are both approximately 95%, but there is variation in the literature, depending on case definition and the test used (80). Approximately 5% of patients are AMA negative, and some of these patients have other autoantibodies, particularly ANAs. The latter patients are sometimes referred to as having autoimmune cholangitis; however, their clinical syndrome is not clearly distinguishable from PBC. Rarely, patients have been identified with normal serum alkaline phosphatase levels and positive AMAs, with typical liver biopsy findings.

Although, historically, liver biopsy was considered mandatory to make a specific diagnosis of PBC and provide prognostic information on the basis of histologic stage, a recent study has suggested that most patients do not need a liver biopsy for diagnosis (81). On the basis of a retrospective analysis of a large sample of patients who had undergone liver biopsy, AMA level determination, and serum biochemical tests, the combination of positive AMAs, alkaline phosphatase levels greater than 1.5 times the upper limit of normal, and AST less than five times the upper limit of normal (found in 112 of 131 patients; 85% of patients reviewed) had a positive predictive value of 98.2% for the diagnosis of PBC. Although other studies confirming this analysis have not been done, patients falling within this profile

probably do not need a liver biopsy unless other clinical features raise the possibility of a different diagnosis. Liver biopsy to confirm the diagnosis should certainly be entertained in the approximately 15% of patients who do not meet these criteria. An additional rationale for restricting the use of liver biopsy in patients suspected of having PBC is that valid prognostic information can be obtained from indices based on noninvasive testing, and histologic stage on liver biopsy is not needed for clinical decisions.

High-quality ultrasound is recommended as an initial diagnostic step in patients first presenting with a diagnosis of cholestasis, on the basis of routine biochemical studies. In the past, patients with PBC typically had endoscopic retrograde cholangiopancreatogram (ERCP) to rule out biliary obstruction or PSC; however, this is not indicated in those with typical clinical features of PBC, including high titer-positive AMAs, and in the absence of other findings that would raise suspicion for PSC, such as presence of inflammatory bowel disease (IBD). Patients with PBC have an increased prevalence of gallstones, but if there is no evidence of biliary obstruction, cholangiography is not indicated.

The differential diagnosis of cholestatic syndromes includes extrahepatic biliary obstruction due to stones, strictures, or tumors; PSC; drug-induced cholestasis; cholestatic viral hepatitis; sarcoidosis; idiopathic granulomatous hepatitis; AIH; and idiopathic adulthood ductopenia (Table 24.6). Other conditions that cause injury to bile ducts should be straightforward to differentiate and include GVHD, hepatic allograft rejection, ischemic cholangitis, and infectious cholangitis in immunosuppressed patients (82). Finally, clinical features of PBC may coexist with features of AIH in an overlap syndrome.

Extrahepatic biliary obstruction is diagnosed by imaging, and only rarely are patients found with positive AMAs. PSC should be suspected in patients with IBD. AMAs are only occasionally positive in patients with PSC. The diagnostic procedure of choice for PSC is cholangiography because the specific liver biopsy specimen lesions of PBC and PSC are each found in only a minority of their respective conditions, and nonspecific liver biopsy specimen features may be similar. Use of drugs known to cause chronic cholestasis could cause difficulty in diagnosis, particularly because some drugs also induce autoantibody production. Patients with viral hepatitis occasionally have a chronic cholestatic syndrome and bile duct lesions on liver biopsy specimens; however, AMAs are negative and serologic tests for viral hepatitis are positive. Occasionally, differentiation of PBC from hepatic sarcoidosis presents a difficult diagnostic problem (83). AMAs are typically negative in sarcoidosis, and the presence of typical extrahepatic manifestations is necessary to make the diagnosis of sarcoidosis. In about one fourth of patients with AIH, AMAs are positive, usually in low titer, and bile duct

lesions may be found on liver biopsy specimens. Idiopathic adulthood ductopenia is a somewhat recently described condition in adults characterized by paucity of bile ducts, chronic cholestasis, and, by definition, absence of any defining characteristics of other ductopenic diseases, including inflammatory liver histologic lesions, autoantibodies, or associated conditions such as IBD (84).

Table 24.6. Differential Diagnosis of Primary Biliary Cirrhosis

Extrahepatic biliary obstruction (e.g., stone, stricture, tumor)
Primary sclerosing cholangitis
Drug-induced cholestasis
Cholestatic viral hepatitis
Sarcoidosis
Idiopathic granulomatous hepatitis
Autoimmune hepatitis
Idiopathic adulthood ductopenia
Special situations with bile duct injury: Graft versus host disease, liver allograft rejection, ischemic cholangitis, infectious cholangitis in immunocompromised host

Treatment

Medical treatments of PBC have included primary therapies aimed at the underlying disease processes and preventing or delaying progression, therapies for symptoms such as fatigue and pruritus to improve quality of life, and therapies directed at complications, including osteoporosis, fat-soluble vitamin deficiency, and complications of portal hypertension, such as ascites, edema, variceal bleeding, and hepatic encephalopathy (Table 24.7). Comprehensive practice guidelines have been published, representing a consensus of expert opinion for management of PBC (85). There are no specific treatments for complications related to portal hypertension in PBC that differ from other causes of end-stage liver disease, and they will not be discussed here. Therapy may also be needed for associated syndromes, such as thyroid disease, arthritis, or Sjögren's syndrome, and they will also not be discussed here. In evaluating treatment trials for PBC, it should be kept in mind that this is a difficult disease to study because of many factors, including the indolent and variable natural history of the disease, sampling error in liver biopsy, and absence of robust biomarkers for early stages of the disease, in which therapeutic interventions might be expected to have the greatest benefit.

UDCA is the only U.S. Food and Drug Administration (FDA)-approved medical therapy for PBC, which is generally agreed to ameliorate serum

biochemical abnormalities and potentially delay progression of disease to death or need for transplantation, although controversy remains about the utility of the drug. A number of mechanisms have been proposed by which UDCA is therapeutic in PBC, including anticholestatic effects and antiapoptotic actions (86); however, the precise mechanisms are unclear and may not involve the primary abnormalities that lead to autoimmune destruction of bile ducts. Numerous treatment trials of PBC with UDCA alone, or in combination with other agents, have been conducted using varying numbers of patients and trial designs, and

these are summarized in detail elsewhere (87,88). In the largest reported trial, a Canadian multicenter double-blinded placebo-controlled study of 222 patients, treatment with UDCA at a dosage of 13 to 15 mg/kg per day resulted in improvement in transaminases, alkaline phosphatase, total cholesterol, and IgM levels and prevention of a rise in serum bilirubin level. However, no improvement in symptoms, liver biopsy results, or need for liver transplantation was noted. In a subsequent meta-analysis of 11 randomized trials involving 1,272 patients, improvement in biochemical studies was found, but no difference between placebo and UDCA was found for progression of liver histology or the need for liver transplantation (89). In contrast, a meta-analysis of the five studies (90,91,92,93,94) that included data obtained from open-label long-term follow-up periods reached a different conclusion, showing a significant reduction in risk of death or liver transplantation (odds ratio 0.68 [95% CI 0.48 to 0.95]) equivalent to a 32% reduction in patients treated with UDCA (95). Because UDCA consistently ameliorates serum biochemistry abnormalities, concern has been raised that predictive models for PBC might underestimate progression of disease; however, models such as the Mayo risk score still accurately predict the clinical course in patients with PBC who are receiving UDCA (96). Studies have also reported a delay in progression of liver fibrosis (97). A subsequent analysis of histologic data from four large placebo-controlled trials demonstrated that UDCA therapy had a beneficial effect in stage 1 or 2 disease, reducing periportal inflammation and ductular proliferation (98). Continuing analyses of open-label follow-up of patients have provided conflicting interpretations of the benefits of UDCA. In one randomized study in which patients received UDCA or placebo for 2 years, followed by open-label treatment in 112 patients for a subsequent 2 years, no differences were found in death or the need for liver transplantation (99). In another study of long-term UDCA treatment comparing treated and nontreated patients for a mean of 5.8 years, there was amelioration of serum biochemical abnormalities in treated patients; however, there was no significant difference in death, need for transplantation, symptoms, or complications. It should be noted that this study did not evolve from a randomized trial, and required data analyses taking into account baseline differences and prognostic models (100). Finally, another analysis of 262 treated patients followed up for a mean of 8 years, using a Markov model and the updated Mayo model for control predictions, found that treatment with UDCA normalizes survival rate (for death or transplantation) for patients with stage 1 or 2 disease who were treated, whereas those with more advanced stages had significantly worse survival. (101). Therefore, UDCA may be useful in earlier stages of the disease, although the search for more effective therapies needs to proceed.

Table 24.7. Treatment

Primary therapy	Ursodeoxycholic acid	13–15/mg/kg per day
Pruritus	Cholestyramine or colestipol Alternatives: Rifampin, phenobarbital, opioid antagonists, plasmapheresis	Up to 16 g/d in divided doses[a]

Metabolic bone disease	Calcium, vitamin D	
Malabsorption	Water-soluble forms of vitamins A, D, E, K	
Sicca	Artificial tears, dental hygiene	
Portal hypertension complications	As indicated	
Other associated syndromes	As indicated	

[a]May interfere with drug absorption; do not administer with other drugs.

Fortunately, UDCA is relatively well tolerated, the main side effect being diarrhea, and therapy appears to have no significant long-term complications. The currently recommended dosage is 13 to 15 mg/kg per day, although higher dosage regimens have been investigated. The cost-effectiveness of UDCA has been examined, with yearly costs estimated in 1998 to be $2,500 and annual cost-savings to be $1,372 on the basis of estimates of reduction in liver transplantation and development of esophageal varices (102). If cholestyramine is used concurrently to treat pruritus, there should be a 4-hour delay between administration of cholestyramine and UDCA. Multiple other agents have been tested as therapies for PBC, including azathioprine (103), methotrexate (104,105), prednisolone (106), chlorambucil (107), cyclosporin A (108), and

D-penicillamine (109). There is no clear overall benefit of most of these therapies, and some, such as systemic corticosteroids, are associated with significant bone complications (3). Although one prospective double-blind trial of colchicine showed improved survival after 4 years in one study, subsequent studies have shown much less benefit and no improvement in survival (20).

UDCA has also been used in combination with other drugs, including prednisolone, budesonide, azathioprine, methotrexate, and colchicine, drugs that individually have not shown consistent benefit for the disease in multiple trials. The results of these trials can be summarized as showing benefits no different from UDCA alone, and sometimes with more side effects (110). Small pilot studies have been undertaken with other agents, including mycophenolate mofetil, silymarin, and bezafibrate, but results of these studies are at best preliminary. At present, there is no clear evidence for any combination therapy using UDCA.

Pruritus is a distressing, and sometimes disabling, symptom of PBC. Although antihistamines are frequently used because they are well tolerated, most patients do not show an adequate response. UDCA treatment is associated with reduction

of this symptom in some patients, but overall results of randomized trials do not demonstrate significant improvement in response to pruritus. Cholestyramine has been the mainstay of therapy for decades (111). There are no randomized controlled trials of the anion exchange resins cholestyramine and colestipol; however, there is extensive clinical experience supporting their efficacy. Most patients have improvement in response to symptoms within about two weeks of initiating therapy. Typically, the drug is administered as 4-g doses, up to four times per day. These drugs are typically not well tolerated because of unpleasant taste, abdominal discomfort, and constipation. Anion exchange resins may contribute to malabsorption and may interfere with the absorption of other medications, including UDCA, thyroxin, digoxin, and oral contraceptives. Phenobarbital has been used occasionally and may be helpful. Rifampin has been used to treat pruritus at a dosage of 300 to 600 mg/day in divided doses (112,113). Although well tolerated, its use has occasionally been associated with hepatotoxicity and bone marrow aplasia. On the basis of the theory that pruritus occurs because of endogenous opioids, opioid antagonists have been used to treat PBC (114). Two randomized controlled trials of intravenous naloxone demonstrated benefit for intractable pruritus (115,116), and subsequent studies with oral naltrexone and oral nalmefene have also shown benefit (117,118). Symptoms of opioid withdrawal may occur as a side effect during initiation of opioid antagonist therapy. It has been suggested that the serotonin system may also be involved in pruritus (114), and drugs such as ondansetron and sertraline have been studied in patients with PBC; however, their potential benefit is as yet not substantiated by rigorous controlled trials. Plasmapheresis has been used as a therapy in intractable patients (119).

Metabolic bone disease, osteopenia, and osteoporosis may present a significant problem in patients with PBC. The pathogenesis is complex and may involve, among other factors, malabsorption of fat-soluble vitamins and, more importantly, direct effects of cholestasis on bone metabolism. Although their efficacy is uncertain, calcium and vitamin D supplementation are routinely provided for patients with PBC (120,121), calcium at 1.5 g/day and vitamin D at 800 IU/day. Two studies of etidronate provided mixed results on the benefits for patients with PBC (122,123); however, a more recent study with alendronate demonstrated favorable effects on bone mass (124). The role of hormone replacement therapy in women with PBC is unclear, given recent results in other conditions questioning efficacy in relation to the increased risk of cancer and vascular disease. Insufficient data are available to recommend calcitonin or sodium fluoride as therapy for bone disease in PBC.

Fat-soluble vitamin deficiencies may secondarily contribute to morbidity in PBC, including night blindness, bone disease, bleeding disorders or, rarely, neurologic symptoms of vitamin E deficiency. Deficiencies have been documented for vitamins A, D, K, and E, in decreasing order of frequency, with approximately one third of patients being deficient in vitamin A (125,126), with deficiencies correlating with advanced-stage disease and higher risk scores. Vitamin A supplementation should be based on serum retinol levels because excessive vitamin A may be hepatotoxic. Although the evidence base for the effectiveness of therapy is limited, it has been recommended that patients with hyperbilirubinemia be treated with water-soluble forms of A, D, E, K, and patients with prolonged prothrombin times can be treated with parenteral vitamin K with a 10 mg/month dosage (84).

Hyperlipidemia and xanthomas are common manifestations of PBC and

cholestasis, although patients with PBC may be relatively protected from the adverse effects of hyperlipidemia (24). Cholestyramine or colestipol (Colestid) is used to treat pruritus and UDCA because primary therapy may improve hypercholesterolemia. Nonetheless, additional therapy may be warranted in patients with other risk factors for cardiovascular disease. Clofibrate has been found to cause a paradoxical elevation of serum cholesterol level in two small studies (127,128). In one small study, a 3-hydroxy-3-methylglutaryl coenzyme A (HMG Co-A) reductase inhibitor (statin) was shown to improve lipid levels without causing evident hepatotoxicity (129).

Other medical therapy considerations should include treatment for sicca syndrome, with artificial

tears, dental hygiene, antireflux, and vaginal lubricants and treatment of thyroid disease when present.

Liver Transplantation

Liver transplantation is the only option for patients with PBC with life-threatening end-stage liver disease and its complications or severe intractable symptoms. PBC is a relatively common indication for liver transplantation, representing 12% of patients in the European Liver Transplant Registry, which includes results for 3,357 patients with PBC undergoing transplantation between 1988 and 2003 (130). In general, patients with PBC are good candidates for transplantation and have a better long-term prognosis compared to those with other common indications for transplantation such as viral hepatitis or alcoholic liver disease, with 1-, 5-, and 10-year survival of 84%, 78%, and 69%, respectively (130); similar results have been obtained in the United States. Most experience is based on cadaveric transplantation, but living-related donor transplantation has also been performed successfully for PBC. The indications for liver transplantation in PBC include symptoms and signs of end-stage liver disease and its complications. In addition, patients have been considered for transplantation because of intractable severe pruritus, profound fatigue, and severe bone disease. Patients are typically considered for transplantation when their predicted survival is 1 year or less. The Mayo risk score has been validated as a reliable prognostic index for patients with PBC. More recently, the allocation of cadaveric organs in the United States is based on the Model for End-Stage Liver Disease (MELD) score (131). Both the Mayo risk score and the MELD score contain multiple factors, with serum bilirubin level being the major component of both, and a serum bilirubin level greater than 8.5 mg/dL generally correlates with Mayo and MELD scores that are indicative of a need for liver transplantation. PBC recurs in approximately 20% to 30% of patients by 10 years after orthotopic liver transplantation (78,132), characterized by typical bile duct lesions and persistence of AMAs. The diagnosis is based on liver biopsy and cannot be made on clinical features alone because of overlap with features of transplant rejection and drug toxicity. There has been interest in the possibility that transplantation immunosuppressive regimens may alter the natural history of the recurrent disease and, in particular, that some regimens may retard progression better than others. However, the recurrent disease does not appear to be of major clinical consequence in most patients, and there is too little information available to select transplantation regimens on the basis of disease recurrence (133). There have only been rare cases of retransplantation for recurrent PBC (78).

Natural History and Prognosis

The initial descriptions of PBC were based on observations in patients diagnosed at a relatively late symptomatic stage of disease, with relatively rapid progression to liver failure and death in approximately 6 years (2,3). The full clinical spectrum of PBC and its natural history are now much better defined. The disease has a variable spectrum but appears to be invariably progressive, whether presenting in asymptomatic or symptomatic patients. Multiple publications have indicated that overall survival to death or transplantation is better in asymptomatic patients, approximately 10 to 15 years (134,135,136), although significantly worse than in control populations. One large study of 770 patients found that the symptom status had little effect on overall mortality from all causes, with median survival of 9.6 versus 8.0 years in asymptomatic versus symptomatic patients, respectively (21). However, in the latter study, less than one third of deaths among asymptomatic patients with PBC were attributable to liver disease. In asymptomatic patients with a recent diagnosis (i.e., patients presumably in the early stages of the natural history of the disease), it is difficult to predict the ultimate course on the basis of serum biochemical or AMA titer, or liver histology. In considering the limited medical therapies currently available that may change the underlying disease (e.g., UDCA), management decisions do not depend on a precise definition of where the patient may be along the course of the natural history of the disease. Considerably more is known about defining the late stages of the natural history of the disease, which is important in considering the optimal timing for liver transplantation. Rising serum bilirubin level is an ominous prognostic sign in PBC (137). Multivariate analysis of survival in PBC as a function of multiple different parameters has resulted in the Mayo index, which has been validated in many subsequent analysis (138). More recently, the timing of transplantation has been supplanted by the use of the MELD score for prioritization for organ allocation. The MELD score is based on serum bilirubin level, creatinine level, international normalized ratio (INR) for prothrombin time, and etiology of liver disease, and it has been validated for prediction of death within 3 months for patients with PBC (139).

Chapter 25

Postoperative Jaundice

Santiago J. Munoz

Mary T. Killackey

Key Concepts

- The causes of postoperative jaundice can be grouped under four major categories: Decompensation of preexisting chronic liver disease, cholestatic disorders, necroinflammatory liver diseases, and overproduction of bilirubin.
- A careful review of the surgical, anesthetic, transfusion, and pharmacologic treatment records, as well as history and physical examination are the initial steps in the evaluation of a patient with postoperative hepatic dysfunction.
- Additional laboratory tests and imaging studies are frequently necessary to exclude common liver disorders and biliary obstruction.
- These additional tests plus the information from the review of records and pattern and timing of liver biochemical abnormalities generally lead to the etiology of postoperative jaundice.
- Patients with chronic liver disease unrecognized before surgery are at risk of developing jaundice, and even liver failure, in the postoperative period.
- Postoperative jaundice caused by overproduction of bilirubin is characteristically associated with an isolated increase in unconjugated serum bilirubin in the setting of large volume transfusion, hematomas, or hemolytic disorders.
- Postoperative cholestasis (i.e., marked increase in alkaline phosphatase and bilirubin levels) should lead to suspicion of either biliary obstruction or entities associated with intrahepatic cholestasis.
- Hepatocellular necrosis caused by hepatic ischemia or acetaminophen and inflammatory disorders (viral and other

hepatitides) should be suspected when the postoperative hepatic dysfunction is expressed by prominent elevation of aminotransferase levels.

Patients who develop jaundice after a surgical procedure present a unique set of challenges to the clinician and require a careful assessment. Although in many instances the hepatobiliary abnormalities gradually resolve over time, often without specific intervention, in some patients the onset of postoperative jaundice may reflect a serious and potentially life-threatening complication. Because clinically significant liver injury can develop in the absence of jaundice, unless stated otherwise, the term *postoperative jaundice* is used in this chapter to also include abnormalities of other liver blood biochemical tests. There are often multiple factors present simultaneously in the postoperative patient that may lead to postoperative jaundice (1,2,3). The investigation of postoperative hepatic dysfunction is optimally accomplished as a joint enterprise by surgeons and physicians evaluating the patient's evolving clinical picture. This review presents a practical yet comprehensive approach to the diagnosis and management of a patient who develops postoperative jaundice.

Evaluation of Preoperative Risk Factors for Jaundice

The evaluation of a patient with postoperative jaundice begins with a careful review of preoperative and operative data, including operating room and anesthesia records. Key preoperative data to be analyzed include medical history, main symptoms, and physical examination performed before the surgical procedure. Preoperative clues for liver disease can be further investigated, if necessary, with the patient or family members. Questions on the existence of known chronic liver disease, use of therapeutic or illegal drugs, and a detailed history of alcohol consumption should be obtained. Preoperative diabetes mellitus, obesity, female gender, hyperlipidemia, and other features of the metabolic syndrome suggest that the patient may have underlying nonalcoholic fatty liver disease (NAFLD) or its more aggressive variant, nonalcoholic steatohepatitis (NASH) (4). Historical risk factors for acquisition of hepatitis B virus (HBV) or hepatitis C virus (HCV) infection, such as a history of intravenous drug use or blood products transfused before 1992, should prompt the determination of HCV antibody and hepatitis B surface antigen (HBsAg) status. A history of recurrent mild jaundice based on unconjugated hyperbilirubinemia suggests Gilbert's syndrome. Although the postoperative patient with Gilbert's syndrome may develop more pronounced jaundice, the prognosis is excellent and no further investigations are necessary other

than documenting a predominantly indirect hyperbilirubinemia.

A review of preoperative physical examination records may reveal signs of the existence of underlying chronic liver disease, which perhaps went unrecognized preoperatively. Spider telangiectasis, gynecomastia, palmar erythema, Dupuytren's contractures, hepatomegaly, and/or splenomegaly would suggest preexisting chronic liver disease.

Evaluation of preoperative laboratory data can also be useful to assess for the presence of preexisting chronic liver disease. Elevated alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels suggest chronic hepatitis, whereas the existence of preoperative thrombocytopenia (even mild), depressed serum albumin level, and/or prolonged prothrombin time suggest the presence of cirrhosis, which may have been otherwise well compensated before the surgical procedure. Similarly, preoperative imaging studies revealing hepatosplenomegaly and/or intra-abdominal varices are helpful in raising the suspicion of preexistent cirrhosis.

After major surgery, patients with cirrhosis have a distinct risk of decompensation (i.e., development of jaundice, ascites, hepatic encephalopathy, or portal hypertensive gastrointestinal bleeding). Furthermore, patients with cirrhosis are more susceptible to hepatic ischemia during intraoperative arterial hypotension or hypoxemia. This in turn can be expressed postoperatively as onset of abnormal liver biochemistries or even frank hepatic decompensation.

In general, the probability of postoperative decompensation and liver failure is related to the existence of residual hepatic reserve before the surgical procedure. This has been traditionally evaluated by determining the patient's Child-Turcotte-Pugh class (5,6). Child-Pugh class A patients are considered to have a probability of decompensation of 10% or less, whereas Child-Pugh class B or C carries postoperative mortality risks of 20% to 30% or 40% to 60%, respectively. Therefore, learning that the patient with postoperative jaundice had a diagnosis of cirrhosis made preoperatively can be important in the evaluation, management, and prognosis of hepatic dysfunction. More recently, the postoperative risk evaluated by the more objective Model for End-Stage Liver Disease (MELD) score was found to be superior to Child-Pugh method in predicting outcome (7,8).

When evaluating a patient with postoperative jaundice or abnormal liver biochemistries, it is reasonable to check the basic viral hepatitis serologies, iron indices, and antinuclear and smooth muscle autoantibodies and obtain a complete abdominal imaging study. If the etiology remains obscure and the abnormalities persist or worsen, additional investigations are warranted. It is important to note that in chronic infection with HCV, and also in other hepatic diseases, cirrhosis may be present in spite of normal aminotransferase levels (i.e., ALT,

AST).

Causes of Postoperative Jaundice

A large number of conditions may lead to postoperative hepatobiliary dysfunction (1,2,3). The main causes can be grouped into four main categories: Cholestatic problems including extrahepatic cholestasis (obstructive jaundice) and intrahepatic cholestasis, necroinflammatory liver diseases, excessive production of bilirubin, and preexisting hepatobiliary disease that becomes apparent postoperatively. The pattern and timing of the abnormalities can be helpful to narrow the differential diagnosis (Tables 25.1 and 25.2).

Postoperative Jaundice due to Biliary Obstruction

Major abdominal surgery can be associated with postoperative jaundice. Classic examples include open

aortic surgery, esophageal surgery, and other procedures involving or adjacent to the porta hepatis. In particular, the occurrence of acalculous cholecystitis after open cardiac or aortic surgery should be kept in mind. Insertion of hepatic arterial infusion pumps with administration of chemotherapy can also lead to cholecystitis, and even to secondary sclerosing cholangitis. Acute portal vein thrombosis is a rare but severe complication after major upper abdominal surgery or in patients with inflammatory bowel disease (9). Acute postoperative portal vein thrombosis can lead to liver failure if not promptly treated. Suspicion should be high in the setting of conditions associated with hypercoagulable states. Idiosyncratic forms of liver dysfunction have also been reported with large abdominal surgery (10). Surgery of the biliary tract may be followed by postoperative jaundice. Patients undergoing cholecystectomy for gallstones may have retained stones, or worse, a bile duct injury (11). Generally, patients present 3 to 4 days after surgery; although in a recent large study, the mean time to referral for bile duct injury was 3 weeks (12). Patients often present with severe right upper quadrant pain or even generalized peritonitis. Fever, nausea, and vomiting may also be present. Variable elevation of the total bilirubin, alkaline phosphatase, and aminotransferase levels can be present. Immediate evaluation with hepatobiliary ultrasonography and magnetic resonance cholangiopancreatography (MRCP) should be obtained to investigate biliary leak, biloma, or abscess. Hydroxy iminodiacetic acid (HIDA) biliary scan may be useful if MRCP is not readily available. Endoscopic retrograde cholangiopancreatography (ERCP) is often subsequently used for confirmation of the diagnosis and therapeutic intervention. If stones are present, removal with or without sphincterotomy is indicated (13,14). If a cystic or bile duct leak is found, placement of an internal

biliary stent is often helpful. In patients who present very late, a biliary stricture may be found. Balloon dilatation, with repeated biliary stent changes, is the first line of therapy (15). If this fails, or in more acute and severe injuries such as complete transection, surgical exploration with repair is necessary (16). In a recent review of 200 patients treated over 13 years for bile duct injury after laparoscopic cholecystectomy, 175 required some form of surgical intervention (12). Jaundice was present in 50%, whereas bile leak, cholangitis, biloma, and uncontrolled sepsis were evident in 59%, 35%, 5%, and 3%, respectively. Early referral to a tertiary care center with surgeons experienced in hepatobiliary surgery is important to minimize complications, number of required surgeries, and overall mortality. Immediate repair appears preferable but if diagnosis is delayed, control of sepsis and persistent bile leak should first be accomplished. Once peritonitis has resolved, biliary reconstruction can be scheduled after 2 to 8 weeks.

Specialized endoscopy and interventional radiology are helpful adjuncts for the successful care of these patients.

Table 25.1. Causes of Postoperative Obstructive Jaundice and Time of Presentation

Within 2 to 3 wk of surgery
Decompensation of preexisting chronic liver disease
Overproduction of bilirubin: Hematomas, transfusions, hemolysis
Hepatic ischemia: Vascular injury, cardiac failure, shock, bleeding, hypoxemia
Benign postoperative intrahepatic cholestasis
Biliary obstruction: Retained stones, bile duct injury or leak, pancreatitis
Therapeutic drug liver injury: Acetaminophen, other drugs
Gilbert's syndrome
After 2 to 3 wk of surgery
Therapeutic drug-induced liver injury
Total parenteral nutrition
Viral hepatitis

Modified from Baker A, Green R. Postoperative jaundice. In: Schiff E, Sorrell M, Maddrey W, Eds. *Diseases of the liver*. 9th Ed. Philadelphia: Lippincott Williams & Wilkins, 2003.

Table 25.2. Common Patterns of Liver Blood Test Abnormalities in Postoperative Jaundice

Mechanism of postoperative jaundice	Pattern
Bilirubin overproduction	Isolated increase in unconjugated bilirubin level, occasionally mild increase in AST, ALT levels
Hepatic ischemia	Mild to severe elevation of ALT, AST, and LDH levels; bilirubin level elevation and prothrombin time prolongation in severe cases; normal AP and albumin concentration
Viral and drug-induced hepatitis	Variable increase in the levels of bilirubin, ALT, AST, and AP; broad spectrum of abnormalities
Biliary obstruction	Moderate increase in level of bilirubin, marked increase in AP level, and mild to moderate increase in ALT and AST levels
Benign postoperative intrahepatic cholestasis	Mild to marked increase in bilirubin and AP levels
Gilbert's syndrome	Mild increase in unconjugated bilirubin content

AST, aspartate amino transferase; ALT, alanine aminotransferase; LDH, lactate dehydrogenase; AP, alkaline phosphatase.
Modified from Baker A, Green R. Postoperative jaundice. In: Schiff E, Sorrell M, Maddrey W, Eds. *Diseases of the liver*. 9th Ed. Philadelphia: Lippincott Williams & Wilkins, 2003.

Postoperative jaundice is predictable in patients undergoing biliary reconstruction for benign or malignant disease. Swelling at anastomotic sites is thought to be responsible, and normalization of liver blood test results may take several days. If laboratory test results do not resolve, bile leak or stricture must be ruled out.

Hepatic resections can lead to postoperative jaundice, although usually of transient duration. However, if there is underlying liver disease, or a substantial portion of normal liver was resected, patients may have more severe, even progressive, liver dysfunction. The course of this form of hepatic failure usually extends over days to weeks, with sepsis frequently responsible for death. If not contraindicated, liver transplantation may be necessary. When an extensive hepatic resection is anticipated, preoperative techniques such as selective portal vein embolization or ligation may be performed to induce growth of the lobe that is free of disease (17,18).

Rarely, postoperative jaundice can be seen in patients who develop pancreatitis after surgery. Often, this is associated with large procedures such as open cardiac or aortic cases (19,20). However, pancreatitis can develop after gastric or splenic procedures as well. Edema of the pancreatic head with external compression of the bile duct probably plays a role in the pathogenesis. Liver blood biochemical test results gradually resolve as the pancreatitis subsides.

Postoperative Intrahepatic Cholestasis

A predominant abnormality of alkaline phosphatase and bilirubin levels in the absence of large duct obstruction clinically defines intrahepatic cholestasis in the postoperative patient. The patient may develop varying degrees of jaundice, dark urine, pruritus, and acholia. The prothrombin time may be prolonged because of vitamin K malabsorption associated with cholestasis. The pathophysiology underlying intrahepatic cholestasis involves processes that disturb bile flow at the microscopic level, either at the biliary membrane of the hepatocytes or at the level of the fine cholangiolar ductules (21). The nonspecific nature of histologic findings (i.e., canalicular bile plugs and bile staining) makes liver biopsy rarely useful in precisely identifying the cause of postoperative intrahepatic cholestasis. Liver biopsy, however, may be helpful in excluding the presence of underlying liver disease before the surgical procedure (see subsequent text).

The most important clinical aspect when diagnosing postoperative cholestasis is to clearly ascertain the absence of mechanical biliary obstruction. Once the patency of the macroscopic biliary tree has been established, the clinician must consider the various causes of intrahepatic cholestasis. A broad number of liver disorders can occasionally present with a cholestatic pattern, including therapeutic drug–induced hepatic injury, infections, and cholestatic variants of

viral hepatitis.

Therapeutic Drug–Induced Hepatic Injury

Several pharmacologic agents frequently utilized in the perioperative period have the potential to cause liver injury. These include excessive use of acetaminophen and idiosyncratic hepatotoxic reactions to many antibiotics, anticonvulsants, and cardiovascular agents. Some commonly used agents with potential for hepatotoxicity include sulfas, penicillin derivatives, nitrofurantoin, phenytoin, amiodarone, statins, metronidazole, and fluconazole. Although acetaminophen administered in therapeutic doses is not hepatotoxic, liver injury may develop with routine doses in patients who regularly consume alcohol and/or have endured prolonged fasting, which deplete glutathione reserves (22). These individuals may develop elevated postoperative aminotransferase levels as a result of inadvertent acetaminophen overdosing, or as a result of the preceding factors that enhance acetaminophen hepatotoxicity. A detailed review of drug-induced hepatotoxicity can be found elsewhere in this textbook (see Chapters 33 and 34). Because of the large number of drugs with the potential to cause postoperative hepatic dysfunction, a careful history and review of the records documenting the agents used before, during, and after the surgical procedure is a key element of the investigation of postoperative liver injury. In general, drugs that the patient had been taking for more than 1 year preoperatively are unlikely to be involved in postoperative hepatotoxicity. Drug-induced liver injury generally develops within a few weeks and up to 12 months of exposure to the offending agent (1,2,3). Consequently, very early postoperative jaundice or liver biochemical abnormalities are unlikely to be related to drugs (with the possible exception of acetaminophen overdose). In contrast, hepatic dysfunction developing 2 to 3 weeks after surgery, or after initiation of new pharmacologic therapy, should be considered suspicious of drug-induced liver injury. The biochemical and histologic patterns of drug-induced liver injury encompass the broad spectrum of hepatic pathology. The cause–effect relation between a suspected agent and postoperative liver damage should be ascertained by assessing the temporal sequence of events and excluding other types of postoperative liver dysfunction, such as hepatic ischemia, viral hepatitis, and the cholestatic disorders outlined earlier. Liver biopsy is occasionally necessary to exclude other

etiologies, but more often, there are no histologic features that are diagnostic of drug-induced liver disease.

Hepatitis and Cholestasis Associated with Anesthetic Agents

General anesthesia is a well-known cause of postoperative jaundice.

Careful review of the anesthetic record is important when determining the etiology of postoperative hepatic dysfunction. Certain anesthetic agents, sustained decrease in systolic blood pressure with subsequent reperfusion, and the need for cardiopulmonary bypass can all lead to severe liver injury (23,24,25).

The most common manifestation, however, is transient hepatic dysfunction resulting from a reduction in splanchnic arterial blood flow during general anesthesia (25). Often, this is not correlated to a dramatic change in systolic blood pressure on the anesthetic record. In patients with portal hypertension, intraoperative hemodynamic changes can be of greater consequence. In cirrhosis, there is frequently reduced portal venous flow, and the hepatic artery is the primary source of inflow to the liver (5).

In cases of true ischemic injury, aminotransferase levels can be elevated up to 100 times the normal value, along with significant elevations in lactate dehydrogenase (LDH) levels within the first few days. Alkaline phosphatase levels increase minimally (26). If the injury is severe, patients can further develop subfulminant or fulminant hepatic failure. In general, the liver blood biochemical test results return to normal within a week, although bilirubin may take longer to normalize. Liver biopsy can be useful to rule out underlying liver disease. Centrilobular (zone 3) hepatocellular necrosis is generally found and congestion is observed when cardiac failure has had a role in the ischemic injury. In general, a liver biopsy is not necessary to confirm the presence of postoperative ischemic hepatic injury (27,28).

Certain volatile anesthetic agents have been implicated in the development of hepatitis. The most well-known instance is that of halothane and its metabolites (29,30,31). Halothane-associated hepatitis is estimated to occur in 1 of 10,000 halothane doses (32). Although hepatitis has been reported to occur after a single administration of anesthetic, the more common history involves multiple exposures. As the number of exposures increases, the severity of the hepatitis worsens. Some lethal reports have involved exposure intervals of less than 3 months. Patients at risk are often obese, older than 30 years, and of female gender (1,33).

The two mechanisms thought to be involved are direct hepatic toxicity and the production of immunogenic protein complexes. All volatile anesthetic agents undergo some degree of biotransformation by the hepatic cytochrome P-450 system. The triacetyl chloride produced is the most troublesome because it binds covalently to hepatic macromolecules (34,35). Although this metabolite can lead to direct hepatocyte injury by itself, the more significant action of this protein immunocomplex is its initiation of the inflammatory response. Activation of the inflammatory cascade leads to amplification of the reaction and sensitization (36). Therefore, there is more severe

reaction with each added exposure.

Although elevation of liver blood biochemistries can be seen early after the exposure, symptoms can manifest as late as 2 to 3 weeks after administration. With each subsequent exposure, symptoms may present earlier. Patients can develop fever, nausea, vomiting, and rash followed by jaundice. They may also complain of arthralgias and right upper quadrant pain and have hepatomegaly on physical examination. Laboratory evaluation reveals significant elevation of liver biochemical test results depending on the severity. In mild to moderate cases, aminotransferase levels will be slightly elevated. However, in severe episodes, aminotransferase levels can be up to ten times the normal value, with significant elevation of LDH and serum bilirubin levels and decrease in concentration of coagulation factors. Usually, the liver function returns to normal within the first few weeks. However, progressive liver failure can occur, and mortality rates of up to 60% have been reported (1). Histology varies among reports (29,37). In moderate cases, pathology reveals centrilobular necrosis, with intense mononuclear infiltrate. In more severe cases, massive hepatic necrosis can be observed. Often, there is eosinophilia, supporting a role for an immune response. Although these changes are usually transient, chronic hepatitis with piecemeal necrosis has been seen on liver biopsy specimens as late as 10 months after exposure (38).

Other halogenated agents used for anesthesia include enflurane, methoxyflurane, sevoflurane, isoflurane, and desflurane. Of these, enflurane and methoxyflurane have been more frequently reported to cause drug-induced hepatitis (39). The likelihood of developing a reaction is associated with the rate of biotransformation of each drug. Halothane, with a rate of 20%, is more likely to cause hepatitis than enflurane, sevoflurane, isoflurane, or desflurane, with rates of 2.5%, 1%, 0.2%, and 0.02%, respectively (35). Scattered reports do exist in the literature for each of these agents, although they remain quite rare. Because there is cross-reactivity among these agents, exposure to any of them may lead to reactions to the rest. For instance, all the reports involving desflurane or isoflurane document prior exposure to halothane or enflurane.

Treatment consists of withdrawal of the causative agent and supportive care. If hepatic failure develops, urgent liver transplantation may be required. Once a

patient has had documented liver dysfunction from any of the halogenated anesthetics, it is recommended that their use be avoided on subsequent surgical procedures.

Postoperative Cholestasis Due to Infection

Postoperative sepsis can be accompanied by abnormal liver biochemical

test results. The total bilirubin level, including an increase in direct-reacting bilirubin, is often elevated to a range between a few milligrams per deciliter and sometimes greater than 20 mg/dL. Alkaline phosphatase and aminotransferase levels may also be abnormal, but generally to a lesser degree than those of bilirubin and in a nonspecific manner. Infections with anaerobes, aerobes, and gram-positive and gram-negative bacteria can lead to postoperative intrahepatic cholestasis. Pyelonephritis or urinary tract infection, appendicitis, cholecystitis, diverticulitis, or peritonitis in the postoperative patient can be associated with the development of cholestatic reactions. Infection-related cholestasis should be suspected in the presence of fever, leukocytosis, positive blood cultures, or evidence indicating an active infectious process (e.g., abscess on imaging studies and/or purulent drainages). The diagnosis of infection-related hepatic dysfunction should also be considered when the etiology of postoperative jaundice remains obscure and other causes of jaundice have been appropriately ruled out. Liver biopsy is not required for the diagnosis because of the lack of specific histopathologic features. If performed, however, hepatic histology often reveals ductular proliferation, polymorphonuclear-based cholangitis, and canalicular cholestasis. The management of postoperative jaundice associated with infection should focus on the treatment and control of the specific infection.

Viral Hepatitis

Currently, transfusion of blood products carries a very small risk of transmitting hepatitis B or C viruses (40). Consequently, acute viral hepatitis has become a rare cause of postoperative jaundice. Postoperative acute viral hepatitis is likely to have been acquired before the surgical procedure, and without knowing this the patient may have undergone the surgery during the incubation period of the hepatitis virus. The elevation of ALT and AST levels may be detected at any time after surgery, depending on the timing of the infection and the virus incubation period. The characteristic biochemical profile is that of a marked elevation of the content of aminotransferases, often to greater than ten times the upper normal level. In severe cases, bilirubin level also increases and coagulopathy may develop. The serologic diagnosis, management and prognosis of acute viral hepatitis A, B, or C, is reviewed in detail elsewhere in this textbook (see Chapter 26). Other viruses that may cause hepatitis (e.g., Epstein-Barr, cytomegalovirus, herpes simplex) are even less common in the postoperative setting, but they should be kept in mind when dealing with immunosuppressed patients (41).

Benign Postoperative Cholestasis

A frank cholestatic syndrome may develop postoperatively with

prominent elevation in alkaline phosphatase levels and mild to moderate hyperbilirubinemia. The abnormalities typically develop during the first two postoperative weeks and occasionally may take weeks or months to resolve. The diagnosis of benign postoperative cholestasis should be considered in patients after major or complicated abdominal or thoracic surgery. Benign postoperative cholestasis may also occur in patients who receive large amounts of transfusions, develop a postoperative infectious process, or undergo surgery in the setting of burns or trauma.

The pathogenesis of benign postoperative cholestasis is not fully understood but it is generally considered a multifactorial process. Factors such as excessive bilirubin production from hematomas or transfusions, infections, prolonged complex surgery, hypoxemia, and decreased hepatic perfusion may play a role in the development of benign postoperative cholestasis. At the cellular level, cytokines resulting from the systemic inflammatory response may interfere with canalicular bile transport and lead to cholestasis (21).

Because there is no specific test to confirm benign postoperative cholestasis, this diagnosis is based on the exclusion of other causes of jaundice, most specifically obstruction. Basic viral hepatitis serologies are necessary if there is prominent ALT level elevation (greater than five to ten times of the upper normal limit) associated with cholestasis. Surgical and anesthesia records may reveal prolonged arterial hypotension, intraoperative heart failure, or sustained hypoxemia in patients who develop benign postoperative cholestasis. Liver biopsy is not required to establish the diagnosis but it may be considered when atypical features are present, or in patients suspected of having underlying cholestatic liver disease not identified preoperatively. If a liver biopsy is performed, histologic findings supportive of benign postoperative cholestasis include canalicular bile plugs and prominent bile staining, especially in the centrilobular areas; foamy degeneration of hepatocytes; and modest focal steatosis (42). Less frequently, serum bilirubin level may peak between 10 and 40 mg/dL. In these instances, repeated assessment of the biliary tract with ultrasonography is necessary to exclude intercurrent biliary obstruction. The prognosis of benign postoperative cholestasis is variable and depends less on the cholestatic reaction than on the

overall condition of the patient and severity of associated comorbidities. Management is directed toward the reversal of factors leading to impaired hepatic function and include appropriate intravascular volume support, correction of anemia, antibiotic therapy for infections, and replacement of potentially cholestatic therapeutic drugs by agents metabolized and excreted by extrahepatic sites. There are no data supporting the routine use of choleretics such as ursodeoxycholic acid to treat or expedite the resolution of benign

postoperative cholestasis. When the cholestasis is prolonged, the associated postoperative decreased enteral nutrition and use of antibiotics may cause vitamin K deficiency and lead to coagulopathy. Parenteral administration of vitamin K is useful in correcting the prolonged prothrombin time in this setting. Failure of vitamin K to correct the prothrombin time should raise the suspicion of underlying parenchymal liver disease.

Hepatic Ischemia

Ischemic injury to the liver is a relatively common cause of postoperative abnormal liver function test results (26,27,28). There are multiple mechanisms by which the liver may experience perioperative ischemic damage, including arterial hypotension leading to diminished splanchnic arterial perfusion and portal vein blood flow, effect of anesthetic agents, right or left cardiac failure, severe hypoxemia, and even ischemic-reperfusion injury. Moreover, the patient with cirrhosis is especially susceptible to intraoperative ischemia because of the increased dependency of the cirrhotic liver on hepatic artery blood flow. Whether patients with NAFLD or NASH are more prone to perioperative hepatic ischemia is not known. A recent report on bariatric surgery in patients with NASH-related cirrhosis did not find increased postoperative ischemic complications (4).

Jaundice may occur in severe cases of hepatic ischemia but more often the injury is characterized by an early and rapid rise of the levels of both aminotransferases within 1 to 10 days of the surgical procedure. The extent of the elevation varies considerably and may range from 2 to greater than 100 times the upper normal limit of AST and ALT concentration. Once the hepatic hypoperfusion is corrected, ALT and AST levels also generally begin to decline at a fast rate. Alkaline phosphatase level is generally normal or only mildly elevated. LDH level is also markedly elevated in hepatic ischemia. It is important to consider that in postoperative trauma patients, AST, ALT, and LDH may not necessarily reflect hepatic injury but these enzymes may also originate from extensive muscle injury or rhabdomyolysis. In severe cases of hepatic ischemia, elements of liver failure may develop, such as coagulopathy, hypoglycemia, and hepatic encephalopathy. However, hepatic ischemia is an uncommon etiology of acute liver failure (43).

The diagnosis of postoperative hepatic ischemia is based on the clinical picture, the time course and pattern of liver biochemical abnormalities, and the identification of perioperative conditions leading to hepatic ischemia. Therefore, a history of intra- or postoperative myocardial infarction, shock, pulmonary embolism, significant hypoxemia, or arterial hypotension of any cause will often be found associated with postoperative ischemic hepatic dysfunction. A review of the intraoperative anesthesia records may reveal periods of sustained

arterial hypotension. If the surgical procedure consisted of a cholecystectomy or surgery near the *porta hepatis*, or involved an anatomic hepatic resection, the possibility of inadvertent ligation of the hepatic artery or a main branch must be considered. Imaging studies (e.g., magnetic resonance imaging [MRI], multiphase computed tomography [CT], and Doppler ultrasonography) may show areas consistent with infarction or absent hepatic vascular flow.

Given the predominant elevation of levels of aminotransferases, the differential diagnosis must include viral hepatitides and drug-induced hepatitis. However, the increase in the levels of these liver enzymes generally occurs later in the postoperative period, and the rise and decline in their concentration are more gradual than the relatively rapid changes observed in hepatic ischemia. Liver biopsy is not necessary to establish the diagnosis of ischemic hepatic injury except when the clinical picture is obscure. Histologic findings of noninflammatory centrizonal hepatocellular necrosis support the diagnosis of postoperative hepatic dysfunction due to ischemic injury.

Management of postoperative hepatic dysfunction due to ischemic injury consists of restoration of hepatic perfusion by appropriate support of the intravascular blood volume.

Hypoxemia should be corrected and the underlying complications (i.e., hemorrhage, cardiac failure, pulmonary embolism, and sepsis) treated accordingly. The outcome of hepatic ischemia is generally favorable but the patient's prognosis is determined by the severity of the associated comorbid conditions.

Postoperative Jaundice due to Increased Bilirubin Load

Mild degrees of unconjugated (indirect-reacting) bilirubin are not uncommonly observed in postoperative patients. Although the liver has a large capacity to take up, conjugate, and excrete bilirubin, under certain circumstances, the amount of bilirubin produced may exceed the capacity of hepatic removal. Therefore,

resorption of large hematomas, large volume transfusion, and underlying hemolytic conditions (e.g., glucose-6-phosphate dehydrogenase [G6PD] deficiency, sickle cell disease, autoimmune hemolytic anemia, and thalassemias) may result in excessive production of bilirubin. In other patients, increased intravascular hemolysis is caused by therapeutic drugs, mechanical heart valves, or infections. The diagnosis should be suspected when mild to moderate hyperbilirubinemia (2 to 6 mg/dL) develops during the first two postoperative weeks. Because of the considerable content of AST and LDH in red blood cells, the hyperbilirubinemia may be accompanied by modest elevation in the levels of AST and/or LDH. ALT level, alkaline

phosphatase level, prothrombin time, and serum albumin level should be normal or only minimally altered. Deformed red blood cells in the peripheral smear, low circulating haptoglobin levels, and increased reticulocyte count point to hemolysis as the cause of postoperative jaundice.

Frequently, patients have multiple factors that may cause postoperative jaundice, including hepatic ischemia, underlying liver disease, infection, and impaired renal function. In this multifactorial setting, the effect of bilirubin overproduction is compounded by hepatic dysfunction. Serum bilirubin levels may reach higher values, have a substantial component of conjugated bilirubin, and may be accompanied by significant elevation in the level of ALT and coagulopathy.

Management consists of close monitoring of the liver biochemical abnormalities while correcting the reversible factors outlined earlier.

Postoperative Jaundice Associated with Parenteral Nutrition

Total parenteral nutrition (TPN)-induced liver dysfunction is not uncommon; however, it is rarely the primary cause of postoperative jaundice. Other etiologies of liver dysfunction must be ruled out before this diagnosis. In fact, the indication for TPN is often associated with significant comorbidities that may lead to postoperative hepatic dysfunction. Discerning the length of time for which the patient has received TPN is another significant factor. Chronic TPN administration, usually for more than 3 months, may lead to the development of liver disease. Bacterial or fungal sepsis is associated with both cholestasis and TPN administration. Bacterial overgrowth from bowel disease and the presence of indwelling catheters predispose patients to systemic infection. Conversion to enteral nutrition as early as possible should be the primary goal.

Within the first 2 weeks of TPN administration, mild elevation of liver biochemical test results is frequently observed. Benign steatosis is the most common finding on biopsy and is often the result of excessive caloric intake, particularly from dextrose (44). Rarely, patients may present with right upper quadrant pain and hepatomegaly (45). The initial step in evaluating abnormal liver biochemical test results in a postoperative patient on TPN should include an assessment of the percentage of calories from carbohydrates and fats and adjustment of the formulation as necessary.

The mechanism for TPN-induced steatosis is multifactorial. Hormonal derangements and nutritional deficiencies that promote production of fat and impair its release from the hepatocyte are involved. Although controversial, several reports support the use of oral lecithin

supplements and choline-supplemented TPN to ameliorate steatosis (45,46). Benign steatosis is associated with a moderate increase in aminotransferase levels along with mild increases in alkaline phosphatase and serum bilirubin levels. These laboratory abnormalities are nonspecific and are present in other etiologies of postoperative liver dysfunction. Therefore, liver biopsy may be helpful when the diagnosis is uncertain. Histology can range from isolated periportal fat to panlobular involvement in severe cases (47,48). The laboratory and histologic changes generally correlate with length of TPN administration. Withdrawal of TPN often leads to complete resolution. If a postoperative patient is TPN dependent, however, manipulation of the TPN formula or cycling over 10 to 12 hours each day may allow for reduction or slowing of the process. As TPN administration is prolonged, steatohepatitis with eventual fibrosis may develop (49). Withdrawal of TPN at this point may or may not lead to improvement in fibrosis. However, many of these patients have intestinal failure and are TPN dependent. These patients may ultimately require combined liver–intestinal transplantation. TPN-induced cholestasis is a less common finding in short-term courses of nutritional support. If it does occur, it may present as early as 3 weeks after starting therapy. In children, cholestasis is the most common presentation and is related to incomplete development of biliary secretory mechanisms in premature infants (50). In adults, cholestasis manifests itself as a slow and progressive elevation of alkaline phosphatase and bilirubin levels. In these patients, early use of metronidazole to prevent bacterial overgrowth and ursodeoxycholic acid to induce bile flow and promote a more hydrophilic bile may help improve the hepatic dysfunction (51,52). Lastly, TPN may directly affect the biliary tract. Patients who are unable to use their gastrointestinal system develop akinesis of the gallbladder with biliary stasis and ultimately develop sludge. Length of TPN therapy correlates with gallbladder dysfunction. After 6 weeks, most patients have evidence of gallbladder sludge on ultrasound (45,53). The presence of sludge promotes the production of biliary stones,

thereby leading to the complications associated with cholelithiasis. Regardless of sludge or stones, TPN may play a role in acalculous cholecystitis. This diagnosis is usually made in critically ill patients, with multiple factors contributing to its development. Because the diagnosis is difficult to make and the morbidity is significant, prevention is the primary goal. Early enteral feeding or administration of cholecystokinin to stimulate gallbladder activity appears beneficial. A calculous cholecystitis can also occur in chronically ill patients who have been TPN dependent for longer than 3 months. The patients may need a cholecystectomy if medically stable or otherwise drainage by a percutaneously placed cholecystostomy tube (54).

Postoperative Jaundice following Liver Transplantation

With current liver allocation based on the MELD score, many patients undergoing liver transplantation have prolonged jaundice in the posttransplantation period. The differential diagnosis for postoperative onset or worsening of jaundice after liver transplantation is broad and include primary allograft dysfunction, ischemic injury, intraoperative transfusions, therapeutic drug hepatotoxicity, biliary and/or vascular complications, hematoma reabsorption, acute cellular rejection, ABO mismatch, disease recurrence, and bacterial, fungal, and viral infections. The evaluation and management of postoperative liver allograft dysfunction is reviewed in detail elsewhere in this book (see Chapters 55 and 56).

Chapter 26

The Hepatitis Viruses

Amany Zekry

John G. Mchutchison

Key Concepts

- *Hepatitis A virus* is a ribonucleic acid (RNA) virus accounting for most cases of acute hepatitis. Seroprevalence rates in industrialized countries have been falling because of vaccination programs and improvements in socioeconomic conditions. As a result, an age-related shift in seroprevalence has taken place in which adults and elderly are presently more at risk of infection.
- *Hepatitis B virus* (HBV) is a deoxyribonucleic acid (DNA) virus, with the highest prevalence rates of infection in Southeast Asia, China, and Africa. Most persons who acquire the infection before 5 years of age develop chronic hepatitis B infection. The natural course of chronic infection is variable. HBV-infected patients have an increased risk of developing hepatocellular carcinoma (HCC) compared to uninfected patients. A variety of therapies are available and approved, including conventional interferon (IFN), pegylated IFN, and nucleoside analogs such as lamivudine, adefovir dipivoxil, and entecavir. Treatment of HBV is, however, still limited by factors such as the development of drug resistance and the low efficacy of available therapies in eliminating covalently closed circular HBV DNA.
- *Hepatitis C virus* (HCV) is an RNA virus, accounting for most patients with chronic hepatitis worldwide. Intravenous drug use is presently the primarily source of infection. The natural course of HCV infection, although slowly progressive usually, is variable. Pegylated IFN has been shown to be effective in permanently eradicating the virus in the setting of acute HCV infection. Presently, the combination of pegylated IFN-α and ribavirin is the standard therapy for chronic HCV infection and appears to cure approximately 50% of treated patients. Response and duration of treatment is dependent on the infecting viral genotype.
- *Hepatitis delta virus* (HDV) relies on HBV for infectivity and persistence. Dual infection with HDV and HBV results in progressive liver disease and increased risk of HCC. IFN remains the only drug to

have any therapeutic effect.

- *Hepatitis E virus* (HEV) is an RNA virus that causes an acute self-limiting hepatitis with no chronic sequelae. Acute HEV infection, however, results in a high mortality rate among pregnant women, particularly during the third trimester.
- *Hepatitis G virus* (HGV) is a recently identified RNA virus. A firm and direct association with liver pathology is still lacking, and it is unclear whether HGV is hepatotropic. Coinfection with HGV and human immunodeficiency virus (HIV) has been shown to improve mortality and morbidity for the HIV-infected individuals and slows progression to acquired immunodeficiency syndrome.
- Herpesviruses are a family of large enveloped DNA viruses. Infection with herpesviruses occurs worldwide. Herpesvirus infection is occasionally associated with hepatitis. Clinically overt severe and fulminant hepatitis may, however, occur, usually in immunocompromised hosts.

There are six identified human hepatitis viruses; these are hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis delta virus (HDV), hepatitis E virus (HEV), and hepatitis G virus (HGV). These viruses have distinctive biologic and clinical properties that have been unraveled over the years. In this regard, substantial advances have been made in our understanding of the genomic structure, life cycle, natural history, and pathogenesis of most of these viruses. We have also been able to exploit our increased knowledge to develop effective therapeutic strategies for each of these viruses, and several advances have been made in this regard (Table 26.1). Despite these ongoing efforts, viral hepatitis continues to represent a major public health challenge worldwide. Also, chronic hepatitis remains a disease with significant morbidity and mortality, and response to current therapy is far from optimal.

This chapter introduces each of these viruses, giving an overview of the epidemiologic aspect, molecular aspect, natural history, immunopathogenesis, and treatment aspect of each. In addition, we discuss briefly the herpesviruses, which are not primarily hepatotropic, but are occasionally associated with hepatitis.

Hepatitis A Virus

Epidemiology

HAV infection is a major cause of acute hepatitis and liver failure throughout the world. HAV infection is particularly common in developing countries of Africa, Asia, and Latin America, where seroprevalence rates approach 100% (1). In these countries, most infections occur by 5 years of age. By contrast, seroprevalence rates in industrialized countries have been falling because of improvements in socioeconomic conditions. As a result, an age-related shift in seroprevalence has taken place, so that adults and

the elderly are at a greater risk of acquiring an HAV infection. Therefore, about one third of the US population has serologic evidence of previous HAV infection, with prevalence rates ranging from 9% among children to 75% among persons aged 70 years or older (1).

HAV is primarily transmitted enterically (fecal–oral route), typically by ingestion of contaminated food or water and through person-to-person contact within the household (2). Crowded or unsanitary conditions are commonly implicated. Although it is rare, parenteral transmission due to the use of contaminated blood products is possible, while vertical transmission is extremely uncommon (2,3). Risk groups for HAV infection include travelers to endemic areas, military personnel, day care workers, and the institutionalized patients. Also, homosexuals with multiple sexual partners and intravenous drug users are at higher risk for HAV acquisition (2).

Table 26.1. Recent Developments in Therapy for Viral Hepatitis

HAV
Effective vaccines are available; however, HAV remains a major cause of acute hepatitis worldwide
HBV
Effective vaccines have reduced HBV prevalence in many countries
Pegylated interferon monotherapy has recently been shown to have significant virologic efficacy in a trial comparing this treatment alone to combination of pegylated interferon and lamivudine or lamivudine alone in largely Asian HBeAg-positive patients
In patients awaiting liver transplantation, lamivudine has been shown to suppress HBV DNA, stabilize the progression of liver disease, delay the need for liver transplantation, and improve survival among these patients
Adefovir dipivoxil suppresses HBV DNA in patients with lamivudine resistance
In HBeAg-negative patients, the virologic response achieved by a 12-mo course of adefovir is not sustained once treatment is ceased
Entecavir effectively suppresses HBV DNA in HBeAg-positive and HBeAg-negative patients, as well as in those with lamivudine resistance
HCV
Pegylated interferon monotherapy is effective in achieving viral clearance in acutely infected patients
Combination pegylated interferon and ribavirin is presently the treatment of choice for chronic HCV infection
Combination pegylated interferon/ribavirin is well tolerated in HCV/HIV coinfected patient and results in acceptable virologic response rates

Combination pegylated interferon/ribavirin is presently used to individually treat significant recurrent HCV infection after liver transplantation
Ongoing research into novel therapeutic agents and vaccine development is proceeding rapidly

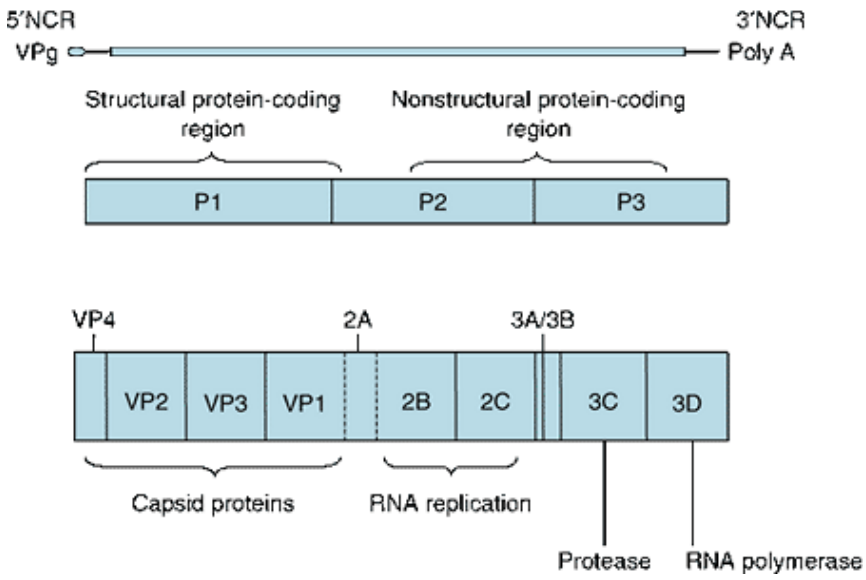
HDV

High-dose prolonged interferon monotherapy remains the most effective therapeutic option, although side effects may limit therapy

HAV, hepatitis A virus; HBV, hepatitis B virus; HBeAg, hepatitis B e-antigen; DNA, deoxyribonucleic acid; HCV, hepatitis C virus; HDV, hepatitis delta virus; HIV, human immunodeficiency virus.

The Hepatitis a Virus Genome and Proteins

HAV is a ribonucleic acid (RNA) virus, a member of the Picornaviridae family. HAV is a nonenveloped icosahedral particle 27 to 32 nm in diameter (4). The infectious particle consists of a capsid protein and the RNA genome. The HAV genome is a positive single-stranded RNA approximately 7.5 kb long (Fig. 26.1). The genome is defined by three distinct regions: The 5′ noncoding region (NCR) of approximately 735 nucleotides contains an internal ribosomal entry site (IRES). As with other picornaviruses, the 5′ end of the genome does not have a cap structure but instead is covalently linked to the viral protein VPg, involved in the initiation of RNA synthesis. The 5′ NCR appears to be the most conserved region of the genome. Some mutations in the 5′ NCR region enhance growth of HAV in cell culture but do not appear to have a major role in determining HAV virulence. The 5′ NCR is followed by a single open reading frame (ORF) for a large polyprotein containing P1, P2, and P3 regions. The P1 region encodes the capsid proteins VP1 to VP4. Mature capsid proteins are the predominant form in virions. VP1 and VP3 form a single, dominant epitope on the viral capsid and elicit a neutralizing antibody response. VP4 harbors a potential myristoylation site and is essential for virion formation. The P2 and P3 regions encode the nonstructural proteins associated with viral replication. Among these proteins, 3C is recognized as the sole protease for HAV, while protein 3D has RNA-dependent RNA polymerase activities. Precursor polypeptides include VP0, which is a VP4/VP2 fusion protein. Finally, the 3′ NCR is about 63 nucleotides in length, terminating in a poly-A tract.



▪ **Figure 26.1** The hepatitis A virus (HAV) genome—the HAV genome is a linear, positive-sense, single-stranded ribonucleic acid (RNA) approximately 7.5 kb in length. A VPg protein is covalently attached to the 5′ end of the genome and a poly-A tail at the 3′ end. The genome codes for a single polyprotein of approximately 2,235 amino acids. The polyprotein is divided into three main functional domains: P1, P2, and P3. P1 encodes the viral capsid proteins while P2 and P3 code for the nonstructural proteins including RNA helicase, protease, and RNA polymerase. 5′ NCR, 5′ noncoding region.

Hepatitis a Virus Life Cycle

It is not clear how the HAV reaches the hepatocytes. The virus is taken up by a mucin-like class I integral membrane glycoprotein, presumed to be the receptor for HAV (5). However, it is not known how the virus reaches the cytoplasm, the site of viral replication. Replication of the genome occurs by a mechanism involving the RNA-dependent RNA polymerase. In this regard, virus-encoded proteins replicate the RNA genome through a negative-strand intermediate. A relatively large number of plus strands are transcribed from the minus strand. The new plus strand may enter another cycle of replication or serve as a template for polyprotein translation. For translation, cis-acting picornaviral IRES is thought to interact with trans-acting cellular factors, so that 40S ribosomal subunits begin translation at the correct initiation codon. The HAV has two initiation codons that can function independently (6). The single ORF of the picornaviruses is translated into one long precursor polypeptide (Fig. 26.1), which is processed by a cascade of proteolytic cleavage to yield the mature viral proteins (7). 3C protein is the primary cleavage enzyme. The primary cleavage takes place cotranslationally at the C-terminus of the VP1/2A precursor. Subsequently, 3C secondarily catalyzes VP2/VP3 and VP3/VP1 to

produce 14S pentamers containing VP0, VP3, and VP1/2A. VP1 is released from 2A by cellular proteases. Maturation

cleavage involves the processing of VP0 to release VP4 and VP2. Trans-acting host factors for HAV may play a role in the translation process. The pentamers assemble to form empty capsids (procapsids) or incorporate virion RNA to form provirions. The mechanisms by which the virus is released and secreted from the infected cell have not been entirely elucidated as yet.

Natural History of Hepatitis a Virus Infection

Humans are the principal host of HAV. Most infections (70%) in children younger than 6 years are asymptomatic, in contrast to a frequently symptomatic course in adults. With increasing age, infections become more and more clinically apparent, and by adolescence, more than 80% of patients develop jaundice (2,8). After acute HAV infection, recovery with lifelong immunity is the norm. Uncommon clinical features of acute HAV infection include the development of cholestatic hepatitis or, less commonly, relapsing hepatitis. In each of these situations, however, the prognosis is good. Fulminant hepatitis develops in less than 1% of acutely infected HAV cases and is more common among infected adults. Therefore, elderly patients and persons with chronic liver disease are at increased risk of progressing to fulminant liver failure (9). Although spontaneous recovery usually occurs, liver transplantation may be necessary for those patients who fail to improve.

Immunopathogenesis of Hepatitis a Virus Infection

HAV is unlikely to be a cytopathic virus, and the host immune response to HAV is believed to be responsible for the observed necroinflammatory lesion. In support of this, increased expression of CD4 and $CD8^+$ T-cell receptors has been demonstrated at inflammatory sites in the livers of acutely infected patients (10). Moreover, HAV-specific $CD8^+$ T cells with cytotoxic activities have been isolated from these affected livers (11). In the acute phase of the illness, a dominant immunoglobulin M (IgM) and IgG immune response against VP1 has been identified. Similarly, antibodies against VP3 and VP0 develop during the late convalescence phase. Circulating antibodies, therefore, seem to limit the viremic phase. Nonsecretory IgG antibody to HAV then persists in the serum after infection, providing lifelong immunity.

