Evidence from three randomized trials comparing LCBDE and ERCP showed no difference in morbidity and mortality between the two approaches [79–81]. **A1c** One trial demonstrated a statistically significant decrease in hospital stay for LCBDE (1 day vs 3–5 days) and another demonstrated a similar trend that was not statistically significant [80, 81]. It should be noted that the rates of complications with ERCP in these studies were relatively high (11–28%). More recent studies demonstrate a much lower complication rate. Masci *et al.* reported a series of 2444 ERCPs where the rate of complications was only 4.95% (pancreatitis in 1.8%, hemorrhage in 1.13%, cholangitis in 0.57%, perforation in 0.57% and death in 0.12%) [82]. Morino *et al.* found that the laparoendoscopic rendezvous technique allows a higher rate of clearance of common bile duct stones (95.6% vs 80%), shorter hospital stay (4.3 vs 8.0 days) and a reduction in costs compared to ERCP with ES followed by laparoscopic cholecystectomy with no significant difference in morbidity and mortality [83]. Grade A evidence regarding timing of surgery for choledocholithiasis following ERCP is available in the randomized trial reported by Boerma *et al.* [84]. These authors randomized 120 patients who underwent ERCP and stone extraction with proven gallbladder stones to a “wait and see” policy or to laparoscopic cholecystectomy after ERCP. In the wait and see group, 47% had recurrent biliary symptoms compared with 2% of laparoscopic cholecystectomy patients (relative risk 22.42, 95% CI: 3.16–159.14,  $p < 0.0001$ ). The conversion rate to open surgery in patients allocated to

“wait and see” was 55% compared with 23% in the laparoscopic group ( $p = 0.0104$ ). Also, morbidity appeared to be increased in the “wait and see” group, although the difference was not statistically significant (32% vs 14%,  $p = 0.1048$ ), and length of stay was longer in the “wait and see” group (9 vs 7 days). **A1c**

Conflicting data with respect to the outcomes observed in these studies may be explained in part by variation in operator expertise. LCBDE and ERCP are highly operator-dependent techniques with a steep learning curve. The approach to CBD stones should be individualized and based on the type of expertise available at each institution.

Department of Surgery, Southampton University Hospitals, Southampton, UK

Acute pancreatitis is a growing clinical problem with an emergency presentation. While many cases resolve spontaneously, some patients become severely ill, requiring intensive care and support of failing organ systems. The incidence of acute pancreatitis has increased in the UK [1], USA [2], Japan [3] and in many other countries [4, 5]. This may be due to changes in gallstone incidence, related to rising rates of obesity, and to changes in alcohol consumption [6, 7], but the evidence to confirm these associations is lacking.

This chapter reviews the current evidence to underpin the assessment and management of patients with acute pancreatitis. These topics have been extensively reviewed over the last decade. There have been many national and international guidelines that have carefully reviewed the published evidence, from the UK, USA [8, 9], Japan [3], and from the World Association of Gastroenterology [10]. The 1998 UK guidelines [11] were updated on the basis of new evidence in 2005 [12], and these two documents provide a clear summary of the evidence available at that time. They should be read together, as the full evidence base was not repeated in the revision. The main recommendations in those guidelines are reproduced in Table 24.1, and the relevant ones are repeated at the head of each section below. The present chapter will focus on the additional evidence that has been acquired since that time. In each section, we take the current UK guidelines as a starting point, and comment on the background to the recommendations before outlining any necessary amendments to the advice based on new evidence.

To prepare the present chapter, the MEDLINE database for the years 2004–2008 was searched for articles with title words “acute pancreatitis” and each section heading

reviewed. Randomized trials, systematic reviews and meta-analyses, and review articles of special interest were read and summarised. A formal meta-analysis was not conducted. In addition, reliance is placed on the international guidelines noted above that were prepared on the basis of critical reviews of the field. Finally, the Cochrane Library was reviewed to identify all Cochrane Reviews related to acute pancreatitis.

---

**Definition of acute pancreatitis**

In 1998, the UK Guidelines [11] defined acute pancreatitis as:

An acute inflammatory process of the pancreas, with variable involvement of other regional tissues or remote organ systems. Severe acute pancreatitis is associated with organ failure and/or local complications such as necrosis (with infection), pseudocyst or abscess. Most often this is an expression of the development of pancreatic necrosis, although patients with oedematous pancreatitis may manifest clinical features of a severe attack. Mild acute pancreatitis is associated with minimal organ dysfunction and an uneventful recovery. The predominant pathological feature is interstitial oedema of the gland.

Pathological changes of acute inflammation are followed by resolution in the majority of cases (mild pancreatitis, edematous pancreatitis). Almost all patients with mild pancreatitis recover without specific intervention. Severe acute pancreatitis is characterized by the presence of local or systemic complications, and by varying degrees of parenchymal damage (necrosis, apoptosis) which may be followed by some acinar regeneration or by fibrosis. Severe pancreatitis may be fatal in 14–25% of cases, with overall mortality rates for acute pancreatitis usually in the range 2.1–7.8% [3]. A recent population based study from the

**Table 24.1** Recommendations published in UK National Guidelines in 1998 [11] and 2005 [12]. Headings in italics are reviewed in this chapter, to incorporate new evidence.

Heading	Recommendations for management of acute pancreatitis	Date	Grade
Initial assessment			
<i>Diagnosis</i>	Although amylase is widely available and provides acceptable accuracy of diagnosis, where lipase is available it is preferred for the diagnosis of acute pancreatitis.	2005	A
	The correct diagnosis of acute pancreatitis should be made within 48 hours of admission. Although this may strain support and diagnostic facilities, the risk of missing an alternative life-threatening intra-abdominal catastrophe demands full investigation.	1998	C
	Where doubt exists, imaging may be useful for diagnosis: ultrasonography is often unhelpful and pancreatic imaging by contrast enhanced CT provides good evidence for the presence or absence of pancreatitis.	2005	C
<i>Etiology</i>	The etiology of acute pancreatitis should be determined in at least 80% of cases and no more than 20% should be classified as idiopathic.	2005	B
<i>Severity</i>	The definitions of severity, as proposed in the Atlanta criteria, should be used. However, organ failure present within the first week, which resolves within 48 hours, should not be considered an indicator of a severe attack.	2005	B
	Severity stratification should be made in all patients within 48 hours. It is recommended that all patients should be assessed by the Glasgow score and CRP. The APACHE II score is equally accurate, and may be used for initial assessment; it should be used for ongoing monitoring in severe cases. <sup>a</sup>	1998	B
	Available prognostic features which predict complications in acute pancreatitis are clinical impression of severity, obesity, or APACHE II > 8 in the first 24 hours of admission, and C reactive protein levels >150 mg/l, Glasgow score 3 or more, or persisting organ failure after 48 hours in hospital. <sup>a</sup>	2005	B
<i>Use of CT</i>	Patients with persisting organ failure, signs of sepsis, or deterioration in clinical status 6–10 days after admission will require CT.	2005	B
Management			
<i>Organization of care</i>	All cases of severe acute pancreatitis should be managed in an HDU or ITU setting with full monitoring and systems support.	1998	B
	Every hospital that receives acute admissions should have a single nominated clinical team to manage all patients with acute pancreatitis.	2005	C
	Management in, or referral to, a specialist unit is necessary for patients with >30% necrosis or with other complications.	2005	B
<i>Antibiotics</i>	The evidence for antibiotic prophylaxis against infection of pancreatic necrosis is conflicting and difficult to interpret. At present there is no consensus on this issue. <sup>a</sup>	2005	C
	If antibiotic prophylaxis is used, it should be given for a maximum of 14 days.	2005	B
	Further studies are needed. <sup>a</sup>	2005	C
	A German trial which compared ciprofloxacin-metronidazole and placebo is the only double-blind, placebo-controlled trial published to date. The results do not support the use of prophylactic antibiotics. This study was stopped after interim analysis of 76 patients with necrosis showed no differences in the primary outcomes of infected necrosis, systemic complications and mortality rates. <sup>a</sup>	2005	C
<i>Enteral nutrition</i>	The evidence is not conclusive to support the use of enteral nutrition in all patients with severe acute pancreatitis. However, if nutritional support is required, the enteral route should be used if that can be tolerated.	2005	A
	The nasogastric route for feeding can be used as it appears to be effective in 80% of cases.	2005	B
<i>Management of gallstones</i>	All patients with biliary pancreatitis should undergo definitive management of gall stones during the same hospital admission, unless a clear plan has been made for definitive treatment within the next two weeks.	2005	C
<i>Early endoscopic sphincterotomy</i>	Patients with signs of cholangitis require endoscopic sphincterotomy or duct drainage by stenting to ensure relief of biliary obstruction.	2005	A
	Urgent therapeutic ERCP should be performed in patients with acute pancreatitis of suspected or proven gall stone etiology who satisfy the criteria for predicted or actual severe pancreatitis, or when there is cholangitis, jaundice, or a dilated common bile duct. <sup>a</sup>	2005	B
	All patients undergoing early ERCP for severe gall stone pancreatitis require endoscopic sphincterotomy whether or not stones are found in the bile duct.	2005	C

**Table 24.1** Continued

Heading	Recommendations for management of acute pancreatitis	Date	Grade
<i>Intervention for necrosis</i>	All patients with persistent symptoms and greater than 30% pancreatic necrosis, and those with smaller areas of necrosis and clinical suspicion of sepsis, should undergo image guided FNA to obtain material for culture 7–14 days after the onset of the pancreatitis.	2005	B
	Patients with infected necrosis will require intervention to completely debride all cavities containing necrotic material.	2005	B
	The choice of surgical technique for necrosectomy, and subsequent postoperative management depends on individual features and locally available expertise.	2005	B

CT: computed tomography.

Grade indicates a recommendation based on: A, at least one randomised controlled trial as part of evidence of overall good quality and consistency; B, clinical studies without randomisation; C, expert consensus.

<sup>a</sup>Indicates recommendations that should be reconsidered in light of new evidence.

USA indicates that overall mortality from acute pancreatitis is falling and is now less than 2% [13].

## Diagnosis

Although amylase is widely available and provides acceptable accuracy of diagnosis, where lipase is available it is preferred for the diagnosis of acute pancreatitis. Lipase is more specific and more sensitive than amylase. Amylase levels generally rise within a few hours after the onset of the symptoms and return to normal values within 3–5 days. However, serum lipase concentrations remain high for a longer period of time than do amylase concentrations, which gives slightly greater sensitivity for lipase than for amylase in patients with delayed presentation [14].

The correct diagnosis of acute pancreatitis should be made within 48 hours of admission. Although this may strain support and diagnostic facilities, the risk of missing an alternative life-threatening intra-abdominal catastrophe demands full investigation. Where doubt exists, imaging may be useful for diagnosis: ultrasonography is often unhelpful and pancreatic imaging by contrast enhanced CT provides good evidence for the presence or absence of pancreatitis.

Clinical diagnosis is usually straightforward, but overlap may exist with the clinical presentation of perforated viscus or gangrenous bowel. These serious alternative diagnoses may require urgent intervention and in case of doubt they must be excluded, usually by CT. It has been known for many years that contrast-enhanced CT shortly after admission has 87–90% sensitivity and 90–92% specificity to confirm the diagnosis of pancreatitis [15–17].

The presence of two of three diagnostic features (typical abdominal pain, elevated concentrations of serum amylase, or lipase above three times the upper limit of normal, and

the presence of inflammatory changes in and around the pancreas on abdominal CT) confirms the diagnosis. These cutoffs for lipase and amylase are widely accepted [18], but the World Association Guidelines [10] point out that:

Pancreatic enzymes are released into the circulation during an acute attack. Levels peak early and decline over 3–4 days. An important concept derives from this: the diagnosis of acute pancreatitis should not rely on arbitrary limits of values three or four times greater than normal, but values should be interpreted in light of the time since the onset of abdominal pain.

## Severe acute pancreatitis

In 1992, our understanding of acute pancreatitis was greatly improved by a consensus conference that took place in Atlanta [19]. This conference defined the terminology of acute pancreatitis and its complications, and has been the basis for much progress in improved management. However, some problems with terminology and definitions have been noted in the Atlanta document. Currently, the International Association of Pancreatology is attempting to revise these definitions by international consensus, focusing on the diagnosis and imaging of severe acute pancreatitis during two distinct phases: the first week (early phase characterized by Systemic Inflammatory Response Syndrome, SIRS, and organ failure), and a later phase characterized by depressed immune response and local complications, especially pancreatic and peripancreatic necrosis. This consensus, led by Doctors Michael Sarr and Peter Banks, aims to collate the views of numerous pancreatic specialists around the world and to present an evidence base to shape clinical practice for the next decade.

## Definition of severe pancreatitis

The definitions of severity, as proposed in the Atlanta criteria, should be used. However, organ failure present within the first week, which resolves within 48 hours, should not be considered an indicator of a severe attack (UK Guidelines 2005).

The Atlanta criteria [19] for severe pancreatitis remain widely accepted. In this definition, severe acute pancreatitis is characterized by the presence of any systemic or local complication. Other criteria of severe disease accepted by the Atlanta conference include the presence of a high Ranson or APACHE-II score (which are markers for systemic complications). The Atlanta criteria represent the first attempt to define cutoff values for organ failure in acute pancreatitis (Table 24.2). This was a useful step to clarify thinking about systemic complications, but it has become clear that the crossing of a threshold for organ failure is an inadequate definition for severe acute pancreatitis.

It is now understood that organ failure in acute pancreatitis is preceded by a phase of activation of the Systemic Inflammatory Response syndrome (SIRS) [20, 21]. The presence of SIRS is clinical evidence of inflammation (Table 24.3), and indicates high risk of progression to complications, but SIRS may resolve without consequence. However, the presence of SIRS in patients on admission to hospital is associated with increased risk of organ failure and death [21]. If SIRS persists for more than 48 hours beyond admis-

sion to hospital, the mortality rate rises to more than 20% [21], and the patient should be regarded as having severe pancreatitis (Figure 24.1).

Since the beginning of this century, it has become clear that the crucial feature of severity in relation to systemic complications during the first week of acute pancreatitis is the duration of organ failure, and that organ failure which resolves during the first week is associated with a very low mortality rate [22]. We showed in a national sample from 78 hospitals [23] that persistence of organ failure for more than 48 hours during the first week of the attack is associated with a 35% risk of fatal outcome. These patients also have a high risk of local complications. Others have confirmed this observation [21, 24, 25], and it is now established that persistent organ failure (>48 hours) during the first week of illness is part of the definition of severe acute pancreatitis.

The severity of early organ failure has also been shown by some authors [26, 27] to be associated with high risk of fatal outcome, but the interaction between severity and duration of organ failure has not been clarified.

Three organ systems are usually sufficient to assess organ failure: respiratory, cardiovascular and renal. In our study of 290 patients with predicted severe acute pancreatitis, these organs were always involved in patients with persistent organ failure, and only 3 of 71 patients with transient organ failure did not have one of these systems affected [23]. Organ failure is easily defined in accordance with the Marshall scoring system [28] as a score  $\geq 2$  for at least one of respiratory, renal or cardiovascular function

**Table 24.2** Atlanta criteria for severe acute pancreatitis (16).

Criteria for severe acute pancreatitis – presence of one or more of the following:

- (1) Ranson score during the first 48 hours, 3 or more
- (2) APACHE II score at any time, 8 or more
- (3) Presence of one or more organ failures
- (4) Presence of one or more local complications

Organ failures include:

- (1) Shock: systolic blood pressure, less than 90 mm Hg
- (2) Pulmonary insufficiency: PaO<sub>2</sub> on room air, 60 mm Hg or lower
- (3) Renal failure: serum creatinine, >2 mg/dL after fluid replacement
- (4) gastrointestinal bleeding: blood loss more than 500 mL/24 hours
- (5) coagulopathy: thrombocytopenia fibrin split products in plasma
- hypofibrinogenemia
- (6) severe hypocalcemia: calcium 7.5 mg/dL or lower

Local complications include

- (1) pancreatic necrosis
- (2) pancreatic abscess
- (3) pancreatic pseudocyst

**Table 24.3** Definition of SIRS [17]. Severe pancreatitis is diagnosed if SIRS criteria persist for >48 hours.**SIRS is defined by the presence of two or more of the following:**

pulse	>90 beats/min
rectal temperature	<36°C or >38°C
white blood count	<4000 or >12,000 per mm <sup>3</sup>
respirations	>20/min
or PCO <sub>2</sub>	<32 mmHg

No. at risk					
No SIRS	547	544	543	542	542
Transient SIRS	74	69	69	68	68
Persistent SIRS	138	112	109	104	103

A

No. at risk					
No MODS	550	548	547	546	546
Transient MODS	120	117	117	116	116
Deteriorating MODS	89	63	59	53	52

B

**Figure 24.1** SIRS and organ failure in the first week are associated with high risk of fatal outcome (reproduced from Mofidi *et al.* [21]).

(Table 24.4). The full Marshall score (which includes the Glasgow coma score and platelet count) and the SOFA scoring system, which takes account of inotropic and respiratory support for patients managed in a critical care unit [29], may also be used for assessment of more severely ill patients with multiple organ/system failure. All these scores can be determined at presentation and daily to create a record of the presence and the severity of organ failure during the first week.

## Prediction of severity

Severity stratification should be made in all patients within 48 hours. It is recommended that all patients should be assessed by the Glasgow score and CRP. The APACHE II score is equally accurate, and may be used for initial assessment; it should be used for ongoing monitoring in severe cases.

Available prognostic features which predict complications in acute pancreatitis are clinical impression of severity, obesity, or APACHE II >8 in the first 24 hours of admission, and C-reactive protein levels >150mg/l, Glasgow score 3 or more, or persisting organ failure after 48 hours in hospital.

These recommendations are still relevant, but a new simple scoring system has been reported (see below).

The management of acute pancreatitis is supportive; mild attacks resolve without specific measures other than ensuring adequate analgesia, oxygenation and circulating volume. For many years it has been believed that early identification of patients with severe disease would be advantageous, leading to early institution of aggressive support for failing systems and early transfer to an appropriate critical care facility. This approach led to many reports of various tests and scoring systems designed to predict severe disease. As noted above, we now identify such patients by the presence of specific clinical markers of severity, especially the presence of persistent SIRS, or persistent organ failure. However, the observation of high risk predictive scores (e.g. Ranson, Glasgow, APACHE II) or high levels of confirmed markers or risk factors of severe disease (C-reactive protein >150mg/l [10, 30], BMI > 30 [12, 31]) may help focus clinical attention on potentially ill patients.

## Clinical markers of severity and predictive scores

Table 24.5 summarizes features that predict a severe attack of acute pancreatitis and that are available shortly after admission to hospital. Age is an independent risk factor, and age >70 years is associated with 17% mortality risk [32]. Obesity is a risk factor for complications and death

**Table 24.4** Criteria from the Marshall Scoring System [25] which define organ failure and measure its severity. Any value scoring 2 or more indicates an organ failure; the total score is a marker of the severity of organ failure.

Organ system	Score				
	0	1	2	3	4
Respiratory (PO <sub>2</sub> /FIO <sub>2</sub> )	>400	301–400	201–300	101–200	≤101
Renal					
(serum creatinine, μmol/l)	≤134	134–169	170–310	311–439	>439
(serum creatinine, mg/dl)	<1.4	1.4–1.8	1.9–3.6	3.6–4.9	>4.9
Cardiovascular (systolic blood pressure, mmHg)	>90	<90 Fluid responsive	<90 Not fluid responsive	<90, pH < 7.3	<90, pH < 7.2
For non-ventilated patients, the FiO <sub>2</sub> can be estimated:					
Supplemental Oxygen (L/min)	FiO <sub>2</sub>				
Room air	21%				
2	25%				
4	30%				
6–8	40%				
9–10	50%				

**Table 24.5** Features that predict a severe attack, that are present within 48 hours of admission to hospital. Modified from reference 12.

Initial assessment	Clinical impression of severity
	Body mass index > 30 Pleural effusion on chest radiograph APACHE II score > 8
24 h after admission	Clinical impression of severity APACHE II score > 8 Glasgow score 3 or more Persisting organ failure, especially if multiple C reactive protein > 150 mg/l
48 h after admission	Clinical impression of severity Glasgow score 3 or more C reactive protein > 150 mg/l Persisting organ failure for 48 h Multiple or progressive organ failure

[31]. The mechanism of this increased risk is unclear, but it seems that obesity is associated with an increased inflammatory response [33, 34]. Other proposed mechanisms include greater risk of respiratory complications and the presence of poorly perfused fat in and around the pancreas,

increasing the risk of pancreatic and peripancreatic necrosis.

Objective parameters should be used to support the clinical examination in the first 24 hours of admission, as clinical examination is specific, but it is not sensitive when used alone [12]. The APACHE II score is widely used as a predictor of severity, and for monitoring progress early in the illness. The Atlanta criteria selected a cutoff score of 8 or more to define severe disease. This cutoff in the first 24 hours identifies almost all patients who will develop a complication. In a meta-analysis of three well-documented series comprising 627 cases (20% severe), Larvin [35] found no deaths in patients with initial APACHE II score below 10. A score of 10 or 11 was very unlikely to lead to death, but scores of 12 or more had a mortality rate over 20%, increasing with higher initial scores (Figure 24.2).

Recently, the Early Warning Score (EWS), based on routine nursing observations, and widely used to monitor the clinical condition of ill patients, has been proposed as a simple means of identifying high risk patients [36, 37]. The EWS also responds to the dynamic nature of the illness: deterioration of scores is associated with a worse outcome [36]. The ability of this system to predict severe pancreatitis has been compared with APACHE II scores, modified organ dysfunction scores, Glasgow scores, CT severity index and Ranson criteria for 181 admissions with acute

**Figure 24.2** Percentage risk of death or complications associated with different initial APACHE-II scores (reproduced from Larvin [35]).

pancreatitis. Scores were calculated daily for the first three days. The APACHE II and EWS performed best in receiver operating curve analysis, with similar areas under the curve (APACHE II 0.876, 0.892 and 0.911; EWS 0.827, 0.910 and 0.934, on days 1, 2 and 3 respectively). These findings suggest that the simple and easily assessed EWS could be used at the bedside to monitor progress and identify severe acute pancreatitis soon after admission to the hospital. In particular, EWS reflects the dynamic nature of the illness in the same way as SIRS and organ failure. This simple clinical observation should permit reliable identification of patients at risk of complicated or fatal course in any hospital setting. Importantly, improvement in the EWS (or other scores discussed above) is reassuring that the patient is likely to recover without complications.

A large population based survey [13] has developed and validated a predictive system for severe acute pancreatitis based on easily obtained features present at the time of admission to hospital. The authors reviewed records of 17,992 patients for features associated with severe disease, that were present within 24 hours of admission. They identified five independent predictors: blood urea nitrogen >25mg/dL (>8.93mmol/L), impaired mental state, SIRS, age > 60 years and pleural effusion on chest X-ray (acronym BISAP score). Allocation of one point for each feature gives a simple BISAP score, which identifies low risk patients with low score, and high risk groups with a >10% risk of death for scores of 4, and >20% risk of death for scores of 5. The strength of this report is that the predictive ability of the scores was confirmed in a new sample of patient records, comprising over 18,000 patients treated in the years 2004–2005. The development and validation cohorts had mortality rates of 1.9% and 1.28% respectively, which

suggests that this study used “real world” data including all cases of mild disease in the contributing hospitals. The BISAP score promises to simplify the assessment of acute pancreatitis, particularly by the rapid identification of the large majority of patients who are at low risk of complications and death.

### Laboratory markers

Plasma C-reactive protein is accurate, but delayed in its response, not peaking until 72–96 hours into the illness. A value >150mg/l identifies patients at risk of pancreatic necrosis and potentially fatal outcome [12]. There is some evidence that serum or urine concentrations of the trypsinogen activation peptide (TAP) [38–41] and urine anionic trypsinogen 2 [42–44] might be useful to predict severity, although to date only the trypsinogen 2 test is available as a rapid bedside test.

Another promising early marker of severity is procalcitonin (PCT). Despite some contrary views (based on relatively small numbers) [45, 46], there is considerable evidence that PCT is a useful early marker of severe disease, and especially of pancreatic necrosis, or infected necrosis. A meta-analysis of the early evidence [47] reviewed nine reports. There was considerable variation of methodological quality. Considering only high quality reports, the sensitivity and specificity of PCT in the first 24 hours in hospital to predict severe disease were 82% and 89%, with an area under the curve value of 94%, indicating very good discrimination. The meta-analysis indicated that PCT may be especially useful for the identification of patients at risk of infected necrosis.

Two further studies support these findings. Rau has long advocated using this marker, and her latest publication [48] provides more evidence from a study of 104 patients in five European centers enrolled within 96 hours of symptom onset. Initial PCT concentrations were significantly elevated in patients with pancreatic infections and associated multi-organ dysfunction syndrome (MODS), all of whom required surgery ( $n = 10$ ), and in non-survivors ( $n = 8$ ). PCT levels were only moderately increased in seven patients with pancreatic infections in the absence of MODS, all of whom were managed non-operatively without mortality. A PCT value of 3.5ng/ml or higher on two consecutive days had a sensitivity and specificity of 93% and 88% for the assessment of infected necrosis with MODS or non-survival. This prediction was possible on the third and fourth day after onset of symptoms with a sensitivity and specificity of 79% and 93% for PCT 3.8ng/ml or higher. Another study of 40 patients (11 severe) supports these findings [49]. There is now strong evidence that early estimation of procalcitonin can identify patients at risk of infected necrosis or death, and the test may be repeated to improve the detection of these most severe cases.

## Role of CT in acute pancreatitis

### During the first week

As noted above, at the time of admission to hospital CT may be required if the diagnosis is in doubt: this may arise with delayed presentation, for example when the plasma enzyme levels have fallen below the diagnostic threshold. Sometimes CT may be helpful to exclude other diagnoses, such as perforation or gangrene of bowel. There is no evidence that early CT is helpful in the management of confirmed acute pancreatitis. Indeed, the UK guidelines [12] recommend that the first scan be delayed until 6–10 days after onset of symptoms. Arguments against early CT in all cases of pancreatitis are that early CT with intravenous contrast has the potential risk of worsening the renal impairment, and that an early CT may underestimate the full extent of pancreatic necrosis, which may evolve for at least four days after the onset. Most importantly, CT is unlikely to change management decisions in the first week. At this stage, treatment is supportive, and surgical or other intervention is avoided, and CT does not affect clinical decision-making.

Early CT may be used to assess the severity of the illness if this is required, for example to stratify patients in treatment trials. Balthazar and colleagues [50] proposed the CT severity index (Table 24.6) based on the grade of inflammation and the extent of pancreatic necrosis determined by enhancement. The sum of these two scores is used to calculate the severity index.

### After the first week

Patients with persisting organ failure, signs of sepsis, or deterioration in clinical status 6–10 days after admission will require CT. CT is usually performed after 6–10 days in patients with persistent SIRS or organ failure to assess local complications such as fluid collections and necrosis [12, 50]. There is some evidence that MRI identifies necrosis and fluid collections better than does CT [51], although the practical difficulty of ensuring MR compatible equipment attached to a patient with organ failure may be a problem in some settings.

The Atlanta criteria are not clear on the distinction between fluid collections, pseudocyst and necrosis. The current international consensus revision of the Atlanta criteria mentioned above is likely to advocate the use of contrast enhanced CT for the characterisation of morphological changes in and around the pancreas, after the first week of the illness, and will probably recognise a number of local complications, namely pancreatic and peripancreatic necrosis, acute peripancreatic collections within four weeks from onset of symptoms, and pseudocyst and walled off

**Table 24.6** Computed tomography (CT) grading of severity.

Computed tomography (CT) grading of severity	Score
CT grade	
(A) Normal pancreas	0
(B) Oedematous pancreatitis	1
(C) B plus mild extrapancreatic changes	2
(D) Severe extrapancreatic changes including one fluid collection	3
(E) Multiple or extensive extrapancreatic collections	4
Pancreatic necrosis (extent)	
None	0
Up to one third	2
Between one third and one half	4
More than half	6
CT severity index = CT grade + necrosis score	
Observed rates of complications and death related to CTSI score	Complications
0–3	8%
4–6	35%
7–10	92%
	Deaths
0–3	3%
4–6	6%
7–10	17%
Modified from the World Association guidelines [10] and based on Balthazar and colleagues [47].	

pancreatic necrosis more than four weeks from onset. The extent of pancreatic necrosis on CT is useful information, because this is related directly to the risk of local and systemic complications [52, 53].

CT is unreliable for the discrimination of pseudocyst from necrosis. The Santorini consensus conference [30] recommended that either ultrasound or magnetic resonance imaging (MRI) should be used to differentiate between fluid and necrotic tissue. In practice, it is wise to consider all localized collections following necrotising pancreatitis to be pancreatic or peripancreatic necrosis until proved otherwise.

## Organization of care

All cases of severe acute pancreatitis should be managed in an HDU or ITU setting with full monitoring and systems support. Every hospital that receives acute admissions should have a single nominated clinical team to manage all patients with acute pancreatitis. Management in, or referral

to, a specialist unit is necessary for patients with >3 0% necrosis or with other complications.

It seems self-evident that the care of these potentially difficult and seriously ill patients should be concentrated in the hands of interested clinicians with appropriate expertise. **C5**

---

## Initial management and resuscitation

Early fluid resuscitation and oxygen supplementation are simple measures that seem likely to be helpful in early resolution of organ failure [54]. Whether these interventions significantly reduce the mortality rate is not known, but it seems sensible to provide simple circulatory and respiratory support designed to achieve rapid resolution of organ failure. **C5** This approach may break the cycle of hypotension and hypoxaemia that can sustain and provoke more organ system failures. The fluid replacement with a mix of crystalloid and colloid solutions should aim to maintain good urine output (0.5 ml/kg) and can be monitored by central venous pressure reading in selected patients. Oxygenation ideally should maintain the arterial saturation above 95%. Oxygen saturations lower than this are associated with significant hypoxaemia [55].

---

## Prophylactic antibiotics

The evidence for antibiotic prophylaxis against infection of pancreatic necrosis is conflicting and difficult to interpret. At present there is no consensus on this issue.

If antibiotic prophylaxis is used, it should be given for a maximum of 14 days. Further studies are needed.

It is pleasing to note that we now have evidence to resolve this issue, outlined below.

Since infected pancreatic necrosis is associated with high mortality rates (40%) and it is one of the leading causes of death in acute pancreatitis, many trials have been done to establish the role of prophylactic antibiotics in reducing the mortality rate and other infective and non-infective complications. The trials discussed up to 2005 had shown benefit for prophylaxis, but there were concerns that the improvements in outcome were seen for different end-points in different studies. The guidelines quoted above should be re-evaluated in light of the publication of more high quality evidence. An interesting analysis [56] has shown an inverse relationship between the quality of studies and the observed effect, i.e. as study quality improves, the differences in outcome diminish.

In discussing the available evidence, the UK guidelines noted:

A German trial [57] which compared ciprofloxacin-metronidazole and placebo is the only double blind placebo

controlled trial published to date. The results do not support the use of prophylactic antibiotics. This study was stopped after interim analysis of 76 patients with necrosis showed no differences in the primary outcomes of infected necrosis, systemic complications, and mortality rates.

A Cochrane Review [58] evaluated all the randomized trials with placebo controls, published up to July 2006. The conclusion of this review was that:

Antibiotic prophylaxis appeared to be associated with significantly decreased mortality but not infected pancreatic necrosis. Beta lactam antibiotics were associated with significantly decreased mortality and infected pancreatic necrosis, but quinolone plus imidazole regimens were not.