Treatment of Hepatitis a Virus Infection

No specific therapy is required for acute HAV, and antiviral therapy is not available. The most effective means of controlling HAV are preventive measures relying on strict hygiene and vaccination programs. Available vaccines are safe, highly immunogenetic, and induce long-lasting (>20 years) protection against HAV. Routine vaccination is currently recommended for high-risk groups aged 2 years or older. These groups

include young children in endemic areas and travelers to these areas, homosexual men, intravenous drug users, and patients with chronic liver disease (12).

Hepatitis B Virus

Epidemiology

The epidemiology of HBV infection varies greatly worldwide. The HBV carrier rate ranges from 8% to 20% in highly endemic areas such as Southeast Asia, China, and Africa to less than 2% in North America, western Europe, and Australia (13). In highly endemic areas, spread of HBV infection is mostly the result of maternal–infant transmission (vertical), while the use of reusable syringes and injectable drugs, and sexual spread, are also important. In contrast, sexual activity and injectable drug use account for most HBV cases in low endemic areas. However, even in low endemic areas, HBV infection is present in a substantial number of immigrants from highly endemic areas. Other less common risk factors for HBV transmission include occupational exposure, hemodialysis, acupuncture, household contact, and the receipt of infected organs or blood products (13).

In several countries, effective strategies have been implemented to reduce the risk of HBV transmission. These include public education, routine infant and adolescent vaccination, HBV screening of pregnant women, and administration of postexposure prophylaxis to infants of infected women (14). In Taiwan, the HBV vaccination program in newborns has dramatically decreased both the prevalence of hepatitis B infection and the incidence of hepatocellular carcinoma (HCC) in this population (15).

Hepatitis B Virus Genome and Proteins

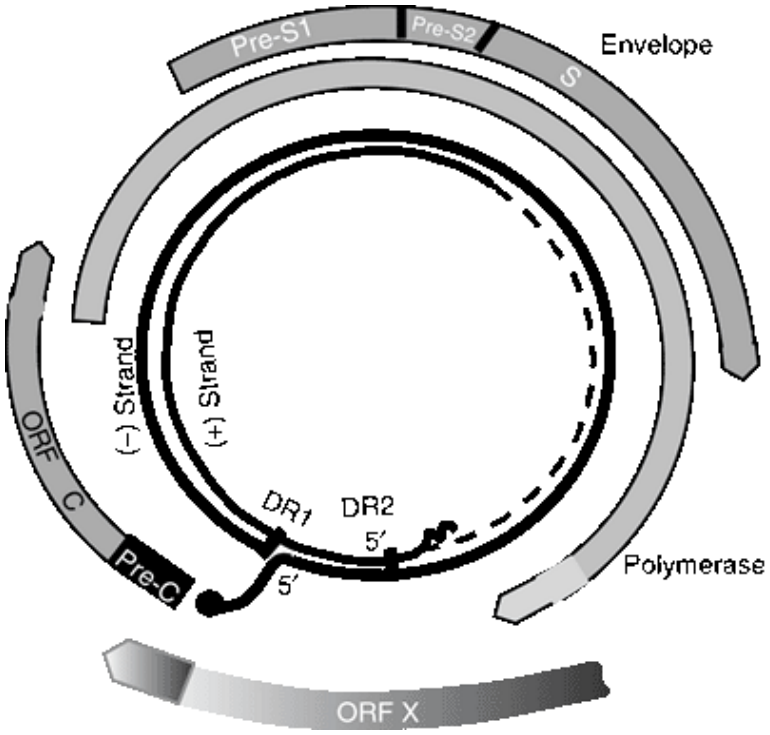
HBV is a member of the Hepadnaviridae family (hepatotrophic deoxyribonucleic acid [DNA] viruses). The mature HBV virion, also known as the *Dane particle*, is 42 nm in diameter, consisting of an outer lipoprotein layer that encodes the viral envelope proteins, the hepatitis B surface antigen (HBsAg), and surrounds a nucleocapsid core, the hepatitis B core antigen (HBcAg) (16). The nucleocapsid contains the viral genome and the viral polymerase. In addition to the mature virions, HBV-infected serum contains two other distinct subviral particles that are either spherical

or filamentous in shape and are approximately 20 nm in width. Subviral particles reach a 10,000-fold higher concentration than virions in the serum. They consist of an envelope glycoprotein and host-derived lipids. The precise biologic significance of this massive overproduction of empty envelopes is unknown; however, it has been speculated that they serve as decoys for the host's immune system.

The HBV genome (Fig. 26.2) is a partially relaxed double-stranded circular DNA of approximately 3,200 base pairs (bp) and encodes four partly overlapping ORFs: The envelope or the surface gene, the core gene, the

polymerase, and the X gene (HBx). The 5′ end of the complete minus DNA strand is covalently linked to the polymerase-coding gene, while the 5′ end of the plus strand is linked with a short piece of capped RNA. The termini of the 5′ end of the minus and plus strands map to the regions of short (11 to 12 nucleotides) direct repeats (DRs) in viral DNA, known as *DR1* and *DR2*. These repeat regions are involved in priming the synthesis of their respective DNA strands.

The viral envelope consists of cellular phospholipids and three virally encoded proteins, the small (S) or major, the middle (M), and the large (L) polypeptides. The L, M, and S proteins share a highly hydrophobic membrane region referred to as the *S domain*. Additionally, the L protein has a long region of 109 to 120 amino acids called *pre-S1*. The M protein has a 55 amino acid region identified as the pre-S2. Translation of these envelope proteins is initiated at three different in-frame start sites within a single ORF and is ended at a common termination codon (17).



▪ **Figure 26.2** The hepatitis B virus (HBV) genome—the viral deoxyribonucleic acid (DNA) is partially double stranded. It encodes seven proteins from four open reading frames (ORFs)—envelope (surface), core, polymerase, and the X gene and three upstream regions: Precore, pre-S1, and pre-S2. A polymerase protein is covalently attached to the minus (–) strand and a capped oligoribonucleotide is attached to the plus (+) strand. Direct repeats 1 and 2 (DR1 and DR2) are 11 base pairs repeat sequences with template functions during replication.

The core gene consists of the precore and core regions. The precore–core region encodes HBcAg and hepatitis B e-antigen (HBeAg) (18). The production of HBcAg is derived by an initiation AUG codon in the core gene, whereas HBeAg requires translational initiation from an AUG codon upstream of the core gene on the precore messenger RNA (mRNA). This 25-kDa precore–core fusion protein is processed by two cleavage events to generate a final circulating 16-kDa HBeAg fragment. Mutations emerging in the precore and core promoter regions result in reduced levels of HBeAg expression (19). Similarly, a recent novel class of mutations immediately preceding the precore AUG codon has been shown to reduce HBeAg expression by a leaky scanning mechanism facilitating early HBeAg seroconversion in carriers of the virus (20). Expression of HBeAg has been shown to be nonessential for virus viability in animal models and humans (17), and its precise biologic role in the life cycle of the virus remains unclear. HBeAg may serve an immunoregulatory function in the infected host.

The polymerase-coding region is specific for the viral polymerase involved in DNA synthesis, as will be discussed in the following sections.

The viral X gene codes for a 16-kDa protein termed the *HBx*, which exhibits pleiotropic activities. Absence of functional HBx in vivo has been shown to reduce core gene expression, supporting the hypothesis that an essential function of HBx is to enhance obligatory virus gene expression during infection (21). HBx also plays an important role in modulating host cell signal transduction and activating several cellular signaling pathways. Distinct from the transactivation, HBx modulates the DNA repair processes and as such has been implicated in the pathogenesis of HCC (22).

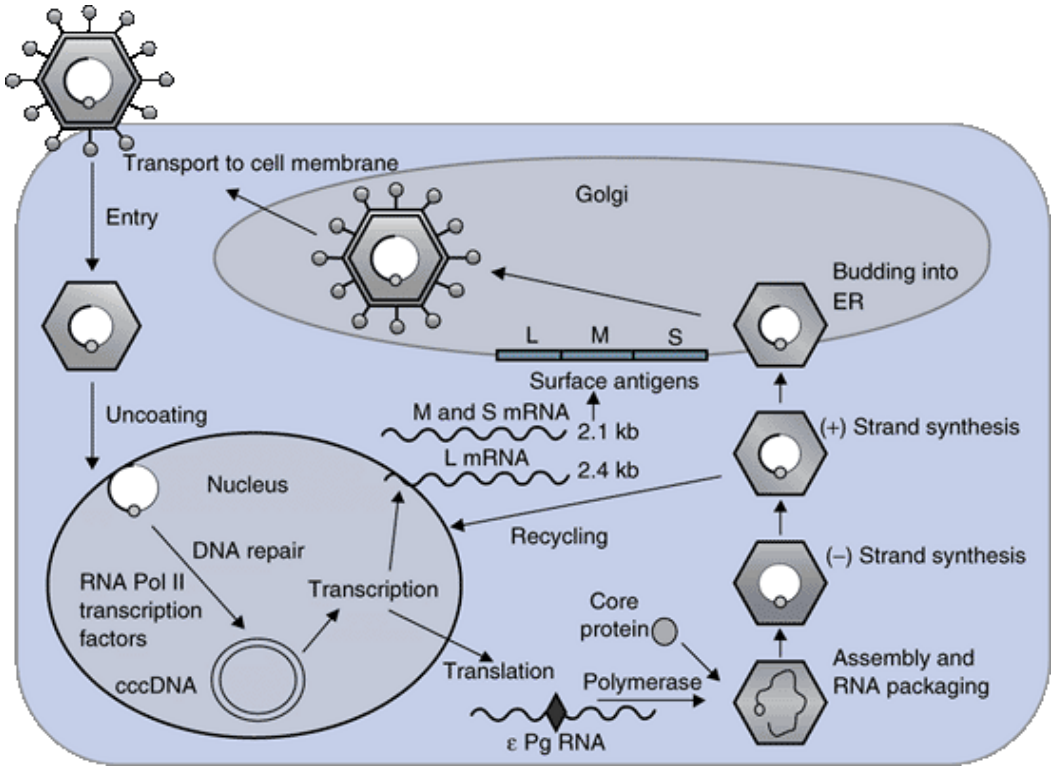
Hepatitis B Virus Life Cycle

The life cycle of HBV (Fig. 26.3) has been elucidated from studies in animal models and tissue cultures.

Entry and uncoating

The cycle begins by viral attachment to the host cell membrane through the envelope protein. Although the precise identity of the actual cellular receptor(s) remains unknown, the pre-S1 domain in the L-envelope region appears to be directly involved in the viral attachment to the host cell surface (23). The heat shock protein (hsp) 70 may also be involved in this process (24). After membrane fusion, the envelope is stripped

off and the nucleocapsid is released into the cytoplasm. Little is known about the postbinding steps in viral entry. It is likely, however, that the capsid "escorts" the viral DNA to the nucleus. Once in the nucleus, the partially double-stranded DNA is converted (or repaired) by viral polymerase into covalently closed circular DNA (cccDNA). This requires removal of its terminal structures (RNA and P protein), repair of the single-stranded gap region, and covalent ligation of the DNA termini.



▪ **Figure 26.3** Schematic representation of the life cycle of hepatitis B virus (HBV) (see text for explanation). L, M, and S are large-, middle-, and small-surface envelope proteins, respectively; ER, endoplasmic reticulum; RNA, ribonucleic acid; cccDNA, covalently closed circular deoxyribonucleic acid; mRNA, messenger ribonucleic acid; Pol II, polymerase II; Pg, pregenomic.

Transcription

Nuclear cccDNA serves as the template for transcription by host RNA polymerase II. Persistence of the virus in infected cells during chronic infections is likely to be dependent on generating, maintaining, and regulating the pool size of transcriptionally active cccDNA molecule.

Two classes of transcripts are synthesized from cccDNA, the genomic and the subgenomic classes. Both classes contain several transcripts, all unspliced and polyadenylated at a common position within the core gene. The subgenomic transcripts function as mRNA for the translation of the envelope proteins (L, M, and S proteins) and HBx protein (25). The two genomic mRNAs encode the precore, core, and polymerase ORFs.

The HBV DNA contains promoters corresponding to independent transcription from pre-S1, pre-S2/S, core, X, and possibly, precore. The HBV pre-S1 promoter directs transcription of the 2.4-kb large envelope, while the S promoter directs the transcription of several mRNAs of about 2.1 kb, which are translated to produce pre-S2 (middle) and S (small)

HBsAg proteins. The core promoter directs the transcription of pregenomic mRNA and precore mRNA. The precore mRNA translates the precore protein, while the pregenomic RNA serves as the template for reverse transcription. The pre-S1 and precore promoters are exclusively liver specific.

Two regions of the HBV DNA are identified to have the properties of transcription enhancers (26,27). These enhancers stimulate transcription in cis configuration in a position- and orientation-independent way. Enhancer I (En I) is located between the S and X ORF, while En II is located just upstream of the core promoter. The activity of En II is largely restricted to hepatic cells and is therefore responsible for activating viral replication in a liver-specific manner (28). In contrast, En I functions in hepatic and nonhepatic cells, strongly upregulating all the major HBV promoters (29,30).

Genomic replication

The first step in replication involves incorporation of viral RNA into the core, together with the polymerase. This encapsidation process is highly selective. The main trigger of this process is binding of the polymerase protein to a 5′-proximal stem loop structure called ε

(which acts as an encapsidation signal) on the pregenomic RNA. Mutations in the polymerase ORF allows capsid formation but not RNA encapsidation. This reaction also requires host proteins such as chaperone hsp90 (31). Encapsidation then proceeds by packaging the viral pregenomic RNA bound to the viral polymerase protein into core particle (32) together with hsp90, forming the nucleocapsid (33).

Viral deoxyribonucleic acid synthesis

Within the viral nucleocapsid, reverse transcription of the pregenomic RNA occurs. The pregenomic RNA is terminally redundant (200 nucleotides), containing the ε stem loop and a copy of the short DR1 sequence. There is growing evidence that initiation of the viral DNA minus strand synthesis occurs within ε and not DR1 as initially thought (34,35). This is initiated by the binding of polymerase to ε, generating a polymerase-linked oligonucleotide of about four nucleotides. These four nucleotides are homologous to the four nucleotides within DR1, allowing DNA transfer and annealing to this position. The strand transfer reaction occurs efficiently and is selectively directed to the 3′ copy of DR1. Once this occurs, elongation of the minus strands proceeds to the end of the template, completing minus strand synthesis. The minus DNA strand serves as the template for synthesis of the plus DNA strand. Plus-strand synthesis is initiated at DR2 and primed by capped oligonucleotides derived from the 5′ of pregenomic RNA. Once cleaved, the new RNA primer is translocated to the 5′ end of the minus strand to base pair with the DR2 region, forming the plus strand. The steps involved in the translocation process are poorly understood. Elongation of the plus strand then proceeds to the 5′ end of the minus strand DNA template, at which point the template becomes

exhausted. At this stage, another transfer is required to complete the plus-strand synthesis. This transfer is made to the 3’ end of the minus strand DNA and is facilitated by eight nucleotides of the sequence derived from the terminal redundancy in the pregenomic RNA. Annealing of the nascent plus-strand DNA to the 3’ end of the minus strand circularizes the DNA and allows further elongation. Finally, the relaxed circular double-stranded DNA virion (the mature DNA) is formed, with the 5’ end covalently bound to a primer protein. The resulting nucleocapsid either moves back to the nucleus and recycles its genome, thereby replenishing the cccDNA pool (36), or buds into the postendoplasmic reticulum where virus envelopment occurs.

Viral assembly and release

S proteins are synthesized in the rough endoplasmic reticulum and then transported to the postendoplasmic reticulum and pre-Golgi regions, where budding of the nucleocapsid occurs. A linear sequence in pre-S domain (residues 103 to 124) of the L envelope protein has been implicated in HBV envelopment and secretion. Other regions in the S domain are also important in viral secretion. Finally, the assembled HBV virion is transferred to the Golgi to be secreted.

Natural History of Hepatitis B Virus Infection

Primary HBV infection is clinically symptomatic in 30% to 50% of persons older than 5 years, yet most patients (95%) will clear the virus, resulting in lifelong immunity. In contrast, 30% to 50% of persons who acquire the infection before the age of 5 years develop chronic hepatitis B infection.

The natural course of the HBV infection has three phases: The first is the immune tolerance phase seen in children and adolescents who acquire HBV perinatally. In this phase, patients are HBeAg positive and have high serum levels of HBV DNA but normal serum aminotransaminase (alanine aminotransferase [ALT]) levels and minimal histologic activity. The second is the immune clearance phase, occurring in adolescents and adults, during which HBV replication declines, accompanied by both increased serum ALT levels and inflammatory activity in the liver. Seroconversion of HBeAg to anti-HBe may then ensue. During this phase, or even after the seroconversion to anti-HBe, replication-competent HBV variants with mutations in the precore or core promoter regions may emerge, preventing HBeAg production. Of interest, HBeAg-negative disease is now becoming the predominant form of chronic HBV infection (37). In the third low-replicative phase, serum HBsAg persists, but HBeAg is no longer detectable and HBV DNA can only be detected by sensitive polymerase chain reaction (PCR) assays. In this inactive HBsAg carrier state, patients are usually asymptomatic and liver disease is inactive. This stage may last indefinitely; however, a proportion of patients may undergo reactivation with the reappearance of high levels of HBV DNA and/or HBeAg. A recent 30-year follow-up study reported the natural course of HBsAg carriers to be generally favorable (38). In particular, these patients did not seem to develop clinically significant liver disease, hepatocellular cancer, or other liver-related morbidity or mortality at a higher rate than uninfected

controls.

In chronically infected patients, cirrhosis and HCC are the two major complications associated with increased morbidity and mortality. In HBeAg-positive patients, the 5-year cumulative risk of developing cirrhosis ranges from 8% to 20% (39). This incidence is even higher in HBeAg-negative patients. Predictors for the development of cirrhosis include older age,

evidence of persistent viral replication, HBV genotype C, excess alcohol intake, and coinfection with HCV, delta hepatitis, or human immunodeficiency virus (HIV) (40,41). Once cirrhosis is established, the 5-year mortality rate is 16% for patients with compensated cirrhosis but increases to 60% to 80% among those with decompensated cirrhosis. Overall, it is estimated that over 250,000 patients worldwide die annually from HBV-related liver disease (13).

HBV-infected patients have a 100-fold increased risk of developing HCC compared to uninfected patients (42). The risk of HCC correlates with age, gender, HBV-replicative status (HBeAg status), and the severity of the underlying liver disease, particularly the presence of cirrhosis (42,43).

Immunopathogenesis of Hepatitis B Virus Infection

The nature of the immune response is crucial for protection from the disease, viral resolution, and the extent of liver injury in response to HBV infection. During acute infection, innate, humoral, and adaptive immune responses are activated and must act in concert to clear the virus. The earliest events after infection involve noncytolytic control of viral replication through interferon-γ (IFN-γ) and tumor necrosis factor-α (TNF-α). These cytokines are initially produced by infected hepatocytes and then by cells of the innate immune system including natural killer (NK) cells and NK-T cells (44). Formation of neutralizing antibodies to HBV envelope antigens is an important T cell–dependent process that aids viral clearance by interfering with viral entry into host cells. However, for complete viral eradication, a strong, polyclonal, and multispecific CD4 and cytotoxic lymphocyte (CTL) immune response is essential. Self-limited infection is therefore characterized by a vigorous CD4 response directed against multiple epitopes within the HBV antigen, in particular, the nucleocapsid (45). This response also supports the induction and activation of CTLs that mediate apoptosis of infected hepatocytes through Fas/Fas-ligand binding and the release of lytic granules (46). Virus-specific CTLs also trigger the production of other cytokines including TNF-α, IFN-γ, interleukin 2, and NK cells, which control viral replication through noncytolytic mechanisms (47). In those patients who become chronically infected, the immune response, although ineffective, appears to persist and therefore mediates ongoing tissue injury. In this context, CTLs induce both direct damage to hepatocytes and produce cytokines that lead to the recruitment of antigen-nonspecific inflammatory cells (e.g., macrophages, NK cells) and IFN-γ. This nonspecific inflammatory response accounts for most of the

subsequent tissue damage in chronically infected patients (48).

Treatment of Hepatitis B Virus Infection

In the last few years, new therapies have emerged for managing chronic HBV infection. However, a number of unresolved issues remain, including whom to treat, how long should the treatment continue, and what are the optimal treatment regimens to be used in various subsets of patients.

Initial therapeutic regimens in HBeAg-positive patients with chronic hepatitis B consisted of 4- to 6-month courses of IFN-α, at varying dosages between 5 million units (MU) daily and 10 MU thrice weekly, achieving HBeAg loss in 33% of patients, compared with 12% of controls (49). In contrast, in HBeAg-negative HBV patients, a 6-month course of IFN therapy was associated with very low sustained response rates because of frequent relapses after the cessation of therapy. Subsequently, prolonged courses of IFN were reported to improve sustained response rates up to 20% to 25% in these patients (50). The wide spectrum of IFN-related side effects, cost, and the inconvenience of administration are the main drawbacks of this therapy.

Pegylated IFN has better pharmacokinetics than standard IFN, allowing once-weekly dosing. A recent worldwide trial evaluating its efficacy in largely Asian HBeAg-positive patients reported an HBeAg seroconversion rate of 32% after 48 weeks of pegylated IFN monotherapy (51). This seroconversion rate was higher than that achieved in patients receiving either a combination of pegylated IFN and lamivudine (27%) or lamivudine alone (19%) (51).

Lamivudine, a nucleoside analog, resulted in HBeAg seroconversion rates of 17% in patients after 12 months of treatment, at 100 mg daily, compared to 6% in untreated patients (52). It is administered orally and has few side effects. Moreover, longer treatment durations in HBeAg-positive patients enhances response rates, with seroconversion occurring in 27%, 40%, 47%, and 50% of patients receiving treatment for 2, 3, 4, and 5 years, respectively. In HBeAg-negative patients, however, a 12-month course of lamivudine is less effective, maintaining remission (as assessed by undetectable HBV DNA levels) in less than 15% of patients after stopping therapy (53). Importantly, lamivudine has also been reported to suppress HBV replication in 60% to 100% of patients awaiting liver transplantation (54,55). In these patients, lamivudine has been shown to stabilize the progression of liver disease, delay the need for liver transplantation, and improve survival among patients awaiting liver transplantation (55,56,57).

A significant problem with lamivudine is that to achieve the desired therapeutic benefit, longer treatment durations are often required. However, with longer courses of therapy, viral-resistance mutations, particularly the YMDD variant, emerge, with the risk

reaching 50% after 3 years of therapy. The emergence of resistance has been associated with significant and serious flares in disease activity. Unfortunately, very high rates of relapse occur on discontinuing lamivudine

therapy, making it more likely to become a longer-term therapy.

Adefovir dipivoxil is a nucleotide analog of adenosine. In HBeAg-positive patients, a 12-month course of adefovir, at a daily dose of 10 mg, achieved loss of HBeAg in 24% of patients compared to 11% in the placebo group (58). In addition, adefovir has also been shown to be effective in suppressing HBV DNA in patients who develop lamivudine resistance.

In HBeAg-negative patients, initial reports indicated that a 12-month course of adefovir resulted in a significant virologic response in 50% of patients compared to placebo (59). However, a recent follow-up data suggests that this benefit was not sustained once treatment was stopped (60). Side effects are uncommon with adefovir; however, the drug is expensive and renal dysfunction may occur. Resistance to adefovir is being increasingly reported, although it is less common than that with lamivudine and tends to emerge later in the course of treatment (61).

Entecavir is a cyclopentyl guanosine analog. Results of phase III studies confirmed the efficacy and safety of entecavir when given for 48 weeks as compared with lamivudine in suppressing HBV DNA in HBeAg-positive and HBeAg-negative patients and in those with lamivudine resistance (62). A dose–response relationship has been observed. Entecavir is well tolerated at all doses, and resistance to the drug is rare.

Emtricitabine and telbivudine are under evaluation for the treatment of chronic hepatitis B infection. Their clinical utility and approval are awaited.

Hepatitis C Virus

Epidemiology

An estimated 3% of the world's population is infected with HCV (63,64). Globally, HCV infection accounts for 70% of chronic hepatitis cases. The prevalence rate of HCV infection ranges from 20% in highly endemic areas such as Egypt to 1.8% in the United States and 1.5% in Australia.

Parenteral exposure accounts for most HCV infections. With the advent of routine blood screening measures, the importance of HCV transmission from infected blood products has declined. Therefore, injection drug use is the primary source of HCV acquisition, and up to 90% of intravenous drug users are HCV infected (65). Other risk factors include occupational exposure, hemodialysis, medical reuse of infected needles, and tattoos; vertical (mother-to-infant) and sexual transmission are uncommon.

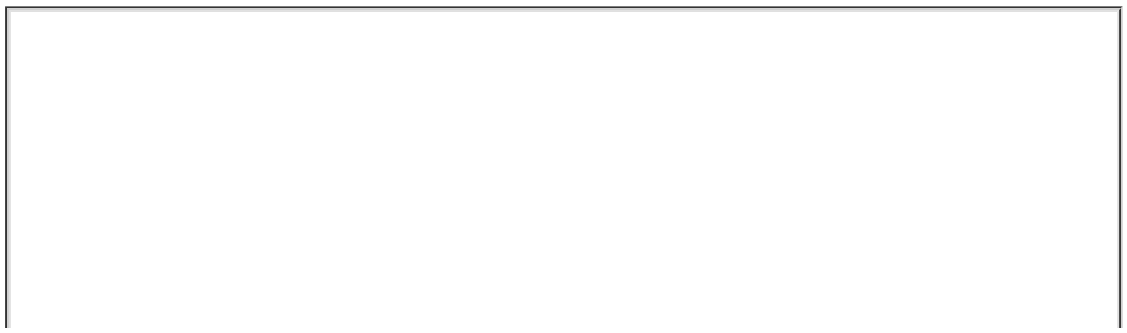
Hepatitis C Virus Genome and Proteins

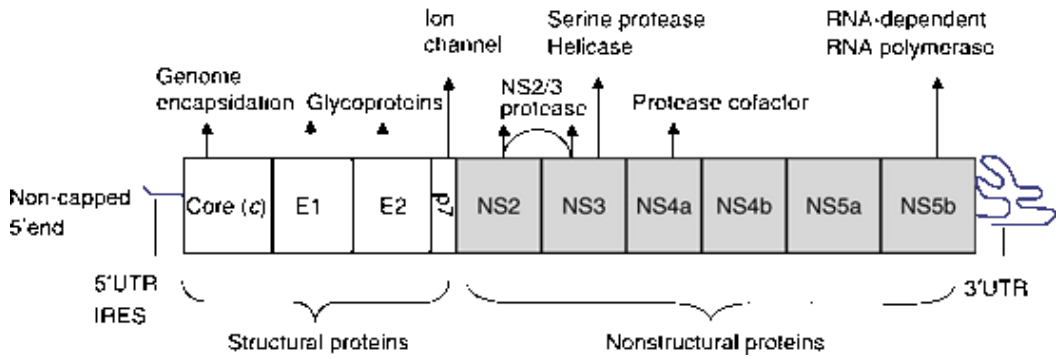
HCV is a member of the Flaviviridae family, of which yellow fever virus and pestiviruses are other members (66). All members of this family are small-enveloped viruses containing a positive-sense, single-stranded RNA genome. The size of the HCV particle is between 30 and 80 nm. The HCV genome is 9.6 kb in length, containing a single ORF flanked by 5′ and 3′ untranslated regions (UTRs) (66) (Fig. 26.4). The 5′ UTR region of the HCV genome contains an IRES for the initiation of translation. This region of

highly conserved nucleotide sequences has been used as the major target for commercial RT-PCR assays. The 3′ UTR region of the genome terminates in polyuridine (poly U) ribonucleotides, followed by another highly conserved region of 98 to 100 nucleotides designated the X tail, which may have functional importance in viral replication (67). The HCV ORF encodes a polyprotein that may vary in length between 3,010 and 3,033 amino acids in a strain-specific manner. Translation of the HCV polyprotein in the endoplasmic reticulum of the infected cell gives rise to at least 10 mature proteins (Figure 26.4). The structural proteins include nucleocapsid protein and two envelope glycoproteins, E1 and E2. This is followed by a small integral protein, p7. The nonstructural (NS) proteins include NS2, NS3, NS4a, NS4b, NS5a, and NS5b.

The HCV core is a basic protein with RNA-binding properties. It is believed to form the nucleocapsid in association with the viral RNA. Additionally, the core protein has been shown to modulate the transcription and translation of several cellular genes (68) and have oncogenic effects in cell cultures and transgenic mice. E1 and E2 envelope proteins coat the virus. Comparison of HCV sequences has shown two hypervariable regions (HVRs) within E2, HVR1 and HVR2. Mutations in HVR1 emerge rapidly under selective host immune pressure (69). E2 may elicit the production of virus-neutralizing antibodies, resulting in immune selection of HCV genomes with escape mutations in HVR1 (69). In addition, E2 has been shown to be involved in the binding process of HCV to the host cell. The function of p7 is partly unknown; however, it may be necessary for HCV replication and may act as a viroporin (70,71). NS2 has protease activity. Together with the N terminus of NS3, NS2 forms an NS2/NS3 protease responsible for autocatalytic cleavage at the NS2/NS3 junction (72). NS3 has both protease and helicase activities. NS4a essentially functions as a cofactor for NS3. Moreover, HCV NS3/4a serine protease has been shown to block the action of IFN regulatory factor-3,

a key cellular antiviral molecule (73). The function of NS4b is unknown, while NS5a plays a role in modulating the effect of IFN on the virus. A region in NS5a has been identified as an IFN-sensitive determining region (ISDR) where a close association is demonstrated between mutations in this region and sensitivity to IFN therapy (74). In addition, NS5a has been shown to be a potent inhibitor of the IFN-induced protein kinase PKR, an antiviral molecule (74). NS5b possesses RNA-dependent RNA polymerase activity and is essential for RNA synthesis and viral replication. The details of how viral RNA-dependent RNA polymerase initiates RNA synthesis remain poorly understood.





▪ **Figure 26.4** Schematic representation of the HCV genome. Unshaded regions indicate the major structural proteins: Core *(c)*, envelope (E1 and E2), and p7. The shaded region indicates the nonstructural proteins NS2, NS3, NS4a/NS4b, and NS5a/NS5b. At the 5′ untranslated region (5′-UTR) resides the internal ribosomal entry site (IRES).

Hepatitis C Virus Life Cycle

The mechanism by which HCV enters target cells is still unknown, but it involves the HCV glycoproteins E1 and E2. Host molecules observed to play a role in HCV cell entry include dendritic cell-specific intercellular adhesion molecule 3-grabbing nonintegrin (DC-SIGN), and liver/lymph node-specific intercellular adhesion molecule 3-grabbing integrin (L-SIGN) (75,76). In particular, CD81 has been shown to function as a postattachment entry coreceptor, while other unknown cellular factors act in concert with CD81 to mediate HCV binding and entry into hepatocytes (77). Similarly, low-density lipoprotein receptor (LDLR) has been shown in vitro to act as entry point for HCV (78,79).

The virus selectively fuses with liver cell plasma membranes. Once fusion of the viral lipid coat and host plasma membrane is complete, the viral core enters the host cell (Fig. 26.5). The HCV genome can be directly read by the host's ribosomes. During translation the ribosomes produce a polyprotein that is then processed into the 10 HCV proteins. The enzymes NS3 serine protease and NS2/NS3 protease cleave the polyprotein. When adequate RNA transcriptase is produced, an antisense version of HCV RNA is made to serve as a template for RNA replication. The enzyme NS3 helicase unwinds the RNA during replication, and NS5b, or the HCV RNA–dependent RNA polymerase, catalyzes RNA synthesis. The newly produced RNA and processed proteins assemble to form viruses that travel to the inside portion of the plasma membrane and then exit the host cell.

Recently, a full-length genotype 2a HCV genome that replicates and produces infectious virus particles in cell culture has been described (80).

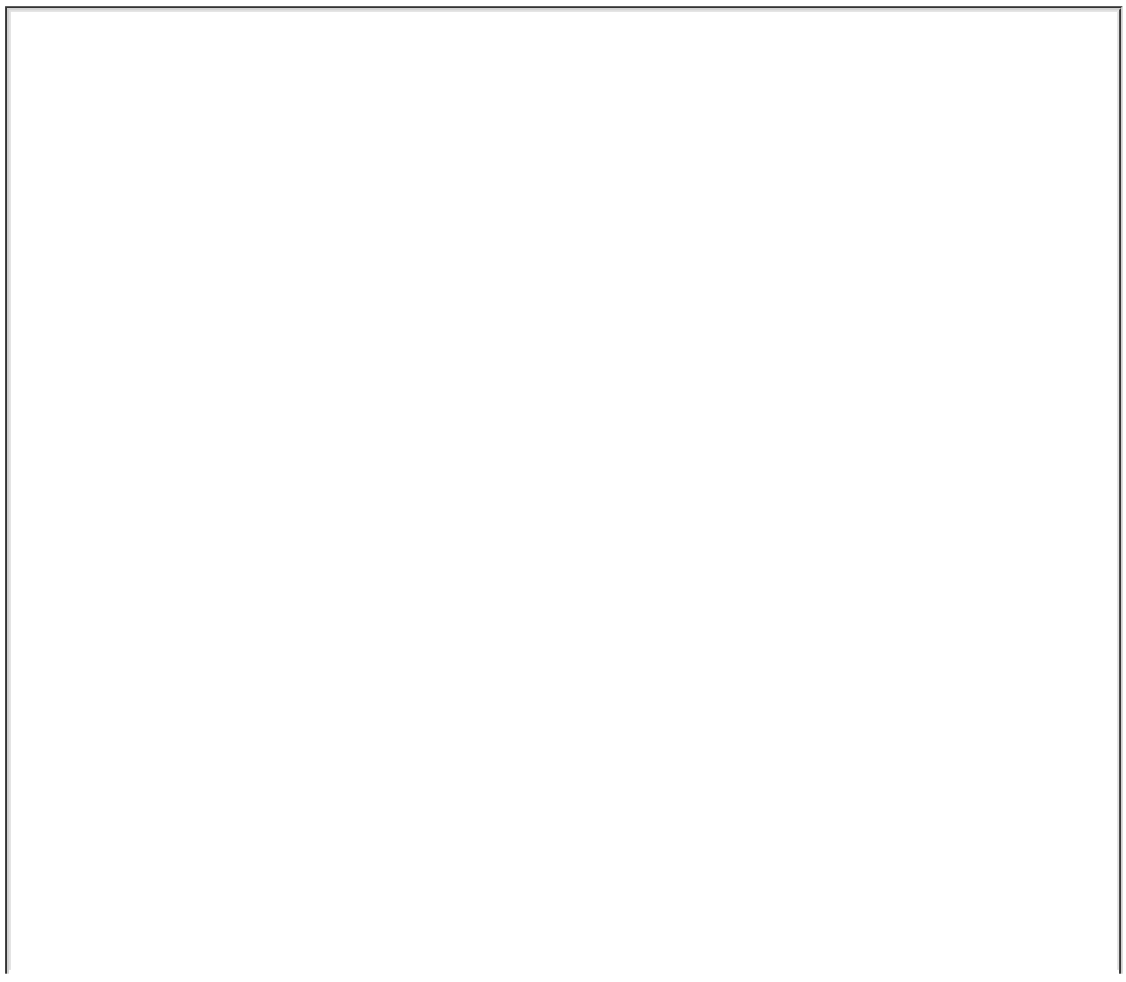
This system promises to lay the foundation for future in vitro studies to examine and shed further light on the life cycle of the virus.

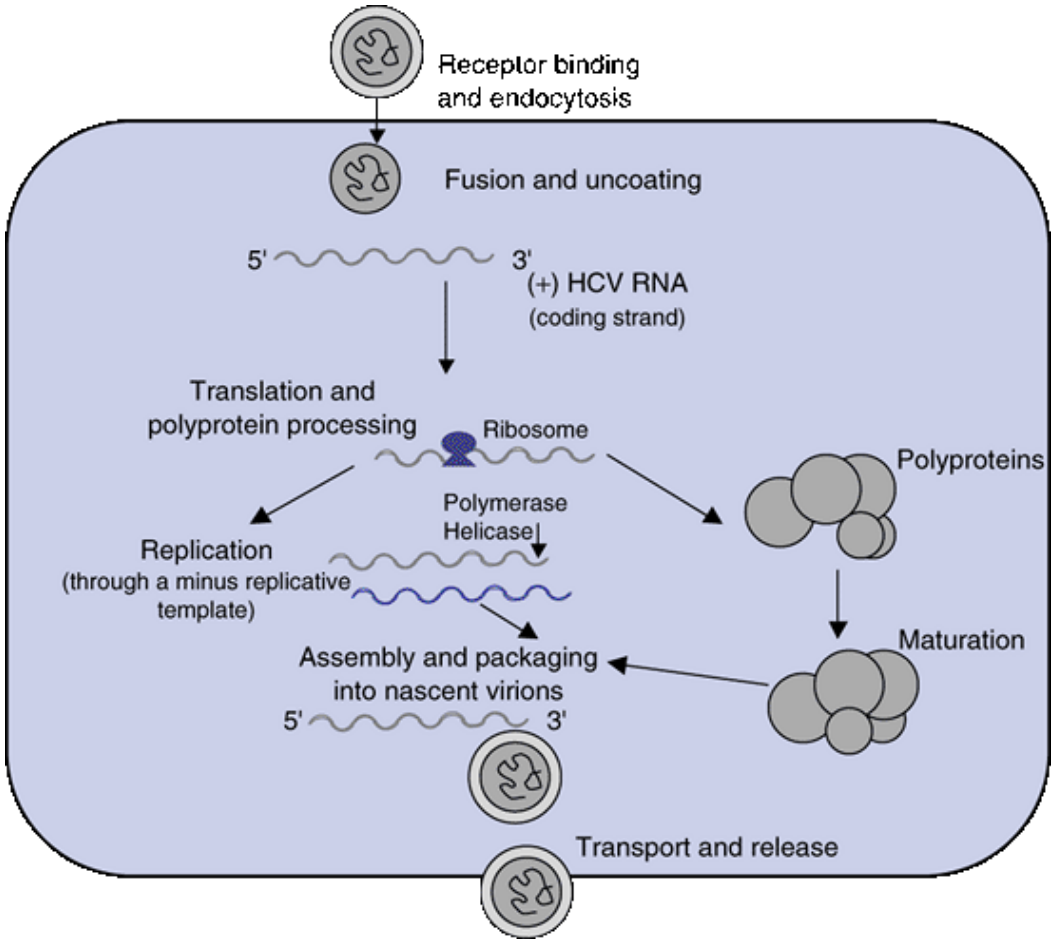
Natural History of Hepatitis C Virus Infection

Acute HCV infection is usually asymptomatic, and therefore, the timing of disease onset is usually assumed on the basis of exposure to specific risk factors. Early studies suggested that most acutely infected patients (80% to 90%) developed chronic HCV infection. However, certain more recent studies with longer follow-up indicate that only approximately 50% of acutely infected patients progress to chronicity (81,82,83). Progression of chronic HCV infection is usually slow, with advanced disease developing only 10 to 30 years or even longer after infection (84,85). The degree of fibrosis on the initial liver biopsy is the main determinant of progression to cirrhosis and the development of subsequent liver complications (85,86). Other factors associated with increased progression to fibrosis include male gender, older age at initial infection, excess alcohol, coinfection with HBV or HIV, and the presence of hepatic steatosis.

In patients with cirrhosis, the 5-year risk of decompensation is 18%, with a 5-year survival probability around 50% in those who decompensate (87,88). Moreover, in patients with cirrhosis, the 5-year risk of developing HCC is around 7% and 18% in those

with compensated and decompensated liver disease, respectively (88).





▪ **Figure 26.5** Schematic representation of the life cycle of hepatitis C virus (HCV). The main steps in the cycle are viral entry and uncoating, translation, replication, and packaging (see text for details). HCV RNA, hepatitis C virus ribonucleic acid.

Immunopathogenesis of Hepatitis C Virus Infection

It is unclear why a substantial proportion of patients with HCV fail to permanently eradicate the virus after acute infection. Several arms of the immune system are important in orchestrating viral clearance. Animal studies indicate that sustained or even transient clearance of HCV is clearly associated with an intrahepatic immune response characterized by increased expression of IFN-γ–inducible genes (89). The upregulation of these genes has been observed to occur as early as 2 days after infection, reflecting activation of the innate immune response and its crucial role in viral clearance (89). Similarly, after acute infection, high and persistent titers of neutralizing antibodies have been detected in patients in whom the virus is eradicated, in contrast to a low and nonsustained neutralizing antibody response in those with persistent infection (90). These neutralizing antibodies are however variant specific and, therefore, do not

provide protection against reinfection with other viral variants (91,92).

The cellular immune response also plays a major role in eradicating HCV infection. Multispecific vigorous intrahepatic CD4 and CTL responses are detected in subjects who have successfully cleared an acute HCV infection (93,94). The CD4 response associated with viral clearance is dominated by a T_H1 cytokine profile with increased IFN-γ production. This T_H1 cytokine response has been shown to coincide with a decline in the levels of viremia in acutely infected chimpanzees (89,95). The CD4 response is also essential for the functional maturation of CTL cells. Successful viral elimination has been shown to be associated with the induction of an early intrahepatic CTL population that possesses cytolytic and noncytolytic activities (95). The CTL cytolytic response is associated with acute hepatitis, and the vigor of the response parallels serum ALT levels and the extent of liver injury (96,97). However, HCV clearance and resolution of infection coincides with the appearance of CTL-induced cytokines (mainly IFN-γ) (96,97).

In addition to the immune response, nonimmunologic genes, in particular, genes associated with lipid metabolism, have been recently recognized to influence HCV clearance (89). Genes related to the serum response element–binding protein signaling pathway appeared to enhance viral replication (89).

Liver injury in patients with chronic infection is primarily immune mediated; however, a cytopathic effect is apparent in association with HCV genotype 3 infection and in immunosuppressed patients. In chronic liver injury, the HCV-specific CTL immune

response may target not only virally infected cells but also uninfected bystander hepatocytes through the release of soluble proapoptotic mediators such as Fas-ligand and soluble TNF-α (98,99). In addition, antigen-nonspecific recruitment of T cells occurs at the site of hepatic damage in chronic hepatitis, further contributing to the extent of liver injury (100).

Nonimmunologic factors such as steatosis and insulin resistance have also been linked to the progression of liver injury in HCV-infected patients. In particular, in patients infected with HCV genotype 3, steatosis and insulin resistance are primarily viral mediated (cytopathic), whereas host factors, principally those associated with insulin resistance and its clinical attributes, are responsible for the development of steatosis in genotype 1–infected patients. The molecular mechanisms responsible for these observations have not been elucidated (101,102).

Treatment of Hepatitis C Virus Infection

In the minority of patients presenting with acute HCV, increasing data indicate that IFN treatment is effective in preventing the progression to chronicity. In particular, a 6-month course of pegylated IFN-α in acute HCV infection has been shown to achieve sustained viral clearance rates (SVRs) of 95% 6 months after treatment (103). These patients remain virus free in the long term (104). There are still, however, several unresolved issues

concerning acute HCV treatment including the timing and optimal duration of therapy and identifying those most likely to benefit from therapy, in particular, intravenous drug users.

Incremental advances have also been made in relation to therapy for chronic HCV infection. Presently, the combination of pegylated IFN-α and ribavirin is the standard therapy for chronic HCV infection. Response and duration of treatment (24 to 48 weeks) is dependent on the infecting genotype, with 76% to 80% of patients with genotypes 2 and 3, but only approximately 40% to 45% with genotypes 1 and 4, achieving an SVR 6 months after completing therapy (105,106). However, SVR after pegylated IFN-α and ribavirin therapy are approximately 10% lower for patients with bridging fibrosis or cirrhosis (105,106), and hence the benefits of maintenance pegylated IFN-α in this group of patients is under evaluation. The benefits of combination therapy also extends to other "difficult-to-treat groups" such as those with recurrent HCV infection after liver transplantation or those with HCV/HIV coinfection (107). In all these groups, however, drug-related adverse events are common, requiring dose reduction and the frequent use of supportive growth factors.

Hepatitis Delta Virus

Epidemiology

HDV has a worldwide distribution but its infectivity relies on HBV envelope proteins (108). Therefore, it has been estimated that around 5% of global HBsAg carriers are also infected with HDV. However, the geographic distribution of HDV and HBV differ, with high HDV prevalence rates in Mediterranean countries, where interfamilial transmission predominates (109). In contrast, HDV infection is uncommon in the United States and northern Europe, where transmission is usually through intravenous drug use (110). Other modes of HDV transmission are similar to HBV spread and include hemodialysis, and sexual and, uncommonly, vertical transmission (110). Given the close link between HDV and HBV, strategies employed to control HBV in recent years, in particular vaccination, have resulted in a significant decrease in the incidence of HDV infection.

Hepatitis Delta Virus Genome and Proteins

The HDV virion is a spherical particle with a diameter of 36 to 43 nm. Its envelope protein is supplied by the HBsAg and contains the HDV genome. The HDV genome is a 1.7-kb single-stranded circular RNA, which encodes a single structural protein, the HDAg, the only gene product of the virus (111). There are two isoforms of the HDsAg, a small form (S-HDAg, 195 amino acids) required for HBV DNA replication and a large form (L-HDAg, 214 amino acids) required for virion assembly and inhibition of replication (112,113).

The genome sequence of HDV is nearly self-complementary such that about 70% of the nucleotides are base paired on a rod-like double-stranded RNA structure (genomic and antigenomic strands) (111). Moreover, its genomic and antigenomic RNA have the capacity to act as ribozymes directing self-

cleavage and self-ligation during HDV replication.

Hepatitis Delta Virus Life Cycle

HDV enters the cells through a cellular receptor shared by HBV; however, the identity of this receptor is still unknown. HDV is then transferred to the nucleus, where replication occurs. The HDV genome utilizes host RNA polymerase II to direct RNA-dependent RNA synthesis. Three forms of RNA gather in the infected hepatocyte during HDV replication—genomic RNA, its complement antigenomic RNA, and an antigenomic-sense mRNA. The antigenomic mRNA encodes the S-HDAg, which promotes the transcription/replication process (114,115). HDV replication occurs in the

nucleus by a double–rolling circle mechanism (116); the ribozymes are central to this mechanism. According to this mechanism, the circular genomic RNA serves as a template for an antigenomic RNA intermediate. This RNA intermediate is processed by autocatalytic cleavage at the ribozyme sites to yield monomeric linear RNA. In the final step, the linear RNA is ligated by HDV ribozyme and a host RNA ligase enzyme into an antigenomic, circular RNA. The circular antigenomic RNA subsequently serves as a template for a second round of rolling-circle replication. During replication, a unique event called *editing* occurs, allowing the generation of L-HDAg from S-HDAg. Up to 30% of the S-HDAg is edited by a host RNA–modifying RNA enzyme called *adenosine deaminase*. This changes the UAG stop codon of S-HDAg to a tryptophan (UGG) codon, resulting in the extension of the C terminal of the S-HDAg by 19 amino acids to generate the L-HDAg (117). Subsequently, L-HDAg inhibits viral replication and triggers the assembly and copackaging of viral particles (118). The editing process is therefore essential for achieving the balance between the conflicting but essential functions of the S-HDAg (RNA replication) and the L-HDAg (RNA inhibition). Virion assembly is triggered by an interaction between L-HDAg and HBsAg. The mechanisms by which this interaction occurs have not yet been fully elucidated.

Natural History of Hepatitis Delta Virus Infection

HDV infection can occur in three settings: An individual who becomes *coinfected* simultaneously with HDV and HBV, a chronic HBV-infected patient who develops *superinfection* with HDV, and finally, reinfection following liver transplantation. The clinical expression and outcome of each of these modes of infection are somewhat different.

In patients who develop *coinfection*, acute delta infection (and similarly that of HBV) is often self-limiting and progression to chronic liver disease is uncommon, occurring in around 2% of cases. The clinical spectrum of *coinfection* may range from asymptomatic disease to fulminant hepatitis.

HDV *superinfection* primarily affects intravenous drug users and chronic HBV carriers in developing countries. The preexisting HBV provides the substrate for rapid replication and spread of HDV, hence *superinfection*

usually results in chronic HDV infection or, alternatively, may cause severe fulminant hepatitis. Patients chronically infected with both viruses have progressive liver disease, with most developing cirrhosis. Moreover, the risk of HCC is increased threefold in patients with cirrhosis and dual HBV/HDV infection (41).

After liver transplantation, HDV reinfects the graft soon after surgery, resulting in subclinical infection that becomes symptomatic only if HBV reactivates, producing a florid hepatitis that does not usually respond to therapy (119).

Immunopathogenesis of Hepatitis Delta Virus Infection

It is not clear whether the enhanced disease severity observed from dual HBV/HDV infection is due to the immune response against viruses, a direct HDV cytopathic effect on hepatocytes, or a combination of these processes. The observation that the extent of portal inflammation correlates with the number of HDAg-positive cells suggests an immunologic mechanism contributing to the liver lesion. Investigations into a potential cytopathic role for the delta virus, however, have generally yielded conflicting results. A cytopathic effect has been suggested because HDAg produces significant cell death in transfected cell lines (120). Additionally, microvesicular steatosis has been frequently observed in association with epidemics of HDV infection and in patients undergoing transplantation who exhibit the delta virus (121). In contrast to these observations, transgenic mice expressing HDAg develop no hepatic damage (122). Similarly, in patients undergoing transplantation who are reinfected with HDV alone, hepatitis does not ensue until the reappearance of HBV antigens in the graft (121,123).

Treatment of Hepatitis Delta Virus Infection

Treatment of chronic hepatitis due to infection with HDV/HBV is unsatisfactory, and IFN-α is the only agent found to have any effect. To achieve therapeutic benefit, patients require treatment with a high dose of IFN-α (5 to 9 MU three times weekly) for at least 12 months (124). This regimen has been shown to result in sustained normalization of ALT levels and improved liver histology in 50% of treated patients. A recent 14-year long-term follow-up report of patients who received this treatment showed that responders also achieved clinical and survival benefits (125). Some long-term responders cleared HDV RNA and, eventually, HBV (125). Similar long-term improvements are observed in hepatic necroinflammatory activity and fibrosis (125). Unfortunately, IFN-related side effects are common in this group, particularly psychiatric problems, often leading to discontinuation of therapy (126,127).

Results with other antiviral agents have been disappointing. Lamivudine alone or in combination with IFN was not associated with any histologic or biochemical improvement (128,129). Hence, in contrast to treatment of HBV infection, available evidence does not support the use of nucleoside

analogs for the treatment of chronic HDV infection.

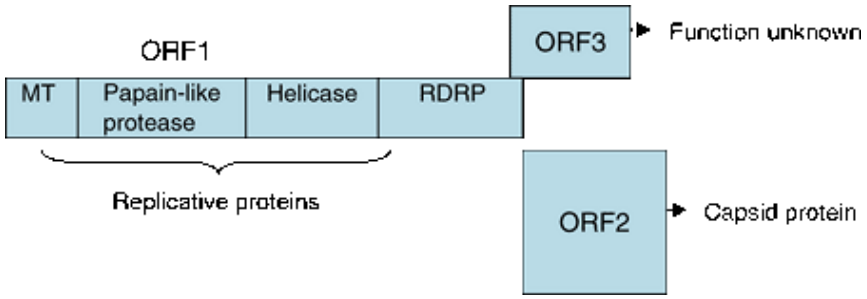
Hepatitis E Virus

Epidemiology

Hepatitis E is a worldwide public health problem and particularly causes acute hepatitis in adults through most of Asia, the Middle East, and northern Africa (130,131). In India, acute HEV is responsible for 60% of patients presenting with fulminant hepatitis. Moreover, cyclic outbreaks of HEV have occurred in India, Iraq, Sudan, Mexico, and parts of Asia. Sporadic cases of acute HEV have occurred in both South America and Europe. In contrast, cases of HEV are rare in the United States and are primarily linked to travel to endemic regions (130). HEV is enterically transmitted, and epidemics are usually linked to contaminated water supplies. Parenteral transmission may occur in endemic areas (132) and vertical (mother-to-infant) transmission has also been reported (133). In contrast to HAV, which predominantly affects children and spreads secondarily in 15% of patients, HEV mainly affects young adults and has only a low rate of secondary spread (2%).

Hepatitis E Virus Genome, Proteins, and Life Cycle

HEV is a small spherical nonenveloped RNA virus of approximately 30 nm diameter. Although its genomic structure shares some morphologic similarities to the Caliciviridae and Picornaviridae families, HEV remains unclassified at this time. The viral genome consists of a 7.5-kb plus-strand RNA with a 5′ capped end and a polyadenylated 3′ end (134). The genome (Fig. 26.6) contains three distinct ORFs (ORF1, ORF2, and ORF3) (134). ORF1 extends approximately 5 kb from the 5′ end and encodes polyprotein-containing sequence motifs of methyltransferase, papain-like protease, RNA helicase, and an RNA-dependent RNA polymerase. ORF2 begins 37 bp downstream of ORF1 and extends approximately 2 kb to the termination codon. The sequence of ORF2 suggests that it encodes the gene for the capsid protein. Moreover, ORF2 contains important epitopes that can induce neutralizing antibodies and has therefore been the focus of vaccine development (135). Finally, ORF3 partially overlaps ORF1 and ORF2 and encompasses only 369 bp. It encodes a protein that may play a role in viral infectivity (136). The genomic organization of the virus is consistent with the 5′-end encoding nonstructural and the 3′-end encoding structural viral gene(s) (134).



▪ **Figure 26.6** The hepatitis E genome—the genome is a capped, single-stranded positive-sense ribonucleic acid (RNA) molecule. It contains three distinct open reading frames (ORFs). ORF1 encodes replicative proteins including methyltransferase (MT), papain-like protease, helicase, and RNA-dependent RNA polymerase (RDRP). ORF2 encodes the capsid protein. The small overlapping ORF3 encodes a protein of unknown function.

The virus cannot be grown reliably and reproducibly in cell cultures and, therefore, the replication cycle is poorly understood. It is assumed that the virus attaches to receptor sites on hepatocytes and, possibly, biliary and intestinal cells. After uncoating, the genome is translated to produce ORF, subsequently cleaved by cellular proteases. It is postulated that replicative negative strand RNA intermediates are synthesized and then act a template for the synthesis of genomic and subgenomic positive strands (137). The mechanisms involved in viral assembly and transport are not known.

Natural History and Immunopathogenesis

HEV causes an acute, self-limiting illness with no chronic sequelae. Serologic follow-up studies of infected patients confirmed that antibodies to HEV provide long-term protection against the disease (138). Acute HEV infection, however, results in a high mortality among pregnant women, particularly during the third trimester, with case fatality rates ranging from 5% to 25% (133).

The mechanisms involved in hepatocyte destruction during acute HEV remain unknown. In HEV-infected cynomolgus macaques, the lymphocytes involved in the liver lesion have been found to be positive for a cytotoxic/suppressor immunophenotype (139). Additionally, hepatocyte culture of the cynomolgus monkey inoculated with a transmissible stool extract of HEV did not show any cytopathic change (139). Therefore,

the data from this single study suggest an immune-mediated rather than a

direct cytopathic mechanism for the liver injury in HEV infection.

Treatment of Hepatitis E Virus Infection

There is no specific treatment for acute HEV infection. Public health strategies to improve sanitation and handling of food and water are currently the best prophylaxis against the disease (131). Vaccine development strategies are under way, particularly examining the ORF2-encoded HEV proteins.

Hepatitis G Virus

Epidemiology

The HGV and the GB-C virus are two variants of the same virus and are therefore often referred to in the literature as GBV-C/HGV; in this review we use the term HGV (140). A direct association with liver pathology, however, is still lacking, and it is therefore unclear whether HGV is a hepatotropic virus. HGV is distributed worldwide, and carriage of the virus has been documented among healthy individuals and different patient groups (141). Between 1% and 4% of healthy blood donors have detectable serum HGV RNA (141,142). The highest prevalence rates are in Thailand, Vietnam, and Africa while China, Japan, and the United States have low prevalence rates (143,144). The virus is frequently found in populations at risk for blood-borne or sexually transmitted viruses, and there is also evidence of transmission vertically from mother to infant (145,146). Because of shared modes of transmission, many patients with HGV are coinfected with other blood-borne viruses such as HCV, HBV, and HIV (147).

The Hepatitis G Virus Genome, Proteins, and Life Cycle

GBV-C/HGV is a single-stranded positive-sense RNA virus, which is a member of the Flaviviridae. It has close sequence homology and genomic organization with HCV (148). The HGV genome is preceded by a 5′ UTR, which is followed by a long ORF (2,842 to 2,933 amino acids), terminating in a 3′ UTR. The structural proteins are E1 and E2, while the nonstructural proteins are NS2, NS3, NS4a, NS4b, NS5a, and NS5b. However, unlike HCV, the coding region for the core gene remains unknown. Also, the E genes are highly conserved among the various isolates of HGV, and therefore, there is no hypervariable region in the HGV genome (148). The 5′ UTR contains an IRES that is capable of directing cap-independent translation of the polyprotein (149). NS2 has a zinc-dependent protease, and the NS3 gene has a helicase motif and is likely to be essential for replication. NS5b gene encodes an RNA-dependent RNA polymerase (148), while the function of the other NS4 proteins is unknown. The exact site of HGV replication is unknown, although it appears that the virus replicates within lymphocytes and, perhaps, hepatocytes (150,151).

Natural History and Immunopathogenesis of

Hepatitis G Virus

The question of whether HGV contributes to liver disease either alone or in association with other chronic hepatitis virus infections has been extensively investigated with conflicting results, ranging from implicating the virus in cases of fulminant hepatitis to negating any role for the virus in liver disease. The prevalence rates of HGV associated with fulminant hepatitis has been reported to range from 5% to 15% (152,153). However, other studies sequentially examining the blood of patients with fulminant hepatitis concluded that the presence of HGV in them was accidental and coincided with the receipt of contaminated blood products in the course of therapy (154,155,156). Most individuals with HGV infection alone appear to have an asymptomatic course; many eventually clear the virus, developing antibodies to the E2 envelope glycoprotein that also protect against reinfection (144,146). The incidence of HGV among patients with HCV infection varies from 11% to 24% (157). However, HGV appears not to influence the clinical or virologic course of HCV infection nor does it have an impact on the response to IFN therapy (158,159). Whether HGV contributes to the development of HCC is still controversial, although it appears unlikely (160,161).

More recently, coinfection with HGV and HIV has been shown to improve mortality and morbidity for the HIV-infected individuals and slow the progression to acquired immunodeficiency syndrome (AIDS) (162,163).

Herpesviruses

Several other viruses, which are not primarily hepatotropic, may also cause hepatitis. These are usually herpesviruses, a family of double-strand DNA viruses, which can cause either chronic infections or enter a period of viral latency. So far, eight human herpesviruses have been identified: Herpes simplex virus 1 and 2 (HSV1 and HSV2), varicella-zoster virus (VZV), Epstein-Barr virus (EBV), Cytomegalovirus (CMV), and human herpesviruses 6, 7, and 8.

HSV1 and HSV2 commonly produce self-limiting vesicular or ulcerative lesions primarily involving the orofacial (HSV1) or the genital areas (HSV2). In the immunocompromised host or neonates, generalized infections including hepatic involvement may occur. Neonatal disseminated HSV infection can cause rapidly progressive multiple organ failure, with an 85% mortality rate if left untreated (164). In adults, the risk factors for the development of HSV hepatitis include third trimester pregnancy, an underlying immune-modifying disease such as malignancy, or the use of immunosuppressive medications particularly in solid organ transplant recipients (165,166). The clinical presentation of HSV hepatitis is nonspecific and includes fever, abdominal pain, and flu-like symptoms. Up to 30% of patients may not have detectable mucocutaneous lesions (167). Most of those who progress to fulminant hepatitis display a characteristic pattern of liver test abnormalities, the so-called anicteric hepatitis, with minimal elevation of serum bilirubin levels in the presence of marked elevations in the levels of serum transaminases. Progressive liver failure

often ensues. Disseminated HSV infection is treated with high-dose intravenous acyclovir (5 to 10 mg/kg three times daily) (168).

VZV is primarily a self-limiting illness of childhood; however, reactivation of VZV occurs in the setting of advancing age or reduced immunity (169). Clinical hepatitis occurs in the context of disseminated VZV and can rarely be fatal. VZV is best managed with high-dose intravenous acyclovir (168).

Latent CMV infections are often reactivated in the setting of immunocompromised hosts. AIDS patients, with low CD4 count are particularly at risk for symptomatic CMV infection. CMV is also a major pathogen in patients undergoing transplantation. CMV infection has been documented in 23% to 85% of liver transplant recipients; half will have symptomatic disease. Moreover, in recurrent HCV infection after liver transplantation, CMV reactivation increases the risk of hepatic fibrosis and allograft dysfunction (170). In immunocompromised hosts, typical liver lesions include CMV inclusion bodies in hepatocytes, vascular endothelium, and particularly, biliary epithelium. Ganciclovir is often used to treat CMV hepatitis; however, drug resistance may emerge and in these cases, foscarnet is the alternative agent of choice (171).

Infectious mononucleosis, as a result of EBV infection, is usually associated with only mild hepatitis. Most cases resolve spontaneously, although acute hepatic failure in immunocompetent patients has occasionally occurred. In addition, primary or secondary EBV infection has been linked to an increased risk of lymphoproliferative disorders after solid organ transplantation (172).

Human herpesvirus (HHV)-6 and HHV-7 are novel members of the betaherpesvirus family. The clinical effect of HHV-6 and HHV-7 reactivation in recipients of liver transplants who are also coinfected with CMV is now being recognized (173). In this regard, primary or secondary HHV-6 or HHV-7 infection after liver transplantation has been observed to be associated with predisposition to invasive and symptomatic CMV infection (173,174).

Chapter 27

Hepatitis A

Maria H. Sjögren

Key Concepts

- Hepatitis A is a worldwide infection whose epidemiology is changing as countries improve water sanitation and use other preventive methods such as immunization.
- The precise mechanism of hepatic uptake in human liver is unknown and the cellular receptor for hepatitis A virus (HAV) has not been definitively identified; once infection occurs, HAV is distributed throughout the liver.
- Infection with HAV does not result in chronic disease. Rarely, it can have a prolonged course or a relapsing course and occasionally, profound cholestasis can occur. Mortality rate is low in previously healthy persons. Morbidity can be significant in adults and older children.
- Acute hepatitis A is clinically indistinguishable from other forms of viral hepatitis. A diagnosis of acute hepatitis A requires demonstration of immunoglobulin M (IgM) anti-HAV in serum.
- Original recommendations in 1999 by the Advisory Committee on Immunization Practices (ACIP) had the overall strategy to immunize populations at risk. In 2005, the ACIP recommended that all children between 1 and 2 years of age receive the hepatitis A vaccine.

Experimental work in humans led to the clinical recognition that viruses were etiologic agents of hepatitis A ("infectious hepatitis") and hepatitis B ("serum hepatitis") (1,2). Later, the existence of two hepatitis viruses was demonstrated: Hepatitis A virus (HAV) and hepatitis B virus (HBV) (3). HAV was first characterized in 1973, when scientists detected the virus in stools from human volunteers who were infected with HAV (4). The ensuing development of sensitive and

specific serologic assays for the diagnosis of HAV infection and the isolation of HAV in cell culture (5) were important advances that permitted the understanding of the epidemiology of HAV infection and, ultimately, control of the disease.

Virology

In 1982, HAV was classified as an enterovirus type 72 belonging to the Picornaviridae family. Subsequent determination of the sequence of HAV nucleotides and amino acids led to questioning of this classification, and a new genus, hepatovirus, was created for HAV (6).

HAV has an icosahedral shape and is a nonenveloped virus. It measures 27 to 28 nm in diameter, has a buoyant density of 1.33 to 1.34 g/cm (3) in cesium chloride, and has a sedimentation coefficient of 156 to 160S by ultracentrifugation. HAV survives exposure to ether and an acid environment at pH 3. It also survives heat exposure at 60˚ C for 60 minutes but is inactivated at 85˚C for 1 minute. HAV is capable of surviving in seawater (4% survival rate), dried feces at room temperature for 4 weeks (17% survival), or live oysters for 5 days (12% survival) (7).

Only one serotype of HAV is known, and there is no antigenic cross-reactivity with the hepatitis B, C, D, E, or G agents. The HAV genome consists of a positive-sense ribonucleic acid (RNA) that is 7.48 kb long, single stranded, and linear. HAV RNA has a sedimentation coefficient of 32 to 33S and a molecular weight of

2.8×10^4. The HAV RNA has a long open reading frame of 6,681 nucleotides and is covalently linked to a 5’ terminal protein and a 3’ terminal polyadenosine tract.

The onset of HAV replication in cell culture systems takes from weeks to months. Primate cells, including African green monkey kidney cells, primary human fibroblasts, human diploid cells (MRC-5), and fetal rhesus kidney cells, are favored for the cultivation of HAV in vitro. The virus is not cytopathic, and persistent infection in the cell cultures is the rule. Two conditions control the outcome of HAV replication in cell culture (8). First, the genetic make-up of the virus is important; HAV strains mutate in distinct regions of the viral genome as they become cell culture adapted. The second condition is the metabolic activity of the host cell at the time of infection. Cells in culture, although infected simultaneously, initiate HAV replication in an asynchronous manner. This asynchronicity may be caused by differences in the metabolic activity of individual cells, but there is no definitive evidence of cell-cycle dependence of HAV replication (9).

An initial step in the life cycle of a virus is its attachment to a cell surface receptor. The location and function of these receptors

determine tissue tropism. Little is known about the mechanism of entry of HAV into cells. Some work has suggested that HAV could infect cells by a surrogate-receptor binding mechanism (by a nonspecified serum protein). HAV infectivity in tissue culture has been shown to require calcium and to be inhibited by the treatment of the cells with trypsin, phospholipases, and β-galactosidase (10). A surface glycoprotein, named HAVcr-1, on African green monkey kidney cells has been identified as a receptor for HAV. Blocking of HAVcr-1 with specific monoclonal antibodies prevents infection of otherwise susceptible cells. Experimental data suggest that HAVcr-1 not only serves as an attachment receptor but may also facilitate uncoating of HAV and its entry into hepatocytes (11).