The review includes a trial from Finland [59] which compared cefuroxime with placebo, and demonstrated a difference in mortality. The validity of these data has been questioned, because only patients with alcohol related pancreatitis were included, and because the excess deaths in the placebo group all occurred in the first week of the illness, before any effect on infection of necrosis could be expected. The Cochrane Review also noted that there were variations in methodological quality and treatment regimens in the trials reviewed. More reliable data were awaited.

A subsequent meta-analysis of prophylactic antibiotic use in acute necrotizing pancreatitis [60] assessed whether intravenous prophylactic antibiotic use reduces infected necrosis and death in acute necrotizing pancreatitis. Six randomized controlled trials were analyzed, including the five analyzed for preparation of the UK Guidelines, and an additional trial published only in abstract form [61]. Primary outcome measures were infected necrosis and death. Secondary outcome measures were non-pancreatic infections, surgical intervention and length of hospital stay. Prophylactic antibiotic use was not associated with a statistically significant reduction in infected necrosis (RR = 0.77; 95% CI: 0.54–1.12;  $p = 0.173$ ), mortality (RR = 0.78; 95% CI: 0.44–1.39;  $p = 0.404$ ), non-pancreatic infections (RR = 0.71; 95% CI: 0.32–1.58;  $p = 0.402$ ) or surgical intervention (RR = 0.78; 95% CI: 0.55–1.11;  $p = 0.167$ ).

A double-blind randomized trial of meropenem versus placebo, published in May 2007, is probably the definitive study [62]. This trial was performed in 32 centers within North America and Europe and included one hundred patients with clinically severe, confirmed necrotizing pancreatitis who were randomized within five days of the onset of symptoms to receive Meropenem (1g intravenously every eight hours) or placebo for 7 to 21 days. The trial was well designed, with entry criteria (>30% necrosis)

that selected patients at greatest risk of infection. The sample size calculation indicated that approximately 120 subjects per group (240 subjects in all) would be required to detect a reduction of pancreatic infection rates by meropenem compared with placebo from 40% to 20% with 90% power and a 5% two-sided significance level. The trial included appropriate secondary endpoints (need for surgery, death). Recruitment was slow, because patients with >30% necrosis are relatively rare. (It is widely agreed that antibiotics should not be given to patients without necrosis, as they are very unlikely to develop pancreatic infections.) The trial was closed early, when it was clear that pancreatic infection rates overall (15%) were lower than expected. Pancreatic or peripancreatic infections developed in 18% (9 of 50) of patients in the meropenem group compared with 12% (6 of 50) in the placebo group. Despite the early closure, this RCT of antibiotic prophylaxis recruited more patients with pancreatic necrosis than any previous trial and it seems improbable that recruitment of a further 140 patients to achieve the initial target would have shown a different outcome. The results of this trial showed no statistically significant advantage for early use of meropenem for prevention of pancreatic or peripancreatic infection, requirement for surgical intervention, or death (Table 24.7).

Further evidence of lack of effect is presented in a single-centre, double-blind RCT of ciprofloxacin in patients with confirmed necrosis [63]. Although this trial included only 41 patients, it produced no evidence of benefit, consistent with the result of the larger trials discussed above.

The weight of evidence has shifted since preparation of the UK Guidelines Revision to favor the position that prophylactic antibiotics, prescribed early in the illness to prevent subsequent infection of necrotic tissue, confer no benefit and should not be part of the treatment plan. **A1c** There is no evidence of benefit in several recent well-designed RCTs, and the unnecessary use of antibiotics has

well-known adverse consequences, notably related to hospital acquired infection. However, it is not easy to define the need for antibiotics on purely clinical grounds. Patients with severe acute pancreatitis are likely to have signs of SIRS; this should not be taken as evidence of infection. In the early stages of the illness antibiotics should be used only when there is proof of infection from a positive culture.

## Nutrition in acute pancreatitis patients

The evidence is not conclusive to support the use of enteral nutrition in all patients with severe acute pancreatitis. However, if nutritional support is required the enteral route should be used if tolerated. **A1d** The nasogastric route for feeding can be used as it appears to be effective in 80% of cases. **B4** We have found no additional evidence that requires a change to this advice.

In mild, acute pancreatitis there is no benefit from passage of a nasogastric tube [64, 65]. These patients can be allowed to drink small volumes of fluids as tolerated from the outset. A full oral diet can be restarted in most patients after a few days, when the pain has settled [66].

In severe disease, enteral feeding may be beneficial for two reasons. First, it may help to reduce the risks of complications when started early in the disease; second, in established, severe pancreatitis nutritional supplements will be required and the enteral route is preferred. Most studies have assumed that the enteral feeding solution should be delivered beyond the duodenum, by means of a nasojejunal tube. However, this placement is often unnecessary [67, 68]. **A1d** About 80% of patients with severe disease tolerate early enteral feeding by nasogastric tube, and this route is simpler and cheaper to establish. Nasojejunal feeding should be reserved for those patients in whom nasogastric feeding is unsuccessful because of failure of gastric emptying.

## Prevention of complications

Enteral feeding is believed to be superior to parenteral nutrition in most critical care conditions. Reasons advanced to support this belief include the suggestion that enteral nutrition may maintain splanchnic protein synthesis and help to maintain normal gut mucosal function, including the mucosal barrier. This helps to reduce bacterial translocation, which may be the main driver for organ failure and sepsis. **C5** Although there were fears that enteral feeding might exacerbate acute pancreatitis because of the stimulatory effect of luminal nutrients on pancreatic enzyme synthesis, this adverse effect has not been found in practice, perhaps because pancreatic enzyme synthesis is inhibited immediately after onset of pancreatitis [69]. Data from

**Table 24.7** Outcomes in the trial [59] of Meropenem versus placebo in the prevention of infection in severe acute pancreatitis. No differences were observed.

	Pancreatic or peripancreatic infections	Requirement of surgical intervention	Mortality
Meropenem group	18% (9 of 50)	26% (13 of 50)	20% (10 of 50)
Placebo group	12% (6 of 50)	20% (10 of 50)	18% (9 of 50)
P value	0.401	0.476	0.799

patients with acute pancreatitis show lower rate of secretions compared to healthy individuals, and this rate is inversely related to the severity of the pancreatitis [70].

In any attempt to prevent complications of pancreatitis, it is logical that enteral feeding should be started early in the course of the disease. Few RCTs have been performed to specifically address this point. In the first small trial 38 patients with severe pancreatitis were randomized to receive either enteral or parenteral nutrition [71]. Significantly fewer infected complications occurred in the enteral feeding group. Windsor *et al.* [72] and Gupta *et al.* [73] investigated markers of the inflammatory response in patients offered enteral or parenteral nutrition. Both studies showed less activation of inflammation with enteral feeding. The superiority of early enteral compared to parenteral nutrition has been confirmed in a meta-analysis [74] of eleven trials. **A1c** This meta-analysis showed benefit in terms of lower infection rates for enteral feeding started within 48 hours of admission, but no difference between the two routes if feeding was started later than this. It is possible that the results of these trials are due to stimulation of inflammation and increased septic complications in patients given parenteral feeding, rather than to a specific benefit of enteral feeding. In a small RCT which compared early enteral nutrition with no nutritional support in 27 patients, Powell *et al.* [75] found no difference in clinical outcomes or in immune markers, but this trial probably lacked adequate power.

### Nutritional support

Concerning the requirement for nutritional support in patients with severe disease, there is conclusive evidence that the outcome is better and the cost is lower if the enteral rather than the parenteral route is used. Several RCTs and two meta-analyses have demonstrated improved infection rates and glucose control with enteral compared to parenteral nutrition [71, 76–79]. **A1c** Enteral nutrition is the cheaper option, and has become the new “gold standard” for nutritional support in acute pancreatitis.

### “Immune-enhanced nutrition”

The type of feeding solution used may influence outcome, by providing a beneficial stimulus to the immune system, and perhaps by specific effects that enhance gut mucosal function. So-called “immune-enhanced nutrition” has been used in a variety of situations, but has not been shown to be superior to routine feeding solutions in acute pancreatitis. Although Hegazi [80] favored the use of immune-enhanced solutions, largely on the basis of experimental data, McClave performed a systematic review [77] that included assessment of the value of specific supplements added to EN, such as arginine, glutamine, omega-3 poly-

unsaturated fatty acids and probiotics. The analysis indicated that these agents may be associated with a positive impact on patient outcome in acute pancreatitis, compared with EN alone, but the studies are too few to support strong treatment recommendations.

The case of probiotic bacteria is of interest, because several small studies have shown benefit from enteral nutrition supplemented with various *Lactobacillus* species, often with added dietary fiber [81–83]. However, when tested in a large multicentre study, the probiotic group suffered an excess of deaths, largely due to bowel perforation, usually at the cecum [84]. This well-designed, double-blind trial included 298 patients with severe pancreatitis (APACHE II 8 or more) randomly allocated within 72 hours of onset to receive either a multispecies probiotic preparation (n = 153) or placebo (n = 145), administered enterally twice daily for 28 days. The groups were well matched. There was no difference in infective complications (probiotic 46 (30%), placebo 41 (28%)), but 24 (16%) of the probiotic group died, compared with nine (6%) of the controls. There were nine cases of bowel ischemia in the trial, of which eight were fatal, and all occurred in the probiotic group. This well designed RCT did not confirm the treatment benefit suggested by earlier smaller studies, in patients with severe acute pancreatitis. **A1a**

### Management of gallstones causing pancreatitis

All patients with biliary pancreatitis should undergo definitive management of gallstones during the same hospital admission, unless a clear plan has been made for definitive treatment within the next two weeks.

It is essential to deal promptly with gallstones, to prevent a further attack of pancreatitis. A recurrence of pancreatitis may occur at any time, and reports from health care systems in which early cholecystectomy is not universally available confirm the risk of fatal recurrence while awaiting treatment. **B4** Definitive treatment is usually by laparoscopic cholecystectomy with intra-operative cholangiography, carried out as soon as symptoms of pain and anorexia have resolved. Some experts prefer a pre-operative cholangiogram obtained by MRCP. Cholecystectomy is usually achieved within 4–7 days of onset of symptoms. At this time, cholangiography will demonstrate bile duct stones in fewer than 10% of these patients (Figure 24.3) [85]. Bile duct stones may be dealt with by laparoscopic bile duct exploration, or by ERCP and sphincterotomy. Approximately 90% of patients will have a normal bile duct at this time. They need no intervention on the bile duct and avoid the risks associated with endoscopic sphincterotomy. The endoscopic approach carries a well-recognised risk of 5–10% of exacerbation of the pancreatitis and of sphincterotomy

**Figure 24.3** Prevalence of gallstones within the common bile duct at the time of cholangiography (days after onset of symptoms) (reproduced from De Waele *et al.* [85]).

bleeding. However, pancreatic duct stenting may reduce the risk of pancreatitis. Endoscopic sphincterotomy may be appropriate in patients in whom there is co-morbidity, which increases the risks of general anaesthesia for cholecystectomy. **C5** In particular, elderly patients without pre-existing symptoms of cholelithiasis may be appropriate for endoscopic sphincterotomy, with conservative management of the gall bladder stones unless further symptoms arise. **C5**

In acute necrotizing pancreatitis, when surgery is indicated, cholecystectomy should always be done at the time of necrosectomy, if that can be achieved safely. **C5** Patients with severe disease who do not undergo surgery should also have the definitive management of their gallstones planned and carried out before discharge from hospital, although there may be circumstances in which a short delay is acceptable, for example to allow combined management of the stones and a pseudocyst. In any case, management of the gallstones must be integrated into the care plan for each individual.

### The role of early ERCP in severe biliary pancreatitis

Patients with signs of cholangitis require endoscopic sphincterotomy or duct drainage by stenting to ensure relief of biliary obstruction. Urgent therapeutic ERCP should be performed in patients with acute pancreatitis of suspected or proven gallstone etiology who satisfy the criteria for predicted or actual severe pancreatitis, or when there is cholangitis, jaundice, or a dilated common bile duct. All patients undergoing early ERCP for severe gallstone pancreatitis require endoscopic sphincterotomy whether or not stones are found in the bile duct. The indications for early ERCP now seem clearer.

Gallstone related pancreatitis is diagnosed when pancreatitis occurs and there are gallstones in the gall bladder, and

in the absence of any other known reason. The mechanism is related to the passage of a gallstone through the ampulla, with temporary obstruction of flow of pancreatic juice, and possible reflux of bile into the pancreatic duct. ERCP and endoscopic sphincterotomy (ES) prevents further damage by releasing stones from the bile duct, and by preventing further obstruction of, or reflux into, the pancreatic duct. Thus, early ES has been proposed as a preventive measure, to reduce complications. Clearly, there can be no rationale for using early ES in this way in mild disease, where the risk if complications is low, or in non-biliary pancreatitis, where there are no stones to pass through the ampulla. There is general agreement in published guidelines and in one large RCT that in pancreatitis associated with cholangitis, early ES can bring about a marked improvement in the patient's condition and should be performed as soon as practicable, ideally within 24 hours [8, 10–12, 86].

If ERC is attempted in patients with pancreatitis, ES should always be performed to minimize the risk of procedure induced cholangitis. This has been recommended on the basis of an RCT published only in abstract form [87], expert opinion and critical analysis of RCT data. A further preliminary report from Katowice [88] has described a randomized comparison of ERCP with or without ES, in patients with acute biliary pancreatitis who had ERCP within 12 hours of admission, but who had no evidence of cholangitis, biliary obstruction or bile duct stones. The complication rate was higher than expected in patients who did not have a sphincterotomy, especially in patients with mild pancreatitis. This result supports the view that if ERCP is undertaken early in acute pancreatitis, ES should be performed. **A1d**

The first two reported trials of early ERCP +/- ES found a significant reduction in the complication rate in severe biliary pancreatitis [89, 90], but subsequently a debate arose whether early ERCP is appropriate, driven by the results of a large RCT performed in Germany [86], which did not show benefit in a group of patients with mild or severe pancreatitis in whom cholangitis had been excluded. This study included patients with mild disease and sphincterotomy was not performed routinely after cholangiography, making it difficult to interpret the results. A Cochrane Review [91] of these three trials pooled data from 172 patients with severe biliary pancreatitis. The reduction in mortality was not statistically significant, but complications were much less likely after early ERCP (OR 0.27; 95% CI: 0.14–0.53) [91].

Two further studies have helped to clarify the indications for early ERCP. Acosta [92] studied 61 patients with gallstone pancreatitis who had evidence of biliary obstruction but no signs of cholangitis, in whom the obstruction persisted for 24 hours. Patients were randomized to early ERCP or to ERCP in the recovery phase; ES was performed only if there was evidence of obstruction. There were no

deaths in this series, but immediate complications (which are likely to be systemic complications) were reduced from 26% to 3% in the early ERCP group. **A1d** There is no comment on the incidence of organ failure in this study, and this study is too small to enable firm conclusions to be drawn. However, the focus on patients with persistence of signs of obstruction is appropriate: there seems little point in early ES if a patient has passed a stone and if signs of systemic disturbance are resolving. **C5**

Oria [93] randomized 103 patients with a dilated bile duct or raised bilirubin, but without evidence of cholangitis, to undergo ES within 72 hours of onset of symptoms, or to standard management without endoscopy. They found no difference in the incidence of organ failure or local complications in the two groups. A crucial unanswered question in considering these trials is the definition of cholangitis. If the presence of SIRS together with biliary obstruction is taken to indicate likely cholangitis, then all patients with severe disease by currently understood definitions are likely to have been excluded.

A recent meta-analysis [94] concluded that there is no benefit from early sphincterotomy in severe gallstone pancreatitis, in the absence of signs of cholangitis. There was no difference in outcome in the treated and control patients in the three trials selected for analysis [86, 90, 93]. This analysis must be questioned, as the inclusion criteria used are puzzling. Two trials were excluded from analysis. The study of Fan *et al.* [89] was excluded on the grounds that all patients with pancreatitis were included, despite the fact that the outcomes for patients with severe pancreatitis and with gallstones are clearly presented in the report. There was a clear reduction in complications in these patients. This trial had been included in the Cochrane Review cited above [88]. The second trial [92] excluded by Petrov *et al.* examined the interesting question of the value of ES in patients who had failed to improve in the first 24 hours of admission. In other words, the investigators did not intervene in patients who did not meet current criteria for severity. Again, this trial showed benefit for early ES in appropriately selected patients. Finally, Petrov *et al.* did include the German study [86] which has been discussed above. This trial is flawed by the inclusion of patients with mild disease, and by the fact that sphincterotomy was not performed routinely. This trial did not support the use of early ES. Thus, the meta-analysis of Petrov *et al.* excluded two trials supportive of early ES and included a flawed trial that failed to support this approach, and the conclusions cannot be accepted.

A new study is consistent with these observations. Patients enrolled in the PROPATRIA trial [84] were randomly allocated to receive probiotics or not in association with enteral feeding. As noted above, the trial intervention did not produce any benefit. The trial data have been secondarily analyzed to throw light on the role of ERCP/ES,

which was used at the discretion of the responsible clinician. All patients had predicted severe pancreatitis and half had cholestasis (bilirubin > 40 micromol/l and or CBD > 8 mm). Differences in baseline features were taken into account in the recent preliminary report [95]. Of 78 patients with cholestasis, 56 had early ERCP/ES, with significant reduction in overall complications and the frequency of necrosis affecting more than 30% of the pancreas. Early ERCP/ES (n = 29) had no effect on complication rates in the 75 patients without evidence of cholestasis. **A1d**

Early (<72 hours of admission) ERCP/ES can be restricted to patients with *severe* acute pancreatitis, especially those with persistent SIRS or organ failure, who have *gallstones*, and who have signs of *cholestasis*. If signs of biliary obstruction, organ failure or SIRS resolve, ES may be deferred. If the bile duct is cannulated, a sphincterotomy should be performed.

---

## Intervention for necrosis

All patients with persistent symptoms and greater than 30% pancreatic necrosis, and those with smaller areas of necrosis and clinical suspicion of sepsis, should undergo image guided fine needle aspiration to obtain material for culture 7–14 days after the onset of the pancreatitis. Patients with infected necrosis will require intervention to completely debride all cavities containing necrotic material. The choice of surgical technique for necrosectomy, and subsequent postoperative management depends on individual features and locally available expertise.

It is widely accepted that infected necrosis requires intervention, and that sterile necrosis can be managed expectantly in the majority of cases [10, 12]. The range of techniques advocated for the management of infected necrosis attests to our lack of knowledge and the difficulty of formulating a simple treatment policy in the face of a complex and variable disease. The crucial information required to determine the choice of antibiotic and the need for intervention, that is the presence or absence of infection and the sensitivities of the infecting organism(s), is usually provided by culture of fine needle aspirates from the necrotic material. Fine needle aspiration is safe and reliable in experienced hands [96, 97]. In a survey of European practice [98] most respondents regularly use fine needle aspiration and, of these, the large majority (131 of 174) use the culture results to determine the need for surgery. **C5** Sometimes aspiration may be omitted, if it is clear from imaging that the patient requires intervention. For example, the presence of gas bubbles in the necrotic cavity is convincing evidence of infection.

Several surgical approaches have been advocated for dealing with infected necrosis. It is difficult to compare different series and different techniques because of varia-

tions in the criteria for selection of patients for treatment. Most guidelines provide recommendations about indications for surgical intervention, but have avoided definitive statements about choice of technique [10, 12]. A small RCT that compared debridement and drainage with debridement and postoperative irrigation, was abandoned because of the poor outcome in the irrigation group [99]. Complete operative debridement of necrotic material by open exploration of all the cavities and blunt dissection or separation of the necrosis is currently the standard approach [100]. There are reports of transperitoneal laparoscopic access to achieve complete debridement [101–104]. Other minimally invasive approaches that are being evaluated include percutaneous debridement, using an image-guided drain track for access [105–116], endoscopic debridement with endoscopic ultrasound guidance [117–123], video-assisted retroperitoneal dissection using a limited posterior incision [124], and non-operative management with targeted antibiotic therapy and percutaneous drainage [125]. Non-operative management may be possible for some patients, but not all respond, and a high proportion go to surgery. Percutaneous necrosectomy is successful in many cases, especially if the necrosis affects mainly the body and tail, but may require multiple treatment sessions, whereas open necrosectomy can achieve complete debridement in one intervention, at the cost of greater morbidity. The newer transgastric and retroperitoneal techniques appear to offer alternative access routes, but are suitable only for patients with an appropriately placed necrotic cavity. Complex and extensive necrosis may need more extensive access, or a combination of approaches. Mortality rates are similar with all these techniques. The conclusion to be drawn from this range of options is that they are complementary rather than competing, and that different situations may be treated by different techniques. **C5** In each center treating pancreatic necrosis, there should be the skills to provide percutaneous drainage, some kind of minimally invasive necrosectomy, and open surgical debridement.

There is growing consensus that delay before operation is advantageous. One RCT showed lower mortality with operation after day 12, compared with operation in the first few days [126]. **A1d** Numerous series report acceptable mortality rates (15–25%) in patients operated for infected necrosis more than two or three weeks from onset. If operation is planned, it is best delayed until after three weeks of the illness if at all possible. At this stage, the cavity is usually demarcated, and the necrotic material is easier to separate from viable tissue than at earlier operation. The optimum period of delay has not been defined, but most patients with infected necrosis will show systemic signs of infection, and will be sufficiently stable for operative intervention, 3–5 weeks after onset. There seems little advantage in delay beyond five weeks in the large majority of patients. **C5**

## Abdominal compartment syndrome

Acute pancreatitis is associated with inflammatory oedema of the pancreas and peripancreatic tissues. There may be accumulation of large volumes of fluid in the peritoneal cavity and the bowel may become distended by oedema and ileus. This can lead to raised intra-abdominal pressure. Organ failure occurs in the abdominal compartment syndrome (ACS) as a result of impaired ventilation (pressure on the diaphragm), hypotension (reduced venous return) and renal failure (increased filtration pressure required). ACS is well recognised in critically ill patients and is best treated by surgical decompression [127–129]. ACS is increasingly recognized as a mechanism of organ failure in acute pancreatitis.

In 2005, Gecalter [130] de Waele [131] and Wong [132] described a total of five cases of ACS in severe pancreatitis with apparent improvement after decompression. Other case reports have suggested similar outcomes [133–136]. Standard surgical management is upper abdominal laparotomy; a less invasive approach by subcutaneous fasciotomy has been proposed [136]. Several case series have indicated the value of surgical decompression, but there are no randomized trials reported. Early experience was reviewed in 2007 [137]. A further seven case series, including a total of 351 patients with severe acute pancreatitis, report consistently that raised intra-abdominal pressure correlates well with increasing severity of pancreatitis, worse organ failure, and with fatal outcome [138–144]. One report showed a correlation of abdominal pressure with CT severity index [142], and it has been suggested that raised intra-abdominal pressure in the first week of illness may predict outcome in terms of organ failure and death [141]. Chen [138] and Albahrani [139] both reported clear improvement in clinical condition in most patients after abdominal decompression. **B4** Although a randomized trial would be difficult to perform, further observational data comparing outcomes in patients who were decompressed with those in similar patients who did not undergo decompression are needed to confirm these observations.

## Obesity management: Considerations for the gastroenterologist

*Leah Gramlich<sup>1</sup>, Marilyn Zeman<sup>1</sup> and Arya M Sharma<sup>2</sup>*

<sup>1</sup>Division of Gastroenterology, Royal Alexandra Hospital, University of Alberta, Edmonton, Canada

<sup>2</sup>Division of Endocrinology, University of Alberta, Edmonton, Canada

### Introduction

Obesity is one of the most prevalent health problems in the Western world [1]. Obesity increases the risk of medical illness and premature death [2] and imposes an enormous economic burden on the health care system [3]. Obesity is also associated with a reduced quality of life, resulting from substantial limitations and restrictions in activities of daily living [4]. Obese individuals are less likely to obtain insurance, employment or promotion or to enjoy personal relationships [5]. Prevention and treatment of obesity is now widely recognized as an important priority for most health care systems.

Obesity is best defined as the accumulation of excess body fat that threatens or affects an individual's mental, physical or economic well-being. At a population level, the body-mass index (BMI) has been widely used to characterize and define obesity. In individuals, however, it is a rather poor measure of health or well-being [6]. Furthermore, current anthropometric definitions of obesity have been challenged with regard to their sensitivity and specificity to determine cardiometabolic risk across ethnic groups. Therefore, in addition to BMI other measures that better characterize fat distribution (waist circumference, waist-to-hip ratio) have been recommended [7], but have yet to be widely used in clinical practice.

### Background

#### Assessing obesity

Obesity, or the accumulation of excess body fat, is best described as a "sign" of a derangement in energy balance (as edema is a "sign" of fluid retention). Given that energy

balance is affected by a wide range of sociocultural, psychological, biological and iatrogenic factors, it is important in each case to determine the root cause of the derangement in energy balance. Derangements can occur in energy intake (e.g. homeostatic or hedonic hyperphagia), energy metabolism (e.g. hypothyroidism, beta-blockers) or energy expenditure (exercise or non-exercise thermogenesis). Work up of the obese patient must include assessment of all components of energy balance [7].

In assessing obesity it is also helpful to remember that overeating (hyperphagia), when present, in itself is not a diagnosis or a "root cause". Rather, increased food intake has to be interpreted as a perturbation of ingestive behavior that may have multiple causes [8]. These can range from simply overeating at meals in response to hunger precipitated from meal skipping or irregular eating (homeostatic hyperphagia), to emotional overeating, binge-eating disorder, or reward-seeking behaviors not unlike other addictions (hedonic hyperphagia). Asking a hyperphagic obese individual simply to eat less without attempting to determine the underlying problem or help develop specific alternative coping strategies is rarely effective or sustainable.

As with ingestive behavior, physical activity levels are also determined by a wide range of sociocultural, psychological, physical and economic factors [9]. Lack of time is probably the most common factor implicated in lack of exercise. However, as with emotional overeating, lack of motivation and low energy levels can be a sign of an underlying depression, sleep disorder, obstructive sleep apnea or vital exhaustion. Physical limitations to increasing physical activity may include back pain, osteoarthritis, trauma or plantar fasciitis. Again, determining the "root cause" of inactivity is important to determine the most likely line of treatment and approach to behavior change.

#### Assessing barriers

Long-term efficacy and effectiveness of obesity treatments is notoriously poor. This may in part be attributable to the

substantial barriers that undermine long-term obesity management strategies [10]. These can include lack of recognition of obesity as a chronic condition, low socioeconomic status, time constraints, “intimate saboteurs” and a wide range of co-morbidities, including mental health, sleep disorders, chronic pain and musculoskeletal, cardiovascular, respiratory, digestive and endocrine diseases. Furthermore, medications used to treat some of these disorders may further undermine weight-loss efforts. Lack of specific obesity training of health professionals, attitudes and beliefs, as well as insurance coverage and availability of obesity treatments can likewise pose important barriers. Health professionals need to take care to identify, acknowledge and address these barriers where possible to increase patient success, compliance and adherence to treatments. Failure to do so may further undermine the sense of failure, low self-esteem and self-efficacy already common among obese individuals. Addressing treatment barriers can therefore save resources and increase the prospect of long-term success.

### Managing expectations

Patients and health care providers generally have exaggerated expectations of what is possible in obesity management [11]. Current studies show that lifestyle management alone is generally associated with a mean weight loss of

about 3–5% that can be maintained over 3–5 years [12]. Adding pharmacotherapy to lifestyle management can help achieve 5–15% weight loss, but the vast majority of patients will likely discontinue treatment and regain most of the weight within 3–5 years (Figures 25.1 and 25.2) [13]. Thus, as with other pharmacological treatments for chronic diseases, the importance of long-term adherence to anti-obesity medications cannot be overemphasized. The best long-term results are currently reported for surgical treatment of obesity, with an average sustained weight loss of 20–30% of initial body weight [14]. However, to achieve and sustain this degree of weight loss, surgical patients have to make substantial changes to their lifestyles, without which, a significant proportion of surgical patients will regain weight and/or develop nutritional deficiencies.

In this context, it is important to remember that even a 5% weight loss can produce dramatic improvements in cardiometabolic risk factors and even quality of life measures [15]. The benefits of even modest weight loss should therefore not be underestimated. Given the natural progression of obesity, even helping patients to maintain their current weight may be deemed successful obesity management.

It is not uncommon for a patient to be asked to lose an unreasonable amount of weight before undergoing an elective diagnostic or therapeutic procedure (e.g. joint replacement). The providers are often unaware that their request

**Figure 25.1** Placebo subtracted weight reduction (kg) with orlistat [17].

**Figure 25.2** Placebo subtracted weight reduction (kg) with sibutramine [17].

for weight loss is unreasonable. For example, even a 20 lb weight loss requires a total energy deficit of 70,000 Kcal. Using the recommended daily energy deficit of 500 Kcal, this would take a patient at least 20 weeks to achieve. However, safely achieving a daily energy deficit of 500 Kcal can be a challenge for sedentary individuals, who may often not need much more than 1500–2000 Kcal to sustain their weight. Thus, reducing energy intake to around 1000–1500 Kcal to achieve the recommended weight loss and still maintain a healthy nutritious balanced diet will pose a major challenge even for the most highly motivated patient. Without professional help, recommendations to lose an unrealistic amount of weight will not only substantially delay the elective procedure, but also increase the patient's sense of frustration and failure and risk promoting nutritional deficiencies.

### Approach to treatment

Given the chronic progressive nature of obesity, obesity management has to be approached with the same persever-

ance and diligence as the management of other chronic diseases [7]. All behavioral, medical or surgical interventions have to be continued beyond the weight-loss phase to prevent weight regain. Therefore, in a given patient, any intervention aimed at weight loss has to be reasonably sustainable in the long term to avoid recidivism or weight regain.

A wide range of behavioral interventions has been shown to be successful in the long term. These include self-monitoring with food journals and pedometers, regular weighing and regular provider contact [7]. Patients with emotional and binge-eating disorder may benefit from cognitive behavioral therapy [16]. Failure to identify and manage binge-eating appropriately is associated with virtually 100% recidivism. Overall the long-term, weight-loss benefit of behavioral intervention is rather modest. In a recent multicentre study that randomized 1029 participants, who had lost an average of 8.5 kg through lifestyle change over six months, to various strategies for weight-loss maintenance (personal contact, unlimited access to an interactive technology-based intervention, or self-directed

control) over 30 months, resulted in weight loss ranging between 2.9 to 4.2 kg at the end of the study [12]. **A1**

Pharmacological treatment for obesity should be considered in all patients who need to achieve a 5–10% weight loss [7]. In Canada and the USA there are currently two compounds licensed for the long-term treatment of obesity: orlistat, a gastrointestinal lipase inhibitor that reduces digestion and absorption of fat by around 30% [17] and sibutramine, a serotonin and norepinephrine reuptake inhibitor that increases satiety and may have modest effects on thermogenesis. Major adverse effects of orlistat include steatorrhea and oily rectal discharge. Use of sibutramine can be associated with xerostomia, constipation, hyperhidrosis, insomnia, palpitation and, in rare cases, an increase in blood pressure [17]. Both compounds have been shown to significantly increase weight loss when added to moderately caloric-restrictive diets. More importantly, continuation of pharmacotherapy is associated with a more significant reduction in weight regain than behavioral treatment alone. Therefore, long-term use of these agents in patients who respond to and tolerate these drugs is recommended. Despite documented effects on obesity-related morbidity, it should be noted that thus far, there is no evidence that behavioral or pharmacological therapy of obesity reduces overall or obesity-related mortality. **A1a**

Bariatric surgery is currently the most effective long-term treatment of severe obesity and has been shown to dramatically reduce the risk for co-morbidities including cardiovascular disease, type II diabetes, obstructive sleep apnea and certain cancers, and the risk for overall mortality alone (by up to 30%). Thus, for example, the recent Swedish Obesity Study was a prospective case control study comparing 2010 surgical to 2037 non-surgical matched controls [14]. During an average of 10.9 years of follow-up (follow-up rate, 99.9%) there were 129 deaths in the control group and 101 deaths in the surgery group (hazard ratio adjusted for sex, age, and risk factors was 0.71;  $p = 0.01$ ). The most common causes of death were myocardial infarction (control group, 25 subjects; surgery group, 13 subjects) and cancer (control group, 47; surgery group, 29). These benefits were seen with average weight loss after 10 years of 25% (gastric bypass), 16% (vertical-banded gastroplasty) and 14% (gastric banding). Currently, the most common surgical procedures are laparoscopic adjustable gastric banding (LAGB) and laparoscopic Roux-en-Y gastric bypass (RYGB) surgery. While overall complication rates at experienced centers are low (1–2%), surgical complications are even lower with LAGB. However, weight loss with this procedure is less pronounced and is more dependent on patient compliance than is the case for RYGB. Other surgical approaches including sleeve gastrectomies and endoluminal approaches are currently under investigation.

Given the complexity of obesity management, interventions are best provided by an interdisciplinary team of nurses, psychologists, physiotherapists, dietitians, social workers, occupational therapists, physicians and surgeons. In light of the widespread bias and discrimination of health professionals against obese clients, bariatric personnel should undergo sensitivity training [5].

Currently there is no cure for obesity – only long-term treatments that require ongoing support and follow-up of all patients to ensure adherence and reduce recidivism. Therefore, it is important to make every effort possible to prevent the development of this chronic and debilitating condition.

## The role of the gastrointestinal tract in ingestive behavior

Appetite is regulated by a complex interaction between central and peripheral signals that affect both the sensation of hunger and how an individual responds to food. While older models suggested that hypoglycemia stimulates food intake and post-prandial hyperglycemia activates the satiety centre of the brain [18], in the last decade a much more complex system has emerged that involves a multitude of neuropeptide and neurotransmitter systems, the enteroendocrine system and peripheral signals derived from adipose tissue (e.g. leptin).

The response to food ingestion is traditionally considered to occur in three phases. The cephalic phase is characterized by the secretion of saliva, gastric acid and pancreatic enzymes that is triggered by visual and olfactory stimulation. Relaxation of the sphincter of Oddi and the gastric fundus, and increased contractions of the gall bladder occur [19]. This cephalic phase is followed by the gastric phase, which involves relaxation of the proximal stomach. This is caused by the activation of inhibitory neurons on the gastric wall (accommodation). Finally, the intestinal or post-ingestion phase is characterized by a combination of duodenal, intestinal and colonic responses that may also play a role in satiety.

A multitude of enteroendocrine hormones or peptides play a role in regulating food intake by activating nearby extrinsic sensory fibers (vagal and spinal) or via the bloodstream (Table 25.1) [20]. They generally have a short half-life, interact with other hormones and they can modulate the sensitivity of the vagal response. Through activation of the vagus nerve or through direct neural stimulation, these peptides stimulate the hypothalamus, which then integrates these signals. The main site of integration is the arcuate nucleus of the hypothalamus (ARC). Two major sub-populations of neurons in the ARC are implicated in the regulation of feeding; cocaine and amphetamine related transcript (CART) and pro-opiomelanocortin (POMC)

**Table 25.1** Role of enteroendocrine hormones and peptides in regulation of food intake.

Hormone	Effect on hunger	Stimulus for secretion	Location secreted	Effect
Ghrelin	↑	Cephalic phase	A-X like cells of the oxyntic glands (stomach)	<ul style="list-style-type: none"> <li>Enhances NPY/AgRP and inhibits POMC pathways.</li> <li>Endogenous ligand for growth hormone secretagogue receptors.</li> <li>Controls secretion of ACTH, prolactin, and plays a role in glucose and lipid metabolism.</li> <li>Increases gastric mobility, gastric acid secretion and insulin secretion.</li> </ul>
Cholecystokinin (CCK)	↓	Nutrients (especially lipids and proteins)	I-cells of the duodenum and ileal	<ul style="list-style-type: none"> <li>Enduces satiety and reduces meal intake through vagus nerve stimulation.</li> <li>Inhibitory effect on gastric motility.</li> </ul>
Glucagon-like peptide-1 (GLP-1)	↓	Nutrients (especially lipids and proteins)	L-cells of the distal small intestine	<ul style="list-style-type: none"> <li>Enhances the glucose-induced stimulation of insulin synthesis and secretion, while suppressing glucagon secretion.</li> <li>Delays gastric acid secretion and emptying.</li> </ul>
Peptide YY (3-36) (PYY <sub>3-36</sub> )	↓	Nutrients (proportional to caloric intake)	L-cells of the distal small intestine	<ul style="list-style-type: none"> <li>Thought to act at the level of the hypothalamus; however, exact mechanism unclear.</li> </ul>
Oxyntomodulin	↓	Nutrients (proportional to caloric intake)	L-cells of the distal small intestine	<ul style="list-style-type: none"> <li>Inhibits gastric acid secretion and gastric emptying.</li> <li>In animals, found to increase gastric somatostatin release, potentiates the effects of PYY and found to inhibit insulin secretion.</li> <li>Thought to work through GLP-1 receptor stimulation</li> </ul>
Leptin	↓	Short chain fatty acids	Adipose tissue	<ul style="list-style-type: none"> <li>Low leptin activates anabolic and inhibits catabolic circuits.</li> <li>Enhances NPY/AGRP while blocking POMC/CART release.</li> </ul>
Pancreatic polypeptide (PP)	↓	Nutrients (proportional to caloric intake)	Pancreas	<ul style="list-style-type: none"> <li>Thought to act at level of hypothalamus and brainstem to decrease intake.</li> <li>Effect unclear as PP injected directly into the brain increases food intake in rats.</li> <li>May potentially affect gastric emptying.</li> </ul>
Insulin	↓	Glucose	Pancreas	<ul style="list-style-type: none"> <li>Centrally, insulin reduces feeding by activating POMC.</li> <li>Insulin also increases AgRP synthesis, which would increase hunger.</li> </ul>

inhibit food intake, whereas neuropeptide Y (NPY) and agouti-related protein (AgRP) stimulate it. Both influence how the hypothalamus signals pituitary hormone secretion and appetite [21]. The neurophysiological pathways involved in triggering hunger and satiety are complex and beyond the scope of this chapter.

In the stomach, neural sensors perceive changes in the tension, stretch and volume of the stomach wall and outputs from these mechanoreceptors are relayed to the brain via the vagus and spinal sensory nerves [20] to the nucleus tractus solitarius (caudal brainstem) and then to the hypothalamus. Gastric distension induces a feeling of satiety [22]. Persistent delayed gastric emptying is known to decrease food intake, and artificial distension of the proximal stomach with a water-filled balloon has been found to reduce oral intake [23, 24]. On the other hand, the stomach is also the source of ghrelin, the only enteric hormone so far known to promote hunger and food intake.

In contrast, there are a number of enteric satiety signals, the best studied of which include cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1) and peptide YY (PYY) [21]. Parental administration of CCK induces satiety in animals and humans [25, 26, 27], an effect that is eradicated by vagotomy. CCK also delays gastric emptying [28] resulting in gastric distension. Due to its short duration of action, attempts to utilize CCK as a treatment for obesity have failed. PYY, another satiety hormone released from the colon, also inhibits fasting small bowel motility and gastric emptying [29]. Parenteral PYY injection decreases food intake in normal and obese humans [30], potentially via a central mechanism. Exogenous GLP-1 has been found to decrease food intake [31], only when administered at doses much higher than those physiologically achieved after a normal meal [32].

## Gastrointestinal symptoms and disease in the obese patient

### Gastro-esophageal reflux disease (GERD)

Obesity is a significant risk factor for GERD. Obese individuals are more than twice as likely as non-obese individuals to admit to a history of GERD or symptomatic heartburn [33] [34]. The prevalence of GERD ranges from 8–26% in individuals with obesity [35] [36]. Similarly, endoscopically diagnosed erosive esophagitis is also more common in individuals with an increased BMI, with an odds ratio (OR) of 1.76 [37]. Several mechanisms have been described to explain this correlation. An increased intra-abdominal and resulting increase in intragastric pressure can precipitate reflux into the esophagus or hiatus hernia [38]. In addition, derangements of esophageal motility, including hypertensive contractions (nutcracker esophagus) or disordered contractions (non-specific motility disorder), decreased lower esophageal sphincter pressure, inappropriate lower esophageal relaxation, a sliding hiatus hernia and delayed gastric emptying have also been implicated (see motility section below) [39]. Finally, diet, refluxate composition and an increased incidence of *Helicobacter pylori* may also play significant roles in increasing the incidence of GERD in obese individuals.

Several (but not all) studies suggest that weight loss is associated with decreased esophageal acid exposure and an improvement in GERD symptoms [40]. The lack of symptomatic improvement in many patients following weight loss may be attributed to the persistence of a hiatus hernia [41]. Modifications in dietary composition may be more effective than an actual change in weight [42, 43]. Symptomatic improvement following bariatric surgery is likely secondary to both weight loss and a change in the anatomy of the gastrointestinal (GI) tract. Roux-en-Y consistently results in a favorable response as an anti-reflux procedure, with a significant improvement in reflux symptoms and a decrease in the use of GERD medication noted postoperatively. Adjustable gastric banding may not be a suitable option in obese individuals with symptomatic GERD, unless combined with anti-reflux surgery, since banding can precipitate the reflux of gastric contents into the esophagus from the small gastric reservoir [44].

### Acute pancreatitis

Severe hypertriglyceridemia, not uncommon in overweight and obese individuals, is a rare but well recognized cause of acute pancreatitis [45]. Increased BMI is, however, considered to be a risk factor for a worse outcome in patients with acute pancreatitis [46, 47]. In a recent meta-analysis severe acute pancreatitis was more frequent in obese

patients (BMI  $\geq 30$  kg/m<sup>2</sup>) (OR 2.6), who also tended to develop more systemic (OR 2.0) and local complications (OR 4.3). Local complications from the greater accumulation of peripancreatic fat included fat necrosis, with necrosis becoming a nidus for infection [46]. This is particularly problematic in obese individuals with hyperinsulinemia and insulin resistance [48]. Obesity is also associated with respiratory, renal and circulatory compromise as well as an increased incidence of death [49]. In light of these observations, adding an obesity score (BMI  $\geq 26$  kg/m<sup>2</sup>) to the APACHE II (Acute Physiology and Chronic Health Evaluation) score has been recommended to improve its predictive value for overweight and obese patients [50, 51]. Thus, the composite APACHE-O (APACHE-II plus obesity) score  $>8$  has greater predictive accuracy than the APACHE-II score, with a sensitivity of 82%, specificity of 86%, positive predictive value (PPV) of 74% and a negative predictive value of 91% (NPV) in predicting morbidity and mortality [50].

### Gallstone disease and cholecystitis

Both obesity and rapid weight loss are associated with an increased risk of gallstone disease, particularly in women. Risk appears highest when obesity begins in late adolescence [52] or if obesity is truncal [53]. The three major factors important in the development of gallstones include gall bladder dysmotility, cholesterol supersaturation of bile (i.e. a higher concentration of cholesterol to bile or phospholipids), and cholesterol nucleation. Obese patients have an increased biliary secretion of cholesterol from the liver, which leads to the formation of bile supersaturated with cholesterol and the precipitation of cholesterol microcrystals [54]. Both diabetes mellitus and insulin resistance are known to be confounding factors with respect to the association of obesity and gallstone disease [55]. Increased hepatic cholesterol synthesis and diets high in calories and refined carbohydrates, but low in fiber, also increase the risk. There is contradictory evidence, however, on the specific role of total fat intake [56]. There has been no correlation found between serum cholesterol level and a predisposition to gallstone formation [57].

Impaired gall bladder emptying or gall bladder stasis, and further cholesterol saturation, as would occur in individuals who lose weight rapidly with restricted dieting or following bariatric surgery, also precipitates stone formation [58]. Low calorie and low fat diets affect biliary lipid composition with increases in the hepatic uptake of cholesterol and hepatic cholesterol synthesis [59]. Weight loss is clearly associated with the development of gallstones, especially in women [51]. In several studies, approximately 11–28% of obese patients who severely restricted their dietary intake [60–62], and 27–43% of patients who underwent bariatric surgery developed gallstones within a

period of 1–5 months [63, 64]. Routine concomitant cholecystectomy with bariatric surgery has been suggested, but remains controversial. The rate of weight loss also influences gallstone development. As gallstone formation appears particularly high when weight loss is more than 1.5 kg per week [65], preventive strategies have been suggested. These include controlling the rate of weight loss, administration of ursodeoxycholic acid to decrease cholesterol saturation, limiting between meal fasting time and maintaining a small amount of fat in the diet [66].

Ursodeoxycholic acid has been shown in several small studies to reduce gallstone formation post-bariatric surgery. These studies are difficult to compare as they used different doses of ursodeoxycholic acid (i.e. 500 [67] to 1000 [68] mg/day), for different lengths of time (i.e. 3 [68] to 24 [67] months). The presence of gallstone formation is based upon different diagnostic imaging modalities. Miller [68], in the longest study to date, found that after 24 months the incidence of finding gallstones by ultrasound or CT scan was 8% in 76 patients treated with 250 mg ursodeoxycholic acid bid for six months postoperatively versus 30% in 76 patients treated with placebo. The true incidence of symptomatic cholecystitis is unknown. Miller [68] reported that 4.7% of patients in the ursodeoxycholic group and 12% in the placebo group underwent postoperative cholecystectomy for symptomatic gallstone disease. Though adverse effects of ursodeoxycholic acid are minor (nausea, constipation), and were not found to be significantly different in the treatment and placebo groups [68], ursodeoxycholic acid is relatively expensive and the pills are large, making passage through a small gastric reservoir difficult. Post-operative prophylactic treatment with ursodeoxycholic acid at this time is not routinely recommended.

### Diverticular disease and diverticulitis

The relationship between diverticular disease and obesity remains unclear. Obese patients are more likely than patients of normal body weight to present with diverticulitis and diverticular perforations. This association has been particularly noted in younger individuals [69, 70], in whom the diagnosis may be missed [71]. In one retrospective case series, individuals diagnosed with recurrent diverticulitis or diverticular perforations were significantly more likely to be obese [72]. Obesity has also been identified as a significant risk factor for mortality following elective sigmoid resection done specifically for diverticular complications.

### Cancer

Several mechanisms have been proposed to explain the increased risk of malignancy in obese individuals. These include the insulin and insulin-like growth factor axis, the

role of sex steroids and the influence of adipokines. Hyperinsulinemia or insulin resistance reduces insulin-like growth factor (IGF) binding protein, which increases free IGF-1 levels. Both insulin and IGF-1 are associated with increased cell growth and proliferation and both may promote neoplastic cell growth [73]. Hyperinsulinemia also reduces sex hormone-binding globulin, which leads to increased estrogen and androgen levels. These hormones have been shown to be involved in the regulation of cell differentiation, proliferation and apoptosis, and to selectively enhance the growth of preneoplastic and neoplastic cells [74]. Increased serum leptin, an adipocyte-derived hormone is considered to be an obesity signal, which acts centrally as a catabolic agent to regulate body weight. *In vitro* leptin has been found to stimulate cancer cells derived from the colon and esophagus [75, 76]. Obesity is also thought to be involved in the immunologic or inflammatory response as described above. Increased levels of cytokines and adipokines, such as adiponectin [77] and transforming growth factor beta [78], may contribute to cell growth and differentiation. A large prospective cohort study assessing cancer mortality in over 900,000 Americans determined that the death rate from all cancers (GI and non-GI) was 52% higher in obese men and 62% higher in obese women compared to men and women of normal body weight. The authors suggested that more than 90,000 deaths per year from cancer could be avoided by maintaining a BMI less than 25 kg/m<sup>2</sup> throughout life. The strongest association between obesity and gastrointestinal cancer risk has been demonstrated for esophageal, gall bladder, pancreas, liver and colorectal cancers [79]. A recent systematic review and meta-analysis found GI malignancies to be more prevalent in obese individuals, with a 5 kg/m<sup>2</sup> increase in BMI leading to an increased risk for gall bladder (RR = 1.59), esophageal (RR = 1.51) and colon adenocarcinomas (RR = 1.09) in women, and esophageal (RR = 1.52) and colon (RR = 1.24) adenocarcinomas in men [80]. For colon cancer, the association was significantly stronger in men than in women, an observation that gives credence to the finding that estrogen plus progestin may be protective against colon cancer formation [81].

### Barrett's esophagus and esophageal adenocarcinoma

Both GERD and high BMI are considered risk factors for esophageal adenocarcinoma. In a recent meta-analysis, individuals with a BMI > 25 kg/m<sup>2</sup> had an OR of 1.52 for esophageal adenocarcinoma compared to an OR of 2.78 in individuals with a BMI > 30 kg/m<sup>2</sup> [37]. Whether or not this risk is directly mediated by obesity remains unclear. It appears that the risk for Barrett's esophagus, the precursor to esophageal adenocarcinoma, may be entirely mediated through the increased risk of GERD in obese individuals [82]. Nevertheless, recent studies have suggested that adi-

pokines like adiponectin and leptin [83] may be directly associated with Barrett's metaplasia. Whether or not weight loss results in a decreased risk of esophageal adenocarcinoma is not known.

### **Proximal gastric adenocarcinoma/cancer of the gastric cardia**

The difficulty in endoscopically differentiating proximal gastric adenocarcinoma from distal esophageal adenocarcinoma complicates risk factor assessment. Several studies have confirmed that obesity is a significant independent risk factor for the development of proximal gastric adenocarcinoma [84–88] but not gastric non-cardiac adenocarcinoma [84, 85, 88]. In a large study of over 500,000 US patients, a BMI > 35 kg/m<sup>2</sup> was found to be a significant risk factor for esophageal and gastric cardia adenocarcinoma, with a hazard ratio of 2.27 and 2.46 respectively [84]. The association between these two cancers is unclear, as GERD was found to be a significant risk factor for the development of esophageal adenocarcinoma (see above esophageal adenocarcinoma section) but not for proximal gastric cancers [84, 88].

### **Pancreatic cancer**

The only universally accepted risk factors for the development of pancreatic cancer are smoking and family history [89]. Data regarding any association with obesity and pancreatic cancer risk are based largely on case-control studies and may be biased by high fatality rates. The RR of obesity as a risk factor for pancreatic cancer was reported to range between 1.2 and 3.0. A recent meta-analysis of six case-control and eight cohort studies found a weak RR of 1.19 for men with a BMI > 30 kg/m<sup>2</sup> compared to individuals with a BMI < 22 kg/m<sup>2</sup>, but not for women [90]. Not all studies corrected for the significant confounders of smoking and diabetes.

Much like the mechanism by which non-alcoholic steatosis leads to liver fibrosis and cirrhosis [91], it has been suggested that non-alcoholic fatty pancreas disease may lead to non-alcoholic steatopancreatitis, which can progress to pancreatic fibrosis and dysfunction (chronic pancreatitis), and eventually pancreatic cancer. The adipose-derived cytokines, IL-1 beta and TNF- alpha are thought to promote this progression [92].

### **Hepatocellular cancer (HCC)**

The relative risk of mortality from primary HCC is 1.68 times higher among women and 4.52 times higher for men, with a baseline BMI ≥ 35 kg/m<sup>2</sup> compared to a BMI of 18.5–24.9 kg/m<sup>2</sup> [79]. In men, HCC had the highest obesity-related relative risk of all cancers. Hepatocellular cancer is a well-recognized complication of cirrhosis, and non-alcoholic fatty liver disease associated with obesity and the metabolic syndrome is a known cause of cirrhosis. A study,

by Nair *et al.* [93] of nearly 20,000 US patients found obesity to be an independent risk factor for HCC. However, on multivariate analysis, obesity was only found to be a significant risk factor in patients with either alcoholic or cryptogenic cirrhosis. This association was not found in patients with other causes of liver cirrhosis such as hepatitis C viral (HCV) infection. Similarly, diabetes mellitus has been suggested to be a risk factor for HCC development [94, 95], though obesity is a significant confounding variable. A recent study in nearly 1500 patients with chronic HCV cirrhosis followed for a mean of six years found that being overweight or obese were significant independent risk factors for HCC development, with a hazard ratio of 1.86 and 3.10 respectively [96]. Obesity, diabetes mellitus and hyperlipidemia are conditions known to have a synergistic effect on the progression of liver fibrosis in patients infected with HCV [97]. It is difficult to know whether fatty infiltration worsens HCV progression itself or whether non-alcoholic fatty liver disease is a potential secondary cause of liver cirrhosis in obese individuals.

### **Cholangiocarcinoma**

Studying the risk factors associated with the development of cholangiocarcinoma is hindered by the fact that it is such a rare disease, and that only 10% of cases are associated with a recognized risk factor [98]. Obesity has been suggested to be a potential risk factor in some studies [99, 100] but not in others [101]. As with other cancers, studies are limited by the presence of confounding variables. Specifically, gallstone disease is a recognized risk factor for the development of cholangiocarcinoma, and obesity is a recognized risk factor for the development of gallstones [102].

### **Colorectal adenocarcinoma**

A recent meta-analysis of 31 prospective studies performed between 1966 and 2007 found that a five-unit increase in BMI was associated with a 30% increased risk of colon cancer in men and a 12% increased risk in women [103]. BMI was a significant risk factor for the development of proximal colon cancer in men, and with distal colon cancer in both sexes. Rectal cancer was significantly related to BMI in men but not in women. Abdominal obesity showed a stronger relationship than overall obesity [103]. The reason for the apparent sex difference in the association between colon cancer rates and obesity is unclear. While obesity imposes a greater risk of colon cancer for men of all ages, the risk has been reported to be higher in premenopausal than in postmenopausal women [104]. Although, increased estrogen levels and insulin resistance in premenopausal women have been suggested to contribute [105], this would not explain why colon cancer risk is higher in men than in women [80] or why exogenous estrogen in the form of hormone replacement therapy may be protective [81].

Confounding factors for all studies related to cancer, but specifically to colon cancer, include the influence of exercise and diet. Physical activity is associated with lower rates of colon cancer [106]. The theoretical explanation for this is that physical activity increases colonic motility [107]. Dietary factors which have been associated with an increased risk of colon cancer include the high consumption of red meat, low consumption of fresh fruits and vegetables, low-fiber diets and diets low in certain vitamins and minerals including calcium and folate [108]. These diets may be more common in overweight individuals.

### Gastrointestinal dysmotility

Alterations in gastrointestinal motility have been recognized in obese individuals, resulting in a variety of symptoms, most notably reflux, nausea, diarrhea and bloating.

#### Esophageal dysmotility

In the esophagus, transient lower esophageal sphincter (LES) relaxation and decreased esophageal clearance capacity may contribute to GERD [109]. Studies on esophageal dysmotility and obesity, however, have produced inconsistent results [110, 111]. Other pathophysiological factors that may contribute to the higher incidence of GERD in overweight and obese individuals include increased esophageal acid sensitivity [112] and the presence of a hiatal hernia. Koppman *et al.* [113] evaluated 116 obese individuals who presented for esophageal assessment by manometry prior to laparoscopic gastric banding, regardless of any dyspepsia or dysphagia history. An abnormal motility pattern was found in 41% of these patients, of whom 23% were diagnosed with non-specific esophageal motility disorders, 11% with nutcracker esophagus, 3% with isolated hypertensive LES, 3% with isolated hypotensive LES, 1% with esophageal spasm and 1% with achalasia. Interestingly, only one patient with abnormal esophageal motility had a history of non-cardiac chest pain. This observation is contrary to what one would expect given the relationship between obesity and GERD. One explanation for the apparent lack of GERD symptoms in this study is that patients with morbid obesity may have a depressed autonomic nervous system and may lack sensory perception through the vagus nerve. In addition, only 3% had evidence of an isolated hypotensive LES. Other studies have suggested a higher incidence of hypotensive LES in obesity, with a prevalence ranging from 14–69% [114–116] and with potential worsening of reflux following adjustable gastric banding [116]. There was no mention in Koppman's study of the number of transient LES relaxations, which has been suggested to be the most significant abnormality causing GERD in this population, through frequent overeating [109].

#### Gastric dysmotility

The relationship between obesity and gastric motility, as assessed by gastric emptying studies, has been contradictory [109]. In general, it is suggested that obese individuals have a larger gastric capacity and accelerated solid food gastric emptying [117]. Rapid emptying may reduce the negative feedback satiety signal and trigger hunger [118]. Myoelectrical studies suggest that individuals with morbid obesity have a decreased gastric slow wave frequency and an increased frequency of dysgastria in both the fasting and fed state, which would explain any increased gastric emptying [119]. No difference in either the gastric emptying of liquids or in gastric accommodation has been found in the obese [118]. Gastric electrical stimulation studies performed so far only in dogs have suggested that this intervention may become a viable therapeutic option to promote weight loss in the future [120].

#### Gall bladder dysmotility

Although decreased gall bladder motility has been implicated as a risk factor for the more frequent prevalence of gall bladder disease in obese individuals, the findings from motility studies have been inconsistent [121]. Insulin resistance [122] and hyperinsulinemia, which may decrease gall bladder sensitivity to cholecystokinin, and thus gall bladder contractions, may also play a role [123].

#### Small and large bowel dysmotility

While small and large bowel motility in obese individuals remain to be studied [118], no differences were found between obese and normal weight individuals in intestinal transit time as measured by hydrogen breath test [124].

### Functional GI symptoms

Obesity and its relationship to upper GI symptoms, specifically GERD and dyspepsia, are well studied (see GERD section). In clinical practice, however, it has been well recognized that many obese patients appear to have gastrointestinal (GI) complaints for which no etiology can be found. Functional GI disorders are thought to be secondary to an initial inflammatory insult on the GI tract that affects visceral sensitivity and/or motility. The proinflammatory effects of obesity are only now being recognized. Functional GI disease may be related to unrecognized changes in GI motility affecting GI function, or to a relative difference in the levels of some GI peptides induced by altered food habits or binge eating [125] and their endocrine or neurological effects. Four studies have addressed the relationship between obesity and GI symptoms [126–129]. The largest, a cross-sectional survey study, done in Olmsted County, evaluated the association of self-reported GI symptoms with BMI in nearly 2000 individuals [126]. Four symptoms were found to be significantly more prominent

in overweight and obese individuals: vomiting, upper abdominal pain, bloating and diarrhea. Similar results, with some variation, were found in the other three studies to date [127–129]. A linear increase in prevalence across BMI categories was not observed for any of the symptoms, though an incremental increase in OR across categories was found for diarrhea (overweight OR 1.0, class I OR 1.7, class II OR 2.7 and class III OR 2.8). An impressive 40.7% of individuals with class II obesity complained of diarrhea. However, 17.1% of patients with a normal weight also listed this as a GI complaint [126]. The authors suggested that the increased frequency of diarrhea may be secondary to changes in GI motility, such as increased gastric emptying, or decreased intestinal or colonic transit time, which have been reported in some studies (see motility section) in overweight individuals, or to the altered intestinal secretory response induced by the direct endocrine effects of some gut released adipokines [126]. Concomitant diabetes mellitus and the use of anti-obesity medications may be significant confounding variables [126]. In type II diabetics, diarrhea but not abdominal pain is associated with BMI independent of glycemic control, suggesting a causal link

between diarrhea and obesity independent of any effect of diabetes on GI function [130].

The Olmsted study [126] also found that upper but not lower abdominal pain is significantly associated with BMI. The association between obesity and irritable bowel syndrome is unclear. Two studies evaluating this relationship have found contradictory results [125, 131]. Despite this contradiction, individuals with abdominal pain have been found to have a significant improvement in their symptoms following laparoscopic Roux-en-Y gastric bypass (LRNY) [132].

**Bariatric surgery – a primer for the gastroenterologist**

Bariatric surgical procedures reduce caloric intake and/or nutrient absorption by modifying the anatomy of the gastrointestinal tract [133]. Expected results include a durable and significant weight loss of 24% of total weight after two years and 16% at 10 years (Figure 25.3) [134], with a remarkable reduction in obesity-related co-morbidities

**Figure 25.3** Mean per cent weight change during a 15-year period in the control group and the surgery group, according to the method of bariatric surgery.

and mortality. In addition, with the advent of laparoscopic surgery, complications have been dramatically reduced [135, 136]. In 2001, the NIH consensus statement identified bariatric surgery as the only long-term treatment for morbidly obese individuals ( $\text{BMI} > 40 \text{ kg/m}^2$ ) [137]. More recently, there has been a dramatic increase in the frequency of bariatric surgical procedures in the USA and worldwide [138, 139]. As a result, the practicing gastroenterologist must be familiar with the common bariatric surgical procedures, their complications and the implications for endoscopy.

### Surgical approaches to obesity

Bariatric surgery reduces nutrient intake and/or absorption by restrictive and/or malabsorptive modification of the gastrointestinal tract. Please see Figure 25.4 [133].

Restrictive procedures create an anatomically smaller proximal stomach (10–20 ml), resulting in early satiety and reduced oral intake. Procedures include gastric stapling gastroplasty, vertical banded gastroplasty (VBG) and the placement, most commonly laparoscopically, of a synthetic, inflatable band around the stomach to create a narrow outlet (LAGB) (Figure 25.4a). These techniques rely on foreign material (silicone or mesh) to maintain a narrow stoma to restrict the passage of food into the stomach. The size of the stomal outlet is typically 10–12 mm. Another recently developed procedure is the “sleeve gastrectomy” (Figure 25.4b), in which resection of much of the gastric body leaves a narrow tube of stomach in continuity with duodenum. While VBG is now largely considered to be obsolete, the use of LAGB is increasing because of its simplicity, ease of implementation, maintenance of intestinal continuity and reversibility [138]. The device can be manipulated in outpatient settings by altering the volume in the band, hence impacting the degree to which the stomal outlet is compromised.

Malabsorptive procedures (Figure 25.4c, d) include the Roux-en-Y gastric bypass (RYGB) in which the small intestine is divided at mid-jejunum and the distal portion is anastomosed to the stomach (often in combination with a restrictive gastrectomy, leaving a small residual gastric pouch to which the intestine is connected). The distal portion of stomach and proximal small bowel (bilio-pancreatic limb) are anastomosed end-to-side further down the jejunum. Although this length can vary (depending upon the amount of malabsorption that is desired) up to 150 cm, it is usually 60–75 cm. The degree of nutrient malabsorption is proportional to the length of the roux limb and inversely proportional to the length of the “common channel” – the portion of bowel remaining where pancreaticobiliary secretions and food come together. Another, less common malabsorptive procedure is the biliopancreatic diversion (BPD), often accompanied by a duodenal switch,

with restriction in the form of a sleeve gastrectomy. This procedure results in a relatively larger pouch and a greater predisposition to malabsorption (common channel of 50–100 cm).

The anatomic implications of bariatric surgery are of significant interest to the gastroenterologist and endoscopist. It is vital to understand the type of surgery that was undertaken, the expected results of this surgery, and the interpretation of patient symptoms and to implement and evaluate a treatment strategy in light of this understanding.

### Complications of bariatric surgery

The complications of bariatric surgery are the topic of several recent review articles [140–142]. In individuals who have undergone Roux-en-Y gastric bypass, complications relate to the anastomosis and to bowel manipulation, and include mortality (0.2%), leaks (2.3%), staple line disruption (1.5%), marginal ulcers (2.5%), strictures (9.9%), bowel obstruction (3.3%), hernias (2.4%) and wound infections (3.4%). Following LAGB, complications relate to band malposition and/or malfunction and include mortality (0.14%), band slippage (5.5%), pouch enlargement (5.5%), obstruction/stenosis (1.9%), band erosion (2.7%), hardware infection (1.2%), hardware leak (3.6%), severe esophageal dilation (3.0%) and esophageal or gastric perforation (1.2%) [141].