Whatever the entry mechanism, once HAV enters a cell, the viral RNA is uncoated, cell host ribosomes bind to viral RNA, and polysomes are formed. HAV is translated into a large polyprotein of 2,227 amino acids. This polyprotein is organized into three regions: P1, P2, and P3. The P1 region encodes the structural proteins VP1, VP2, VP3, and a putative VP4. The P2 and P3 regions encode nonstructural proteins associated with viral replication.

The HAV RNA polymerase copies the plus RNA strand. The RNA transcript, in turn, is used for translation into proteins, which are used for assembly into mature virions. It appears that downregulation of HAV RNA synthesis occurs as defective HAV particles appear (12). In addition, a group of specific RNA-binding proteins have been observed during persistent infection (13). The origin and nature of these proteins is unknown, but they exert activity on the RNA template and are believed to play a regulatory role in the replication of HAV (14).

Numerous strains of HAV exist, with considerable nucleotide sequence variability (15% to 25% difference within the P1 region of the genome). Human HAV strains can be grouped into four different genotypes (I, II, III, and VII), whereas simian strains of HAV belong to genotypes IV, V, and VI (15). Despite the nucleotide sequence heterogeneity, the antigenic structure of human HAV is highly conserved among strains.

The HAV VP1/2A and 2C genes are thought to be responsible for viral virulence, on the basis of experiments in which recombinant HAV caused acute hepatitis in animals following the construction of 14 chimeric virus genomes from two infectious complementary deoxyribonucleic acid clones that encoded a virulent and an attenuated HAV isolate (HM175 strain) and the genotype and phenotype of each virus were compared (16).

Among the many strains of HAV, the HM175 and CR326 human HAV strains are important because they are used for the production of commercially available vaccines. Strain HM175 was isolated in 1978,

from the human feces of Australian patients in a small outbreak of hepatitis A. CR326 was isolated from Costa Rican patients infected with HAV. The nucleotide and amino acid sequences showed 95% identity between the two strains. Vaccines prepared from these strains are thought to provide protection against all relevant human strains of HAV.

Variations in the HAV genome are thought to play a role in the development of fulminant hepatic failure (FHF) during acute HAV infection. The 5′ untranslated region of the HAV genome was sequenced in serum samples from 84 patients with HAV infection, including 12 with FHF (17). The investigators observed relatively fewer nucleotide substitutions in the HAV genome of patients with FHF than in those without FHF ($P < 0.001$). The differences were most prominent between nucleotides 200 and 500, suggesting that nucleotide variation in the central portion of the 5′ untranslated region influence the clinical severity of HAV infection.

Epidemiology

Acute hepatitis A is a reportable infectious disease in the United States, with a rate of infection of 4/100,000 (18). In 2001, 10,616 cases of HAV infection were reported in the United States and in 2003, 7,653 cases of acute HAV infection were reported to the Center for Diseases Control and Prevention (CDC), the lowest number to date. Taking into consideration the underreporting of cases and the occurrence of asymptomatic infections, the true number of annual HAV infections

has been calculated to be 93,000 and 61,000 for both years, respectively (19). The highest rate of reported disease is among children aged 5 to 14 years; 25% of reported cases are among persons aged 20 years or less (19), but HAV infection can occur in any age-group.

The epidemiologic risk factors for HAV infection reported for the US population in 2002 were as follows: Unknown, 57%; sexual or household contact with a patient who has hepatitis A, 12%; international travel, 9%; male homosexual activity, 8%; injection drug use, 5%; child or employee in a day-care center, 1%; food or waterborne outbreak, 1%; contact with a day-care child or employee, 3%; and other contact with a patient who has hepatitis, 4% (20).

HAV infection generally follows one of three epidemiologic patterns (21). In countries where sanitary conditions are poor, most children are infected at an early age. Although earlier seroepidemiologic studies routinely showed that 100% of preschool children in these countries had detectable antibody to HAV (anti-HAV) in serum, presumably reflecting previous subclinical infection, subsequent studies have

shown that the average age of infection has increased rapidly to 5 years and above, when symptomatic infection is more likely. For example, 82% of 1,393 Bolivian school children were shown to have detectable anti-HAV, but when they were stratified into two groups according to family income, a significant difference was found between the groups: 95% of children from low-income families had detectable anti-HAV as against 56% of children from high-income families (22).

The second epidemiologic pattern is seen in industrialized countries, where the prevalence of HAV infection is low among children and young adults. In the United States, the prevalence of anti-HAV is approximately 10% in children but 37% in adults (23).

The third epidemiologic pattern is observed in closed or semiclosed communities, such as some isolated communities in the South Pacific, where HAV is capable (through epidemics) of infecting the entire population, which then becomes immune. Thereafter, newborns remain susceptible until the virus is reintroduced into the community.

Table 27.1. Detection of Hav and Infectivity of Human Secretions or Excretions

Secretion/excretion	Comment	References
Stool	Main source of infection. HAV is detectable during incubation period and for several weeks after the onset of disease. After the onset of symptoms, HAV is detectable in 45% and 11% of fecal specimens from first and second week, respectively, whereas HAV ribonucleic acid (by a polymerase chain reaction assay) is detectable for 4 to 5 mo.	(28,29)
Blood	Viremia is present	(30,31)

	during incubation period. Blood collected 3 and 11 days before the onset of symptoms caused posttransfusion infection in donors. Chronic viremia does not occur.	
Bile	HAV has been detected in the bile of chimpanzees infected with HAV.	(32)
Urine	HAV is detected in low titer during the viremic phase. A urine sample infected 1 of 12 subjects after oral inoculation. Urine contaminated with blood was also infectious.	(33,34)
Nasopharyngeal	Unknown in humans. HAV has been identified in the oropharynx of experimentally infected chimpanzees.	(35)
Semen, vaginal fluid	Uncertain. HAV may be detectable during viremic phase.	(36)

HAV, hepatitis A virus.

Whatever the epidemiologic pattern, the primary route of transmission of HAV is the fecal–oral route, by either person-to-person contact or ingestion of contaminated food or water. Although rare, transmission of HAV by a parenteral route has been documented following blood transfusion (24,25) or use of blood products (26). Cyclic outbreaks

among users of injection and noninjection drugs and among men who have sex with men (up to 10% may become infected in outbreak years) have been reported (27). Table 27.1 provides information about the detection of HAV and its infectivity in human body fluids (28,29,30,31,32,33,34,35,36).

Approximately 11% to 22% of patients with acute hepatitis A require hospitalization, with an average cost of $6,914 per patient (37). In one outbreak involving 43 persons, the total cost was approximately $800,000. On average, 27 workdays are lost per adult case of hepatitis A, with a total loss of 829,000 workdays/year in the United States. Combined direct and indirect costs associated with HAV infection in the United States totaled more than $200 million in 1989 and approximately $488.8 million in 1997 (27,37).

Pathogenesis

Once HAV is ingested and survives gastric acid, it traverses the small intestine mucosa and reaches the liver through the portal vein. The precise mechanism of hepatic uptake in humans is unknown (see preceding text). In an experimental model on African green monkey kidney cells (11), the putative cellular receptor for HAV has been identified as a surface glycoprotein.

Once the virus reaches the hepatocyte, it starts replicating in the cytoplasm, where it is seen on electron microscopy as a fine granular pattern, but it is not present in the nucleus. HAV is distributed throughout the liver. Although HAV antigen has been detected in other organs (lymph nodes, spleen, kidney), the virus appears to replicate exclusively in hepatocytes. Once the virus is mature, it reaches the systemic circulation through the hepatic sinusoids and is released into the biliary tree through the bile canaliculi, passed into the small intestine, and eventually excreted in the feces.

The pathogenesis of HAV-associated hepatocyte injury is not completely defined. The lack of injury to cells in cell culture systems suggests that HAV is not cytopathic. Immunologically mediated cell damage is more likely. The emergence of anti-HAV could result in hepatic necrosis during the immunologically mediated elimination of HAV.

Clinical Features

Infection with HAV does not result in chronic disease, but in an acute self-limited episode of hepatitis. Rarely, acute hepatitis A can have a prolonged or a relapsing course, and occasionally profound cholestasis can occur. Commonly, the incubation period is 2 to 4 weeks, rarely up to 6 weeks. The mortality rate is low in previously healthy persons.

Morbidity can be significant in adults and older children.

The clinical characteristics of cases of hepatitis A reported in 2002 were similar to those in previous years with a preponderance of cases in men of all age-groups. Overall, 72% of patients manifested jaundice, 25% required hospitalization, and 0.5% died (26). The need for hospitalization increased with age, from 5% among children older than 5 years of age to 34% among persons 60 years of age or older.

HAV infection usually presents in one of five different clinical patterns: (i) Asymptomatic without jaundice; (ii) symptomatic with jaundice and self-limited to approximately 8 weeks; (iii) cholestatic, with jaundice lasting 10 weeks or more; (iv) relapsing, with two or more bouts of acute HAV infection occurring over a 6- to 10-week period; and (v) FHF.

Children older than 2 years of age are usually asymptomatic; jaundice develops in only 20%, whereas symptoms develop in most children (80%) aged 5 years or older. A high rate of symptoms occurs in adolescents and adults. HAV infection with prolonged cholestasis is a rare variant but occasionally leads to invasive diagnostic procedures (inappropriately), because the diagnosis of acute hepatitis may not be readily accepted in patients with jaundice for several months, even in the presence of detectable anti-HAV of the immunoglobulin M (IgM) class (see the following sections) (38). A relapsing course is observed in approximately 10% of patients with acute hepatitis A. Shedding of HAV in stool has been documented during the relapse phase (39). This variant is benign, and the infection ultimately resolves (39). Neither the cholestatic variant nor the relapsing hepatitis A is associated with increased mortality. In all cases, treatment is symptomatic. Acute hepatitis A, unlike hepatitis E, is not associated with an increased mortality rate in pregnant women.

Prodromal symptoms in patients with acute hepatitis A include fatigue, weakness, anorexia, nausea, vomiting, and abdominal pain. Less common symptoms include fever, headache, arthralgias, myalgias, and diarrhea. Dark urine precedes other symptoms in approximately 90% of infected persons; this symptom occurs within 1 to 2 weeks of the onset of prodromal symptoms. Symptoms of hepatitis may last from a few days to 2 weeks and usually decrease with the onset of clinical jaundice. Right upper quadrant tenderness and mild liver enlargement are present on physical examination in 85% of patients; splenomegaly and cervical lymphadenopathy are each present in 15%. Complete clinical recovery is achieved in 60% of affected persons within 2 months and in almost everyone by 6 months. The overall prognosis of acute hepatitis A in otherwise healthy adults is excellent. Potentially fatal complications (e.g., FHF) develop in a few patients (see later sections).

Acute HAV infection must be differentiated from other causes of acute viral hepatitis, autoimmune hepatitis (AIH), and other causes of acute hepatitis by appropriate serologic testing (see Chapters 29 and 30). However, in some cases the diagnosis may be difficult to make because the patient may harbor more than one viral infection, such as chronic hepatitis B or chronic hepatitis C, with superimposed acute HAV infection.

Fulminant Hepatitis A

FHF caused by HAV is rarely seen in children, adolescents, or young adults. However, the case-fatality rate in people over 49 years of age with acute hepatitis A is reported to be 1.8%, compared with an overall rate of 0.3% in persons of all ages (39). Hepatic failure caused by hepatitis A becomes manifest in the first week of illness in approximately 55% of affected patients and during the first 4 weeks in 90%; FHF is rarely seen after 4 weeks (40).

The contribution of HAV to acute liver failure has been reported to be increased in populations classified as hyperendemic for HAV. In a report from India, where 276 patients with FHF were seen between 1994 and 1997, 10.6% of the cases among adults were caused by HAV. HAV had been responsible for only 3.5% of cases among 206 patients with FHF seen in the same community from 1978 to 1981 (41).

Certain populations have increased morbidity and a high risk of acute liver failure from HAV infection. Among these groups are the elderly (42) and persons with chronic liver disease. A 1998 report described the clinical outcome of 256 persons hospitalized for acute hepatitis A in Tennessee from January 1994 through December 1995 (43). On admission, 89% had experienced prolonged nausea or vomiting and 26% had a prolonged prothrombin time (>3 seconds); 39 had serious complications (19 were hepatobiliary in nature and 20 were extrahepatic complications), and 5 (2%) died. Morbidity and mortality correlated with age. Twenty-five percent of patients aged 40 and above had at least one complication, as compared with 11% of patients younger than 40 years of age ($P = 0.014$).

Although two reports since the late 1990s have described a decline in the number of cases of acute viral hepatitis among patients with FHF in the United States (44,45), this decline is attributable principally to the control of hepatitis B. The contribution of HAV infection to FHF has remained unchanged since the 1970s, despite the availability of highly efficacious vaccines.

Autoimmune Disease Following Acute Hepatitis A

Several viruses have been reported to trigger the onset of AIH. In rare cases, hepatitis A has been followed by the development of type 1 AIH. Genetic predisposition is thought to play a role (46,47).

Diagnosis

Acute hepatitis A is clinically indistinguishable from other forms of viral hepatitis. The diagnosis of infection is based on the detection of specific antibodies against HAV (anti-HAV) in serum. A diagnosis of acute hepatitis A requires demonstration of IgM anti-HAV in serum. The test is positive from the onset of symptoms (48) and usually remains positive for approximately 4 months (49). Some patients may have low levels of detectable IgM anti-HAV for more than 1 year after the initial infection (48). IgG anti-HAV is also detectable at the onset of the disease, remains present usually for life, and, following clinical recovery, is interpreted as a marker of previous HAV infection.

Testing for HAV RNA is limited to research laboratories. HAV RNA has been detected in serum, stool, and liver tissue. Viral RNA can be amplified by polymerase chain reaction (PCR) methodology (26). With a PCR assay, HAV RNA has been documented in human sera for up to 21 days after the onset of illness (50). The use of hepatitis C virus (HCV) RNA testing has been described in a report of 76 French patients with acute HAV infection seen between January 1987 and April 2000; 19 of them had FHF (51). Ten patients required liver transplantation, and one patient died while awaiting liver transplantation. The HAV RNA status was determined in 39 of the 50 patients in whom sera and clinical data were available, including the 19 with FHF. HAV RNA was detected in 36 of these 50 patients (72%). The likelihood that HAV RNA was undetectable was greater in patients with FHF than in those with nonfulminant hepatitis ($P < 0.02$). When HAV RNA was detectable, titers were lower in patients with encephalopathy than in patients with nonfulminant hepatitis (3.6 log vs. 4.4 log, $P = 0.02$). These data suggest that the detection of IgM anti-HAV and undetectable or low-titer HAV RNA in patients with severe acute hepatitis may signal an ominous prognosis and the need for early referral for liver transplantation. As in other studies, HAV genotype did not seem to play a role in the severity of clinical manifestations (52).

Prevention and Treatment

Recommendations concerning immunoprophylaxis of HAV were published in December 1999 by the Advisory Committee on Immunization Practices (ACIP) (27). The overall strategy is to protect persons from disease and to lower the incidence of HAV infection in the United States. The available vaccines are not licensed for use in children less than 1 year of age. Currently, all children should receive hepatitis A vaccine at age 1 year or older (52a), high-risk populations

are targeted for immunization; Table 27.2 lists these populations. Because children who reside in high-risk areas are targeted for vaccination, the overall rate of HAV infection has declined steadily, and in 2002, it was 3.1/100,000, the lowest rate yet recorded. The decline in rates has been greater among children than adults and in states where routine childhood vaccination is recommended,

suggesting that childhood vaccination has had a positive impact. Hepatitis rates declined 20-fold during the years 1997 to 2001 among American Indian and Alaska Native children where routine hepatitis A vaccine was implemented (53).

Table 27.2. Groups at High Risk of Hepatitis A Virus Infection

Healthy persons who travel to endemic areas, work in occupations for which the likelihood of exposure is high, are family members of infected patients, or adopt infants or children from endemic areas
Persons with chronic liver disease
Human immunodeficiency virus–positive patients
Men who have sex with men
Users of injection and noninjection illicit drugs
Persons with clotting factor disorders
Persons who live in communities with high or intermediate rates of HAV infection
Children who live in areas where the rate of HAV infection is at least twice the national average (≥20 cases/100,000 population)

HAV, hepatitis A virus.

However, a 2003 CDC analysis of hepatitis A vaccination coverage for children aged 24 to 35 months, who reside in the 11 states where the HAV vaccine is routinely recommended, showed that immunization ranged from 6.4% to 72.7% with an average of 50.9%, whereas immunization among children of the same age residing in the six states where HAV vaccination should be considered averaged 25% (range 0.6% to 32.3%). The analysis concluded that HAV immunization rates for children aged 24 to 35 months are lower than the overall rates for other children vaccines (54).

It is likely that universal immunization was not recommended in the United States because communities were considered to have high, intermediate, and low rates of hepatitis A and US government

surveillance data demonstrated that communities with high and intermediate rates were primarily responsible for an average of 50% of reported HAV cases each year (27). Hence, the recommendation was based on the concept that reducing the incidence of hepatitis A in states with high or intermediate average annual incidence of hepatitis A (Table 27.1) through routine vaccination of children would substantially reduce the incidence of the national disease. However, recent outbreaks in Georgia, Tennessee, and Pennsylvania where more than 600 symptomatic cases and three deaths were reported and thousands of exposed individuals required immediate passive immunization (55) seems to contradict the recommendation for immunization for high or intermediate rates of endemic HAV and it is likely that immunization directed to specific groups would not control the infection as efficiently as universal immunization would do. In October 2005, the CDC advisory committee recommended that all children in the United States receive the vaccine; therefore, it is expected that all children between the age of 1 and 2 years would have the HAV vaccine integrated into their childhood immunization programs (CDC press release October 28, 2005).

Table 27.3. Recommended Regimens for Hepatitis A Vaccination[a]

Vaccine	Age (y)	Dose	Volume (mL)	Dosing schedule (mo)
Havrix	2–18	720 EL.U.	0.5	0, 6–12
	>18	1440 EL.U.	1.0	0, 6–12
Vaqta	2–18	25 U	0.5	0, 6–18
	>18	50 U	1.0	0, 6–18
Twinrix	≥18	720 EL.U. hepatitis A virus	1.0	0, 1, 6

		20 µg hepatitis B virus		

[a]Vaccines are injected intramuscularly in the deltoid area. EL.U., enzyme-linked immunosorbent assay (ELISA) units.

There are no specific medications to treat acute hepatitis A; symptomatic treatment is the rule. Attention to sanitation and administration of serum Ig are the mainstays of preventing HAV infection. The availability of excellent HAV vaccines has rendered the use of Ig for pre-exposure prophylaxis unnecessary. When Ig is used for postexposure prophylaxis, it should be given within 2 weeks of exposure. In these cases, the recommended dose is 0.02 mL/kg by intramuscular injection. Although considered safe, Ig can cause fever, myalgias, and pain at the injection site. Postexposure prophylaxis with Ig can be accompanied safely with the initiation of active immunization with the vaccine (56).

The HAV vaccine was first licensed in the United States in 1995; two inactivated HAV vaccines are commercially available. Extensive use of the vaccines in clinical trials and postmarketing surveillance support the safety and efficacy of these products. Havrix is manufactured by SmithKline Biologicals, Rixensart, Belgium, and Vaqta, by Merck Sharp & Dohme, West Point, Pennsylvania. Both vaccines are derived from HAV grown in cell culture. The final products are purified and formalin inactivated; they contain alum as an adjuvant. The basic difference between the two commercially available vaccines is the HAV strain used for preparation. Havrix was prepared with the HM175 strain, whereas Vaqta was prepared with the CR326 strain (56,57); the difference is of little practical importance, because both vaccines are safe and immunogenic. The doses and schedule of immunization are shown in Table 27.3. Following vaccination with Havrix, anti-HAV is estimated to remain detectable in serum for approximately 20 years; immunity may last longer (58).

From the time the HAV vaccine was licensed in the United States through 1998, more than 6.5 million doses were administered, including 2.3 million pediatric doses. Worldwide, more than 65 million doses of HAV vaccine were administered through 1999. Among adults,

the most frequent local side effects were soreness at the injection site (56%), headache (14%), and malaise (7%). In children, the most frequent side effects were soreness at the injection site (15%),

feeding problems (8%), headache (4%), and injection site induration (4%).

In the United States, through 1998, the national Vaccine Adverse Event Reporting System received 247 reports of unexplained adverse events within 6 weeks of immunization. Approximately one third of these reports occurred with concurrent vaccinations and could not be attributed to the HAV vaccine. Thirteen events in children (0.6/100,000 doses distributed) and 85 events in adults (1.4/100,000 doses distributed) were considered serious. These events included neurologic, hematologic, and autoimmune syndromes. However, no reported serious event could be attributed definitively to the HAV vaccine, and the reported rates did not exceed the expected background rates. For example, the incidence of the Guillain-Barré syndrome ranges from 0.5 to 2.4 cases/100,000 person-years, and the 5 cases of Guillain-Barré syndrome among adult HAV vaccine recipients represented an incidence of 0.2 cases/100,000 person-years (27). Postmarketing reports have not shown a higher incidence rate in vaccine recipients.

A combined formulation of hepatitis A and B vaccines (Twinrix) is available and has an excellent record of efficacy and safety (59). The dosing schedule is shown in Table 27.3.

Immunization Against Hepatitis A Virus in Patients with Chronic Liver Disease

Persons with chronic liver disease are at increased risk of HAV-related morbidity and mortality if they acquire the infection. Therefore, pre-exposure prophylaxis with the HAV vaccine has been recommended for patients with chronic liver disease who are susceptible to HAV (60). This recommendation should be extended to pre- and post–liver transplant recipients, although the immunogenicity of the HAV vaccine is reduced in these persons (61,62).

An episode of acute hepatitis in a patient with underlying chronic liver disease poses the risk of considerable morbidity and mortality. Although the current guidelines recommend immunization against HAV for all patients with chronic liver disease (27), the results of several cost-effective analyses have been conflicting. A report published in 2000 found that saving the life of one patient with HCV infection by HAV vaccination would cost 23 million Canadian dollars (63). However, some of the assumptions in this report have been challenged (64). Two other studies of patients with chronic hepatitis C showed a decided benefit to immunization against HAV (65). The methods used in these studies were dissimilar, and some analyses may have been insensitive

to the incidence of HAV or may have underestimated the economic and societal costs of a case of FHF. Universal immunization against HAV during childhood, before the possible occurrence of chronic liver disease, offers the promise of preventing HAV infection (66).

Chapter 28

Hepatitis E

Maria H. Sjögren

Key Concepts

- Hepatitis E virus (HEV) infects humans by causing outbreaks of hepatitis or being the source of sporadic self-contained infections.
- Antibody to hepatitis E has been observed in many areas of the world; in the United States, 1% to 5% of healthy blood donors have detectable anti-HEV.
- Histopathologic features of HEV infection in the human liver include necroinflammatory processes and cholestatic hepatitis.
- The clinical features of HEV are difficult to differentiate from other viral hepatitis, the diagnosis needs to be suspected and corroborated with serologic tests.
- Case fatality rates among HEV-infected pregnant women have been reported to be between 15% and 25%.
- Development of a hepatitis E vaccine has successfully completed a phase III trial.

After hepatitis A and hepatitis B were diagnosed with the aid of accurate serologic testing, it became apparent that at least two non-A, non-B infectious agents existed, one similar to hepatitis B, mainly transmitted parenterally, and another similar to hepatitis A, transmitted by the fecal–oral route and without sequelae of chronic liver disease. In the 1980s, two seminal discoveries correctly identified the first one as hepatitis C (1) and the second one became known as *hepatitis E* (2).

Since then, hepatitis E has been recognized as the agent responsible for enterically transmitted non-A, non-B hepatitis. Research to understand the epidemiology, viral characteristics, and immunity against this viral agent was galvanized by the work of Balayan et al.

(2) and in recent years by cloning the virus (3), which allowed the development of assays not only to diagnose the infection but also to better understand its epidemiology and develop vaccine candidates.

Virology

Hepatitis E virus (HEV) was first visualized in 1983 when it was transmitted to a human volunteer and subsequently to an experimental animal model, thereby establishing its role as the etiologic agent of hepatitis E (2). HEV is a spherical nonenveloped virus 32 to 34 nm in size with spikes and indentations on its surface. It was recently classified into the separate genus *Hepatitis E–like viruses* (4). The genome of the virus is a single positive-stranded polyadenylated ribonucleic acid (RNA) of approximately 7.5/kb. It consists of three overlapping open reading frames (ORFs) and short untranslated regions at the 5′ and 3′ termini. ORF1 is located at the 5′ end and consists of the nonstructural genes while the 3′ end ORF2 represents one or more structural or capsid proteins. ORF2 contains important epitopes that can induce neutralizing antibodies

and is the prime genomic area selected for vaccine development (4). The function of ORF3 has not been elucidated.

Table 28.1. Hepatitis E Virus Genotypes (4)

Genotypes	Isolates
Genotype 1	Southeast Asia (e.g., Burmese, Indian) North and Central Asia (e.g., China, Pakistan, Kyrgyzstan, India)
	North Africa
Genotype 2	North America (Mexico)
Genotype 3	The United States
	(humans and swine)
Genotype 4	Subset of isolates from China and Taiwan

Heterogeneous	Europe, Argentina

Although there is no consensus on genotype classification, it is generally accepted that on the basis of viruses having nucleotide divergence of not more than 20% of the nucleotides in the ORF2 region, four major HEV genotypes exist (Table 28.1). In addition, genetically heterogeneous isolates from several European countries have been designated as new genotypes, but this concept is not widely accepted; similarly, two novel HEV genotypes have been described from Argentina (4). Despite the diversity of HEV genotype, it is accepted that HEV exists as a single serotype (5), a concept that has important implications in vaccine development because it makes the development of a broadly protective vaccine possible.

In 1990 the genome of HEV was cloned from infectious experimental animal bile. These experiments established that the clone ET1.1 represented a genuine portion of the HEV genome (3). Such advances permitted the development of sensitive and accurate assays that allow the diagnosis of the infection, the better understanding of its epidemiology, and development of candidate vaccines.

Epidemiology

HEV appears to infect humans by causing outbreaks of hepatitis or by being the source of sporadic self-contained infections. Although the hepatitis E outbreaks are newsworthy, anti-HEV has been detected in many areas of the world, including industrialized countries, where no defined epidemics have been reported, for example, in the United States 1% to 5% of healthy blood donors have detectable anti-HEV (6). The meaning of such a high prevalence is still a source of controversy. In addition to representing true HEV infection, some scientists attribute the high prevalence to the nonspecificity of the serologic assays, whereas others believe that it may be a cross-reaction with another agent. The massive waterborne outbreaks of acute hepatitis in New Delhi in the 1955 to 1956 period (7) were diagnosed as "classical"

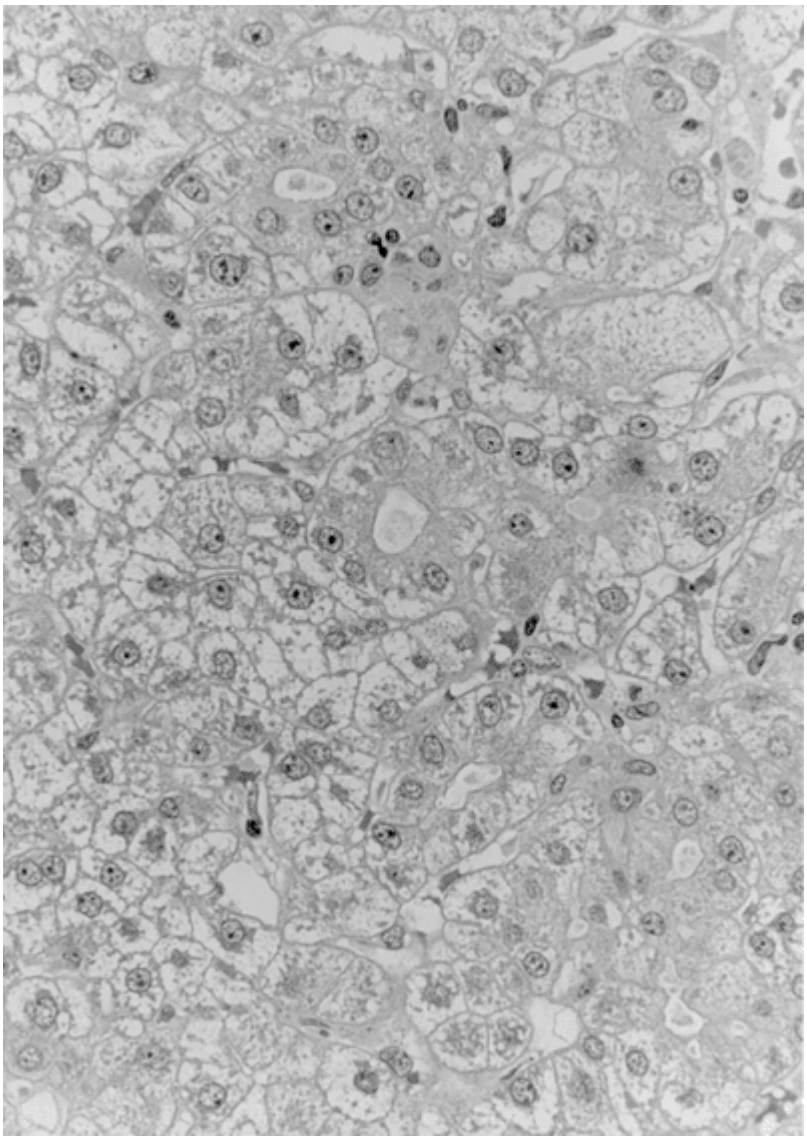
waterborne hepatitis A. However, serologic testing of the available specimens in 1980 ruled out acute hepatitis A or acute hepatitis B and allowed the recognition of the infection as non-A, non-B hepatitis (8). Since then at least 17 HEV outbreaks have occurred in India (9) and more than 50 in Asia, Africa, and the American continents (4). In 1975, sporadic cases from Costa Rica were reported in which the illnesses were neither hepatitis A nor hepatitis B (10). In 1986 and 1987, outbreaks of acute hepatitis occurred in two rural villages located 70 miles south of Mexico City; 223 cases were diagnosed as non-A, non-B hepatitis, and stool samples from some cases yielded viral particles 32 to 34 nm in size, similar to the enterically transmitted non-A, non-B hepatitis from Asia (11). Hepatitis E has been detected among US travelers to endemic regions (12). However, a unique HEV whose genome is significantly different from the Burmese or Mexican strains has been described in the United States in humans and swine (13).

In 2004, approximately 4,000 suspected cases of hepatitis E were reported by health clinics in Darfur, Sudan. Thousands of possible cases were also reported among refugees in Chad and Iraq (14). Hepatitis E is not an uncommon disease in many areas of the world, and it is recognized as a frequent cause of sporadic hepatitis in Asia.

Some species of animals (rodents, swine, monkeys, etc.) have been found to have detectable anti-HEV (15), raising the possibility of HEV being a zoonotic disease that can be acquired from animals; however, there is no confirmation of such transmission.

Pathogenesis

At least two human volunteers and studies in animal models have permitted the characterization of the pathogenesis of HEV. In the human volunteers, abnormal levels of aminotransferases were detected 4 to 5 weeks after ingestion of contaminated material and they remained abnormal for 1 to 3 months (2,16). Viral particles were excreted in stool approximately 4 weeks after ingestion of the inoculum, and the shedding lasted approximately 2 weeks when tested by immune electron microscopy. Using molecular biology techniques, shedding of viral particles has been observed close to 2 months after the ingestion. Immunoglobulin M (IgM) antibody to HEV parallels the rise of aminotransferase levels and declines in titer quickly, disappearing in a few weeks, although some patients may have detectable IgM anti-HEV for a few months. IgG anti-HEV level rises slowly and remains detectable for months, probably years after the infection.



▪ **Figure 28.1** Hematoxylin–eosin stain (×100) of a liver biopsy specimen from a 30-year-old Pakistani man with acute hepatitis E. Acinar transformation (gland-like) and cholestasis are observed along with necroinflammatory changes in the hepatic parenchyma.

Little is known about what happens once the virus is ingested; it is likely that the virus traverses through the small intestine and reaches the liver through the portal vein. The precise mechanism of hepatic uptake in humans is not known. Histopathologic features of HEV infection include necroinflammatory processes seen in all acute viral hepatitis and cholestatic hepatitis. HEV antigen was observed in the cytoplasm of infected hepatocytes as soon as 10 days after experimental intravenous inoculation and persisted for approximately 3

weeks (17). Interestingly, in some outbreaks, the cholestatic hepatitis has been described as a gland-like transformation of hepatocytes with bile stasis (Fig. 28.1).

The pathogenesis of HEV-associated hepatocyte injury is not completely defined.

Clinical Features

The clinical features of HEV are difficult to differentiate from those of other types of viral hepatitis. The incubation period ranges between 15 and 60 days, usually becoming symptomatic 40 days after exposure. Adults appear to be at a greater risk of developing symptoms than adolescents and children. Most patients experience malaise, lack of appetite, nausea, and vomiting. A third of infected patients experience fever or abdominal pain. Few patients experience diarrhea, arthralgias, or skin rash. Serum tests show abnormal levels of aminotransferases and hyperbilirubinemia. Most patients do well, and because there are no chronic sequelae, they recover fully. However, fulminant hepatitis is associated with HEV more often than with any other viral hepatitis (18), particularly among pregnant women. Case fatality rates among HEV-infected pregnant women have been reported between 15% and 25% (19,20). However, work with experimental pregnant animals failed to show differences in severity of HEV infection when compared to nonpregnant animals (21).

Diagnosis

Development of modern diagnostic tests was possible in part because of cloning of the virus (3) and the development of four recombinant viral antigens representing two distinct antigenic domains from two HEV strains (6). Before this advance, scientists relied on immune electron microscopy to detect viral particles in stool, with the consequent limitations of intensive labor and reduced sensitivity. Enzyme immunoassays are available to detect antibodies against HEV, and IgM or IgG classes of antibodies (6). These tests have an 80% to 100% probability of detecting the markers of acute infection (e.g., IgM anti-HEV). Data are limited to evaluate the longevity of IgG anti-HEV. Some studies have shown that IgG anti-HEV persists for at least 1 year after an acute infection (22); others have found that it may last longer. When 53 children from the outbreak in Mexico in the period 1986 to 1987 (11) were tested for anti-HEV 9 years later, 70% were found to have detectable IgG antibody (23).

Prevention and Treatment

No defined antiviral therapy exists, and treatment for acute HEV is mainly supportive. In cases of fulminant HEV, liver transplantation

should be considered.

Some investigators have evaluated the efficacy of pre- or postexposure to Igs as prophylaxis to prevent acute HEV hepatitis. Unfortunately, even when using Igs from endemic regions (e.g., India) there was no clinical benefit observed (24). Prevention against HEV infection is associated with hygienic measures and clean water. No vaccine for human use is commercially available yet, but several recombinant HEV proteins have been evaluated as vaccine candidates. Table 28.2 shows some of these vaccines (25).

Table 28.2. Status of Hepatitis E Vaccines

Type	Pharmaceutical company or research group	Clinical stage
56-kDa ORF2 protein VLPs (baculovirus)	GlaxoSmithKline/United States Army/United States National Institutes of Health	Phase II, III
DNA vaccine	United States Navy	Preclinical
Live swine virus vaccine	United States National Institutes of Health	Preclinical

ORF, open reading frame; VLP, virus-like particles; DNA, deoxyribonucleic acid.
Modified from World Health Organization. *New vaccines against infectious diseases: research and development status*, April 2005; http://www.who.int/vaccine .

GlaxoSmithKline (GSK) Biologicals has been working on the development of a hepatitis E vaccine to protect adolescents and adults. The vaccine is a 56-kDa recombinant product, expressed in insect cells from a baculovirus vector, initially developed at the National Institutes of Health (NIH), United States, and subjected to successful phase I studies (26). Recently, a blinded placebo-controlled study has been conducted in Nepal, involving 2,000 adults from the Royal Nepalese Army. The study is a collaboration between GSK, The United States Army, the Royal Nepalese Army, and the US NIH. The vaccine was administered as three injectable doses at 0, 1, and 6 months, and it was shown to be safe and immunogenic. The vaccine efficacy was

calculated to be 97% among vaccine recipients because only three subjects among the 898 who were fully immunized developed acute HEV, while 66 of the 896 placebo recipients had acute HEV (Robert H. Purcell, *personal communications* 2006). The prospect of controlling hepatitis E is likely a reality in the near future.

Chapter 29

Hepatitis B and D

Anna S.F. Lok
Hari S. Conjeevaram
Francesco Negro

Key Concepts

- There are approximately 400 million hepatitis B carriers worldwide and 1.25 million carriers in the United States. The prevalence of hepatitis B virus (HBV) infection is related to the predominant mode of transmission and the age at infection.
- Acute HBV infection may manifest as subclinical hepatitis, icteric hepatitis, or fulminant hepatitis. Chronic HBV infection may manifest as inactive carrier state, chronic hepatitis, cirrhosis, or hepatocellular carcinoma (HCC).
- Many lines of evidence support an etiologic association between chronic HBV infection and HCC.
- The aims of antiviral treatment of chronic hepatitis B are to suppress HBV replication, induce remission in liver disease, and prevent the development of cirrhosis and (HCC).
- Approved treatments of chronic hepatitis B include interferon-α (standard and pegylated), lamivudine, adefovir, and entecavir.
- Hepatitis D virus is dependent on HBV. Hepatitis D occurs as coinfection with HBV or superinfection in persons with chronic HBV infection.

Epidemiology

Hepatitis B infection is a global public health problem. It is estimated there are approximately 400 million hepatitis B virus (HBV) carriers in the world, of whom over 500,000 die annually from hepatitis B–associated liver disease (1). In the United States, an estimated 1.25 million individuals are chronically infected with HBV (2,3). Hepatitis B carrier rate varies from 0.1% to 20% in different areas of the world (Table 29.1). The wide range in carrier rate is related to differences in the predominant mode of transmission and the age at infection. Understanding the epidemiology of hepatitis B is important in the implementation of vaccination programs for the prevention of HBV infection.

Prevalence

The prevalence of HBV infection varies in different geographical areas (Table 29.1) (4). In low prevalence areas such as the United States, western Europe, Australia and New Zealand, the hepatitis B surface antigen (HBsAg) carrier rate is approximately 0.1% to 2%. In intermediate prevalence areas like the Mediterranean countries, Japan, India and Singapore, the carrier rate is approximately 3% to 5%. In high prevalence areas such as Southeast Asia and sub-Saharan Africa, the carrier rate is 10% to 20%. The prevalence of current and past HBV infection is estimated to be 5% in the United States and close to 100% among adults in some parts of Southeast Asia and Africa. In general, there is an increasing prevalence of HBV infection with age. Within the United States, the prevalence of HBV infection is higher among African Americans, Hispanics and Asians than in the white population (3). Several communities have been reported to have higher carrier rates than their neighboring regions, namely, Alaskan Eskimos, Asian-Pacific Islanders and Australian Aborigines.

In most high prevalence areas such as Hong Kong and China, perinatal transmission is the major mode

of spread accounting for 40% to 50% of chronic HBV infection (5,6). However, horizontal spread during the first 2 years of life is the major mode of transmission in other endemic areas including Africa and the Middle East (7,8). The exact reason for the preponderance of perinatal transmission among Orientals is not clear but is at least in part related to the high prevalence of hepatitis B e antigen (HBeAg) among Asian carriers of reproductive age—40% to 50% versus 10% to 20% among African carriers of the same age-group (6,9). In intermediate prevalence areas, transmission occurs among all age-groups but early childhood infection accounts for most cases of chronic infection. In low prevalence areas, most infections are acquired in early adult life through unprotected sexual intercourse or intravenous drug abuse. The age at infection has a significant impact on the clinical outcome because chronic infection occurs in

approximately 90% of infants infected at birth, in 25% to 50% of children infected between the age of 1 and 5 years, and in less than 5% of those infected during adult life (5,10,11,12).

Table 29.1. Patterns of Hepatitis B Virus Infection

Prevalence	High	Intermediate	Low
Carrier rate	8%–20%	3%–7%	0.1%–2%

Mode of Transmission

Transfusion

In the 1960s, the risk of hepatitis B infection from transfusions of commercial blood was as high as 50% and HBsAg was detected in up to 60% of patients with post-transfusion hepatitis. The exclusion of paid donors and the application of hepatitis B serologic screening in the 1970s dramatically reduced the incidence of post-transfusion HBV infection (13). Currently, approximately 80 cases of transfusion-associated HBV infection are reported in the United States each year (14). In the United States, both HBsAg and hepatitis B core antibody (anti-HBc) are used for blood donor screening. Anti-HBc was initially used as a surrogate marker for non–A non–B hepatitis virus. Anti-HBc has been retained after the implementation of hepatitis C testing to detect donors who are in the window phase during recovery from acute hepatitis B or who have low level chronic HBV infection. The practical value of anti-HBc screening is not clear because of the possibility of false-positive test result, the low incidence of transfusion-associated HBV infection with HBsAg screening only in low prevalence areas, and the need to exclude as many as 22% of the donor population in high prevalence areas (15,16,17,18). Currently, the risk of transfusion related hepatitis B from blood donors who test negative for HBsAg and anti-HBc is estimated to be 1 in 63,000 (range 1:30,000 to 1:250,000 episodes per unit transfused) (19).

Recently there have been debates on serology versus nucleic acid testing (NAT) of blood donors. A recent review concluded that NAT for HBV will probably detect only a few more donor units that may be associated with risk of transmitting HBV infection compared to serologic screening for HBsAg and anti-HBc (20). With the current estimated 13 million donations per year in the United States and 1.8 transfused components per donation, introduction of NAT would be expected to prevent 30 to 35 HBV-containing transfusions per year. Because of the low rates of viral persistence and clinical disease following HBV transmission in the setting of seronegative blood transfusion, the clinical impact and cost-effectiveness of NAT is expected to be low. NAT of whole blood was estimated to avert 9 to 37 HBV infections at an additional cost of US $39 to 130 million per year (21).

Percutaneous transmission

Percutaneous inoculation of blood or body fluid plays a major role in the transmission of hepatitis B infection. Needle sharing by intravenous drug users is an important route of transmission of hepatitis B. Reuse of contaminated needles for tattoos, acupuncture and ear piercing also provide opportunities for percutaneous transmission.

Sexual transmission

In the United States and many developed countries, sexual transmission is the most important mode of spread

of HBV. The Centers for Disease Control and Prevention reported that sexual transmission accounts for almost 50% of acute HBV infection among individuals in whom data on risk factors were available (22). A high prevalence of chronic HBV infection has been reported in men who have sex with men as well as in heterosexuals with multiple sex partners. The annual incidence of new HBV infections among homosexual men decreased significantly in the 1980s as a result of education on safe sex practice to prevent human immunodeficiency virus (HIV) infection (23). However, recent reports in the United States suggest that both heterosexual transmission and transmission among homosexual men are on the rise (22). The risk of sexual transmission of HBV infection is proportional to the number of lifetime sex partners, low education level, paid sex, and history of sexually transmitted diseases.

Perinatal transmission

The rate of neonatal HBV infection from an infected mother is less than 10% in Western countries. Nonetheless, an estimated 20,000 infants are born to HBsAg carrier women in the United States annually (24). In areas with high endemicity such as China, perinatal infection is the most common mode of transmission. The risk of maternal–infant transmission is related to the HBV replicative status of the mother. The risk is 85% to 90% for infants born to HBeAg-positive mothers and 30% for infants born to HBeAg-negative mothers (25). More recent studies demonstrated that maternal serum HBV DNA levels correlate better with the risk of transmission (26). Maternal–infant transmission takes place at the time of delivery by maternal–fetal transfusion or exposure to maternal blood during passage through the birth canal and postnatally through intimate mother–baby contact. Intrauterine transmission is uncommon as HBsAg is detected in infants much later. In addition, passive–active immunization at birth has been demonstrated to have an efficacy rate of more than 90% in the prevention of HBV infection (27). Cesarean section has not been shown to eliminate the risk of perinatally acquired HBV infection (28) and should not be routinely recommended for carrier mothers. Although HBsAg can be detected in breast milk, there is no evidence that HBV infection can be transmitted by breast-feeding (29); infants born to carrier mothers may be breast-fed if they have been vaccinated. The risk of transmission during amniocentesis is also low (30). Universal vaccination of all newborns and additional administration of hepatitis B immune globulin (HBIG) to those who are born to carrier mothers were initiated in many Southeast Asian countries in the 1980s. These programs have led to significant reduction in HBsAg carrier rate as well as decrease in the incidence of hepatocellular carcinoma (HCC) among children (31).

Health care environment

HBV is the most commonly transmitted blood-borne virus in the health care setting (32). Transmission generally occurs from patient to patient or from patient to health care personnel via contaminated instruments or accidental needle stick injury. The risk of acquiring HBV infection after needle stick injury is related to the HBeAg status of the source patient. There have been several outbreaks of hepatitis B infection in the health care environment. One report involved transmission from a patient with diabetes to another through the contaminated platform of a spring-loaded lancet device for finger sticks (33). Outbreaks of HBV infection were also reported in several hemodialysis units as a result of failure to identify and isolate patients who were infected and to vaccinate those who were susceptible (34). Transmission of HBV infection from health care workers to patients is rare. One outbreak was traced to a cardiothoracic surgeon despite no identified flaws in precautions on infection control during operations (35). Transmission was thought to be related to tears in the gloves and minor cuts on the surgeon's fingers during prolonged suturing. Nosocomial transmission can be prevented by screening of blood and blood products, use of disposable needles and equipment, proper sterilization of surgical instruments, enforcement of infection control measures, and vaccination of health care workers.

In many developed countries, guidelines have been established to define the parameters within which health care workers with hepatitis B can operate. In the United States, health care workers who are HBeAg positive are restricted from performing invasive procedures (36,37). The Centers for Disease Control and Prevention recommends that health care workers with HBV infection should not perform exposure prone procedures unless they have sought counsel from an expert review panel and have been advised on the circumstances under which they may perform such procedures. The difference in the scope of permissible work between HBeAg-positive and HBeAg-negative carriers is related to the traditional concept that HBeAg is a reliable marker of infectivity. However, a recent report found that transmission of HBV infection occurred from four HBeAg-negative surgeons. These surgeons had detectable HBV DNA in serum and were infected with precore stop codon variants (38). This and other similar incidents have led to the proposal that serum HBV DNA levels be used to categorize the infectivity of health care workers but it is also known that serum HBV DNA levels can fluctuate and may be intermittently undetectable in patients with chronic HBV infection (37,39,40). As vertical transmission is rarely documented with maternal HBV DNA levels below 10^7 copies/mL, it is thought that transmission of HBV

via needle-stick injury is also unlikely to occur at HBV DNA levels below 10^7 copies/mL (39). It has been proposed that health care workers with higher HBV DNA levels receive antiviral therapy to enable them to return to work without risking nosocomial infection.

Hemodialysis patients

Patients with renal failure on hemodialysis may be infected through blood transfusions, contamination of dialysis machines or equipment, as well as interpersonal horizontal transmission in the dialysis units. Improved infection control and the availability of vaccines have reduced the incidence of HBV infection among hemodialysis patients from 3% in 1980 to 0.1% in 1993 in the United States and has remained stable in the past decade (34,41). However, dialysis patients have impaired antibody response to vaccines. Therefore, vigilance is still needed to prevent outbreaks.

In a recent survey of all US chronic hemodialysis centers (41) the percent of patients vaccinated against HBV infection increased from 47% to 56% and the percent of staff vaccinated increased from 87% to 90% between 1997 and 2002. Although the overall incidence of HBV infection did not correlate with the infection control practices, it was noted that the incidence of HBV infection in 2002 was higher among patients in centers where injectable medications were prepared on a medication cart compared to a dedicated medication room.

A possible contributing factor for continued transmission of HBV infection in adult hemodialysis units appears to be the presence of occult HBV infection (serum HBsAg negative but HBV DNA positive). In a recent study of 241 adult hemodialysis patients in a North American urban center (42), only two patients (0.8%) were HBsAg-positive but nine (4%) HBsAg-negative patients were HBV DNA positive.

Transplantation

Currently, organ donors are routinely screened for HBsAg. Transmission of HBV infection has been reported after transplantation of extrahepatic organs such as kidneys from HBsAg-positive donors. This may be related to residual blood in the vascular pedicles due to inadequate flushing or the presence of infectious virions in the kidneys. Transmission of HBV infection has also been reported after transplantation of avascular tissues such as cornea (43).

The role of anti-HBc testing in organ donor screening is uncertain because of the possibility of false-positive results, the potential loss of up to 5% of donors even in low endemic areas (44), and the uncertainty about the infectivity of organs from donors who have isolated anti-HBc (45). The incidence of HBV infection from donors with isolated anti-HBc is very low (0% to 2%) in heart and kidney recipients but varies from 0% to 78% in liver recipients (44,46,47,48). A recent study found that the estimated probability of undetected hepatitis B viremia is higher among tissue donor**s** compared to first-time blood donors and the addition of NAT to the screening of tissue donor**s** is expected to reduce the risk of HBV infection (49).

Others

In endemic areas, horizontal transmission among children may result from close bodily contact leading to transfer of virus across minor skin breaks and mucous membranes. Blood-feeding insects like mosquitoes have been demonstrated to serve as vectors for HBV transmission in animal models but firm evidence for this mode of transmission in humans is lacking. Various body secretions have been reported to test positive for HBsAg but only semen and saliva have been consistently shown to harbor infectious virions (50,51). Although HBV DNA has been detected in the saliva of some hepatitis B carriers, there is no convincing evidence that hepatitis B can be transmitted orally (52,53). As HBV survives for a long time outside the human body, transmission via contaminated environmental surfaces and daily articles such as toothbrushes, razors, eating utensils or even toys may also be possible.

High-Risk Groups

Health care workers have a higher hepatitis B carrier rate than the general population. The prevalence is particularly high among surgeons, pathologists, and physicians working in hemodialysis and oncology units. Apparent skin breaks, minor cuts and accidental needle stick injuries serve as portals of entry. Other health care workers having increased risk of HBV infection include dentists and laboratory personnel who have contact with serum. Institutionalized mentally handicapped persons as well as their attendants and family members also have a high rate of hepatitis B infection. Despite screening of blood products, patients requiring frequent transfusion of blood or blood products—those with thalassemia and hemophilia—have an increased risk of contracting hepatitis B infection. Other high-risk groups include intravenous drug users particularly those who share syringes, men who have sex with men and promiscuous heterosexuals, immigrants from HBV endemic countries, and spouses, sexual partners, and household members of HBV carriers.

Changing Epidemiology

The worldwide incidence of HBV infection is decreasing (1,22). Mass vaccination for newborns and catch-up vaccination for children and adolescents play a major role in reducing HBV infection among infants and

children. Increased public awareness of hepatitis, educational campaigns to prevent HIV infection leading to modification of high risk sexual behavior, and reduction of syringe sharing among intravenous drug

users have contributed to the decrease in HBV infection among adults.

In the United States, the incidence of acute hepatitis B has significantly declined over the past decade. According to the Centers for Disease Control and Prevention, the incidence of acute hepatitis B during the years 1990 to 2002 has declined from 8.5 per 100,000 population to 2.8 per 100,000 population (22); the most significant decline was seen among ages 0 to 19 years (rate of 3.0 to 0.3). The decline was more marked in women compared to men. However, incidence has remained the same if not increased among certain adult groups: Those with multiple sexual partners, men who have sex with men, and injection drug users. Sexual transmission among susceptible individuals remains a significant risk factor for hepatitis B transmission in the United States. This is in part related to lack of resources and infrastructure for vaccination of adults as well as missed opportunities. In a recent study of 833 men who have sex with men, aged 15 to 29 years, 44% were susceptible to HBV infection; most of these men were found to be either unaware of protective vaccines, had never been offered vaccination, or perceived themselves at low risk (54).

Another important aspect of HBV epidemiology is that in many developed countries, immigrants from countries that are endemic for HBV infection now constitute an increasing proportion of those with chronic HBV infection (55). In addition, some studies also showed that these immigrants have a higher incidence of acute HBV infection (56). These and other studies (57) suggest that screening and immunization of susceptible adults along with immunization of children (especially if they were born in countries where universal vaccination is not in place) whose parents immigrated from HBV endemic countries may be of great importance in controlling HBV infection in developed countries.

Vaccination

Indications

Vaccination against hepatitis B remains the mainstay of prevention. Universal vaccination of all newborn or at least newborn of all HBV-infected mothers is currently practiced in most countries throughout the world. The World Health Organization (WHO) has recommended that combination of hepatitis B and childhood vaccines be used where possible, to reduce the logistic costs of vaccine delivery especially in areas where it is most needed. However, due to decreased immunogenic potential of other vaccines especially during the initial 6 weeks after birth, it is currently recommended that only monovalent vaccines should be administered to the newborn. In some developed countries, where universal vaccination of all newborn is not in place, vaccination of adolescents to prevent sexual transmission is implemented. Vaccination of adults is recommended for high risk groups including health care workers, men who have sex with men, persons with multiple sex partners, injection drug users, sex partners, and household members of HBV carriers, public safety workers, institutionalized patients, and patients on chronic hemodialysis (Table 29.2) (58).

Table 29.2. Indications for Hepatitis B Vaccine

1. All newborns[a]
2. All children and adolescents not vaccinated at birth
3. High-risk adults:
    a. Health care workers
    b. Men who have sex with men
    c. Persons with multiple sexual partners
    d. Injection drug users
    e. Patients on hemodialysis
    f. Institutionalized patients
    g. Health care workers and public safety workers
    h. Spouse, sexual partners and household members of HBV carriers

[a]For infants born to carrier mothers, hepatitis B immune globulin (HBIG) is also administered at birth.

Administration Schedule

There are two types of hepatitis B vaccines, plasma-derived and recombinant, the latter is currently used in most countries. Recombinant HBV vaccines consist of HBV small S protein (HBsAg) produced by yeast or mammalian cells. Hepatitis B vaccine is usually administered intramuscularly in three doses at 0, 1 and 6 months, the dose being 10 to 20 μg in adults and 5 to 10 μg in children (Table 29.3). For adults, the injections are given in the deltoid muscle, whereas in newborns and young children the recommended site is the anterolateral thigh. In patients with hemophilia,

it is recommended to administer the vaccine subcutaneously.

Table 29.3. Hepatitis B Vaccines and Dosage Recommendations

Vaccine brand	Age-group (y)	Dose (μg)	Volume (mL)	Number of doses
Engerix-B	0–19	10	0.5	3
	≥20	20	1.0	3
Recombivax HB	0–19	5	0.5	3
	≥20	10	1.0	3
(Optional two doses)	11–15	10	1.0	2
For hemodialysis patients, recommended dose is 40 μg with each dose (Engerix-B 40 μg/2.0 mL and Recombivax HB dialysis formulation 40 μg/1.0 mL).				

For infants born to HBsAg-negative mothers and unvaccinated children/adolescents up to 19 years of age, 3 doses (0, 1 and 6 months) of vaccine at half strength should be administered. For adults 20 years and older, the same regimen is implemented using full dose (10 μg of Recombivax HB and 20 μg of Engerix-B). An alternative two-dose schedule had been approved for adolescents.

For newborns of HBsAg carrier mothers, HBIG 0.5 mL and the first dose of vaccine should be administered at birth, using different sites. Combination of HBIG and hepatitis B vaccine has been shown to be 95% efficacious in preventing perinatal transmission of HBV infection (27,59,60).

For patients on hemodialysis or immunocompromised patients, higher doses of vaccine are needed: 40 μg of Recombivax HB or Engerix-B. Anti-HBs titer should be monitored annually, and booster doses administered when hepatitis B surface antibody (anti-HBs) titer falls below 10 IU/L.

Follow-up testing for protective antibodies is recommended for individuals who continue to be at risk including infants born to HBsAg-positive mothers, health care workers, hemodialysis patients, and sexual partners of HBsAg carriers (58).

Some vaccines have also incorporated pre-S1 (large S) and/or pre-S2 (middle S) proteins to increase the immunogenicity but these vaccines are not available in most countries.

Efficacy

A protective response defined as an anti-HBs titer more than 10 IU/L is achieved in approximately 95% of vaccine recipients. Several studies have shown that vaccination is effective in inducing protective immunity and in preventing HBV infection even in men who have sex with men, (61,62,63) and newborns of carrier mothers (27,59,64). In countries where the prevalence of HBeAg among carrier mothers is low, it has been shown that the vaccine alone has similar efficacy in preventing HBV infection as a combination of vaccine and HBIG in preventing perinatal infection (64). Although this approach can be cost saving, it may not be adequate in countries where the prevalence of HBeAg among carrier mothers is high or in countries where a high percent of HBeAg-negative mothers have high serum HBV DNA levels.

Factors Associated with Nonresponse and Management of Vaccine Nonresponders

Approximately 2.5% to 10% of vaccine recipients fail to respond with adequate anti-HBs titers after one course of HBV vaccine. The reasons for nonresponse are several and include older age, obesity, chronic medical illnesses such as renal failure, diabetes, cirrhosis, immunosuppression such as patients with HIV infection or organ transplantation, and technical problems such as intragluteal injection and inadvertent freezing of the vaccines.

Nonresponse to HBV vaccine has been reported to be associated with impaired lymphocyte activation as well as genetic factors including certain human leukocyte antigen (HLA) class II genes such as HLA-DRB1*0301 and cytokine gene polymorphisms (65,66,67).

For individuals who failed to respond after a full course of vaccination the recommendation is to repeat another course of vaccine. If a person still remains a nonresponder, further vaccination is usually not effective but most of these individuals can mount an adequate immune response upon infection because

exposure to HBV stimulates both T and B cell responses to HBsAg as well as hepatitis B core antigen (HBcAg). Nonresponders to two courses of vaccine should be tested for HBsAg as some may be undiagnosed carriers.

Durability of Vaccine Response and Need for Boosters

Several studies showed that 30% to 66% of individuals had protective levels of anti-HBs (≥10 mIU/mL) for even 15 years or more after receiving plasma derived HBV vaccines and 90% had anamnestic response after booster vaccination (68,69,70,71). Breakthrough infections appear to occur mostly among those who did not have an initial response to vaccination (70). Two recent studies found that persistence of anti-HBs response up to 18 years after administering plasma-derived and recombinant vaccines was comparable (68,72).

Although anti-HBs titers decline with time, the incidence of HBV infection among individuals who were vaccinated at birth is low and there is no consensus on the need for booster vaccination. The European Consensus Group on hepatitis B Immunity in 2000 recommended that booster doses be considered in those who are immunocompromised or at a high risk of exposure (73). A recent report of the Steering Committee for the prevention and control of infectious diseases in Asia (74) recommended booster vaccination approximately 10 to 15 years after primary vaccination especially among children vaccinated as infants; when monitoring of antibody levels is not feasible; in all immunocompromised patients with anti-HBs levels below 10 mIU/L; and for health care workers in endemic countries. By contrast, a Viral Hepatitis Prevention Board that convened in 2004 concluded that existing data do not support the need for booster doses in universal HBV immunization programs, but the risk of

infection through sexual or occupational exposure later in life on those vaccinated as neonates is unknown (75).

Impact of Hepatitis B Virus Vaccination

HBV vaccination has been shown to reduce the incidence of acute HBV infection and HCC, and the prevalence of chronic HBV infection (31,57,76,77). HBV vaccine is the first vaccine that has been shown to prevent cancer (HCC) in humans. After the implementation of a nationwide vaccination program for newborn and children in 1984, the carrier rate among children decreased from 10% in 1984 to less than 1% in 1999 (31) while the incidence of HCC declined from 0.79 cases per 100,000 between the years 1981 and 1986 to 0.36 cases between the years 1990 and 1994 (77). In the United States, universal vaccination of all newborns was implemented in 1991 and it was expanded to include vaccination of all adolescents aged 11 to 12 years in 1995, and children aged less than 18 years, who had not been vaccinated previously, in 1999. This has resulted in a significant 89% reduction of acute hepatitis B in children and adolescents during 1990 to 2002 (22).

Safety of Hepatitis B Vaccination

The safety of hepatitis B vaccination has been well established. The most common adverse reaction is soreness over the injection site. Other adverse reactions include low-grade fever, malaise, headache, arthralgia and myalgia. Hepatitis B vaccines have no teratogenic effects and can be administered during pregnancy (78,79).

There has been concern about the possibility of hepatitis B vaccine leading to the development of demyelinating central nervous system diseases including multiple sclerosis (80,81) and also Guillain-Barre syndrome (82). It has been speculated that these "adverse reactions" could be related to "molecular mimicry." However, many studies have failed to show a statistically significant temporal or causal association between HBV vaccine and these neurologic or immunologic conditions (83,84,85,86,87). Because of concerns about mercury exposures, current preparations of HBV vaccines do not contain thimerosal as a preservative.

Based upon current evidence and the proven benefit of hepatitis B vaccine, the WHO has recommended that all countries continue their hepatitis B vaccine programs (88).

Special Settings

Isolated antihepatitis B core individuals

The presence of an isolated anti-HBc does not always denote prior exposure to HBV infection. HBV vaccination has been recommended to differentiate those who had prior exposure from those with false-positive anti-HBc test results (15). With improved specificity of current anti-HBc assays, most individuals with isolated anti-HBc have genuinely positive test results and do not need to be vaccinated but there is no harm if vaccine is administered.

Patients on chronic hemodialysis

Response to HBV vaccine is impaired in patients with renal failure. A recent report from the Cochrane group found that there was no difference in response between plasma derived and recombinant HBV

vaccines (89). Response to HBV vaccine was similar in hemodialysis versus peritoneal dialysis patients (90).

Patients with chronic liver disease

Hepatitis B vaccination along with vaccination against hepatitis A is currently recommended for all patients with underlying chronic liver disease. Acute hepatitis B superimposed on chronic hepatitis C has been reported to be associated with increased risk of liver failure (91). Immune response to HBV vaccines among patients with chronic liver disease varies from 70% to 90% (91). In general, response rates are similar to healthy subjects with no liver disease except in patients with cirrhosis but response rates are substantially lower (<50%) in patients with decompensated cirrhosis awaiting liver transplantation (92,93). Therefore, it is recommended that HBV vaccination should be administered early, before a patient develops cirrhosis.

Patients with human immunodeficiency virus infection

Several reports have suggested that patients with HIV infection have a blunted response to HBV vaccine compared to HIV-negative individuals. A recent large randomized, double-blind study of two doses of recombinant HBV vaccine (standard dose of 20 µg and double dose of 40 µg) (94) showed that a response was seen in 34% and 47% in the standard and double dose groups, respectively. Response rates were higher in those with high CD4 count and low HIV RNA level.

Novel methods of vaccine administration

In an effort to reduce the number of injections and increase compliance, several combination vaccines have been developed. They include combinations of hepatitis A and B vaccine for adults and children, and a hexavalent combined vaccine against diphtheria, pertussis, tetanus, polio, *Haemophilus*, and hepatitis B for children. These combined vaccines have been shown to be well tolerated and safe. They have comparable rates of development of protective antibody levels compared to monovalent vaccines (95,96).

Various strategies have been examined to improve immunogenicity of HBV vaccines. One approach is to use more potent adjuvants (97,98). Another approach is to activate mucosal T cells through nasal vaccination (99). Other approaches include intradermal administration, coadministration with interleukin-2, and incorporation of pre-S1 and/or pre-S2 antigens (100,101,102,103).

Diagnosis

The diagnosis of hepatitis B was revolutionized by the discovery of Australia antigen, now called *HBsAg*, by Blumberg in 1965 (104). During the ensuing decade, serologic assays for HBsAg and anti-HBs with increasing sensitivity and specificity were developed. In the 1970s, additional HBV antigens and antibodies were identified and serologic assays for their detection established. Advances in molecular biology techniques in the 1980s led to the development of hybridization assays for direct determination of virus replication and polymerase chain reaction (PCR) assays that permitted the detection of as little as ten molecules of HBV DNA per mL of serum. Diagnosis of HBV infection can also be made by the detection of HBsAg or HBcAg in liver tissues by immunohistochemical staining and of HBV DNA by Southern hybridization, in situ hybridization or PCR.

Serologic Diagnosis

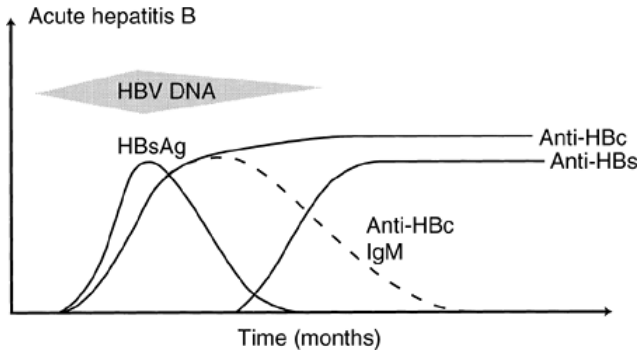
Serological markers during HBV infection are shown in Figures 29.1 and 29.2 and Table 29.4.

Hepatitis B surface antigen and hepatitis B surface antibody

HBsAg is the serologic hallmark of HBV infection. It can be detected by radioimmunoassays (RIAs) or enzyme immunoassays (EIAs). HBsAg appears in serum 1 to 10 weeks after an acute exposure to HBV, approximately 2 to 6 weeks before the onset of hepatitis symptoms or elevation of alanine aminotransferase (ALT) (105). In patients who subsequently recover, HBsAg usually becomes undetectable after 4 to 6 months. Persistence of HBsAg for more than 6 months implies chronic infection. The disappearance of HBsAg is followed by the appearance of anti-HBs. Although anti-HBs is produced early in the course of acute infection in individuals who subsequently recover, they are frequently not detectable until after a window period of several weeks to months when neither HBsAg nor anti-HBs can be detected (105) (Fig. 29.1). The appearance of anti-HBs marks the recovery from hepatitis B. In most patients, anti-HBs persist for life, therefore conferring long-term immunity. Anti-HBs is the only protective antibody induced by most of the currently available vaccines, which consist of recombinant HBsAg only.