### Gastrointestinal symptoms and complications

Post-bariatric surgery patients will present in a number of different ways. Early complications occur within two months of the surgical procedure and are usually managed by the surgeon. In this population, because of large abdominal girth, physical findings may not correlate with postoperative complications, and there should be a low threshold for ordering contrast radiologic studies or computed tomograms. Later complications are more likely to require investigation by a gastroenterologist, and patients may present with various ill-defined symptoms, including abdominal pain, nausea and vomiting, abnormal, insufficient or excessive degrees of weight loss, diarrhea and gastrointestinal bleeding (Table 25.2).

Abdominal pain in the post-bariatric surgery patient may simply be due to the effects of rapid food consumption in the setting of a relatively fixed outlet. In patients with RYGB, pain may be related to stomal ulceration or stenosis or from an internal hernia. Biliary tract disease including cholelithiasis and choledocholithiasis occurs in up to 20% of patients in the setting of obesity and rapid weight loss and must be considered in the differential diagnosis. In individuals with RYGB, accessing the biliary tree is problematic and deserves special consideration, as does consideration for cholecystectomy in patients with gallstones at

**Figure 25.4** Common surgical procedures for weight loss. Restrictive operations for the treatment of morbid obesity and its coexisting conditions, popular today particularly because of laparoscopic surgical approaches, include adjustable gastric banding (LAGB) (a) and vertical (sleeve) gastrectomy (b). Roux-en Y gastric bypass (RYGB) (c), a procedure that combines restriction and malabsorption, is considered by many to be the gold standard because of its high level of effectiveness and its durability. More extreme malabsorption accompanies biliopancreatic diversion procedures, commonly performed with a duodenal switch (BPD-DS) (d), in which a short, distal, common-channel length of small intestine severely limits caloric absorption. This procedure also includes a sleeve gastrectomy.

**Table 25.2** Diagnostic considerations after bariatric surgery.

Gastrointestinal symptom	Risk by procedure	Luminal considerations	Hepatobiliary considerations
Abdominal pain	RYGB	Stomal ulceration, stenosis, hernia, adhesions, band erosion	Gallstones
Vomiting	LAGB, RYGB	Stenosis, ulceration, functional	Bile reflux
Insufficient weight change	LAGB	Dehiscence, diet, fistulae, pouch enlargement	
Excessive weight change	RYGB, BPD	Obstruction, bacterial overgrowth, neoplasm	
Diarrhea	RYGB, BPD	Dumping, bile salt diarrhea, bacterial overgrowth, IBS, diet	Bile salt diarrhea
GI bleeding	RYGB	Ulceration, gastric remnant, NSAIDS	

the time of bariatric surgery, although this approach is somewhat controversial [143–145]. Post-LAGB, the differential diagnosis includes band erosion or migration. Nausea and vomiting may be seen in any of these patients, but is more common post-LAGB, and an excessively tight band must be ruled out. Pre-existing esophageal and gastric motility disorders and functional upper gastrointestinal disorders may also play a role in the genesis of these symptoms. Insufficient weight loss (less than 50% of excess weight) is seen in 15% of patients. This lack of efficacy may be due to dietary indiscretion (high calorie liquids and snacks), insufficient activity or surgical result. Surgical considerations include enlarged pouch, deflation of band, a long common channel and dehiscence of the staple line. Excessive weight loss is less common after LAGB and more common after BPD or duodenal switch, because of the malabsorptive implications of these surgeries. Undernutrition in these individuals may be difficult to recognize. Other considerations include stomal stenosis or ulceration leading to obstruction. Eating disorders may also play a role in patients with excessive weight loss post-bariatric surgery, and history pertaining to this problem must be pursued. Diarrhea in the post-bariatric surgery patient may simply be a reflection of malabsorption and maldigestion expected from intestinal bypass, or it may be due to bile salt diarrhea or dumping. Dumping syndrome symptoms of flushing, lightheadedness, fatigue and post-prandial diarrhea may occur following intake of sugars and can be seen in 5–10% of patients. Bacterial overgrowth in the bypassed intestinal limb may also contribute to the development of secretory diarrhea and may also be associated with symptoms of bloating and flatulence. Gastrointestinal bleeding may occur from stomal ulceration in both RYGB and BPD patients and may be exacerbated by concomitant use of NSAIDS or steroids. It is important to identify the site of bleeding endoscopically and to recognize that ulceration at the distal intestinal anastomosis and in the gastric remnant may not be accessible endoscopically using standard techniques.

In the evaluation of patients post-bariatric surgery who have GI complaints, radiologic imaging modalities includ-

ing contrast studies to assess the possibility of leakage or perforation, computed tomography to detect herniation, bowel obstruction or fluid collections, and ultrasound to aid visualization of the hepatobiliary system are appropriate.

### Nutritional complications

Medical professionals caring for bariatric surgery patients must be aware of the potential risk of nutritional deficiencies that are common in these patients and of strategies to prevent and treat nutrient deficiencies.

It is recognized that management of post-operative nutrition begins pre-operatively with nutritional status assessment, education and reinforcement of principles associated with long-term weight loss. This topic has recently been reviewed [146, 147]. Prior to bariatric surgery, micronutrient deficiencies that have been documented include vitamin D (60–80%), B-complex vitamins (important for carbohydrate metabolism), iron (50%), zinc, selenium and the antioxidant vitamins A, E and C.

The risk of micronutrient depletion is greatest in patients with surgical interventions affecting digestion and absorption of nutrients (RYGB, BPD). These procedures can result in either primary or secondary nutrient deficiency. BPD is thought to cause weight loss through both protein (25%) and fat (75%) malabsorption. This has implications for (mal) absorption of micronutrients, including vitamins A, D, E, K and zinc. The decrease in transit time associated with intestinal bypass can also result in the secondary malabsorption of nutrients bypassing the duodenum and jejunum. Malabsorption can also be due to limited contact with the intestinal mucosa secondary to a short common channel. Inadequate dietary intake in these patients may also result in nutrient deficiencies. This is particularly relevant for iron, calcium, vitamin B12, thiamine and folate. Purely restrictive procedures such as LAGB usually result in micronutrient deficiencies due to changes in dietary intake (Table 25.3).

Vitamins and minerals are factors and cofactors in many biologic processes that regulate body size, including appetite, hunger, nutrient absorption, metabolic rate, thyroid

**Table 25.3** Nutrient deficiencies and suggested treatments after bariatric surgery[46].

Nutrient	Preoperative deficiency	Postoperative deficiency	Screening	Symptom of deficiency	Suggested treatment: AGB	Suggested treatment: RYGB	Suggested treatment: BPD/DS
Iron	9–16%	20–49%	ferritin	anemia	MVM* May require extra Fe	MVM bid +18–27 mg/d elemental Fe	MVM bid + 18–27 mg elemental Fe
Vitamin B12	10–13%	12–33%	Serum B12, methylmalonic acid	Megaloblastic anemia, neuropathy, delusions, hallucinations	MVM	MVM + 1000 ug/mo or 350–500 ug po/d	MVM
Folate	Uncommon	Uncommon	RBC folate	Megaloblastic anemia, neurologic symptoms	MVM, B-complex	MVM	MVM
Vitamin B1 (Thiamine)	15–29%	Rare but can occur	Serum thiamine	Wernike-Korsakoff syndrome	MVM, thiamine 50–>100 mg/d (consider parenteral repletion with WKS)	MVM	MVM
Vitamin A	Uncommon (>7%)	Common (50%) with BPD, may occur with RYGB/LAGB	Plasma retinol	Ocular findings, night blindness	MVM	MVM	MVM + 10,000 IU/d vitamin A
Vitamin D	Common (60–70%)	Common, prevalence unknown	25(OH) D	Osteoporosis, associated risks of malignancy, autoimmune disease	MVM, 400–800 IU/d	MVM	MVM + 2000 IU/d vitamin D
Vitamin E	Uncommon	Uncommon	Plasma alpha tocopherol		MVM	MVM	MVM
Vitamin K	Variable	Uncommon	INR		MVM	MVM	MVM + 300 ug/d vitamin K
Zinc	Uncommon but increased risk with obesity	Common with BPD after one year, may occur with RYGB	Plasma zinc	Change taste acuity	MVM	MVM	MVM
Protein	Uncommon	Rare but can occur	Serum albumin, total protein				
Calcium	Common	Common	Bone density, PTH	Osteoporosis	1500 mg/d	1500 mg/d	1500 mg/d

and adrenal function, energy storage, glucose homeostasis and others. Micronutrient repletion is vital for maximal weight loss and weight loss maintenance. Although obtaining micronutrients from food is the most desirable way to ensure adequacy of minerals and vitamins, for patients

with severe obesity, multivitamin and mineral supplementation (MVM) is essential for repleting micronutrients before and after surgery. Table 25.3 identifies the prevalence of micronutrient deficiencies before and after bariatric surgery. Various algorithms have been designed to help

the bariatric surgery team proactively address the potential for micronutrient deficiency and support the use of standard MVMs. Strategies must target the maintenance of stores as well as the repletion of losses and take into account the time course of development following a given bariatric surgery procedure.

### Considerations in endoscopy

Endoscopy units providing care to the bariatric surgery patient need to be properly equipped for the care of these patients, commensurate with standards for a bariatric center of excellence. This equipment includes stretchers designed to support weights in excess of 350 lbs and physiologic monitoring equipment for larger individuals. Conscious sedation in patients with morbid obesity may be complicated due to the high prevalence of obstructive sleep apnea and increased risk for desaturation [148, 149]. Increased BMI has also been recognized as an independent risk factor predictive of difficult colonoscopy [150].

The role of endoscopy in the bariatric surgery patient has recently been reviewed by the American Society for Gastrointestinal Endoscopy [151]. The value of routine endoscopy before bariatric surgery in the patient without symptoms is controversial but is recommended in some guidelines [152]. Considerations for the endoscopist include the presence of a large hiatus hernia, which represents a relative contraindication to LAGB because of increased risk of band slippage. In patients undergoing RYGB and BPD/DS, because the surgery renders the distal stomach and/or duodenum inaccessible by a standard upper endoscope, the threshold for performing a pre-operative endoscopic evaluation of the upper GI tract is lower than for other surgeries. *Helicobacter pylori* infection is present in 30–40% of patients scheduled for bariatric surgery and may be associated with abnormal endoscopy and risk for marginal ulcers postoperatively. Pre-operative testing in these patients may be useful.

In the postoperative patient, endoscopy may be performed because of the symptoms discussed previously. The endoscopist should be aware of which operative procedure was performed and of findings on pre-procedural imaging studies. The choice of endoscope will depend on the indication and on the need for intubation of the excluded limb or on the need for therapeutic intervention (e.g. ERCP). In the early postoperative patient, insufflation may have potentially detrimental effects, and the endoscopist should first consider contrast radiography studies. After a RYGB, endoscopic findings should include a normal esophagus and gastroesophageal junction, a variably sized gastric pouch and a gastrojejunal stoma with a width of 10–12mm in diameter. There may be a short blind limb

visible alongside of the efferent jejunal limb. The distal or excluded stomach cannot be visualized in the absence of a fistula. A VBG produces a pouch similar to the appearance of a RYGB with a 10–12mm stoma and once this is traversed, the distal stomach and duodenum can be seen. LAGB produces a variable amount of extrinsic circumferential compression on the proximal stomach, evident at endoscopy. The endoscopist should note the length of the pouch and should evaluate the possibility of band erosion into the gastric wall.

Morbid obesity is a risk factor for gallstone formation, and rapid weight loss is an independent and potentially compounding risk factor. Whereas an ERCP can usually be performed after LAGB, an ERCP in an individual who has undergone RYGB represents a significant technical challenge. Factors influencing success in this group include endoscopic skill, jejunal loop length and afferent loop length. When standard endoscopy is not possible, laparoscopically assisted transgastric ERCP has been employed [153, 154]. Alternative diagnostic modalities such as magnetic resonance cholangiopancreatography (MRCP) and therapeutic modalities such as percutaneous trans-hepatic intervention should also be considered. Both prophylactic cholecystectomy and the administration of ursodiol in these patients have been shown to reduce the incidence and complications of gallstones [155, 156]. **A1d**

### Endoscopic treatments for obesity

Current endoscopic devices used for the treatment of obesity are space occupying balloons placed endoscopically into the stomach to promote weight loss. In a recent review of 30 studies, of which 18 were prospective including 5 randomized trials – and 12 were retrospective case studies, only one of three sham controlled studies found a significantly higher weight loss with the gastric balloon. In non-randomized studies, the average weight loss was 17.8kg, with resolution or improvement in comorbidities in 52–100% of patients. Complications from these devices include gastric perforation (0.2%) and obstruction (0.2%) and intolerance necessitating removal (2.5%) [157]. These devices are not approved for use in the USA and the best indications for this intervention remain to be defined.

Natural orifice transluminal endoscopic surgery (NOTES), using a hybrid of endoscopic and laparoscopic approaches, is increasingly described in patients with morbid obesity or with complications from bariatric surgery. Although not ready for “prime time”, surgeons and endoscopists together are devising approaches to care of the bariatric surgery patient, and there is a large potential for development in this field [158].

## Hepatitis C

*Keyur Patel, Hans L Tillmann and John G McHutchison*

Division of Gastroenterology, Duke Clinical Research Institute and Duke University Medical Center, North Carolina, USA

---

### Introduction

Hepatitis C virus (HCV) was identified in 1989 as a major cause of the parenterally transmitted non-A non-B hepatitis. The majority of patients develop chronic hepatitis C infection (CHC) that has a global prevalence of 2.2% and infects over 120 million people worldwide [1]. CHC is characterized by varying degrees of inflammation and hepatic fibrosis, and 20% of patients are likely to develop progressive liver damage with cirrhosis and complications of end-stage liver disease over 20 to 40 years. CHC is now the leading indication for liver transplantation in developed nations and is expected to pose a significant health and economic burden over the next 10 to 20 years.

---

### HCV genome

Hepatitis C virus (HCV) is an enveloped positive-sense virus classified in the *Hepacivirus* genus within the *Flaviviridae* family, and was discovered in 1989 from a cDNA clone derived from blood-borne non-A non-B viral hepatitis genome sequences. The virus consists of a single open reading frame of 9.6 kb flanked by 5' and 3' untranslated regions that are required for viral translation and replication. The 5' UTR contains the internal ribozyme entry site (IRES) that initiates translation of a 3000 aminoacid polypeptide, which is subsequently processed by viral and host cellular proteases into ten mature structural (core, E1, E2 and p7) and non-structural HCV proteins (NS2, NS3, NS4A, NS5A and NS5B). The non-structural proteins encode several key enzymes involved in viral replication such as the NS3 protease and NS5B RNA-dependent

RNA polymerase. The lack of small animal model systems for HCV has rather limited our understanding of HCV replication and pathogenesis, but the recent development of *in vitro* and cell culture systems has resulted in significant progress in this regard in recent years [2].

HCV is characterized by a high degree of heterogeneity, resulting from the high replication rate ( $\sim 10^{12}$  particles per day) and the lack of a proof-reading repair mechanism in the viral RNA polymerase. The genetic heterogeneity of HCV is complex and may contribute to immune escape and the development of chronic infection in the majority of patients [3].

HCV has evolved into at least six major genetic groups (genotype) and over 50 subtypes, and is recognized by sequence variation in E1 and NS5b regions [4]. Different isolates of the same subtype may vary as much as 5–15%, and differing genotypes by more than 30% in nucleotide sequence. There is significant variation in the geographic distribution of HCV genotypes: genotype 1a is the prototype genotype and found commonly in the USA and Northern Europe; subtype 1b is common in Japan and Southern and Eastern Europe. Genotypes 2a and 2b represent 10–30% of all types and are particularly common in Japan and Northern Italy; genotype 3 is prevalent in the Indian subcontinent and Australasia; genotype 4 is common in Africa and the Middle East; genotypes 5 and 6 are found in South Africa and South East Asia respectively. Clinical studies have been able to identify that viral genotype affects response to antiviral therapy, but it does not have a significant influence on transmission, pathogenesis and the natural history of the disease.

---

### Prevalence and transmission

There are significant differences in the global prevalence of CHC, with seroprevalence rates ranging from 0.6% to 22%. Lower rates are seen in industrialized nations such as Germany (0.6%), France (1.1%), USA (1.8%), Japan (1.5–

2.3%), and higher rates in developing nations such as China (3.2%) and Pakistan (2.5–6.5%) [1]. The highest reported seroprevalence rates are in Egypt (22%) due to past exposure through parenteral antischistosomal therapy [5]. HCV infection is transmitted by percutaneous or permucosal exposure to infected blood or body fluids. Although routes of infection may vary by geographic region, injection drug use (IDU) and receipt of a blood transfusion prior to implementation of donor screening in 1992 are the most common factors associated with transmission in developed nations. In these countries, transmission risks have been further reduced following the use of nucleic acid testing for HCV in donor blood, and the American Red Cross estimates that the risk of HCV infection is now 1/2,000,000 blood units [6]. However, most developing countries do not screen blood donations for HCV, and transmission risks from blood product transfusion remain much higher. Injection drug use remains the most significant risk factor for HCV transmission in developed nations, accounting for 68% of newly acquired cases, with high seroprevalence rates of 60–90% amongst those with long-term IDU [7]. In the USA, the incidence of HCV amongst IDU has continued to decline over the last decade, and current prevalence rates among IDU are likely to be lower [8]. Other routes of HCV transmission include sexual exposure to an infected partner, or multiple sex partners that account for 18% of new infections in epidemiological surveys, although transmission is rare between long-term monogamous heterosexual partners. The US Centers for Disease Control does not recommend barrier protection for heterosexual monogamous couples [9]. Nosocomial, iatrogenic and perinatal exposures are responsible for around 1% of cases, but in 9% of cases no definite source is identified. Indeterminate risk factors include household transmission (e.g. sharing razor blades or toothbrushes), tattooing, body piercing, intranasal cocaine use, dental procedures and acupuncture [7]. In general, although screening and testing of blood donors in developed nations has been successful in reducing the risk of HCV transmission, strategies for eliminating transmission from high risk behavior still need to be widely implemented.

### Acute hepatitis C infection

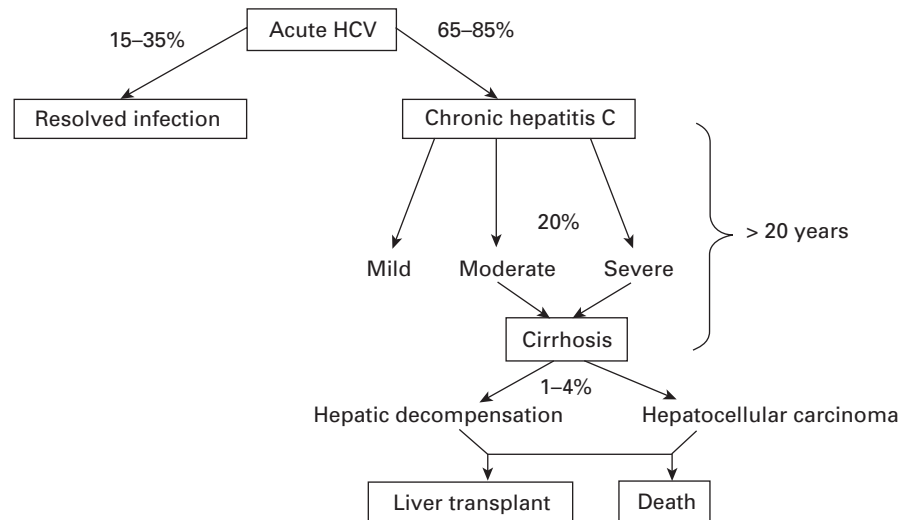

Most patients with acute HCV infection are asymptomatic, and only 10–15% may develop symptoms, such as jaundice, febrile illness, abdominal pain and nausea, that may be indicative of acute hepatitis. Marked elevations in serum alanine aminotransferase (ALT) levels of 10–20 times upper limit of normal may be observed at this time. HCV RNA appears in the serum within 1–2 weeks of exposure, and HCV antibodies become detectable over the subsequent 4–6 weeks. Diagnosis of acute infection relies on HCV RNA

detection, as antibody responses such as HCV-IgM antibody remain detectable during both acute and chronic infection [10]. Spontaneous viral clearance and resolution of infection may occur in 10–35% of asymptomatic individuals, but in up to 52% of symptomatic cases [11]. There are no reliable factors in acute hepatitis C that predict progression to chronic infection, but age, gender and mode of transmission may be important [12, 13]. There are no specific guidelines for post-exposure prophylaxis, but HCV RNA and ALT, and HCV antibodies are usually measured at baseline, at 4–8 weeks and at three months after potential exposure, as these tend to fluctuate significantly during the acute phase of illness. Controversies still exist regarding the optimal regimen and timing of antiviral therapy in acute hepatitis C infection. To allow for spontaneous clearance, antiviral therapy may be delayed for three months following exposure. **B4** Depending on viral genotype, HCV RNA levels, and early viral response, sustained virologic response rates of over 80% are possible with a 12–24 week duration of pegylated interferon-alpha (PEG-IFN) therapy, either as monotherapy or in combination with ribavirin [14]. **B4** However, due to inherent difficulties in performing clinical studies in this population, the optimal treatment regimen has yet to be determined [15]. **B4**

### Natural history and progression of chronic infection

Persistent or chronic infection, as defined by detectable serum HCV RNA for at least six months, develops in 65–85% of HCV-infected patients, based on data from post-transfusion hepatitis, blood donors and injection drug use cohorts (Figure 26.1). Women and younger patients may have lower rates of chronic infection of 55–71% following exposure to contaminated blood products [12, 13, 16]. Factors such as age at infection, gender, race, severity of acute illness, and immune status likely determine persistence or spontaneous resolution of HCV infection. A broad multispecific CD4+ and CD8+ T-lymphocyte immune response targeting multiple HCV epitopes is associated with viral clearance and resolution of infection, and a weaker cellular immune response is associated with development of chronic infection. Patients with chronic infection are often asymptomatic or may have non-specific complaints of malaise, fatigue and abdominal discomfort. The diagnosis of CHC often follows routine investigations that have noted elevated ALT levels. However, at least one-third of patients may have persistently normal ALT levels and the majority of these patients are likely to have mild and non-progressive disease.

Following a diagnosis of CHC, estimating the duration of infection and an assessment of disease severity may also help guide treatment decisions. The rate of fibrosis pro-

**Figure 26.1** Natural history and progression of HCV infection. Following acute infection, 15–35% of patients achieve spontaneous viral clearance. The majority of patients develop chronic infection with variable rates of disease progression. A small proportion of patients with chronic infection will develop progressive disease over >20 years, with subsequent complications of end-stage liver disease.

gression varies amongst CHC infected patients. Host, viral and environmental factors can all influence disease progression in CHC infection (Table 26.1). Some of these co-factors may be potentially modifiable, including alcohol consumption, smoking, metabolic factors (insulin resistance, obesity, steatosis) and HIV co-infection [17, 18]. Studies assessing fibrosis progression have mostly been cross-sectional, and based on a single liver biopsy and estimated duration of infection. Prospective studies have been based on selected cohorts attending tertiary referral centers. These estimates indicate that fibrosis progression is non-linear and may be slow, moderate or rapid. For example, only 0–2% of younger women that acquired HCV from anti-D immune globulin progressed to cirrhosis over a 20-year period, compared to an average of 13 years for older male patients that consumed at least 50 g of alcohol daily [12]. CHC patients with compensated cirrhosis have slowly progressive disease, with an estimated annual hepatic decompensation rate of 4–5%, and 1–4% for incidence of hepatocellular carcinoma (HCC) that remains the most frequent initial complication in these patients [19, 20]. Current estimates of HCC incidence rates are higher in countries such as Japan that have a longer natural history of HCV infection, but these are expected to double in the USA over the next decade.

## Diagnosis and evaluation

Diagnostic tests for HCV infection comprise serologic assays for antibodies and molecular techniques for virus particle detection. Anti-HCV is typically identified using second or third generation enzyme immunoassays that detect antibodies directed against various epitopes in the core, NS3, NS4 and NS5 proteins, with a specificity of 99%.

**Table 26.1** Host-viral factors associated with disease progression.

Established factors	Possible factors
Age	Genotype 1b
Duration of infection	Quasispecies diversity
Male gender	Race
HIV or HBV co-infection	Smoking, cannabis use
Alcohol abuse	Genetic polymorphisms
Co-morbid disease (NAFLD, iron, schistosomiasis)	Environmental toxins
Increased ALT, necroinflammation or fibrosis	Source of Infection
Metabolic factors (insulin resistance, obesity)	
HLA class II polymorphisms	

NAFLD: non-alcoholic fatty liver disease; ALT: alanine aminotransferase; HLA: human leucocyte antigen.

In low-risk populations, false-positive tests may occur, and recombinant immunoblot assays (RIBA) are used in some centers to confirm positive EIAs. False negative tests may occur in HIV-1 infection, renal failure and HCV-associated cryoglobulinemia. Confirmatory testing involves molecular techniques that are useful in detecting and quantifying viral genomes using target or signal amplification methods. Several reliable qualitative and quantitative assays for detection are now commercially available. The newer real-time PCR and target mediated amplification assays have lower limits of detection for HCV of below 10IU/ml.

However, these tests are expensive and not recommended for low prevalence population screening. They are used for confirmatory testing in acute infection prior to development of anti-HCV, immunocompromised patients, newborns, and in CHC patients to predict and monitor virologic responses to antiviral therapy.

All patients with confirmed CHC should have genotype testing to determine duration and likelihood of response to currently available antiviral therapy. A liver biopsy in CHC patients also provides useful baseline information in regards to necroinflammatory activity and fibrosis stage that can help determine prognosis, urgency of therapy, prediction of response to treatment, and evaluation of co-morbid states such as steatosis. In the absence of co-morbid issues that preclude treatment, patients with HCV genotype 2 and 3 infection have excellent predicted responses to antiviral therapy, and may not require a biopsy prior to therapy. However, percutaneous liver biopsy is an invasive procedure that is costly, and may be associated with a significant risk of complications that increase with age and the presence of cirrhosis. An additional concern with liver biopsy is that it samples only 1/50000<sup>th</sup> of the liver, and thus is subject to sampling error, particularly in non-homogeneously distributed chronic liver disease. Several studies have highlighted the inaccuracy of liver biopsy even for staging of advanced liver disease [21]. Some countries have adopted non-invasive serum tests of fibrosis, or imaging modalities such as transient elastography, as an alternative to liver biopsy to guide therapeutic decisions in CHC patients [22]. Despite these limitations, most experienced clinicians considering treatment for CHC infection are likely to recommend obtaining a liver biopsy, unless there are obvious contraindications.

## Treatment for chronic hepatitis C

The main goal of treatment of patients with CHC infection is the prevention of progressive hepatic fibrosis through long-term eradication of HCV. The benefits of a sustained virologic response (SVR), defined as the absence of serum HCV RNA at 24 weeks after the end of treatment measured by a sensitive molecular assay, include normalization of serum alanine aminotransferase levels, improvement in hepatic necroinflammation and fibrosis, potential health-related quality-of-life benefits, reduced mortality and risk of developing complications of end-stage liver disease, in the majority of patients. Current standard-of-care therapy results in SVR rates that appear to be durable in at least 99% of patients over the subsequent five years, although 1–2% of patients may still harbor intrahepatic virus despite undetectable serum HCV RNA [23, 24]. **A1b** However, the presence of intrahepatic virus alone in these patients is likely to remain clinically insignificant.

**Table 26.2** Contraindications to current pegylated IFN and ribavirin therapy.

Definite contraindication	Relative contraindication
Severe cardiovascular disease (e.g. symptomatic coronary artery disease, severe hypertension, severe congestive heart failure)	Poor compliance
Uncontrolled diabetes mellitus	Active substance abuse
Severe pulmonary disease	Chronic renal insufficiency
Recent or active malignancy	Reduced life expectancy from co-morbid illness
Decompensated liver disease	Seizure disorder
Major psychiatric illness	Poorly controlled inflammatory disease (e.g. rheumatoid, connective tissue, inflammatory bowel disease)
Pregnancy or age < 3 yrs	Inability to comply with birth control recommendations
Active autoimmune disease	
Non-liver organ transplant	
Significant anemia (e.g. hemoglobinopathy) or other cytopenia	

## Patient selection

All patients with CHC without definite contraindications to currently available IFN-based treatment should be considered as potential candidates for antiviral therapy (Table 26.2) [25]. **A1a** The decision to treat patients must take into account the variable natural history and rate of disease progression, associated co-morbid states, social situation and supports, risk-benefit aspects and cost-effectiveness of therapy in the individual. Patient preferences need to be considered, along with an assessment of behavioral and lifestyle aspects that may influence their ability to adhere to a prolonged duration of therapy associated with significant side effects. Patients also need to be reminded that CHC may be associated with non-specific symptoms such as fatigue, lethargy, asthenia and abdominal discomfort, which may significantly impact upon the quality of life of the individual, but do not correlate with severity of liver disease, and may not remit with successful viral eradication. Patients with significant co-morbid states that pose a relative contraindication to antiviral therapy require assessment and management in a multi-disciplinary setting with experienced health care providers. Several host and virus

**Table 26.3** Factors predictive of favorable virologic response to current therapy.**Before therapy**

Treatment naïve to IFN  
 Genotype 2 or 3  
 Low HCV RNA levels (<800,000 IU/mL)  
 Absent bridging fibrosis or cirrhosis on liver biopsy  
 Age < 40 years  
 Female gender  
 Absence of steatosis  
 Normal BMI  
 No insulin resistance  
 HCV mono-infection

**During therapy**

RVR (week 4)  
 EVR (week 12)  
 Adherence to therapy  
 No dosage reduction

RVR: rapid virologic response; EVR: early virologic response.

factors may determine successful responses to IFN-based therapy, of which the most important appear to be HCV genotype, baseline HCV RNA levels and undetectable virus at week 4 of therapy (rapid virologic response) (Table 26.3).