Table 29.4. Interpretation of Hepatitis B Virus (HBV) Serologic Markers

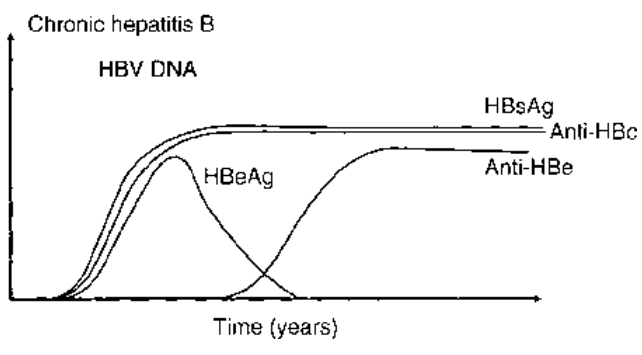
Hepatitis B surface antigen	HBV infection: acute or chronic
Hepatitis B e antigen	High levels of HBV replication and infectivity
Anti-HBe	Low levels of HBV replication and infectivity
Anti-HBc (IgM)	Recent HBV infection
Anti-HBc (IgG)	Recovered or chronic HBV infection
Anti-HBs	Immunity to HBV infection
Anti-HBc (IgG) + anti-HBs	Past HBV infection
Anti-HBc (IgG) + HBsAg	Chronic HBV infection



▪ **Figure 29.1** Serologic markers during acute hepatitis B virus infection. HBV, hepatitis B virus; HBsAg, hepatitis B surface antigen; anti-HBc, hepatitis B core antibody; anti-HBs, hepatitis B surface antibody; IgM, immunoglobulin M.

HBV can be classified into eight genotypes (106,107) and four major serotypes (108). All HBV serotypes share one common antigenic determinant, "a," which is a conformational epitope located in the HBsAg. There are two additional pairs of mutually exclusive subtypic determinants "d" or "y" and "w" or "r" constituting the four major serotypes—adr, ayr, adw, and ayw. Antibodies to the "a" determinant confer protection to all HBV serotypes (109). At least 50% of the anti-HBs

that develops after recovery from acute hepatitis B or immunization with hepatitis B vaccines are directed against the "a" determinant, therefore providing cross-protection against other serotypes of HBV.



▪ **Figure 29.2** Serologic markers during chronic hepatitis B virus infection. HBV, hepatitis B virus; HBsAg, hepatitis B surface antigen; anti-HBc, hepatitis B core antibody; anti-HBe, hepatitis B e antibody.

Coexistence of HBsAg and anti-HBs has been reported in approximately 24% of HBsAg-positive individuals (110). In most instances, the antibodies are directed against one of the subtypic determinants and not the common "a" determinant and are unable to neutralize the circulating virions (111). These individuals should therefore be regarded as carriers.

Pre-S1 and pre-S2 antigens have been detected in patients infected with HBV. In general, the presence of these antigens correlates with the detection of HBV DNA and virus replication (112). During recovery from acute hepatitis B, antibodies to pre-S1 and pre-S2 antigens appear early (113), prior to the detection of anti-HBs.

Hepatitis B core antigen and antihepatitis B core antibody

HBcAg is an intracellular antigen that is expressed in infected hepatocytes. It is not detectable in serum. Its antibody—anti-HBc—however, can be detected throughout the course of HBV infection. During acute HBV infection, anti-HBc is predominantly immunoglobulin (Ig) M class. IgM anti-HBc is the first antibody to be detected (Fig. 29.1). It usually appears within 1 month after the appearance of HBsAg, approximately 1 to 2 weeks before ALT begins to rise (105). It is the sole marker of HBV infection during the window period, that is, the time gap between the disappearance of HBsAg and the appearance of anti-HBs (114). During convalescence, the titer of IgM anti-HBc declines while the titer of IgG anti-HBc increases. Therefore, the detection of IgM anti-HBc is usually taken as an indication of acute HBV infection. However, in 20% of patients, IgM anti-HBc may remain detectable up to 2 years after the acute infection (115). In addition, low-titer IgM anti-HBc persists in most patients with chronic HBV infection. Therefore, the reliability of IgM anti-HBc in the differentiation of acute from chronic HBV infection depends on the cutoff level in the assay. Even in assays with high cutoff values, IgM anti-HBc can be detected in patients with chronic HBV infection during exacerbations (116). This may lead to misdiagnosis of acute hepatitis B in patients who are not previously known to have chronic HBV infection and overestimation of the rate of progression to chronicity. Recent studies in endemic areas demonstrated that many patients presenting with acute hepatitis who test positive for HBsAg have exacerbations of chronic hepatitis B and not acute hepatitis B, and that less than 1% of immunocompetent adult patients with genuine acute hepatitis B progress to chronic infection (12,117).

IgM anti-HBc titers have been reported to correlate with ALT and serum HBV DNA levels in patients with chronic hepatitis B especially during exacerbations (118). It has also been suggested that serial IgM anti-HBc titers may be useful in monitoring response to interferon (IFN) therapy (119).

IgG anti-HBc persists along with anti-HBs in patients who recover from acute hepatitis B and in association with HBsAg in those who progress to chronic HBV infection.

Isolated presence of anti-HBc in the absence of HBsAg and anti-HBs has been reported in 0.4% to 1.7% among blood donors in low prevalence areas (120,121) and in 10% to 20% of the population in endemic countries (15,122). Isolated detection of anti-HBc may occur during the window period of acute hepatitis B when the anti-HBc is predominantly IgM class, many years after recovery from acute hepatitis B when anti-HBs has fallen to undetectable levels, or after many years of chronic HBV infection when HBsAg titer has decreased below the level for detection. The clinical significance of isolated anti-HBc is complex. Although HBV DNA has been detected in the serum of individuals with isolated anti-HBc when tested by PCR assays, the frequency of detection varies from 0% to 20% (18,123,124). Transmission of HBV infection has been reported from blood and organ donors with isolated anti-HBc but the incidence ranged from 0.4% to 78% (18,47,48,125,126), the risk being highest when livers from anti-HBc-positive donors are transplanted into seronegative recipients. Several studies found that 50% to 70% of asymptomatic individuals with isolated anti-HBc have false-positive test results (15,16), the false-positive rate has decreased with improved anti-HBc assays. The evaluation of individuals with isolated anti-HBc should include repeat testing for anti-HBc, HBsAg, anti-HBs, and hepatitis B e antibody (anti-HBe). Individuals with evidence of chronic liver disease should be tested for HBV DNA to exclude low-level chronic HBV infection.

Hepatitis B e antigen and hepatitis B e antibody

HBeAg is a secretory protein that is processed from the precore protein. It is generally considered to be a marker of HBV replication and infectivity. Its presence is usually associated with the detection of HBV DNA polymerase (127) and HBV DNA (128) in serum. Epidemiologic studies reported significantly higher rates of transmission of HBV infection from HBeAg-positive carrier mothers to their babies (129,130) and from HBeAg-positive patients to health care workers who sustain needle stick injuries (127).

During acute HBV infection, HBeAg appears shortly after the appearance of HBsAg. In patients who recover,

HBeAg to anti-HBe seroconversion precedes that of HBsAg to anti-HBs seroconversion (105) (Fig. 29.1). Anti-HBe may persist for many years after resolution of acute hepatitis B. In patients with chronic HBV infection, HBeAg may persist for years to decades (Fig. 29.2). During the HBeAg-positive phase, most patients have detectable HBV DNA in serum and active liver disease. In patients with perinatally acquired HBV infection, there may be an immune tolerant phase with normal ALT levels and minimal inflammation in the liver (131,132,133). Seroconversion from HBeAg to anti-HBe is usually associated with marked decrease in serum HBV DNA level and remission of liver disease (134,135,136). However, some anti-HBe–positive patients continue to have active liver disease and detectable HBV DNA in serum (128,137). This may be due to low levels of wild type HBV or the presence of precore HBV variants (138).

Tests for Hepatitis B Virus Deoxyribonucleic Acid in Serum

Assays for HBV DNA polymerase activity were developed in the 1970s to directly assess and quantify HBV replication (139). These assays are cumbersome and have been superseded by assays to detect HBV DNA. Serum HBV DNA levels can be quantified by molecular hybridization or signal amplification assays, which have sensitivity limits of 10^5 to 10^6 viral copies/mL. PCR assays are more sensitive and are capable of detecting less than 10^2 copies/mL (140). An arbitrary value of greater than 10^5 copies/mL has been chosen as a diagnostic criterion for chronic hepatitis B (141). However, there are problems with this definition. First, assays for HBV DNA quantification are not well standardized (Table 29.5) (142,143,144,145,146). In the last few years, there has been concerted effort to mandate standardization of all HBV DNA assays against WHO standards and to report results in international units (147,148), but this process of standardization has not been yet been implemented worldwide. Second, some patients with chronic hepatitis B have fluctuating HBV DNA levels that may at times fall below 10^5 copies/mL (149,150,151). Therefore, a single HBV DNA level on a random occasion may not be accurate in assessing HBV replicative status and need for antiviral therapy in individual patients. Third, the threshold HBV DNA level that is associated with progressive liver disease is unknown.

Table 29.5. Comparison of Hepatitis B Virus (HBV) DNA Quantification Assays

Assay (manufacturer)	Volume of sample	Sensitivity[a]		Linearity (copies/mL)
		pg/mL	Copies/mL	
Branched DNA (Bayer)	10 µL	0.002	2×10^3	3×10^3–8×10^8
Hybrid capture (Digene)	30 µL	0.5	1.4×10^5	2×10^5–1×10^9
	1 mL	0.02	5×10^3	5×10^3–3×10^6
PCR—Amplicor (Roche)	50 µL	0.001	4×10^2	4×10^2–1×10^7 Cobas: 10^2–10^5 Taqman: 10^2–10^{10}
Molecular Beacons	10–50 µL	—	<50	50–1×10^9

1 IU = approximately 5.6 copies/mL (depending on assay).
[a]One picogram of hepatitis B virus DNA = 283,000 copies (approximately 3×10^5 viral genome equivalents).

Using hybridization assays, HBV DNA can be detected approximately 1 week after the appearance of HBsAg in patients with acute hepatitis B (152). In rare cases, HBV DNA can be detected before HBsAg. PCR assays can detect HBV DNA earlier, up to 2 to 3 weeks before the appearance of HBsAg. Recovery from acute hepatitis B is usually accompanied by the disappearance of HBV DNA in serum as determined by hybridization or bDNA assays. However, HBV DNA may remain detectable in serum for many years if tested by PCR assays (153).

In patients with chronic HBV infection, spontaneous or treatment induced HBeAg seroconversion is usually accompanied by the disappearance of HBV DNA in serum as determined by unamplified assays but HBV DNA frequently remains detectable by PCR assays except in patients who have HBsAg seroconversion (154). The major role of serum HBV DNA assays in patients with chronic HBV infection is to assess HBV replication and candidacy for antiviral therapy. Patients with high pretreatment serum HBV DNA levels are less likely to respond to IFN therapy but pretreatment serum HBV DNA levels seem to be less important in predicting

response to nucleoside/nucleotide analogs (155,156). Tests for HBV DNA in serum are also important in assessing response to antiviral treatment.

Rarely, tests for HBV DNA in serum help to identify HBV as the etiology of liver disease in HBsAg-negative patients (157,158). This is especially important in patients with fulminant hepatitis B, who may have cleared HBsAg by the time they present (159). In patients with chronic liver disease due to occult HBV infection, most cases are due to low levels of HBV whereas a small percent may be related to HBV mutants that downregulate the production of HBsAg or produce aberrant HBsAg that cannot be detected in conventional serologic assays (160).

Table 29.6. Diagnosis of Hepatitis B Virus (HBV) Infection

	HBsAg	HBeAg	IgM anti-HBc	IgG anti-HBc	Anti-HBs	Anti-HBe	HBV DNA	Interpretation
Acute HBV	+	+	+		–		+++	Early phase
infection	–	–	+		–	+	+	Window phase
	–	–	–	+	+	+	±	Recovery phase
Chronic HBV	+	+	–	+	–	–	+++	HBeAg+ chronic hepatitis
infection	+	–	–	+	–	+	±	Inactive carrier state
	+	–	–	+	–	+	++	HBeAg– chronic hepatitis
	+	±	±	+	–	±	++	Exacerbations of chronic hepatitis

HBsAg, hepatitis B surface antigen; HBeAg, hepatitis B e antigen; IgM, immunoglobulin M; anti-HBc, hepatitis B core antibody; IgG, immunoglobulin G; anti-HBs, hepatitis B surface antibody; anti-HBe, hepatitis B e antibody.

Currently, most diagnostic laboratories use real-time PCR assays which have a wider range of linearity and are more accurate in quantification of HBV DNA. Some real-time PCR assays can also differentiate among various HBV genotypes and wild type versus HBV mutants such as precore mutation and antiviral-resistant mutations (161,162).

Diagnostic Algorithm

Diagnosis of HBV infection is shown in Table 29.6 and Figures 29.1 and 29.2.

The diagnosis of acute hepatitis B is based on the detection of HBsAg and IgM anti-HBc. During the initial phase of infection, markers of HBV replication: HBeAg and HBV DNA are present. Recovery is accompanied by the disappearance of HBV DNA, HBeAg to anti-HBe seroconversion and subsequently HBsAg to anti-HBs seroconversion. Rarely, patients may have entered the window period at the time of presentation; IgM anti-HBc is the sole marker of acute HBV infection in these patients. This situation is more common in patients with fulminant hepatitis B where virus clearance tends to be more rapid.

Past HBV infection is diagnosed by the detection of anti-HBs and anti-HBc (IgG). Immunity to HBV infection after vaccination is indicated by the presence of anti-HBs only.

The diagnosis of chronic HBV infection is based on the detection of HBsAg and IgG anti-HBc. Additional tests for HBV replication: HBeAg and serum HBV DNA should be performed to determine if the patient should be considered for antiviral therapy. Additional tests for hepatitis C and hepatitis D should also be performed to rule out superinfection with other hepatitis virus(es).

Clinical Manifestations

The spectrum of HBV infection varies from subclinical hepatitis, anicteric hepatitis, icteric hepatitis to fulminant hepatitis during the acute phase; and from inactive carrier state to chronic hepatitis, cirrhosis and HCC during the chronic phase. The clinical manifestations and outcome of HBV infection depend on the age at infection, the level of HBV replication and the immune status of the host. Perinatal or childhood infection is usually associated with few or no symptoms but a high risk of chronicity whereas adult acquired infection is usually associated with symptomatic hepatitis but a low risk of chronicity. The consensus definition and diagnostic criteria for clinical terms relating to HBV infection adopted at a recent National Institutes of Health (NIH) workshop are summarized in Table 29.7 (141).

Acute Hepatitis B Virus Infection

Approximately 70% of patients have subclinical or anicteric hepatitis during acute HBV infection, only 30% have icteric hepatitis. Symptomatic hepatitis is rare in neonates and it occurs in approximately 10% of children less than 4 years old and in approximately 30% of adults (163).

Symptoms and signs

The incubation period of acute HBV infection lasts 1 to 4 months. This period may be shorter in patients who have been exposed to a large inoculum (164). During the prodromal period, a serum sickness–like syndrome may develop. This is followed by insidious onset of constitutional symptoms including malaise, anorexia, nausea and occasionally vomiting, low-grade fever, myalgia and easy fatigability. Patients may have altered gustatory acuity and smell sensation. Some patients may experience intermittent mild to moderate right upper quadrant or midepigastric pain. In patients with icteric hepatitis, jaundice usually begins within 10 days after the onset of constitutional symptoms. Constitutional symptoms generally subside as jaundice develops. Clinical symptoms and jaundice usually disappear after 1 to 3 months but some patients may have persistent fatigue even after the ALT levels have returned to normal.

Table 29.7. Glossary of Clinical Terms Used in Hepatitis B Virus (HBV) Infection

DEFINITIONS
Chronic hepatitis B Chronic necroinflammatory disease of the liver caused by persistent infection with hepatitis B virus. Chronic hepatitis B can be subdivided into HBeAg positive and HBeAg negative chronic hepatitis B. **Inactive HBsAg carrier state** Persistent HBV infection of the liver without significant, ongoing necroinflammatory disease. **Resolved hepatitis B** Previous HBV infection without further virological, biochemical or histologic evidence of active virus infection or disease. **Acute exacerbation or flare of hepatitis B** Intermittent elevations of aminotransferase activity to more than ten times the upper limit of normal and more than twice the baseline value. **Reactivation of hepatitis B** Reappearance of active necroinflammatory disease of the liver in a person known to have the inactive HBsAg carrier state or resolved hepatitis B. **HBeAg clearance** Loss of HBeAg in a person who was previously HBeAg positive. **HBeAg seroconversion** Loss of HBeAg and detection of anti-HBe in a person who was previously HBeAg positive and anti-HBe negative, associated with decrease in serum HBV DNA to $<10^5$ copies/mL. **HBeAg reversion** Reappearance of HBeAg in a person who was previously HBeAg negative, anti-HBe positive.
DIAGNOSTIC CRITERIA
Chronic hepatitis B
1. HBsAg+ >6 m 2. Serum HBV DNA $>10^5$ IU/mL (may be lower for HBeAg negative patients) 3. Persistent or intermittent elevation in ALT/AST levels 4. Liver biopsy showing chronic hepatitis (necroinflammatory score ≥4)[a]

Inactive HBsAg carrier state
1. HBsAg+ >6 m 2. HBeAg–, anti-HBe+ 3. Serum HBV DNA $<10^5$ IU/mL (usually $<10^3$ IU/mL) 4. Persistently normal ALT/AST levels 5. Liver biopsy confirms absence of significant hepatitis (necroinflammatory score <4)[a]
RESOLVED HEPATITIS B
1. Previous known history of acute or chronic hepatitis B or the presence of anti-HBc ± anti-HBs 2. HBsAg– 3. Undetectable serum HBV DNA[b] 4. Normal ALT levels

[a]Optional.
[b]Very low levels may be detectable using sensitive PCR assays.
HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBc, hepatitis B core; anti-HBs, hepatitis B surface antigen; ALT, alanine aminotransferase; AST, aspartate aminotransferase.
Adapted from Lok AS, Heathcote EJ, Hoofnagle JH. Management of hepatitis B: 2000—summary of a workshop. *Gastroenterology* 2001;120(7):1828–1853.

P.756

Physical examination can be unrevealing in many patients. The most common findings include low-grade temperature, clinical icterus, and soft mildly tender hepatomegaly. Splenomegaly may be found in approximately 5% to 15% of patients. Rarely palmar erythema or spider nevi can be detected. Mild lymph node enlargement may be present, but generalized lymphadenopathy is not a feature of acute hepatitis B.

Patients with fulminant hepatitis may present with features of hepatic encephalopathy—disturbance in sleep pattern, asterixis, mental confusion, disorientation, somnolence and coma, progressive decrease in liver span, and ascites.

Laboratory findings

Elevation of liver enzymes—alanine aminotransferase (ALT) and aspartate aminotransferase (AST)—is the

P.757

hallmark of acute hepatitis. Values of 1,000 to 2,000 IU/L are typically seen during the acute phase. Increase in liver enzymes may precede the onset of symptoms. The ALT levels are usually higher than the AST levels. In patients with icteric hepatitis, increase in bilirubin levels usually lags behind increase in ALT levels. Although the peak ALT level reflects the degree of hepatocellular injury, it has no correlation with prognosis. Prothrombin time, which is a measure of liver derived clotting factors II, VII, IX, and X, is the best indicator of prognosis in patients with acute hepatitis. Because of the short half-life of these clotting factors (6 hours for factor VII), prothrombin time reflects the instantaneous synthetic function of the liver and the mass of viable hepatocytes. Serum albumin level is not a good marker of liver function during acute hepatitis because of its long half-life (21 days). Mild leukopenia with relative lymphocytosis is a common finding. Although red cell survival is slightly shortened in acute hepatitis, hemoglobin and hematocrit are usually within normal limits. Rare hematologic findings include hemolytic anemia associated with glucose-6-phosphatase deficiency (165) and aplastic anemia (166). In patients who recover, ALT levels usually return to normal values after 1 to 4 months, followed by normalization in bilirubin levels. Persistent elevation of ALT levels for more than 6 months suggests chronic liver injury and persistent infection.

Histologic findings

Liver biopsy is seldom indicated in acute hepatitis. Histologic changes of acute hepatitis include lobular disarray, acidophilic degeneration of hepatocytes, focal lobular necrosis, disruption of bile canaliculi with cholestasis, portal and parenchymal infiltration of inflammatory cells, as well as hypertrophy and hyperplasia of Kupffer cells and macrophages. Inflammatory infiltrates are predominantly lymphocytes and macrophages, with occasional eosinophils and neutrophils, but rarely plasma cells. In patients with severe hepatitis, hepatocyte necrosis is more extensive leading to bridging or linking up of necrotic areas in adjacent lobules. Resolution of hepatitis is signified by reduction of inflammatory infiltrates and parenchymal cell regeneration. In some cases of subfulminant hepatitis, liver biopsy may be indicated to assess the extent of liver necrosis and the need for a liver transplantation.

Sequelae

The risk of chronicity is inversely proportional to the age at infection. Less than 5% of immunocompetent adults with acute HBV infection progress to chronic infection, but up to 90% of those infected during infancy will develop chronic infection (5,10,11,12). Acute HBV infection is estimated to account for 35% to 70% of all virally related cases of fulminant hepatitis (167,168,169) but only 0.1% to 0.5% of acute hepatitis B runs a fulminant course (167,170). Mortality from fulminant hepatitis B is high, approaching 80%, unless liver transplantation can be performed. Contrary to transplantation for HBV-cirrhosis, reinfection after liver transplantation for fulminant hepatitis B is uncommon.

Chronic Hepatitis B Infection

Symptoms and signs

In areas of low or intermediate prevalence, approximately 30% to 50% of patients with chronic HBV infection have a history of classical acute hepatitis that progressed to chronic infection (171,172). The remaining 50% to 70% of patients with chronic HBV infection in these areas and most of those in high prevalence areas (predominantly perinatal infection) have no prior history of acute hepatitis. Many patients with chronic HBV infection are asymptomatic while others have nonspecific symptoms such as fatigue. Occasionally mild right upper quadrant or midepigastric pain may be present. Patients with chronic HBV infection may experience exacerbations that may be asymptomatic or mimic acute hepatitis with fatigue, anorexia, nausea and jaundice and in rare instances hepatic decompensation.

Physical examination may be unrevealing or there may be stigmata of chronic liver disease such as spider angioma and palmar erythema, and a mild hepatomegaly. In patients with cirrhosis, additional findings such as splenomegaly may be present. As the liver disease advances, hepatic decompensation may develop manifesting as variceal bleeding, ascites, peripheral edema, jaundice, and hepatic encephalopathy.

Laboratory findings

Laboratory tests can be entirely normal even in patients with well-compensated cirrhosis. Mild to moderate liver enzyme elevation may be the only biochemical abnormality in many patients with chronic hepatitis B. ALT levels may range from normal to fivefold elevated and are generally higher than AST levels, except in patients who have progressed to cirrhosis. Very high ALT levels, up to 1,000 IU/L, may be seen during exacerbations. Markers of impaired hepatic synthetic function may be observed during the exacerbations, especially in patients with underlying cirrhosis. In addition, increase in α-fetoprotein (AFP) levels, up to 1,000 ng/mL, may be present (173). The AFP levels tend to parallel or follow the ALT levels. Progression to cirrhosis is suspected when platelet count is decreased, when there is hypoalbuminemia, hyperbilirubinemia and prolongation in prothrombin time, and when AST/ALT ratio is greater than 1.

Histologic findings

Liver biopsy is useful in assessing the severity of liver damage, in predicting prognosis and in monitoring response to treatment. However, it must be recognized that liver histology can improve significantly in patients who have sustained response to antiviral therapy or spontaneous HBeAg seroconversion. Liver histology also can worsen rapidly in patients during exacerbations of hepatitis.

The predominant histologic findings include inflammatory cell infiltration in the portal tracts and periportal necrosis. The inflammatory infiltrate consists mainly of mononuclear cells. Periportal necrosis may be mild or severe leading to disruption of the limiting plate (piecemeal necrosis or interface hepatitis). As the liver damage progresses, fibrous tissue is deposited initially within the portal tracts, later extending into the centrilobular areas and adjacent portal tracts forming bridging fibrosis and eventually cirrhosis. In some patients, ground glass hepatocytes that stain positive for HBsAg can be found. Recent studies showed that these cells are found in association with retention of HBsAg (174). Traditionally, the histology of chronic hepatitis B is divided into chronic persistent hepatitis (CPH), chronic active hepatitis (CAH), and cirrhosis (175). CPH represents a milder form of liver injury with limitation of chronic inflammatory infiltrates to the portal tracts whereas CAH represents a more severe form of liver injury characterized by the presence of piecemeal necrosis. A third form of liver injury had been described—chronic lobular hepatitis (CLH) (176). CLH is characterized by spotty necrosis and inflammation within the lobules with minimal or mild portal inflammation. It is most often seen during exacerbations of chronic hepatitis B. CPH and CAH were thought to represent two dichotomous reactions to chronic HBV infection with different prognosis. The advent of antiviral therapy and the availability of serial liver biopsies before and after spontaneous or treatment induced HBeAg seroconversion revealed that patients may progress from CPH to CAH and vice versa suggesting that these two forms of liver injury may be seen during different phases of chronic HBV infection in the same patient. To provide more objective assessment of liver injury, several numerical scoring systems have been established to permit statistical comparisons of necroinflammatory activity and fibrosis (177,178,179). An international panel recommended that the histologic diagnosis include the etiology of hepatitis, the grade of necroinflammatory activity, and the stage (extent of fibrosis) of the liver disease (180).

Immunohistochemical staining reveals the presence of HBsAg in patients with chronic HBV infection. The distribution of HBsAg can be either membranous or cytoplasmic. In patients with high levels of HBV replication, HBcAg can also be demonstrated. The distribution of HBcAg is usually nuclear but it has been observed that the distribution is shifted to the cytoplasm in patients with exacerbations or active liver disease (181).

Extrahepatic Manifestations

Extrahepatic manifestations have been reported in patients with both acute and chronic HBV infection. Extrahepatic manifestations are more commonly associated with acute hepatitis B than other forms of acute viral hepatitis and may be present in approximately 10% to 20% of patients with chronic HBV infection. They are believed to be mediated by circulating immune complexes, the formation of which is favored by high levels of HBV replication (182,183).

Serum sickness

Acute hepatitis B is sometimes heralded by a serum sickness–like syndrome manifested as fever, skin rash, polyarthralgia, and arthritis. Skin and joint manifestations usually subside rapidly with the onset of jaundice.

Polyarteritis nodosa

Approximately 10% to 50% of patients with polyarteritis nodosa (PAN) are found to be HBsAg positive. The decline in HBV infection over the past decade, especially in developed countries has also been associated with a decrease in frequency of HBV-related PAN (183,184). Immune complexes involving HBV antigens and antibodies are believed to trigger the vascular injury (185). Vasculitis may affect large, medium and small sized vessels in multiple organs including cardiovascular (pericarditis, hypertension, cardiac failure), renal (hematuria, proteinuria), gastrointestinal (abdominal pain, mesenteric vasculitis), musculoskeletal (arthralgia, arthritis), neurologic (mononeuritis, central nervous system involvement) and dermatologic (rashes) systems. The course is highly variable. Gastrointestinal involvement, especially perforation and bleeding, are the most severe manifestations and can be fatal (186). For many years, HBV-related PAN had been treated similar to non–virus-related PAN. Despite combination treatment with corticosteroid, immunosuppressive drugs and plasma exchange, mortality is high: 20% to 45% in 5 years and the outcome appears to be poorer than in non–virus-related PAN (184,187). The fact that HBV-related PAN is related to virus-mediated immune complexes suggests that therapy should be directed against HBV itself. Case reports and small case series have suggested a possible role of IFN therapy alone or in combination with plasma exchange (188,189,190), nucleoside analogs (191) or corticosteroids (192), as well as prednisone followed by lamivudine (193).

Glomerulonephritis

HBV-related glomerulonephritis is more often found in children. Membranous glomerulonephritis is most common especially among children but membranoproliferative glomerulonephritis, mesangiocapillary and focal glomerulonephritis, minimal change disease and IgA nephropathy have also been reported (194). Immune complexes of hepatitis B surface, core, and e antigens and antibodies together with complement components have been demonstrated in glomerular basement membrane and mesangium (195). Liver disease tends to be mild in patients who present with HBV-related glomerulonephritis (196). Severity of the renal disease does not correlate with the severity of the liver disease or the level of HBV replication.

Approximately 30% to 60% of children with HBV-related membranous glomerulonephritis undergo spontaneous remission. Disease remission is especially evident after HBeAg seroconversion (197,198). A significant percent of adults (30%) may progress to renal failure and as many as 10% will require maintenance dialysis (199,200). Corticosteroids are usually ineffective for treatment of HBV-related glomerulonephritis and may potentiate HBV replication (201). IFN has been reported to induce remission of HBV-related renal disease in small clinical trials (202,203) but the response has been poor especially in Asians. In Western countries, response to IFN has been more favorable in adults, especially among patients with membranous glomerulonephritis (204). Improvement of renal disease has also been reported with lamivudine (205). Recent reports suggest that the incidence of HBV-related glomerulonephritis in children has been decreasing since the implementation of the HBV vaccination programs (206,207).

Essential mixed cryoglobulinemia

Mixed cryoglobulinemia is a systemic disease involving mainly small vessels presenting as glomerulonephritis, arthritis and purpura. HBsAg, anti-HBs and HBV-like particles have been demonstrated in cryoprecipitates (208) but recent studies questioned the association between chronic HBV infection and essential mixed cryoglobulinemia.

Papular acrodermatitis (Gianotti-Crosti disease)

Papular acrodermatitis is found to be strongly associated with HBs antigenemia in children particularly

among those under the age of 4 (209,210). Circulating HBsAg and anti-HBs immune complexes are thought to play a role in the pathogenesis (209). It manifests as symmetrical, erythematous, maculopapular, nonitchy eruptions over the face, buttocks, limbs and occasionally the trunk lasting for 15 to 20 days. Mucous membranes are spared. Lymphadenopathy particularly in the axillary and inguinal regions is common. Evidence of acute hepatitis may coincide with the onset of the skin eruption or, more commonly, begins as the dermatitis starts to wane.

Aplastic anemia

Isolated cases of severe aplastic anemia occurring in the early phase of acute hepatitis have been reported (166). However, a recent study suggested that most hepatitis associated aplastic anemia are not related to hepatitis virus but mediated by immunopathologic mechanisms (211).

Special Patient Groups

Pediatric patients

HBV infection remains the most important cause of chronic hepatitis in pediatric patients. The clinical manifestation of chronic HBV infection in children is dependent on the age at infection. Perinatal HBV infection results in a high rate (90%) of chronic infection and a prolonged replicative phase. Children with perinatally acquired HBV infection are usually asymptomatic with normal ALT values despite high serum HBV DNA levels.

Acute HBV infection has been estimated to account for 10% to 25% of all cases of childhood acute hepatitis (212,213). Extrahepatic manifestations including arthralgia, arthritis, skin rash and Gianotti's papular acrodermatitis are common and have been reported in 25% of patients (213).

Approximately 15% to 30% of children with chronic HBV infection, who were infected during early childhood are symptomatic with elevated ALT levels and have chronic hepatitis on liver biopsies (214,215). These children have higher rates of spontaneous HBsAg and HBeAg seroconversion: approximately 2% and 15% to 20% per year, respectively (215) compared to children who were infected perinatally. Loss of HBsAg is uncommon (216,217,218,219).

Children with chronic HBV infection are more likely than adults to develop HBV-related glomerulonephritis. Progression of disease activity over time can be seen in approximately 50% of children (216,217), cirrhosis is uncommon but has been demonstrated in approximately 3.5% of children with chronic HBV infection at the time of presentation (214,220). Cirrhosis appears to be more frequent in boys and in those with a history of acute hepatitis (220). HCC has also been reported among children with chronic HBV infection (216,221). It is more common among Asian children, and in children with cirrhosis or a family history of HCC. Therefore, regular follow-up is important even in asymptomatic carrier children in these settings.

HBV related fulminant hepatitis is extremely rare in children. Most reported cases occurred in infants born to HBeAg-negative mothers (222,223). In a case series in Taiwan, 65% of 17 cases of childhood fulminant hepatitis were caused by HBV infection (224).

Immunocompromised patients

The clinical manifestations and natural course of chronic HBV infection in immunocompromised patients may be different from that in immunocompetent patients because of enhanced HBV replication and weak immune response.

Immunosuppressive therapy can increase HBV replication directly by stimulating the glucocorticoid responsive element in the enhancer region of the HBV genome (225) or indirectly by diminishing immune clearance. Abrupt withdrawal of immunosuppressive therapy as in cyclical chemotherapy or rapid tapering of steroid treatment has been reported to be associated with exacerbations of liver disease in HBsAg carriers as well as in immune individuals (226). These exacerbations are believed to be due to massive lysis of infected hepatocytes as the immune system recovers. Although most of the exacerbations are asymptomatic, fatal hepatic decompensation has been reported (227).

Patients with chronic renal failure on hemodialysis have an increased risk of HBV infection (228,229). Dialysis patients are usually HBeAg and serum HBV DNA positive but have no symptoms, normal ALT levels and minimal liver damage on liver biopsies (230). The clinical course of postrenal transplantation is, however, very different, with exacerbations, rapid progression to cirrhosis and an increased risk of HCC and death from liver failure (231,232,233,234,235). Recent reports showed that preemptive treatment with lamivudine decreased the risk of reactivation of hepatitis B post transplantation (236,237). In addition, lamivudine has been reported to be effective in treating hepatitic flares and hepatic decompensation due to reactivation of hepatitis B after renal transplantation (236,238). The American Society of Nephrology recommended that HBsAg-positive renal allograft recipients should receive lamivudine beginning at the time of transplantation and continuing for at least 18 to 24 months (239).

Patients with HIV infection have a high prevalence of HBV infection. This is probably related to the similarities in the mode of transmission of HBV and HIV. Patients who are coinfected with HBV and HIV

tend to have higher serum HBV DNA levels, lower ALT levels, lower rate of spontaneous as well as treatment related HBeAg seroconversion, and higher risk of cirrhosis (240,241,242,243). Reactivation of HBV replication has been described in association with HIV infection (244) and may lead to acceleration of liver disease progression (245). The response to HBV vaccination in HIV infected patients is also impaired (246). In contrast, HBV coinfection does not appear to have any significant effect on the rate of progression of HIV disease (242,247). More recently, severe cases of HBV disease exacerbation and deaths due to liver failure are being increasingly reported in patients receiving highly active antiretroviral therapy (HAART). The exacerbations are felt to be related to "immune reconstitution" with subsequent immune-mediated injury directed against infected hepatocytes (245,248). Several studies have shown that patients coinfected with HIV and HBV have increased risk of liver-related mortality compared to those with HIV or HBV monoinfection (249,250).

Natural History

The natural course of HBV infection is determined by the interplay between the virus: HBV replication, HBV genotype and viral variants; host: Age, gender, race/ethnicity, genetic make-up, and immune response; and environment: Alcohol, concomitant infection with other viruses—hepatitis C, hepatitis D, human immunodeficiency virus (HCV, HDV, HIV), and carcinogens such as aflatoxin.

Progression from Acute to Chronic Hepatitis B Virus Infection

The overall rate of progression from acute to chronic HBV infection has been estimated to be 5% to 10%. The risk is inversely proportional to the age at infection: 90% for perinatal infection, 20% for childhood infection, and less than 5% for adult infection (5,10,11,12). Careful analyses of patients presenting with "acute hepatitis B" found that the risk of progression to chronic HBV infection among immunocompetent adults was less than 1% after exclusion of patients who had acute exacerbations of chronic HBV infection.

Hepatitis B Virus Infection is a Life-Long Infection

The advent of sensitive molecular virology assays has revolutionized the concept of viral clearance and recovery from HBV infection. Many studies found that HBV DNA and vigorous immune response to HBV antigens can be detected more than 10 years after recovery from acute HBV infection—HBsAg to anti-HBs seroconversion (251,252). These findings indicate that HBV persists but is contained by the host immune response. This accounts for reports of chemotherapy induced reactivation of HBV replication in patients with "recovered" HBV infection (226).

The likelihood of spontaneous viral clearance in patients with chronic HBV infection is very low because

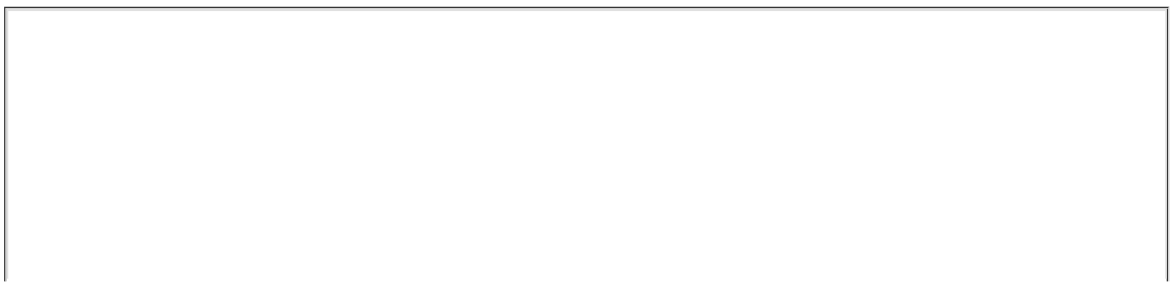
of the presence of extrahepatic reservoirs of HBV, integration of HBV DNA into the host genome, and the presence of an intracellular conversion pathway whereby newly replicated HBV DNA re-enters the hepatocyte nuclei and is used to amplify covalently closed circular HBV DNA (cccDNA) (253). This intracellular pathway enables the establishment of a pool of transcriptional templates in the hepatocyte without the need for multiple rounds of reinfection. Therefore, spontaneous viral clearance is unlikely to occur once chronic HBV infection is established.

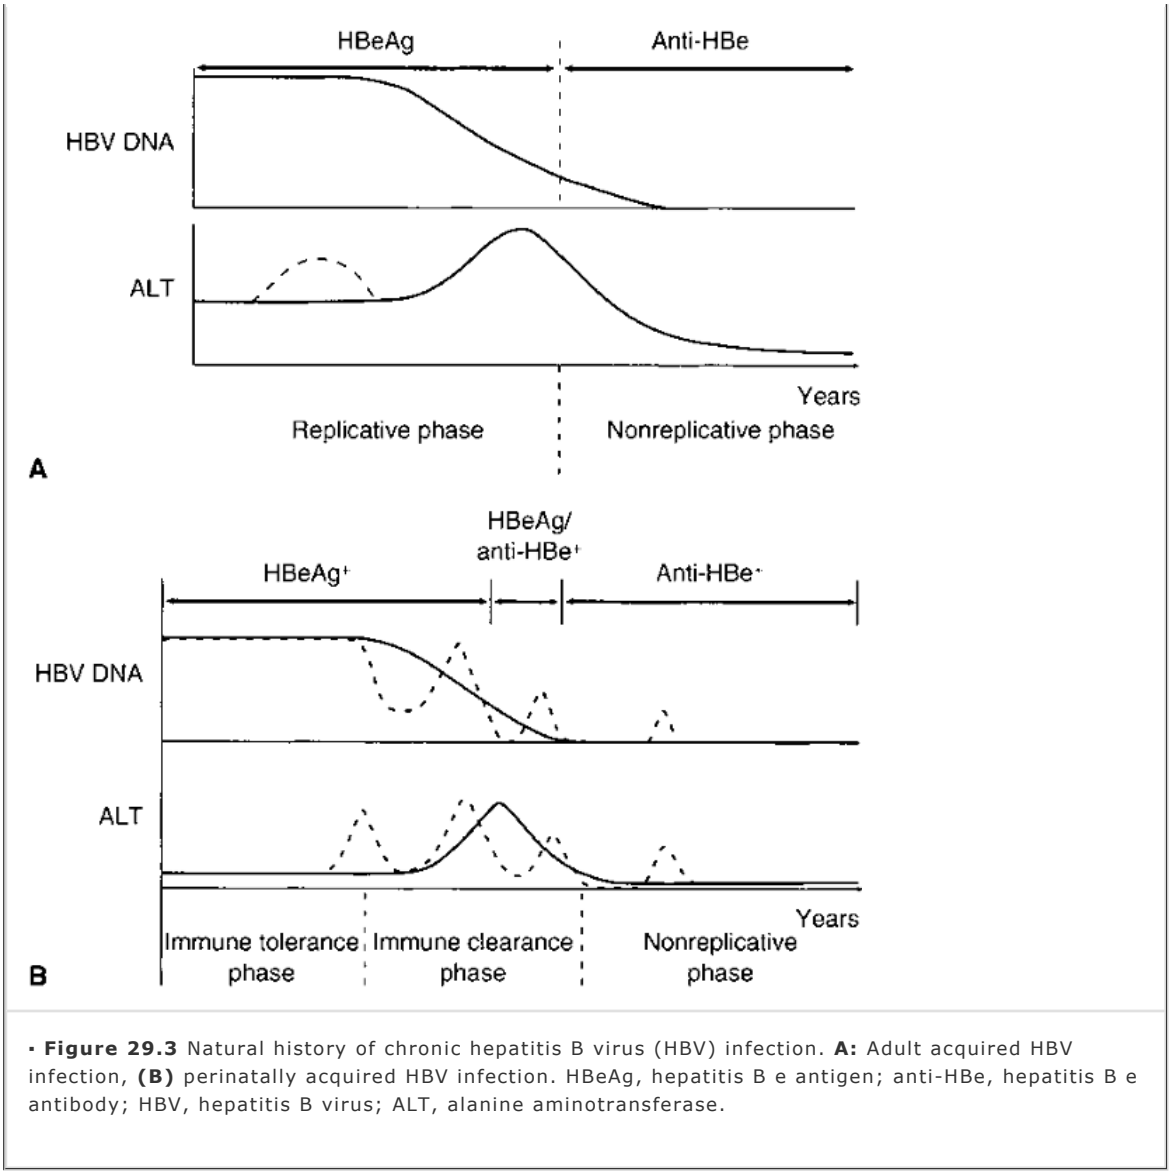
Clinical Course of Chronic Hepatitis B Virus Infection

The natural course of chronic HBV infection is characterized by fluctuations in level of HBV replication and activity of liver disease. The clinical course of chronic HBV infection can be considered as comprising four phases (Fig. 29.3) although not all patients go through every phase.

Immune-tolerant phase

In patients with perinatally acquired HBV infection, the initial phase is characterized by high levels of HBV replication: Presence of HBeAg and high levels of HBV DNA in serum (10^{6-10} IU/mL), normal ALT and minimal changes on liver biopsy (131,133,254). A mild degree of liver injury despite high levels of HBV replication is believed to be due to immune tolerance to HBV. The exact mechanism(s) for immune tolerance is unknown. Experiments in mice suggest that transplacental transfer of maternal HBeAg may induce a specific unresponsiveness of helper T cells to HBeAg (255). Because HBeAg and HBcAg are cross-reactive at the T-cell level, deletion of T-helper cell response to HBeAg results in ineffective cytotoxic T-cell response to HBcAg (256).





· Figure 29.3 Natural history of chronic hepatitis B virus (HBV) infection. **A:** Adult acquired HBV infection, **(B)** perinatally acquired HBV infection. HBeAg, hepatitis B e antigen; anti-HBe, hepatitis B e antibody; HBV, hepatitis B virus; ALT, alanine aminotransferase.

During the immune tolerance phase, which lasts 1 to 4 decades, there is a very low rate of spontaneous HBeAg clearance. The cumulative rate of spontaneous HBeAg clearance is estimated to be approximately 2% during the first 3 years (133,257) and only 15% after 20 years of infection (258). Persistence of high levels of viremia in adolescents and young adults accounts for the high frequency of maternal–infant transmission of HBV in Asia. The lack of assistance from immune-mediated viral clearance also contributes to a low rate of treatment-related HBeAg seroconversion.

A study from Taiwan followed 240 adult patients (54% men, mean age 28 years) who presented during this phase and found that only 5% progressed to cirrhosis and none to HCC during a mean follow-up of 10.5 years (259). The risk of cirrhosis was higher in

patients who had HBeAg seroconversion at an older age and those who had relapse of hepatitis after HBeAg seroconversion. These findings indicate that presence of HBeAg at presentation is not invariably associated with high risks of cirrhosis and HCC, rather the risk of adverse clinical outcome is related to a long duration of high levels of HBV replication and active hepatitis.

In patients with childhood or adult acquired HBV infection, the "immune-tolerant" phase is short-lived or absent.

Immune clearance phase/hepatitis B e antigen–positive chronic hepatitis

This phase is characterized by the presence of HBeAg, high levels of serum HBV DNA and active liver disease (elevated ALT and necroinflammation on liver biopsy). In patients with perinatally acquired HBV infection, transition from the immune tolerant to the immune clearance phase usually occurs during the second to fourth decades of life. Most patients with childhood or adult acquired HBV infection are already

in the immune clearance phase at presentation.

During this phase, spontaneous HBeAg clearance occurs at an annual rate of 10% to 20% (258,259,260) (Fig. 29.3). HBeAg seroconversion is frequently but not always accompanied by biochemical exacerbations (215,258,261). These exacerbations are believed to be due to a sudden increase in immune-mediated lysis of infected hepatocytes, and are often preceded by an increase in serum HBV DNA level (262) and a change in distribution of HBcAg from nuclear to cytoplasmic localization in the hepatocytes (181).

Most exacerbations are asymptomatic but some are accompanied by symptoms of acute hepatitis. Occasionally, IgM anti-HBc may be detected leading to misdiagnosis of acute hepatitis B in previously unrecognized carriers (117). Exacerbations may be associated with increase in α-fetoprotein levels (173,260). In approximately 2.5% of patients (especially those with preexisting cirrhosis), exacerbations may result in hepatic decompensation and rarely death from hepatic failure (263).

Not all exacerbations lead to HBeAg seroconversion (258,264,265). Some patients have suboptimal immune response and abortive immune clearance. These patients may develop recurrent exacerbations with intermittently undetectable serum HBV DNA with or without transient loss of HBeAg. Repeated episodes of necroinflammation may increase the risk of cirrhosis and HCC. Exacerbations are more commonly observed in men than in women (265) and may account for a higher incidence of HBV-related cirrhosis and HCC among men.

An important outcome of the "immune clearance" phase is HBeAg to anti-HBe seroconversion. Factors associated with higher rates of spontaneous HBeAg seroconversion include older age, higher ALT levels and more recently HBV genotype B (258,260,266,267,268,269,270). High ALT level is believed to be a reflection of vigorous host immune response accounting for its strong correlation with spontaneous as well as treatment-related HBeAg seroconversion. Studies from Asian countries where genotypes B and C predominate showed that HBV genotype B is associated with a lower prevalence of HBeAg, HBeAg seroconversion at an earlier age, and more sustained virologic and biochemical remission after HBeAg seroconversion (266,270).

Inactive carrier phase

This phase is characterized by absence of HBeAg, presence of anti-HBe, persistently normal ALT levels, and low or undetectable serum HBV DNA (usually $<10^3$ IU/mL) (141). Liver biopsy generally shows mild hepatitis and minimal fibrosis but inactive cirrhosis may be observed in patients who had accrued substantial liver injury during the preceding "immune clearance" phase.

The inactive carrier phase may persist indefinitely, in which case the prognosis is generally favorable especially if this phase is reached early. This is supported by the finding of comparable survival between HBsAg-positive blood donors (almost all were HBeAg negative and had normal ALT at baseline) and uninfected controls over a 30-year period (271).

Some patients in the inactive carrier phase eventually clear HBsAg. The annual rate of HBsAg clearance has been estimated to be 0.5% to 2% (267,272). Despite HBsAg clearance, some patients have residual liver disease and some may develop HCC, the risk of HCC is higher in those who have progressed to cirrhosis prior to HBsAg clearance (273,274,275).

Some inactive carriers have reactivation of HBV replication later in life. Reactivation may occur spontaneously or as a result of immunosuppression, and may be due to wild type HBV or HBV variants that abolish or downregulate HBeAg production. In one study of 283 Chinese patients followed for a median of 8.6 years after spontaneous HBeAg seroconversion, 67% had sustained remission, 4% had HBeAg reversion and 24% had HBeAg-negative chronic hepatitis (276). Cirrhosis developed in 8% and HCC in 2%, the risk being higher in those who had active hepatitis after HBeAg seroconversion.

Reactivation of hepatitis B virus replication/hepatitis B e antigen–negative chronic hepatitis

This phase is characterized by absence of HBeAg, presence of anti-HBe, detectable serum HBV DNA, elevated ALT, and chronic inflammation ± fibrosis on biopsy (Fig. 29.3) (141,277).

Patients in this phase are usually older and have more advanced liver disease because this represents a later phase in the course of chronic HBV infection. Serum HBV DNA levels are lower than in HBeAg-positive patients but may reach 10^{8-9} IU/mL.

The hallmark of this phase is its fluctuating course. In one study where patients were monitored at monthly intervals, 36% had persistently elevated ALT, 20% had fluctuating abnormal ALT, and 44% had fluctuating ALT with intermittently normal values (278). Several investigators have attempted to define cutoff HBV DNA levels that would differentiate patients with HBeAg-negative chronic hepatitis from inactive carriers; because of the fluctuating course, serial testing is more reliable than any single HBV DNA level at a random time point (213,215,279).

HBeAg-negative chronic hepatitis was originally reported in Mediterranean countries. It has now been reported in all parts of the world (280). The geographic variations in prevalence of HBeAg-negative chronic

hepatitis are related to the predominant HBV genotype in that region. Recent studies in Europe, Asia and the United States have all reported an increased prevalence of HBeAg-negative and a decreased prevalence of HBeAg-positive chronic hepatitis (281,282). This may be related to increased awareness, decrease in new HBV infections due to vaccination, and progression of the existing pool of HBV carriers to later stages of chronic HBV infection.

Latent/Occult Hepatitis B Virus Infection

Occult HBV infection is defined as the detection of HBV DNA in persons who are HBsAg negative (283). HBV DNA is more often detected in liver than in serum. It has been proposed that diagnosis of occult HBV infection be made only when HBV DNA can be detected using at least two sets of primers from different regions of the HBV genome in duplicate assays.

Prevalence of occult HBV infection is higher in countries that are endemic for HBV and in individuals with serologic markers of HBV exposure. (283). HBV-DNA detection rate is highest in subjects who are anti-HBc positive/anti-HBs negative; some of these individuals probably have low-level HBV infection with subdetectable HBsAg. The HBV-DNA detection rate is intermediate in subjects who are positive for both anti-HBc and anti-HBs. These individuals may have recovered from previous infection. The HBV-DNA detection rate is lowest in seronegative subjects. These individuals have recovered from previous HBV infection but lost all serologic markers. Rarely, they may be infected with HBV mutants that do not express HBV serologic markers.

Occult HBV infection is more common among patients with cirrhosis or HCC (284). Many of these patients probably had chronic HBV infection for decades leading to liver damage but HBsAg is no longer detectable when cirrhosis or HCC is diagnosed. Low levels of HBV may also be a cofactor of liver disease in patients with chronic HCV infection, nonalcoholic fatty liver disease, α_1-antitrypsin deficiency and other causes of chronic liver disease. Whether occult HBV infection alone can cause cirrhosis or HCC is unclear.

Sequelae of Chronic Hepatitis B Virus Infection

The sequelae of chronic HBV infection vary from inactive carrier state to chronic hepatitis, cirrhosis, hepatic decompensation, HCC and death. The clinical outcome of patients with chronic HBV infection depends on the severity of liver damage prior to sustained HBeAg seroconversion and the durability of the inactive carrier phase.

Annual rate of progression from chronic hepatitis to cirrhosis has been estimated to be 2% to 6% for HBeAg-positive and 8% to 9% for HBeAg-negative patients (171,267,285,286,287), the higher rate in HBeAg-negative patients is related to older age and more advanced liver disease at presentation. Factors that have been reported to be associated with increased rate of progression to cirrhosis include: Host (older age, men), virus (persistent high levels of HBV replication, HBV genotype [C > B], coinfection with HCV, HDV, and HIV), and environment (alcohol and more recently obesity) (267,285,287,288,289,290,291,292,293,294). One study from Taiwan found that the 10-year cumulative probability of cirrhosis among chronic hepatitis B patients with HCV, HDV, and no superinfection was 48%, 21%, and 9%, respectively (290). Several studies showed that patients who had HBeAg reversion had increased risk of cirrhosis compared to those who had sustained HBeAg seroconversion (267,276). One study reported that the adjusted relative risk of cirrhosis for patients with serum HBV DNA greater than 10^4 and greater than 10^6 copies/mL was 2.3 and 9.3 compared to carriers with serum HBV DNA less than 10^4 copies/mL (294). These data suggest that persistent high levels of HBV replication (with accompanying hepatitis) increase the risk of cirrhosis. Studies in Asia found that genotype C is associated with a more rapid rate of progression to cirrhosis than genotype B (291,292,293) possibly related to a longer duration of high levels of HBV replication and more active hepatitis.

Annual rate of progression from compensated cirrhosis to hepatic decompensation has been estimated to be 4% to 6% (287,295,296). Survival after the development of compensated cirrhosis is favorable initially (85% at 5 years) but decreases dramatically after the

onset of decompensation to 55% to 70% at 1 year and 14% to 35% at 5 years (276,295,297,298,299,300). The lifetime risk of a liver-related death was estimated to be 40% to 50% for men and 15% for women among Chinese patients with chronic HBV infection (301). Several studies revealed that persistent high level HBV replication is associated with increased mortality in patients with cirrhosis, while biochemical remission, clearance of HBeAg or HBV DNA from serum after the diagnosis of cirrhosis were associated with significantly higher rate of survival. (298,299).

Annual rate of HCC development has been estimated to be 0.5% to 1.0% for noncirrhotic carriers and 2.5% to 3% for patients with cirrhosis (171,285,295,296,297,300,302,303). Risk factors for HCC include host (older age, male gender, being Asian, and having first-degree relatives with HCC), virus (high levels of HBV replication, HBV genotype [C > B], core promoter mutations and coinfection with HCV), and environment (alcohol, aflatoxin, and more recently smoking, obesity, and diabetes) (291,292,295,296,297,300,301,303,304,305,306,307,308,309,310). It is important to note that although HCC is more common among patients with cirrhosis, 30% to 50% of HCC associated with HBV occurs in the absence of cirrhosis.

Recent studies found an association between HBV replication and the risk of HCC. In one study of 11,893 Taiwanese men aged 30 to 65 years, followed for a mean of 8.5 years, the adjusted relative risk of HCC was six- to sevenfold higher among HBsAg men who were HBeAg positive at entry than those who were HBsAg positive, HBeAg negative (306). Another study from Taiwan found that the risk of HCC increased with increasing baseline serum HBV DNA levels (307). These findings were confirmed by studies in Senegal and Mainland China (311). Unfortunately, none of these studies monitored serum HBV DNA and ALT levels over time. It is likely that the duration of high levels of HBV replication as well as the duration and severity of hepatitis activity are more important than a single high HBV DNA level on a random occasion in predicting the risk of HCC in individual carriers.

Several studies from Asia including the above study from Taiwan reported that genotype C is associated with increased risk of HCC compared to genotype B (291,292,307). This may be related to a longer duration of high levels of HBV replication and active hepatitis and a higher frequency of core promoter mutations. Core promoter mutations have been shown in some studies to be associated with increased risk of HCC and to precede HCC diagnosis (308,309,312). Core promoter mutations have been found to be associated with more active hepatitis and the most common mutations ($A_{1762}T$, $G_{1764}A$) result in corresponding changes in the overlapping *X* gene. In vitro studies found that the HBx protein is a potent transactivator and may activate host genes including oncogenes (313).

Coinfection of Hepatitis B Virus and Hepatitis C Virus

Acute coinfection of HBV and HCV has been reported in transfused patients as well as in intravenous drug users (314,315). Coinfection with HCV may delay the onset and shorten the duration of HBs antigenemia as well as lower the peak ALT levels compared with acute HBV infection alone (314). These findings suggest that HCV coinfection may interfere with the replication of HBV leading to attenuation of liver damage. However, acute coinfection of HCV and HBV has been reported to increase the risk of fulminant hepatic failure (316). HCV superinfection in HBsAg carriers typically manifests as acute icteric hepatitis and is associated with a high risk of hepatic decompensation and death from hepatic failure (290). HCV superinfection has also been reported to decrease HBV DNA levels and to be associated with earlier HBsAg clearance (317,318,319,320). Most patients coinfected with HCV and HBV have detectable serum HCV RNA but not HBeAg or HBV DNA indicating that HCV infection is dominant. Nevertheless, liver disease is usually more severe and the risks of cirrhosis and HCC are higher compared to patients infected with either virus alone (321,322).

Hepatitis B Virus and Hepatocellular Carcinoma

Worldwide, HCC is the third most common cause of cancer deaths in men and the fifth most common cause of cancer deaths in women accounting for approximately 500,000 deaths each year (323). The vast majority (85%) of HCC is concentrated in eastern and southeastern Asia and sub-Saharan Africa (324) where HBV infection is endemic. Several lines of evidence support an etiologic association between chronic HBV infection and HCC.

Epidemiologic Association

There is a close correlation between the geographic distribution of HBsAg carriers and the occurrence of HCC (325,326,327). A high proportion of patients with HCC have chronic HBV infection, and HBV infection precedes HCC. The strongest evidence for an etiologic association between chronic HBV infection and the development of HCC is derived from a study of 22,707 Taiwanese men who were followed for a mean of 8.9 years (301). The incidence of HCC was 495/100,000

per year for HBsAg positive and 5/100,000 per year for HBsAg-negative men, with a relative risk of 98. The incidence of HCC/100,000 per year among HBsAg-negative men was 10, 5, and 0 for individuals who were anti-HBc alone positive, anti-HBc and anti-HBs positive, and seronegative, respectively.

Animal Models

Chronic infection with other hepadnaviruses has also been shown to be associated with the development of HCC. In one study, virtually 100% of the woodchucks chronically infected with woodchuck hepatitis virus (WHV) developed HCC 2 to 4 years after the onset of infection (328). These woodchucks were bred and raised in captivity and were fed strictly regulated food free of aflatoxin and other carcinogens. In the same study, only 6.5% of woodchucks had recovered from transient WHV infection and none of the uninfected woodchucks developed HCC. These data suggest that chronic infection with hepadnavirus alone is sufficient to cause HCC.

Physical Presence

The physical presence of HBV in HCC has been demonstrated by the finding of integrated HBV DNA in neoplastic liver tissues from most of the HBsAg-positive patients as well as some HBsAg-negative patients (329,330). In most instances, HBV DNA is present as a discrete high-molecular-weight band suggesting clonal expansion of hepatocytes that contain integrated HBV DNA. It should be noted that integrated HBV DNA can also be detected in adjacent non-neoplastic liver tissues as well as in liver tissues of patients with

HBV-related chronic hepatitis or cirrhosis (330,331).

Prevention of Hepatocellular Carcinoma Through Vaccination and Antiviral Therapy

Recent studies demonstrating that HBV-related HCC can be prevented through HBV vaccination and antiviral therapy provided further support of the etiologic association. Studies from Taiwan reported a significant decrease in the incidence of childhood HCCs that accompanied the decline in prevalence of chronic HBV infection among Taiwanese children after the implementation of universal vaccination of newborns (77).

Several follow-up studies of chronic hepatitis B patients who received IFN or lamivudine therapy observed a decrease in incidence of HCC among patients with long-term virologic response. The best evidence that antiviral treatment can prevent HCC was provided by a prospective double blind placebo-controlled trial of lamivudine treatment in patients with high levels of HBV replication and bridging fibrosis or cirrhosis. After a median duration of 32 months, a significantly lower percent of treated patients had HCC (332). The efficacy of antiviral therapy in preventing HCC was also demonstrated in woodchucks that received lamivudine, clevudine and entecavir for chronic WHV infection (333,334).

Mechanisms of Hepatocarcinogenesis

Chronic HBV infection can induce HCC directly by activating cellular oncogenes or by inactivating tumor suppressor genes, or indirectly through chronic liver injury, inflammation, and regeneration (335).

To date there is no evidence that HBV DNA is directly oncogenic. Transfection of HBV DNA has not been demonstrated to induce malignant transformation of cultured cells. Analyses of integrated HBV DNA in neoplastic tissues from patients with HCC revealed varying portions of the HBV genome with deletions and duplications (335,336). An intact region of the HBV genome that is universally incorporated has not been identified. The long latent interval between the onset of HBV infection and the development of HCC also make it unlikely that HBV is an oncogenic virus.

Integration of HBV DNA may activate cellular proto-oncogenes or suppress growth-regulating genes. Recent studies found that HBV DNA integration frequently targets genes that regulate key cellular pathways such as calcium homeostasis, mean arterial pressure (MAP) kinase–dependent signaling pathways, and the telomerase gene (335,337).

Integration of HBV DNA can also induce carcinogenesis via transactivation. The HBx protein has been shown to be a potent and promiscuous transactivator of viral as well as cellular enhancer and promoter (313,338). Integration of the intact or truncated versions of the *X* gene is found in most HCCs. These sequences retain their transactivating capacity and may activate cellular oncogenes (339). It has also been reported that HBx protein binds the tumor suppressor gene p53 leading to decreased transcription and reduced cellular growth inhibition (340,341). Moreover, HBx protein has been shown to regulate proteasome function and to have an effect on calcium homeostasis and mitochondrial function (335). Finally, mutations in amino acids 130 and 131 of the X protein which corresponds to the most common core promoter mutations have been found in many patients with HCC and to precede HCC development (312). Another viral protein that may play a role in hepatocarcinogenesis is the 3′-truncated preS/S sequence which is frequently found in HCCs (342). More recently, a spliced HBV transcript and its encoded protein (HBSP) has also

been incriminated as playing a role in HCC development through its effect on HBV replication and liver fibrosis (343).

Integration of HBV DNA can also cause cancers indirectly via chromosomal deletions or translocations.

An alternate path by which chronic HBV infection leads to HCC is through induction of liver injury. Chronic liver cell injury initiates a cascade of events characterized by increased rates of cellular DNA synthesis and impaired cellular repair thereby setting the scene for acquired mutations. Mutations may be promoted by the release of inflammatory cytokines and exposure to environmental carcinogens. During regeneration, transformed cells that have a growth advantage are selected resulting in clonal expansion and eventually tumor formation. Experimental evidence for this hypothesis is derived from observations that transgenic mice which overexpress HBV large S protein develop severe hepatocellular injury followed by regenerative hyperplasia, transcriptional dysregulation, aneuploidy and finally neoplasia (174). Clinical studies support the conclusion that long durations of high levels of HBV replication and active hepatitis increase the risk of HCC.

Hepatitis B Virus Genotypes and Variants

The HBV genome consists of four partially overlapping open reading frames: The *pre-S/S* gene that codes for the envelope proteins, the *pre-C/C* gene that codes for the e antigen and core protein, the *P* gene that codes for the DNA polymerase and reverse transcriptase, and the *X* gene that codes for a protein of unclear significance. Although HBV is a DNA virus, it is prone to mutations with a rate of nucleotide substitutions estimated at 1×10^{-5} to 3×10^{-5}/site per year (344). This is related to the reverse transcription of an RNA

intermediate during the replication cycle of HBV. Mutations occur at random along the HBV genome but the overlapping open reading frames limit the number and location of viable mutations. Mutations that confer a survival advantage to the virus by enhancing replication or evading immune response tend to be selected.

Hepatitis B Virus Genotypes

HBV can be classified into eight genotypes designated A-H based on an intergroup divergence of 8% or more in the complete nucleotide sequence (106,107,345). The geographic distribution of HBV genotypes is summarized in Table 29.8. There is an association between HBV genotypes and precore and core promoter variants. The most common precore variant ($G_{1896}A$) is predominantly found in patients with HBV genotypes B, C, and D and rarely in patients with genotype A (266,346,347,348). This accounts for the high prevalence of HBeAg-negative chronic hepatitis and precore stop codon variant ($G_{1896}A$) in Asia and the Mediterranean basin and their low prevalence in the United States and Northern Europe. The most common core promoter variant ($A_{1762}T$, $G_{1764}A$) is more frequently found in patients with HBV genotypes A, C, and D (266).

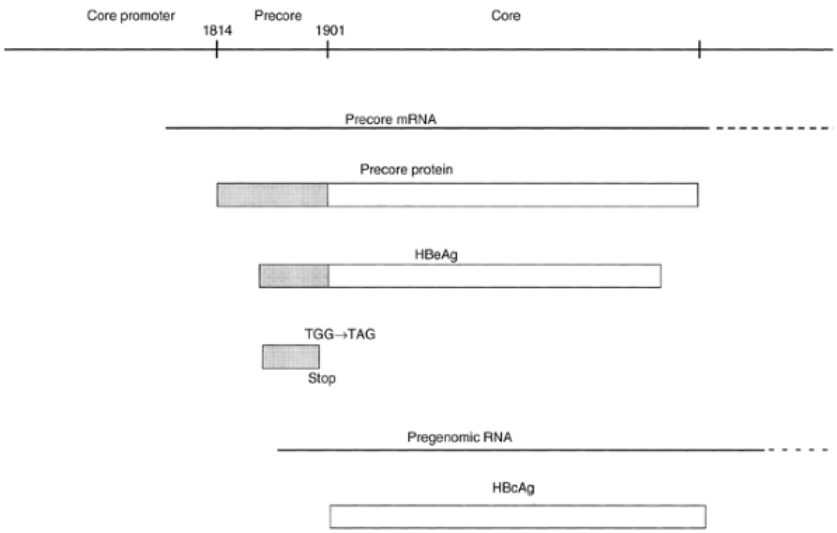
Table 29.8. Geographic Distribution of Hepatitis B Virus (HBV) Genotypes

HBV genotypes	Distribution areas
A	North-west Europe, North America, Central Africa
B	China, Japan, Indonesia, Vietnam
C	China, Japan, East Asia, Korea, Vietnam, Polynesia
D	Mediterranean basin, Middle East, India
E	Africa
F	American natives, Polynesia
G	United States, France
H	Mexico, Latin America

Several studies suggest that HBV genotypes may be related to the rate of recovery or likelihood of a fulminant course during acute infection (349,350,351,352); these studies involved small numbers of patients and the data need to be confirmed.

Studies in Asia where genotypes B and C are predominant found that genotype B is associated with a lower prevalence of HBeAg, earlier HBeAg seroconversion, higher likelihood of sustained remission after HBeAg seroconversion, and less active liver disease compared to genotype C (107,266,270,353,354). HBV genotype B is also associated with a slower rate of progression to cirrhosis and HCC (291,292,293,355,356,357). Data on the relation between other HBV genotypes and HBV replication and liver disease are scanty. Available data suggest that genotype A is associated with a higher likelihood of sustained virologic and biochemical remission after HBeAg seroconversion than genotype D (358).

HBV genotype may also impact response to IFN therapy. Several studies reported that HBeAg-positive patients with genotypes A and B have higher rates of HBeAg loss than those with genotypes C and D (359,360,361). There is as yet no evidence that HBV genotypes are related to IFN response among HBeAg-negative patients. Nucleoside/nucleotide analogs appear to be equally effective in virus suppression across all HBV genotypes (362). Data on the association between HBV genotypes and durability of response and rate of drug resistance are conflicting and limited by the small number of patients studied and heterogeneity in treatment regimen (363,364,365,366).



▪ **Figure 29.4** Transcription and translation of precore/core open reading frame. Precore mRNA is translated into precore protein which is processed at the N and C terminal ends to hepatitis B e antigen (HBeAg). Mutation of nucleotide 1896 from G to A converts codon 28 in the precore region from tryptophan to stop codon thereby preventing production of HBeAg. Pregenomic RNA is translated into core and polymerase protein and reverse transcribed into hepatitis B virus DNA. HBcAg, hepatitis B core antigen.

Precore Variants

Among the naturally occurring HBV mutations, mutations in the precore region have been most extensively studied (Fig. 29.4). The precore region consists of 87 nucleotides (29 amino acids) that precede the core region. The *preC/C* gene codes for two 3.5-kb RNA transcripts. The precore mRNA is slightly longer and initiates upstream of the pregenomic RNA. It codes for a precursor protein which includes the entire precore/core gene. The nascent precore/core protein is processed at both the N and C terminal ends giving rise to a smaller secretory protein—HBeAg (367). The pregenomic RNA serves as a template for reverse transcription into the (−) strand HBV DNA. It also serves as an mRNA for translation into the core protein and polymerase protein.

The predominant mutation in the precore region is a G-A change at nucleotide 1896, creating a stop codon at codon 28 ($G_{1896}A$, eW28X) (138) (Table 29.9). This mutation leads to premature termination of the precore/core protein, therefore preventing the production of HBeAg. Because the precore region is not essential for HBV replication and the $G_{1896}A$ mutation is upstream of the core region, HBV replication and HBcAg expression are not affected. Precore variants may be selected because of their ability to evade immune clearance or to enhance HBV replication.

Epidemiology and transmission

Initial reports of the $G_{1896}A$ variant came from the Mediterranean countries and Japan (138,368,369,370). Recent studies found that this variant can be detected in diverse geographical areas (280,371,372). Although it was previously thought to be rare in North America and Western Europe, recent studies found that precore variant can be found in up to 30% patients with chronic HBV infection in the United States (282,373,374). The variability in the prevalence of the $G_{1896}A$ variant in different countries is related to the predominant HBV genotype and the nucleotide at position 1858, located opposite 1896 in the stem-loop structure of the pregenome encapsidation sequence (ε) (371,375). The $G_{1896}A$ variant is replication competent and infectious. Transmission has been documented in humans from infected mothers to infants, between sexual partners, and nosocomially, as well as in chimpanzee experiments (369,376,377,378). However, infection with precore HBV variant is less likely to progress to chronic

infection possibly due to the lack of the tolerogenic effect of HBeAg.

Table 29.9. Common Forms Of Hepatitis B Virus (HBV) Variants/Mutants

HBeAg NEGATIVE PHENOTYPE			
Pre-core region			
G-A at nt 1896, tryptophan-stop at codon 28 (G1896A, eW28X)			
G-A at nt 1899, glycine-aspartate at codon 29 (G1899A, eG29D)			
Core promoter region			
A-T at nt 1762 and G-A at nt 1764 (A1762T, G1764A, ×K130M, ×V131I)			
HBIG/HBV VACCINE ESCAPE			
***S* Gene**			
Glycine-arginine at codon 145 (sG145R)			
ANTIVIRAL-RESISTANCE			
***P* gene (reverse transcriptase/polymerase region)**			
Lamivudine	L180M	M204V/I	
Adefovir	A181V/T	N236T	
Entecavir	T184G	S202G/I	M250V

M250V	Methionine to valine at codon 250		

HBeAg, hepatitis e antigen; HBIG, hepatitis B immune globulin; nt, nucleotide.

Many other mutations in the precore region have been reported including mutations of the start codon but they are less common and their clinical significance is less certain.

Pathogenesis and clinical manifestations

The $G_{1896}A$ variant is usually found in HBeAg-negative patients but may be present as a mixture with wild

type virus in HBeAg-positive patients. It has been observed to emerge or become selected as the predominant species around the time of HBeAg seroconversion (368,370,379). The $G_{1896}A$ variant was initially thought to cause more severe liver disease because it was found in patients with CAH or fulminant hepatitis (138,368,369,377,378). However, some of the studies on patients with fulminant hepatitis reported that the same mutation was also found in the source patients (369,377,378). The $G_{1896}A$ variant has also been detected in anti-HBe–positive asymptomatic carriers (370,372,380). Therefore, the $G_{1896}A$ mutation alone may have no direct pathogenic role; instead host immune response and mutations in other regions of the HBV genome may be more important in determining the severity of liver disease.

Diagnosis

The presence of the $G_{1896}AG_{1896}A$, presence of variant should be suspected in patients who are HBsAg positive, HBeAg negative, anti-HBe positive; but continue to have elevated ALT levels, active hepatitis and HBcAg expression on liver biopsies. Confirmation that the liver disease is due to persistent HBV replication should be made by detection of HBV DNA in serum and by excluding other causes of liver disease including superimposed hepatitis C and D. Detection of the $G_{1896}A$ variant can be achieved by many methods including direct sequencing, restriction fragment length polymorphism (RFLP), line probe assay, ligase chain reaction, colorimetric point mutation assay, and real-time PCR assay.

Treatment

Anti-HBe–positive patients who have the $G_{1896}A$ variant have been reported to have lower rates of sustained response to IFN as well as nucleoside/nucleotide treatment compared to HBeAg-positive ones (381). The role of the $G_{1896}A$ variant in response to IFN therapy in patients with HBeAg-positive chronic hepatitis is less clear. One study reported that HBeAg-positive patients who had $G_{1896}A$ variant either as the predominant species or as a mixture with wild type HBV had higher rates of response (379). It is possible that these patients

were on the way to spontaneous HBeAg seroconversion and IFN therapy merely hastened the process. There is no evidence that antiviral treatment induces a higher rate or unique pattern of mutations in the precore region (379).

Core Promoter Mutations

Mutations in the core promoter region can also prevent HBeAg production without affecting HBV replication or HBcAg expression by selectively downregulating the transcription of the precore mRNA but without affecting the pregenomic RNA (382,383). The most common core promoter variant had dual mutations involving A to T change at nucleotide 1762 and G to A change at nucleotide 1764 ($A_{1762}T$, $G_{1764}A$) (Table 29.9). These two changes result in amino acid substitutions in codons 130 and 131 of the overlapping X gene. Unlike precore variants, core promoter variants can be detected in similar proportions of HBeAg-negative and HBeAg-positive patients (281,282,384,385). One study demonstrated that emergence of the core promoter changes was more common among HBeAg-positive patients who subsequently seroconvert compared to those who remained HBeAg positive (386), indicating that the selection of the core promoter variant may play a role in HBeAg clearance. Core promoter variants are more commonly found in patients with CAH, fulminant hepatitis or HCC (308,387,388,389,390,391). Core promoter mutations have been shown in several studies to be associated with HCC, whether this is related to more active liver disease, frequent association with genotype C, or mutations in the overlapping *X* gene is unclear.

Core Gene Mutations

The HBV core protein is essential for virus replication. Mutations in the HBV core gene have been detected in patients with chronic HBV infection (392,393,394,395). Mutations in the core gene are more often reported in association with older age, HBeAg negativity, active liver disease and presence of the precore variant (392). Longitudinal studies found that most of the mutations occur around the time of HBeAg seroconversion or exacerbations of chronic hepatitis (396). Naturally occurring mutations involving critical residues in the HLA-A2 restricted CTL epitope (amino acids 18 to 27) leading to T-cell receptor antagonism have been reported (397). However, CTL escape mutant is not the cause of persistent infection in most of the patients with chronic HBV infection (398).

Pre-S/S Regions

The pre-S/S region codes for two RNA transcripts that are separately regulated by the pre-S1 promoter and the pre-S2/S promoter. The larger transcript encompassing the pre-S1, pre-S2, and S regions is translated into the large S protein. The smaller transcript encompassing the pre-S2 and S regions is translated into the middle S and small S proteins. The large S protein is essential for virion formation. The middle S protein is dispensable. The small S protein, HBsAg, is the major envelope protein. The "a" determinant of HBsAg is the predominant B cell epitope, and is common to all HBV serotypes. It is a conformational epitope.

S Gene Mutations

Vaccines

Mutations in the *S* gene have been described in infants born to carrier mothers despite adequate anti-HBs response after vaccination (399,400,401). The most common mutation involves a glycine to arginine substitution at codon 145 (G145R) in the "a" determinant (Table 29.9). This mutation has been shown to exhibit decreased binding to monoclonal anti-"a" antibodies thereby allowing the virus to escape neutralization. The G145R mutant has now been reported in many countries. Chimpanzee experiments demonstrated that this mutant is infectious and pathogenic (402). These findings raise concerns about the possibility of widespread dissemination of vaccine escape mutants. A recent study from Taiwan found that the prevalence of HBV S mutants among HBsAg-positive children increased after the introduction of universal vaccination, from 7.8% in 1984 to 23% in 1999 (403,404,405). However, the carrier rate among Taiwanese children decreased from 9.8% to 0.7% (31) during the same period. Another study among 784 preschool children in four Pacific Island countries, who received HBV vaccine failed to detect any "a" determinant mutation (406). These data suggest that the emergence of vaccine escape mutants occurs rarely and has not diminished the efficacy of HBV vaccines. Apart from the G145 R mutant, other mutations in the 'a' determinant have also been reported in lower frequencies (407). Many of these mutants have also been shown to reduce binding to monoclonal anti-"a" antibodies. This raises concerns that some of the S mutants may yield false negative results in serology assays. However, practically all the S mutants that have been identified to date can be detected in HBsAg assays that utilize polyclonal anti-HBs for capture and/or detection.

Liver transplant recipients

Mutations in the HBV *S* gene have also been reported in liver transplant recipients who developed HBV reinfection despite prophylaxis with monoclonal or polyclonal anti-HBs (HBIG) (408,409,410). Most of the mutations are

located in the "a" determinant, the most common being the G145R mutation. One study found a direct correlation between the incidence of the G145R mutant and the duration of HBIG administration, and reversal of the mutation after cessation of HBIG (410). Prophylaxis with combination of HBIG and lamivudine decreases the risk of immune escape and rate of reinfection (411,412,413,414).

Pre-S Mutations

Mutations in the pre-S1 and pre-S2 regions have also been described in patients with chronic HBV infection (415,416,417). The prevalence and the clinical significance of most of these mutations are uncertain. Several investigators reported a high incidence of deletions or mutations in pre-S1 that may cause dysregulation of small S protein synthesis and secretion (418). Retention of HBsAg has been demonstrated to induce liver injury and HCC in transgenic mice (174).

P Gene Mutations

The HBV polymerase gene consists of four distinct regions: A primer involved in priming of reverse transcription, a spacer with no known function, a reverse transcriptase/DNA polymerase which is responsible for reverse transcription of the pregenomic RNA into the first (−) strand HBV DNA and for synthesis of the second (+) strand HBV DNA, and an RNAse H which removes the RNA template (419). The reverse transcriptase/DNA polymerase region has five conserved domains: A, B, C, D, E. Domains A, C and D are involved in nucleoside triphosphate binding and catalysis, whereas domains B and E participate in the positioning of the RNA template and the primer relative to the catalytic site (420,421). The putative catalytic domain is believed to reside in the tyrosine–methionine–methionine–aspartate (YMDD) locus in domain C. This locus is conserved in all viral reverse transcriptases as well as in all isolates of hepadnaviruses (419). Naturally occurring HBV polymerase gene mutations are rarely reported. The most common *P* gene mutations have been found in association with the use of nucleoside/nucleotide analogs for the treatment of chronic HBV infection.

X Gene Mutations

The HBV *X* gene regulates HBV replication through activating and regulating viral and cellular genes. Several studies found that mutations affecting codons 130 and 131 of the *X* gene are more common in patients with HCC (308,390,391) but these *X* gene mutations correspond to the dual core promoter mutations $A_{1762}T$, $G_{1764}A$, which have also been found in many patients with nonmalignant HBV-related chronic liver disease. Therefore, the role of *X* gene mutations in the development of HCC remains to be established.

Treatment

The main goal of treatment of chronic hepatitis B is to prevent cirrhosis, hepatic failure and HCC. This goal is best achieved by eradicating HBV before there is irreversible liver damage. However, it is not possible to eradicate HBV because of the presence of extrahepatic reservoirs of HBV, the integration of HBV DNA into the host genome, and the presence of an intracellular conversion pathway that replenishes the pool of

transcriptional templates (covalently closed circular HBV DNA [cccDNA]) in the hepatocyte nucleus without the need for reinfection (253). Currently, there are five approved treatments for hepatitis B: Standard and pegylated IFN-α, and three nucleoside/nucleotide analogs—lamivudine, adefovir, and entecavir. Many new antiviral and immunomodulatory therapies are being evaluated; some have shown promise and may play a key role in the treatment of chronic HBV infection (Table 29.10).

Definition of Response and Endpoints of Treatment

At the 2000 National Institutes of Health workshop on Management of Hepatitis B, it was proposed that definition and criteria of response to antiviral therapy of chronic hepatitis B be standardized. The proposal categorized responses as biochemical (BR), virological (VR), or histologic (HR), and as on-therapy or sustained off-therapy (Table 29.11) (141). The increased availability of sensitive PCR assays for quantification of HBV DNA has called for more stringent definition of virological response, suppression of serum HBV DNA to

undetectable level by PCR ($<10^2$ IU/mL), particularly for patients with HBeAg-negative chronic hepatitis.

Table 29.10. Treatment of Chronic Hepatitis B

APPROVED TREATMENTS IN THE UNITED STATES
Standard Interferon-α 2b (Intron A)
Pegylated Interferon-α 2a (Pegasys)
Lamivudine (Epivir, 3TC)
Adefovir dipivoxil (Hepsera)
Entecavir (Baraclude)
TREATMENTS APPROVED FOR HUMAN IMMUNODEFICIENCY VIRUS WITH EFFICACY AGAINST HEPATITIS B VIRUS
Emtricitabine (Emtriva, FTC)
Tenofovir (Viread)
Emtricitabine + Tenofovir (Truvada)

Table 29.11. Definition of Response to Antiviral Therapy of Chronic Hepatitis B

CATEGORY OF RESPONSE	
Biochemical (BR)	Decrease in serum ALT to within the normal range
Virological (VR)	Decrease in serum HBV DNA to $<10^5$ IU/mL and loss of HBeAg in patients who were initially HBeAg positive; undetectable serum HBV DNA ($<10^2$ IU/mL) in patients who were initially HBeAg negative
Histologic (HR)	Decrease in histologic activity index by at least two points compared to pretreatment liver biopsy
Complete (CR)	Fulfill criteria of biochemical and virological response and loss of HBsAg
TIME OF ASSESSMENT	
On-therapy	During therapy
Maintained	Persist throughout the course of treatment
End-of-treatment	At the end of a defined course of therapy
Off-therapy	After discontinuation of therapy

Sustained (SR-6)	6 mo after discontinuation of therapy
Sustained (SR-12)	12 mo after discontinuation of therapy

HBV, hepatitis B virus; ALT, alanine aminotransferase; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen.
Adapted from Lok AS, Heathcote EJ, Hoofnagle JH. Management of hepatitis B: 2000—summary of a workshop. *Gastroenterology* 2001;120(7):1828–1853.

Although IFNs are administered for predefined durations, nucleoside/nucleotide analogs are usually administered until specific endpoint is achieved. The difference in approach is related to the observation that HBeAg seroconversion frequently occurs a few months after cessation of IFN treatment, presumably because of the lag between immune priming and decrease in expression of viral protein; viral rebound is inevitable if nucleoside/nucleotide analogs are withdrawn prior to achieving therapeutic endpoint. For HBeAg-positive patients, virus suppression can be sustained in 50% to 90% patients if treatment is stopped after HBeAg seroconversion is achieved. For HBeAg-negative patients, relapse is frequent even when HBV DNA has been suppressed to undetectable levels by PCR assays for more than a year; therefore, the endpoint for stopping treatment is unclear.

Interferons

IFNs have antiviral, antiproliferative and immunomodulatory effects. IFN-α and -β bind to the same receptor and have predominantly antiviral effects, whereas IFN-γ binds to a separate receptor and has more marked immunoregulatory but less potent antiviral effects. The antiviral effects of IFN depend on its binding to specific receptors, which then triggers a series of intracellular events including activation of 2′ 5′-oligoadenylate synthetase (2′5′-AS). IFNs also have immunomodulatory functions that may be important in eradicating virus infections.

Standard Interferon-α

Efficacy

1. *HBeAg-positive chronic hepatitis*. Clinical studies confirmed that IFN-α suppresses HBV replication. A positive response as defined by loss of viral replication markers (HBeAg and serum HBV DNA by unamplified assays) within 12 months of initiation of treatment can be achieved in 30% to 40% of HBeAg-positive patients who have elevated ALT (Table 29.12) (155,422,423,424,425). Loss of HBsAg is less common and occurs in 5% to 10% of patients only. It should be noted that spontaneous loss of HBeAg can occur in 5% to 15% of untreated controls. Therefore, a treatment-related benefit is only seen in approximately 20% to 25% of patients. Despite the wide range in response rates in reported studies, several meta-analyses confirmed a beneficial effect of IFN therapy (426,427).
    a. *HBeAg-positive patients with normal ALT*. This pattern is usually seen in children or young adults who are in the immune tolerance phase of HBV infection. HBeAg seroconversion occurs in less than 10% of these patients (428,429,430,431).
    b. *Oriental patients*. Asian patients with elevated ALT levels have comparable rates of HBeAg seroconversion as white patients (429). However, a higher proportion of Asian patients have normal ALT levels, so overall response is poor if treatment is extended to include those with normal ALT levels.
    c. *Children*. Ideally, treatment should be instituted as early as possible before there is irreversible liver damage. Among children with elevated ALT, HBeAg clearance has been reported in 30% of those who received IFN-α compared to 10% of controls (432,433,434,435). However, most children, particularly those with perinatally acquired HBV infection have normal ALT and less than 10% of these children who received IFN-α cleared HBeAg (430,431).
2. *HBeAg-negative chronic hepatitis*. Results of four randomized controlled trials involving a total of 86 IFN-α treated patients and 84 controls showed that the end-of-treatment response ranged from 38% to 90% in treated patients compared to 0% to 37% of controls (436,437,438,439). A major problem with

IFN-α treatment of HBeAg-negative chronic hepatitis is the high rate of relapse. Approximately 50% of the responders relapse when therapy is discontinued and relapses can occur up to 5 years post-

therapy. A study from Italy reported a higher rate (30%) of sustained response after 24 months of IFN-α therapy compared to 15% to 20% rates reported in other studies that administered IFN-α for 12 months (438) suggesting that longer duration of treatment may increase the rate of sustained response.

3. *HBV DNA positive clinical cirrhosis*. Patients with histologic cirrhosis but no evidence of hepatic decompensation appeared to tolerate IFN-α treatment and responded as well as patients with precirrhotic chronic hepatitis B (155,429). However, IFN-α even when administered in very low doses (3 MU thrice weekly) is associated with a high risk of serious infections and severe exacerbations leading to hepatic failure in patients with clinically evident cirrhosis (440,441).
4. *Nonresponders to IFN-α treatment*. Most studies found that IFN-α retreatment of HBeAg-positive patients who previously failed to respond to IFN-α was associated with a very low rate of response. One trial of 57 HBeAg-positive patients reported an HBeAg clearance rate of 33% among patients retreated with IFN-α versus 10% in untreated controls (442). However, this trial included patients who were previously treated with suboptimal doses of IFN-α and may have overestimated the benefits of IFN-α retreatment.

Limited data suggest that 20% to 30% HBeAg-negative patients who relapsed or had no response during previous IFN-α treatment had a sustained response after a second course of IFN-α (443).

Role of prednisone priming

Steroid withdrawal has been observed to be frequently accompanied by a flare in serum ALT levels and HBeAg seroconversion. A meta-analysis of seven studies that examined prednisone priming followed by IFN-α treatment (when immune response recovers) found that prednisone priming had very little additional beneficial effect compared to IFN-α alone (444). A subsequent study of 200 European patients reported that patients who received prednisone priming had a significantly higher rate of HBeAg seroconversion compared to those who received IFN-α alone (445). The overall data suggest that a small subset of patients may benefit from prednisone priming but there is a risk of fatal exacerbation in patients with underlying cirrhosis. With the availability of new treatment options, prednisone priming is not recommended for patients with chronic hepatitis B.

Long-term outcome of therapy with interferon-α

Hepatitis B e antigen–positive patients

Most HBeAg-positive patients who responded to IFN-α therapy are able to maintain their response unless they become immunocompromised. Delayed reactivation has been observed in 10% to 20% of responders only, most of which occurred within 1 year of cessation of treatment (154,446). Nevertheless, complete disappearance of markers of HBV replication as determined by PCR assay for serum HBV DNA is seldom achieved in patients who cleared HBeAg only. In addition, several studies reported that the 5-year cumulative rates of HBeAg clearance were similar in treated patients and controls (447,448,449) suggesting that the main role of IFN-α may be to reduce the duration of active liver disease by hastening viral clearance.

Among the sustained responders, an increasing proportion cleared HBsAg during the course of follow-up. However, the percent of sustained responders who cleared HBsAg within 5 years of HBeAg clearance varied from 65% in one US study (446) to 19% to 24% in European studies (447,450,451,452) to 0% to 9% in two studies from Asia (154,453) despite similar durations of follow-up. A sustained antiviral response, especially in those who clear both HBeAg and HBsAg, is almost invariably accompanied by normalization of ALT levels and decrease in necroinflammation but residual liver damage may be present. Data to substantiate the hypothesis that a sustained antiviral response can lead to decreased risks of cirrhosis and HCC and improved survival are limited because chronic hepatitis B is an insidious disease and complications may not be evident until decades later. In addition, patients initially randomized to the control group frequently receive treatment after completion of the trial. There has been only one report comparing the outcome of IFN-α–treated patients and controls. An 8-year follow-up of 101 male patients (67 IFN-α–treated and 37 untreated controls) who participated in a controlled trial of IFN-α therapy in Taiwan found that treated patients had a lower incidence of HCC (1.5% vs. 12%, $P = 0.04$) and a higher survival rate (98% vs. 57%, $P = 0.02$) but there was no difference in the rate of new onset of cirrhosis (453). However, clinical benefits were not observed in a follow-up report from Hong Kong of 208 IFN-α treated and 203 untreated controls (449). IFN-α has not been shown to decrease the incidence of HCC in European or North American patients probably because of the low rate of HCC in untreated patients but studies comparing the outcome of responders vs nonresponders found that patients who cleared HBeAg had better overall survival and survival free of hepatic decompensation; a clinical benefit was most evident among patients with cirrhosis (427,447,451,454,455).

Hepatitis B e antigen–negative patients

Contrary to HBeAg-positive patients, relapse after cessation of IFN-α treatment is frequent, with sustained response rates of only 15% to 30% (443,456). Among the long-term responders, approximately 20% cleared HBsAg after 5 years of follow-up (457). IFN-α therapy did not have any overall effect on survival, complication-free survival or HCC but patients with sustained response had significantly lower rates of hepatic decompensation (456,457).

Dose regimen

IFN-α is administered as subcutaneous injections. The recommended dose for adults is 5 MU daily or 10 MU thrice weekly and for children 6 MU/m^2 thrice weekly with a maximum of 10 MU.

Hepatitis B e antigen–positive patients

The recommended duration of treatment for patients with HBeAg-positive chronic hepatitis B is 16 to 24 weeks. There are very little data to support the use of a longer duration of IFN-α treatment in HBeAg-positive patients. One study reported that among patients who have not cleared HBeAg after 16 weeks of IFN-α, those randomized to continue treatment until week 32 had significantly higher rates of HBeAg clearance compared to those who stopped treatment (458). However, other studies found that response rates after 24 or 12 weeks of IFN-α therapy were similar.

Hepatitis B e antigen–negative patients

Current data suggest that patients with HBeAg-negative chronic hepatitis B should be treated with IFN-α for at least 12 months; one study suggested that higher rates of sustained response can be achieved with 24 months of treatment but that study did not include a comparison group with 12 months treatment (438).

Table 29.12. Comparison of Percentages of Patients with Antiviral Responses to Approved Treatments of Hepatitis B

Response	Standard IFN	Pegylated IFN	Lamivudine	Adefovir	Entecavir	No treatment
HBeAg+ patients	**12–24 wk**	**48 wk**	**52 wk**	**48 wk**	**48 wk**	**48–52 wk**
Undetectable HBV DNA	NA	10–25/7–14	40–44	21	67	0–16

IFN, interferon; HBV, hepatitis B virus; ALT, alanine aminotransferase; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen.

Pegylated Interferon-α

The attachment of polyethylene glycol to a protein (pegylation) reduces its rate of absorption following subcutaneous injection, reduces renal clearance, and decreases immunogenicity of the protein, with resultant increase in the half-life of the pegylated protein. PegIFN-α has the advantage of more convenient administration and more sustained virus suppression. Clinical trials suggest that efficacy of pegIFN-α is similar or slightly better than standard IFN-α.

Efficacy

1. *HBeAg-positive chronic hepatitis*. In one phase II trial, 194 patients were randomized to receive 90, 180 or 270 μg pegIFN-α2a weekly or 4.5 MU standard IFN-α2a thrice weekly for 24 weeks (Table 29.12). A higher percent of patients who received pegIFN-α had HBeAg seroconversion, 32% versus 25% of those who received standard IFN-α (459). Although this study used a suboptimal dose of standard IFN-α, the convenience of once weekly dosing has led to the replacement of standard IFN with pegIFN. In a subsequent phase III trial, 814 patients were randomized to receive pegIFN-α2a 180 μg weekly, pegIFN-α2a 180 μg weekly + lamivudine 100 mg daily, or lamivudine 100 mg daily for 48 weeks. At the end of treatment, virus suppression was most marked in the group that received combination therapy, mean HBV DNA reduction in the three groups was 4.5, 7.2, and 5.8 $\log_{10}$ copies/mL, respectively (460). HBeAg seroconversion was similar in the three groups at the end of treatment: 27%, 24%, and 20%, respectively, but significantly

higher in the two groups that received pegIFN-α when response was assessed 24 weeks after treatment was stopped: 32%, 27%, and 19%, respectively. These data indicate that pegIFN-α2a monotherapy was superior to lamivudine monotherapy in inducing HBeAg seroconversion, and comparable to the combination therapy of pegIFN-α2a and lamivudine. Similar results were reported in two trials, in which pegIFN-α2b was administered in tapering doses (100 → 50 μg) for 52 weeks or 1.5 μg/kg for 32 weeks. Twenty-four weeks after treatment was stopped, one study reported identical rates (29%) of HBeAg seroconversion in patients who received pegIFN-α2b monotherapy with and without lamivudine (359), whereas the other study reported a significantly higher rate of HBeAg seroconversion in those who received a combination of pegIFN-α2b and lamivudine versus those who received lamivudine only, 36% versus 14% (461). Follow-up of patients in the latter study found that a significant difference in HBeAg seroconversion was maintained up to 76 weeks after treatment was stopped (462).

2. *HBeAg-negative chronic hepatitis*. In the only published report of peg IFN-α in HBeAg-negative patients, 552 patients were randomized to receive 48 weeks of pegIFN-α2a 180 μg weekly, combination of pegIFN-α2a 180 μg weekly + lamivudine 100 mg daily, or lamivudine 100 mg daily. As in HBeAg-positive patients, virus suppression was most marked in the group that received combination therapy, mean HBV DNA reduction at week 48 in the three groups was 4.1, 5.0, and 4.2 $\log_{10}$ copies/mL, respectively (463). However, sustained response (HBV DNA undetectable by PCR and normalization of ALT at week 72) was comparable in the groups that received pegIFN-α2a alone or in combination with lamivudine, and superior to the group that received lamivudine monotherapy: 15%, 16%, and 6%, respectively.

Dose regimen

Currently, only pegIFN-α2a is approved for the treatment of chronic hepatitis B. The recommended dose is 180 μg weekly for 48 weeks. However, given the similarity in response rates between 90 and 180 μg doses in the phase II trial, and the comparable response rates between 24 and 48 week treatment in the phase II and phase III trials (459,460), it is possible that lower doses and/or shorter duration of treatment may suffice for HBeAg-positive patients. Whether longer duration of treatment (>48 week) will result in higher

rates of sustained response in HBeAg-negative patients remains to be determined.

Although the two formulations of pegIFN-α likely have similar efficacy, the optimal dose and duration of pegIFN-α2b for hepatitis B is unclear.

Adverse effects of interferon-α therapy

IFN-α therapy is associated with a broad spectrum of side effects (464). The most common side effect is an initial influenza-like illness: Fever, chills, headache, malaise and myalgia. Other common side effects include fatigue, anorexia, weight loss and mild increase in hair loss. IFN-α has myelosuppressive effects but significant neutropenia (<1,000/mm^3) or thrombocytopenia (<60,000/mm^3) requiring dose reduction or premature termination are uncommon except in patients who have decreased cell counts prior to treatment. The most troublesome side effect of IFN-α is emotional lability: Anxiety, irritability, depression and even suicidal tendency. These symptoms can occur in the absence of a prior history of emotional problems. IFN-α has been reported to induce the development of a variety of autoantibodies. In most instances, this is not accompanied by clinical illness. However, both hyper- and hypo-thyroidism that require treatment have been reported. In addition, there have been reports of worsening liver disease as a result of IFN-α induced exacerbation of an underlying autoimmune hepatitis. Rarely have retinal changes and even impaired vision been reported. Side effects of pegIFN-α are similar to that of standard IFN-α.

Predictors of response to standard and pegylated interferon-α

Predictors of response to standard and pegIFN-α are similar. The strongest predictor of response in HBeAg-positive patients is pretreatment ALT level (429,465). Other factors that have been identified to be associated with a higher rate of IFN-related HBeAg seroconversion include high histologic activity index, low HBV DNA level, and more recently HBV genotypes A and B (359,360,361). There is no consistent predictor of sustained response among HBeAg-negative patients. Some studies found that rapid normalization of ALT and high titer IgM anti-HBc are associated with a higher rate of sustained response but they have not been validated by other studies.

Interferon-β/γ

Early studies using IFN-β from fibroblast cultures were disappointing. More encouraging results were obtained using recombinant IFN-β, but the data are limited. IFN-γ can inhibit HBV replication, but the antiviral efficacy is less than that of IFN-α. In vitro studies suggest that IFN-γ may have anti-fibrotic effects but its in vivo efficacy remains to be proven. Combination therapy of IFN-γ with IFN-α/β has no additional antiviral effects.

Lamivudine (Epivir-Hepatitis B Virus, Triphosphate)

Lamivudine is the (−) enantiomer of 2′,3′-dideoxy-3′-thiacytidine. It is phosphorylated to the triphosphate (3TC-TP) which competes with dCTP for incorporation into growing DNA chains causing chain termination. This may occur during reverse transcription of the first strand as well as during synthesis of the second strand HBV DNA (466).

Efficacy

Lamivudine monotherapy is effective in suppressing HBV replication and in ameliorating liver disease (Table 29.12). One-year treatment with lamivudine results in similar rate of HBeAg seroconversion as 16 week of standard IFN-α, but is inferior to a 1-year course of pegIFN-α. Longer duration of treatment is associated with higher rates of HBeAg seroconversion but also increasing rates of drug-resistant mutations.

1. *HBeAg positive chronic hepatitis B*. Three randomized clinical trials involving a total of 731 patients who received lamivudine for 1 year reported that HBeAg seroconversion occurred in 16% to 18% of treated patients compared to 4% to 6% of untreated controls (467,468,469). Histologic improvement defined as reduction in necroinflammatory score 2 points or greater was observed in 49% to 56% treated patients and in 23% to 25% controls. HBeAg seroconversion rates increased with the duration of treatment to approximately 50% at 5 years (470,471,472,473). Whether the incremental HBeAg seroconversion can be attributed to the additional years of lamivudine treatment is unclear because an untreated control group was not available for comparison.
    a. *HBeAg-positive patients with normal ALT*. As with IFN-α therapy, HBeAg seroconversion rate is less than 10% in patients with pretreatment ALT less than two times normal after 1 year and 19% after 3 years of treatment (156,465,471).
    b. *Oriental patients*. Oriental patients respond similarly to lamivudine as whites (465,467,468,469).
    c. *Children*. Experience with lamivudine in children is limited. One controlled trial involved 286 children, aged 2 to 17 years, with ALT more than 1.3 times normal randomized in a 2:1 ratio to receive lamivudine (3 mg/kg per day up to 100 mg/day) or placebo for 52 weeks. A significantly higher proportion of treated children developed HBeAg seroconversion compared to placebo

controls, 22% versus 13% (474). As with adults, HBeAg seroconversion rate was higher among children with pretreatment ALT greater than three times normal: 34% versus 16% than those with ALT less than or equal to two times normal: 12% versus 8%. Lamivudine was well tolerated but the benefit must be carefully balanced against a high (19%) rate of drug resistant mutations.

2. *HBeAg-negative chronic hepatitis B*. Lamivudine has been shown to benefit patients with HBeAg-negative chronic hepatitis B (475,476,477,478,479). In the only placebo-controlled study, virological and biochemical response (HBV DNA undetectable by bDNA assay and normalization of normal ALT) was achieved in 34 of 54 (63%) patients who received 24 weeks of lamivudine therapy versus 3 of 53 (6%) patients on placebo ($P < 0.001$) (475). Several studies have shown that HBV DNA is suppressed to undetectable levels by PCR assay in 60% to 70% patients after 1 year of treatment. However, the vast majority (approximately 90%) of patients relapsed when treatment was stopped (476). Extending the duration of treatment results in progressively lower rates of maintained response due to selection of drug-resistant mutants. In one study of 78 patients, virologic remission (HBV DNA undetectable by PCR assay) decreased from 77% at 1 year to 52% at 2 years and 42% at 3 years; the corresponding rates of biochemical remission were 90%, 63%, and 53%, respectively (480).
3. *Nonresponders to* IFN-α *treatment*. In a multicenter trial on IFN-α nonresponders, 238 HBeAg-positive patients were randomized to receive lamivudine monotherapy for 52 weeks, combination of 24 weeks lamivudine and 16 weeks of standard IFN-α or no treatment. Patients who received lamivudine monotherapy had the highest HBeAg seroconversion rate, 18% compared to 12% and 13%, respectively in the other groups (481). These data suggest that patients who failed IFN-α treatment have similar response to lamivudine as treatment-naïve patients and retreatment with combination of standard IFN-α and lamivudine did not confer any added benefit compared to retreatment with lamivudine monotherapy.
4. *Advanced liver disease*. Lamivudine has been shown to delay clinical progression in patients with advanced fibrosis or cirrhosis by significantly reducing the incidence of hepatic decompensation and HCC. In a double blind, randomized placebo controlled trial, 651 Asian patients who were HBeAg positive or had detectable HBV DNA by branched DNA assay (>700,000 genome equivalents/mL), and bridging fibrosis or cirrhosis on liver biopsy were randomized to receive lamivudine or placebo in a 2:1 ratio. After a median duration of 32 months, a statistically significant difference was observed between the two groups for overall disease progression (increase in Child-Pugh score, hepatic decompensation or HCC): 7.8% versus 17.7%; as

well as HCC development: 3.9% versus 7.4% (332). The benefit was observed mainly among the patients who did not have breakthrough infection. These data indicate that antiviral therapy can improve clinical outcome in patients who have maintained virus suppression. Whether a similar benefit can be observed in patients who have lower serum HBV levels is unclear. It is also uncertain if clinical benefit can be maintained if treatment is stopped after HBV has been suppressed for several years.

5. *HBV DNA–positive clinical cirrhosis*. Lamivudine does not have myelosuppressive effect and rarely induces significant ALT flares during treatment. Therefore, it is a safer treatment than IFN-α in patients with decompensated cirrhosis. In one study of 35 patients (10 with Child's C and 25 with Child's B), improvement in liver disease defined as a decrease in Child-Pugh score of 2 or more was observed in 22 of 23 patients who received a minimum of 6 months treatment (482). However, seven patients had progressive liver disease necessitating liver transplant and an additional five died during the first 6 months. Among the initial responders, two had since died and three had developed breakthrough infection. These data indicate that clinical improvement is slow. The delay in clinical benefit was confirmed in a retrospective analysis of 154 patients who received lamivudine for HBsAg-positive decompensated cirrhosis (483). Of the 32 deaths, 25 (78%) occurred during the first 6 months. Among the patients who survived more than 6 months, the estimated 3-year actuarial survival was 88%. Multivariate analyses showed that high pretreatment bilirubin, creatinine, and HBV DNA levels were significantly associated with 6-month mortality.

Data from these and other studies demonstrate that lamivudine is safe and can stabilize or improve liver function in patients with decompensated cirrhosis thereby obviating or delaying the need for liver transplant (482,483,484,485). However, these studies showed that HCC can still occur even among patients with clinical improvement; therefore, continued surveillance is warranted.

Predictors of response

Hepatitis B e antigen–positive patients

Pretreatment serum ALT is the strongest predictor of response. Multivariate analysis of the data from the multicenter Asian study found that lamivudine treatment and pretreatment serum ALT but not pretreatment serum HBV DNA level or histologic activity index correlated with HBeAg seroconversion (156). Pretreatment serum ALT remained the most important predictor of response when data from four studies with a total of

406 patients who received lamivudine for 1 year were pooled for analysis. HBeAg seroconversion occurred in 2%, 9%, 21%, and 47% patients with pretreatment ALT levels within normal, one to two times normal, two to five times normal and more than five times normal; while the corresponding figures for 196 patients in the placebo group were 0%, 5%, 11%, and 14%, respectively (465).

Hepatitis B e antigen–negative patients

There are no data on predictors of response to lamivudine treatment of HBeAg-negative patients.

Durability of response

Durability of HBeAg seroconversion has been reported to vary from 50% to 80%. In a follow-up report of patients in the United States and Europe, who completed 1 year of lamivudine treatment, 30 of 39 (77%) patients with HBeAg seroconversion had a durable response after a median follow-up of 37 months (range 5 to 46 months) (486). In addition, 8 (20%) patients developed HBsAg seroconversion. The estimated durability of lamivudine-induced HBeAg seroconversion was lower, 64% at 36 months, based on intention to treat analysis. Studies from Asia reported lower rates of durability—50% to 60% (365,487,488,489,490), in part related to a shorter duration of treatment, mean 8 to 9 months. Several factors have been identified to be associated with increased durability of HBeAg seroconversion including longer duration of consolidation treatment (continued treatment after HBeAg seroconversion), younger age, lower HBV DNA level at the time treatment was stopped, and genotype B versus C, the most consistent factor appears to be duration of consolidation treatment (365,488,489,490). Although there are no good direct comparison data, it appears that durability of lamivudine-induced HBeAg seroconversion is less than that for IFN (491).

Among HBeAg-negative patients, durability of virus suppression after 1-year of lamivudine treatment is less than 10%. One study reported that durability of virologic response (undetectable HBV DNA by PCR assay) can be improved to 50% in patients who have completed 2 years treatment and had undetectable HBV DNA by PCR assay on at least three consecutive occasions (3 months apart) (492). Confirmation of these data may help in identifying a subset of patients who do not need to be on life-long treatment.

Lamivudine resistance

Selection of lamivudine resistant mutants is the main concern with lamivudine treatment. The most common mutation affects the YMDD motif of the HBV DNA

polymerase (M204V/I). This mutation is frequently accompanied by L180M (493,494), other mutations that have been commonly observed include V173L and changes at L80. Lamivudine resistance is usually manifested as breakthrough infection defined as greater than 1 $\log_{10}$ increase in serum HBV DNA from nadir. However, breakthrough infection also can be a result of noncompliance.

Genotypic resistance can be detected in 14% to 32% of HBeAg-positive patients after 1 year of lamivudine treatment (467,468,469) and increases with the duration of treatment to 60% to 70% after 5 years of treatment (470,472,473). Retrospective analysis of 998 HBeAg-positive patients who received a median of 4 years of lamivudine treatment identified Asian ethnicity, high pretreatment serum HBV DNA levels, male gender, and longer duration of lamivudine treatment as factors that correlated with the development of lamivudine resistance (473). One study found that a high level of residual virus: Serum HBV DNA greater than 10^3 copies/mL after 6 months of treatment was associated with a higher rate of lamivudine resistance: 63% versus 13% (495). The rates of lamivudine resistance in patients treated for HBeAg-negative chronic hepatitis B appear to be more variable, 0% to 27% at 1 year and 10% to 56% at 2 years (475,476,477,496).

The clinical course of patients with lamivudine resistant mutants is variable. In vitro studies showed that M204V/I mutation decreases replication fitness of HBV (497,498) but compensatory mutations selected during continued treatment, such as L180M, can restore replication fitness. Therefore, serum HBV DNA levels tend to be lower than baseline when breakthrough infection is first diagnosed. However, over time, serum HBV DNA levels increase and may become higher than pretreatment values. Virologic breakthrough is usually followed by biochemical breakthrough (480). In some patients emergence of lamivudine resistant mutants may be accompanied by acute exacerbations of liver disease (499,500) but exacerbations associated with emergence of lamivudine resistance may also lead to HBeAg seroconversion (470,501). The frequency of hepatitis flares increases with the duration of lamivudine resistance, from 43% in year 1 to greater than 80% after 3 years (473). The occurrence of icteric flares and hepatic decompensation is rare in young precirrhotic patients (6% after 4 years of lamivudine resistance), but more common and may be fatal in older patients and those with advanced fibrosis or cirrhosis. Withdrawal of treatment in patients who have developed lamivudine resistance has been reported to be associated with rapid outgrowth of wild-type virus and flares in liver disease (502,503). However, two studies in Asia found that hepatitis flares and decompensation were similar among patients with lamivudine breakthrough, who stopped or continued lamivudine treatment (504,505).

Long-term outcome of lamivudine-treated patients

Follow-up of patients receiving continued lamivudine treatment showed that the rates of maintained virologic and biochemical response decrease with time due to selection of drug-resistant mutants. As a group, liver histology after 3 years of treatment is improved compared to baseline but histologic benefit after the first year of treatment is negated among patients with breakthrough infection (479,486). Despite increasing rates of breakthrough infection, two studies with median follow-up of 2 to 4 years reported that lamivudine treatment decreased the overall rate of hepatic decompensation as well as liver-related mortality (506,507).

Adverse events

In general, lamivudine is very well tolerated. Various adverse events including a mild (two- to threefold) increase in ALT level have been reported in patients receiving lamivudine, but these events occurred with the same frequency among the controls.

Dose regimen

The recommended dose for adults with normal renal function (creatinine clearance >50 mL/minute) and no HIV infection is 100 mg daily PO. Dose reduction is necessary for patients with renal insufficiency. Patients with HIV coinfection should be treated with 150 mg b.i.d. doses in addition to other antiretroviral therapies.

Hepatitis B e antigen–positive patients

The end point of treatment for HBeAg-positive patients is HBeAg seroconversion. In general, lamivudine should be administered for a minimum of 6 months after confirmed HBeAg seroconversion. With the availability of newer treatments with lower risk of drug resistance, whether lamivudine should be continued in patients who have been on treatment for more than a year and have not achieved HBeAg seroconversion nor developed breakthrough infection or switched to new therapies is unclear. For patients who have breakthrough infection due to drug resistance, the vast majority should receive rescue therapy with antiviral agents that are effective against lamivudine-resistant HBV mutants. A minority of patients who do not have underlying cirrhosis or immunosuppression may consider stopping treatment, particularly if the indications for initial treatment were weak.

Acute exacerbations of hepatitis with or without hepatic decompensation may occur after discontinuation of lamivudine therapy. Exacerbations may occur even in patients who have developed HBeAg seroconversion and may be up to 1 year (median 4 months) after

cessation of treatment (501,502). Therefore, all patients should be closely monitored after treatment is discontinued. Reinstitution of lamivudine treatment is usually effective in controlling the exacerbations in patients who have not developed breakthrough infection, and may result in subsequent HBeAg seroconversion but the benefits of retreatment are usually transient in patients with breakthrough infection as resistant mutants are quickly selected when lamivudine treatment is resumed (496,503).

Hepatitis B e antigen–negative patients

The end-point of treatment for HBeAg-negative chronic hepatitis B is unknown. Post-treatment relapse can occur even in patients with undetectable serum HBV DNA by PCR assay. Because of the high rate (approximately 90%) of relapse in patients who responded after 1 year of treatment, longer duration of treatment is recommended. However, the criteria for discontinuation of treatment and the optimal duration of therapy have not been established.

Famciclovir

Famciclovir is the oral prodrug of penciclovir, an acyclic deoxyguanosine analog. Penciclovir is phosphorylated to its triphosphate (PCV-TP) which competes with 2′-deoxyguanosine-5′-triphosphate (dGTP) for incorporation into the nascent HBV DNA chains. In addition, PCV-TP may compete with dGTP for the priming of reverse transcription (synthesis of the first DNA strand) (508).

A phase III clinical trial of 417 patients with HBeAg-positive chronic hepatitis B found that the median decrease in histologic activity index among the patients who received famciclovir 500 mg t.i.d., famciclovir 1,500 mg daily or placebo were 1.5, 1, and 0, respectively. Compared to controls, a higher rate of HBeAg seroconversion was observed among the patients who received famciclovir 500 mg t.i.d. (9% vs. 3%), but not in the group who received famciclovir 1,500 mg daily (509).

Drug resistant mutants have also been reported in patients who have been on long-term famciclovir treatment (510). In view of the low efficacy, need for administration thrice daily, and potential for cross-resistance with lamivudine, it is unlikely that famciclovir will have a major role in the treatment of chronic hepatitis B.

Adefovir Dipivoxil (Hepsera, Bis-Pom PMEA)

Adefovir is a nucleotide analog of adenosine monophosphate. It can inhibit reverse transcriptase as well as

DNA polymerase activity (511). In vitro and clinical studies showed that it is effective in suppressing wild type as well as lamivudine-resistant HBV (512).

Efficacy

1. *HBeAg-positive chronic hepatitis*. A phase III clinical trial included 515 patients with compensated liver disease randomized to receive two doses of adefovir (30 or 10 mg daily) or placebo (Table 29.12) (513). After 48 weeks of treatment, histologic improvement was observed in 59%, 53%, and 25%, respectively. Median decrease in serum HBV DNA level was -4.8, -3.5, and -0.6 $\log_{10}$ copies/mL, while the proportion of patients with undetectable HBV DNA by PCR assay was 39%, 21%, and 0, respectively. Normalization of ALT was observed in 55%, 48%, and 16% whereas HBeAg seroconversion occurred in 14%, 12%, and 6%, respectively. All assessments of response showed a statistical difference between the two treatment groups and the placebo group, and a trend indicating superiority of the higher dose (30 mg) group. However, the 30-mg dose was associated with nephrotoxicity albeit less frequently than the doses (60 and 120 mg) initially used for HIV infection.
2. *HBeAg-negative chronic hepatitis*. A phase III clinical trial included 185 patients with compensated liver disease randomized to receive adefovir 10 mg daily or placebo (514). After 48 weeks of treatment, patients who received adefovir were more likely to have improvement in liver histology (77% vs. 33%), undetectable HBV DNA by PCR assay (51% vs. 0), and normalization of ALT (72% vs. 29%). A follow-up report of 70 patients found that after 144 weeks of continued adefovir treatment, median HBV DNA decrease compared to baseline was 3.6 $\log_{10}$ copies/mL, 79% patients had undetectable HBV DNA by PCR, and 69% patients had normalization of ALT (515). Two patients lost HBsAg. These data indicate that response can be maintained in 70% to 80% patients but as many as 20% to 30% failed to achieve virologic or biochemical response after 3 years of continued adefovir treatment.
3. *Decompensated cirrhosis/liver transplantation*. Data on adefovir as de novo therapy in patients with decompensated cirrhosis or liver transplantation are not available. It is likely that the efficacy will be similar to that in patients who received adefovir as salvage therapy for lamivudine-resistant HBV.
4. *Lamivudine-resistant HBV*. Clinical trials confirmed that adefovir is effective in suppressing lamivudine-resistant HBV (516,517,518,519). One study that included 19 patients randomized to receive adefovir monotherapy found that antiviral efficacy of adefovir alone was comparable to that of combination therapy of adefovir and lamivudine (516). However, hepatitis

flares were more common during the transition period. In addition, recent data showed that sequential monotherapy increases the risk of adefovir resistance (520). In patients with decompensated liver disease, addition of adefovir has been shown to result in clinical improvement, reduction in risk of recurrent hepatitis B post–liver transplant, and possibly increased survival (518,519). One study included 128 pre- and 196 post-transplant patients (518). Among the patients who received 48 weeks treatment, 81% of the pre- and 34% of the post-transplant patients had undetectable HBV DNA by PCR assay, and 76% and 49%, respectively had normalization of ALT. Child-Turcotte-Pugh score improved in more than 90% of patients in both groups, and 1-year survival was 84% for the pre- and 93% for the post-transplant patients. Adefovir when added to existing HIV treatment regimen which included lamivudine 150 mg b.i.d. has also been shown to be effective in decreasing serum HBV DNA levels in patients with HIV and HBV coinfection and lamivudine-resistant HBV (521).

Predictors of response

Detailed analyses of predictors of response had not been performed. Retrospective analyses of data from the two phase III clinical trials showed that HBV DNA reduction was comparable across the four major HBV genotypes (A to D) (362), but an association between adefovir-related HBeAg seroconversion or durability of response and HBV genotypes could not be analyzed because of the small number of responders. HBV DNA reduction was also similar among Asians and Caucasians. Limited data suggest that HBeAg-positive patients with high pretreatment ALT were more likely to undergo HBeAg seroconversion and to have histologic improvement.

Durability of response and long-term outcome of adefovir-treated patients

Hepatitis B e antigen–positive chronic hepatitis

Analyses of long-term data were hampered by errors in treatment assignment during the second year of the phase III trial. HBeAg seroconversion rates increased during the second and third years of treatment but the exact figures were unclear. Durability of HBeAg seroconversion was examined in 76 patients who had achieved HBeAg seroconversion after a median of 80
(30,31,32,33,34,35,36,37,38,39,40,41,42,43,44,45,46,47,48,49,50,51,52,53,54,55,56,57,58,59,60,61,62,63,64,6

weeks adefovir treatment, and had been followed for a median of 52 (5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34,35,36,37,38,39,40,41,4 weeks off treatment. HBeAg seroconversion was maintained in 69 (92%) patients (522). The seemingly higher rate of durability of adefovir-related HBeAg seroconversion compared to lamivudine may be related to a longer duration of treatment (80 vs. <52 weeks) and more importantly, a longer duration of consolidation treatment.

Hepatitis B e antigen–negative chronic hepatitis

A follow-up report found that almost all 40 patients who received adefovir in year 1 of the phase III trial, who were randomized to placebo in year 2 relapsed. At week 96 (48 weeks after stopping adefovir), only 8% patients had undetectable HBV DNA by PCR assay and 32% had normal ALT (515). These data indicate that longer duration (>48 weeks) of treatment is necessary to achieve sustained response but the optimal duration remains to be determined. Most patients maintained their response when adefovir was continued for 3 years, but there was minimal incremental response during years 2 and 3.

Hepatitis B s antigen loss

A retrospective analysis of 578 patients who received adefovir monotherapy found that nine (1.6%) patients had HBsAg seroconversion after a median of 73 weeks (523), indicating that HBsAg loss is a rare event.

Dose regimen

The approved dose of adefovir is 10 mg daily PO. Although higher doses appeared to have more potent antiviral effect, concerns for nephrotoxicity limit their use in clinical practice. Adefovir at the approved dose of 10 mg daily is ineffective in inhibiting HIV replication.

For HBeAg-positive patients, treatment should be administered for an additional 6 months after HBeAg seroconversion is achieved. For HBeAg-negative patients, long-term treatment is needed but the optimal duration of treatment has not been determined. Patients must be closely monitored for relapse when treatment is stopped. Because of the weak antiviral effects of the 10-mg dose, 25% to 50% patients will have a suboptimal virologic response with less than 3.5 $\log_{10}$ reduction in HBV DNA after 48 weeks of treatment (524); whether these patients should be switched to other more potent antiviral agents such as entecavir and when the switch should occur have not been examined.

Adverse events

Adefovir is in general well tolerated with similar side effect profile as placebo in the phase III clinical trials in patients with compensated liver disease. The most worrisome adverse event is nephrotoxicity—increase in serum creatinine and/or renal tubular defects manifested as hypophosphatemia and Fanconi's syndrome, which was common at high doses (60 to 120 mg daily). A reproducible increase in serum creatinine by greater than or equal to 0.5 mg/dL has not been reported in

patients who received 10 mg doses after 48 weeks and in 6% after 192 weeks of treatment (513,514,515,525). In all cases, the increase in serum creatinine was reversible but a few patients had to be withdrawn from treatment. Nephrotoxicity was more common in patients with decompensated cirrhosis and in those who had undergone liver transplantation; a reproducible increase in serum creatinine by greater than or equal to 0.5 mg/dL was observed in 15% to 22% of these patients after 48 weeks of 10 mg doses (518). Whether the high frequency of nephrotoxicity in this setting is a direct result of adefovir, concomitant nephrotoxic medications, preexisting renal dysfunction or hepatorenal syndrome or a combination of these factors is unclear. Renal function should be monitored in all patients receiving adefovir and dosing intervals adjusted in patients with estimated creatinine clearance less than 50 mL/minute.

Adefovir resistance

Resistance occurs at a slower rate during adefovir treatment compared to lamivudine. Several mechanisms have been suggested that might contribute to the low rate of resistance to adefovir. The adefovir molecule is structurally similar to 2′-deoxyadenosine 5′-triphosphate (dATP), which limits steric discrimination by HBV polymerase. The phosphonate bond in adefovir may be less susceptible to chain terminator removal once the molecule is incorporated into viral DNA. In addition, its flexible molecular structure permits it to bind HBV polymerase even in the presence of minor alterations in the nucleotide binding pocket. Resistance to adefovir has not been detected in clinical trials of patients who received 48 weeks of treatment (526). However, novel mutations conferring resistance to adefovir (asparagine to threonine substitution N236T and alanine to valine or threonine substitution A181V/T) have been described (527,528). Aggregate data from five studies including three studies using combination of adefovir and lamivudine in patients with lamivudine-resistant HBV estimated the cumulative rate of resistance to be 15% by 192 weeks (529). Another study of adefovir monotherapy in 67 HBeAg-negative patients found that the cumulative rate of resistance was 0%, 3%, 11%, and 18% at week 48, 96, 144, and 192 respectively (525).

In vitro studies showed that adefovir-resistant mutations decrease susceptibility by 3 to 15-fold (528,530). Nevertheless, clinical studies found that viral rebound, hepatitis flares and even hepatic decompensation can occur (531). Therefore, all patients receiving long-term adefovir should be closely monitored for resistance. Risk factors for adefovir resistance that have been identified include suboptimal virus suppression and sequential monotherapy. A pooled study of 467 patients with lamivudine-resistant HBV found that resistance to adefovir occurred only in patients who stopped lamivudine (520). Sequential treatment with lamivudine followed by adefovir had also been reported to select dual-resistant HBV mutants.

In vitro and human studies showed that adefovir-resistant HBV mutants are susceptible to lamivudine and entecavir (527,528,531). However, the duration of benefit is unknown, and may be short lived in patients with earlier lamivudine resistance.

Entecavir (Baraclude)

Entecavir is an orally administered cyclopentyl guanosine analog. In vitro studies as well as studies in woodchucks showed that it has potent antiviral effects against HBV. One study found that long-term treatment of woodchucks chronically infected with WHV infection resulted in decreased incidence of HCC and increased survival (334). In vitro studies showed that entecavir is effective in suppressing lamivudine-resistant HBV but susceptibility is reduced compared to wild type HBV (414). Entecavir has also been found to be effective in suppressing adefovir-resistant HBV in in vitro studies. Clinical trials confirmed the efficacy of entecavir in humans (532).

Efficacy

1. HBeAg-positive patients. In a phase III clinical trial 715 patients with compensated liver disease were randomized to receive entecavir 0.5 mg or lamivudine 100 mg daily (Table 29.12). At week 48, entecavir resulted in statistically higher rate of histologic (72% vs. 62%), virologic (HBV DNA undetectable by PCR) (67% vs. 36%) and biochemical (68% vs. 60%) responses (533) compared to lamivudine. However, despite more potent viral suppression (6.9 vs. 5.4 log10 copies/mL), HBeAg seroconversion rates were similar in the two groups: 21% versus 18%.
2. HBeAg-negative patients. In a phase III clinical trial 648 patients with compensated liver disease were randomized to receive entecavir 0.5 mg or lamivudine 100 mg daily. At week 48, entecavir resulted in statistically higher rate of histologic (70% vs. 61%), virologic (90% vs. 72%) and biochemical (78% vs. 71%) responses compared to lamivudine (534).
3. Lamivudine-refractory HBV. In one study 286 patients, who had persistent viremia while on lamivudine with or without confirmed lamivudine-resistant mutations, were randomized to receive entecavir 1.0 g or lamivudine 100 mg daily. At week 48, entecavir resulted in statistically higher rate of histologic (55% vs. 28%), virologic (21% vs. 1%) and biochemical (75% vs. 23%) responses compared to lamivudine (535).

Predictors of response

Predictors of response have not been examined in detail. Entecavir appears to be equally effective in decreasing serum HBV DNA level and in inducing histologic improvement in Asians and Whites, across HBV genotypes A-D and a wide range of pretreatment HBV DNA and ALT levels. However, HBeAg seroconversion rates are lower in patients with pretreatment ALT less than 2 × normal.

Durability of response

Limited data suggest that durability of response to entecavir is similar or better than lamivudine.

Dose regimen

The approved dose for nucleoside-naïve patients is 0.5 mg daily PO and for lamivudine-refractory patients is 1.0 mg daily PO. Doses should be adjusted for patients with estimated creatinine clearance less than 50 mL/minute.

Adverse events

Entecavir had a similar safety profile including on-treatment ALT flares as lamivudine in clinical trials. Studies in mice found an increased risk of lung adenomas (at exposures 3 to 40 times those in humans) (532). In addition, HCC were increased in male mice while brain gliomas were increased in male and female rats. Whether these observations have relevance to humans is unclear. To date, no difference in incidence of HCC or other neoplasms has been observed between patients who received entecavir versus lamivudine but the duration of follow-up is limited.

Entecavir resistance

No resistance was observed after 48 weeks of treatment in the two phase III clinical trials of nucleoside-naïve patients, although resistance was detected in 7% of patients by week 48 in the trial of lamivudine refractory patients (533,534,535). Mutations associated with entecavir resistance have been localized to rtI169, rtT184, rtS202, and rtM250 (536). These mutations on their own have minimal effect on susceptibility to entecavir, but when present with lamivudine-resistant mutations, decrease susceptibility to entecavir by greater than 1,000-fold (537).

Emtricitabine (Emtriva, FTC)

Emtricitabine is a potent inhibitor of HIV and HBV replication. FTC has been approved for HIV treatment as Emtriva (FTC only) and as Truvada (in combination with tenofovir as a single pill). Because of its structural similarity with lamivudine (3TC), treatment with FTC selects for the same resistant mutants.

A phase II trial that included 98 patients (77 HBeAg positive) with chronic hepatitis B randomized to receive varying doses of FTC found that 200 mg had the maximum effect on viral suppression (538).

In another study, 248 patients (63% were HBeAg positive) were randomized to receive FTC 200 mg daily or placebo in a 2:1 ratio (539). At week 48, FTC resulted in a significantly higher rate of histologic (62% vs. 25%), virologic (undetectable HBV DNA by PCR assay) (54% vs. 2%) and biochemical (65% vs. 25%) responses but HBeAg seroconversion rates were identical—12% in the two groups. FTC-resistant mutations were detected in 13% patients who received FTC. The high rate of drug resistance and the lack of improvement on HBeAg seroconversion indicate that FTC on its own has no role in the rapidly expanding treatment armamentarium for hepatitis B.

Tenofovir (Viread)

Tenofovir disoproxil fumarate is a nucleotide analog that has been approved for the treatment of HIV infection as Viread (tenofovir only) or Truvada (tenofovir + emtricitabine as a single pill). Tenofovir is structurally similar to adefovir. In vitro studies showed that tenofovir and adefovir are equipotent. Because tenofovir appears to be less nephrotoxic, the approved dose is much higher than that of adefovir, 300 mg versus 10 mg daily. This may explain why tenofovir has more potent antiviral effects in clinical studies. Tenofovir has not been approved for treatment of hepatitis B; clinical studies designed to evaluate its safety and efficacy in patients with chronic hepatitis B, particularly those with HBV monoinfection and no earlier lamivudine treatment are under way. Currently, most of the data on tenofovir are based on studies of patients with HBV and HIV coinfection, who have lamivudine-resistant HBV.

Retrospective analysis of two large multicenter HIV trials that included subsets of patients with chronic hepatitis B (n = 23) demonstrated that tenofovir was associated with a significant reduction in HBV DNA levels both in patients who had not previously received anti-HIV therapy, as well as those who had already been exposed to anti-HIV therapy (540). Several pilot studies and case series confirmed that tenofovir is effective in decreasing serum HBV DNA levels in patients (with and without HIV coinfection) with lamivudine-resistant HBV (541,542,543,544,545).

In a study of 53 patients with lamivudine-resistant HBV, tenofovir led to a greater reduction in serum HBV DNA levels than adefovir (546). Although the study was not randomized, and there was heterogeneity in patient characteristics and treatment regimen (some but not all continued lamivudine), the finding that

tenofovir is superior to adefovir in clinical practice is not surprising due to the 30-fold difference in dose. Viral rebound has also been reported when patients were switched from tenofovir to adefovir (547).

Tenofovir is less nephrotoxic than adefovir. However, tenofovir has been occasionally reported to cause Fanconi's syndrome and renal insufficiency (548,549,550). Almost all of these adverse events occurred in patients with HIV coinfection receiving antiretroviral therapy. The likelihood of tenofovir-associated nephrotoxicity in patients with HBV monoinfection is unclear. Nevertheless, all patients receiving long-term tenofovir should be closely monitored, particularly those with baseline impaired renal function and those with decompensated liver disease.

L-Deoxythymidine (LdT, Telbivudine) and VAL-Deoxycytosine (VAL-LdC)

L-deoxythymidine (LdT) and val-deoxycytosine (val-LdC) are nucleoside analogs with potent antiviral effects against HBV. However, they select for the same mutations as lamivudine, FTC and clevudine.

A phase II trial included 104 HBeAg-positive patients who were randomized to receive LdT (400 or 600 mg daily) alone or in combination with lamivudine 100 mg daily, or lamivudine alone (551). The two LdT monotherapy groups had higher rates of virologic (61% vs. 32%) and biochemical (86% vs. 63%) responses compared to the lamivudine group. HBeAg seroconversion rates were similar in the two groups: 31% versus 22%. Combination of LdT and lamivudine did not confer any benefit; in fact the combination group appeared to fare worse than the LdT monotherapy group. Mutations in the YMDD motif were detected in 4.5%, 9.8% and 15.8% of patients who received LdT alone, LdT and lamivudine, and lamivudine alone,

respectively. A follow-up report on 90 patients who continued treatment for 96 weeks showed that LdT continued to be superior to lamivudine in virologic and biochemical responses but the difference in HBeAg seroconversion rates was not statistically significant (38% vs. 21%) (552). Mutations in the YMDD motif were detected in six additional patients in the LdT alone group during the second year of therapy, resulting in a cumulative resistance rate of 18% at the end of year 2. Phase III clinical trial is ongoing. Given the availability of newer antiviral agents with lower risk of drug resistance, the role of LdT in hepatitis B treatment is limited.

Val-LdC is a well absorbed oral prodrug of LdC. Phase I/II clinical trials showed that it is effective in suppressing HBV replication (553). In vitro and woodchuck studies found that val-LdC and LdT have additive antiviral effects.

Clevudine (LFMAU, 2′-Fluoro-5-Methyl-L-Arabinofuranosyl Uracil)

Clevudine is a pyrimidine nucleoside analog that is effective in inhibiting HBV replication in vitro and in animal models. Phase I/II clinical trials confirmed that a 4-week course of clevudine can decrease serum HBV DNA levels by 2 to 3 $\log_{10}$ copies/mL and at high doses, HBV DNA levels remained suppressed for up to 24 weeks after stopping treatment (554,555). Clinical trials are ongoing to determine the optimal dose regimen of clevudine and to determine if sustained response can be achieved after a longer (24 week) course of treatment. One drawback of clevudine is that it selects for the same mutations as lamivudine and FTC.