### Treatment options

The current standard-of-care treatment for CHC is a combination of pegylated interferon-alpha (PEG-IFN) and ribavirin [26–28]. **A1a** Interferons (IFN) are a group of naturally occurring cytokines that exhibit a variety of immunomodulatory, antiproliferative and antiviral effects. Pegylation refers to the covalent attachment of an inert, water soluble polymer of polyethylene glycol (PEG) to the IFN molecule in either a linear (Peginterferon alfa-2b (PEGINTRON), Schering-Plough, Kenilworth, NJ) or branch chain configuration (Peginterferon alfa-2a (PEGASYS), Hoffmann-La Roche, Basel, Switzerland) with differing molecular weights. Compared to standard interferon-alpha, the pegylated IFN compounds exhibit improved pharmacokinetic profiles and a prolonged elimination half-life, thus allowing for increased efficacy and a convenient once-weekly subcutaneous dosing schedule (PEGINTRON, 1.5 µg/kg/wk and PEGASYS, 180 µg/wk). Data from a recently completed large randomized multicenter study evaluating individualized dosing efficacy in 3070 HCV genotype 1 infected patients noted similar efficacy (SVR rates 38–41%) and safety and tolerability (discontinuation rate 10–13%) for patients receiving either PEG-IFN-2a or -2b in combination with ribavirin [29]. **A1a**

Ribavirin is a synthetic purine nucleoside analog that likely exhibits antiviral effects through multiple pathogenic mechanisms including immunomodulation, depletion of intracellular guanosine triphosphate, and weak inhibition of HCV RNA-dependent RNA polymerase. Ribavirin acts synergistically with IFN to induce antiviral responses and reduce relapse rates, and is administered orally twice daily at weight-based doses depending on viral genotype (1000–1400 mg/day for HCV genotype 1 ( $\leq 75$  kg = 1000 mg/d, 75–105 kg = 1200 mg/d and  $> 105$  kg = 1400 mg/d) and at a fixed dose of 800 mg/day for HCV genotype 2 and 3) [30, 31]. **A1c**

Combination PEG-IFN and ribavirin therapy can achieve a sustained virologic response in 54–56% of patients, including 42–46% of patients with genotype 1 infection, and around 80% of those with genotype 2 and 3 infection. Most patients with genotype 1 require 48 weeks of combination therapy and those with genotypes 2 and 3 can be treated for only 24 weeks. Many of the large clinical trials have been based in Europe or North America, and there is limited treatment efficacy data available for genotypes 4–6. As a result, these patients should continue to receive treatment as for HCV genotype 1 infection [25, 32]. **A1c**

### Early response prediction

Studies of early viral kinetics in response to PEG-IFN and ribavirin indicate a rapid initial first phase decline in HCV RNA, due to virus inhibition, and a slower second phase response due to loss of HCV from infected hepatocytes. This resulted in the development of early virologic predictors in the first 12 weeks of therapy to select patients that would benefit from ongoing therapy, thereby reducing duration of treatment, cost and continued exposure to poorly tolerated drugs for non-responders. Early virologic response (EVR) is defined as a decline in HCV RNA of at least  $2 \log_{10}$  units or to undetectable levels by the first 12 weeks of treatment. Although 75–85% of patients receiving combination therapy achieve EVR, failure to achieve this early response is associated with a minimal (1.6%) chance of achieving SVR with continued treatment [33]. **B2** Assessment of EVR at week 12 of combination therapy has thus been adopted into clinical practice for HCV genotype 1 patients.

Response predictors at earlier stages during treatment have also been evaluated in relation to shortening the duration of therapy for CHC patients. A study evaluating shorter 24-week duration therapy for HCV genotype 1 patients with low baseline HCV RNA (<600,000 IU/mL) noted SVR rates of 89% in a subgroup of patients that achieve rapid virologic response (RVR, defined as HCV RNA < 29 IU/mL by week 4). This was comparable to SVR rates of 85% observed in historical controls achieving RVR with treatment duration of 48 weeks [34]. **A1c** Similar

assessments in other study cohorts confirmed that patients with lower baseline HCV RNA and undetectable virus at week 4 of combination therapy achieve SVR rates of over 80% with 24 weeks of treatment [35]. **A1c** In general, 10–15% of HCV genotype 1 infected patients have a low baseline HCV RNA and achieve RVR, and thus may be theoretically considered for reducing treatment duration from 48 weeks to 24 weeks. Until further data is available, HCV genotype 1 infected patients with advanced stage disease, African-Americans, or those requiring early dose adjustments during therapy, should continue to receive the standard-of-care 48 weeks duration treatment. Furthermore, the HCV RNA threshold that defines low baseline viremia has not been clearly delineated and varies from 400,000–800,000 IU/mL. In addition, a sensitive HCV RNA real-time PCR or TMA assay must be utilized to detect minimal residual viremia at week 4 that increases the likelihood of relapse with reduced duration therapy [36]. **B4**

Viral quantitation is not performed routinely during treatment for HCV genotype 2 or 3 infection, as most of these patients become HCV RNA negative early during combination therapy, and achieve excellent SVR rates with 24 weeks of therapy. A number of studies have evaluated shortened treatment duration for HCV genotype 2 or 3 infected patients. Results from a large study of 1469 patients randomized to receive PEG-IFN 2a at 180 µg/wk and ribavirin 800 mg/day for 16 or 24 weeks indicate that SVR rates were higher for the longer duration treatment arm (62% versus 70%) [37]. Based on these results, shortened duration therapy is not recommended for genotype 2 or 3 patients. However, subgroup analysis from this study indicated that two-thirds of patients had RVR, with subsequent SVR rates of 90% with 24 weeks of treatment. Patients with RVR and low baseline HCV RNA (<400,000 IU/mL) had SVR rates of 95% and 90% with 24-week and 16-week treatment regimens respectively. Another study of 283 HCV genotype 2 and 3 infected patients noted overall SVR rates of 85% and 91% for patients that were treated for 12 and 24 weeks respectively, with PEG-IFN-2b and weight-based ribavirin (1000/1200 mg/day), and achieved RVR [38]. **A1c** Thus, an abbreviated treatment regimen may be considered in a proportion of patients that are poorly tolerant to combination therapy.

In contrast to patients that exhibit rapid viral responses, HCV genotype 1 slow responders (patients that have detectable HCV RNA at weeks 4 and 12, but are negative at week 24) may benefit from a longer duration therapy of 72 weeks that reduces relapse rates. One study noted that HCV genotype 1 patients that were still HCV RNA positive at week 12 had higher SVR rates of 29% with 72 weeks of therapy compared to 17% with 48 weeks treatment. However, both discontinuation and relapse rates were around 40% with extended therapy [39]. **A1c** Patient reluctance, cost issues and potential availability of newer anti-

viral therapies in the future, have further limited the implementation of extended therapy for slow responders into routine clinical practice.

## Individualized treatment

In recent years, an increased understanding of the host and viral factors that either predict or affect virologic response to current standard-of-care therapy has led to the concept of tailored therapy for CHC patients [36, 40]. The aim of this individualized treatment is to obtain optimal treatment efficacy, reduce risk of side effects, and increase cost-effectiveness of current therapy. For example, as outlined above, prediction of rapid viral responses may reduce duration of therapy for a proportion of CHC patients. Older age, male gender, obesity, insulin resistance, advanced disease, higher HCV RNA levels and race may negatively influence response rates, irrespective of genotype, and some of these patients could potentially benefit from longer duration or higher dose therapy [41]. For example, genotype 3 patients with high HCV RNA (>600,000 IU/mL) may have three-fold higher relapse rates with recommended 24-week combination therapy, compared to those with lower baseline HCV RNA [42]. Retrospective data have also indicated that HCV genotype 2 or 3 infected patients that do not achieve RVR have lower relapse rates with the longer duration 48 weeks of weight-based ribavirin 1000/1200 mg/day combination therapy compared to the standard 24-week fixed dose 800 mg/day ribavirin regimen (4% versus 26% respectively) [43]. Although these studies indicate that a proportion of patients may benefit from intensified dosing and longer duration therapy, it remains important that such treatment decisions are evaluated on an individual basis in clinical practice [44, 45]. **B4**

## Management of side effects of therapy

Side effects of current PEG-IFN and ribavirin therapy are relatively common and range from mild, non-specific, flu-like symptoms to major neuropsychiatric disturbance with suicidal ideation. PEG-IFN induced thyroid dysfunction with or without thyroid antibodies may be observed in up to 3–5% of patients [46]. Patients should be screened for thyroid disease at baseline, every three months during treatment, and at least once following completion of anti-viral therapy. Other autoantibodies, such as antinuclear and anti-smooth muscle antibodies, are commonly present in low titers in CHC patients, but rarely result in clinical manifestations of autoimmune disease during therapy. One-third of patients with CHC have a history of neuropsychiatric disturbance that may be further exacerbated during PEG-IFN therapy. Symptoms range from mood disturbance and emotional lability to severe depression, sui-

cidal ideation and psychosis. This may lead to premature dose reductions and drug discontinuation, further reducing efficacy of the prescribed antiviral regimen. IFN-induced depression may be a result of changes in cytokine expression and modulation of serotonergic pathways. A multi-disciplinary approach is required to determine risk and management of neuropsychiatric disturbance before and during therapy. Selective serotonin reuptake inhibitors (SSRI) are commonly used before and during therapy, and appear well tolerated in CHC patients [47].

Most side effects abate following the end of treatment. Early recognition and management of symptoms is important in maintaining adherence to therapy. This often requires a multi-disciplinary approach that includes allied health care providers and support groups, along with adjunctive use of simple antipyretics, growth factors, and antidepressants to ensure compliance to the prescribed regimen. Such strategies to improve adherence, particularly in the initial 12 weeks of therapy, may result in improved virologic response rates and associated health-related quality of life (HRQOL) in CHC patients.

PEG-IFN may result in neutropenia that requires dose reduction in 18–20% of patients, although the risk of serious infection remains low even with severe neutropenia ( $<500/\text{mm}^3$ ). Recombinant granulocyte-colony stimulating factor (G-CSF) is often used to stimulate granulopoiesis and maintain PEG-IFN dose, but is associated with significant expense and uncertain benefit. Dose reductions for thrombocytopenia are also relatively frequent in patients with advanced disease receiving PEG-IFN. The ongoing clinical development of thrombopoietin receptor agonists as adjunctive therapy will be important in this regard [48]. Ribavirin results in a risk of dose-dependent hemolytic anemia that is associated with hemoglobin  $<10\text{ g/dL}$ , requires dose reduction, or drug withdrawal, in 9% of patients, with higher risk estimates observed in Asian cohorts. Recombinant erythropoietin compounds are frequently used to maintain ribavirin dosage and improve HRQOL, but are associated with significant expense, potential for complications such as thrombosis, and at present there is no data indicating benefits in terms of early or sustained virologic response to combination therapy [49]. **B4**

### Treatment of specific patient populations

Most of the recommendations for therapy in CHC patients are based on data from selected patients enrolled in tertiary multicenter clinical registration studies. Data from community centers indicate that less than one-third of patients diagnosed with CHC are eligible or actually receive antiviral therapy [50]. These difficult-to-treat CHC patients often have significant co-morbid illness and behavioral factors that reduce eligibility for current combination therapy.

Financial restrictions also limit treatment eligibility for many patients in countries without universal health care, such as the USA. Treatment options in commonly encountered patient cohorts are considered below.

#### Mild disease

In clinical practice treatment is usually considered for patients with persistent elevations of serum ALT. However, around 30% of CHC patients may have persistently normal ALT levels, and many of these patients will have mild disease, with slow rates of disease progression. Response rates, however, are similar to patients with biochemically active and more advanced histological disease. Treatment decisions again need to be individualized in patients with normal ALT levels, and should consider factors such as genotype, age, liver histology, patient motivation and co-morbid illnesses. Watchful waiting is appropriate for many of these patients, but progression of liver disease may occur in one-third of cases, and a liver biopsy should be repeated at five-yearly intervals [51]. **B4** In the future, patients with mild disease may be considered for newer treatments with improved efficacy and tolerance.

#### Advanced stage disease

Patients with stable or compensated cirrhosis should also be considered for treatment, but require close monitoring due to the higher risk of complications with PEG-IFN therapy. Subgroup data from the PEG-IFN registration trials that included small numbers of patients with compensated advanced disease (bridging fibrosis or cirrhosis) indicate overall SVR rates of 43–44% [52]. **A1d** Improvement in advanced stage fibrosis may occur in one-half of patients that achieve SVR, but there may also be histological benefits for some patients that fail to respond to therapy [53]. Select patients with decompensated cirrhosis and model for end-stage liver disease (MELD) score  $<18$  may be considered for treatment in experienced transplant centers, given that achievement of SVR prior to transplant reduces recurrence of infection in the allograft [54, 55]. **B4**

#### Non-responder patients

There are an increasing proportion of patients that have failed PEG-IFN and ribavirin treatment, either as initial therapy or following retreatment of prior standard-IFN alpha based treatment failures. This latter group appear to have incremental SVR rates of 10–15% following re-treatment with current standard-of-care therapies [25]. Patients that relapsed to previous standard IFN based or shorter duration treatment should be retreated with 48 weeks of PEG-IFN and ribavirin. There are limited therapeutic options for true non-responders to PEG-IFN and ribavirin. Re-treatment with higher dose induction PEG-IFN or consensus IFN based combination therapy results in SVR rates of around 10–15%, depending on dose and duration of 48

or 72 weeks [56, 57]. **B4** However, these induction regimens are often poorly tolerated and result in frequent treatment withdrawal. In the absence of factors such as compliance or financial constraints that negatively influenced outcomes to initial therapy, non-responder patients are unlikely to benefit from re-treatment with the same agents. Lifestyle measures such as weight loss and reducing alcohol, cannabis use, or smoking tobacco, should be encouraged to reduce progression of disease in all patients.

The rationale for low dose IFN maintenance therapy was based on the antifibrotic and antiproliferative properties of interferon, and the absence of viable therapeutic options for non-responder patients with advanced disease. Maintenance therapy has been evaluated in three large studies utilizing low dose PEG-IFN monotherapy for up to four years. Although there may be possible benefits in terms of reduced portal hypertension with extended duration therapy, data from the large multicenter HALT-C trial, that randomized non-responder patients with advanced disease to receive 90 µg of PEG-IFN 2a or placebo for three and one-half years, indicated no differences in fibrosis progression, development of hepatoma, complications of cirrhosis, need for transplantation, or mortality. **A1d** The COPILOT study indicated no overall differences in clinical endpoints between low dose PEG-IFN 2b and colchicine, although a proportion of patients on PEG-IFN 2b had reduced incidence of variceal bleeding. **A1d** At present, maintenance therapy cannot be recommended for CHC non-responder patients. Such patients with advanced disease should be considered for clinical studies that include the newer specific targeted antiviral therapies (STAT-C) that are currently in phase III evaluation.

### Substance abuse

Patients with active or recent injection drug use (IDU) on methadone maintenance treated successfully with combination therapy achieve comparable SVR rates to non-IDU patients [58]. **B4** Interestingly, cannabis use may improve compliance to antiviral therapy in some patients by helping with symptoms such as nausea, reduced appetite and insomnia [59]. These patients need to be evaluated and treated in an experienced multi-disciplinary setting. Alcohol dependence may reduce virologic response rates and increase disease progression. Safe thresholds of alcohol consumption have not been established, and abstinence should be encouraged during therapy and in the long term [9].

### HIV co-infection

Around one-third of patients with HIV infection are co-infected with HCV. Liver-related morbidity and mortality has increased significantly among the HIV-HCV co-infected population following the advent of highly active antiretroviral therapy (HAART) for HIV infection, and increased

disease progression in this group. Virologic responses to combination therapy are 10–15% lower than HCV mono-infected patients, with SVR rates of 14–38% and 53–73% for HCV genotypes 1–4 and 2–3 respectively [25]. Patients should be treated for 48 weeks regardless of HCV genotype, although shorter duration therapy may be considered for HCV genotype 2 and 3 infected patients with low HCVRNA levels and minimal stage disease. HIV infection should be controlled with HAART, preferably with CD4 cell counts >250/mm<sup>3</sup> prior to initiation of PEG-IFN and ribavirin therapy [60]. **B4** Due to potential drug interactions or adverse event in advanced disease, HAART therapies that include didanosine, stavudine, zidovudine and nevirapine should be avoided in co-infected patients being considered for treatment [61].

### End-stage renal disease

Patients with end-stage renal disease requiring hemodialysis have a higher prevalence of HCV infection, increased disease progression, and reduced post-transplant graft and patient survival. There is a substantial risk of ribavirin induced hemolytic anemia as this drug is renally excreted and not removed by dialysis. Treatment needs to be individualized and administered prior to renal transplantation using dose reductions for both PEG-IFN and ribavirin [62].

### **B4**

### Other patient cohorts

Combination therapy after liver transplantation is poorly tolerated and results in SVR rates <20% [63–65]. However, this has to be balanced against the substantial risk of disease progression in the immunosuppressed patient, resulting in graft loss and reduced patient survival. Treatment also needs to be individualized for other CHC population cohorts with higher likelihood of treatment related toxicity, including elderly patients, or those with co-morbid cardiovascular or respiratory compromise [66]. Patients with thalassemia, inherited coagulation disorders, or other hemoglobinopathies have a higher incidence of CHC transmitted through repeated transfusion of blood products prior to screening of donors. Small studies have indicated that patients with beta-thalassemia major may achieve SVR rates comparable to non-thalassemic patients, but transfusion requirements and potential iron toxicity require close monitoring [67]. **B4** Children appear to have slower rates of disease progression and response rates are similar to adult cohorts [68]. Treatment is not recommended for those age < 3 years. Patients with extrahepatic manifestation of HCV associated immune complex disease and mixed cryoglobulinemia resulting in cutaneous vasculitis, neuropathy or glomerulonephritis should be offered antiviral therapy, but in practice sustained viral eradication rates and resolution of clinical sequelae are somewhat disappointing [69]. Rituximab (anti-CD 20 monoclonal anti-

body) has been used in combination with PEG-IFN and ribavirin therapy in refractory cases [70]. An increase in HCV RNA may be observed in patients receiving rituximab therapy, but this remains of uncertain clinical significance. Phlebotomy is often performed in select CHC patients with iron overload conditions or porphyria cutanea tarda, but the benefits of iron depletion on virologic response to therapy remain relatively minor and uncertain [71, 72]. **B4**

### Future treatment options

Therapeutic approaches in development for CHC include newer IFNs, ribavirin analogues, specific viral inhibitors and immune modulation [73, 74]. Several IFN compounds are in development, including consensus IFN, Omega IFN and albinterferon alfa-2b which is an 85.7-kD protein consisting of recombinant human IFN $\alpha$ -2b genetically fused to recombinant human albumin that allows for two or four-week dosing intervals, and is currently being evaluated in phase III trials for treatment naive CHC patients [75]. Viramidine (taribavirin hydrochloride) is a ribavirin pro-drug that does not lead to accumulation in erythrocytes, and results in a lower frequency of anemia. However, recent data indicated that SVR rates were 14% lower for viramidine combined with PEG-IFN compared to ribavirin, although higher doses may result in improved SVR for this compound. Technological advances in high throughput screening have resulted in the preclinical development of many potential compounds that aim at several targets during the HCV lifecycle. Two promising targets are NS5B RNA-dependent RNA polymerase (NS5-RdRP) and NS3 serine proteases. Inhibitors active at these sites are often referred to as STAT-C drugs. Valopicitabine (NM283) is an example of NS5-RdRP inhibitor that demonstrated efficacy in early clinical studies, and did progress to phase III trials in combination with standard-of-care therapy. However, further development of this compound was halted due to poor efficacy and tolerability. Several other NS5-RdRP compounds are currently in clinical development. Recent data indicate that telaprevir (VX-950), an orally bioavailable slow-binding inhibitor of HCV NS3-4A protease, administered for 12 weeks, in combination with PEG-IFN and ribavirin, resulted in significant incremental SVR in both treatment naive and non-responder patients. This compound is currently being evaluated in multicenter phase III clinical trials for both naive and non-responder cohorts. Selection of viral resistant HCV strains is an issue for STAT-C compounds, and future use will require multi-targeted therapy with potent antiviral compounds without cross resistance, most likely in combination with IFN. Other NS3/4A compounds that have shown adequate safety and efficacy during clinical development include Boceprevir (SCH 503034). Immune modulation targets

through toll-like receptors, that are present on the cell surface and function to recognize pathogen-associated molecules, are also in early stage clinical development, and may potentially allow for non-IFN based therapy in the future. Several other promising approaches to inhibit viral replication are in development, but at present appear to have limited efficacy without the use of IFN-based therapy. The continued discovery and development of new therapeutic targets that are effective and tolerable will be important for treating the increasing pool of CHC patients that have not responded, have yet to be diagnosed, or are intolerant to, or hesitant to receive currently available therapies.

---

### Summary

HCV infection is a global health problem that leads to significant morbidity and mortality from complications of end-stage liver disease in a proportion of patients. Current standard-of-care therapies can result in long-term eradication of virus, but treatment is not suitable for all patients and is often poorly tolerated. Individualized and tailored therapeutic approaches may be appropriate for some patients to improve efficacy and reduce the potential for side-effects. Implementation of primary prevention methods, providing access to health care, and identification of CHC patients at greatest risk of disease progression remain significant challenges. The recent development of specific targeted antiviral therapies provides optimism for CHC infected patients that have failed to achieve SVR, or remain ineligible to receive current standard-of-care therapy.

## Background

Hepatitis B virus (HBV) infection, together with hepatitis C and alcohol abuse, is among the leading causes of cirrhosis and hepatocellular carcinoma (HCC) worldwide [1, 2]. It thus represents a major cause of morbidity and mortality [3–5], and induces substantial direct and indirect social costs. Effective treatment of HBV-related conditions in association with extensive mass vaccination for HBV would significantly reduce the global burden of chronic liver disease.

Alpha interferon (IFN) has been the mainstay of therapy for chronic hepatitis B since the early 1980s. Meta-analyses of randomized clinical trials (RCTs) conclusively prove its effectiveness in normalizing alanine aminotransferases (ALT) and clearing HBeAg and HBV-DNA from blood in 25–40% of HBeAg positive treated patients [6–9]. However, no specific data are available from these reviews on improvements of liver histology. Standardized response criteria have been set by the use of these “surrogate” markers of cure on the grounds of clinical and biological plausibility [10, 11]. “True” disease endpoints (i.e. progression to cirrhosis, to HCC and death) cannot usually be assessed in short-term trials of IFN due to the slow natural course of chronic hepatitis B. A major issue of concern is the fact that RCTs of IFN for chronic hepatitis B have been mostly performed in patients without advanced fibrosis or cirrhosis. The transferability of results to the whole spectrum of subjects with chronic liver disease due to HBV is hence questionable. Since IFN is today in widespread use as the first-line therapy for chronic hepatitis B, no addi-

tional prospective cohort studies on the course of untreated disease will be feasible [1, 2, 10, 11]. Long-term retrospective or prospective studies to evaluate the benefits of IFN therapy on true endpoints, that is, prevention of cirrhosis, liver failure, HCC and death, will also be difficult to perform due to the prolonged and slow course of the disease.

In the last few years a new form of IFN, namely pegylated IFN, has become available on the market for treatment of chronic hepatitis B. This drug has been evaluated both alone or in combination with other antiviral molecules, namely nucleoside/nucleotide analogs (see later), in order to increase its efficacy.

A number of molecules which inhibit viral replication by selectively blocking the HBV-DNA polymerase enzyme activity are currently available to treat patients with chronic HBV infection. They include nucleoside analogs, lamivudine (LAM), entecavir (ETV) and telbivudine (LdT), and nucleotide analogs, adefovir dipivoxyl (ADV) and tenofovir (TDF). Some of them, when compared to IFN, are less expensive and better tolerated but their long-term efficacy is limited by inability to obtain sustained viral suppression after withdrawal. As a matter of fact, prolonging the administration of LAM beyond one year of therapy causes the emergence of LAM resistant HBV mutants at a yearly rate of 15–25% [12, 13].

Other drugs, such as Emtricitabine (FTC), are currently undergoing phase II and III evaluation as potential anti-HBV treatments. Initial results would also suggest that other antiviral compounds, current in phase 2 testing, even if endowed with a strong antiviral effect, cannot by themselves eradicate HBV infection. Phase II and III studies of combination therapy using IFN and nucleoside/nucleotide analogs or combinations of analogs are ongoing.

We have appraised the available evidence for drugs which are currently on the market in order to estimate the effectiveness of antiviral therapy on “surrogate markers” of response and its long-term benefit.

## Evaluation of available evidence

### What effect has anti-viral therapy of chronic hepatitis B on “surrogate” markers of response?

#### IFN in HBeAg positive chronic hepatitis B

Twenty-one RCTs which compared IFN to no treatment in adult patients with chronic hepatitis B due to wild type (HBeAg positive HBV) were recovered by Medline search (1985–2008) (see Table 27.1) [14–34]. These RCTs included a total of 1216 patients, 745 receiving active treatment. Overall, IFN treatment had a favorable, statistically significant effect in comparison to no treatment. Meta-analysis showed the following risk differences, all in favor of IFN:

- Clearance of HBeAg (see Figure 27.1): 0.24 (95% CI: 0.08–0.30,  $p < 0.001$ ); NNT 4.1.
- Loss of HBsAg (see Figure 27.2): 0.05 (95% CI: 0.03–0.08,  $p < 0.001$ ); NNT 18. **A1a**

The amount of IFN used was clearly important. Subjects receiving a total dose of <200 MU had a 1.37 odds ratio (OR, 95% CI: 0.95–1.98) of HBeAg clearance above controls, while those who received >200 MU had an OR of 2.05 (95% CI: 1.5–2.78).

Overall experience suggests that the optimal cost-effectiveness ratio on surrogate endpoints is reached by treating HBeAg positive patients with 9–10 MU IFN tiw for four to six months. Predictive factors of a favourable response are:

- Low serum HBV-DNA or a low amount of HBeAg in the hepatocytes
- High levels of ALT

**Table 27.1** Randomized controlled trials of interferon (IFN) treatment of HBeAg positive chronic hepatitis B.

ID	Study	Year	Patients	Schedule	Total dose	Type of IFN
1	Carreno [14]	1987	20	5.5 MU/m <sup>2</sup> IM daily for 3 weeks then twice weekly for 6 months	380 MU/m <sup>2</sup>	r-IFN $\alpha$ -2a

10	Brook [23]	1989	60	2.5, 5, 10 MU/m <sup>2</sup> IM TIW for 6 months	180, 360, 720 MU	r-IFN $\alpha$ -2a
11	Williams [24]	1990	30	2.5, 5, 10 MU/m <sup>2</sup> IM TIW for 6 months	180, 360, 720 MU	r-IFN $\alpha$ -2a
12	Waked [25]	1990	40	5 MU/m <sup>2</sup> SC 3 or 7 times weekly for 4 months	240 or 560 MU/m <sup>2</sup>	r-IFN $\alpha$ -2b
13	Realdi [26]	1990	79	4.5 MU IM TIW for 4 months	216 MU	r-IFN $\alpha$ -2a
14	Muller [27]	1990	58	3 MU SC TIW for 4 months	144 MU	r-IFN $\alpha$ -2b
15	Perrillo [28]	1990	125	1 or 5 MU, SC daily for 4 months	112 or 560 MU	r-IFN $\alpha$ -2b
16	Lok [29]	1992	75	10 MU SC TIW for 4 months	480 MU	r-IFN $\alpha$ -2b
17	Di Bisceglie [30]	1993	47	10 MU SC TIW for 4 months	480 MU	r-IFN $\alpha$ -2b
18	Bayraktar [31]	1993	35	5 MU TIW SC for 6 months	360 MU	r-IFN $\alpha$ -2b
19	Wong [32]	1995	50	10 MU/m <sup>2</sup> TIW for 3 months	360 MU	r-IFN $\alpha$ -2
20	Sarin [33]	1996	41	3 MU SC TIW for 4 months	144 MU	r-IFN $\alpha$ -2b
21	Janssen [34]	1999	162	10 MU SC TIW for 4 or 8 months	480 or 960 MU	r-IFN $\alpha$ -2b

rIFN: recombinant-interferon.

**Figure 27.1** Meta-analysis of interferon therapy for HBeAg positive chronic hepatitis B: effect of treatment, measured as risk difference, on HBeAg clearance.

**Figure 27.2** Meta-analysis of interferon therapy for HBeAg positive chronic hepatitis B: effect of treatment, measured as risk difference, on loss of HBsAg.

- High value of histological activity index (HAI) at liver biopsy
- Infection acquired in the adult age and/or a history of acute hepatitis
- Non-Asian ethnic origin [8, 9, 25, 28, 29, 35–37]

### **Pegylated IFN in HBeAg positive chronic hepatitis B**

Only two RCTs comparing peginterferons to IFN in patients with HBeAg positive chronic hepatitis B have been published so far [38, 39]. The first study used different doses of pegylated IFN  $\alpha$ -2a (90, 180 and 270  $\mu$ g sc weekly for 24 weeks); in the second one patients received pegylated IFN  $\alpha$ -2b at a dose of 1.0  $\mu$ g/kg weekly for 24 weeks. The rate of combined response at the end of follow-up (HBeAg negative, HBV DNA  $< 5 \log_{10}$  copies/ml, and ALT normalization) was significantly higher in patients treated with pegylated IFN (21.3% vs 11.2%; OR, 2.16; 95% CI: 1.34–3.51). **A1d**

### **IFN and corticosteroids in HBeAg positive chronic hepatitis B**

An alternative approach to chronic HBV infection is based on the induction of a brief period of immunosuppression by steroids [40, 41], then a withdrawal to provoke an abrupt ALT elevation due to the host immune reconstitution, and a subsequent decline of HBV-DNA. IFN administration is then started 2–4 weeks after stopping steroids. The sequential schedule has been studied in some RCTs and their results have been pooled in a meta-analysis [42]. The overall rate of HBeAg loss in 13 RCTs was significantly higher in the prednisone-IFN group (34.7% vs 29.1%, OR 1.41; 95% CI: 1.03–1.92). Similar results were observed for loss of HBV-DNA (39.7% vs 31.6%; OR, 1.51; 95% CI: 1.12–2.05). However, the loss of HBsAg was similar across the two groups (7.3% vs 5.4%; OR, 1.41; 95% CI: 0.77–2.59). Pre-treatment ALT levels had no impact on evaluated outcomes but only the low dose of prednisone was significantly associated with HBsAg loss (OR, 2.76; 95% CI: 1.18–6.43) as compared to high dose (OR, 0.69; 95% CI: 0.29–1.66).

Even if there could be an advantage in pre-treatment with steroids of this subset of patients, this must be balanced against the risk of flare of liver disease after steroid withdrawal. A severe, sometimes fatal “seroconversion hepatitis” has been reported in subjects with pre-existing cirrhosis [43, 44]. This treatment algorithm is not recommended.

### **Pegylated IFN and lamivudine in HBeAg positive chronic hepatitis B**

Another approach to increase the rate of viral clearance is to add another antiviral drug to the current therapy. Three RCTs have tested this hypothesis and patients were randomized

to receive peginterferon plus LAM or peginterferon alone [45–47]. The rate of persistent viral clearance, as evaluated by serum HBV-DNA levels  $< 400$  copies/ml at the end of follow-up, was similar across the two groups (11.6% vs 10.9%; OR, 1.07; 95% CI: 0.73–1.58), and therefore it can be concluded that the association of pegylated IFN with LAM is not superior to peginterferon alone in treating patients with HBeAg positive chronic hepatitis B and this schedule is not recommendable in the clinical practice. **A1c**

### **IFN in HBeAg negative chronic hepatitis B**

Data on the efficacy of IFN therapy in HBeAg negative chronic hepatitis B are few compared to HBeAg positive. The results of published RCTs remain inconsistent and the overall assessment of the treatment effect is difficult to evaluate. The drawing of firm conclusions based on the results of these studies is hampered by the small sample size of the studies and by heterogeneity of baseline severity of patients and the schedule of treatment. An evaluation of treatment efficacy on HBV-DNA clearance and sustained ALT normalization was performed by a meta-analysis on seven RCTs [48–54] enrolling patients infected by the HBe minus mutant. Five RCTs compared IFN regimens with non-active treatment; two trials compared different doses of IFN. We combined the results of IFN arms of these two trials and made a single pair-wise comparison with the overall control rate of the other five RCTs. All the RCTs were performed in centers from the Mediterranean area, indirectly confirming the high geographical prevalence of this mutation. Pooled data totalling 301 subjects, showed a significant effect of IFN therapy on sustained loss of HBV-DNA (Risk difference 0.17; 95% CI: 0.07–0.27; NNT 5.9) (see Figure 27.3). **A1c**

### **IFN or pegylated IFN and lamivudine in HBeAg negative chronic hepatitis B**

No study has properly compared peginterferon to IFN therapy in patients with HBV mutant infection, but, similarly to HBeAg positive patients, the combination therapy of IFN or peginterferon plus LAM in comparison to IFN alone has been tested also in anti-HBeAg positive subjects. One study used IFN- $\alpha$  [55] and three PEG IFN [56–58]. Overall, 225 patients received combination therapy and 219 IFN alone. The rate of HBV-DNA undetectability at the end of follow-up was 18.2% and 21.0% respectively (OR, 0.83; 95% CI: 0.51–1.35), so addition of LAM does not improve efficacy of IFN.

### **Nucleoside and nucleotide analogs**

Evidence of effectiveness from phase III randomized trials is available in the literature for nucleoside analogs (LAM, LdT and ETV), and nucleotide analogs (ADV and TDF). These drugs are administered by the oral route and display

**Figure 27.3** Meta-analysis of interferon therapy for HBeAg negative chronic hepatitis B: effect of treatment, measured as risk difference, on sustained loss of HBV-DNA.

a powerful inhibitory effect on HBV-DNA polymerase [59]. The examined “surrogate” endpoints (6–24 months) were ALT normalization, reduction of serum HBV-DNA levels during therapy, the rate of undetectable serum HBV DNA at the end of therapy, the rate of HBeAg loss or anti-HBe seroconversion at the end of therapy for patients with HBeAg positive hepatitis, the rate of HBsAg loss, anti-HBs seroconversion and the histological improvement at the end of treatment. Regarding the values of serum HBV-DNA during treatment and at the end of therapy, the RCTs reported different methods and different units to measure viral load. The serum HBV-DNA load was measured using polymerase chain reaction (PCR) assay or reverse transcription PCR assay or solution hybridization assay. The detection limits to evaluate the response ranged from 1.6 pg/ml (150,000 copies/ml) to 300 copies/ml.

Finally, the majority of studies evaluated the rate of appearance of mutations in specific regions of the polymerase-encoding HBV gene (so-called YMDD mutant and others) which were associated with the loss of efficacy of the drugs [60].

**Lamivudine** The original observations on the anti-HBV efficacy of LAM came from the treatment of HIV infected subjects who were also HBsAg positive [61–62]. The optimal dosage in immunocompetent patients with HBV chronic hepatitis, found by a dose-ranging study [63] and confirmed by an RCT [64], was 100 mg daily. It is important to consider that only a minority of published full papers are controlled trials with an appropriate control group.

The first two RCTs evaluated the efficacy of LAM therapy in HBeAg positive chronic hepatitis previously untreated and used a control arm treated with placebo. The first RCT performed in China [64], included exclusively Oriental

subjects, and the second trial was performed in USA and included prevalently white patients [65]. Both studies reported that a course of 12 months of LAM had favorable effects on histological, virological, and biochemical features of the disease and was well tolerated. At the end of treatment the rate of HBeAg seroconversion was 16% and 17% respectively in treated groups and 4% and 6% in control groups (OR, 3.06; 95% CI: 1.56–6.01). The histological response, evaluated as a reduction of at least two points of grading Knodell score, was more frequent in treated groups with a rate between 49% and 52%. Finally, the overall incidence of YMDD mutations at the end of treatment was of 14% in the Chinese trial and 32% in the American trial.

RCTs which compared the efficacy of 48–52 weeks LAM therapy versus IFN monotherapy (standard or pegylated IFN) or combination therapy with IFN and LAM [66–70], reported that among patients allocated in the LAM arm the rate of ALT normalization ranged between 23% and 78%, the rate of HBe seroconversion ranged between 19% and 28%, and the incidence of YMDD mutations was 8–40%. The identified predictors of virological relapse were older age, male sex and low levels of aminotransferases at the start of therapy.

The only published RCT including patients with anti-HBe positive chronic hepatitis used a schedule of 52 weeks of therapy with LAM [75]. Patients were randomized to receive 100 mg LAM orally once daily for 52 weeks or placebo for 26 weeks. The primary efficacy endpoint was loss of serum HBV-DNA with a cutoff of 1.6 pg/ml plus normalization of ALT at week 24. A significantly higher proportion of patients receiving LAM (63%) had a complete response at week 24 compared with patients receiving placebo (6%) ( $p < 0.001$ ). In a ranked assessment of

pretreatment and post-treatment biopsy pairs 11% improved, 86% showed no change, and 2% worsened in fibrosis. At week 52, 27% of patients receiving LAM had YMDD variant HBV.

There are two major problems with LAM treatment: the occurrence of YMDD mutants under therapy and the stability of viral suppression after drug discontinuation. Appearance of the YMDD mutant was associated with an ALT relapse in 30–70% of cases, and usually both the YMDD mutant and the ALT peak subside rapidly upon stopping LAM. The efficacy of LAM to inhibit HBV replication was limited only to the period of drug exposure [72–75].

**Telbivudine** LdT is a potent and specific inhibitor of HBV-DNA polymerase. A double-blind pre-clinical study evaluated the efficacy and safety of two different doses of LdT (400 or 600 mg/day) alone or plus LAM (100 mg/day) compared with LAM alone in adult patients with HBeAg positive chronic hepatitis [76]. At the end of 52 weeks of therapy, LdT monotherapy showed a significantly greater mean reduction in HBV-DNA levels ( $6.01$  vs  $4.57 \log_{10}$  copies/ml;  $p < 0.05$ ), rate of undetectable HBV-DNA by PCR with a cutoff limit of  $10^5$  copies/ml (61% vs 32%;  $p < 0.05$ ), and rate of ALT normalization (86% vs 63%;  $p < 0.05$ ) compared with LAM monotherapy. The rate of HBeAg seroconversion (31% vs 22%) was not significantly different. Combination treatment with LdT and LAM was not better than LdT alone. **A1d**

In a phase III RCT [77], 1370 patients (more than 80% Asian) with HBsAg positive chronic hepatitis (921 HBeAg positive and 446 HBeAg negative) were randomly assigned to receive 600 mg of LdT or 100 mg of LAM once daily. At week 52, a significantly higher proportion of HBeAg positive and HBeAg negative patients receiving LdT than of those receiving LAM had a reduction in the serum HBV-DNA levels to fewer than  $5 \log_{10}$  copies/ml (60.0% vs 40.4%,  $p = < 0.001$  and 88.3% vs 71.4%,  $p < 0.001$  respectively). The histological response was different in HBeAg positive patients (64.7% vs 56.3%,  $p = 0.01$ ), but not in HBeAg negative patients (66.6% vs 66.0%,  $p = 0.90$ ). The rate of HBeAg loss and HBeAg seroconversion was comparable in HBeAg positive patients in both groups of treatment. The incidence of viral resistance during 52 weeks of therapy was lower in patients treated with LdT than in those treated with LAM (5.0% vs 11.0% in HBeAg positive patients,  $p < 0.0001$ , and 2.2% vs 10.7% in HBeAg negative patients,  $p < 0.001$ ). The frequency of adverse events was similar for patients receiving LdT and LAM, and serious adverse events were reported in 2.6% of patients receiving LdT and 4.8% receiving LAM. **A1c**

In another RCT trial conducted in China, 332 HBeAg positive or HBeAg negative patients were treated with 600 mg of LdT or 100 mg of LAM daily for 104 weeks [78]. The primary efficacy endpoint was reduction in serum

HBV-DNA levels at week 52 of treatment. Secondary endpoints included clearance of HBV-DNA to undetectable levels, HBeAg loss, seroconversion and ALT normalization. At week 52, among 290 HBeAg-positive patients, mean reductions of serum HBV-DNA ( $6.3 \log_{10}$  versus  $5.5 \log_{10}$ ,  $p < 0.001$ ) undetectable serum HBV-DNA by PCR (67% vs 38%,  $p < 0.001$ ), ALT normalization (87% vs 75%,  $p < 0.007$ ), and HBeAg loss (31% vs 20%,  $p < 0.047$ ) were significantly more common in the LdT group. Viral resistance in LdT recipients was approximately half that observed with LAM, but this difference was not statistically significant. **A1c**

Finally, a randomized open-label trial compared the antiviral efficacy of LdT and ADV in 135 treatment-naïve HBeAg positive patients with chronic hepatitis [79]. Patients were randomly assigned to received 52 weeks of LdT or ADV or 24 weeks of ADV and then LdT for the remaining 28 weeks. The primary efficacy comparison was serum HBV-DNA reduction at week 24 and at week 52. At week 24, mean HBV-DNA reduction was greater in patients with received LdT than in two groups who received ADV ( $-6.30$  vs  $-4.97 \log_{10}$  copies/ml;  $p < 0.001$ ), and more patients treated with LdT had undetectable HBV-DNA by PCR, which has a lower limit of detection of 300 copies/ml. (39% vs 12%;  $p < 0.001$ ). At week 52, the rate of undetectable HB-DNA by PCR (60% vs 40%,  $p = 0.06$ ), the rate of HBeAg loss (30% vs 21%,  $p = 0.3$ ), HBeAg seroconversion (18% vs 19%,  $p = 0.3$ ) and the rate of ALT normalization (79% vs 85%,  $p = 0.4$ ) were similar in patients treated with LdT or ADV.

**Entecavir** ETV is a cyclopentyl guanosine analog that inhibits both the priming and elongation steps of viral replication. In a phase III RCT [80], 715 nucleoside naïve patients (60% Asian and 40% white) with HBeAg positive chronic hepatitis were randomized to receive 0.5 mg of ETV or 100 mg of LAM once daily for 52 weeks. The primary efficacy endpoint was histological improvement (a decrease by at least two points in the Knodell necroinflammatory score) at week 48. Secondary endpoints included a reduction in the serum HBV-DNA level, HBeAg loss and seroconversion, and normalization of ALT level.

At 48 weeks, the ETV treated patients had higher rates of histological improvement (72% vs 62%,  $p = 0.009$ ), HBV-DNA reduction ( $-6.9$  vs  $-5.4 \log_{10}$ ), undetectable HBV-DNA (67% vs 36%,  $p < 0.001$ ), and ALT normalization (68% vs 60%,  $p = 0.02$ ). HBeAg seroconversion occurred in 21% of ETV treated patients and 18% of those treated with LAM ( $p = 0.33$ ). Safety was similar in the two groups. **A1c**

Another study showed that the antiviral activity of ETV is greater than that of ADV in patients with HBeAg positive chronic hepatitis who are treatment-naïve [81]. In this study 69 patients with high levels of baseline HBV-DNA ( $>10^8$  copies/ml) were treated with ETV 0.5 mg/day or

ADV 10mg/day for 52 weeks. ETV was superior to ADV for mean change from baseline in serum HBV-DNA levels at week 12 ( $-6.23 \log_{10}$  copies/ml vs  $-4.42 \log_{10}$  copies/ml respectively;  $p < 0.0001$ ). The proportion of patients achieving HBV-DNA less than 300 copies/ml were greater in ETV-treated than ADV-treated patients at weeks 12, 24, and 48. At week 48 only 3% of ETV treated patients versus 47% of ADV treated patients had HBV-DNA of  $10^5$  copies/ml or more. **A1c**

In HBeAg negative chronic hepatitis only one RCT compared ETV and LAM treatment [82]. A total of 648 patients were randomized to receive either ETV 0.5mg/day or LAM 100mg/day for 48 weeks. More patients in the ETV group than in the LAM group had undetectable serum HBV-DNA levels ( $<300$  copies/ml) (90% vs 72%;  $p < 0.001$ ) at the end of treatment. ALT normalization was also observed more frequently with ETV than with LAM (78% vs 71%,  $p = 0.045$ ), but there was no difference in improvement in fibrosis. There was no evidence of resistance to ETV. Safety and adverse-event profiles were similar in the two groups. **A1c**

*Adefovir dipivoxyl* ADV, a nucleotide analog, has a potent *in vitro* and *in vivo* effect against herpes virus, retroviruses and hepadnaviruses. The drug, when given orally at a dose of 10mg daily, inhibits both the wild type and LAM-resistant HBV strains with an excellent safety profile [83]. Renal tubular damage has been observed when prolonged treatment with higher doses has been given [84]. Two phase III multicenter RCTs, one in HBeAg positive patients have been published [85, 86]. In the first study, 1515 patients worldwide with HBeAg positive chronic hepatitis B were randomized to receive 10mg or 30mg of ADV or placebo for 48 weeks. Most of them were treatment naive, since only 123 had been previously treated with IFN. The observed reduction of HBV-DNA levels was 4.76 with 30mg vs  $3.52 \log$  copies/ml with 10mg of ADV; in both cases a significantly greater suppression than that observed in the placebo group. The rate of biochemical and histological improvement was comparable between two ADV regimens (59% vs 53% and 55% vs 48% respectively). HBeAg seroconversion, although significantly more common in patients receiving ADV (12% at 30mg, 14% at 10mg) than in the control group (6%,  $p = 0.049$  and 0.01 respectively), was relatively uncommon. No ADV-associated resistance mutations were identified in the HBV-DNA polymerase gene. Mild nephrotoxicity was observed with the 30mg regimen, and thus 10mg was considered to be the best regimen. In the second RCT 480 Chinese subjects with hepatitis HBeAg positive chronic hepatitis were enrolled in a multicenter, double-blind, randomized, placebo-controlled study of ADV 10mg once daily [26]. There was a significant difference in reduction of serum HBV-DNA levels after 12 weeks between subjects who received ADV

and those who received the placebo (3.4 and  $0.1 \log_{10}$  copies/ml respectively,  $p < .001$ ). A higher proportion of subjects with undetectable serum HBV-DNA and with normal ALT was observed in ADV treated subjects at week 52 (median HBV-DNA reduction of  $4.5 \log_{10}$  copies/ml, 67% with HBV-DNA  $<10^5$  copies/ml, 28% with HBV-DNA undetectable, and 79% with ALT normalization). Subjects with YMDD mutant HBV at baseline had virological, biochemical, and serological responses to treatment that were similar to those of subjects with wild-type HBV. The incidence of clinically adverse events was similar in nature and severity between the treatment groups, and there was no evidence of renal toxicity. No ADV related HBV mutations were identified. **A1c**

Patients with chronic HBeAg negative, HBV-DNA positive chronic hepatitis were studied in a multicenter trial [87], comparing the efficacy of 10mg of ADV daily for 48 weeks to placebo. Viral suppression was obtained in 51% of patients on ADV vs none in the placebo group. The median HBV-DNA level of ADV-treated patients at 48 weeks ( $3.91 \log$  copies/ml) was lower than observed with placebo ( $1.35 \log$  copies/ml,  $p < 0.001$ ). HBsAg seroconversion was never achieved. Histology changed significantly in the ADV group, with 64% of patients improved as compared with 33% of those on placebo, and alanine aminotransferase level normalized in 72% on ADV and 29% on the placebo. In both studies, YMDD or other repetitive mutations in the HBV polymerase region did not occur under either dose of ADV during the 48 weeks of treatment.

*Tenofovir* TDF is an acyclic nucleotide analog with a molecular structure related to that of ADV. Data from several small studies suggest that TDF might be more potent than ADV in inducing the early and rapid suppression of HBV-DNA in LAM resistant patients [88–90]. In two double-blind, phase III RCTs [91], patients with HBeAg positive or HBeAg negative chronic hepatitis were assigned in a 2:1 ratio to receive 300mg of TDF or 10mg ADV once daily for 48 weeks. The primary efficacy endpoint was HBV-DNA level less than 400 copies/ml and histologic improvement (a reduction in the Knodell necroinflammation score of two or more points without worsening of fibrosis) at week 48. The first RCT included 176 HBeAg positive patients which were treated with TDF, and 90 HBeAg positive patients treated with ADV. At 48 weeks, a higher proportion of patients in the TDF arm than in the ADV arm achieved HBV-DNA levels  $<400$  copies/ml (76% vs 13%,  $p < 0.001$ ). The respective rates for ALT normalization were 69% vs 54% ( $p = 0.03$ ) and for HBeAg seroconversion were 21% vs 18% ( $p = 0.02$ ). A higher proportion of patients treated with TDF had HBsAg loss (3% vs 0%,  $p = 0.02$ ). The incidence of severe adverse events was similar in the TDF and ADV arms. **A1c**

In the second RCT, 375 HBeAg negative patients with chronic hepatitis were randomized to receive TDF 300mg (250 patients) or ADV 10mg (125 patients) for 48 weeks. At week 48, a significantly higher proportion of patients treated with TDF achieved the primary endpoint, compared with patients treated with ADV (71% vs 49%,  $p < 0.001$ ). At the end of treatment, 93% of the patients in the TDF group had HBV-DNA levels greater than 400 copies/ml, compared with 63% of patients in the ADV group ( $p < 0.001$ ). The rates of ALT normalization were similar in both treatment groups. No patients treated with TDF had a confirmed 0.5mg increase in serum creatinine level or creatinine clearance of  $<50$  ml/min. **A1c**

## What are the long-term benefits of anti-viral therapy for chronic hepatitis B?

### IFN therapy and HCC development

We reviewed the available literature to estimate whether IFN reduces the incidence of HCC and liver-related mortality in HBV-related cirrhosis. All potentially relevant papers were initially classified into two subsets (1: controlled trials; 2: cohort studies).

**Subset 1: controlled trials** The rate of HCC in treated and untreated patients with HBV cirrhosis was reported in 11 studies, including 2560 patients [92–102]. The benefit of IFN on cancer development is shown in Figure 27.4. IFN seemingly decreased the rate of HCC occurrence in all but one trial, and a significant difference was observed in three studies. The pooled estimate of the preventive effect of

treatment was significantly in favor of IFN (rate difference:  $-0.04$ ; 95% CI:  $-0.01$ – $0.07$ ). A remarkable heterogeneity was detected among studies (heterogeneity: 39.12 with 10 df;  $p < 0.001$ ).

Since the trials showed a significant inconsistency, subgroup analyses were performed in relation to the ethnic origin of patients (European versus Oriental studies). Consistent results were observed only when assessing data pooled from European reports; in this subgroup no preventive effect of HCC was found. **A1c**

**Subset 2: cohort studies** It has been suggested from long-term cohort studies that IFN treatment may have a protective effect against HCC development in patients with chronic HBV infection. We reviewed the clinical course and outcome of patients enrolled in long-term, follow-up studies [98, 99, 102, 103–111]. The 12 studies (11 prospective and one retrospective) included a total of 1952 patients, 1187 of them not receiving active treatment. Length of follow-up ranged from 2.1 to 8.9 years. Meta-analysis of longitudinal studies with prolonged follow-up showed no significant differences in the rate of HCC between treated patients (1.9%; 95% CI: 0.8–3.0%) and controls (3.16%; 95% CI: 1.8–4.5%). **A1c**

All data dealing with HCC development coming from studies with prolonged follow-up must be interpreted with caution because possible biases can lead to erroneous estimates:

- Data collected from both prospective and retrospective studies conducted in tertiary care centers with limited generalizability

**Figure 27.4** Meta-analysis of the 11 controlled trials of IFN for prevention of HCC in patients with HBV-related cirrhosis. Risk difference and 95% CI for each study and the pooled estimate of the treatment effect CI are plotted on the graph. Studies are arranged by publication year.

**Figure 27.5** Probability distribution of the loss of HBsAg rate in HBeAg-positive chronic hepatitis B from IFN-treated (T) patients and controls (C). Data from cohort studies.

- Lack of randomization reducing the internal and the external validity of the studies
- Heterogeneity of patients enrolled, both in respect of clinical and demographic features and of possible co-factors
- Slow and prolonged course of the disease not allowing an inception cohort
- Few clinically relevant events, relatively small sample size, and duration of follow-up less than eight to ten years
- High mortality from non-hepatic causes
- Selection and increased surveillance for cases with more severe disease and unfavorable course
- Progressive shift over the years of the global spectrum of the disease due to intervening factors (e.g. new diagnostic tests and screening programs; new available treatments)

In conclusion, there is no sound evidence from controlled trials and prospective cohort studies to support a recommendation for widespread use of IFN to prevent HCC in these patients.

### IFN therapy and long-term outcome

**HBeAg positive chronic hepatitis B** In the setting of HBeAg-positive CHB, the long-term benefits of IFN treatment for chronic HBV infection were assessed by meta-analysis of 12 studies involving 1975 patients in which the length of follow-up ranged from 2.9 to 8.9 years [98, 99, 102, 103–111].

Loss of HBsAg occurred in 11.4% of treated patients, compared to 2.6% of controls, a four-fold benefit (see Figure 27.5). In contrast, a smaller effect was evident for the reduction in the incidence during the observation period of

**Figure 27.6** Probability distribution of disease decompensation rate in HBeAg-positive chronic hepatitis B from IFN-treated (T) patients and controls (C). Data from cohort studies.

**Figure 27.7** Probability distribution of liver-related mortality rate in HBeAg-positive chronic hepatitis B from IFN-treated (T) patients and controls (C). Data from cohort studies.

decompensation (see Figure 27.6) or liver-related deaths (see Figure 27.7), but the differences were not statistically significant. As the authors pointed out, however, all clinically relevant events (such as liver-related deaths) occurred infrequently in these studies to explain the lack of association with the therapy. **A1c**

**HBeAg negative chronic hepatitis B** There have been controversies about the long-term benefit of IFN therapy in the HBeAg negative form of chronic hepatitis B. Differences of the baseline severity of illness in the population of the studies, the length of follow-up, type and frequency of post-treatment monitoring, and treatment regimens limit the assessment of the impact of IFN therapy on the course of the disease. Overall, the four cohort studies with a length of follow-up ranging from two to seven years showed that

the response appeared to be less durable at long-term follow-up compared to HBeAg positive cases and that relapses can occur even years after therapy [112–115]. The rate of HBsAg loss ranged from 4.5% to 13%.

An RCT performed by Lampertico *et al.* [116] has demonstrated that long-term suppression of viral replication by 24-month IFN therapy improved the outcome of sustained responders defined as subjects with normal aminotransferase levels and undetectable hepatitis B virus DNA. Liver disease progressed in none of the sustained responders but in 16 with treatment failure (0% vs 22%;  $p = 0.002$ ) while HCC developed with similar frequency in both groups (7%). Overall, estimated eight-year complication-free survival was longer for the 30 sustained responders than the 71 patients with treatment failure (90% vs 60%,  $p < 0.001$ ), but eight-year patient survival was similar in the two groups (100% and 90%).

### Nucleos(t)ide analogs therapy and HCC development

It has been argued that long-term suppression of HBV replication could reduce hepatocyte turnover and lessen the risk of dysplasia and cancer [117]. In 2004, a large RCT [118] showed a decrease in the incidence of HCC in patients with HBV-related advanced liver disease treated with LAM as compared to untreated controls. In the wake of this study, further controlled trials and retrospective or prospective cohort studies [119–123] were performed, mostly in patients with advanced liver disease. These studies collected cohorts of HBeAg positive and negative patients and showed a marked degree of heterogeneity, making it difficult to assess the actual level of benefit obtained by nucleos(t)ide analogs treatment.

We have pooled the available literature data to evaluate whether nucleos(t)ide treatment reduces the incidence of HCC in patients with HBV-related chronic liver disease. The effect of nucleos(t)ide on cancer incidence was assessed in six studies: two RCTs [118, 122], and four non-randomized or cohort studies [119–121, 123]. The six studies included 2394 patients, 1372 of whom received nucleos(t)ide therapy (1166 as LAM monotherapy and 206 as LAM and ADV combination therapy) and 1022 were untreated controls. Since in the cohort study a control arm of untreated patients was not included, we indirectly compared the rate of HCC development in the treatment arm to the mean control rate pooled from all the other included studies [123].

The percentage of males ranged from 73% to 85%. The sample size of each study varied greatly, ranging from 754 to 105 patients. Mean patient age ranged from 34 to 50 years. The proportion of patients with cirrhosis differed greatly among studies, ranging from 0% [121] to 100% [122]. Similarly, a great variability was observed among trials in the HBeAg status, ranging from 0% [120] to 100%

[121]. A large variability of nucleos(t)ide schedules between trials was found in the length of treatment (ranging between 19 and 96 months) and in the treatment follow-up (ranging between 2.7 and 8.2 years).

Nucleos(t)ide treatment seemingly decreased HCC rate in all the six evaluable studies, a significant difference being observed in three. The pooled estimate of the treatment effect by *random effect model* was significantly in favor of a preventive effectiveness of NA (RR: 0.26, 95% CI: 0.12–0.48). **A1c** We found a remarkable statistical quantitative heterogeneity among the studies, in the difference of the magnitude of the treatment effect on the risk of cancer development. Large differences were observed in the baseline risk of HCC among the different studies: the HCC rate in the untreated group ranged from 2.4% to 32.4%.

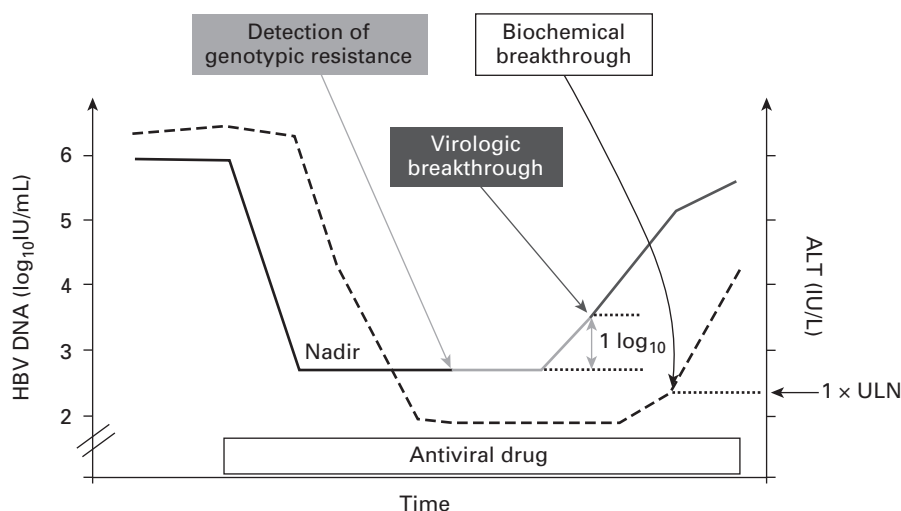

The results of this meta-analysis demonstrate that the heterogeneity in the magnitude of the preventive effect of nucleos(t)ide on the risk of cancer is the most impressive feature of these studies. Regarding HBV-related chronic infection, the pooled data suggested a preventive effect of nucleos(t)ide analogs on HCC development in patients without cirrhosis and in subjects with HBeAg positive infection. The benefit on HCC prevention was observed in studies from Asia. As with all meta-analyses, a methodological issue of the meta-analysis described above, is the potential limitation of the generalizability of its results to new populations and settings, particularly in western populations and in real clinical practice outside highly specialized centers.

### Nucleos(t)ide analogs therapy and long term outcome

There have been only a few studies assessing the effects of LAM alone or in combination with ADV on hepatic decompensation and mortality. Five previously published long-term studies have shown that continuous treatment with LAM alone or in combination with ADV delays clinical progression in patients with advanced fibrosis or cirrhosis by reducing the incidence of hepatic decompensation [119–123]. In the large RCT by Liaw, 436 LAM-treated patients and 215 controls were followed for a mean time of 32 months. A significant difference was observed in the incidence of the primary endpoint, a composite endpoint combining hepatic decompensation, HCC, spontaneous bacterial peritonitis, bleeding gastresophageal varices or death related to liver disease between treated patients and controls.

Similar results were observed by Di Marco *et al.* in a large retrospective multicenter observational study [124]. On LAM therapy for four years a virological suppression was obtained in 616 patients (93.9%), and the rate of sustained virological response was 39% after four years. During follow-up, 47 (7.2%) patients underwent liver transplantation, liver disease worsened in 31 (4.7%), HCC developed in 31

**Figure 27.8** Genotypic resistance, virologic rebound and biochemical rebound. From: Ahmed S *et al. Hepatology* 2000; **32**: 1078–1088. Lok ASF, McMahon BJ. *Hepatology* 2007; **45**: 507–539.

(4.7%), and 24 patients (3.6%) died of liver-related causes. Patients who had cirrhosis and who maintained virological response were less likely than those with viral breakthrough to develop disease worsening. Survival was better in Child-Pugh A patients with cirrhosis and sustained virological suppression.

The relationships between HBV suppression, development of viral resistance and disease outcome are clarified in a small single center prospective study enrolling 59 patients mainly with HBeAg negative compensated cirrhosis [125]. Event-free survival was significantly longer in patients who maintained virological suppression than in those who did not have a complete virological response or suffered a breakthrough. Patients with advanced cirrhosis were more likely to develop liver failure after the emergence of YMDD mutants. Profound and maintained HBV-DNA suppression correlates with a better outcome.

Finally, data of the long-term benefit of subjects treated with others nucleos(t)ide analogs are not available as yet.

### Resistance rates to nucleos(t)ide analogs associated with therapies for chronic hepatitis B

Antiviral drug resistance reflects reduced susceptibility of a virus to the inhibitory effect of a drug. Resistance results from a process of adaptive mutations under therapy, influenced by:

- High replication rates
- Low fidelity of the viral polymerase
- Selective pressure of the drug
- Genetic barrier of the drug
- Replication space (liver turnover)
- Fitness of mutant

Indications of emergence of drug-resistant HBV is given by:

- Increasing viral load ( $\geq 1.0 \log \text{IU/ml}$ )
- Identification of known genotypic markers of drug resistance within viral polymerase:
  - primary resistance mutations (e.g.: LAM  $\rightarrow$  rtM204I)
  - secondary resistance mutations (e.g.: LAM  $\rightarrow$  rtL180M with rtM204V)
  - compensatory mutations (e.g.: LAM  $\rightarrow$  rtV173L)
- Increasing serum ALT levels
- Clinical deterioration

The following definitions are currently adopted to classify resistance to therapy (see Figure 27.8) [126]:

- Virologic breakthrough: increase in serum HBV DNA by  $>1 \log_{10}$  (ten-fold) above nadir after achieving virologic response, during continued treatment
- Viral rebound: increase in serum HBV DNA to  $>20,000 \text{ IU/ml}$  or above pretreatment level after achieving virologic response, during continued treatment
- Biochemical breakthrough: increase in ALT above upper limit of normal after achieving normalization, during continued treatment
- Genotypic resistance: detection of mutations that have been shown in *in vitro* studies to confer resistance to the nucleos(t)ide analog that is being administered
- Phenotypic resistance: *in vitro* confirmation that the mutation detected decreases susceptibility (as demonstrated by increase in inhibitory concentrations) to the nucleos(t)ide analog administered

Long-term use of nucleos(t)ide analogs is associated with an increased risk of developing resistance at varying rates, depending on the drug used. The overall profile of resistance is reported in Table 27.2. The main mutations occurring on treatment with the nucleos(t)ide analogs in current usage are reported in Figure 27.9. Overlap in many of these mutations is remarkable across various analogs. This highlights the importance of careful assessment of virologic response in patients so that drug resistance can be quickly

**Table 27.2** Annual prevalent resistance rates for lamivudine, adefovir, entecavir, emtricitabine and telbivudine.

DRUG	Resistance at each year of therapy expressed as percentage of patients				
	1	2	3	4	5
Lamivudine <sup>a</sup>	23	46	55	71	80
Adefovir <sup>b</sup> (naive HBeAg-neg)	0	3	11	18	29
Adefovir (LAM resistant) <sup>c</sup>	0–18	—	—	—	—
Entecavir <sup>d</sup> (naive)	0.1	0.4	1.1	1.1	1.2
Entecavir <sup>d</sup> (LAM resistant)	6	15	35	43	—
Emtricitabine <sup>d</sup>	9–16	19–37	—	—	—
Telbivudine <sup>e</sup> (HBeAg-pos) <sup>f</sup>	4.4 <sup>d</sup>	21.6 <sup>e</sup>	—	—	—
(HBeAg-neg) <sup>f</sup>	2.7	8.6	—	—	—

<sup>e</sup>In the LAM comparator arm, the percentage was only 8% based on a complex case definition of anti-viral drug resistance/treatment failure. One would thus expect a comparable relative level of

<sup>f</sup>10–12% based on genotypic resistance compared with lamivudine (25% per annum). Lok A & McMahon B. *Hepatology* 2007; 45: 507.