Combination Therapies

Monotherapy with a single antiviral agent or IFN-α is unlikely to be sufficient for the eradication of HBV infection in most patients with chronic hepatitis B. Combination therapies have been proven to be more effective than monotherapy in the treatment of HIV and HCV infection. The potential advantages of combination therapies are additive or synergistic antiviral effects, and diminished or delayed resistance. The potential disadvantages of combination therapies are added costs, increased toxicity, and drug interactions. Various combination therapies have been evaluated; to date, none of the combination therapies has been proven to be superior to monotherapy in inducing a higher rate of sustained response or in decreasing the rate of drug resistance. Nonetheless, continued effort should be expended to develop an optimal combination therapy for hepatitis B.

Standard or pegylated interferon-α and lamivudine

The combination of IFN-α and lamivudine seems logical because monotherapy with each agent is effective, and IFN-α and lamivudine have different mechanisms of action.

Treatment-naïve patients

Five large trials (one using standard IFN-α and four using pegIFN-α, 4 in HBeAg-positive patients and one in HBeAg-negative patients) were conducted comparing combination of IFN-α and lamivudine to lamivudine alone and/or IFN-α alone (359,460,461,463,469). All studies found that combination therapy had greater on-treatment virus suppression but there was no difference in sustained off-treatment virologic response compared to IFN-α alone. All studies showed that

combination therapy resulted in higher rates of sustained off-treatment response compared to lamivudine alone. Although combination therapy was associated with lower rates of lamivudine resistance compared to lamivudine monotherapy, a low rate of lamivudine resistance was encountered compared to none in patients who received IFN-α alone.

Interferon-α nonresponders

Combination therapy of standard IFN-α and lamivudine is not more effective than lamivudine alone in the retreatment of IFN-α nonresponders (481).

Lamivudine and adefovir

Nucleosid(t)e naïve patients

One trial included 115 patients randomized to receive a combination of lamivudine and adefovir or lamivudine alone. At week 52, there was no difference in HBV DNA suppression, ALT normalization or HBeAg loss (556). However, combination therapy was associated with a lower rate of detection of lamivudine-resistant mutations: 20% versus 2% suggesting that the benefit of combination therapy may be observed with continued treatment.

Patients with lamivudine-resistant hepatitis B virus

One small trial in patients with compensated liver disease showed that combination of adefovir and lamivudine was not superior to adefovir alone in decreasing serum HBV DNA levels (516). However, hepatitis flares were less frequent during the transition period in the combination therapy group. Recent

data suggest that continuation of lamivudine reduces the risk of resistance to adefovir (520). There is therefore increasing evidence to support the conclusion that combination of adefovir and lamivudine is superior to adefovir monotherapy for patients with lamivudine-resistant HBV.

Lamivudine and telbivudine

One trial conducted in nucleoside naïve HBeAg-positive patients demonstrated that combination of lamivudine and telbivudine had no advantage over telbivudine alone (551). In fact, the combination group showed a trend toward an inferior result in all parameters: Virus suppression, ALT normalization, HBeAg seroconversion, and mutations in the YMDD motif. These data suggest that lamivudine and telbivudine, both being L-nucleosides, may antagonize each other by competing for the same binding site on the HBV reverse transcriptase.

Adefovir and Emtricitabine

A pilot trial on 30 HBeAg-positive patients found that patients randomized to receive combination of adefovir and emtricitabine had greater decrease in serum HBV DNA levels compared to those who received adefovir alone (557). Whether this was related to an additive or synergistic effect of these two compounds or an unusually poor response in the adefovir monotherapy group (2 to 3 $\log_{10}$ reduction in serum HBV DNA after 1 year of therapy) is unclear.

Novel Antiviral Approaches

Several innovative antiviral approaches have been evaluated in in vitro as well as in animal models of chronic hepatitis.

Selective targeting of antiviral agents to the liver

Conjugation of antiviral agents to ligands that are selectively taken up by the liver may permit these agents to be used in lower doses with decreased systemic adverse effects. Several systems of selective delivery have been evaluated including conjugation to lactosaminated human serum albumin, liposome encapsulation, and incorporation into recombinant chylomicrons (558,559).

Antisense approaches

Transcription and translation of HBV DNA and HBV RNA can be prevented by antisense molecules or ribozymes that are complementary to the DNA or RNA templates (560,561). These molecules can be delivered by the administration of preformed molecules or vector DNA. The advantage of this approach is that specific targets can be precisely selected. In addition, the risk of drug-resistant mutants can be reduced by targeting multiple sites in the viral DNA or RNA or by targeting regulatory sequences that would not tolerate mutations. In vitro studies have confirmed that this approach is feasible. The major impediments to the clinical use of antisense treatment include rapid degradation of the antisense molecules by nucleases in vivo, lack of an efficient delivery system into the target cells, and hindrance of access to target DNA or RNA sequences by secondary structure.

Short interfering RNA

RNA interference (RNAi) is a recently discovered cellular mechanism that detects and destroys double-stranded RNA and seems to play a role in the cell's antiviral defense system (562). Short interfering RNA (siRNA) molecules are approximately 21-nucleotide,

double-stranded RNA intermediates of the RNAi mechanism that guides a unique RNA-induced silencing complex to target RNA, leading to its subsequent degradation. Administration of synthetic siRNAs that use the endogenous cellular mechanism to downregulate the expression of HBV genes is a potential novel approach to treatment of hepatitis B. Several investigators have demonstrated the efficacy of siRNA in inhibiting HBV expression in cell culture systems and more recently in animal models (563,564,565,566,567). Nevertheless, major hurdles in delivering adequate amounts of siRNA to the target cells need to be overcome before this approach can be tested in humans.

Immunomodulatory Therapy

Nonspecific immunomodulation is largely ineffective in clearing HBV infection.

Thymosin

Thymic-derived peptides can stimulate T cell function. Thymosin is well tolerated but data on efficacy are conflicting (568,569,570,571). A meta-analysis that included five controlled trials with a total of 353 patients concluded that patients treated with thymosin were significantly more likely than controls to have a virologic response (572). The maximal rate of response was not seen until 12 months after discontinuing therapy (odds ratio 1.67, 95% CI, 0.83 to 3.37). Thymosin is approved for the treatment of hepatitis B in some countries, mainly in Asia.

Hepatitis B virus–specific immunomodulation

In the past few years, several HBV-specific immunomodulatory therapies have been developed, some of which have shown promise.

S and pre-S antigen vaccines

Several uncontrolled trials reported that vaccines with HBV S with or without pre-S antigens used for prevention of HBV infection were effective in inducing anti-HBs response and in decreasing serum HBV DNA levels in patients with chronic hepatitis B (573,574). These data need to be confirmed in controlled clinical trials.

Deoxyribonucleic acid vaccination

Unlike peptide vaccines, vaccination with plasmid DNA that express viral proteins in situ can stimulate not only B cell but also T cell (both helper and cytotoxic) response. In addition, DNA vaccines lead to more prolonged expression of viral proteins (575). Studies in mice have shown that vaccination with plasmids that contain HBV surface gene can induce anti-HBs response. DNA vaccination has been demonstrated to decrease the production of HBsAg in transgenic mice that express the HBV surface gene (576). One pilot study reported that DNA vaccination was also effective in activating T cell response and in decreasing serum HBV DNA levels in patients with chronic HBV infection (577).

T cell vaccines

Patients with chronic HBV infection have been demonstrated to have impaired cytotoxic T lymphocyte response to HBV antigens, resulting in ineffective virus clearance. In vitro and animal (transgenic mice) studies show that CTL response to HBcAg can be induced by repeated exposure to peptides that correspond to major HBcAg epitopes. Moreover, administration of HBsAg primed CTLs to transgenic mice that express HBV surface gene can result in decreased transcription of viral RNA and translation of viral antigens with minimal cell damage (578). These data suggest that vaccination with synthetic peptides that stimulate CTL response to HBV antigens can induce viral clearance without causing massive hepatocyte damage. One Phase II study showed that CTL response can be stimulated in patients with chronic HBV infection, who were inoculated with a vaccine that contained an HLA-restricted HBcAg CTL epitope but the antiviral effect was weak (579).

Recommendations for the Treatment of Chronic Hepatitis B

Current therapy of chronic hepatitis B has limited long-term efficacy. Therefore a, careful balance of patient's age, severity of liver disease, likelihood of response, and potential adverse events and complications is needed before treatment is initiated. Except for patients with decompensated cirrhosis, where IFN-α or pegIFN-α are contraindicated, all approved treatments should be considered. For patients who require long-term therapy such as patients with HBeAg-negative chronic hepatitis and those with cirrhosis, lamivudine is not an optimal therapy because of the high risk of drug resistance. For patients with severe acute exacerbation lamivudine or entecavir is preferred as initial therapy because of the slow and sometimes inconsistent antiviral effects of adefovir. The pros and cons of the approved therapies are listed in Table 29.13. Table 29.14 summarizes current recommendations for the treatment of chronic hepatitis B (580,581,582).

Treatment of hepatitis B has evolved at a rapid pace in the past 10 years. With the availability of many new treatment modalities, it is now possible to contemplate combination therapy for hepatitis B. The question is which is the right combination? As our understanding

of hepatitis B improves, it is also possible that future therapies will be tailored to the viral (HBV genotype), immunologic (ALT) and clinical characteristics (stage of liver disease) of the patient.

Table 29.13. Pros and Cons of Approved Treatments of Hepatitis B

	Standard/pegylated IFN	Lamivudine	Adefovir	Entecavir
Route of administration	Parenteral	Oral	Oral	Oral
Duration of treatment	Finite, ~12 m	Indefinite, y	Indefinite, y	Indefinite, y

Viral suppression	Weakest, but has immunomodulatory effects	Potent	Weak, suboptimal response in ~25%	Most potent
Efficacy against lamivudine-resistant HBV	Unclear	NA	Yes	Yes, activity lower than for wild type HBV
Resistant mutations	None identified	15%–30% y 1, 70% y 5	0% y 1, 29% y 5	0% y 1
Side effects	Frequent, may be serious	Negligible	Nephrotoxic, ~5% y 3	Limited safety record carcinogenic in rodents at high doses

IFN, interferon; HBV, hepatitis B virus.

Table 29.14. Recommended Strategies for Patients with Chronic Hepatitis B

HBeAg	HBV DNA[a] > 5 $\log_{10}$ IU/mL	ALT[a]	Recommended strategy
+	+	≤2 × ULN	• Low efficacy of available therapies • Monitor ALT and HBV DNA levels every 3–6 m • Consider treatment if ALT increases to >2 × ULN
+	+	>2 × ULN	• Consider treatment with one of the five approved therapies • Endpoints of treatment: Standard IFN—16 wk PegIFN—48 wk • Oral nucleoside/tide analogs: Lamivudine, adefovir and entecavir, extend therapy for 6 m after HBeAg seroconversion Lamivudine resistance—Adefovir or Entecavir
–	–	≤2 × ULN	• No treatment required • Monitor ALT and HBV DNA levels every 6–12 m
–	+	>2 × ULN	• IFN and pegIFN preferred in young patients because of finite duration of therapy • Adefovir or Entecavir preferred if oral therapy is chosen because of low rates of antiviral resistance with prolonged therapy • Lamivudine only if cost is a significant factor • Goals of treatment: Undetectable HBV DNA by PCR and normal ALT • Duration of treatment: IFN and pegIFN—48 wk Adefovir and Entecavir—>48 wk

+	+	Cirrhosis	• Compensated—Lamivudine or Adefovir or Entecavir • Decompensated—refer for transplant. IFN/pegIFN contraindicated
+	–	Cirrhosis[b]	• Compensated—observe • Decompensated—refer for transplant

[a]Liver biopsy should be considered for patients with HBV DNA of 4–5 $\log_{10}$ IU/mL and ALT 1–2 × ULN, or with fluctuating HBV DNA or ALT levels; those with moderate/severe inflammation, and bridging fibrosis or cirrhosis may benefit from treatment.
[b]Treatment may be considered for patients with cirrhosis even if ALT is normal or HBV DNA is 3–5 $\log_{10}$ IU/mL, especially if decompensated.
HBeAg, hepatitis B e antigen; HBV, hepatitis B virus; ALT, alanine aminotransferase; ULN, upper limit of normal; IFN, interferon; PCR, polymerase chain reaction.
Modified from Lok A, McMahon BJ. AASLD practice guidelines: chronic hepatitis B http://www.aasld.org/netFORUMAASLD/eweb/docs/chronichep_B.pdf . *Hepatology* 2004;39:857–861.

Hepatitis D

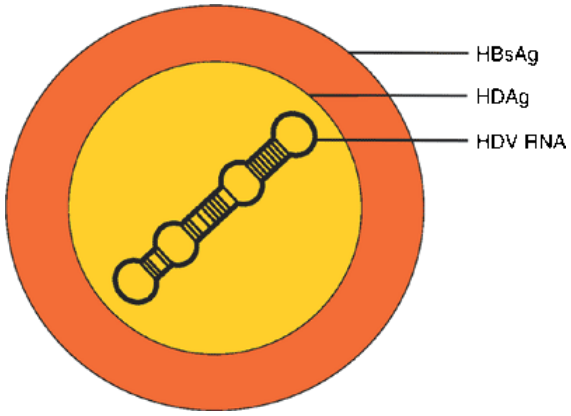
Hepatitis D is caused by a defective virus: The HDV. Although HDV is often referred to as hepatitis delta virus, the term HDV is preferred. HDV can replicate autonomously (583), but the simultaneous presence of HBV is required for complete virion assembly and secretion.

Hepatitis D Virus Structure and Replication

The HDV virion comprises an RNA genome, a single HDV encoded antigen, and a lipoprotein envelope provided by HBV and consisting of the same proteins found in the envelope of the HBV virion. The HDV genome is a small single-stranded circular RNA (1676 to 1683 nucleotides in size) with structural analogies to plant viroids and a high degree of self-complementarity causing the molecule to collapse into a rod-like structure (584). Significant sequence heterogeneity exists among HDV isolates and a classification into three genotypes has been proposed (585), although recent data suggest an even more complex phylogenetic differentiation of HDV into as many as seven clades (586). The only antigen associated with HDV, the hepatitis D antigen (HDAg), is a structural component of the virion: Approximately 70 molecules of HDAg are complexed with the HDV RNA genome to form a ribonucleoprotein structure (587) (Fig. 29.5). Hepatocytes are the only host cells where HDV replicates at very high levels (588) by transcription into a full-length complementary RNA (antigenomic HDV RNA) (584). HDV virion assembly and release is dependent on the simultaneous presence of HBV, which provides the envelope proteins. In the absence of HBV, HDV infection is abortive, unless promptly rescued by HBV (see the following text).

Patterns of Hepatitis D Virus Infection

Due to its dependence upon HBV, HDV infection always occurs in association with HBV infection. The clinical and laboratory findings vary with the type of infection. *Coinfection of HBV and HDV* in an individual susceptible to HBV infection results in an acute hepatitis clinically indistinguishable from classical acute hepatitis B and is usually transient and self-limiting, although a fulminant course was frequently reported among drug addicts (589). The rate of progression to chronic infection is similar to that observed after HBV monoinfection (590). *HDV superinfection* of a chronic HBsAg carrier may present as a severe acute hepatitis in a previously unrecognized HBV carrier, or as an exacerbation of preexisting chronic hepatitis B. Progression to persistent HDV infection is typical (591). A third form of infection is a *helper-independent latent HDV infection*, as reported in the woodchuck experimental model (592) and initially thought to occur in the liver transplant setting.



▪ **Figure 29.5** Schematic representation of the hepatitis D virus (HDV) virion with extensive intramolecular base-pairing of the HDV RNA genome. HBsAg, hepatitis B surface antigen; HDAg, hepatitis D antigen.

Epidemiology of Hepatitis D Virus

Data on HDV epidemiology have mostly been gathered in HBV carriers superinfected with HDV. It was estimated that approximately 5% of the HBV carriers worldwide may be infected with HDV (593). However, substantial changes in HDV epidemiology have occurred in the past 10 years. Improvements in socioeconomic conditions, an increased awareness of the risk of transmitting infectious diseases fostered by acquired immunodeficiency syndrome (AIDS) prevention policy, and aggressive vaccination campaigns against HBV have all contributed to a dramatic decrease in the incidence of HBV infection and the spread of HDV infection, especially in those countries that were previously endemic (594,595,596,597).

Although HDV infection is dependent on HBV infection, the geographical distribution of HDV infection does not parallel that of HBV, as areas endemic for HBV may be almost HDV free. The level of HDV endemicity is partly related to the route of transmission. HDV infection is endemic in the Mediterranean basin, where infection tends to occur early in life and is associated with low socioeconomic status. In the Far East, the prevalence of HDV infection among HBV carriers varies

from 5% in Japan to 90% in some Pacific islands (593). HDV infection is not infrequent in Taiwan (598), being predominantly transmitted sexually, but is rare in Hong Kong where it is largely confined to intravenous drug users (599). In most other Western countries, HDV infection is uncommon and predominantly confined to high-risk groups such as intravenous drug addicts and multiply transfused individuals (e.g., hemophiliacs). Transmission of HDV among HBsAg-positive homosexuals is rare (600). It must be emphasized that the studies mentioned in the preceding text were conducted more than 10 years ago, and the prevalence and risk factors of HDV infection in many parts of the world have not been reexamined.

Diagnosis of Hepatitis D Virus Infection

HDAg elicits a specific immune response consisting of antibodies of the IgM and IgG class (anti-HDV). In HDV infected individuals, the timing of appearance and level of HDV RNA, HDAg and anti-HDV in serum, together with the pattern of HBV markers, allow three HDV-related clinical entities to be identified: Acute HBV/HDV coinfection, acute HDV superinfection of a chronic HBV carrier and chronic HDV infection (Table 29.15). Owing to the dependence of HDV on HBV, the presence of HBsAg is necessary for the diagnosis of HDV infection. The additional presence of IgM antibody to hepatitis B core antigen (IgM anti-HBc) is necessary for the diagnosis of acute HBV/HDV coinfection.

In acute HDV infection, serum HDAg appears early and is short-lived and may escape detection (601). Total anti-HDV antibody appears late in acute infection, and repeated testing is recommended as anti-HDV seroconversion may be the only way to diagnose acute HDV infection in the absence of other markers of HDV infection (601,602). Anti-HDV of the IgM class is transient and delayed if the course of acute hepatitis D is self-limiting, but high-titer and long lasting if HDV infection progresses to chronicity. Although it may be the only serum marker of acute HDV infection (601), anti-HDV IgM lacks specificity, as it is usually found at high titers in chronic hepatitis D. As discussed in the preceding text, the differential diagnosis between HBV/HDV coinfection and HDV superinfection in an HBV carrier depends on the detection of high-titer IgM anti-HBc, found only in patients with coinfection.

Table 29.15. Diagnosis Of Hepatitis D Virus (HDV) Infection

	Acute HDV/HBV coinfection	HDV superinfection of HBV carrier	Chronic HDV infection
HDAg	Early and short-lived	Early, but soon masked by anti-HDV	Undetectable (masked by antibodies)
Anti-HDV, IgM	Transient and delayed	High-titer and long-lasting	High-titer
Anti-HDV, IgG	Late, increasing titers	Late, increasing titers	High-titer
HDV RNA	Early and sensitive marker	Early and sensitive marker	Usually high-level
IgM anti-HBc	Positive	Negative	Negative

HDV, hepatitis D virus; HBV, hepatitis B virus; HDAg, HDV antigen; IgM, immunoglobulin M; IgG, immunoglobulin G; anti-HBc, hepatitis B core antibody.

Development of anti-HDV hampers detection of HDAg further along the course of infection, due to formation of immune complexes. Therefore, in the chronic phase, detection of serum HDV RNA in serum by molecular hybridization or reverse transcriptase-polymerase chain reaction (RT-PCR) is preferred. HDV RNA is an early and sensitive marker of HDV replication in acute hepatitis D (603) and confirms infection in chronic hepatitis D. Furthermore, quantitative determination of HDV RNA is the test of choice for measuring HDV replication in patients undergoing antiviral treatment (604,605).

The detection of intrahepatic HDAg by immunohistochemistry has been proposed as the "gold" standard for the diagnosis of ongoing HDV infection (606). However, at late stages of the disease the detection of HDV RNA in serum by RT-PCR may be more sensitive.

In summary, the diagnosis of HDV infection should be considered in the following clinical situations.

In patients with acute hepatitis B, HDV coinfection should be suspected in patients at high risk, such as intravenous drug users or persons from endemic countries, and those presenting a severe course. Coinfected patients have high titer IgM anti-HBc. Markers of HBV replication may precede or follow those of HDV. Occasionally, patients may have already seroconverted to anti-HBs, for example, at the time of the second phase of a biphasic hepatitis. These patients should still be positive for IgM anti-HBc. Serum HDV RNA is usually positive at presentation, but if this assay is not available, total anti-HDV should be repeatedly tested to document seroconversion.

In acute hepatitis of undetermined origin in a HBV carrier, tests for HDV should be considered to rule out HDV superinfection. As this may occur in previously unrecognized HBV carriers, distinguishing between this condition and acute HBV/HDV coinfection may be difficult.

Testing for HDV should also be carried out in patients with chronic hepatitis B, who live in HDV endemic countries or are at high risk of HDV infection, to rule out simultaneous chronic HDV infection.

This is best achieved by screening for total anti-HDV antibody and then confirmed by staining for HDAg in liver tissues and/or measurement of serum HDV RNA. In chronic HDV infection, HBV replication is usually suppressed, and patients are typically anti-HBe positive.

Pathogenesis of Hepatitis D Virus-Induced Liver Damage

The mechanisms by which HDV induces liver damage (referred to as hepatitis D) are unknown, but are largely thought to be due to the host immune response (584). Overall, the degree of expression of HDV-related liver disease depends on the interplay of HDV-associated (such as HDV genotype) (585,607), host-associated (such as the immune response) and helper virus-associated factors (such as HBV genotype and replication level) (608).

Natural History of Chronic Hepatitis D

The clinical sequelae of HDV infection encompass a spectrum of manifestations from fulminant liver failure to an asymptomatic carrier state. Several studies have suggested that clinical outcome may be related to

the different HDV genotypes (585,609).

Genotype I is more prevalent in the West (610). Here, acute hepatitis D has an increased risk of a fulminant course when compared to acute hepatitis B (589). Once chronic HDV infection is established, it usually exacerbates the preexisting liver disease due to HBV (589) and progression toward cirrhosis is accelerated (611). HDV-associated chronic liver disease may also run an indolent course (612) and asymptomatic HDV carriers have been found in some western countries (613). An unfavorable course toward liver failure has been reported in patients with ongoing HBV and HDV replication (608). It is not clear whether superinfection with HDV accelerates the development of HCC (288).

Genotype II prevails in the Far East, where acute hepatitis D infrequently runs a fulminant course, and chronic hepatitis D seems less progressive (609).

Genotype III is mainly found in South America, where severe outbreaks of acute hepatitis D with a high incidence of liver failure have been reported (585).

Treatment of Hepatitis D

The primary endpoint of treatment is the suppression of HDV replication, which is accompanied by normalization of the serum aminotransferase (ALT) level and amelioration of necroinflammatory activity on liver biopsy. Undetectable HDV RNA in serum and HDAg in the liver document suppression of HDV replication. A secondary, albeit rarely observed endpoint is the eradication of HBV infection, with HBsAg to anti-HBs seroconversion.

The only drug that has been shown to be effective in the treatment of chronic hepatitis D is IFN-α. The mechanism of action of IFN-α in hepatitis D is unclear. IFN-α does not possess in vitro antiviral activity against HDV (614,615). Therefore, the efficacy of IFN-α in patients with chronic hepatitis D may depend on its antiviral activity on HBV or immune modulatory effects. The total number of chronic hepatitis D patients who have been treated with IFN-α and reported in the literature is small. Therefore, it is difficult to draw firm conclusions on the efficacy, optimal dose regimen, and factors predictive of response to IFN-α. Eradication of HDV infection and resolution of liver disease after IFN-α treatment have been reported anecdotally in uncontrolled studies with occasional permanent suppression of HDV replication and improvement of liver fibrosis (616,617,618). However, these favorable effects of IFN-α have not been unequivocally confirmed.

In the largest multicenter trial, 61 Italian patients with chronic hepatitis D were randomly assigned to receive IFN-α in doses of 5 MU/m^2 TIW for 4 months, followed by 3 MU/m^2 TIW for an additional 8 months, or placebo (619). Eight (25%) of the 31 treated patients versus none of the 30 controls had normal ALT at the end of treatment. However, only one patient had normal ALT level at the end of the 12 months follow-up. Fourteen (45%) treated patients were HDV RNA negative at the end of treatment; but a similar proportion (27%) of controls were also HDV RNA negative, suggesting that the "benefit" of treatment may be related to spontaneous fluctuations in HDV viremia. The proportion of HDV RNA-negative patients at the end of follow-up was similar in the two groups (45 vs. 33%). Liver histology also improved with similar frequency in the two groups (57 vs. 36%, *P* = NS). Therefore, the authors concluded that IFN-α therapy did not produce any significant benefit in patients with chronic hepatitis D.

In another study, 42 patients with chronic hepatitis D were randomly assigned to receive two different doses (9 vs. 3 MU TIW) of IFN-α or placebo for 48 weeks (620). Normal serum ALT levels at the end of treatment occurred more frequently in the patients receiving 9 MU doses of IFN-α than in the other two groups (70%, 29%, and 8%, respectively). Complete response (normal ALT level and undetectable serum HDV RNA at the end of treatment) was also more frequent with 9 MU dosing (50%, 21%, and 0%, respectively). Treatment with 9 MU doses of IFN-α was associated with a marked improvement in liver histology. However, none of the patients had sustained clearance of HDV RNA. The authors concluded that high-dose IFN was effective in suppressing HDV replication but that the antiviral effect was not sustained. Five of the ten responders in the 9-MU dose group

had normal ALT levels that lasted for up to 4 years. In a follow-up report they found that ALT normalization correlated with improved hepatic function (621). Compared to treatment with low-dose IFN or placebo, those who received the high dose had a sustained decrease in serum HDV RNA levels, and some patients had HDV clearance. Patients in the high dose group were also more likely to have improvement in histologic activity and fibrosis and survival.

The only feature, which may be associated with an increased likelihood of response, is a short duration of disease (616,617,619). Therefore, although the rate of success is low, it is generally accepted that patients with chronic hepatitis D and active liver disease, as evidenced by elevated ALT levels and/or chronic hepatitis on liver biopsy, should be treated and treated early. The recommended dose regimen is IFN-α 9 MU TIW for at least 12 months. It is very likely that improved results may be achieved by using pegylated IFN-α. Controlled studies are under way.

Lamivudine, a potent inhibitor of HBV replication, has little or no effect on HDV (622,623). There are no data on the efficacy of adefovir or entecavir in patients with HDV infection.

Prevention of Hepatitis D Virus Infection

The mainstay of prevention of HDV infection is vaccination against its helper virus, the HBV. Anti-HBs–positive chimpanzees are protected against experimental HDV infection (624). However, passive prophylaxis with hepatitis B immunoglobulin has not completely prevented reinfection of transplanted livers by HDV.

Chapter 30
Hepatitis C

Gary L. Davis

Key Concepts

- Hepatitis C virus (HCV) is a single-stranded ribonucleic acid (RNA) virus that replicates at a rapid rate but lacks proofreading ability. As a consequence, it has a high degree of genetic diversity that has led to evolution into several distinct viral genotypes. This genetic diversity affects the biology of the virus, in particular its susceptibility to interferon-based therapy. It may also be an important factor, along with signaling interference and effector modulation, in allowing the virus to evade elimination by the host immune response.
- The serologic test (anti-HCV) is sensitive for diagnosing HCV infection. Molecular tests that measure HCV RNA levels are extremely sensitive and are helpful in confirming infection and managing treatment.
- The incidence of acute HCV infection has fallen dramatically in the United States. The major risk factor for infection remains intravenous drug use.
- Chronic infection develops in 50% to 90% of acutely infected persons; it occurs less commonly in the young. Despite the declining incidence of HCV, the prevalence remains high (3 to 4 million persons) because of this high chronicity rate.
- Both acute and chronic HCV infections are usually asymptomatic. Chronic hepatitis C is a slowly progressive disease but results in significant disease morbidity in only a minority of infected persons. However, because HCV infection is so highly prevalent, chronic hepatitis C is among the most common causes of chronic liver disease in the United States and the leading indication for liver transplantation.
- There is no effective pre- or postexposure prophylaxis for HCV infection. Interferon-based regimens are the only effective treatment for patients with acute or chronic hepatitis, although many patients with acute infection recover spontaneously. Sustained loss of virus is now achievable in more than 50% of patients with chronic hepatitis C who are treated with the combination of long-acting (pegylated) interferons and ribavirin. Patients who have a sustained virologic response to treatment also have significant and persistent histologic improvement.

History

Although our awareness and understanding of viral hepatitis has risen dramatically over the last 4 decades, this is not a new problem. Descriptions of jaundice exist in the literature as far back as several centuries BC and are referenced in the Babylonian Talmud and the writings of Hippocrates (1). The infectious nature of the disease was first recognized in the 8th century BC

by Pope Zacharias (2). However, most of the reports of large population epidemics over the last several centuries were probably due to enteral transmission of what is now known as *hepatitis A*. It was not until the introduction of the practice of inoculation for smallpox vaccination in the 1880s that the percutaneous route of transmission of the disease was recognized (3). Numerous reports of jaundice occurring in patients receiving vaccines or injections for diabetes or syphilis followed during the early 20th century (4,5,6). The first association of blood transfusion with the development of hepatitis was reported in 1943 (7). The landmark studies of Krugman et al. at the Willowbrook State School in New York documented the transmissibility of hepatitis by human plasma (8) and confirmed the long-standing clinical observations that both parenteral ("serum hepatitis") and enteric ("infectious hepatitis") transmission could occur (9). Frustrating and largely unsuccessful efforts to identify the specific agents responsible for hepatitis continued over several decades (10). A serologic marker for hepatitis B was first identified by Blumberg in 1965 (11), although its association with the parenterally transmitted entity then known as *serum hepatitis was* not recognized until 2 years later (12). The recognition of the specific viral agents responsible for hepatitis B and A was made over the next few years (13,14). These discoveries were obviously major breakthroughs, but it quickly became apparent that most cases of hepatitis could not be explained by either the hepatitis A virus or the hepatitis B virus (HBV).

The entity of non-A, non-B hepatitis was formally christened by Prince in 1974 (15). An infectious agent was suspected on the basis of the observations that it was parenterally transmissible to chimpanzees and humans by blood transfusion (16). A series of experiments by Bradley et al. at the Centers for Disease Control and Prevention (CDC) characterized the nature of the infectious agent (17,18). Filtration studies suggested that the agent was between 30 and 50 nm in size. Its infectivity was abolished by chloroform, suggesting the presence of a lipid envelope (17), as well as by formalin, heat (100°C for 5 minutes or 60°C for 10 hours), and β-propiolactone ultraviolet light (18). However, the conventional virologic and immunologic techniques of the time failed to isolate the responsible agent. Scientists at Chiron Corporation, Emeryville, CA, and in Japan used a different tactic based on recently described molecular biologic techniques (19,20). This was based on Bradley's work, which suggested that the non-A, non-B agent was a virus. However, because the genomic nature of this putative virus was not known (although a flavi-like ribonucleic acid [RNA] viral agent was suspected), both deoxyribonucleic acid (DNA) and RNA were extracted for cloning from a large volume of infected serum (19). After extensive ultracentrifugation, which was sufficient to pellet down the smallest of known infectious agents, total nucleic acid was extracted and both RNA and DNA were converted to complementary DNA (cDNA). Restriction fragments were cloned into a recombinant bacteriophage vector to form a cDNA library. These phages were then inserted in *Escherichia coli* capable of transcribing and expressing the encoded peptide, and the resulting products were screened against sera from patients with non-A, non-B hepatitis under the assumption that sera from infected patients should contain antibody against the agent. After more than 1 million clones were screened, 5 clones were found to be reactive. Of these, one clone (5-1-1) was shown to bind not only antibodies present in the serum of patients with non-A, non-B hepatitis but also those in experimentally infected chimpanzees who appeared to seroconvert several weeks after exposure (21). Identification of other clones with overlapping regions of the viral complimentary DNA allowed these investigators to establish the entire viral genome.

This breakthrough led to an explosion of research on this viral agent, now designated as *hepatitis C virus* (*HCV*), and its disease, now called *hepatitis C*. With the development of antibody-based detection systems (see later), HCV was found to be the major cause of non-A, non-B hepatitis (22,23,24). An estimated 170 million persons worldwide are infected by HCV, and it is perhaps the most common cause of chronic liver disease in the United States.

Virology

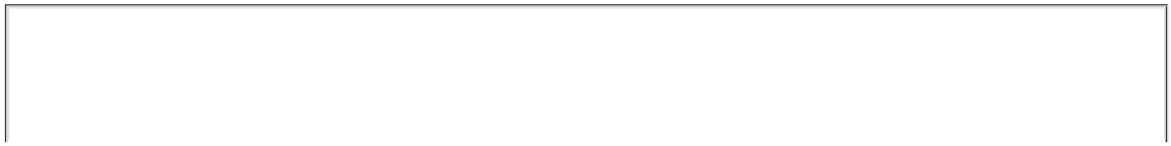
HCV is the only member of the Hepacivirus genus of the Flaviviridae family. The viral genome is contained within a nucleocapsid that is encased in an envelope derived from host membranes into which viral-encoded glycoproteins are inserted (25). Spherical 50-nm viral particles have been identified by electron microscopy (26,27). Two populations of virus appear to exist in serum on the basis of density-gradient analysis (26). The high-density fraction is thought to represent free or immunoglobulin-bound virus, whereas a lower-density fraction appears to be bound to low-density lipoproteins (LDL) (28,29). The pathogenic significance of the latter is discussed later.

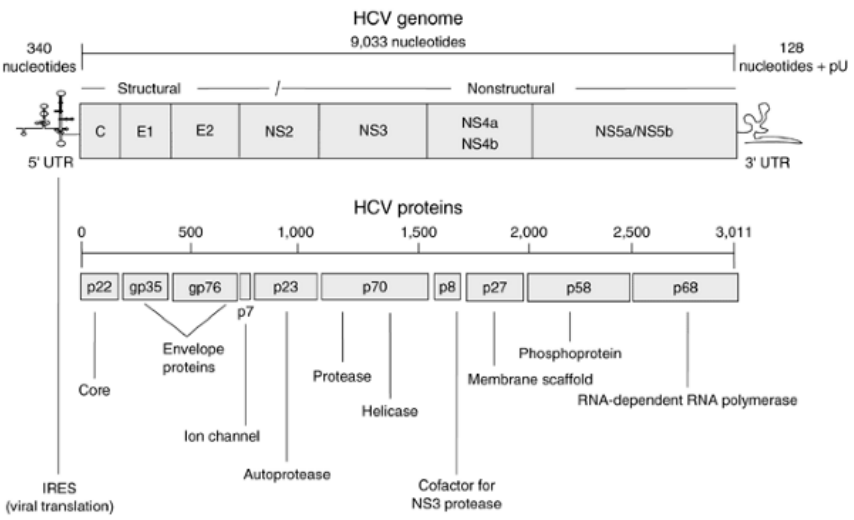
Genomic Organization, Viral Proteins, and Replication

HCV contains a 9.6-kb positive-sense, single-stranded RNA genome that consists of a highly conserved 341-base 5′ noncoding region, a single long open reading frame (ORF) of 9,033 to 9,099 bases, and a 3′ noncoding region. The ORF encodes a polyprotein precursor of approximately 3,000 amino acids (25). This polyprotein is cleaved co- and post-translationally by both

cellular and viral proteases to produce at least ten polypeptides with various functions in replication and virus assembly (30,31) (Fig. 30.1).

On the basis of phylogenetic tree analysis, genetic organization, and hydrophobicity patterns, HCV is related to flaviviruses and pestiviruses and distantly to plant viruses (32). However, HCV has sufficient diversity to justify classification into a separate genus and therefore it has been assigned as the single member of the Hepacivirus genus of the family Flaviviridae (33). The nomenclature of the respective viral proteins is also in accordance with that of the Flaviviridae family (34). Given the factors that influence viral diversity, it is difficult to estimate the age of the HCV by phylogenetic analysis. Nonetheless, ancestors of the oldest genotypes of HCV probably originated in western and sub-Saharan Africa (genotypes 1, 2, and 4) and Southeast Asia (genotypes 3 and 6) (33). Some genotypes and common subtypes evolved later. For example, the subtypes of genotype 2 probably evolved within the last 90 to 150 years. Subtypes 1b likely evolved 60 to 70 years ago, and its global distribution suggests that it disseminated over a short period (33). The recent evolution of genotype 3a (about 40 years) and its high prevalence among intravenous drug users suggest that it may have evolved and spread through the practice of needle sharing in the 1960s (33).





▪ **Figure 30.1** Hepatitis C virus (HCV) genome and encoded polyprotein showing regions and functions. C, core; E, envelope; NS, nonstructural; IRES, internal ribosomal entry site; UTR, untranslated region; RNA, ribonucleic acid; pU, poly-uradine.

Virus Replication

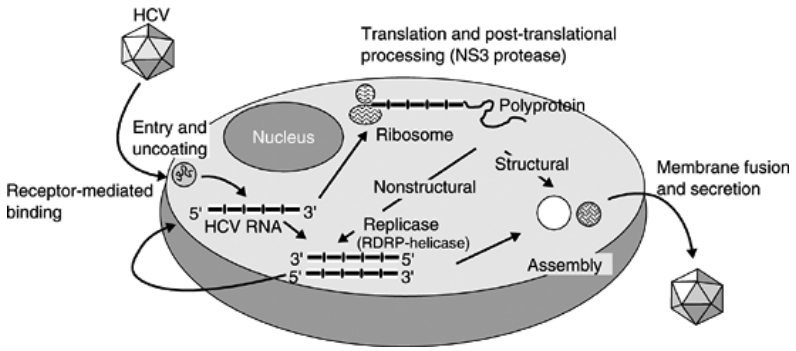
Identification of HCV in the cytoplasm of hepatocytes by immunohistochemistry and in situ hybridization suggests that the liver is the site of viral replication (35,36). This is further supported by the detection of negative-strand HCV RNA, the replication template, in hepatocytes. Although there is some evidence to support extrahepatic reservoirs of virus, including lymphocytes, gut epithelial cells, and the central nervous system, it remains unclear whether these sites simply harbor virus or are actually sites of replication (37,38,39).

Our early understanding of the replication of the HCV was based on the assumption that it must resemble the replication of genetically related flaviviruses. An important breakthrough was the creation of functional subgenomic replicons by Lohmann et al. in 1999 (40). These replicons consisted of subgenomic (incomplete) HCV RNA engineered to express a selectable marker (e.g., neomycin resistance) instead of a virus-related gene, in this case the structural gene region. A heterologous internal ribosomal entry site (IRES) was inserted to facilitate the expression of nonstructural proteins. This replicon was then inserted into Huh-7 human hepatocellular carcinoma cells and transfected cells were selected. Subsequently, replicons derived from other genotypes (Lohmann's original replicon was genotype 1b) and nonhuman and nonliver cell lines have been

used. It became apparent that replicon RNA developed adaptive mutations that allowed it to replicate efficiently in cell culture and these increased replication manyfold (41). One persistent problem with replicon systems was that they did not release viral particles into the media despite containing the full-length HCV genome. The reasons for this were not entirely clear, but it appeared that the adaptive mutation that allowed it to replicate in culture prevented virus assembly. Recently, a full-length replicon derived from a genotype 2a isolate from a Japanese patient with fulminant hepatitis was found to replicate in culture without adaptive mutations and produce infectious particles (42). Despite the engineered and artificial nature of these recombinant constructs, these cell-based replicon systems have provided incredible information on HCV replicative mechanisms and they have also proved useful in screening potential therapeutic agents.

Figure 30.2 illustrates a simplified view of the infection and replication of the HCV in the hepatocyte (43). The mechanisms of HCV attachment and cell entry are still poorly understood. The envelope proteins E1 and E2 contain several *N*-linked glycosylation sites that are conserved and critical for cell entry and protein folding (44). E2 on the HCV particle surface binds to the extracellular loop of the human tetraspanin CD81 with high affinity (45). Although CD81 may serve as an essential attachment receptor for HCV, this binding is not sufficient for cell entry and, in fact, it internalizes ligand poorly (46). Other putative receptors that may participate in HCV entry include the LDL receptor (28,47), scavenger receptor class-B type 1 (SR-B1), liver/lymph node–specific intercellular adhesion molecule 3–grabbing integrin (L-SIGN), and dendritic cell–specific intercellular adhesion molecule 3–grabbing nonintegrin (DC-SIGN) (48). Once bound, the viral and cell membranes fuse, the virus is transported into the cell in an endocytotic vesicle whose acid pH uncoats the virus, releasing the positive strand of the

HCV RNA into the cytosol.

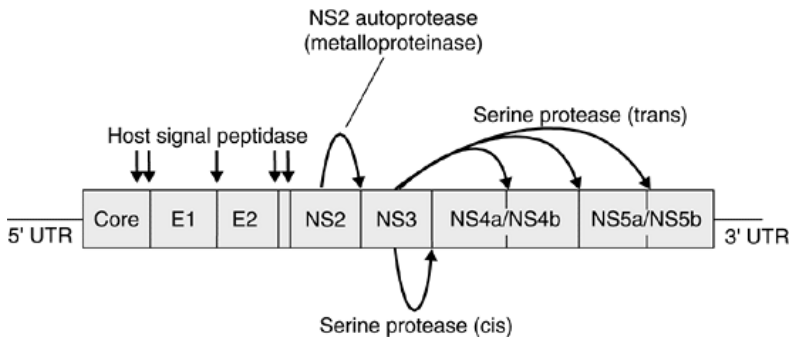


▪ **Figure 30.2** Schematic of the intracellular replication cycle of the hepatitis C virus (HCV). Replication takes place within the cytoplasm and is associated with the endoplasmic reticulum membrane. Assembly occurs in the Golgi. RNA, ribonucleic acid; RDRP, RNA-dependent RNA polymerase.

The 5′ end of the HCV genome contains a highly conserved 341-nucleotide region with a complex secondary structure containing four stem loops or hairpins (49). This untranslated region (UTR) contains critical features necessary for replication and initiation of protein synthesis. First, the last stem loop of the 5′ UTR and the initial part of the core gene functions as an IRES, similar to that first described in poliovirus (50,51). Because HCV lacks a 5′ cap, and therefore does not replicate within the nucleus, it requires an IRES to direct and bind it to ribosomal subunits in the cytoplasm to form the translation complex where HCV replication ensues (51,52,53). This causes conformational changes in the ribosome and binding to eucaryotic initiation factor 3 (eIF3) that serves to position the AUG start codon of the viral structural gene at the decoding site of the endoplasmic reticulum membrane. In this way the positive-strand RNA serves as the messenger for translation of viral proteins.

The ORF of HCV encodes an uninterrupted stretch of 3,011 amino acids, which contains the viral proteins that are necessary for viral replication. This large polyprotein is processed co- and post-translationally by cellular and viral proteases into numerous polypeptides (Fig. 30.3). The proteins encoded by the gene are, in order from the N terminus, the structural proteins, C, E1, E2, and p7, followed by the nonstructural proteins, NS2, NS3, NS4a, NS4b, NS5a, and NS5b. The structural proteins are encoded by nucleotides in the 5′ third of the genome. Three proteolytic activities mediate the cleavages separating structural from nonstructural proteins (Fig. 30.3). Internal leader sequences within the structural precursor direct precise cleavage of the proteins by host signal peptidases within the rough endoplasmic reticulum (54). The structural proteins are produced in

more than 100-fold excess compared to positive- and negative-strand RNA (55).



▪ **Figure 30.3** Hepatitis C virus genome showing protease cleavage sites for corresponding polyprotein. E, envelope; NS, nonstructural; UTR, untranslated region.

The nucleocapsid or core is an unglycosylated basic protein, with RNA-binding capacity controlled by its N terminus and an essential signal for translocation to the endoplasmic reticulum located in the C terminus.

The core protein modulates cell-signaling pathways, transcription, and transformation through its interactions with host proteins. Its sequence is highly conserved and contains several B-cell epitopes (40).

The envelope proteins are highly glycosylated, and some of these glycans play an essential role in protein folding and cell entry (44,56). The proteins are type I transmembrane glycoproteins with tails that serve as endoplasmic reticulum retention signals. They form noncovalently linked heterodimers and disulfide-linked aggregates, the latter being misfolded forms (56). Immune electron microscopic studies have confirmed that these proteins do, indeed, form the structural envelope of the virus (26). Both envelope proteins contain several B-cell epitopes including neutralizing epitopes. The N-terminal residues of E2 exhibit significant amino acid variation between viral genotypes and even within the same host (quasispecies) (57). These variable regions, termed *hypervariable regions* (*HVR1* and *HVR2*), are highly unstructured and are therefore able to tolerate considerable sequence variation (57). Much of this variability may be the result of immune pressure from neutralizing antibodies. Indeed, HVR1 is expressed on the viral surface, and its variability probably contributes in part to the ability of the virus to escape neutralizing antibodies (58). Studies in chimpanzees appear to confirm this because antibody against E2 confers only transient protection against HCV infection (59). p7 is a small protein that is required for replication and may function as an ion channel (60).

In sequence, the nonstructural proteins are then cleaved from the polyprotein. First, the viral autoprotease, a zinc-dependent proteinase encoded by NS2, cleaves the NS2/NS3 junction (61,62). Second, the serine protease, a chymotrypsin-like enzyme encoded by N-terminal third of the NS3 region, cleaves the remaining nonstructural viral proteins at NS3/NS4a, NS4a/NS4b, NS4b/NS5a, and NS5a/5b junctions (Fig. 30.3) (63,64,65). The enzyme is obviously essential to viral replication and contains three highly conserved sites that are thought to represent the catalytic triad of the enzyme (66). The reversible binding of NS4a acts as a cofactor for the protease, allowing the enzyme to assume a more traditional trypsin-like configuration and increasing activity (67). Binding of NS4a to the protease also increases the stability of the enzyme and directs it to the endoplasmic reticulum (68). Interestingly, NS4a from heterotypic isolates can also activate the NS3 protease, although genotype 2 NS4a is a less efficient cofactor (69). In vitro studies have shown that the NS5a/NS5b junction is the most efficiently cleaved site. Protease activity is susceptible to inhibition by its cleavage products (70). The carboxy end of NS3 encodes a nucleotide triphosphatase energy source and another NS3 enzyme, the nucleoside triphosphate-binding RNA helicase, which is thought to facilitate unwinding of the RNA strands during replication (71). The unwinding activities of HCV helicase operate at the 3′ UTR for the generation of the negative-strand RNA replication template and at the 5′ UTR for the production of positive-sense RNA for assembly into infectious viral particles. The NS4 region is cleaved next, producing the NS4a and NS4b proteins. The C terminus of NS4a has been shown to be a cofactor of the NS3 serine protease as described in the preceding text (65,72). It is not essential for the function of the protease but stabilizes it and significantly improves its efficiency (66,67).

The function of NS4b has recently been clarified. It produces vesicular structures in hepatocytes that serve as a membranous web or scaffolding for the replication complex (see subsequent text) (73). NS5a is a phosphorylated protein that has been implicated in RNA binding and interferon (IFN) resistance, at least in some

isolates (74). The region has also been found to contain mutations that allow efficient replication of HCV replicons in Huh7 hepatocellular carcinoma cells (41).

The NS5b region contains the viral RNA–dependent RNA polymerase that elongates HCV RNA strands during replication (75). The enzyme is produced in excess because only approximately 1% of the total polymerase content appears to participate in replication (76). The nonstructural components assemble with the polymerase to form the membrane-associated replication initiation complex. Host cellular factors are involved with this complex as well. This multisubunit, membrane-associated replication complex is called *replicase*. The stem loop structures at the 3′ end of the coding region, but not the entire 3′ UTR, are critical for specific binding of NS5b and probably explain the specificity of the HCV polymerase (77). After binding of the 3′ end of the positive strand to the replication complex, the nascent negative–stranded RNA is elongated and the viral helicase helps separate the RNA strands (71). The negative strand of genomic length can then serve as the template for the production of nascent-positive RNA strands, which can be incorporated into the nucleocapsid that is then encoated with the viral envelope to form the mature HCV virion progeny (78,79,80,81). The HCV particles then bud from the hepatocyte.

The in vivo dynamics of HCV replication have been investigated in humans. On the basis of these studies, it is estimated that HCV replication results in more than 10^{12} viral copies per day (82). Because the half-life of these particles is short (about 2.7 hours), there is a turnover of more than 99% of viral particles daily (82). Turnover is slower (<1% to 33% per day) in infected cells, and the longevity of these hepatocytes is estimated to be 1.7 to 70 days (82).

Genetic Heterogeneity

The HCV RNA polymerase is error prone because it lacks a proofreading exonuclease. As a result of this

low-fidelity system of replication, random uncorrectable nucleotide errors are inevitably introduced, resulting in a heterogeneous population of viral genomes. The spontaneous nucleotide substitution rate of HCV is very high, with a frequency of between 10^{-2} and 10^{-3} substitutions per nucleotide site per year (57,83). Many of these substitutions are lethal and are not reproduced, whereas others do not result in amino acid changes and therefore remain silent. Some amino acid changes may result in increased susceptibility to elimination by the immune system and disappear quickly. Still other substitutions, especially in aggregate over time, can result in amino acid changes that have the potential to alter the biology of the virus. Regardless of the outcome of substitutions at individual sites, the virus as a whole is continually undergoing genetic evolution. As a result, HCV is a heterogeneous virus, with only approximately 70% homology among all known isolates, a level of variability similar to that of other flaviviruses (84). Obviously, the sequence heterogeneity is not evenly distributed throughout the genome. Sequences essential to replication and function are highly conserved because of constraints imposed on nucleotide substitution by secondary structures (85). For example, the 5′ UTR is 95% to 99% conserved, as is the catalytic triad site in the NS3 protease. Less well-conserved regions include core (81% to 91%), envelope (E1, 55% to 75% and E2, 65% to 72%), NS2 (57% to 71%), NS3 (70% to 80%), NS4 (65% to 79%), and NS5 (66% to 79%) (86).

Genotypes

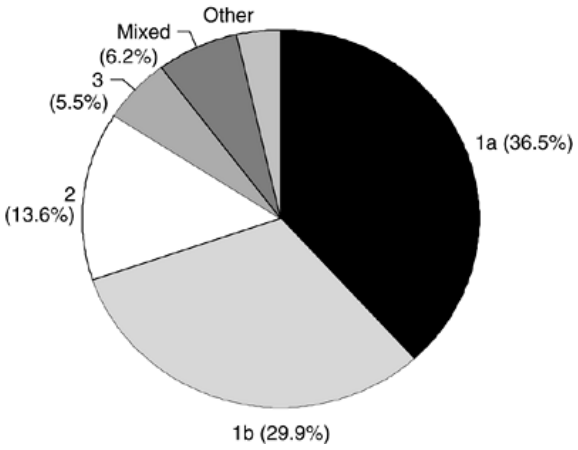
Isolates of a virus are usually distinguished by their genetic relatedness (genotype), much as bacteria, and sometimes viruses, are often separated by antibody reactivity (serotypes). The striking genetic heterogeneity of HCV suggested that the virus might have different genotypes. The validity of this reasoning was supported by a combination of molecular biology and statistical techniques including pair-wise distance determination and phylogenetic tree construction. Different isolates could indeed be classified by their nucleotide variability into genotypes or subtypes (33,86,87). Isolates of the same genotype have an average sequence homology of 95%, with a range of 88% to 100% on the basis of sequencing of relatively well-conserved regions of E1, NS4, or NS5. Subtypes within the same genotype have an average sequence homology of about 80% (range, 70% to 85%). By contrast, different genotypes have sequence similarity of only about 65% (range, 55% to 70%). The distribution of divergence is discontinuous, making the genotypes distinctive relatives rather than a spectrum of variants resulting from random genetic drift (86). A consensus system for HCV nomenclature based on sequence homology in at least two regions confirmed by phylogenetic tree analysis has been established by Simmonds et al. (88). In this system, major genotypes are assigned a number, and subtypes within each genotype are assigned a small letter. The numbering and lettering are assigned in the order in which the type or subtype was originally identified (88). There are six HCV genotypes and more than 100 subtypes. Reports of other genotypes have not withstood scrutiny. HCV genotypes 7, 8, and 9 were proposed several years ago on the basis of unweighted pair-group method with the arithmetic mean analysis of isolates from Southeast Asia (89). However, reanalysis by conventional phylogenetic analysis found these isolates to be subtypes of genotype 6 (88,90). Similarly, reanalysis of isolates reported to represent genotypes 10 and 11 showed that

they were most appropriately classified within types 3b and 6, respectively (91).

There are many methods for determining viral genotype. Although the most accurate is undoubtedly the sequencing of the complete 9,500 nucleotide genome with subsequent phylogenetic tree construction, this is prohibitively expensive and time consuming (92). Furthermore, multiple clones would need to be examined to exclude mixed genotype infections. Therefore, subgenomic genotyping methods have evolved, which are usually based on relatively well-conserved regions of the genome such as the 5′ UTR, core, E1, and NS5b. The nucleotide sequences within these relatively conserved regions are genotype specific, and therefore isolates can be accurately typed regardless of which of these regions is used for analysis (86,87,93). Subgenomic genotypic methods include amplification and region sequencing (94), polymerase chain reaction (PCR) with genotype-specific primers (95), restriction fragment length polymorphism of PCR amplicons (96), differential hybridization including the reverse hybridization line probe assay (LiPA, Bayer Diagnostics, Emeryville, CA) (97), and serologic genotyping (98). The line probe assay is the most popular commercial assay for genotyping. In general, these methods produce equivalent results when confirmed by amplification, sequence comparison, and phylogenetic tree construction (93). However, the method using PCR based on type-specific primers derived from the core region has been shown to be unreliable because its 1b primers frequently react with non-1b isolates, falsely suggesting a mixed genotype infection (95). This technique was one of the first genotyping methods described and was based on the very limited sequence data available at the time. Subsequent modification of the method has apparently resolved these drawbacks (99).

HCV genotype 1 is the most common genotype (40% to 80%) and has a worldwide distribution. Subtypes 1a and 1b are the most prevalent in the United States, each accounting for about a third of cases (Fig. 30.4) (100). Subtype 1b is the most prevalent genotype in Europe, Turkey, Japan, and Taiwan. Genotype 2 is also widely distributed but is less common than genotype 1 (10% to 40%). Type 3 is more common in India, Pakistan, Australia, and Scotland. Type 4 is found predominantly in the Middle East and Africa, type 5 in South Africa, and type 6 in Hong Kong and Macau (86). The geographic differences in genotype

distribution appear to result from several factors. The geographic segregation of genotypes 4 and 6, their phylogenetic distances from more common genotypes, and the diversity within these genotypes all suggest that the major genotypes diverged and evolved in isolation, beginning 500 to 2,000 years ago. By contrast, the common subtypes of genotypes 1 and 2 are more widely distributed and less genetically diverse, suggesting that they evolved more recently, perhaps within the last 50 to 300 years, and were spread by population migration (33,101,102).



▪ **Figure 30.4** Hepatitis C virus genotype distribution in the United States. (See reference 93.)

Quasispecies

Nucleotide substitution over time results in the evolution from a single isolate of HCV to a highly related but heterogeneous population of isolates known as *quasispecies* (103). Sequences begin to diverge about 8 weeks after infection, possibly related to the development of an HCV-specific host immune response (104). Thereafter, the same isolate may evolve into different populations of quasispecies in different patients (105). This probably reflects both some degree of randomness in nucleotide substitution and selective immune pressure. Furthermore, the diversity of the quasispecies probably reflects the duration of infection and the level of replication (103,104,105). Taken together, these factors result in a level of divergence after 11 to 15 years that is just as great among patients infected by the same isolate as it is in unlinked subjects (104). Nonetheless, overall sequence diversity is usually less than 5% in most infected individuals with chronic infection, even after decades of infection. The pathobiologic implications of HCV quasispecies are not well understood but they might play some role in recovery and persistence (106). The implications of quasispecies to the pathogenesis, natural history, and therapy of liver disease are discussed later.

Host Responses and Pathogenesis of Liver Disease

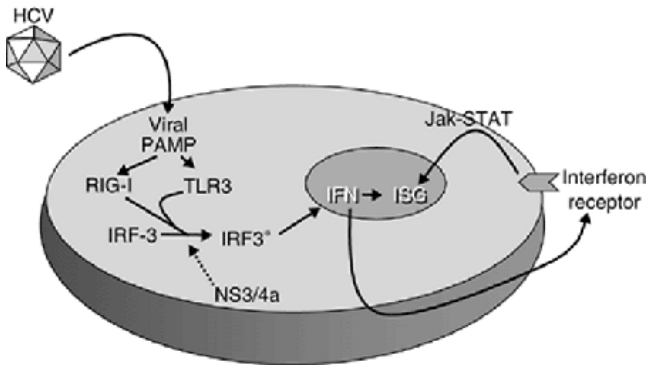
Multiple factors influence the interaction between the HCV virus and the infected host, thereby resulting

in an extremely variable presentation of the infection and liver disease. Viral factors include replication efficiency, expression of viral proteins, virus genotype and diversity, immunoreactivity of viral peptides, and, perhaps, direct liver cell injury. Host factors may include the competence of the innate immune response, local and systemic cytokine production, humoral response, and cellular immune responses. Finally, environmental factors such as alcohol intake and exogenous immune suppression may affect the course of disease. The lack of a small animal or efficient cell culture model has hampered efforts to better define the immunopathogenesis of HCV infection. As a result, most studies have been observational in infected patients. Not surprisingly, the results of these studies are often quite disparate and difficult to interpret because individual variation in the host immune response and subtle methodologic differences in experimental design may influence the findings.

It has become increasingly apparent that persistence of the virus and resistance to IFN-based therapy are related to the host's inability to overcome the viruses' defense mechanisms. The critical factor for virus clearance is the ability of the host to mount and sustain an endogenous IFN response. As described in the subsequent text, the virus works to ameliorate this response and in so doing lessens the chance for early viral clearance and subsequent immune-mediated responses. Viral heterogeneity may also contribute to persistence, but is likely not sufficient in and of itself.

Innate Host Antiviral Defenses

Proteins and nucleic acids of viruses trigger receptors that initiate antiviral mechanisms within the cells (107). The triggers for these mechanisms, termed *pathogen-associated molecular patterns* (*PAMPs*), may include viral envelope proteins or double-stranded RNA segments within the HCV genome (e.g., stems and loops in the UTRs) (108). In the case of HCV, two major pathways exist to initiate host defenses, namely the retinoic acid inducible gene-I (RIG-I) and the toll-like receptors (Fig. 30.5) (109,110). Activation of these pathways by PAMP awakens latent cellular transcription factors that trigger the expression of early response genes in the host cell. IFN regulatory factor-3 (IRF-3) and nuclear factor κB (NF-κB) are the major factors that trigger this response, although other IFN regulatory factors may also be involved (111). This process leads to the secretion of type 1 IFNs in and from the infected cell (112). NF-κB also induces other chemokines and proinflammatory cytokines that modulate the inflammatory response to infection. The secreted IFN then engages its cell surface receptor on both the infected and adjacent cells and activates the Jak-STAT pathway through which dozens of IFN-stimulated genes that produce protein kinases, oligoadenylate synthetase, and other host-protective factors are activated (113). IFN primes the further production of both IFN and the IFN-sensitive genes, thereby amplifying the antiviral responses even further. Finally, IFN modulates the host immune response by enhancing cell surface antigen expression and promotion of immune effector cells.



▪ **Figure 30.5** Schematic of the host innate antiviral responses to hepatitis C virus (HCV) infection. Pathogen-associated molecular pattern (PAMP) bind to retinoic acid inducible gene-I (RIG-I) or toll-like receptor (TLR3) resulting in the phosphorylation (*) and activation of IFN regulatory factor (IRF-3). IRF-3 translocates to the nucleus where it results in interferon (IFN) production. Interferon leads to activation of the Jak-STAT pathway and induction of interferon-sensitive genes (ISGs). NS, nonstructural. (See references 107 and 114.)

The effectiveness of the host response to infection relates in large part to the ability of the infected host to activate and sustain these innate cellular defenses. Some of these responses may be genetically regulated, but it also appears that the levels of IFN signaling, IFN response gene induction, and HCV-induced adaptive immune responses are controlled by the virus itself (Table 30.1) (107). Perhaps most importantly, the NS3/4a protease complex disrupts activation of IRF-3 and NF-κB by the RIG-I and toll-like receptor signaling paths. This reduces the ability of the host to effectively express antiviral defense genes and interrupts

the IFN amplification loop that attempts to suppress HCV replication (114).

Table 30.1. Influence of Hepatitis C Viral Components on Host Antiviral Responses

HCV viral component	Effect on host antiviral response
AUGMENT HOST RESPONSE	
HCV viral particle	Binding to dendritic cell activates host IFN production and immune induction
dsDNA	Triggers IFN and activates PAMPs
Core	Activates PKR

NS5a	Activates STAT3
INHIBIT HOST RESPONSE	
E2	Inhibits PKR
Core	Increased suppressor of cytokine signaling blocks Jak-STAT signaling
NS3/4a protease	Disrupts RIG-I and TLR3 signaling for IRF-3 activation
NS5a	IFN antagonist
	Induces IL-8 that interferes with IFN actions
	Inhibits PKR signaling and IRF-1 action
HCV genomic sequences	RNase L recognition sites reduced in genotype 1

HCV, hepatitis C virus; IFN, interferon; dsDNA, double-stranded deoxyribonucleic acid; PAMP, pathogen-associated molecular patterns; PKR, protein kinase R; NS, nonstructural; E2, envelope protein 2; RIG-I, retinoic acid–inducible gene-I; TLR, toll-like receptor; IRF, interferon regulatory factor; IL, interleukin; RNase, ribonucleic acid proteinase.

Acquired Immunity

The host immune response to HCV infection is composed of both a nonspecific immune response, including endogenous cytokine production (see preceding text) and natural killer (NK) cell activity, and a virus-specific immune response, including both humoral and cellular components (Table 30.2). Antibodies to HCV structural and nonstructural proteins develop late during acute infection and form the basis for the detection assay of the host's exposure to the virus (See "Diagnostic Tests"). A variable cellular immune response also occurs early during acute infection and results in the emergence of $CD4^+$ and $CD8^+$ cells that recognize and respond to processed HCV antigens.

Humoral immune response

Evidence for activation of the host humoral response in HCV infection includes the presence of hepatic lymphoid aggregates containing activated B cells (115), elevated levels of the B-cell–activating interleukin-4 (IL-4) (116), and a B-cell–mediated response with the production of antibodies to several structural and nonstructural polypeptides (117). Antibodies to HCV peptides form the basis of current diagnostic assays (See "Diagnostic Tests"). However, the role of this humoral immune response in the control of infection and pathogenesis of liver disease is still largely unknown.

Antibodies to HCV antigens develop in most acutely infected patients within 4 to 8 weeks of the onset of infection. However, their relatively late onset, low level during acute infection (117,118), decrease and occasional disappearance when infection resolves (119,120), and persistence at higher levels when infection persists raises questions about their relevance in control of infection. Nonetheless, the humoral response may influence liver disease associated with HCV infection in other ways such as extracellular viral neutralization. Antibodies against envelope proteins often have neutralizing capability that could prevent viral entry into uninfected cells. Antibodies against conserved epitopes of the HCV envelope proteins (E1, E2) are found in more than 90% of patients with chronic HCV infection (117). However, the persistence of infection in most patients with anti-E1/anti-E2 suggests that either the antibodies do not have sufficient neutralization ability or the target is not relevant to viral persistence. There is no doubt that neutralizing antibodies can be raised, and these can even neutralize infectious virus ex vivo, thereby preventing infection (121,122). However, the in vivo neutralizing antibody response is usually weak and short lived. Farci et al. demonstrated that the infectivity of plasma can be neutralized by serum obtained from the same chimpanzee 2 years after infection but not by serum obtained 11 years later, presumably because of the evolution of quasispecies (123). Similarly, in other experiments, convalescent animals could be reinfected by either heterologous or autologous challenge (124). Therefore, it appears that

although neutralizing antibodies are formed, evolution of the virus may allow escape from this response. This is not unexpected because the envelope proteins are not highly conserved. E2 contains two HVRs in which nucleotide substitutions are largely unconstrained and wide genetic differences evolve. It has been suggested that antibodies to these regions (especially HVR1) neutralize existing strains of the virus and drive genetic drift, but this is controversial and most recent evidence weighs against such an effect (125,126,127,128).

Table 30.2. Summary of Components of the Hepatitis C Virus

HUMORAL
Activated B cells in lymphoid aggregates
Peripheral expansion of $CD5^+$ B-cell population
Antibodies to structural and nonstructural peptides
No evidence for antibody-dependent cellular cytotoxicity
CELLULAR
Innate
Inflammatory cytokine and IFN release
Natural killer cell activation
Natural T-cell activation
CD4 lymphocytes
Early response
Augments antibody production by B cells
Primarily act peripherally
Possible role to control infection and protect liver
Stimulates CD8 cells
Later response
Compartmentalization to liver
May target different HCV peptides from peripheral CD4
CD8 lymphocytes
Compartmentalization in liver
Predominant infiltrating lymphocyte
Probable role in controlling replication and causing liver injury
Activity possibly results from upregulation of adhesion molecules to recruit CD8 cell upregulation of Fas proteins may facilitate CD8 target killing induction of local cytokine release (IFN-γ, TNF-α)
Cytokine response
T_H1 response early in infection and persists locally in liver
T_H2 response may be a peripheral autoregulatory response to T_H1 activation

HCV, hepatitis C virus; IFN, interferon; TNF, tumor necrosis factor.

Antibodies may also direct the destruction of their bound target through activation of other mechanisms, specifically the complement-mediated antibody-dependent cell-mediated cytotoxicity (ADCC). However, for these antibodies to contribute to cell injury, they must recognize HCV antigens on the hepatocyte cell membrane. Although HCV antigens (core, E1, E2, NS3, and NS4) have been detected in the cytoplasm of infected hepatocytes, membranous antigens have not been observed (129). Even when intracellular expression of HCV viral proteins is driven to very high levels by a recombinant vaccinia system, neither HCV antigens nor immunoglobulins could be detected on the cell membrane (130). These data suggest that ADCC is unlikely to play an important role in mediating hepatocellular damage.