**Figure 27.9** Primary resistance mutations occurring on treatment with the nucleos(t)ide analogues.

identified and multidrug resistance can be avoided. If cost and access are not issues because of insurance reimbursement, geographic location, or agent approval, clinicians should choose the most potent nucleoside analog available with the least likelihood of developing resistance. In this regard, the two drugs that would be preferable as monotherapy appear to be ETV and TDF. No head-to-head efficacy or resistance data are available for ETV and TDF in treatment-naïve patients. The use of TDF might be warranted over ETV in LAM-resistant patients. **B4**

Management of resistance to one analog must take into account previous exposure to other drugs in this class. Current EASL recommendations are reported in Table 27.3.

### Combination vs monotherapy with nucleos(t)ide analogs

A generally accepted concept in virology is that the use of combination therapy may increase the genetic barrier to resistance, resulting in a decrease in the occurrence of viral

**Table 27.3** AASLD recommendations for managing virologic breakthrough.

Resistance	Rescue therapy
LAM	<ul style="list-style-type: none"> <li>• Add ADV (superior to ADV switch)</li> <li>• Switch to ETV (increased risk of ETV resistance development)</li> <li>• Add TDF<sup>a</sup> or switch to FTC/TDF<sup>a</sup></li> </ul>
ADV	<ul style="list-style-type: none"> <li>• Add LAM (superior to LAM switch)</li> <li>• Switch to or add ETV (only in the absence of LAM resistance)</li> <li>• Switch to FTC/TDF<sup>a</sup></li> </ul>
ETV	<ul style="list-style-type: none"> <li>• Add or switch to ADV or TDF<sup>a</sup></li> </ul>
LdT	<ul style="list-style-type: none"> <li>• Add ADV (superior to ADV switch)</li> <li>• Switch to ETV (increased risk of ETV resistance development)</li> <li>• Add TDF<sup>a</sup> or switch to FTC/TDF<sup>a</sup></li> </ul>

<sup>a</sup> Off label.From Lok A *et al.* *Hepatology* 2007; **45**: 507–39.

resistance; this has been well documented in the treatment of HIV. Much discussion has focused on the potential benefits of combination therapy or add-on therapy vs sequential monotherapy. Although many believe that combination therapy may still play a role in improving long-term prevention of resistance, data are currently insufficient regarding the efficacy of combinations of nucleoside analogs or combinations of nucleos(t)ide analogs with peginterferon to determine any significant benefit over monotherapy. Therefore, although a theoretical benefit to combination therapy may exist, it cannot be recommended as a first-line treatment strategy.

The use of a more potent antiviral as de novo monotherapy is the current alternative to the combination of two drugs with low genetic barriers to resistance or suboptimal efficacy. The patient's virologic response should also be monitored, considering the need for a therapy change at 12–24 weeks if a robust virologic suppression is not achieved, depending on the agent with which the patient is treated [127]. In general, choosing the most potent first-line monotherapy, if available, is a reasonable approach.

**B4**

The ultimate goal is to maintain very low levels of viral replication or undetectable replication for as long as possible; the prevention of viral replication results in preventing development of resistance [128]. To achieve this, potent drugs with a high genetic barrier to resistance should be selected, or, if these drugs are not available de novo combination therapy could be used, while full adherence to the regimen should be strongly encouraged in either circumstance.

## Conclusions

Data from studies of natural history and RCTs or non-randomized studies of antiviral treatment give sufficient data to conclude that:

- (1) The natural history of chronic hepatitis B is variable, according to phenotypic and ethnic background, and is also influenced by viral co-infections and toxic co-factors. At least 20% of patients develop clinically significant liver disease in the long term.
- (2) Presence of significant HBV replication and of continuing liver necroinflammation predict an adverse outcome.
- (3) IFN therapy results in stable clearance of HBeAg in 25% of all patients chronically infected by wild type HBV, but only rarely results in HBsAg clearance.
- (4) IFN therapy results in stable clearance of HBV-DNA in 25% of all patients chronically infected by HBe minus HBV.
- (5) All available oral analogs effectively reduce HBV-DNA and normalize ALT during therapy in at least two-thirds of patients within one year of treatment.
- (6) Viral resistance to analogs appear at variable frequency (more with nucleosides, except entecavir, less with nucleotides) and affects their long-term effectiveness.
- (7) Effects of anti-viral treatment on survival, although biologically plausible and already evident when treating patients with advanced disease, have yet to be proven in non-cirrhotic chronic hepatitis.
- (8) A protective effect of IFN against development of HCC is still unproven.

## Screening

In heavy drinkers, liver-related mortality is mainly attributed to cirrhosis and hepatocellular carcinoma (HCC). Therefore, the main objectives of the screening are: to identify patients with significant liver injury; to characterize the main risk factors for HCC; and to diagnose HCC early.

We focus on the non-invasive screening of cirrhosis and on screening of HCC.

## Non-invasive screening of cirrhosis

Assessment of the stage and severity of liver injury requires liver biopsy, an invasive procedure associated with complications leading to death in 0.02% of patients [1]. Less than 30% of heavy drinkers have significant liver injury such as extensive fibrosis, alcoholic hepatitis or cirrhosis [2]. Routine liver biopsy is not essential in 70% of heavy drinkers. The recent development of non-invasive methods for the screening of extensive fibrosis and/or cirrhosis is an important progress to identify the subgroup with significant alcoholic liver disease (ALD) and will avoid screening with liver biopsy.

## Initial development of biomarkers of fibrosis

Serum hyaluronate was identified to be useful for the diagnosis of cirrhosis [3–5], with a good AUROC for the diagnosis of significant fibrosis (Metavir class  $\geq$  F2 versus F0–F1).

Prothrombin time (PT) predicts liver fibrosis and is inversely correlated with the area of fibrosis [4, 6]. A study showed that PT has a high diagnostic accuracy for severe fibrosis or cirrhosis, particularly in those with ALD [7].

Results of the studies evaluating serum procollagen III propeptide (PIIIP) in assessing fibrosis are controversial [4, 8–11]. A major problem, beside the heterogeneity of the assays, is that even with the same assay the PIIIP screening cutoff is unknown.

Apolipoprotein A-I (ApoA-I) has an independent and discriminative value for the diagnosis of fibrosis [12]. A simple index called PGA, developed by combining PT,  $\gamma$ -glutamyl transpeptidase and ApoA-I was efficient for screening of cirrhosis [6].

Serum  $\alpha$ -2 macroglobulin has been evaluated as a marker of cirrhosis. Levels were higher in patients with cirrhosis than in patients without [13, 14]. Based on these results, the hypothesis that serum  $\alpha$ -2 macroglobulin could improve the accuracy of PGA index for the diagnostic of cirrhosis was confirmed [15].

These studies constitute the background for the development of the new blood tests for screening of fibrosis. As an example, PT, Apo A-1 and serum  $\alpha$ -2 macroglobulin have been incorporated in the formula of non-invasive methods such as Fibrotest® and Fibrometer®.

## Non-invasive tests to screen for fibrosis

Several new blood tests combining different biomarkers of fibrosis are now available. These tests have been initially designed for patients with hepatitis C but seem to be as efficient in patients with ALD.

Aspartate aminotransferase (AST) to platelet ratio index (APRI) is an accurate non-invasive marker of fibrosis in chronic hepatitis C, and has been evaluated in heavy drinkers. A total of 1308 subjects from two studies of ALD were evaluated, with a liver biopsy available from 781 non-cirrhotic patients and a history of decompensation in 527 [16]. In the 507 patients with biopsy-confirmed fibrosis, the sensitivity of APRI for significant fibrosis was 13.2% and the specificity 77.6%. Twenty percent were misclassified. Thus, APRI has low sensitivity and specificity for the diagnosis of significant fibrosis in patients with ALD. The use of this test to screen fibrosis is not recommended.

Fibrotest® combines alpha-2-macroglobulin, haptoglobin, GGT, ApoA1 and bilirubin, corrected for age and sex. It was designed to predict advanced fibrosis in chronic hepatitis C, and is also known to have high predictive values for the detection of significant fibrosis in ALD [5, 17]. In a study of 221 consecutive patients with biopsy-proven ALT, the mean Fibrotest® value ranged from 0.29 in those without fibrosis to 0.88 in those with cirrhosis. For the diagnosis of cirrhosis, the AUROC was very high at 0.95 [5]. FibrometerA®, combining PT, alpha-2-macroglobulin, hyaluronic acid and age has similar accuracy in ALD [18]. In the validating step, the Fibrometer® AUROC curve was 0.892 in overall patients and 0.962 in patients with ALD. Hepascore® combines bilirubin, GGT, hyaluronic acid, alpha-2-macroglobulin, age and sex. The diagnostic accuracies of Fibrotest®, Fibrometer® and Hepascore® were compared in patients with ALD [19]. The diagnostic values of FibrometerA® and Hepascore® did not differ from that of FibroTest® for advanced fibrosis (AUROCs around 0.80) and cirrhosis (AUROCs around 0.90), and were significantly greater than those of non-patented biomarkers APRI, Forns, FIB4). The combination of any of these tests was useless to improve diagnostic performance.

In addition to their diagnostic performance in the screening of fibrosis, non-invasive tests may be as useful as biopsy to predict liver-related mortality. A recent study compared the prognostic and diagnostic values of these biomarkers in 218 patients with ALD followed up for a median of 8.2 years. Five-year survival was inversely correlated with baseline Fibrotest® value: 98.7% if baseline Fibrotest® between 0–0.31, 92.1% if 0.32–0.58 and 68.3% if 0.59–1 [19]. Among the different tests (FibrometerA®, Hepascore®, APRI, Forns, FIB4) Fibrotest® was the only biomarker strongly associated with overall survival in multivariate analysis.

The estimation of fibrosis by measurement of liver stiffness is another alternative to biopsy. In patients with ALD, liver stiffness was correlated with the amount of fibrosis and ranged from 5.7 kPa in patients with Metavir score F1, 8.3 kPa in F2, 17.5 kPa in F3, to 40.9 kPa in F4. The optimal cutoff (kPa) for the screening of cirrhosis was 22.7 kPa with positive predictive value at 0.85 and negative predictive value at 0.82 [20]. A study comparing the diagnostic performance of transient elastography (TE) to those of biopsy and biomarkers in patients with alcohol abuse demonstrated that TE has a good diagnostic performance [21]. Liver stiffness is correlated with fibrosis. A cutoff at 19.5 kPa identifies cirrhosis with a PPV of 68.6% and a NPV of 87.9%. In this cohort, the diagnostic performance of TE was not significantly different than those of Fibrotest® and Fibrometer® but higher than those of APRI and Hepascore®. Thus, TE is a useful tool for the screening for cirrhosis in

populations with chronic alcohol abuse, and could identify patients requiring biopsy.

## Screening for hepatocellular carcinoma

Chronic alcohol abuse (>50–80 g/day during at least ten years) increases the risk of hepatocellular carcinoma (HCC) by five [22]. This risk does not decrease with abstinence. In alcoholic cirrhosis, the cumulative risk of developing HCC at five years is approximately 8% [23], with a yearly incidence rate of 1% in decompensated alcoholic cirrhosis [22].

Identification of patients at high risk for HCC, and its early detection are of crucial importance. In heavy drinkers, presence of cirrhosis, age >50 years, male sex, serum alpha fetoprotein (AFP) = 15 ng/ml, HBsAg and antiHCV antibodies were independently associated with the occurrence of HCC [24–26]. A clinicobiological score identifies two groups at low (three-year cumulative incidence, 0%) and high risk of HCC (three-year cumulative incidence, 24%) [27]. The pre-neoplastic role of liver large cell dysplasia (LLCD) has been suggested [28]. A study estimated the cumulative incidence of HCC at three years at 38% in patients with LLCD and 10% in patients without [27]; another study found that LLCD was associated with a five-fold increase in the risk of HCC [29]. Nevertheless, in another study, LLCD was not an independent risk factor for HCC [30]. Taken together, these data do not support LLCD to be a direct precursor for HCC, but support its significance as a marker able to predict HCC development. Patients without the lesions are at low risk of HCC [31]. High grade dysplastic nodules are associated with a high risk of malignant transformation and are clearly classified as pre-neoplastic lesions [32]. Based on these results, biopsy would be useful to identify patients with a higher risk for HCC.

Screening for HCC is usually done with ultrasonography and concentration of AFP. Contrasting data have been reported on the effectiveness of ultrasonography for early detection of HCC: a French center observed that diagnosis of tumour less than 3 cm was made in only 21% of cases [33], but other studies detected small HCC in 76% of cases [34, 35]. A recent Markov model assessed that screening by AFP and ultrasonography was cost-effective [36]. In an RCT evaluating screening in hepatitis B versus no screening, the screening strategy decreased the mortality rate by HCC by 37% [37]. Regardless of these data, screening for HCC by biannual AFP testing and ultrasonography is recommended.

## Summary of screening in heavy drinkers

At present, non-invasive methods are available and will be helpful to define the best strategy to identify significant

fibrosis in heavy drinkers in routine practice. Patented blood biomarkers (Fibrotest®, Fibrometer® and Hepascore®) and TE are simple, non-invasive, cost-effective and reproducible. As observed in HCV patients, the combination of serum biomarker tests and TE need to be tested in patients with ALD for the screening of fibrosis. This practice can select candidates for liver biopsy and at risk of development of portal hypertension and HCC. HCC screening should be done using biannual AFP dosage and ultrasonography, and the presence of high grade dysplasia at biopsy is a strong predictive marker for high risk of malignant transformation. However, future studies are required to validate these screening strategies.

## Treatment

In heavy drinkers, pharmacological treatments and liver transplantation (LT) have been tested to improve survival of heavy drinkers with severe liver injury such as severe alcoholic hepatitis (SAH) or cirrhosis. Except for SAH, the usefulness of pharmacological treatments for controlling the alcohol-induced liver injury is still unsettled.

## Pharmacological treatments

### Anti-fibrotic therapies

**Colchicine** Colchicine is an anti-fibrotic therapy which has been widely evaluated in the treatment of alcoholic or non-alcoholic fibrosis. In the first RCT evaluating its effect on long-term survival of patients with alcoholic cirrhosis, five and ten-year survival rates were significantly higher in the colchicine group (75% and 56%, respectively) than in the placebo group (34% and 20%,  $p < 0.001$ ) [38]. Nevertheless, in patients with AH, two other studies did not observe any effect on short-term survival [39, 40]. A recent RCT did not observe any difference between the colchicine and the placebo groups in terms of liver-related mortality: 32% vs 28% [16]. The ineffectiveness of colchicine was confirmed by a meta-analysis combining all the RCTs evaluating colchicine [41]. **A1a**

**Propylthiouracil** Two RCTs did not document any effect of propylthiouracil on short-term survival [42, 43]. Meta-analysis of these RCTs confirms the lack of benefit on survival, with a mean difference of 1% (CI: 7–9%) between propylthiouracil-treated and controlled patients.

The effect on long-term survival was analyzed in an RCT with 310 alcoholic patients receiving propylthiouracil ( $n = 157$ ) or placebo ( $n = 153$ ) for two years [44], which found that two-year mortality was lower in propylthiouracil group than in placebo group (13% versus 26%,  $p < 0.05$ ). Nevertheless, this study was limited by two biases: the use

of “per protocol analysis” and the cumulative drop-out rates in both groups were approximately 60%.

A systematic review of six RCTs including 710 patients demonstrated no survival benefit of propylthiouracil compared with placebo (odds ratio 0.99) [45]. Moreover, propylthiouracil was associated with a non-significant trend towards an increased risk of adverse events and serious adverse events (leukopenia). Taking into account these data, propylthiouracil is not considered as an effective therapy in alcoholic cirrhosis. **A1a**

**Other drugs** D-penicillamine, vitamin E, (+)-cyanidanol-3, thiocetic acid, malotilate and amlodipine have been evaluated in RCTs, but none improved survival [46–51]. **A1d**

**Silymarin** The first RCT suggested an improvement in long-term survival of patients with cirrhosis [52]. However, another larger RCT involving 200 patients did not confirm any effect on survival [53]. **A1d**

**S-adenosyl methionine** In an RCT, there was a trend toward greater decrease in overall mortality/liver transplantation in S-adenosyl methionine than in placebo patients (16% vs 30%,  $p = 0.077$ ) [54]. A sensitivity analysis restricted to patients with Child A or B classes observed a significant lower mortality/liver transplantation in S-adenosyl methionine patients (12 vs 29%,  $p = 0.025$ ). In summary, because of the absence of statistical difference on overall patients, the benefit of S-adenosyl methionine is still unknown and future studies are needed. **A1d**

**Phosphatidylcholine** This has demonstrated a trend towards a decrease in transaminase and bilirubin levels in heavy drinkers, in a trial on alcoholic cirrhosis. Nevertheless, there was no improvement on survival or histology at 24 months [55].

## Therapies for acute severe alcoholic hepatitis

Alcoholic hepatitis (AH) occurs in approximately 20% of heavy drinkers. Several investigators have studied SAH intensively, due to its significant early mortality (50–75% in severe forms) [56]. Despite the impact of abstinence on survival in ALD [57–59], pharmacological treatments are required. The treatment of SAH remains controversial and is one of the main challenges in ALD.

Evaluation of any effect on short-term survival requires identification of patients with significant risk of death at one or two months. Until the Maddrey function became available, no reproducible objective criterion existed to predict the risk of early death. Prior to the era of the Maddrey Discriminant Function (DF), survival in untreated control arms ranged from 0% to 81% [56, 60–71]. Maddrey

*et al.* described a DF [56] and later modified it [61]. This modified DF identifies patients at high risk of early mortality: 4.6 (PT-control time in seconds) + bilirubin (in mg/dl). In the absence of treatment, the spontaneous survival of patients with a DF  $\geq 32$  fluctuated between 50% and 65% [61, 72, 73].

Insulin-glucagon infusion [74–76] and nabolic-androgenic steroids [71, 77–79] are not effective in SAH. A systematic review confirmed that anabolic-androgenic steroids did not have any benefit on mortality and were associated with serious adverse events [80]. **A1a** Furthermore, their use is questionable when considering the potential associated risk of HCC.

### Corticosteroids

Thirteen RCTs have evaluated corticosteroids in patients with AH [56, 60–71]. These yielded inconsistent results, attributed to the wide differences between studies, since survival of placebo groups ranged from 0% to 81%. The last two RCTs included only patients with either a DF  $\geq 32$  or spontaneous encephalopathy [60, 61]. Survival in corticosteroid groups was significantly higher than in placebo groups: 94% vs 65% at 28 days ( $p = 0.006$ ) [61] and 88% vs 45% at 66 days ( $p = 0.001$ ) [60]. The response to steroids was lower in case of bleeding [81]. The survival benefit of steroids is restricted to short term [82].

A recent meta-analysis using multivariate statistics to adjust for confounding variables between corticosteroid and control groups concluded that corticosteroids are ineffective [83]. Nevertheless, this was problematic in identifying the effect of steroids because of the limited number of trials ( $n = 12$ ) and the inclusion of lower-quality trials [84]. Moreover, meta-analysis of published results is not designed to identify the effect of treatment in distinct patients [85]. In the particular setting of AH, this method cannot pool the results restricted to patients with DF  $\geq 32$ , as most of the previous RCTs did not supply the survival data on this subgroup.

To conclude this controversy, individual data of the most recent RCTs were combined [72]. The analysis was restricted to patients with a DF  $\geq 32$ . The findings were: (1) at 28 days, corticosteroid patients had significantly better survival than placebo patients:  $84.6 \pm 3.4\%$  vs  $65.1 \pm 4.8\%$ ,  $p = 0.001$ ; (2) steroids, age and creatinine were independently associated with survival at 28 days; (3) steroids induced rapid improvement in liver function by seven days of treatment [72]. The final argument for the benefit of corticosteroids is that all the studies observed that two-month survival of patients treated with corticosteroids was approximately 80% [60, 61, 86–89]. **A1a**

To progress in the management of SAH, a criterion for early identification of non-responders to steroids has been proposed [87]. This criterion, “early change in bilirubin levels (ECBL)” is defined as a bilirubin level at seven days

lower than these on the first day of treatment [87]. However, the ECBL was highly specific but not sensitive enough for predicting death. A specific prognostic model, the so-called Lille model, was developed to identify subjects early on who are unlikely to survive and propose new management based on this specific model [90]. Patients above the ideal cutoff of 0.45 showed a marked decrease in six-month survival as compared to others:  $25 \pm 3.8\%$  vs  $85 \pm 2.5\%$ ,  $p < 0.0001$ . Using the 0.45 Lille model cutoff, close to 40% of patients do not benefit from corticosteroids, which is higher than the 25% previously identified by ECBL [90]. In non-responders (i.e.  $0.45 \geq$  Lille model) corticosteroids should be interrupted at day seven. A recent study evaluating a two-step strategy consisting of early withdrawal of corticosteroids and a switch to pentoxifylline for 28 additional days in non-responders observed that non-responders to corticosteroids do not obtain any benefit from an early switch to pentoxifylline. Thus, the issue of management of non-responders remains unsettled.

In summary, even if steroids improve short-term survival in SAH, new treatments are required to improve the probability of being alive within the year following the onset of the disease.

### New therapies

**Extracorporeal liver support** Liver support devices have been developed to provide additional time for liver regeneration and improvement of liver function. Extracorporeal liver support, consisting of a molecular adsorbent recirculating system (MARS), detoxifies blood of protein-bound toxins having a molecular weight  $<50$  kDa and water-soluble substances. In a recent pilot study, eight patients with SAH were treated with MARS [91]. Improvement in bilirubin, creatinine, DF and International Normalized Ratio (INR), and in circulatory disturbances was observed. The efficacy of MARS is still unsettled and requires future studies.

**Enteral nutrition** Total enteral tube feeding was compared to corticosteroids in a RCT [92], using a low-fat diet with a lipid content constituted of medium-chain triglycerides and oleic acid, considering the deleterious effects of a high-fat diet on ALD in animal models [93–95]. Mortality occurred earlier in the enteral group: 7 days vs 23 days,  $p = 0.025$ . During follow-up after the treatment, deaths were observed more frequently in the corticosteroid group (10/27) than in the enteral group (2/24,  $p = 0.04$ ). **A1d** The same groups recently suggested that combined treatment (enteral nutrition plus corticosteroids) should be investigated in SAH [96].

**Pentoxifylline** Pentoxifylline, an inhibitor of TNF $\alpha$  synthesis, was evaluated in a double-blind RCT [97]. In this study 101 patients with SAH randomly received pentoxifylline

( $n = 49$ ) or a placebo ( $n = 52$ ). The mean DF in the pentoxifylline and placebo groups was 45.9 and 45.3 respectively. Twenty-four percent of pentoxifylline-treated patients and 46.1% of controls (relative risk: 0.57,  $p = 0.04$ ) died after a mean of 29 and 33.1 days respectively. The survival benefit of pentoxifylline is related to a significant reduction of hepatorenal syndrome [97]. Contrary to corticosteroids, pentoxifylline did not improve liver function. At the end of the treatment, the two groups had similar values of DF, PT and bilirubin levels. During the treatment, there were no differences between the groups in values or decrease of TNF $\alpha$ . **A1d** The development of a new first-line therapy which is more efficient than corticosteroids or pentoxifylline alone is warranted for improving short and medium-term survival. Amongst available options, a combination of these two drugs remains attractive in light of their potential synergistic action. Indeed, in naive patients, corticosteroids improve liver function, whereas the effect of pentoxifylline was thought to be related to prevention of hepatorenal syndrome, but not to improvement in liver function. This combination warrants comparison with corticosteroids alone or pentoxifylline alone in randomized controlled trials.

*Anti-TNF $\alpha$  strategy* Production of TNF $\alpha$  by inflammatory cells in response to oxidative stress and endotoxin is a critical mediator of ALD. In animal models, anti-TNF $\alpha$  antibodies attenuated liver injury, and lack of TNF $\alpha$ -receptor-1 avoids the development of ALD [98]. The anti-TNF $\alpha$  strategy was tested in two pilot studies and two RCTs [86, 88, 99, 100], evaluating infliximab (chimeric human/mouse antibody), binding with high affinity to TNF $\alpha$ . The first study randomized 20 patients with SAH, treated by prednisolone 40 mg/day for 28 days, to receive infliximab 5 mg/kg IV ( $n = 10$ ) or placebo ( $n = 10$ ) [88]. At day 28, DF and IL-8 decreased significantly, contrary to the placebo group [88]. Infliximab was well tolerated, but the sample size did not allow comparison between two groups. Another study tested a single dose of 5 mg/kg without steroids in 12 patients with SAH [100]. Despite the use of norfloxacin, two patients died from infection within three weeks. The levels of IL-6 and IL-8 decreased the day after infliximab administration. At 28 days, bilirubin, DF and C-reactive protein decreased, whereas PT did not change significantly [100]. Bilirubin levels and DF remained stable during 14 days and began to decrease after 21 days [100], suggesting that the effect of infliximab is delayed compared to steroids [87, 100].

To determine its survival impact, an RCT was conducted [86]. However, the first interim analysis was not performed, because of the unbalanced rate of deaths before the planned enrollment of 38 patients [86]. After 36 patients, 7 deaths in the infliximab group and 3 deaths in the steroid group occurred. Two-month survival was lower in the infliximab group than in placebo (61% vs 82%). The frequency of

severe infections increased in the infliximab group compared to placebo. There were no differences in the course of DF [86]. **A1d** Compared to previous studies, the dosage of infliximab varied drastically: a single dose of 5 mg/kg in other studies, three infusions of 10 mg/kg in the French trial. It was felt that high doses were required to inhibit the higher TNF $\alpha$  levels observed in SAH compared to Crohn's disease. This was controversial, because serum TNF $\alpha$  level was not indicative of treatment response [101]. Second, the discrepancies in disease severity between studies may also explain these different results: in the French study, patients with fatal infection had a DF significantly higher than patients without [86].

A recent RCT evaluated etanercept, a soluble extracellular ligand binding portion of the human p75 TNF receptor which binds and neutralizes unbound serum TNF $\alpha$ , in 48 patients with moderate to severe AH (MELD score  $\geq 15$ ) randomized to six injections of either etanercept or placebo. The one-month mortality was similar but the six-month mortality was significantly higher in etanercept than in placebo group (57.7% vs 22.7%). Infectious serious adverse events were significantly more frequent with etanercept group than with placebo (34.6% vs 9.1%). Thus, etanercept is not effective for the treatment of SAH. **A1d**

In summary, the anti-TNF approach is associated with an increased risk of infection and does not seem to be effective with the proposed regimens.

*Antioxidants* The rationale for the use in SAH is that numerous data suggest that oxidative stress is a key mechanism in ALD. Corticosteroids were compared with antioxidants cocktail in an RCT of 101 patients with SAH. At 30 days there were 16 deaths (30%) in the corticosteroid treated group, compared with 22 deaths (46%) in the antioxidant treated group. The odds of dying by 30 days were 2.4 greater for patients on antioxidants (95%; CI: 1.0–5.6) [102]. **A1d** Another study evaluated N-acetylcysteine plus an antioxidant cocktail in patients with SAH, stratified by gender and corticosteroid use, but did not demonstrate any impact of antioxidants [103]. **A1d**

## Liver transplantation

Liver transplantation (LT) is an effective option for end-stage liver disease, leading to survival rates similar in alcoholic and non-alcoholic cirrhosis [104–106]. During the past two decades, the percentage of transplantations performed for ALD patients has increased (20% in the USA and 21% in Europe) [107]. Nevertheless, only 6% of patients at risk of dying from alcoholic cirrhosis receive a LT [108].

## Alcohol-related cirrhosis and survival benefit from LT

Timing of LT is crucial to avoid harm due to intervening too early, and ineffectiveness from transplanting too late.

In patients with alcoholic cirrhosis, the efficacy of LT has been estimated by comparison with matched and simulated non-transplanted controls [73, 109]. Among Child class C, transplanted patients had higher one and five-year survival than matched controls, whereas among Child class A or B, there was no survival difference between transplanted patients and controls [73, 109].

At the present time, MELD score is used to prioritize patients on a LT waiting list [110–112], and it is recommended to list only patients with a MELD score  $\geq 15$  [113]. The MELD score has been validated as a useful prognostic score in patients with a broad spectrum of ALD [114–116].

**Abstinence and LT for ALD** Long-term studies showed that moderately heavy drinking did not impact graft or patient survival [117–120]. Conversely, the effect of drinking is controversial. Initial studies focusing on short-term survival did not observe any survival difference between recipients who resumed heavy drinking and others [119–121]. However, the duration of the follow-up period is critical in assessing the effect of alcohol relapse on survival. Recent studies focused on long-term survival [122, 123]. Recipients who resumed drinking consistent with levels within the range of alcohol abuse showed significantly lower long-term survival than those who were abstinent or those with minor relapses. Analysis revealed that recurrent ALD was responsible for 90% of deaths in recipients with heavy levels of drinking. In summary, abusive drinking after LT worsens long-term survival [123].

The main source of concern about LT in alcoholic patients is the risk of relapse into alcohol abuse after transplantation. A documented period of abstinence is generally considered as a good prognostic indicator. Most programs require a six-month period of abstinence prior to evaluation for LT [124]. The six-month period of abstinence is presumed: (1) to permit some patients to recover and obviate the need for LT; and (2) to identify patients likely to maintain abstinence. Nevertheless, this criterion alone cannot predict relapse and its use alone forced numerous candidates with low risk of relapse to wait for listing [118, 125–130]. ROC curve analysis of the value of pre-transplantation abstinence revealed it was a relatively poor indicator [128]. For patients with mild alcoholism, less than six months' abstention does not significantly affect the risk of relapse, but may exclude patients at low relapse risk from prompt listing and transplantation [125].

One important aspect is the absence of consensus concerning the definition of alcohol relapse [131–134]. For some centers, all drinking is considered a relapse, whereas others have defined heavy drinking, which is the only relapse associated with liver injury, as relapse.

In conclusion, patients with alcoholic cirrhosis benefit from LT. Most of the centers recommend six-month abstinence

before listing the patients. However, this sole criterion is insufficient to predict abstinence after transplantation.

## Introduction

Non-alcoholic fatty liver disease (NAFLD) is increasingly diagnosed worldwide and considered to be the commonest liver disorder in Western countries. It comprises a disease spectrum ranging from simple steatosis (fatty liver), through non-alcoholic steatohepatitis (NASH) to fat with fibrosis and ultimately cirrhosis. Simple steatosis is largely benign and non-progressive, whereas NASH, characterized by hepatocyte injury, inflammation and fibrosis can lead to cirrhosis, liver failure and hepatocellular carcinoma (HCC). NAFLD is strongly associated with obesity, insulin resistance, hypertension and dyslipidemia and is now regarded as the liver manifestation of the metabolic syndrome. Rapid spread of the obesity “pandemic” in adults and children, coupled with the realization that the outcomes of obesity-related liver disease are not entirely benign, has led to rapid growth in clinical and basic studies in NAFLD over the past decade.