Although evidence suggesting a role for the humoral response in HCV liver disease is still lacking, the antibody response may be associated with other manifestations of infection (See "Extrahepatic Manifestations"). It has been suggested that binding of HCV to the CD81 receptor on B cells could activate these cells, thereby facilitating the production of antibodies (131,132). Indeed, patients with chronic HCV infection commonly develop autoantibodies (133). One of these, the antibody to the human-derived epitope GOR, appears to result from molecular mimicry between the HCV core sequence and GOR (134). This is supported by the rarity of anti-GOR in patients infected with HCV genotype 3, which has amino acid differences within the proposed molecular mimicry site. However, there is no evidence to suggest that autoantibodies have clinical significance or a role in disease pathogenesis (135).

Humoral activation during HCV infection is not limited to antibody production. More than half the patients with chronic HCV infection show expansion of $CD5^+$ B lymphocytes in peripheral blood (136). Again, this

might be related to binding of HCV to B-cell CD81 receptors (131,132). Activation of CD5 B cells has previously been associated with autoimmune diseases such as rheumatoid arthritis (137), and it is possible that a similar mechanism plays a role in the development of B-cell lymphomas in patients with HCV infection (138). HCV is also associated with the development of mixed essential cryoglobulinemia, in which deposition of immune complexes composed of inmmunoglobulin G (IgG) and rheumatoid factor precipitates in small blood vessels (139). This appears to be due to antigen-driven benign proliferation of B cells. The mechanism may be through the CD81 mechanism discussed earlier or due to impaired ability of hepatocytes to endocytose HCV–very low density lipoprotein (VLDL) complexes containing apo E2 through the LDL receptor. Retention of the complexes in the circulation may then stimulate rheumatoid factor production (139).

Cellular immune response

The cellular immune response to viral infection involves innate nonspecific mechanisms, such as those described in the preceding text and NK cell activity, and adaptive antigen-specific mechanisms, including cytotoxic T lymphocytes with accompanying inflammatory cytokine release (Table 30.2). Although nonspecific cellular responses may act early to limit some infections, eradication of infection appears to also require specific and classical $CD4^+$ and $CD8^+$ cytotoxic T-lymphocyte (CTL) responses. However, as previously described, activation of endogenous antiviral mechanisms and adaptive cellular responses may be linked.

In contrast to the humoral response triggered by the binding of unprocessed extracellular antigens to B-cell immunoglobulin receptors, the cellular (T-cell) immune response is triggered by peptides that have been processed within the cell cytoplasm and expressed on cell membranes in conjunction with a major histocompatibility complex (human leukocyte antigen [HLA])

molecule. Processed peptides are generally presented to $CD8^+$ T cells by HLA class I molecules, which are expressed on virtually all cells, or to $CD4^+$ T cells by the HLA class II molecules, which are found on specialized antigen-presenting cells. Although the subsequent events that lead to the death of the infected presenting cells are not entirely clear, both direct cytolysis and secreted antiviral factors (tumor necrosis factor-α [TNF-α] and IFN-γ) can be implicated.

Innate cellular response

The liver has a dense population of lymphoid cells representing approximately 10% of all lymphocytes and 35% of T lymphocytes in the host (140). These cells comprise a highly regulated immune environment within the liver for monitoring and implementing responses to foreign stimuli. The innate response is the earliest phase of immune defense to viral infection and helps regulate the subsequent adaptive responses of the host. Over a third of hepatic lymphoid cells are NK cells that can be nonspecifically activated by a variety of signals and are able to kill targets in the absence of antibody or antigenic stimulation. Histocompatibility antigen expression appears to inhibit NK activity. In the case of viral infection, downregulation of endogenous class I histocompatibility antigens occurs, possibly to assist the virus in evading CTLs, and this may result in early NK cell activation (141). NK cells appear to exert their activity against HCV by releasing IFN-γ (142), but it appears that they are only able to control acute infection at low levels of replication (143). Natural T (NT) cells (also called innate T cells) are $CD3^+$, common in the normal liver, and prevalent in HCV-infected liver (144). These cells produce IL-4 and probably play a role in modulating both early and subsequent immune responses. Finally, memory HCV–specific T cells are sometimes present before HCV exposure because of cross-reacting antigens. For example, immunodominant HCV-specific CTL response to the NS3 epitope can be induced by influenza A infection because of sequence homology between NS3 and the neuraminidase protein (145). Although these latter two cell types are active in HCV infection, their role in the initial control of infection is not known.

$CD4^+$ T-lymphocyte response

The $CD4^+$ T-cell response to viral proteins is critical for host protection. It occurs early, augments antibody production by B cells, and is a prerequisite for subsequent $CD8^+$ T-cell responses, including those that are specific for virus-infected cells (146,147). Therefore, its role has typically been viewed as a protective one. $CD4^+$ T-cell responses to viral infection have traditionally been determined by measuring the ability of these peripheral lymphocytes to proliferate or produce IFN-γ when exposed to viral proteins. No one viral antigen is responsible for this $CD4^+$ response, although peptides derived from core and NS4 result in the strongest proliferative responses (148). Interestingly, proliferative $CD4^+$ responses are most robust in infected individuals in whom acute infection resolves (149), who have persistent infection without histologic evidence of liver damage (150), or who have chronic hepatitis that responds to IFN (151). These observations suggest that a vigorous $CD4^+$ response to HCV infection provides early control of infection and protects against subsequent hepatocellular damage.

The studies of peripheral blood proliferative responses must be considered with some degree of skepticism because these circulating $CD4^+$ cells may not accurately reflect the immunologic climate at the

site of infection. Indeed, it appears that HCV-specific proliferative responses tend to home in on the liver once chronic infection is established (152). Although studies of intrahepatic $CD4^+$ responses have been limited, proliferative responses to core, E1, and NS4 have been reported (152,153). Several striking differences from peripheral $CD4^+$ responses have been noted. First, the reactive $CD4^+$ clones do not always react to the same HCV peptides that are recognized peripherally (152), and second, proliferative response appears to correlate with more active liver disease (153). Finally, intrahepatic $CD4^+$ T cells differentiate into both T-helper cell 1 (T_H1) (IFN-γ) and T_H2 (IL-4) populations, although the former predominate (154).

In summary, $CD4^+$ cells play a role early in infection, perhaps by local cytokine production, providing help for B cells and protection of the hepatocyte from injury. $CD4^+$ cells seem to compartmentalize to the liver after the resolution of the acute phase, produce predominantly T_H1 cytokines, and may even generate or directly develop HCV-specific CTL activity (146). However, $CD4^+$ activity is typically weak in patients with chronic infection, and this may impair the development of an effective $CD8^+$ response. It has been proposed that HCV core binds to the complement receptors of $CD4^+$ T cells and dendritic cells, thereby impairing the production of IL-2 and IFN-γ that are required to generate T-cell effector functions (155).

$CD8^+$ T-lymphocyte response

The $CD8^+$ arm of the cellular immune system has been shown to be important in the control of viral infections and pathogenesis of cell injury in vivo. Several lines of evidence suggest that these cells also play an important role in HCV infection. First, immunophenotyping studies have demonstrated that a significant proportion of the activated cells in the livers of patients with chronic hepatitis C are $CD8^+$ T lymphocytes (156,157). Second, expression of adhesion molecules,

one pathway for recruitment and priming of T cells, is upregulated in the inflamed hepatic portal tracts (158). Third and most important, HCV-specific cytotoxic $CD8^+$ T lymphocytes have been isolated from both liver and peripheral blood in a significant proportion of patients with chronic HCV infection (159,160,161). These cells are restricted by HLA class I molecules, suggesting that HLA subtypes might present different processed viral peptides to lymphocytes and affect the severity of cell injury. Indeed, target epitopes from within both structural and nonstructural regions have been identified (162,163,164). The immunodominant CTL epitopes are most commonly located within the HCV structural antigens (core/E1/E2); CTL responses to nonstructural regions occur in a smaller subset of patients (161). However, multiple epitopes may be targeted by the same patient, and the magnitude of the CTL is variable both within the same patient and between different patients (165). Interestingly, HCV-specific CTL cannot usually be detected in peripheral blood without HCV-specific stimulation (161). The estimated frequency of HCV-specific CTL in the peripheral blood mononuclear cells of patients with chronic hepatitis C is only 1 per 30,000 to 1 per 300,000 (162). This tissue-dependent prevalence suggests compartmentalization of HCV-specific CTL activity, similar to what was described earlier for $CD4^+$ cells (152). Of course, it is not surprising that the liver, the primary and perhaps only site of HCV replication, is the recruiter of HCV-specific CTL. However, although HCV-specific $CD8^+$ cells may be more frequent in the liver, they appear to be dysfunctional, with impaired ability to secrete IFN-γ compared to peripheral cells (166). The mechanism for this is not clear but could be related to the viral inhibition of IFN production (107).

Nonetheless, HCV-specific CTL appears to have an important role in the control of viral replication and promotion of hepatocellular damage in chronic HCV infection. Using an in vitro protocol to expand liver-derived $CD8^+$ cells without HCV-specific stimulation, Nelson et al. (161) have measured HCV-specific CTL activity in bulk-expanded $CD8^+$ T cells isolated from liver. Patients with measurable HCV-specific CTL activity had higher serum alanine aminotransferase (ALT) levels and more histologic activity in the liver biopsy. Furthermore, these patients also had significantly lower HCV RNA levels, suggesting that HCV-specific CTL activity may be important in regulating HCV replication. A similar role for virus-specific CTL has also been reported for lymphocytic choriomeningitis virus (LCV) infection (165). In fact, in LCV infection, $CD8^+$ CTL may lead to viral clearance through direct lysis of infected cells or cytokine-mediated viral inhibition (167). Current evidence suggests that HCV-specific T-cell responses do not lead to viral escape mutations (168).

The means by which the HCV-specific CTL mediates these effects remains largely speculative. CTL may reduce viral replication by the local production of lymphokines such as IFN-γ and TNF-α (135,136,137), although some studies have shown that this response is impaired compared to the response to other viruses such as influenza (166). Apoptosis may be the most important mechanism of hepatocyte death by CTL (169). This is likely to occur by a variety of apoptotic pathways. CTLs can be directly cytopathic to their targets by inducing the formation of pores in the target cell membrane. This occurs through a sequence of events resulting in the secretion of the pore-forming protein perforin, a series of granule serine proteinases (granzymes), and other molecules (170). CTL can also induce apoptosis by facilitating the interaction of the Fas/Apo 1 antigen with its receptor ligand on the surface of the activated $CD8^+$ cells (171). In fact, hepatic expression of c-Fas is increased in patients with chronic HCV infection, and Fas-bearing cells are more sensitive to CTL killing (172,173). HCV core expression may be important in

making cells susceptible to Fas-mediated apoptosis (174).

Cytokine response

The high replication rate of HCV and the large number of infected hepatocytes present a formidable challenge to the cellular immune system. The fact that this infectious burden exceeds the capacity of the CTL response is apparent from the persistent nature of the infection. However, other mechanisms may assist in controlling the infection. Cytokines are regulatory molecules that play an important role in orchestrating several physiologic and pathologic processes. Cytokine responses are referred to as T_H1, T_H2, or the inactive T_H0, after the original description of the cytokine profiles produced by subsets of the $CD4^+$ T_H cells (175). T_H1-like responses include IL-2, TNF-α, and IFN-γ secretion and are required for CTL generation and NK cell activation during the host's antiviral immune response. T_H2-like responses produce IL-4 and IL-10, which help augment antibody production and inhibit the development of the T_H1 response (176).

Patients with chronic HCV infection have an activated T-cell response pattern and have been reported to have elevated serum levels of both T_H1 and T_H2 cytokines (177,178). Peptide stimulation of either peripheral blood- or liver-derived HCV-specific T-cell clones results in a predominantly T_H1 cytokine response with release of IFN-γ and TNF-α (179). Furthermore, IFN-γ and IL-2 messenger RNA (mRNA) levels are increased in the livers of patients with chronic hepatitis C, suggesting that these cytokines are produced locally by resident $CD4^+$ cells (180). The levels of IFN-γ and IL-2 mRNA correlate with fibrosis

and portal inflammation, suggesting that T_H1 cytokines play a role in mediating hepatocellular damage. To further support this hypothesis, elevated plasma levels of TNF-α appear to be associated with more severe hepatocellular damage (181). However, others have reported a predominantly T_H2 profile with elevated serum IL-4 and IL-10 levels and some T_H2 cell markers in hepatic inflammatory infiltrates (116,177). IFN treatment appears to reduce this T_H2 cytokine response in parallel to the reduction in viral levels (182). Given the ability of IL-4 and IL-10 to inhibit immune cell function, T_H2 cells may provide an autoregulatory mechanism through which the host is able to partially offset the potentially detrimental effects of the T_H1 response.

From the existing data, it appears that the T_H1 response is activated in the liver in response to HCV infection. This may be an attempt to control viral replication, and its persistence results in hepatocyte injury. The T_H2 cytokine response probably represents an autoregulatory response that originates outside the liver and attempts to confine the T_H1 response to the site of infection (the liver) to prevent systemic effects.

Direct viral cytopathicity

Some viruses can kill cells directly without invoking immune-mediated pathways. This may occur through the ability of some viruses or viral gene products to increase lysosomal permeability, alter cellular membranes, or interfere with normal cellular functions such as the synthesis of cellular macromolecules. Characteristic morphologic alterations of cellular architecture such as cell rounding and shrinkage and nuclear pyknosis suggest a cytopathic effect.

It has been difficult to determine whether HCV is directly cytopathic because cell culture systems that allow replication of unmodified HCV have not yet been perfected. However, several lines of evidence support a cytopathic role for HCV. First, other members of the Flaviviridae family, such as the yellow fever virus, cause direct cytopathic injury to infected cells (183). Second, histologic examination of HCV-infected livers occasionally reveals dying hepatocytes without adjacent inflammation (184,185). Third, serum aminotransferase levels and hepatic inflammation decline relatively parallel to viral levels during treatment with antiviral agents such as IFN (186). And finally, some studies have found a correlation between serum HCV RNA levels and the degree of hepatocellular damage (187,188). In fact, high-level cellular expression of HCV has been seen in some patients with severe hepatic injury. This was first reported in an immunosuppressed heart transplant recipient who acquired acute HCV infection from the donor organ (189), but a similar picture has since been reported in other immunosuppressed patients particularly after liver transplantation (190,191). In many of these cases an unusually high proportion of the liver cells contain HCV, and liver biopsies reveal an atypical histologic picture of pericellular fibrosis, marked intracellular cholestasis, and only mild inflammation. This pathology is similar to the fibrosing cholestatic hepatitis sometimes seen in highly viremic immunosuppressed patients with chronic hepatitis B (192). If HCV is indeed cytopathic at high levels, one would anticipate that high-level expression of HCV proteins in vitro might alter hepatocellular structure or function. Indeed, evidence supporting this hypothesis was recently provided in cell lines expressing high levels of HCV structural proteins. These cells showed mitochondrial and endoplasmic reticulum proliferation, distension of the endoplasmic reticulum, and hepatocellular ballooning similar to those seen in the infected transplant recipients described in the preceding text (193).

On the other hand, there is also evidence to suggest that HCV is not directly cytopathic. In the overwhelming majority of patients, particularly immunocompetent patients, biochemical or histologic markers of disease activity do not correlate with serum viral levels or the amount of HCV RNA or antigen

in the liver (194,195). In fact, many patients with HCV infection have persistently normal serum ALT levels and minimal liver injury despite the presence of detectable HCV RNA in serum (196). Furthermore, a transgenic mouse model with high-level expression of HCV structural proteins does not demonstrate cytopathic changes in the liver, and this has called into question the cell culture findings discussed in the preceding text (197). Taken together, these observations suggest that direct cytopathic injury due to expression of HCV structural proteins is not typical but might be possible when the unusually high levels of the virus exceed a certain threshold. However, such injury is not predictable and therefore is probably dependent on factors other than simple expression of virus or protein.

Diagnostic Tests

Screening and Supplemental Antibody Tests

The screening diagnostic test for HCV infection is a sensitive and unique enzyme immunoassay (EIA) in which antibodies to several different viral antigens (anti-HCV) are simultaneously detected. This commercially available assay is simple to perform, reproducible, and relatively inexpensive. A supplemental recombinant antigen immunoblot assay (RIBA) is available to resolve false-positive results in the screening tests, although this assay is rarely necessary today. Three versions of the anti-HCV EIA test have been developed over the last

several years. The antigens included in the tests and the sensitivity of the different versions are important to recognize for historical purposes (Tables 30.3 and 30.4).

Table 30.3. Hepatitis C Virus Peptides in Immunodiagnostic Assays

Peptides	EIA-1	RIBA-1	EIA-2	RIBA-2	EIA-3	RIBA-3
5-1-1 (NS4)		X		X		
C100-3 (NS3-4)	X	X		X		X
C33c (NS3)				X		X
C200 (fusion C100/C33)			X		X	
C22-3 (core)			X	X	X	X
NS5					X	X

EIA, enzyme immunoassay; RIBA, recombinant antigen immunoblot assay; NS, nonstructural.

The first-generation test (EIA-1), introduced immediately after the discovery of HCV (21), was an important first step in diagnosis, particularly for the screening of blood donors to reduce post-transfusion hepatitis (22,198). However, because the assay used only a single target antigen, it lacked sensitivity. In fact, only 80% of infected patients were antibody positive by this test (199). However, false-positive results were also common. Therefore, the supplemental RIBA test that used the same and sometimes additional HCV peptide antigens affixed to a solid phase was often required to resolve the specificity of the EIA result (Table 30.3) (200). This assay allowed visualization of the peptide target of the reactive serum of the patient, confirming or refuting whether the serum reacted specifically against HCV antigens. The importance of the supplemental RIBA test was particularly evident in a low HCV prevalence setting, such as with screening healthy blood donors. In this situation, 50% to 70% of the positive EIA-1 results were subsequently shown to be false-positives when tested by the supplemental assay (199). It is important to recognize that the RIBA assay is not as sensitive as the EIA test and, therefore, should not be used for screening purposes. It is most appropriately used to confirm positive EIA results in low-prevalence settings such as with healthy blood donors and anti-HCV–positive patients with normal ALT levels. Because most infected patients are EIA positive, confirmation by RIBA is generally not necessary when the serum ALT level is elevated or risk factors for infection are present.

Table 30.4. Sensitivity and Predictive Value of Serologic Tests for Hepatitis C Virus Infection

Assay	Sensitivity (%)	Positive predictive value		Time to positive (wk)[a]
		Low prevalence (%)	High prevalence (%)	
EIA-1	70–80	30–50	70–85	16
EIA-2	92–95	50–60	88–95	10
EIA-3	97	25	98	7–8

[a]Time after infection.
EIA, enzyme immunoassay.
Adapted from Carithers RL, Marquardt A, Gretch DR. Diagnostic testing for hepatitis C. *Sem Liver Dis* 2000;20:159–172.

The first-generation anti-HCV test was replaced in 1992 by a multiantigen test, EIA-2 (201), which had HCV antigens from the core and third and fourth nonstructural regions (NS3 and NS4) (Table 30.3). This provided greater sensitivity and specificity. EIA-2 detects anti-HCV in at least 95% of infected patients, which is a great advantage over EIA-1 (199). Because the test is more sensitive, it is capable of identifying new infections at an earlier time (mean, 10 weeks postinfection vs. 16 weeks with EIA-1) (201). Finally, the more sensitive EIA-2 improved the identification of potentially infectious blood donors and resulted in a further reduction in the incidence of post-transfusion hepatitis C (202,203). The use of multiple target peptides also appeared to improve the specificity and reduce the false-positive rates in low-prevalence groups to 40% to 50% (204,205).

EIA-3 was approved for screening blood products in the United States in 1997. Although the EIA-3 test contains reconfigured core and NS3 antigens, as well as an NS5 peptide not included in earlier versions of the assay (Table 30.3), these changes result in only a small increase in sensitivity (206). The major advantages of EIA-3 are earlier identification of acute infection (7 to 8 weeks in up to a third of patients) and fewer false-positive tests in low-prevalence populations (204,206).

A third-generation supplemental test (RIBA-3) consists of the antigens added to EIA-3 and the peptides already present in RIBA-2 (Table 30.3). RIBA-3 is more specific than RIBA-2 (correlates better with HCV PCR) and has fewer indeterminate results (207,208).

Measurement of Viral Ribonucleic Acid

Detection of HCV RNA in blood by a highly sensitive assay is important for confirming the diagnosis of hepatitis C and for assessing the antiviral response to IFN therapy. Qualitative HCV RNA tests such as the reverse transcription PCR (RT-PCR) or transcription-mediated amplification (TMA) are particularly useful as a diagnostic tool in confirming the presence of infection in special situations such as in immunocompromised individuals in whom antibody is less likely to be present or in seropositive patients with a normal serum ALT level (209). In the latter the HCV infections may either have resolved (i.e., HCV RNA negative) or be viremic (HCV RNA positive) despite normal liver enzyme levels. Although the natural history and management of such patients remains controversial, testing of HCV RNA seems medically prudent so that patients with viremia may be counseled about the potential risks of virus transmission, disease progression, and the possibility of antiviral treatment. Qualitative testing is also important to confirm the clearance of HCV after antiviral therapy. Quantitative HCV RNA tests, by either PCR or signal amplification, are used to guide antiviral therapy. In this role, HCV RNA testing can provide a reference point before initiation of therapy. Monitoring HCV RNA during therapy allows early prediction of response (See "Prevention and Treatment").

Qualitative hepatitis C virus ribonucleic acid tests

Qualitative assays for HCV RNA simply determine whether the virus is present. These tests have the potential to be extremely sensitive (Table 30.5). There are two methods that are widely available in commercial laboratories for testing clinical samples—RT-PCR and TMA. Both methods require extraction of nucleic acid from the specimen. RT-PCR then involves reverse transcription of the sample RNA to its cDNA using specific primers based on highly conserved sequences of the virus genome. The DNA product is then repeatedly amplified with a bacterial DNA polymerase until the amount of product reaches a level that can be detected by autoradiography, ethidium bromide staining, or colorimetric testing. Most of the early RT-PCR assays for HCV RNA were designed by individual laboratories (so-called home-brew tests),

had limited sensitivity (1,000 to 2,000 copies per milliliter), and were subject to error related to lack of standardization and sample contamination (205). The development of RT-PCR tests by commercial diagnostic laboratories has employed standardized methodology, easier assay formats, and routine assay controls. These measures have eliminated many of the problems experienced with the early assays. The widespread availability of commercial PCR tests for HCV RNA such as the Amplicor assay (Roche Diagnostics, Nutley, NJ) has made diagnosis and clinical management of hepatitis C much easier.

Table 30.5. Characteristics of Commercially Available Hepatitis C Virus Ribonucleic Acid Assays

Test	Manufacturer	Method	Application	Dynamic range (IU/mL)[a]		Conversion factor (copies/IU)
				Lower limit	Upper limit	
Amplicor	Roche	PCR	Qualitative	42	N/A	N/A
UltraQuant	NGI-LabCorp	PCR	Qualitative	30	N/A	N/A
Versant-TMA	Bayer	TMA	Qualitative	5	N/A	N/A
Amplicor Monitor 2.0	Roche	PCR	Quantitative	600	500,000	2.4
SuperQuant	NGI	PCR	Quantitative	60	1,500,000	3.4
QuantaSure[b]	NGI	PCR	Quantitative	2	2,000,000	2.5
Versant Quant 3.0	Bayer	bDNA	Quantitative	520	8,300,000	4.8
LCx	Abbott	kLCR	Quantitative	23	2,300,000	4.3
Heptamax	Quest	kPCR	Quantitative	50	50,000,000	2.7
TaqMan ASR	Roche	kPCR	Quantitative	25	5,000,000	0.6

[a]Limits of detection are approximated on the basis of published data.
[b]This test increases the lower limit of detection by centrifugation of a larger sample.
PCR, polymerase chain reaction; N/A, not applicable; NGI, National Genetics Institute; TMA, transcription-mediated amplification; bDNA, branched deoxyribonucleic acid; LCx, ligase chain reaction; kLCR, kinetic ligase chain reaction; kPCR, kinetic PCR also known as *real time PCR*.

TMA is an extremely sensitive method for detecting HCV RNA. The test involves a three-step process (target capture, amplification, and detection) and has the advantage of being performed in a single tube, thereby eliminating the concern about sample contamination (210). Nucleic acid is released from the sample by a lysis agent and isolated by hybridization to capture oligonucleotides that bind to magnetic microparticles. Amplification of the viral RNA is performed by autocatalytic, isothermal production of RNA transcripts using two enzymes (reverse transcriptase and T7 RNA polymerase) and two primers, one of which contains a T7 promotor. The promotor-containing primer hybridizes to viral RNA, and cDNA is synthesized by reverse transcriptase. The RNA of this complex is degraded by the RNase H activity of the reverse transcriptase,

and a second primer then binds to the cDNA already containing the promotor sequence. Therefore, new DNA can be synthesized by reverse transcriptase. The RNA polymerase recognizes the T7 promotor sequence in the double-stranded DNA molecule and synthesizes numerous RNA transcripts. Each of the

newly synthesized RNAs reenters the TMA process and serves as a template for a new round of replication, resulting in exponential amplification of target RNA. The RNA amplicons are detected by a hybridization protection assay with amplicon-specific chemiluminescent probes and compared to an internal control standard. The sensitivity of TMA is in the range of 25 to 50 copies per milliliter. According to the World Health Organization HCV RNA standard, the sensitivity is 96% (5 IU/mL) and 100% (10 IU/mL) (211).

Quantitative tests for hepatitis C virus ribonucleic acid

Two different technologies have evolved to quantitate HCV RNA levels. These include target amplification methods that use PCR-based technology and signal amplification technologies such as branched DNA (bDNA) assay (212,213,214).

Target amplification methods typically spike the initial reaction mixture with a known amount of a tag that is amplified along with the sample. The ratio of the initial tag to the amount in the final reaction mixture can then be used to estimate the original amount of sample RNA. The major limitations of early PCR tests were sensitivity and the potential for contamination (false-positives). Standardization of commercial tests reduced these problems. Recently, real-time PCR techniques such as TaqMan have been developed. These assays are based on the cleavage of fluorescent dye-labeled probes by the 5′ → 3′ exonuclease activity of the DNA polymerase during PCR. Measurement of fluorescence intensity by a sequence-detection system provides a measure of RNA over time (cycles) and optimizes detection across a wider dynamic range of virus levels. These assays are rapid, are sensitive, have broad dynamic ranges, provide precise quantitation of viral load, and are done in a closed-tube system that prevents crossover contamination by PCR products (215).

Signal amplification is a novel methodology that involves capturing sample nucleic acid in a microtiter well by hybridization with a number of primers targeted to different conserved regions of the genome. An amplification multimer (the branched label probe or bDNA) then hybridizes to the captured RNA complexes, and its signal can then be further amplified and detected by a chemiluminescent reaction. The test is currently marketed by Bayer Diagnostics as the Versant version 3.0 (Table 30.5). The test is highly standardized and reproducible and is accurate over a wide range of viral levels (187,216).

Limitations of hepatitis C virus ribonucleic acid measurement

A major problem and limitation of quantitative HCV RNA testing has always been standardization. This was especially problematic with early tests. A blinded survey of 31 laboratories in Europe demonstrated that only 16% correctly identified all samples in the coded test panel (217). A similar series of laboratory surveys in the United States found accurate identification ranging from 12% to 95% (218). Several factors may have explained these inaccuracies. Delayed serum separation, inadequate storage conditions, and specimen contamination can reduce the amount of nucleic acid in the specimen (219). The sensitivity of the actual assay is limited by the design of amplification primers, length of the amplicon, efficiency of reverse transcription, utilization of reaction substrates and other inefficiencies during amplification, dilution steps, and efficiency of postamplification detection systems (220,221). Even small inefficiencies are exponentially amplified during PCR, and therefore significant errors can be seen. A 12% reduction in efficiency early in the process (e.g., during primer hybridization) results in a 10-fold reduction of the product, and a 24% reduction in efficiency results in a 100-fold decrease (43). Primer hybridization efficiency may also be affected by viral heterogeneity, even within the well-conserved 5′ UTR region used for PCR amplification (87,95), and the use of synthetic RNA transcripts can result in different amplification efficiency for the various HCV genotypes (43). Although this problem potentially affects all PCR-based assay and bDNA systems, appropriate modifications of the reaction mixtures and primers have since corrected the differences in genotype sensitivity in the commercial tests (43,213). Despite the early problems with both qualitative and quantitative HCV RNA assays, testing has been made easier and more reliable by the availability of commercial assays that use familiar test formats that are easily adaptable to hospital laboratories.

Differences in methods lead to variability in quantitation of both the target RNA and standard. Therefore, results with different assays are generally not comparable (222,223,224). Incorporation of a World Health Organization standard into all assays and use of international units were implemented in the hope of resolving these differences, but have not. Therefore, it is important that clinicians understand the technology and limitations of the assays they or their laboratory choose to use. Because levels of HCV RNA measured by different assays are not necessarily the same, care should be taken to ensure that the same assay is used when it

is important to document changes in virus levels (e.g., during treatment).

Hepatitis C Virus Genotyping

HCV is a remarkably heterogeneous family of viruses, with at least six distinct genotypes and numerous subtypes of HCV identified throughout the world (86,87). The methods used to determine genotypes have been described in the preceding text (See "Genotyping"). Currently, the reverse hybridization line probe

assay (LiPA, Bayer Diagnostics, Emeryville, CA) (97) is the most commonly used genotyping method in practice. HCV genotype is highly associated with response to antiviral therapy and is essential in determining the optimal treatment duration (See "Prevention and Treatment").

Histology

The morphologic features of chronic viral hepatitis are similar regardless of the etiology. These features are described in detail in Chapter 26 of this book. In general, the degree of inflammation in chronic hepatitis C is mild to moderate. Severe bridging necrosis and confluent necrosis are unusual in chronic hepatitis C. A few histologic features are highly suggestive of chronic hepatitis C, although they are not entirely pathognomonic. These include epithelial damage of small bile ducts, lymphoid aggregates and sometimes lymphoid follicles in portal tracts, and microvesicular or macrovesicular steatosis (225,226). These histologic features are rarely seen in chronic viral hepatitis B or autoimmune hepatitis and therefore strongly suggest the diagnosis of chronic viral hepatitis C. The pathogenesis of these characteristic changes has not been determined, but the presence of lymphoid aggregates in portal tracts and lymphocyte infiltration of lobules and bile ducts suggest that immune mechanisms play a role in the mediation of cell injury.

Coexistence of chronic viral hepatitis C with other causes of liver diseases is not uncommon and this may modify the morphologic appearance of the liver biopsy. Alcoholic liver disease and chronic viral hepatitis C frequently coexist, and alcoholic liver damage may play an important role in the progression to cirrhosis and hepatocellular carcinoma (HCC) in these patients (227,228,229). Iron overload is more common in patients with chronic viral hepatitis C than in the normal population but does not seem to influence the severity of necroinflammatory activity or fibrosis of the disease (230). Other conditions include coinfection with other viruses, particularly hepatitis B (231,232), and nonalcoholic steatohepatitis. Occasionally, epithelioid granulomas of unknown etiology have been observed in the nodular parenchyma of patients with HCV-related cirrhosis (233).

Table 30.6. Staging Systems for Hepatic Fibrosis Pattern in Patients with Chronic Hepatitis C

Score	Knodell	Ishak	Scheuer	Metavir
0	None	None	None	None
1	Portal	Portal	Portal	Portal
2		Periportal	Periportal	Septae
3	Bridging fibrosis	Focal bridging	Architectural distortion without cirrhosis	Bridging fibrosis
4	Cirrhosis	Diffuse bridging	Cirrhosis	Cirrhosis
5		Extensive bridging		
6		Cirrhosis		

Characterization of the degree of histologic injury is usually performed using one of several scoring systems that utilize descriptive terminology for inflammatory activity and fibrosis in an attempt to group similar degrees of histologic severity. The inflammatory (grade) portions of these different systems typically utilize combinations of numerical assessment for portal, periportal, lobular, and focal inflammation and therefore ignore the specific implications of inflammation in different portions of the lobule. However, inflammation is typically mild to moderate in patients with chronic hepatitis C and is therefore less likely to be important in determining change over time or in making clinical decisions. On the other hand, fibrosis is important in assessing prognosis and has become a critical piece of information in making treatment decisions. Therefore, a quantitative classification of fibrosis (stage) is important. The different staging systems are summarized in Table 30.6. The Knodell system was the first staging system but is noncontiguous and no longer used (234). The Ishak system uses four of its total of seven stages to subdivide the extent of fibrosis between periportal septae and marked bridging (235). This may be helpful in clinical studies when fine gradations of fibrosis pattern are required to

demonstrate change, but this system is not commonly used in practice. The Scheuer and Metavir systems are essentially the same and each has five stages (236,237). Metavir is the most commonly used system in practice today. The accuracy of grading and staging is dependent on the adequacy of

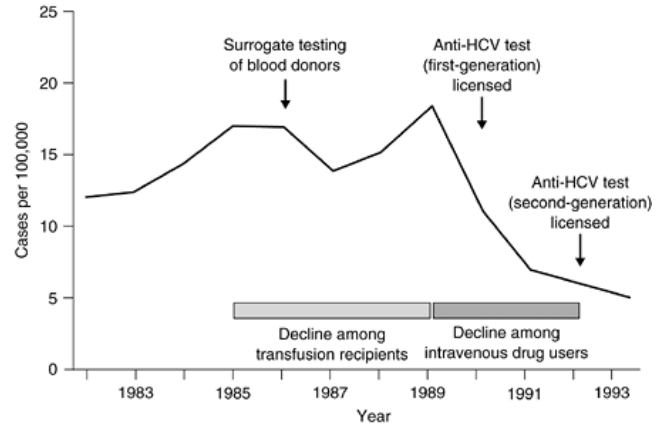
the specimen and the experience of the pathologist, but considerable sampling error can exist as well (238,239).

Epidemiology

Acute Incidence and Population Prevalence

Estimates of the incidence of acute hepatitis C infection in the United States have been extrapolated from age-specific prevalence data and indicate that the new infection rate was low (18/100,000) before 1965, increased rapidly for the next 15 years, and remained high (130/100,000) throughout the 1980s (Fig. 30.6) (240). Prospective surveillance studies conducted by the CDC in four sentinel counties in the United States have indicated a dramatic decline by more than 80% over the last decade (24,241). These rates correspond to 240,000 annual cases in the 1980s and approximately 28,000 to 35,000 cases per year since then (242,243).

The incidence of new infections is most common in young people (aged 20 to 39), especially Hispanics, with a slight predominance of men. The most common risk factor for new infection, accounting for 60% of cases, is intravenous drug use (Fig. 30.7) (243). Identifiable risk factors are present in most acute cases of hepatitis C. Between 10% and 40% of patients do not have a recent or readily identifiable risk factor for infection, although a history of remote high-risk behavior is common in them because such patients tend to underreport such behavior (244,245). Although the incidence of transfusion-associated hepatitis declined dramatically after 1984 because of the testing of potential donors with surrogate markers such as ALT and anti-HBc, and later anti-HCV, this had little impact on the more recent incidence of infection (241). In fact, the recent slowing of new cases is due to a precipitous fall in the occurrence of infections in intravenous drug users (246). This is surprising in the absence of specific public health changes, preventative therapy, or widespread testing for infection.

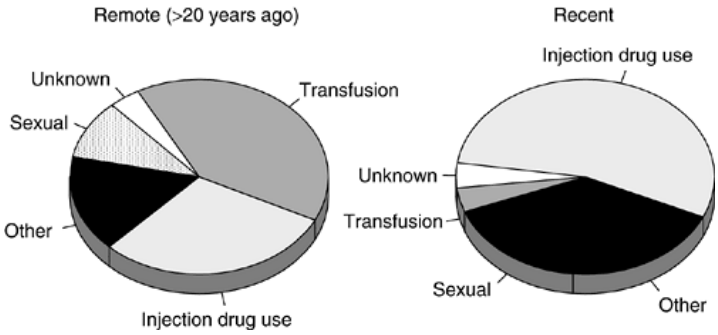


▪ **Figure 30.6** The incidence data in this chart indicate reported cases in the Centers for Disease Control and Prevention Sentinal Countries study of Acute Viral Hepatitis and are not indicative of the national incidence.(See reference 240 for further explanations of incidence calculations.)

The prevalence of HCV infection throughout the world is low, averaging 2% to 3% or 170 million persons (21,247,248,249,250,251). These estimates are often based on volunteer blood donor prevalence rates and may therefore underestimate the true population prevalence (242). Nonetheless, these estimates provide some idea of the worldwide pattern of infection. Overall and age-specific prevalence varies considerably from country to country. Wasley and Alter suggests that this is due to the predominant risk factors (242). For example, in the United States and Europe, the prevalence is low and concentrated in young men who predominantly acquire infection in early adulthood from intravenous drug use (see subsequent text). By contrast, infection is most common in older persons in Japan and Italy, indicating a risk in the distant past. Furthermore, the high prevalence across all adult age-groups in Egypt indicates a common risk factor, namely medical injections (242,252,253). The antibody prevalence is low (0.01% to 0.1%) in the United Kingdom and Scandinavia; slightly higher (0.2% to 1%) in the United States, western Europe, Australia, and parts of South America and Africa; and intermediate (1% to 5%) in eastern Europe, the Mediterranean, Middle East, Indian subcontinent, Brazil, and parts of Africa and Asia (242). The highest prevalence is in northern Africa (6% in Zaire, 7% in Libya, and 17% to 26% in Egypt)

(242,252,253). The

prevalence is also high in some areas of Saudi Arabia (254) and isolated communities in Japan (255).



▪ **Figure 30.7** Sources of acute hepatitis C virus infection over time. (Modified after data from the Centers for Disease Control and Alter MJ. The epidemiology of acute and chronic hepatitis C. *Clin Liver Dis* 1997;1:559–568, with permission.)

Although the prevalence of antibodies to HCV is approximately 0.6% in blood donors, the National Health and Nutrition Examination Survey, conducted during 1988 to 1994, found the prevalence of anti-HCV to be 1.8% in the general population of the United States (251,256). Given that approximately 80% of these are probably infected, this accounts for more than 4 million infected persons in the United States. However, some high-risk and high-prevalence populations have not been included in many prevalence surveys. There are currently more than 2 million incarcerated persons in the United States (257), and the prevalence of infection in this group is nearly one in four (258). Therefore, these prevalence estimates may underestimate the true rate. Prevalence begins to rise over the age of 20 and is highest among men aged between 30 and 49 years. African Americans and Hispanics have a higher prevalence of HCV infection than do whites, but the prevalence of HCV infection varies in the population on the basis of risk factors for infection (246). In contrast to what is currently observed in patients presenting with acute hepatitis, transfusion was a more important risk factor in the past (Fig. 30.7). Therefore, transfusion is a common identifiable risk factor only in patients older than 50 years (259).

Chronic hepatitis C is the most common cause of chronic liver disease in the United States, accounting for 40% to 60% of cases (Fig. 30.8) (243,260). This results from the high incidence of acute hepatitis before 1990 and the propensity of acute infection to persist. Because progression to cirrhosis mainly depends on the duration of infection (see subsequent text), each year an estimated 8,000 to 10,000 deaths result from HCV-associated chronic liver disease (243). Most patients who develop cirrhosis have had infection for more than 20 years (261). In the year 2000, approximately 30% of patients with chronic hepatitis C had a history of infection for at least this long (262). This proportion will increase in the future with the cohort of chronically infected patients' age. It is estimated that by the year 2010, more than 60% of patients will have had infection for more than 2 decades (262,263). This has obvious and significant implications for the prevalence of cirrhosis in the infected population. Mathematic models estimate that the proportion of HCV-infected patients with cirrhosis will increase by more than 50% (from 22% of infected cases to 35%) and that complications of cirrhosis such as liver failure and HCC will nearly double (263).

Routes of Transmission

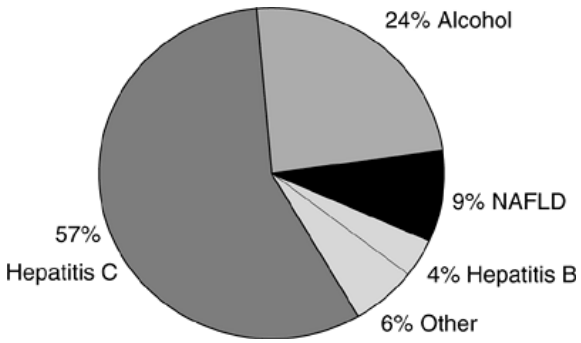
HCV can be transmitted through a variety of routes. Infection is most efficiently transmitted by large or repeated percutaneous exposures such as through transfusions, transplantation from an infected donor, or sharing illicit drug paraphernalia. Transmission of HCV may also occur from exposures to infected contacts through sexual activity, household contacts, perinatal exposure, and parenteral exposures in the health care setting (264).

Intravenous drug use

Intravenous drug use has been the most common risk factor for acquiring HCV infection for more than

25 years and currently accounts for 60% to more than 90% of new infections (Fig. 30.7) (265,266). Sharing of needles and other paraphernalia during parenteral drug use is an extremely efficient means of transmitting infection (243,267). Although both the incidence and prevalence of HCV infection remain high in this group, the incidence of acute hepatitis C among intravenous drug users has declined

dramatically since about 1989 (Fig. 30.6). HCV is rapidly acquired after initiation of drug injection behavior; 50% to 80% of users became anti-HCV positive within 12 months of initiation of drug injection behaviour (268), and nearly all seroconvert by 8 years (269). The risk factors for acquisition of HCV include frequent use, shared paraphernalia, injecting cocaine, sharing with an older user, and long duration of use (270,271). However, it has also been suggested that intranasal cocaine use may be a risk factor (272). Although this route of infection might be possible (e.g., sharing of blood-contaminated straws), it is likely a surrogate for injecting behavior. In addition, two other factors appear to be important in facilitating exposure in this group. Although about a half of infected drug users are either aware of or willing to admit seropositivity, and many continue high-risk behavior despite knowing that they have infection and are at a risk of spreading it to others (244,273).



▪ **Figure 30.8** Etiology of newly diagnosed cases of chronic liver disease. NAFLD, nonalcoholic fatty liver disease. (See reference 260.)

Health care workers; other percutaneous routes

Health care workers have increased exposure to patients infected with HCV. A serologic survey of emergency department patients found that 18% were infected with HCV (274). The proportion with HCV infection was even higher in patients with a history of intravenous drug use (83%), past blood transfusion (21%), or a male homosexual lifestyle (21%) (274). Although all potential routes of transmission of HCV infection to hospital workers are not obvious, needle-stick injuries probably account for a large proportion of cases. Cases of needle-stick transmission of HCV have been clearly documented (275). Skin exposure to blood is not thought to be a risk factor (276). A recent review of follow-up studies of health care workers who sustained percutaneous exposure to blood from anti-HCV–positive patients found that anti-HCV seroconversion after accidental needle-stick/sharp exposures averaged only 1.8% (range, 0% to 6.6%) (Table 30.7) (243,277,278). The risk is greatest with the hollow needles used to draw blood, as compared to hollow infusion needles (278). In another study, an incidence of 10% was found on the basis of detection of HCV RNA by PCR (279). In these prospective studies, none of the infections was associated with mucous membrane or exposure to nonintact skin, although there have been case reports of the transmission of HCV from a blood splash to the conjunctiva (280,281). Several points deserve comments with regard to the risk of transmission by isolated percutaneous exposure. First, the reported risk of transmission by needle stick is greater for HCV than for human immunodeficiency virus (HIV) or HBV (assuming that hepatitis B immunoglobulin is given) (282,283). Second, even a low risk of infectivity has grave implications, given the high risk of progressing to chronic infection.

Table 30.7. Risk of Hepatitis C Virus Transmission after Exposures to Anti–Hepatitis C Virus–Positive Blood

Exposure	Number tested	Number seroconverted (%; range)
Needle sticks/sharps	911	16 (1.8; 0–6.6)
Hollowbore	331	4 (1.2)
Other	105	0

HCV RNA–positive	68	7 (10.3)[a]
Mucous membrane	114	0
Nonintact skin	165	0
Total	1,302	16 (1.2; 0–6.6)

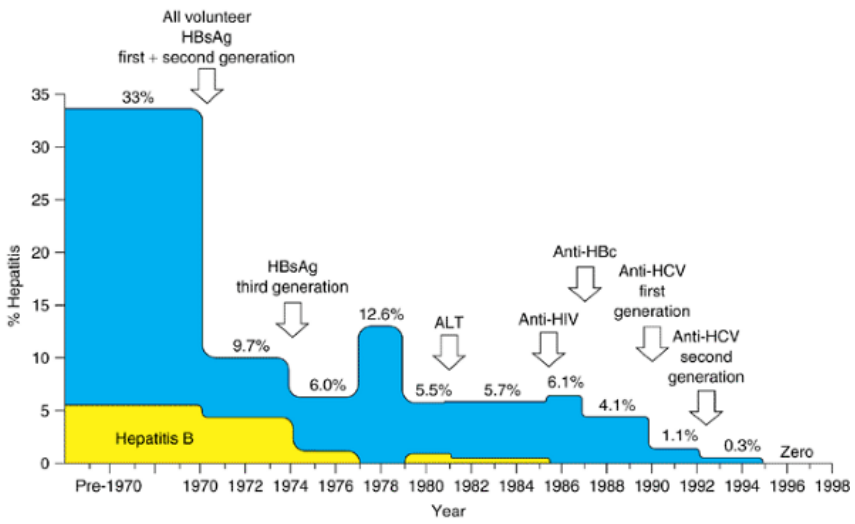
[a]HCV RNA–positive.
HCV, hepatitis C virus; RNA, ribonucleic acid.
See Alter MJ. The epidemiology of acute and chronic hepatitis C. *Clin Liver Dis* 1997;1:559–568.

Although health care workers have increased risk of being exposed to HCV infection, it is debatable whether this occupational exposure results in more than an occasional infection. There were several early reports with seroprevalence rates in health care workers ranging from 0.6% to 4.5%; in all surveys these exceeded the rates in blood donors from the same institution by as much as 4.5-fold (284,285,286). For example, dentists and oral surgeons had seroprevalence rates of 1.75% and 9.3%, respectively, compared with 0.14% in their patients (287). However, other surveys have not found an increased prevalence among health care workers, even in those with regular exposure to blood, including surgeons, dentists, and early responders (276,282,283,284,285,286,287,288).

The risk of nosocomial transmission of blood-borne infections has been dramatically reduced by the use of screening of blood and organ donors, effective

disinfection protocols, disposable equipment, and universal precautions. Transmission of HCV from medical procedures or personnel is exceedingly rare when these precautions are followed. Nonetheless, some cases of nosocomial HCV infection have been reported, although they have usually been associated with breaks in usual technique, such as reusing equipment or multidose drug vials in different patients (See "Hemodialysis") (289). The risk of transmission from an infected health care worker is very low and there does not appear to be sufficient evidence to restrict the practice of these workers. Modeling projections estimate that the risk of transmission from an infected surgeon to a patient is 0.014% or approximately 1:10,000 (290). Nonetheless, there have been two reports of transmission from infected cardiothoracic surgeons. The first, from Spain, involved transmission to five patients over a 6-year period, but the factors responsible for transmission were not identified (291). The other report, from the United Kingdom, found transmission to 1 of 277 at-risk patients during a 1-year period (292).

In countries other than North America and western Europe, unsafe injections, especially involving reusable needles during routine or mass inoculations, have been an important route of nosocomial transmission of HCV. Such practices probably explain the high seroprevalence in Egypt, although these practices appear to have improved (252,253). In many areas, unsafe injection practices, such as reuse of syringes and needles or unnecessary injections, continue (293). Although unsafe injection practices may still be typical in some areas, the lack of available medical supplies is also a factor. Other causes of percutaneous transmission of HCV have included contaminated instruments, equipment, and supplies that were used during the performance of procedures involved in traditional medicine, folk medicine, tattooing, body piercing, and commercial barbering (294,295,296,297,298,299). These routes of transmission have not been documented in the United States.



▪ **Figure 30.9** Risk of post-transfusion hepatitis due to non-A, non-B/hepatitis C in transfusion recipients over the last 3 decades. HbsAg, hepatitis B surface antigen; ALT, alanine aminotransferase; HIV, human immunodeficiency virus; HBc, hepatitis B core; HCV, hepatitis C virus. (See reference Alter HJ, Houghton M. Clinical Medical Research Award. Hepatitis C virus and eliminating post-transfusion hepatitis. *Nat Med* 2000;6:1082–1086, with permission.)

Transfusion associated

HCV is easily transmitted by blood and blood products (22,300,301). In the past, HCV was the major cause of post-transfusion hepatitis, accounting for at least 85% of cases (22,302). As a result, transfusion has often been thought to be the predominant route of transmission of the infection. Early epidemiologic studies supported this because 37% to 58% of patients with chronic hepatitis C, particularly those older than 50 years, gave a history of blood transfusion before 1990 (259). However, the risk of acquiring post-transfusion hepatitis has declined dramatically in recent years (Fig. 30.9) (243,267,303,304,305). The largest drop in post-transfusion hepatitis incidence resulted from adoption of a volunteer donor system and, to a lesser degree, mandatory testing of donor units for hepatitis B surface antigen (HBsAg). Introduction of testing for surrogate

markers of non-A, non-B hepatitis (serum ALT and antibodies to the hepatitis B core [anti-HBc] antigen) reduced the risk of transfusion-associated hepatitis by nearly two thirds (305). Further reduction in the risk of post-transfusion hepatitis was observed after institution of testing for antibodies to HIV and screening of donors for a history of risk factors. Finally, introduction of donor testing for antibodies to HCV was initiated on May 2, 1990, shortly after the discovery of the virus. Retrospective testing of sera from donors and patients who participated in the multicenter Transfusion-Transmitted Viruses Study between 1974 and 1979 predicted that screening of donors for anti-HCV alone would reduce the risk of hepatitis to a level comparable with that of the nontransfused control population (300). Indeed, the incidence of transfusion-associated HCV infection is currently estimated at 0.01% to 0.001% per unit transfused sera (306).

In the past, multiply transfused recipients of blood and blood products had an extremely high risk of acquiring HCV infection. The likelihood of multiply transfused patients developing HCV infection before institution of anti-HCV donor screening was 8.3% in a trauma intensive care unit setting (307) and 18% in a burn unit (308). Patients with transfusion-dependent hemolytic disorders such as thalassemia (309) or hemophilia were at particularly high risk (310,311,312). The risk in patients with hemophilia stemmed from the requirement that factor concentrates be prepared from plasma pooled from hundreds of individuals, who, in many cases, were commercially paid donors (311,312). Before initiation of donor screening, the seroprevalence of anti-HCV ranged from 10% to 16% in paid donors as compared to less than 0.5% in volunteer donors (22,313). Before 1990, between 60% and 90% of factor-dependent patients with hemophilia had serologic evidence of HCV infection (314). HCV infection was more prevalent in those who received greater volumes of concentrate, especially unpasteurized products, and was virtually nonexistent in patients who either had not required factor transfusion or had received exclusively vapor-treated factor concentrates (311). The recent move of vapor-heat sterilization of pooled plasma concentrates and recombinant clotting factors has nearly eliminated the risk of acquiring hepatitis C from replacement therapy (315,316). However, an outbreak of hepatitis C 10 years ago was reportedly associated with contaminated intravenous immunoglobulin (317). This outbreak involved

recipients of a single product produced from the plasma that had been screened by the second-generation anti-HCV assay but on retrospective testing remained positive for HCV RNA (318). Intramuscular immunoglobulin has never been associated with the transmission of any infectious disease in the United States. Currently, all immunoglobulin products (intravenous and intramuscular) commercially available in the United States must undergo an inactivation procedure and be HCV RNA–negative before release.

Hemodialysis

HCV infection is common in patients on dialysis and, currently, is present in approximately 8% of patients in the United States (22,248,319,320,321,322,323). This may, however, be an underestimate because approximately 4% to 15% of infected patients have falsely negative antibodies to HCV (209,321,322). Most dialysis patients are already infected when they present with end-stage renal disease, but acute infection is common in dialysis centers (320,323,324,325). The annual risk of acute HCV infection is currently estimated by the CDC to be 0.15% in hemodialysis patients and 0.03% in continuous ambulatory peritoneal dialysis patients (relative risk, 5.7). Others have estimated the annual incidence to be as high as 0.44% to 1.7% (320). Chronic HCV infection develops in most of those who are acutely infected (70% to 90%) (319). About a third of acute HCV infections are acquired outside the dialysis unit (319,325). However, nosocomial outbreaks have been reported in hemodialysis centers and have been confirmed by molecular sequencing and mapping (326,327). Such infections are usually related to breaks in infection control procedures. Dedicated dialysis machines might reduce much of this risk (328), but this is not common practice in the United States. Other factors such as reuse of multiuse vials and care by specific health care workers have all been implicated (327,329). The cause in many cases remains elusive (329). The improved safety of the blood supply, the availability of recombinant erythropoietin, and the phasing out of pretransplant "immune conditioning" transfusion protocols have significantly reduced the risk of hepatitis C in these patients.

Transplantation

The magnitude of risk assumed by receiving an organ from a donor with HCV infection is subject to some debate. However, HCV infection is not uncommon in cadaveric donors (330,331). In a large study of cadaveric donors evaluated by eight procurement centers in the United States, 4.2% were anti-HCV positive and 2.4% of these were HCV RNA positive by PCR (332). There is no doubt that recipients of organs from these HCV RNA–positive donors are likely to develop infection and liver disease. Some studies have shown nearly universal transmission from anti-HCV–positive donors to recipients (333), whereas others have been unable

to demonstrate such a strong association (331,334). Pereira et al. reported that 75% of the 29 recipients of organs (19 kidneys, 6 hearts, and 4 livers) from 13 anti-HCV–positive donors became anti-HCV or HCV RNA positive (333). By contrast, Roth et al. found post-transplantation liver disease in only 13 of 46 (29%) recipients of kidneys from RIBA-positive donors. HCV RNA levels were not checked (331). Despite the latter study, concern over the risk of transmission is great. Most procurement organizations and transplantation centers have now developed policies for selective utilization of organs from anti-HCV–positive donors (335,336). Modeling strategies have demonstrated that patients without HCV infection who receive an organ from an infected donor incur high cost and have a poor outcome (336). Therefore, donor screening is a necessity. Exclusion of all anti-HCV–positive or HCV RNA–positive donors would incur high costs through the loss of up to 4% of donors and extended waiting times (336). The most cost-effective strategy appears to be transplantation of HCV-positive organs into patients already infected with the virus (336). Most studies have shown that HCV-positive patients who are recipients of an HCV-positive graft have the same graft and recipient survival as those who receive an HCV-negative organ (335,337,338). Furthermore, the waiting time is usually shorter for those who elect to receive an HCV-positive organ (339). After transplantation, either the recipient or the donor strain may become predominant after a few weeks, and this strain then generally persists indefinitely (340). Although the limited data in humans to date does not suggest a genotype advantage in such cases, genotype 1b appears to overtake other genotypes in chimpanzees (341). Despite these many reports to the contrary, however, one recent study has questioned the advisability of using HCV-positive donor organs for kidney transplantation in patients with chronic HCV infection (342).

Sexual transmission

Although sexual transmission is frequently listed in the epidemiology literature as a common risk factor for acquisition of hepatitis C, the data supporting this is poor. Although cases of probable sexual transmission have indeed been reported (343), the extent to which sexual transmission of HCV occurs is not known and it is likely to be exceedingly uncommon during normal sexual activity (264,344,345,346,347,348,349,350,351). The risk of transmission in prospective studies of monogamous heterosexual couples is estimated to be near zero (347,348,349,350). Although these prospective studies have documented a few cases of HCV infection in spouses, these were either phylogenetically unrelated or the spouse had ongoing risk factors in addition to sexual exposure.

The likely explanation for most cases attributed to sexual or so-called sporadic transmission is underreporting of risk factors. One and often many risk factors are present in at least 80% of carefully questioned patients with chronic hepatitis C, but sexual behavior has not been implicated with any certainty as a sole risk factor (352). The risk of overestimating the importance of sexual transmission by not carefully assessing other risk factors has been emphasized (353). Indeed, although the prevalence of infection is usually increased in groups with high-risk sexual practices, it is difficult to exclude all other risk factors for infection. Furthermore, among sexually active individuals without other apparent risk factors attending sexually transmitted disease clinics, the risk does not appear to be increased (344,345).

This being said, there does appear to be circumstantial evidence for sexual transmission among those who practice high-risk sexual behavior. There is a higher seroprevalence of antibodies to HCV, ranging from 0.8% to 22%, in men who have sex with men (MSM) (248,259). In population surveys, antibody prevalence is sixfold higher in MSM than in heterosexuals (259). The risk for HCV appears to be related to the number of sexual contacts, acquisition of other sexually transmitted diseases, use of noninjection drugs during sexual activity, and traumatic sexual practices, particularly anal intercourse (354,355). Heterosexual intercourse, particularly with multiple exposures, is also likely to play a role, although probably a small one, in the transmission of HCV infection. Antibodies to HCV is common in sexual partners of intravenous drug abusers (6%), prostitutes and their clients (3.5% to 9% and 16%, respectively), and heterosexuals with multiple sexual partners (4% to 6%) (343,354). Nonetheless, direct documentation of HCV transmission by high-risk sexual practices has been difficult to obtain. Furthermore, the transmissibility of HCV by this route appears to be extremely low by comparison with HBV, HIV, and other sexually transmitted diseases (354). In one study of sexual partners of HIV–HCV coinfected individuals, 29 pregnancies, one HIV seroconversion, and no cases of HCV infection occurred during an estimated 5,800 unprotected vaginal or anal contacts (351). Importantly and not to be forgotten, barrier contraception with condoms has been shown to reduce the risk of transmission of sexually transmitted infections.

Perinatal transmission

Perinatal transmission is known to occur, but the predominant route (i.e., intrauterine, intrapartum, or perinatal) is not known (356). Antibodies to HCV usually passively transferred from the infected mother to the infant and may remain detectable in the baby for

up to a year (357,358). The risk of transmission of HCV from viremic (HCV RNA–positive) mothers to their infants is 3.2% (356,359). The risk of transmission in viremic women coinfected with HCV and HIV (HCV RNA positive) is 7.9% (359). This higher rate of transmission may, in part, relate to higher levels of HCV RNA in coinfected women; however, some studies have not shown a relationship between risk and viral levels (356,358,360,361). The rate of mother-to-infant transmission is similar for vaginal and caesarean delivery (356). However, prolonged duration of membrane rupture appeared to increase the risk of infection in the infant in one study (362). HCV is not transmitted by breast-feeding (363). Finally, despite development of infection (HCV RNA positive) in the infant, occurrence of abnormal serum ALT levels or liver disease is unusual, with a weighted rate of 1.7% (356,357,358,359).

Sporadic hepatitis

Large public health surveys have suggested that up to 40% of patients with acute hepatitis C have no identifiable risk factor (24,241,267,284). These cases have been called *sporadic* or *community-acquired hepatitis*. The implication is that such cases result from previously unidentified modes of transmission. However, the fact that nearly all anti-HCV–positive patients with chronic liver disease have identifiable risk factors suggests the possibility that the number of sporadic cases is not as great as that reported, and the lack of identifiable risk factors may be more dependent on the patients' recognition of or willingness to reveal their high-risk behaviors (353,364).

The prevalence of HCV infection in the population and the difficulties in clarifying its epidemiology make it obvious that a search for other routes of transmission is important. Although some studies have failed to identify nonparenteral routes of transmission (346), familial and community clustering of hepatitis C cases with seroprevalence of antibodies to HCV ranging from 0% to 34% have been reported (365,366). Although sexual partners appear to be at increased risk in such surveys (366,367), a similar antibody prevalence has been noted in nonsexually exposed family members including children, parents, and siblings, particularly in the older individuals exposed for a longer period (367,368). Sharing of hygiene items such as combs, razors, toothbrushes, and nail scissors has been proposed as a possible means of transmission in such cases (369). Saliva has been implicated as a vector of transmission (370), and indeed, infection through saliva has been documented in chimpanzees (371) and by a human bite (372). However, the existence of infectious virus in saliva is controversial (370,373,374). Occasional casual contact is not likely to transmit infection, and only 3% of patients with acute HCV infection give such a history (284).

Natural History

Acute Hepatitis C Virus Infection

Clinical presentation

Acute hepatitis C is typically asymptomatic and unrecognized. When identified prospectively, cases present with an elevation of the levels of serum aminotransferases anywhere from 2 to 26 weeks after exposure (375). The mean incubation period is intermediate between that for hepatitis A and hepatitis B, with a peak onset of 7 to 8 weeks after infection. Eighty percent of cases occur between 5 and 12 weeks (376). It is not known whether the route of infection, inoculum size, viral genotype, or other factors influence the variability in the incubation period. However, a shorter incubation period was noted in several early reports of hepatitis after transfusion of pooled blood products (377,378). Serum ALT levels are usually high, with about three fourths of patients having elevations more than 15 times the upper limit of normal (379). HCV RNA is present in the blood within days of exposure and usually remains detectable throughout the infection (380). By contrast, anti-HCV is often not detectable until 5 to 6 weeks after exposure (204,206). The mean times to detection of anti-HCV by the second- and third-generation tests are 10 weeks and 7 to 8 weeks, respectively (204,206). Symptoms occur in less than 30% of patients and are usually so mild that they do not interfere with the daily routine (24). When present, the symptoms of acute hepatitis C are nonspecific and do not differ from other forms of hepatitis. The most common symptoms are flu-like and include anorexia, weight loss, abdominal pain, myalgia, arthralgia, and fatigue. Less common symptoms include fever and rash. Jaundice occurs in less than one third of all patients (24,379) and is most common in symptomatic patients (375). The symptoms associated with acute hepatitis usually resolve within 1 to 3 months.

Fulminant hepatic failure due to HCV is extremely uncommon (381). Although some early studies reported detection of serum HCV RNA in up to 60% (mean, approximately 10%) of fulminant hepatitis cases without an obvious etiology (382,383,384,385,386), most clinicians feel that HCV accounts for only rare cases. Large studies in the United States and Japan have failed to identify any case (387,388).

Risk of chronicity

Early reports based on observations in transfusion recipients suggested that about half of the patients with

acute non-A, non-B hepatitis recovered spontaneously; later reports challenged that this event occurred in only 10% to 20% of cases (376,389,390). It is clear that there is considerable variability in the risk of progression to chronic infection, with a range from 50% to 90% (390,391). Resolution of acute infection appears to be more common in young people and women but may also be related to viral genotype (391). Clearance of acute infection is documented by persistent loss of detectable virus because liver test results may normalize or the virus may become transiently undetectable in some patients who go on to develop chronic infection (392). Indeed, chronic viremia persists in at least half of the 30% to 40% of cases in whom the serum ALT level returns to normal (375). Overall, approximately 80% of acutely infected patients develop chronic infection (viremia) and most of these (80% to 90%) have chronic hepatitis with elevated ALT levels (248,393,394,395,396,397,398,399). Factors that determine viral clearance or persistence are not clear. Although several retrospective serologic studies have identified anti-HCV–positive patients who are HCV RNA negative, suggesting the possibility of late viral clearance, it is not possible to exclude the possibility that in these cases virus clearance occurred during acute infection (396,400,401). Indeed, most data suggest that spontaneous eradication of chronic infection is extremely unusual (402).

Chronic Hepatitis C Virus Infection

Clinical presentation

Most patients with chronic hepatitis have asymptomatic elevations of serum aminotransferase levels and do not have physical signs of liver disease (403). Only about 6% have symptomatic liver disease (404). Fatigue is the most common symptom, but its onset is insidious and is usually mild (403). Dull right upper quadrant pain, which is often intermittent and positional, is also common. Less common symptoms include anorexia, nausea, pruritus, arthralgia, and myalgia. Importantly, although symptoms are more common in patients with fibrosis or cirrhosis, the correlation with the histologic severity of disease in individual patients is poor (403). The physical examination may be more helpful once cirrhosis has developed. In these patients, a palpable firm liver is present in 79%, splenomegaly in 34%, and stigmata of chronic liver disease in 31% (405).

Serum ALT levels are usually only mildly elevated. Up to one third of patients have normal serum ALT levels, whereas only about 25% have a level more than twice normal (261,405,406). However, there is a wide variability in enzyme level elevation when patients are followed up over time. In those with ALT level elevations, the levels are persistently elevated in only 26% of cases and elevated in most

determinations in 22%. ALT levels fluctuate down to the normal range in 17%. Finally, 30% to 40% of cases have only occasional ALT level elevations over a 12- to 18-month period of testing (375,376). Furthermore, although in group analyses higher ALT levels suggest more hepatic inflammation, the variability is marked and ALT has little predictive value in individual patients (261,403,407,408). Only a 10-fold or greater elevation of serum ALT level is predictably associated with significant piecemeal necrosis (408). Therefore, ALT alone should not be used to estimate disease severity, prognosis, or necessity of treatment.

Histologic and clinical progression

Although chronic hepatitis C develops in approximately 80% of acutely infected individuals, the disease progresses slowly, if at all, in most patients. However, the true rate of histologic progression has been the subject of debate and uncertainty. Some authorities have suggested that progression to severe end-stage liver disease is inevitable provided the infected person does not succumb first to another lethal illness, whereas others have concluded that disease progression is extremely unusual and restricted to a limited few. These opposing views can be accounted for by the slow pace of progression, the usual lack of symptoms in chronically infected patients, and the limitations of available natural history data (390). For example, studies based on exposed or acutely infected patients such as the post-transfusion hepatitis studies of the 1970s report few significant sequelae of infection (see subsequent text), whereas short-term prospective and retrospective studies of patients who already have established liver disease clearly show a significant risk of progressing to cirrhosis, liver failure, and HCC (409,410,411). The limitations of each of these types of studies have been discussed (411). Interestingly, mathematic models of the natural history of chronic hepatitis C appears to resolve this debate (412). These clearly demonstrate that both perceptions of the natural history are accurate, but progression is more easily observed in studies focused on the later stages of the disease.

Several long-term follow-up studies of recipients of contaminated blood products show that few patients with acute hepatitis C progress to liver failure and liver-related death. The classic study by Seeff reported the outcome in patients who had participated in five transfusion surveillance studies from 1968 to 1980 and had been prospectively followed up after the development of acute transfusion-associated non-A, non-B hepatitis (mostly hepatitis C) (404,413,414,415,416,417). Approximately half of these individuals were known to have developed chronic hepatitis with elevated aminotransferase levels, and, of these, slightly more than 30% had developed cirrhosis (411). Although more than 40% of patients with cirrhosis had some

evidence of hepatic decompensation, all-cause mortality was not significantly different from that of transfusion recipients who had not developed hepatitis (404). Most deaths were due to cardiac disease, which was not unexpected because most subjects received their transfusions during cardiac surgery. Nevertheless, liver-related mortality after 18 years was higher among patients with hepatitis (3.2%) than in controls (1.5%). A follow-up report 7 years later found a liver-related mortality of 4.1% versus 1.3% in controls (418). In both groups, liver-related mortality was strongly correlated with alcohol consumption. A similar study among HIV-negative, transfusion-dependent patients with hereditary bleeding disorders found liver-related mortality of just 3.4% after 25 years (396). A major limitation of transfusion studies is the high (50% to 67%) all-cause mortality related to the comorbid conditions that necessitated transfusion in the first place (404,418,419). However, long-term retrospective data are available in healthy young women who received HCV-contaminated lots of immunoglobulin products more than 20 years ago (420,421,422). More than 400 of the 53,178 (0.8%) recipients of eight HCV-contaminated lots of anti-D immunoglobulin in Ireland in 1977 were found to be anti-HCV positive on subsequent testing 17 years later (420). Liver biopsies revealed mild or moderate hepatitis in 93%. Although 15% already had bridging fibrosis, only 2% had cirrhosis. In a similar study from Germany, 160 of 2,533 (6.3%) women who received anti-D immunoglobulin between 1978 and 1979 became anti-HCV positive (421). Slightly more than half developed chronic hepatitis, but a large proportion appeared to recover completely. The low transmission and high recovery rates in these studies are quite atypical and may relate to the size of the inoculum, age of recipients, or both. Nonetheless, taken together, the studies in transfusion and immunoglobulin recipients confirm that most patients with acute hepatitis infection do well and are not at high risk of developing cirrhosis or liver failure, even after 20 to 25 years.

In contrast to these studies, some prospective studies of patients with acute post-transfusion hepatitis C have reported cirrhosis in 16% to 24% after follow-up of just 8 to 14 years (262,409,423,424,425). The prevalence of cirrhosis may increase to more than 40% after 40 years (426). Furthermore, the subset of patients who present with established chronic hepatitis C appears to have an even higher rate of progression to cirrhosis, liver failure, and liver-related death, although a self-selection bias is probably responsible for this observation (261,427,428,429). Evidence to support this derives from the estimated duration of infection in patients presenting with complications of liver disease; it is similar to the period of observation in the transfusion studies described earlier. Retrospective studies of patients with cirrhosis have suggested that the mean duration of infection before the development of cirrhosis is about 21 years, although this interval may occasionally exceed 50 years (261,430).

The rate of progression to cirrhosis has been estimated in several studies but is probably not linear in most individuals and depends upon several host and environmental factors (see subsequent text). The annual rate of fibrosis progression is estimated by dividing the fibrosis score (Metavir stage) by the estimated number of years after infection (431,432). Using this method, the average rate of fibrosis accumulation is 0.133 units per year (95% CI, 0.125 to 0.143) in patients with elevated serum ALT levels (432,433). Therefore, if progression is linear, it will take an average of 30 years to develop cirrhosis. However, many factors may influence the rate of progression in individuals, and therefore, it has been proposed that most patients fall into one of three groups with fibrosis rates that are rapid (less than 20 years to cirrhosis), intermediate (late cirrhosis), or slow (no cirrhosis or after 50 years) (433). Patients with persistently normal liver test results fall into the latter group because their mean fibrosis rate is only 0.05 units per year, which extrapolates to a mean time to cirrhosis of 80 years (434). Hepatic inflammation also influences the rate of progression (428,433). The 10-year risk of cirrhosis is less than 10% to 13% among patients with minimal or mild chronic hepatitis and 44% to 100% in those with moderate hepatitis (Table 30.8) (428,433).

There are several environmental, host, and viral cofactors that accelerate disease progression. The most important of these cofactors is alcohol intake (227,435). The association between HCV infection and alcoholic liver disease was first noted in early epidemiologic surveys of anti-HCV prevalence (435,436,437). It is now apparent that regular alcohol intake, particularly heavy intake, may accelerate liver injury in persons with chronic HCV infection (435,436,437,438,439,440,441). The risk of progressing to cirrhosis appears to be 1.5 to 3 times higher in those who consume alcohol (435,438,439,442,443,444,445). Furthermore, the effect appears to be dose–dependent, with a 15-fold higher

risk in the heaviest consumer compared to teetotalers (446). Alcohol presents greater risk for progression than duration of infection, age, gender, or coinfection with either HBV or HIV (444). Finally, patients who die from liver disease are more likely than others to be alcohol users (447). It is not yet clear whether the mechanism for this outcome is increased HCV replication or an additive injury from both the virus and the alcohol (228,435,448). Heavy alcohol use has been shown to inhibit hepatic expression of Bcl-2, an inhibitor of apoptosis, and to increase oxidant exposure in patients with chronic hepatitis C (449,450). Regardless of the mechanism, the outcome of alcohol use is clear and its use in persons with chronic HCV infection is to be strongly condemned. Evidence supporting a role for other environmental factors, such as toxins, in the progression of HCV infection is limited.

Table 30.8. Likelihood of Histologic Progression to Cirrhosis

Initial histology	Risk of cirrhosis (%)		
	5 y	10 y	20 y
Minimal-to-mild hepatitis	7	7	30
Moderate hepatitis	25	44	95
Severe hepatitis	68	100	100
Bridging fibrosis	58	100	100

Adapted from Yano M, Kumada H, Kage M, et al. The long-term pathological evolution of chronic hepatitis C. *Hepatology* 1996;23:1334–1340.

Other host-related factors are also important. The rate of disease progression seems to increase if HCV infection is acquired after the age of 50 to 55 years (261,428,432). Age may also play a role in those already infected chronically and might explain the more rapid progression that sometimes occurs as the disease advances beyond the second decade (428,432). The low rate of both acute and chronic infection in the contaminated anti-D immunoglobulin studies suggests the possibility that female gender, possibly in combination with young age, might reduce the risk of infection (420,421). Other host-related factors, particularly ethnic background, deserve further study because there is some evidence that disease progression and the development of HCC is more common in Japan and Italy (451). African Americans appear to have histologically somewhat less severe liver disease than do Hispanics or whites (452). Finally, host immune status may influence progression. Some studies suggest that HLA DRB1 might be important in the susceptibility to infection (453), and other phenotypes might be important in defining

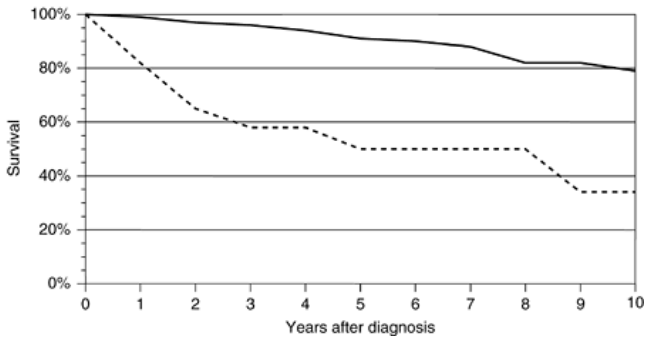
the host's ability to regulate viral replication (454). Furthermore, immunosuppression from HIV infection or immunosuppressive drugs after organ transplantation may accelerate disease. HIV-infected patients have higher HCV levels (455) and a higher rate of fibrosis progression, although there may be other confounding factors involved (400,456). Progression to cirrhosis is threefold higher in HIV-infected persons and is more common in patients with low CD4 counts (457). Liver transplantation and the necessity for exogenous immunosuppression results in accelerated liver injury. HCV infection persists in almost all patients who undergo transplantation for chronic hepatitis C and results in severe and progressive chronic hepatitis in many (458,459). Virus levels increase 10- to 15-fold after transplantation (459). The actuarial risk of developing cirrhosis is 3.7%, 8.5%, and 28% after just 1, 2, and 5 years of transplantation, respectively (460). More than 40% of these patients with cirrhosis will decompensate within 1 year, and survival is only 41% within a year of the decompensation event (461). Surprisingly, however, rapid progression and decreased early survival is not present in recipients of other solid organs or bone marrow (462,463,464).

There is currently insufficient data to suggest that viral factors influence the progression of HCV infection. Early studies suggested that genotype 1 caused more severe disease than genotype 2 (465) and that 1b was more harmful than 1a (466,467). However, the relationship of genotype 1 to more severe disease may be related to a longer duration of infection, and more recent studies suggest that genotype plays no role in influencing disease outcome (468,469). However, viral genotype significant influences treatment response and may therefore have considerable impact on the long-term disease outcome (see subsequent text).

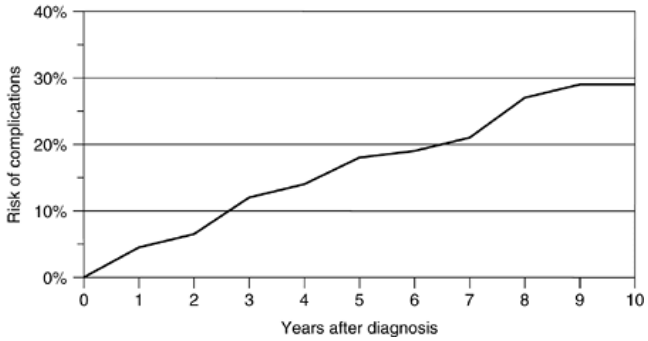
Liver-related morbidity and mortality among HCV-infected persons is directly related to complications of cirrhosis including hepatic failure and HCC (405,428,429). Liver-related mortality in those with compensated cirrhosis is low before the first episode of decompensation supervenes or the onset of synthetic dysfunction (Fig. 30.10) (405,470). Among patients with compensated cirrhosis, the annual risk of decompensation is 3.9% (Fig. 30.11). Decompensation is most commonly manifested by the development of ascites (48%) or variceal hemorrhage (22%), although multiple complications may occur simultaneously (17%) (405,470). At least one third of deaths in patients with cirrhosis occur as a consequence of these two complications. When ascites first presents, it can usually be managed quite easily with diuretics and salt restriction. Varices can often be managed effectively with endoscopic therapy. However, one should not be lulled into complacency with patients who can be managed medically because the excess mortality is still 10% to 33% after 3 years (471). Therefore, such patients should be considered for transplantation at the time when ascites or bleeding varices first appear. Survival in patients with decompensated cirrhosis is poor, with only approximately 50% surviving for more than 5 years (Fig. 30.10) (405). Hepatic synthetic dysfunction alone without other complications of cirrhosis has less impact on survival. Elevated bilirubin level, decreased albumin level, or thrombocytopenia results in a 16% to 19% decrement in 10-year survival compared with those with normal synthetic function (405). However, an elevated prothrombin time is a poor prognostic sign associated with a 39% reduction in 10-year survival compared with patients with cirrhosis who have normal synthetic function (405).

HCC is the fifth most common cancer worldwide. HCC is a significant complication of HCV infection and HCV is the most common etiologic factor in the United

States (472). Its incidence is also increasing in Europe (473). HCV-related HCC rarely occurs in the absence of cirrhosis (474,475). The annual risk of HCC is 1.4% to 3.3% in patients with cirrhosis in the United States, most of Europe, and Australia (261,405,476,477,478). It is estimated that the risk of HCC will double over the next 10 years (263) and may approach the higher risk rates (2.6% to 6.9%) observed in Japan and Italy (439). The mechanism for development of HCC in HCV disease is not known. Associations with small cell dysplasia and mutations in the protein kinase receptor binding domain, serine protease region, or CD81 genes have been reported (479,480,481). There is no association with mutations of tumor suppressor genes, virus levels, or viral genotype (482,483). The mean duration of HCV infection in patients with HCC is 28 to 29 years (261,405). HCC is more common in the presence of the following factors: Longer disease duration, hepatic synthetic dysfunction, cytopenia, male gender, and alcohol use (438,476,477,478,479,480,481,482,483,484,485). HCC appears to occur earlier in HIV-coinfected patients (486). Diagnosis of HCC is by imaging examinations and α-fetoprotein (AFP). AFP level is elevated in a variable proportion of patients with HCC and the risk of HCC is increased 30-fold when the AFP level is elevated (485,487). However, AFP is not specific and its level may be elevated in 30% to 45% of patients with chronic hepatitis C without HCC, although it is usually less than 100 ng/mL (405,487,488,489,490). Magnetic resonance is the most sensitive screening test, followed by computerized tomography and ultrasonography (490). However, the more sensitive imaging modalities are quite expensive. Imaging is most sensitive when performed every 6 months (490). Treatment of HCC is discussed in Chapter 44 of this book.



▪ **Figure 30.10** Survival in patients with cirrhosis due to chronic hepatitis C. Effect of complications and decompensation (*top line*, compensated cirrhosis; *bottom line*, decompensated cirrhosis). (See Fattovich G, Giustina G, Degos F, et al. Morbidity and mortality in compensated cirrhosis type C: a retrospective follow-up study of 384 patients. *Gastroenterology* 1997;112:463–472, with permission.)



▪ **Figure 30.11** Risk of developing decompensated liver disease among patients with stable cirrhosis due to chronic hepatitis C. (See Fattovich G, Giustina G, Degos F, et al. Morbidity and mortality in compensated cirrhosis type C: a retrospective follow-up study of 384 patients. *Gastroenterology* 1997;112:463–472, with permission.)

Currently, hepatic decompensation and HCC related to chronic hepatitis C are common indications for liver transplantation. HCV is the leading indication for liver

transplantation in the United States, accounting for approximately half of the nearly 6,000 liver transplantations performed each year. Liver transplantation for hepatitis C is described in detail in Chapter 53 of this book.

Prevention and Treatment

Public Health, Passive Protection, and Vaccines

Public health

Health care professionals must be informed about appropriate medical management of HCV-infected patients, known and potential risks for infection, the need to identify risk factors in their patients, appropriate evaluation of high-risk patients, and recommendations for prevention. All anti-HCV–positive patients should be considered infectious and informed of the possibility of transmission to others, although no tests are available to reliably determine infectivity. Counseling recommendations to prevent transmission of HCV were published by the U.S. Public Health Service in 1998 and were incorporated, in part, into the 2002 National Institutes of Health (NIH) Consensus Development Conference report on the management of hepatitis C (491,492). These recommendations are summarized in Table 30.9.

Passive protection

Neutralizing antibodies directed against immunodominant epitopes of HCV should protect the susceptible hepatocytes and other target cells from HCV infection. Experimental studies in chimpanzees have shown that plasma from a patient with chronic hepatitis C was capable of neutralizing isolate-specific HCV in vitro, thereby preventing infection (123). Neutralizing antibodies may be acquired passively by the administration of immunoglobulin preparations containing these antibodies. Before identification of HCV and elimination of anti-HCV–positive patients from the donor pool, it would be reasonable to assume that antibodies directed against HCV envelope proteins were present in the immunoglobulin prepared from pooled donors. On the basis of this assumption, passive immunization with conventionally prepared immunoglobulin was attempted to reduce the risk of transfusion-associated non-A, non-B hepatitis. Four prospective, randomized (three of which were placebo-controlled) clinical trials of immunoglobulin for the prevention of transfusion-associated non-A, non-B hepatitis provided conflicting results (415,417,493,494). Piazza et al. found that only 1 of 450 heterosexual partners of patients with HCV antibodies who received immunoglobulin enriched with anti-HCV became infected compared to 6 of 449 partners who received placebo (495). Feray et al. demonstrated indirect evidence that passive immunization may prevent HCV infection in liver transplant recipients. Among 218 HBsAg-positive patients who had HCV coinfection before transplantation, the prevalence of HCV viremia after transplantation was lower in those receiving hepatitis B immunoglobulin prepared before 1990 when screening of donors for anti-HCV began (25 of 46 [56%] patients) compared to others who received immunoglobulin free of HCV antibody (162 of 172 [94%] patients) (496). The 3-year actuarial rate of recurrent hepatitis C was also lower in those who underwent transplantation before 1990 (10%) than in those who underwent transplantation after 1990 (61%). Among patients who did not receive immunoglobulin therapy, the proportion who developed hepatitis C after transplantation was similar to that in patients who underwent transplantation before (63%) or after 1990 (71%) (496).

These studies suggested the possibility that pretransfusion administration of immunoglobulin containing antibodies to HCV would reduce the risk of non-A, non-B hepatitis, but the results are far from conclusive. Furthermore, these studies have much less relevance today. First, plasma collected for fractionation is screened for anti-HCV, and it is therefore likely that HCV-neutralizing antibodies are either absent or present in exceedingly low titers in currently manufactured conventional immunoglobulin. Second, the risk of post-transfusion hepatitis has nearly been eliminated by donor screening (306). In summary, postexposure prophylaxis with standard immunoglobulin is not effective in preventing HCV infection and is not recommended by the Advisory Committee on Immunization Practices (277).

It might be possible to produce immunoglobulin containing high titers of HCV-neutralizing antibodies. In fact, hyperimmune serum prepared against a synthetic peptide derived from the HVR of the HCV envelope protein is capable of neutralizing HCV and preventing infection when mixed with HCV in vitro before inoculation into chimpanzees (497). Postexposure prevention of HCV infection has also been studied by using a human HCV hyperimmunoglobulin prepared from anti-HCV–positive plasma that tested negative for HCV RNA (498). Intravenous infusion of this polyclonal product into a chimpanzee within 1 hour of inoculation with an infectious dose of HCV did not prevent infection but did appear to delay the onset of liver injury. Similar preparations have now been used in humans (499,500). Both studies infused antibody at the time of and after liver transplantation in patients with chronic hepatitis C. Neither study demonstrated any effect on HCV RNA levels or recurrence in the graft.

Table 30.9. Guidelines for High-Risk and Hepatitis C Virus–Infected Individuals from the 2002 National Institutes of Health Consensus Development Conference on Management of Hepatitis C (491,492)

HIGH-RISK BEHAVIOR

- Get vaccinated against hepatitis A and B
- Persons who continue to use or inject illegal drugs should
  Never reuse or share syringes, needles, water, or drug
  Use only new and sterile syringes and water obtained from a reliable source
  Use new or disinfected containers and filters to prepare drugs
  Clean the injection site with alcohol
  Dispose of syringes after one use
- Persons at risk for sexually transmitted diseases should
  Have sex only with a single uninfected partner or abstain, which is the best way to avoid infection
  If having high-risk sexual activity, use latex condoms correctly and every time

HEMODIALYSIS PATIENTS

- Use dedicated dialysis stations, chairs, and beds; clean after each use
- Avoid sharing ancillary nondisposable supplies; clean after each use
- Medication and supplies should not be shared and medication carts should not be used
- A central medication and supply prep area should be used
- Separate clean and contaminated areas

HCV-INFECTED PERSONS

- Consider all anti-HCV or HCV RNA–positive persons to be potentially infectious
- Do not donate blood, organs, tissues, or semen
- Avoid sharing of household items such as toothbrushes and razors
- Changes in sexual practices are not required within a monogamous relationship (however, a low potential for sexual HCV transmission exists; anti-HCV–positive persons and their partners should be informed of the potential risk of sexual transmission and an informed decision regarding the need for precautions should be made)
- Vaccinate against hepatitis A and B
- Avoid exposure to risk factors for transmission to others
- Avoid alcohol consumption

PERSONS REQUIRING ROUTINE TESTING FOR HCV INFECTION

- Persons who have at any time injected illegal drugs regardless of number of events
- Persons who received clotting factor concentrates before 1987
- Persons who were at any time on long-term hemodialysis
- Persons with persistently abnormal alanine aminotransferase levels
- Persons who received a transfusion or organ transplant July 1992
- Persons with needlestick, sharp, or splash exposure to HCV-positive blood
- Children born to an HCV-positive mother
- Routine testing is *not* recommended for:
  Health care, emergency medical or public safety workers
  Pregnant women
  Household contacts
  General population

HCV, hepatitis C virus; RNA, ribonucleic acid.

Because of the lack of an effective immunoglobulin, persons with percutaneous exposure to HCV should be closely monitored for infection. At a minimum, this requires serial testing of serum ALT and anti-HCV levels at baseline and 4 to 6 months postexposure (491). However, others have suggested serial HCV RNA determinations by PCR to identify early acute infection that might prove more amenable to IFN treatment (see subsequent text) (501).

Vaccination

Development of an effective vaccine against HCV has faced several obstacles. First, it appears that neutralizing antibodies against the hypervariable envelope proteins, although potentially protective, are largely isolate specific and therefore likely to provide only temporary protection against a heterogeneous virus such as HCV (126). Second, little is yet known about the ability of HCV-specific cellular immune responses to induce protection. Finally, it will be difficult to test the efficacy of a potentially protective vaccine when the risk of acute infection is so low. Nonetheless, some progress has been made in developing hepatitis C vaccines. A recombinant E1E2 heterodimer vaccine administered four times over a year to healthy volunteers induced antibodies that bound to E1E2 and

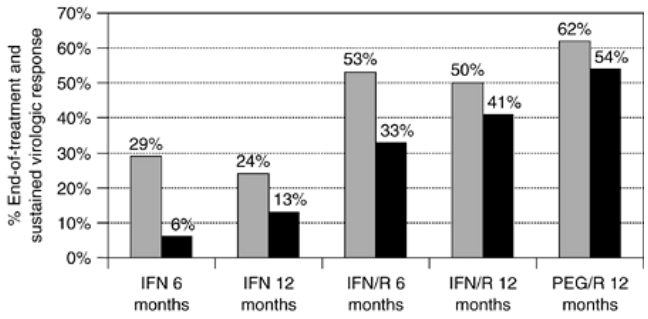
CD81, the putative HCV receptor (502). Furthermore, the antibodies neutralized E1E2-encoated vesicular stomatitis virus pseudovirions and induced lymphocyte proliferation. In another study, a recombinant E1 vaccine was given to 24 HCV-infected patients in repeated courses. All but three patients developed a significant de novo E1-specific T-cell response. Anti-E1 antibodies increased and higher levels correlated with the decrease in total Ishak score in 9 of the 24 subjects (503).

Antiviral Therapy

The major goal of treatment of HCV infection is to prevent the development of decompensated liver disease and death. This can be accomplished by preventing new infections, reducing the chance of acute infection progressing to chronic hepatitis, or effectively treating chronic infection. The goals in treating chronic hepatitis should include eradication or prolonged suppression of viral replication, reduction of hepatic inflammation, and ultimately, slowing the rate of progressive liver injury. Not all these goals may be achievable in every patient. However, eradication of chronic HCV infection is now possible in half or more of treated patients (504).

Evolution of treatment for chronic hepatitis C

Increasingly more effective treatment regimens for chronic hepatitis C have evolved rapidly over the last 2 decades (Fig. 30.12). In the mid-1980s, IFNs became the first agent studied for the treatment of what was then called *chronic non-A, non-B hepatitis*. IFNs are glycoproteins produced in vivo by leukocytes in response to viral infection. IFNs can be commercially manufactured by cell culture or recombinant technology and have been commercially available for the treatment of chronic hepatitis for more than a decade. IFNs inhibit the replication of many viruses, including hepatitis viruses, through a variety of mechanisms including direct antiviral mechanisms (inhibition of virus attachment and uncoating, and induction of intracellular proteins and ribonucleases) and amplification of specific (CTL) and nonspecific (NK cell) immune responses (505). The specific mechanism(s) of action for IFN in chronic hepatitis C infection remain(s) poorly understood. However, viral kinetic modeling in IFN-treated subjects shows a biphasic decline in HCV RNA level after IFN treatment (506). The first 24- to 48-hour phase is characterized by a rapid decline in virus level, which is thought to represent degradation of free virus, while replication of new virions and infection of naïve cells is inhibited (506). The second phase has a slow exponential decline in viral levels and is thought to represent loss of residual infected hepatocytes (506).



▪ **Figure 30.12** Changes in the end-of-treatment and sustained response rates with different interferon (IFN) treatment regimens (*shaded bar*, end-of-treatment response; *solid bar*, sustained response). IFN/R, interferon and ribavirin; PEG/R, polyethylene glycol and ribavirin.

Recombinant IFN was first approved by the U.S. Food and Drug Administration (FDA) for the treatment of non-A, non-B hepatitis in 1991. Initially, the recommended treatment course was 6 months, but it was subsequently shown that prolonging treatment to 12 months doubled the sustained response rate, and this longer regimen was subsequently approved as the standard of care (507,508,509). Sustained biochemical (normalization of the serum ALT level) and virologic (loss of detectable serum HCV RNA) responses were relatively uncommon with IFN monotherapy, ranging from 6% to 15% after a 6-month course of IFN to 13% to 25% after 12 months of therapy (509). More recent studies that have carefully assessed virologic endpoints of treatment with different regimens have clearly shown that sustained responses to IFN monotherapy are at the lower end of these previously described ranges (510,511).

Ribavirin was added to the treatment regimen almost 10 years later. Ribavirin (1-β-D-ribofuranosyl-1H-1,2,4-triazole-3-carboxamide) is a synthetic nucleoside analog that structurally resembles guanosine (512). Ribavirin has in vitro activity against several DNA and RNA viruses, including Flaviviridae (513). The mechanism of action in HCV infection is not clear, but the

predominant current opinion is that ribavirin induces lethal mutations in viral genome, a mechanism known as *viral error catastrophe* (512,513,514). Early studies of ribavirin alone found that serum ALT levels fell to within the normal range in 40% of treated patients, but virus levels did not significantly change (515,516,517). However, when combined with IFN, ribavirin reduces relapse after response

during treatment, and this results in a dramatic improvement in the sustained virologic response (SVR) rate (510,511,518,519). The results of two similarly designed large randomized controlled trials comparing combination therapy to IFN monotherapy have been combined and reported (520). These studies compared 6- and 12-month courses of combination therapy (3 million units of IFN-α-2b thrice weekly plus 1,000 to 1,200 mg oral ribavirin daily) to similar duration courses of IFN alone (510,511). The combined results showed sustained viral-negative responses in 41% and 33% of subjects treated with 12 and 6 months of combination therapy, respectively, compared to 16% and 6% in those treated with IFN alone for 12 and 6 months, respectively (520).

Long-acting pegylated IFNs increase host exposure to IFN and double the response seen with standard IFN preparations (521,522,523). These formulations replaced standard IFNs after their approval by FDA in 2001. Pegylation involves the attachment of a large inactive molecule (polyethylene glycol [PEG]) to a protein to reduce clearance. This process results in some variable loss of activity of the native protein that is dependent on the size and site of attachment of the PEG molecule (524). In the case of IFNs, pegylation results in a 10-fold increase in drug half-life and a corresponding decrease in clearance (525,526). It is this longer half-life that allows large doses of the drug to be administered less frequently (once weekly instead of three times per week). The PEG molecule is cleaved after binding of the complex to the IFN receptor and cleared. Short PEG molecules, such as the 12-kDa tail attached to the IFN α-2b protein, are renally cleared while longer molecules, such as 40-kDa tail on the α-2a drug, are hepatically metabolized (527). At the present time, there is no evidence that either PEG molecule has any deleterious effects.

Pegylated IFNs are more effective than standard IFN, and there is a clear dose response with increasing doses of the PEG-IFNs (521,522,523,524,525,526,527,528). Studies of monotherapy with pegylated IFN α-2a at a fixed dose of 180 μg weekly for 48 weeks resulted in an SVR rate twice that observed with the standard IFN α-2a thrice-weekly dosing control group (39% vs. 19%) (522). Similarly, studies of pegylated IFN α-2b using weight-based dosing of 1.0 or 1.5 μg/kg weekly for 48 weeks demonstrated an SVR rate twice that observed with the standard IFN α-2b control group (25% and 23%, respectively, vs. 12%) (523). It is important to point out that the study groups were not comparable and the sustained response rates cannot be directly compared; it is likely that any differences in efficacy between the two drugs, if they exist at all, are minimal.

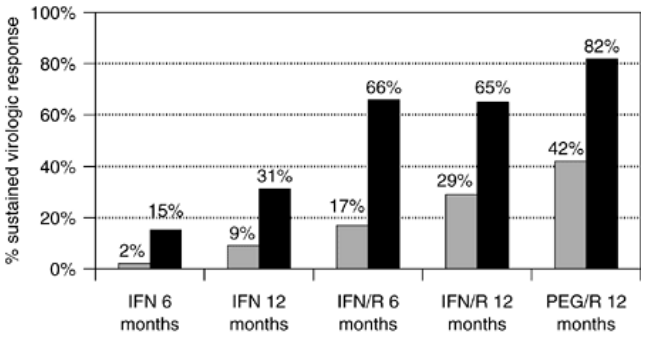
Neither pegylated IFN preparation alone has clinical efficacy approaching the combination of standard IFN and ribavirin. Therefore, the clear role of pegylated IFNs is in combination with ribavirin, and this combination is currently the standard of care for chronic hepatitis C. Large international randomized controlled studies confirmed the advantage of the pegylated combinations over standard IFN combinations (528,529). PEG-IFN α-2b 1.5 μg/kg once weekly plus 800 mg daily ribavirin led to an SVR rate of 54%, although the dose of ribavirin in this study was suboptimal (528). Sustained response was 42% in patients infected with genotype 1 and 82% in those with genotype 2 or 3 (528). In another trial, PEG-IFN α-2a 180 μg once weekly plus 1,000 to 1,200 mg of ribavirin per day resulted in an SVR rate that was 56% (529). Sustained response was 46% in patients infected with genotype 1 and 76% in those with genotype 2 or 3 (529). In both studies, tolerance including cytopenia and discontinuation of drug was similar to that of standard IFN and ribavirin, although fever, nausea, and injection site erythema were seen more commonly.

Optimal treatment regimens

The sensitivity of different HCV genotypes to IFN-based therapies varies considerably (Fig. 30.13). Therefore, determination of the virus genotype before treatment remains a critical step, and the optimal dosing regimens for the predominant genotypes have been more clearly defined (Table 30.10). For patients with genotype 1, the optimal regimen includes 1 year of PEG-IFN plus ribavirin. Although the approved dose of ribavirin is 1,000 to 1,200 mg/day for those with weight less than or greater than 75 kg, respectively (530), an extended weight-based dose ranging from 800 to 1,400 mg/day is commonly used (Table 30.11). It is not known whether such dosing improves response or is appropriate for other genotypes. Recently, some investigators have suggested that "rapid viral response" (RVR) (undetectable HCV RNA after 4 weeks of treatment) in patients with genotype 1 identifies a small subgroup (approximately 20% of treated patients) who may be treated for only 24 weeks and still achieve an SVR rate of 73% to 91% (531). Others have found a lower SVR rate with 24 weeks of treatment, so this needs to be confirmed before this regimen is made standard practice (532).

Patients with genotype 2 or 3 respond as well with doses of 800 mg/day and just 6 months of treatment as they did with higher doses and a longer duration (530). Recently, studies have suggested that some patients with genotype 2 or 3 infection who respond rapidly to

treatment can be treated for as little as 14 to 16 weeks with excellent outcomes (537).



▪ **Figure 30.13** Influence of viral genotype on sustained virologic response to interferon (IFN)-based treatment (*shaded bar*, genotype 1; *solid bar*, genotype 2 or 3). IFN/R, interferon and ribavirin; PEG/R, polyethylene glycol and ribavirin.

Patients who are infected with genotype 4 have viral response rates similar to or perhaps slightly better than those infected with genotype 1 and, like genotype 1, some achieve good responses with only 24 weeks of therapy (533). Genotypes 5 and 6 have SVR rates approaching those achieved with genotypes 2 and 3, although they require a full year of therapy (534,535).

Patient selection, drug administration, and monitoring therapy

Rational treatment management decisions are based on a clear understanding of the epidemiology and natural history of chronic hepatitis C, as well as the factors that influence the response to treatment. These decisions require that both the patient and the physician be fully informed about the disease. In the individual patient, general health factors such as age, comorbid disease, psychosocial circumstances, compliance, desire to be treated, contraindications to treatment, and financial issues must be weighed in arriving at an initial decision about whether treatment is appropriate. Counseling about transmission, natural history, treatment options, and possible treatment risks and outcomes is indicated regardless of what intervention, if any, is ultimately decided on. All should be counseled about the significant risks of alcohol use with this disease (538). Patients should also clearly understand the risks of complications should they or their sexual partners become pregnant during or shortly after the treatment course. All patients, particularly those with a history of depression, should be forewarned of the risk of depression and the need to treat it early. If treatment is not considered at this time, the importance of long-term follow-up must be emphasized. If the physician and patient agree to proceed with the treatment, assessment of the status of the disease (as determined by liver biopsy) and infection (as determined by viral genotype and HCV RNA level) should be made. This allows a more accurate estimate of the prognosis and chance of response to available treatment. It also allows the physician to use these patient characteristics that may independently influence treatment response to personalize the treatment strategy to achieve the optimal response. Although most hepatologists use only viral genotype and histology to choose the best treatment duration (539), others have recommended a more complex "a la carte" method that also incorporates gender, age, and viral level into the equation (540). Retrospective analysis suggests that such algorithms might improve

SVR rates to 50% to 83%. However, the wisdom of complicated algorithms that would, in effect, treat a higher proportion of infected cases with a longer and more costly regimen is controversial and has not been confirmed prospectively.

Table 30.10. Interferon and Ribavirin Dosing According to Viral Genotype (530,533,534,535,536)

Genotype	Interferon dose (/wk)	Ribavirin dose (mg/d)	Duration (wk)	SVR (%)
1	180 µg PEG α-2a *or* 1.5 µg/kg PEG α-2b	800–1,400 weight based	48	41–42
2	180 µg PEG α-2a *or* 1.5 µg/kg	800	24	60–84

	PEG α-2b			
3	180 μg PEG α-2a *or* 1.5 μg/kg PEG α-2b	800	24	60–84
4	180 μg PEG α-2a *or* 1.5 μg/kg PEG α-2b	1,000–1,200	48	55
5	180 μg PEG α-2a *or* 1.5 μ/kg PEG α-2b	1,000–1,200	48	64
6	180 μg PEG α-2a *or* 1.5 μg/kg PEG α-2b	1,000–1,200	48	63

SVR, sustained virologic response; PEG, polyethylene glycol.

Table 30.11. Dosing Guidelines for Combination Therapy with Pegylated Interferon and Ribavirin (536)

Body weight in kilograms (pounds)	Peg-IFN α-2a dose (μg)	Peg-IFN α-2b dose (μg)	Ribavirin dose (≥13 mg/kg)
<40 (<88)	180	50	800
40–50 (88–100)	180	64	800
50–65 (112–141)	180	80	800
65–75 (143–165)	180	112	1,000
76–85 (167–187)	180	120	1,000
86–104 (189–229)	180	150	1,200
>105 (>231)	180	150	1,400

- U.S. Food and Drug Administration–approved dosing for pegylated IFN α-2b and ribavirin is 1.5 μg/kg once per week and 800 mg/d in divided dose, respectively (454,460).
- Traditional doses of ribavirin based on licensed recommendations with nonpegylated regimens are 1,000 mg/day if body weight is less than 75 kg or 1,200 mg if weight is more than 75 mg.

Baseline assessment of liver tests, complete blood counts, and HCV RNA level are important to later determine treatment response and drug-related toxicity. The patient should be instructed in injection techniques and forewarned about what drug-related symptoms are expected. Treatment tolerance is improved if the patients are educated about the potential side effects of therapy and what they might expect. Some easy measures such as evening dosing, exercise, adequate hydration, and use of acetaminophen at the time of each IFN dose will reduce anxiety, side effects, and noncompliance. Reinstitution of antidepressants should be considered in patients with a significant past history of depression. Physician extenders such as nurses, pharmacists, and commercial treatment support services are extremely helpful in this respect.

Standard treatment of chronic hepatitis C should consist of the combination of pegylated IFN α- 2b (PEG-

Intron™, Schering Plough, Kenilworth, NJ, at a dose of 1.5 μg/kg body weight) or pegylated IFN α-2a (Pegasys, Roche, Nutley, NJ, at a fixed dose of 180 μg) administered subcutaneously once per week and 13 to 15 mg/kg (minimum dose, 800 mg) of oral ribavirin per day in divided doses (Table 30.11). Pegylated IFN α-2b is dosed on the basis of body weight because it has a larger volume of distribution than pegylated IFN α-2a (20 L vs. 8 L), which has a volume of distribution approximately equivalent to plasma volume and can therefore be administered as a fixed dose (529). The listed doses of ribavirin are based on retrospective analyses of ribavirin dose response in clinical trials (528,529,530,536,540). Although this extended weight-based dosing method has become common, the advantage of extended dosing method appears to be marginal in comparison to the previous limited weight-based dose (1,000 or 1,200 mg) (536). Nonetheless, a recent study demonstrating that even higher doses of ribavirin may improve response rates justify the use of this dosing method (541,542). Viral genotype determines the duration of therapy (Table 30.10).

Monitoring response and potential drug toxicity is essential. Symptoms related to treatment rarely necessitate dose adjustments. However, hematologic alterations, particularly anemia, can be significant and clinically important during the first few weeks. Therefore, blood counts including hemoglobin, white count, differential, and platelet count should be repeated 2 and 4 weeks after starting therapy. Transient IFN dose reduction is indicated only for a white count less than 1,500/mL, a neutrophil count less than 750/mL, or platelets less than 50,000/mL. Ribavirin should be reduced if the hemoglobin level falls to less than 10 g/dL. The amount of dose reduction required to reverse cytopenia has not been established. Although the labeling of the drugs calls for reducing doses by half, this is usually not necessary. Temporary dose modifications are common in patients treated with combination therapy. In fact, in large controlled trials dose modifications were required at least transiently in 34% to 42% of patients, respectively (510,511,528,529). Between 8% and 13% of patients require reduction of the ribavirin dose for anemia, usually during the first 4 weeks of treatment (543). Ribavirin-induced anemia is dose dependent, and therefore, anemia usually stabilizes or improves with dose reduction. Occasionally, transfusion or support with erythropoietin is necessary, although it generally takes 4 to 8 weeks before the hemoglobin level increases after erythropoietin is started (544). The hemolytic anemia is accompanied by a vigorous reticulocytosis that usually serves to maintain stable levels of hemoglobin after the first few weeks of treatment and result in its return to baseline within 4 weeks of stopping treatment. Approximately 15% to

20% of patients treated with pegylated IFN require dose reductions for neutropenia (528). Growth factor support is rarely required. Significant thrombocytopenia necessitating dose reduction is uncommon because the anemia caused by ribavirin induces a reactive thrombocytosis. Therefore, platelet counts tend to remain relatively stable throughout combination therapy, even when the pretreatment count is low. IFN should be permanently stopped only if symptoms are incapacitating, the absolute neutrophil count is less than 500/mL, or the platelet count is less than 25,000/mL. Discontinuation of therapy for cytopenia is uncommon if patients have been monitored and dose adjusted appropriately. It is extremely important that treatment not be stopped prematurely or for decreases in blood counts that do not meet the criteria stated earlier. Inappropriate dose reduction and discontinuation significantly reduces the likelihood of a treatment response. Early discontinuation of treatment can reduce the likelihood of a sustained treatment response by 80% (545). Management of other side effects is discussed later.

Side effects of treatment

The safety and tolerability of combination therapy have been reviewed in detail elsewhere and will only be highlighted here (543,546). Overall, IFN-based therapies are reasonably well tolerated. Most patients experience flu-like side effects including fatigue, fever, headache, myalgia, and arthralgia (528,543). These are most severe when treatment is initiated and often abate to a large degree as treatment is continued. Gastrointestinal symptoms including nausea, vomiting, or diarrhea occur in about a third of patients but are rarely severe. Psychiatric symptoms such as depression, impaired concentration, irritability, and insomnia occur in about a third of cases but are also common in untreated patients with chronic hepatitis C (510,528,547). Dermatologic signs and symptoms occur in about a quarter of patients, but injection site erythema is seen in 30% to 60% of cases and is more common and pronounced with pegylated IFNs (528).

As described in the preceding text, ribavirin causes a predictable dose-related hemolysis. Therefore, the drug should be used with great caution or avoided completely if there is preexisting anemia, a hemolytic disorder, coronary artery disease, or hypoxia. Because ribavirin is renally excreted, it can cause profound hemolysis in patients with renal failure and should generally be avoided. Careful consideration should be given to the potential effects of an acute anemia in each patient in whom combination treatment is considered. The mean fall in hemoglobin is level 2 to 3 g/dL (510,511,517). The decline occurs gradually during the first 4 weeks of treatment and the hemoglobin level usually remains relatively stable thereafter.

Severe adverse events, including severe psychiatric symptoms, suicide attempts, and profound cytopenia, are extremely uncommon, being reported in fewer than 1 in 1,000 treated cases (546). Development of immune-mediated disorders such as thyroid disease, diabetes, dermatologic conditions, neuropathy, and

other autoimmune-like signs was seen in about 1% in a large retrospective series (546). Development of autoantibodies is not necessarily associated with autoimmune disease. Autoantibodies are common in patients with HCV infection and may be more common during IFN treatment (133,548). Finally, ribavirin has embryotoxic and teratogenic effects in animals and should be avoided in patients with childbearing potential unless adequate contraception is assured. Trial and postmarketing surveillance data suggests that most patients or spouses of patients who become pregnant during or within 6 months of treatment will spontaneously abort if the pregnancy is not otherwise terminated (GL Davis, unpublished data, 2002).

Assessing treatment response

Treatment responses are defined by changes in the HCV RNA level during and after treatment; these are listed and described in Table 30.12. Early studies also utilized serum ALT level to assess the response to therapy, but virologic endpoints are now most appropriate. Serum ALT level does not always reflect on treatment response because ribavirin may normalize serum ALT level in the absence of a virologic response and ALT level may occasionally be elevated despite a virologic response, especially in those receiving pegylated products (517,528,529).

The implications of RVR are described in the preceding text, but this is a new concept and requires confirmation before influencing treatment duration in most patients. Early virologic response (EVR) is used to assess nonresponsiveness to treatment during the first weeks of therapy. EVR is based on the concept that the slope of the second-phase decline in HCV RNA levels during treatment correlates with the likelihood of eventual virus clearance (82,549). Obviously, it requires a quantitative HCV RNA assay with a wide dynamic range to assess this decline (See "Diagnostic Tests"). Genotype 1–infected patients who do not achieve at least a 2-log reduction (99%) in HCV RNA level after 12 weeks of treatment have less than 1% chance of reaching an SVR with continued therapy (Fig. 30.14) (550). This has served to justify discontinuation of therapy after 12 weeks in the 20% or so of patients without EVR. Patients with genotype 2 or 3 almost always reach an EVR, so it is usually not helpful to assess HCV RNA levels in them during treatment (550).

Measurement of HCV RNA at the end of therapy is helpful in identifying those in whom the virus has

cleared (end-of-treatment response) and who require subsequent screening to confirm the durability of the response. Approximately 15% of patients with end-of-treatment response will relapse during the first few months after treatment is stopped (528,529). SVR is confirmed by the absence of detectable HCV RNA by a sensitive molecular test 6 months after completing therapy. SVR is the major goal of treatment and is durable.

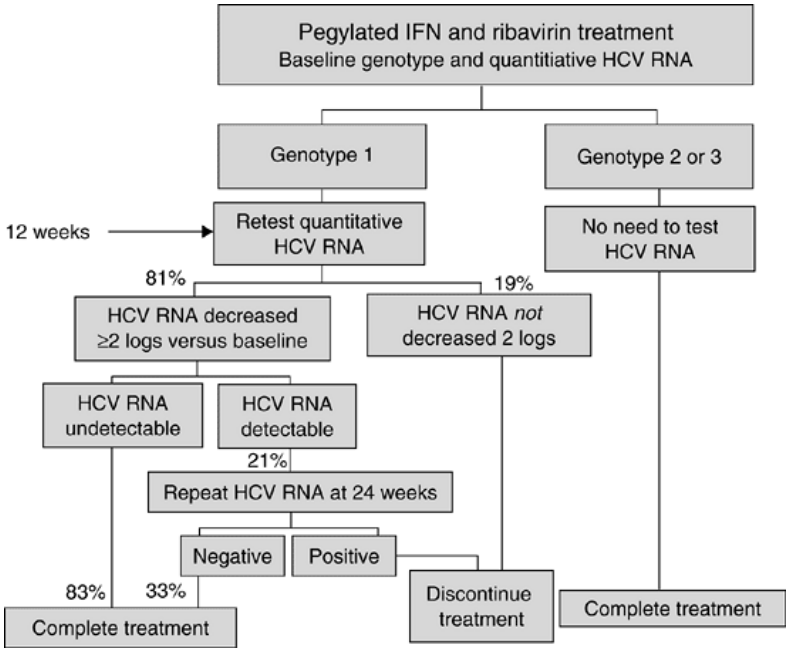
Table 30.12. Definitions of Treatment Responses

Response	Time to assess	Definition	Implication
RVR	4 wk	HCV RNA undetectable by PCR or TMA	Higher chance of SVR; may respond as well with only 24 wk of treatment
EVR	12 wk	HCV RNA decreased by ≥two logs from baseline or HCV RNA undetectable	Failure to achieve EVR associated with almost no chance of SVR and treatment can usually be stopped
ETR	End of treatment	HCV RNA undetectable by PCR or TMA	On treatment response; observe for SVR
SVR	24 wk after treatment	HCV RNA undetectable by PCR or TMA	Eradication of virus

RVR, rapid viral response; HCV, hepatitis C virus, RNA, ribonucleic acid; PCR, polymerase chain reaction; TMA, transcription-mediated amplification; SVR, sustained virologic response; EVR, early virologic response; ETR, end-of-treatment response.

Clinical implications of sustained virologic response

SVR is the primary goal of treatment. It is durable and connotes eradication of infection (551). Furthermore, SVR results in long-term histologic improvement with fibrosis regression at a rate of 0.28 Metavir units per year (552,553,554,555). By contrast, nonresponders to IFN-based therapy continue to have progression of fibrosis at a rate of 0.10 Metavir units per year (555). It is reasonable to assume that these benefits would translate into a reduction in disease-related morbidity and mortality. Indeed, patients with fibrosis or cirrhosis who achieve SVR have gradual improvement in quantitative hepatic function, reduction in portosystemic shunting, significant reduction in the risk of developing HCC, and improved survival (556,557).



▪ **Figure 30.14** Algorithm for determining early virologic response. IFN, interferon; HCV, hepatitis C virus; RNA, ribonucleic acid.

Treatment in special patient groups

Fibrosis or cirrhosis

The presence of bridging fibrosis or cirrhosis negatively impacts treatment response to IFN-based regimens. SVR among patients with stage 3 or 4 fibrosis is 41% to 44% compared to 54% to 55% in those with stage 0 to 2 (528,529).

The justification for treating patients with advanced fibrosis is clear because these patients have a greater risk of progressing to develop HCC or complications of cirrhosis. Patients with fibrosis or cirrhosis who achieve SVR have a reduced risk of developing these complications (557).

Higher doses of IFN may overcome some of the lack of response to IFN. In a trial using a dose of 3.0 μg/kg of pegylated IFN α-2b, SVR was the same in patients with and without advanced fibrosis, although this was not the case with the standard IFN dose (558). Finally, it has been suggested that chronic low-dose IFN might also delay progression of fibrosis and reduce complications of liver disease in patients with fibrosis or cirrhosis who have failed to reach an SVR with standard antiviral therapy. This is currently being evaluated in prospective clinical trials (See "Viral Nonresponders").

Treatment of patients with decompensated cirrhosis can be considered in the hope of eradicating infection before liver transplantation. SVR in this group usually prevents recurrence of HCV infection after transplantation (559). However, such treatment is extremely difficult. Most patients have cytopenia that prevents them from receiving the optimum doses of medications, and severe complications usually require dose reductions or discontinuation of therapy (559,560). These problems may be partially avoided by initiating treatment at low doses and escalating as tolerated (559). Despite the problems, SVR is possible in approximately 25% of patients. Treatment in this group of patients is best managed by experienced transplantation hepatologists.

High viral load

High levels of HCV RNA are associated with a decreased chance of clearing virus, at least with genotype 1 infection (528,529). SVR in patients with more than 2 million copies per milliliter achieved SVR in 30% to 39% compared to 56% to 68% in those with lower levels (528,529). Furthermore, patients with low levels of HCV RNA before treatment are also more likely to reach an RVR that may allow them to discontinue treatment early (531). It does not appear that higher doses of IFN are able to overcome the impaired response in patients with high viral loads.

African Americans

SVR rates have consistently been lower in African Americans than in whites in trials of IFN-based therapy. Recent studies with pegylated IFN and ribavirin in previously untreated patients with genotype 1 infection observed SVR rates of 19% to 26% in African Americans versus 39% to 52% in whites (561,562). Several factors including the higher proportion with genotype 1, higher body weight, and a slower decline in HCV RNA in viral kinetic studies might at least partially explain this observation. However, the apparent ability of higher doses of IFN or ribavirin to improve responses suggests that the explanation may lie in the impaired ability of intracellular antiviral mechanisms to be turned on at standard doses of these medications (558,563).

Human immunodeficiency virus–hepatitis C virus coinfection

HCV infection is common in HIV-infected individuals (564). Coinfected patients tend to have high HCV RNA levels, and some studies suggest that they have more severe liver disease, more rapid disease progression, and a higher prevalence of hepatic fibrosis (455,565,566,567,568). Liver disease due to hepatitis B, hepatitis C, or alcohol is second only to acquired immunodeficiency virus as a cause of death in patients with HIV (569). Several clinical trials of pegylated IFN and ribavirin have recently been reported (570,571,572). Treatment responses vary considerably in these studies because of differences in design and compliance. However, SVR in genotype 1 patients was low (14% to 29%) while it was reasonably intact in genotype 2 and 3 subjects (62% to 73%). Overall, SVR rates appeared to be 10% to 15% below what would be expected in an HIV-negative population. Several points are worth making. First, SVR is possible in the HIV–HCV coinfected patient and treatment should be considered. Second, failure to achieve EVR reliably predicts lack of response in this group and this should be discussed before treatment is started because the treatment goals are different from those of HIV. Finally, patients receiving highly active antiretroviral therapy (HAART) or with low CD4 counts appear to be more likely to experience adverse effects from treatment, including drug hepatotoxicity (564,573). Severe hepatotoxicity, especially related to ritonavir, is almost four times higher in patients with HIV who are coinfected with HCV, having a risk of approximately 12% (573). However, 88% do not develop severe hepatotoxicity. Furthermore, ribavirin may increase phosphorylation of zidovudine and dideoxyinosine and potentiate toxicity of these drugs (574,575). However, despite a case report implicating ribavirin in multiorgan failure and lactic acidosis, most HIV physicians have not found the potential drug interaction to be a clinical problem.

Obesity and fatty liver disease

Obesity and hepatic steatosis are both associated with a reduced response of HCV-infected patients to IFN-based treatments (528,529,576). For genotype 1 and 2, hepatic steatosis is associated with a fall in SVR from 57% to 25% and 96% to 86%, respectively (576). Genotype 3 infection induces steatosis in and of itself, and

this is not associated with reduced SVR. The mechanism(s) by which obesity or steatosis reduce(s) SVR is (are) not known, but it has recently been suggested that it may be related to insulin resistance and hyperinsulinemia. Sanyal et al. studied the effect of insulin on the action of IFN in an HCV replicon system composed of a Huh-7 hepatocellular carcinoma cell line stably transfected with full-length HCV RNA (577). IFN predictably inhibited HCV replication in this model. However, addition of insulin to the media resulted in a significant increase in HCV replication and a marked blockade of IFN's ability to decrease HCV RNA. The mechanism of insulin interference appeared to be impairment of activation of the STAT pathway with resulting blockade of the IFN-mediated increase in protein kinase R and IRF-1. Other mechanisms may also be involved.

Acute hepatitis C

Acute hepatitis C has a high propensity for progression to chronicity in the absence of antiviral therapy. Over the last 15 years, there have been numerous studies assessing the efficacy of IFN for the prevention of chronic infection. These studies vary considerably in design, type and dose of IFN, use of ribavirin, duration of therapy, and presence of controls. Nonetheless, it is clear that acute hepatitis C is extremely sensitive to the effects of IFN and most treated patients resolve the infection regardless of the regimen utilized (397,398,399,509,578,579,580,581,582). More recent studies have utilized either daily doses of a standard IFN or weekly doses of pegylated IFN for 4 to 24 weeks (579,580,581,582). SVR rates ranged from 75% to 98%. One study randomized patients to immediate treatment or a delay until 1

year after onset (582). Chronicity was reduced from 60% to 13% by early intervention.

Although these results are quite encouraging, treatment of patients with acute HCV infection must be considered in the proper perspective. The incidence of acute hepatitis C in the United States has fallen dramatically to about 28,000 infections per year (243). Only a small proportion of these cases are recognized by either the patient or physician. Furthermore, prospective surveillance to identify acute infection in those at risk (e.g., intravenous drug users) is impractical. Therefore, most cases of acute hepatitis will never come to medical attention. Nonetheless, treatment of identified cases with 6 months of pegylated IFN should be strongly considered. There is no data suggesting that ribavirin is required.

Extrahepatic manifestations

Mixed cryoglobulinemia is the most common extrahepatic manifestation in patients with chronic hepatitis C. It typically manifests as cutaneous vasculitis, glomerulonephritis (GN), neuropathy, or systemic vasculitis (583,584). IFN alone, or in combination with ribavirin, is able to suppress cryocrits in most patients with mixed essential cryoglobulinemia, and treatment may be indicated solely on the basis of the presence of clinical complications of cryoglobulinemia, regardless of the presence or severity of the liver disease (583,584,585,586,587). The fall in cryocrit observed during treatment usually correlates with a drop in serum HCV RNA levels, normalization of complement levels, and clinical improvement (583,586,587). However, polyneuropathy appears to be relatively resistant to treatment (585,586). Although results in this small series vary considerably, SVR after discontinuation of IFN-based treatment appears to be lower than that in patients without cryoglobulinemia (587).

GN has been associated with chronic HCV infection (588,589). Most of these cases present with proteinuria, which may reach nephrotic syndrome range, and have cryoglobulinemia (588,589,590). The histologic lesion is usually one of membranoproliferative GN, so-called cryoglobulinemic GN, although other histologic forms such as mesangial proliferative GN (usually IgA nephropathy) and membranous GN may also occur (588,589,590,591,592). In contrast to membranoproliferative GN, the latter two histologic lesions are typically not associated with cryoglobulinemia (588,591). Membranous GN responds poorly, if at all, to IFN (588,592). Furthermore, a recent report cautions that GN not caused by HCV may worsen under IFN treatment (593). Finally, ribavirin is renally excreted and should be used with great caution, if at all, in patients who have developed significant renal insufficiency as a consequence of their GN (578).

Post-transplantation

Complications of chronic hepatitis C including HCC and decompensated cirrhosis are the most common indication for liver transplantation, accounting for more than 40% of transplantations performed in the United States and Europe. If HCV RNA is detectable at the time of transplantation, infection will always recur (458). HCV RNA levels increase rapidly after transplantation as a consequence of immunosuppression (594,595,596,597). These patients often have very high HCV RNA levels, which may result in sometimes rapidly progressive chronic hepatitis, or, less commonly, an aggressive cholestatic hepatitis, which leads to liver failure (458,598,599,600,601).

Several options for treatment should be considered in the setting of liver transplantation including treatment of listed patients awaiting transplantation, preemptive therapy for patients shortly after transplantation before histologic recurrence is noted,

or treatment once recurrent disease is apparent (458,559,560,602,603). Treatment of such patients is predictably difficult regardless of which strategy is chosen because most patients have genotype 1 infection and high viral loads, have previously failed to respond to or tolerate IFN-based therapy, often have preexisting cytopenia and renal insufficiency, and have drug interactions that increase the risk of cytopenia or symptoms. Although antiviral treatment is successful in some patients with recurrent hepatitis C, it is extremely difficult to administer and requires dose reductions in most cases (458,604). Furthermore, acute and chronic rejection may ensue during or after treatment (604). Nonetheless, approximately 30% of treated patients can achieve SVR if both the patient and physician are committed to therapy (458,603).

IFN-based antiviral therapy should generally be avoided in recipients of other solid organ transplants because of the risk of rejection (605). However, treatment appears to be safe in autologous and allogeneic bone marrow transplant recipients (606).

Normal alanine transaminase level

Approximately 15% to 20% of patients with chronic HCV infection have persistently normal serum ALT levels (264). Although most of these patients have some degree of inflammation on liver biopsy, most studies have shown that few have significant fibrosis. In one review of 11 published studies, cirrhosis was found in only 0.3% (607). Others have reported fibrosis in up to 10% (608). However, in the absence of alcohol use, the rate of fibrosis progression is very low in patients with persistently normal serum ALT levels (609,610). Virologic response to IFN-based therapy appears to be the same as that in

patients with elevated ALT levels (611). Therefore, treatment can be considered on an individual basis in these patients, balancing the cost and difficulty of therapy with the estimated likelihood of progression. Although it may be hard to justify the cost and side effects of therapy in many patients, it is easy to make an argument for treating patients with hepatic fibrosis or genotypes 2 and 3.

Viral relapsers

Virologic relapse occurs in 45% to 80%, 35% to 40%, and 15% of those who lose detectable HCV RNA during IFN monotherapy, standard combination therapy, or pegylated combination therapy, respectively (186,510,511,528,529). There is little or no benefit in retreating patients with the same treatment regimen (612,613). However, treatment of relapsers to monotherapy with higher doses or a longer duration of IFN, or combination therapy, may achieve a sustained response (614,615,616,617). However, patients previously treated with suboptimal regimens should always be given the current standard of care regimen if they are retreated. A recent study found that half of patients who relapsed after standard IFN and ribavirin achieved SVR when retreated with pegylated IFN and ribavirin (618).

Viral nonresponders

Mathematically, one would predict that approximately 10% to 20% of viral nonresponders to IFN monotherapy or standard combination therapy might achieve a sustained response when retreated with pegylated combination therapy. Indeed, prospective trials have confirmed this to be the case (618). However, much of the published literature is quite confusing because of differences in definitions of nonresponse (some include relapsers and partial responders), different retreatment regimens, and inclusion of high proportions of patients with factors that favor response (i.e., patients without cirrhosis, those with genotypes 2 or 3, and those with low HCV RNA levels) (619). Furthermore, the reasons for nonresponse are often not given in such studies. Many patients fail to respond to treatment because of incorrect dosing, early and sometimes inappropriate dose reductions or discontinuations, and poor side effect management. These patients might be expected to respond better to retreatment than those who were given full dosages whose virus was refractory to the drugs. Indeed, patients who have partial HCV RNA response to the initial course of treatment are far more likely to respond to retreatment than those whose virus level did not change (620,621).

Several strategies for improving response to retreatment of nonresponders have been proposed. Several trials with high-dose IFN induction therapy were unsuccessful. A longer duration of treatment might be helpful in patients with slow and partial response. Berg et al. found that although the overall response was similar in patients treated for 48 or 72 weeks, those who had EVR but still had low levels of virus (<50,000 IU/mL) were most likely to benefit from prolonged treatment (622). Another study randomized genotype 1 patients who remained PCR positive at week 4 to 48 or 72 weeks (623). This study found a higher SVR rate among those who received the longer course of treatment, but the study was hard to interpret because it utilized a suboptimal dose of ribavirin and the overall SVR rate was accordingly low. More recently, a few studies have suggested that high doses of antiviral drugs throughout the treatment course might be successful in achieving SVR in patients who were resistant to the effects of standard doses. Leevy et al. initiated 48 weeks of high-dose daily consensus IFN and ribavirin in patients who failed to achieve an early viral response (563). One would expect that almost no patient without EVR would achieve SVR with continued treatment with the initial doses (550). Nonetheless, the SVR rate with

this intensive regimen was similar to that with treatment of naïve subjects (27% in African Americans and 41% in whites). These data are intriguing and suggest that higher drug doses throughout treatment might be effective in some difficult-to-treat subgroups. Indeed, Gross et al. reported the results of the REtreatment of NonrEsponders with Weight-based dosing (RENEW) study in which 704 subjects who had failed to clear HCV RNA during a previous treatment course were treated with either 1.5 μg/kg or 3.0 μg/kg of pegylated IFN α-2b in combination with weight-based ribavirin (800 to 1,400 mg/day) for 48 weeks (558). SVR was significantly higher in the high-dose group (17% vs. 12%). Importantly, while SVR was lower in African Americans and patients with advanced fibrosis who received a standard dose of pegylated IFN, these differences were not seen in the high-dose group. Similarly, Shiffman et al. reported that high-dose ribavirin significantly reduced relapse and as a result almost doubled the SVR rate, particularly in difficult-to-treat patients such as African Americans (624).

Another strategy for retreating nonresponders is long-term IFN maintenance. It is clear that some patients who do not clear HCV RNA during treatment have a reduction in hepatic inflammation and fibrosis (186,426,510,511,528,529). However, it is not known whether this effect persists with maintenance therapy or whether it might result in a lower risk of disease complications such as liver decompensation or HCC. Shiffman et al. found that fibrosis could be reduced with long-term IFN administration in the subset of patients who demonstrated early histologic improvement despite viral persistence (625). Everson reviewed the results of three trials that administered IFN treatment of patients with cirrhosis (626). The overall incidence of HCC was 15% in untreated patients, 4% in IFN nonresponders, and 0% in sustained responders (626,627,628,629,630). Although the accumulated data suggests that IFN might provide a beneficial long-term effect, no prospective studies have confirmed any benefit to date. However, three trials are currently under way to examine the efficacy of long-term

pegylated IFN in preventing progression of fibrosis and development of decompensation (the federally sponsored Hepatitis C Long-term Treatment against Cirrhosis (HALT-C) study and the pharmaceutical company–sponsored Colchicine versus PEG-INTRON Long-Term [COPILOT] and Evaluation of PEG-INTRON in Control of Hepatitis C Cirrhosis [EPIC3] studies).

In summary, retreatment should be strongly considered in patients who previously received IFN monotherapy or standard IFN in combination with ribavirin. This is particularly true in patients who already have advanced fibrosis. Retreatment of patients who failed to respond to pegylated IFN and ribavirin is unlikely to be beneficial and cannot be recommended. Several studies with high-dose antiviral therapy need to be confirmed before these aggressive regimens are routinely used. To date, there is no good evidence to justify maintenance IFN therapy outside the clinical trials.

Nonprescription Agents Used for Chronic Hepatitis

The use of alternative medicines is increasingly common in the United States and Europe, with nearly half of surveyed adults using some form of these agents (631). Several agents, including α-tocopherol, bayberry, blessed thistle, milk thistle, blue flag, dandelion root, fringe tree bark, gentian, yellow dock, and various Chinese herbal remedies, have been touted as effective remedies for chronic hepatitis in the lay literature, although there are little data available to support their use. Silymarin, commonly referred to as *milk thistle*, is the most popular of the herbals and is used by approximately 12% of patients with chronic hepatitis C, although this is probably a significant underestimation because nearly 40% of patients fail to report the use of such compounds to their physicians (632). The active ingredients in milk thistle are the flavanoid silymarin and its main structural component silybin. Animal and cell culture studies have demonstrated that these compounds inhibit the lipoxygenase pathway and have antioxidant properties that diminish toxicity induced by a variety of hepatotoxins including *Amanita phalloides*, acetaminophen, and allyl alcohol if the drug is administered before toxin exposure (633,634). However, both silymarin and silybin have been shown to induce cell damage in cell culture systems (635). The popularity of milk thistle among patients with liver disease must be attributed to word-of-mouth, lay literature, and highly effective although misleading Internet marketing ("nature's premier herbal liver tonic with specific protective benefits for liver tissues"; "supports the production of new liver cell to replace the old or damaged ones") because the compound has repeatedly been shown to be ineffective for the treatment of chronic hepatitis C (636,637,638,639). Milk thistle does appear to be well tolerated for short periods except for occasional gastrointestinal symptoms and rash (640,641). Nevertheless, all herbal and nonprescription agents should be used with extreme caution, especially in patients with significant liver disease, because the safety profiles of these remedies have not been critically studied.

Future Treatment Options

Future options for combination therapy may include antibodies or envelope inhibitors to prevent binding to receptors and cell entry, oligonucleotides such as interfering RNA or antisense molecules to prevent

attachment to the endoplasmic reticulum and translation, protease inhibitors to prevent processing of the translated polypeptide, polymerase inhibitors to prevent production of viral RNA progeny, glucosidase inhibitors to prevent assembly and secretion of virions, immune-modulating agents to enhance host response to infection, and antifibrotics that decrease the fibrogenic response to inflammation (Fig. 30.2). The most promising agents in development are the inhibitors of intracellular HCV replication. Development of these drugs has been facilitated by descriptions of the three-dimensional structures of the NS3 protease, helicase, and RNA-dependent RNA polymerase (642,643,644). These enzymes are unique to HCV and significantly different from the HIV protease. Several protease inhibitors have entered trials in humans and show significant promise (645,646). These agents block the ability of HCV to cleave the nonstructural proteins from the large translated polypeptide. They are orally bioavailable, well tolerated, and potent inhibitors of HCV replication. Furthermore, as predicted, these drugs appear to increase the sensitivity of infected cells to IFN, perhaps through reduction of NS3 activity (107,114,647). All agents to date have short half-lives and must be dosed frequently to maintain inhibitory trough levels, and this may represent a temporary obstacle to their clinical use. The HCV polymerase replicates the negative-strand template and produces positive-strand progeny RNA for incorporation into new virions. Several HCV polymerase inhibitors are in development, and one agent is well along in development in humans (648). Although the drug has only modest antiviral activity by itself, it too acts in synergy with IFN and thus far in early clinical trials has not selected drug-resistant variants.

The major challenge as these new agents are developed and tested will be figuring out just how to integrate them into current treatment regimens to increase efficacy, improve tolerability, or both. Given the ability of our current IFN-based therapy to eradicate infection in more than half of treated patients, it is likely that IFNs will remain the foundation of future therapeutic regimens for some time.