## Epidemiology

NAFLD is often an asymptomatic illness in which the liver blood tests may be completely normal. This has made studies on prevalence extremely difficult, with most relying on ultrasound, which is known to be sensitive only when more than one-third of the liver is affected by steatosis. With this proviso the prevalence of NAFLD appears to be around 20–30% in Western adults [1, 2], and 15% in Asians [3]. Due to the lack of prospective studies, the true inci-

dence of NAFLD is not well defined, although from the information available, it appears to be low [4]. Since liver biopsy is the only method of accurately diagnosing steatohepatitis, incidence/prevalence studies of NASH are rare. According to available data, NASH is much rarer than NAFLD, affecting 2–3% of the general population [5]. NAFLD and NASH are strongly associated with the presence and severity of obesity. Studies in severely obese patients (BMI > 35 kg/m<sup>2</sup>) undergoing bariatric surgery have reported prevalences of NAFLD and NASH of 91% and 37% respectively [6], while a large post-mortem study reported NASH to be present in 3% of non-obese, 19% of obese and 50% of a morbidly obese individuals [7]. A recent novel observational study in NAFLD patients has demonstrated that while central obesity correlates with the severity of inflammation, dorsocervical lipohypertrophy correlates with hepatocyte injury, inflammation and fibrosis [8]. Type 2 diabetes mellitus (T2DM) is the other major association of NAFLD, with a prevalence of 70% recently reported from an ultrasound survey of almost 3000 unselected Italian T2DM patients [9, 10]. Even in the absence of obesity and T2DM, NAFLD is closely associated with other features of the metabolic syndrome, with one study of non-diabetics with NAFLD reporting that 18% of normal weight patients and 67% of obese fulfilled criteria for the metabolic syndrome [11].

There are no accurate data regarding temporal changes in the prevalence of NAFLD; however, the rising prevalence of obesity, diabetes and the metabolic syndrome seems likely to be reflected in an increasing prevalence of NAFLD. This trend is of particular concern in the paediatric population where the reported increase in obesity will undoubtedly result in a higher incidence and prevalence of paediatric and adult NAFLD in the future. To date, studies in children have reported a prevalence of NAFLD of 3% in the general paediatric population and 53% in obese children [12, 13]. Reports of toddlers with NAFLD and primary school children with NAFLD-related cirrhosis are clearly a cause for alarm [14].

## Natural history of NAFLD

In marked contrast to alcoholic steatohepatitis, the short-term prognosis of NAFLD is good. The largest prospective histological study of the natural history of NAFLD, with a mean follow-up of 13 years, has recently been published [15]. Data from this and other studies suggest that the long-term hepatic prognosis of patients with NAFLD depends on the histological stage of disease at presentation [16]. Among patients with simple steatosis 12–40% will develop NASH with early fibrosis after 8–13 years. For patients presenting with NASH and early fibrosis, around 15% will develop cirrhosis and/or evidence of hepatic decompensation over the same time-period, increasing to 25% of patients with advanced pre-cirrhotic fibrosis at baseline. In the most recent study, weight gain and the presence of portal tract fibrosis on index biopsy were the only significant predictors of fibrosis progression [15]. About 7% of subjects with compensated cirrhosis associated with NAFLD will develop a hepatocellular carcinoma (HCC) within ten years, while 50% will require a transplant or die from a liver-related cause [17]. The risk of HCC in NAFLD-related cirrhosis is comparable to that in cirrhosis associated with alcohol or hepatitis C [18]. This may partly explain the recently reported associations of HCC with high BMI and T2DM [19]. Liver transplantation is increasingly available to those with chronic liver failure and about 10–12% of liver transplants in the USA are for NAFLD cirrhosis [20]. Unfortunately the condition can recur in transplanted organs. The overall and liver-related mortality of patients with NAFLD is higher than in an age and sex-matched population, with adjusted hazard ratios of 1.038 and 9.32 respectively [21, 22].

## Susceptibility

While the vast majority of individuals with obesity, insulin resistance and the metabolic syndrome will have steatosis, only a minority will ever develop steatohepatitis, fibrosis and cirrhosis. Potential environmental determinants of NAFLD are dietary factors and small bowel bacterial overgrowth [23, 24]. Recent studies have shown that diets high in saturated fat, fructose-containing soft drinks and meat, and low in antioxidants and omega-3 containing fish are associated with an increased risk of NAFLD/NASH [25, 26, 27]. With respect to alcohol intake, while there is no doubt that obesity increases risk of cirrhosis in heavy drinkers [28], emerging evidence suggests that “sensible” light alcohol intake may be protective versus NAFLD/NASH [29, 30], an effect that appears likely to be due to the beneficial effect of light alcohol intake on insulin sensitiv-

ity. Family studies and inter-ethnic variations in susceptibility suggest that genetic factors may be important in determining disease risk. Thus far, only one genetic association with advanced NAFLD has been replicated in an independent population – an association between a functional polymorphism in the gene encoding the tumor suppressor gene Kruppel-like factor 6 and fibrosis [31]. More recently the first genome-wide association study has been performed in patients with proton magnetic resonance spectroscopy (<sup>1</sup>H-MRS) diagnosed NAFLD and found an association between hepatic fat content and genetic variation in the *PNPLA3* gene encoding a protein involved in lipid metabolism [32].

## Disease associations with NAFLD

### Cardiovascular disease

Given the close association between NAFLD and classical cardiovascular risk factors it is perhaps not surprising that, when compared to controls, patients with NAFLD have a higher prevalence of atherosclerosis, as shown by increased carotid wall intimal thickness, increased numbers of atherosclerotic plaques and increased plasma markers of endothelial dysfunction [9, 33, 34]. This association also extends to children, with the prevalence of coronary and aortic atheroma higher in children with fatty liver compared to controls in an autopsy based report [35]. Consistent with these observations three natural history studies have reported that the increased age-related mortality observed in patients with NAFLD is attributable to cardiovascular as well as liver-related deaths [15, 17, 22]. Although an indirect association between NAFLD and cardiovascular disease is expected, a growing body of evidence supports a direct role for NAFLD in the pathogenesis of atheromatous cardiovascular disease. A recent study of unselected patients with T2DM reported that the prevalence of cardiovascular, cerebrovascular and peripheral vascular disease was significantly greater in those with NAFLD than in those without, independent of the individual components of the metabolic syndrome [10]. A similar finding has been observed for microvascular diseases, nephropathy and retinopathy [36]. The mechanism of any direct effect of NAFLD on cardiovascular risk remains unclear; possibilities include the release of atherogenic inflammatory cytokines and pro-coagulant factors from the steatotic liver [37].

### Polycystic ovary syndrome [PCOS]

As with the association between NAFLD and the metabolic syndrome, the now well-established association between

NAFLD and the PCOS seems likely to be indirect as a result of both conditions being characterized by insulin resistance. Up to 30% of females with PCOS have elevated alanine transaminase (ALT) levels [38], and NAFLD prevalence of 42% has been reported in a series of PCOS patients with a mean age of 25 years [39]. More recently, advanced fibrotic liver disease has been reported in patients with PCOS, suggesting that women with this syndrome require careful hepatic evaluation [40].

### Obstructive sleep apnoea

Chronic intermittent hypoxia, as seen in obstructive sleep apnoea (OSA), has been associated with cardiovascular disease, the metabolic syndrome and insulin resistance [41]. As might be expected, therefore, a proportion of patients with OSA have elevated liver enzymes and histological features of NASH independent of body weight [42]. The severity of histology and the associated insulin resistance both correlate with the severity of OSA, strongly implicating insulin resistance as the pathogenic mechanism linking OSA to NASH although not entirely excluding a role for hypoxic liver injury. As with PCOS, this and other similar reports suggest that patients with OSA require hepatic evaluation, and that the diagnosis of OSA should be considered in NAFLD patients reporting daytime somnolence, sleep disturbances or any other symptoms suggesting a diagnosis of OSA.

### Clinical presentation

NAFLD is a largely asymptomatic condition that may reach an advanced stage before it is suspected or diagnosed. Symptoms such as right upper quadrant discomfort, fatigue and lethargy have been reported in up to 50% of patients, but are uncommon modes of presentation. Fatigue is a significant problem in NAFLD patients and associates with objectively measured inactivity, but not histological disease severity [43]. Most patients with NAFLD are diagnosed after they are found to have hepatomegaly, or, more commonly, unexplained abnormalities of liver blood tests performed as part of routine health checks or during drug monitoring (e.g. statin therapy). NAFLD is the commonest cause of incidental abnormal liver blood tests, accounting for between 60–90% of such cases [44, 45]. Importantly, the vast majority (around 80%) of patients with NAFLD have normal liver blood tests [2], and there is no difference in histological severity between those with and without abnormal tests [46]. Accordingly, NAFLD should be suspected and sought in all patients with established risk factors, including PCOS and OSA, regardless of

liver blood tests. The history should concentrate on determining the presence/absence of conditions commonly associated with “primary” NAFLD – metabolic syndrome components, cardiovascular disease and OSA – and on excluding alternative causes of steatosis, including excessive alcohol intake, previous abdominal surgery (leading to bacterial overgrowth) and drugs causing NAFLD, such as amiodarone and tamoxifen. On examination, most patients are centrally obese and dorsocervical lipohypertrophy (a “buffalo hump”) appears to be a particular feature of the fat distribution in patients with advanced NAFLD [8]. Features of PCOS (hyperandrogenism) should be sought in young women with suspected NAFLD [39], and clinical evidence of lipodystrophy should be sought in young, non-obese patients in view of its association with NAFLD [47].

### Investigation

In the absence of advanced disease routine liver blood tests are either normal or typically show mild elevations of transaminases, alkaline phosphatase and gamma glutamyl transpeptidase (GGT) 1.5–3 times the upper limit of normal. The ALT/AST ratio is greater than one unless there is advanced fibrotic NAFLD or the patient is a covert heavy drinker. Other blood tests are aimed at detecting associated conditions, such as dyslipidemia, and excluding alternative causes of abnormal liver blood tests. Regarding lipids, it is worth measuring serum levels of apolipoprotein B (apoB) in patients either with no obvious risk factors for NAFLD or with low levels of LDL and HDL cholesterol, looking for evidence of hypobetalipoproteinemia a rare, familial cause of NAFLD [48]. Serum ferritin is often raised in NAFLD patients [49], and has been associated with advanced fibrosis [50]. *HFE* genotyping should be carried out when hyperferritemia is accompanied by raised transferrin saturation. Autoantibodies associated with autoimmune hepatitis (AIH), including ANA SMA, are often present at low titers in patients with NAFLD and have been associated with more advanced disease in some, but not all studies [51, 52]. Around one in ten of these patients have histological features of autoimmune hepatitis on biopsy and fulfil diagnostic criteria for probable/definite AIH [51]. Currently available imaging modalities including ultrasound, CT and routine MR imaging are all excellent at detecting steatosis (once more than around one-third of the liver is affected) but none can reliably detect NASH or fibrosis [53]. Newer imaging techniques, including proton magnetic resonance spectroscopy [54], and transient elastography [55] show promise (particularly in children [56]), but require further study prior to routine use for disease staging.

## The role of liver biopsy

Undoubtedly the most important and controversial issue to consider in the investigation of patients with suspected NAFLD is whether or not to perform a liver biopsy. For diagnosis, biopsy is not required in a “typical” patient with abnormal liver blood tests, classical risk factors for NAFLD (obesity, T2DM, dyslipidemia) and an ultrasound showing steatosis; however, a high ferritin with *HFE* mutations, positive autoantibodies (ANA, SMA) or the use of medications associated with drug-induced liver injury all may justify a biopsy to exclude alternative/additional diagnoses. The main indication to perform a biopsy is, however, the accurate staging of the disease since (1) different stages have different prognoses and therefore require different management strategies, and (2) no currently available imaging techniques can perform this role [53].

## Non-invasive markers for staging NAFLD

The current reliance on liver biopsy for disease staging has prompted many studies aimed at defining clinical or laboratory-based variables capable of acting as surrogate markers of disease stage [57]. Various clinical and laboratory markers have been shown to be associated with advanced fibrosis (bridging fibrosis or cirrhosis) in patients with NAFLD, notably advanced age (>45 years), BMI > 30 kg/m<sup>2</sup>, central obesity, T2DM (or raised fasting blood glucose), the severity of OSA [42] an AST:ALT ratio greater than one, hyperferritinemia [50] and positive autoantibodies [45]. In patients with normal ALT increased insulin resistance is the best predictor of advanced fibrotic disease [58]. At present, it would seem reasonable to restrict liver biopsy to patients with at least some, if not all, of these risk factors. Some of these markers (age, BMI, T2DM, AST/ALT ratio) have recently been combined together with platelet count and serum albumin concentration, into a NAFLD fibrosis “score” that accurately predicts the presence or absence of advanced fibrosis in the majority of patients with NAFLD [59]. This score has recently been combined with the European Liver Fibrosis (ELF) panel of serum fibrosis markers [60] and shown to have an accuracy of over 90% in differentiating the fibrosis stages in NAFLD [61]. An even simpler score – the **BARD** score – combining **B**MI, **A**ST/ALT **R**atio and **D**iabetes has recently been developed that reliably identifies patients without advanced disease [62]. With respect to the non-invasive diagnosis of NASH rather than fibrosis stage, serum levels of a caspase cleavage product of the hepatocyte protein cytokeratin-18 (a putative marker of hepatocyte apoptosis) have recently been shown to accurately predict the presence of NASH in a small pilot study [63]. Clearly this and other tests and scoring systems require further validation before they can be used in routine clinical practice but they do appear, at

last, to offer real potential to replace the need for liver biopsy in the majority of patients with NAFLD.

---

## Overall management strategy for NAFLD

Almost no large randomized controlled trials (RCTs) have been published on which to establish evidence-based treatment recommendations for NAFLD. Accordingly, current management strategies are directed at treating, where present, the individual components of the metabolic syndrome since this will reduce risk of cardiovascular disease and may also be beneficial for the liver. Alcohol intake should not exceed “sensible” limits, but there is no need to advise complete abstinence, as an emerging body of data suggest that light to moderate intake may actually reduce the risk of NAFLD [29, 30]. In view of their largely benign prognosis these strategies are all that is required for patients with simple steatosis who can be managed by general or primary-care physicians with no requirement for formal hepatological follow-up. In contrast, patients with more advanced NAFLD require long-term follow-up by hepatologists in light of their increased propensity for disease progression and the resulting need for surveillance for complications, including esophageal varices and HCC. These patients will also be candidates either for emerging “second-line” therapies currently being evaluated in large RCTs or for entry into these trials. The rationale for NAFLD therapies is based on a growing understanding of disease pathogenesis, with a particular focus on reducing insulin resistance, hepatic free fatty acid (FFA) levels, oxidative, endoplasmic reticulum and cytokine-mediated stress and influencing the balance and effects of profibrotic, pro-inflammatory and antifibrotic, anti-inflammatory adipokines released from adipose tissue [64]. Current and emerging therapies for NAFLD can be divided into those directed at the metabolic syndrome components with potential liver effects and those directed primarily at the liver.

---

## Treatments directed at components of the metabolic syndrome

### Obesity

Obesity is a rational target for NAFLD therapy since weight loss should reduce many of the putative mediators of liver injury, including insulin resistance, hepatic FFA supply and pro-inflammatory, profibrotic adipokines.

### Diet and exercise

Several small, largely uncontrolled studies have shown an improvement in either ALT or steatosis following diet

(with or without exercise) induced weight loss. **B4** There is very little evidence that necroinflammation or fibrosis can be improved by weight loss alone although a few small case series have shown some improvement in these parameters with drastic weight loss [65]. To date, almost all studies of diet-induced weight loss have employed simple calorie restriction, with very few attempting to manipulate specific dietary components. This area seems worthy of study, since intakes of both saturated fat and fiber are known to influence insulin resistance and diets high in saturated fat, soft drinks and meat, and low in omega 3 containing fish appear to be associated with both NAFLD and NASH. Dietary fat intake has also been shown to correlate with liver fat content and insulin resistance in short-term studies of obese, non-diabetic women – independently of changes in total-body, subcutaneous or abdominal fat [66]. The value of exercise in achieving and maintaining weight loss and improving insulin resistance is well established and thus far the only controlled study of weight loss that has reported histological improvement (steatosis) combined calorie restriction with increased exercise [67].

**B2**

### Pharmacological anti-obesity agents

Encouraging improvements in liver histology have been reported from pilot studies of the intestinal lipase inhibitor orlistat in patients with NASH [68, 69]. However, there is no evidence as yet that this improvement is over and above what would be expected from the resulting weight loss. Nonetheless, data from currently ongoing large RCTs of orlistat are awaited with interest. The cannabinoid receptor 1 (CB<sub>1</sub>) antagonist rimonabant has been shown to be effective in reducing weight and waist circumference, with improvements in several metabolic parameters, including insulin resistance [70]. **A1d** Animal data demonstrating that CB<sub>1</sub> blockade is both anti-steatotic [71] and anti-fibrotic [72] provide strong rationale for drugs directed at the CB<sub>1</sub> receptor in NAFLD. However, their adverse psychological side-effect profile is likely to limit their clinical utility severely.

### Bariatric surgery

Various surgical procedures are currently in use for the treatment of obesity. Biliopancreatic diversion appears to carry a significant risk of liver failure and worsening fibrosis, and should therefore be avoided in patients with NAFLD. However, more encouraging results have been reported for gastric bypass and gastric banding surgery [73, 74]. To date all studies have shown improvements in metabolic parameters and steatosis, with some, but not all, reporting improvements in necroinflammation and fibrosis [73]. **B4**

## Type 2 diabetes mellitus and insulin resistance

Evidence that insulin resistance may contribute to both inflammation and fibrosis in NAFLD has led to several pilot studies of metformin and other insulin-sensitizing agents in patients with NAFLD with and without diabetes. There is as yet no direct evidence of hyperinsulinemia *per se* adversely affecting the liver; however, evidence from animal studies that insulin is a direct cause of both hepatic steatosis and fibrosis might suggest that insulin or sulphonylureas should be avoided if possible [75]. It is of interest, therefore, that a recent pilot study in patients with T2DM has shown that long-term high dose insulin therapy results in a reduction of transaminases and hepatic steatosis, presumably reflecting the beneficial effects of insulin on blood glucose and adipose tissue lipolysis [76]. Whether or not long-term insulin therapy increases fibrosis in patients with NAFLD is, however, as yet unknown.

### Metformin

Pilot studies of metformin in diabetic and non-diabetic patients with NAFLD have shown inconsistent effects on liver blood tests and steatosis (determined by MRI or MR proton spectroscopy). However, the largest RCT to date, in non-diabetic NAFLD patients, has been more encouraging. In this 12-month, randomized open-label trial, metformin treatment (2g/day) was associated with significantly higher rates of normalized aminotransferase levels and with significant decreases in liver fat, necroinflammation and fibrosis, compared with either vitamin E treatment or weight-reducing diet treated patients [77]. The low number of patients who agreed to a second biopsy does, however, limit the strength of the conclusions that can be drawn from this study. **A1d**

### Thiazolidinediones (TZDs)

TZDs act as agonists for the peroxisome proliferator activated receptor- $\gamma$  (PPAR $\gamma$ ). They improve insulin sensitivity, at least in part, via anti-steatotic effects in liver and muscle which may in turn result from an increase in the secretion of the anti-inflammatory, anti-fibrotic adipokine, adiponectin by adipocytes. Moreover, their potential as a therapy for NAFLD is further increased by evidence from animal models that they may also exert direct anti-fibrotic effects in the liver [78]. Pilot studies of the second-generation TZDs, pioglitazone and rosiglitazone, have consistently reported encouraging improvements in insulin sensitivity, liver blood tests and liver histology and several large RCTs are currently in progress. Two placebo-controlled RCTs of pioglitazone in the treatment of patients with NASH have recently reported significant improvements in steatosis, inflammation and ballooning necrosis associated with a non-significant decrease in fibrosis [79, 80]. **A1d** A note of caution over the use of TZDs in the treatment of NASH has

arisen recently as a result of several meta-analyses of trials of TZDs in T2DM patients that have consistently shown that rosiglitazone increases the incidence of myocardial infarction and heart failure [81]. **A1a** The risk of heart failure is also increased by pioglitazone but it is associated with a lower risk of myocardial infarction and stroke compared to placebo-treated patients [82]. **A1d** This is reassuring since a recent study suggests that pioglitazone treatment for NASH has to be continued long term since stopping it led to a worsening of steatosis and inflammation [83]. **B4**

### Dyslipidemia

Hypertriglyceridemia affects 20–80% of patients with NAFLD. As with anti-obesity and insulin-sensitizing drugs, there are sound scientific reasons to support the use of fibrates – the conventional triglyceride-lowering agents – in patients with NAFLD. Fibrates are agonists for the PPAR $\alpha$  receptor, a transcription factor that up-regulates the transcription of genes encoding various proteins that would be expected to reduce hepatic FFA levels and also exerts anti-inflammatory effects. As with many other potential therapies for NAFLD, studies of PPAR $\alpha$  agonists in animal models of NASH have been encouraging [84]. However, the only controlled study in patients with histological follow-up reported that one year of clofibrate had no effect on liver biochemistry or histology [85]. **A1d** There is less rationale for using HMG CoA reductase inhibitors (statins) to treat NAFLD; however, they can be safely prescribed for “conventional” indications, including T2DM and high cardiovascular risk. Importantly, there is no evidence that patients with pre-existing NAFLD are at increased risk of statin-induced idiosyncratic hepatotoxicity, or that statins are associated with a higher frequency of hepatic steatosis or serum ALT abnormalities in these subjects [86].

### Hypertension

No RCTs have specifically examined the effect of different anti-hypertensive agents on the liver in hypertensive patients with NAFLD. However, a growing body of evidence from animal models of hepatic fibrosis and NASH suggests that therapy directed at the renin-angiotensin system and  $\alpha$ -blockers may be beneficial for the liver [87, 88]. As yet, only one pilot study has examined the use of angiotensin II receptor blockade in patients with NASH and showed a reduction in serum markers of fibrosis [89]. Newer angiotensin II receptor blockers with insulin sensitizing effects seem worthy of study in NAFLD [90].

## Treatments directed at the liver

An increased understanding of the mechanisms of progressive liver damage in NAFLD has stimulated the search for

therapies specifically targeting the liver rather than at the individual components of the metabolic syndrome that may have beneficial effects.

### Antioxidants

Several encouraging pilot studies of various agents indicate potential beneficial effects which may be related to their anti-oxidant effects. These include probucol [91], betaine [92], iron depletion through venesection [93], and vitamin E [94]. However, a recent RCT of vitamin E combined with vitamin C in patients with NASH found no overall improvement in hepatic fibrosis score compared with placebo [95]. **A1d**

### Anti-cytokine agents

Beneficial effects of anti-TNF $\alpha$  therapies have been demonstrated in animal models of NASH, and the two pilot studies in patients with NAFLD have reported improvements in aminotransferase levels and histology [96, 97]. Given the emerging importance of pro-inflammatory cytokines in both liver pathology and insulin resistance in obesity, it seems likely that cytokines and their regulatory molecules, including NF- $\kappa$ B, will become major therapeutic targets in both NAFLD and T2DM in the near future.

### Ursodeoxycholic acid (UDCA)

Given its long history as a hepatoprotectant and recent evidence that bile acids may act as molecular chaperones capable of reducing ER stress implicated in NASH pathogenesis it is hardly surprising that UDCA has been considered as a potential treatment for NASH [64, 98]. To date, however, the only large, placebo-controlled RCT in patients with NASH showed no benefit of UDCA (13–15 mg/kg/day) on liver histology after two years' treatment [99]. **A1d** More encouraging results have recently been reported from a study combining UDCA with vitamin E [100].

### Liver transplantation for patients with NAFLD

Patients with NAFLD who progress to decompensated cirrhosis or who develop HCC are candidates for liver transplantation. A favorable outcome depends on removing the factors that originally caused liver damage. Perhaps unsurprisingly, steatosis recurs in most patients within four years, with 50% developing NASH and fibrosis; cases of recurrent cirrhosis are also reported [101, 102]. Risk factors for recurrence are the presence of insulin resistance or T2DM pre and post-transplantation, weight gain following transplantation and a high cumulative steroid dose. These findings highlight the importance of ensuring weight and metabolic control in reducing the risk of disease recur-

rence, in a group of patients who will undoubtedly contribute increasing numbers to transplant programmes in the future.

## Introduction

Hemochromatosis is the most common genetic disease in populations of European ancestry. Despite the estimated prevalence in different countries, ranging from 1 in 100 to 1 in 300, hemochromatosis is still considered by many physicians to be a rare disease. The diagnosis can be difficult because of the non-specific nature of the symptoms. The discovery of the major hemochromatosis gene in 1996 has led to new insights into the pathogenesis of the disease and new diagnostic strategies [1, 2].

---

## Pathogenesis of hemochromatosis

The regulation of dietary iron absorption and intracellular iron homeostasis is controlled by hepcidin, a protein synthesized in the liver and rapidly excreted by the kidneys [3, 4]. Hepcidin binds to ferroportin, a membrane bound iron transporter present on the basolateral surface of enterocytes, and regulates the transfer of dietary iron from the enterocyte cytoplasm into the body in response to body iron requirements. Hepcidin also regulates iron export from macrophages via ferroportin. Decreased levels of hepcidin allows for increased dietary iron absorption and vice versa. Inappropriate decreased levels of hepcidin are present in hemochromatosis and this results in increased dietary iron absorption and iron overload [5, 6]. HFE, transferrin receptor 2 and hemojuvelin are three proteins that have been found to regulate the expression of hepcidin [3, 7, 8]. Mutations in any of these five proteins have been associated with hemochromatosis. The C282Y mutation in HFE was the first to be identified and is the most frequent cause of hemochromatosis [1].

---

## Diagnosis of hemochromatosis

A paradox of genetic hemochromatosis is the observation that the disease is underdiagnosed in the general population, and overdiagnosed in patients with secondary iron overload.

### Underdiagnosis of hemochromatosis

Population studies using genetic testing in patients of northern European ancestry have demonstrated a prevalence of C282Y homozygotes of approximately 1 in 227 [9]. The fact that many physicians consider hemochromatosis to be rare implies either a lack of penetrance of the gene (non-expressing homozygote) or a large number of undiagnosed patients in the community.

Barriers to the diagnosis of hemochromatosis include the lack of symptoms and the non-specific nature of symptoms. An elderly patient who presents with joint pain and diabetes is not often considered to have genetic hemochromatosis. The presenting features vary depending on age and sex but fatigue is the most common complaint. Women are more likely to have fatigue, arthralgia and pigmentation than liver disease [10].

## Diagnostic tests for hemochromatosis

### Serum iron

An elevated serum iron is found in most but not all cases. Serum iron can vary throughout the day and it has been estimated that approximately 5–10% of C282Y homozygotes have a normal serum iron [11].

### Transferrin saturation

The transferrin saturation is the serum iron/total iron binding capacity. The transferrin saturation has a sensitivity of greater than 90% for hemochromatosis in referral studies of iron loaded patients. However, in population studies the sensitivity may be as low as 50% [12, 13]. The

transferrin saturation is often elevated, even in children or young adults with hemochromatosis, before the development of iron overload and a rising ferritin. The threshold to pursue further diagnostic studies has varied from 45% to 62% in previous studies. A lower threshold picks up more patients with hemochromatosis but also leads to more investigations in patients without hemochromatosis. A higher threshold leads to fewer investigations overall, with a greater possibility of missing some patients. These concepts are most relevant when considering population screening. A large population screening study demonstrated wide biological variability in transferrin saturation (see Figure 30.1) and there was no advantage in using fasting blood samples (see Table 30.1) [14].

### Serum ferritin

The relationship between serum ferritin and total body iron stores in hemochromatosis has been clearly established by strong correlations with hepatic iron concentra-

tion and amount of iron removed by venesection [15]. However, serum ferritin can be elevated secondary to chronic inflammation and histiocytic neoplasms and not be associated with increased body iron stores. A major diagnostic dilemma in the past was whether the serum ferritin was related to hemochromatosis or another underlying liver disease such as alcoholic liver disease, chronic viral hepatitis or non-alcoholic steatohepatitis. These difficult cases can now be resolved in the majority by HFE genetic testing. The result of the obesity epidemic in developed countries is that the commonest cause of abnormal LFT and mild elevation in ferritin (300–1000 µg/l) is non-alcoholic fatty liver disease. Large population studies have demonstrated that a mild elevation in ferritin (300–1000 micrograms/l) is very common, and may be related to obesity with NAFLD, regular alcohol consumption or inflammation. These observations have limited the use of serum ferritin as a screening test for hemochromatosis because of the lack of specificity for iron overload. **B4**

**Table 30.1** The use of transferrin saturation as a screening test to detect C282Y homozygotes in a population-based study. There was no advantage to the use of fasting samples (PPV = positive predictive value [14].

Blood test	n	Sensitivity (%)	Specificity (%)	PPV (%)
Fasting TS	31,796	77 (65–86)	93 (92–93)	2.3 (2–3)
Random TS	64,230	75 (67–81)	95 (95–96)	3.5 (3–4)

### Iron removed by venesection

Historically hemochromatosis was diagnosed when symptoms developed in the fifth or sixth decade and patients had significant iron overload at the time of diagnosis. The removal of 500 ml of blood weekly (0.25 g iron) was well tolerated, often for years, without the development of significant anemia. If a patient became anemic (hemoglobin < 100 g/l) after only six venesections, this suggested mild iron overload incompatible with the diagnosis of hereditary hemochromatosis. We now know that these guidelines no longer apply as population and pedigree studies uncover patients in their second and third decade

**Figure 30.1** A comparison of the transferrin saturation at initial screening (random) and at the clinical examination (fasting) in all participants recalled for a clinical exam (• = C282Y homozygotes, o = non-C282Y homozygote, n = 2285). The apparent gap around 40% is related to the requirement of control participants to have a TS between the 25th and 75th percentile (reprinted with permission from the *Am J Med*).

[16]. At our center only 71% of homozygotes would have met the arbitrary criterion that more than 5 g of iron (20 venesections) were removed without anemia [17]. This historical diagnostic criterion for hemochromatosis is no longer relevant in the era of genetic testing. **B4**

### Liver biopsy

Liver biopsy has been the “gold standard” diagnostic test for hemochromatosis, but its use has shifted from a diagnostic tool to staging the degree of fibrosis. The need for liver biopsy seems less apparent in the young asymptomatic patient with a low clinical suspicion of cirrhosis based on history, physical examination and iron studies. Clinical guidelines have been suggested, such as a serum ferritin < 1000 micrograms/l or age < 40 years to reduce the need for liver biopsy [18]. Clinical judgment and assessment of concomitant risk factors (alcohol, viral hepatitis) would be a better guide for the need for liver biopsy than an arbitrary threshold. Most non-cirrhotic patients with hemochromatosis have serum ferritin < 1000 micrograms/l and a normal aspartate transaminase (AST) [19, 20]. Cirrhosis can be predicted non-invasively in C282Y homozygotes if the serum ferritin is >1000 micrograms/l, the platelet count is less than  $200 \times 10^6/l$  and the AST is >40 U/l [21]. The presence of fibrosis can also be assessed using hepatic elastography [22].

Patients with cirrhosis have a 5.5-fold relative risk of death compared with non-cirrhotic hemochromatosis patients [23, 24]. Cirrhotic patients are also at risk of hepatocellular carcinoma. The mean age of cirrhotic patients with hepatocellular carcinoma was 68 years in a Canadian series, but was lower in Italian patients with concomitant viral hepatitis [25]. Although early detection of hepatocellular cancer has been clearly demonstrated by serial ultrasound and  $\alpha$ -fetoprotein determination, curative treatment options remain limited. An elderly cirrhotic patient may not withstand a major resection and the residual cirrhotic liver remains a fertile ground for new tumor development. Organ shortages often preclude the possibility of immediate liver transplantation, although living related adult liver transplantation may improve this situation in the future.

### Hepatic iron concentration and hepatic iron index

The traditional method of assessing iron status by liver biopsy uses the semi-quantitative staining method of Perls. However, when moderate iron overload is present, the degree of iron overload can be difficult to interpret. Iron concentration can be measured using atomic absorption spectrophotometry. This can be done on a piece of paraffin embedded tissue, so special preparation is not required at the time of the biopsy. An advantage of cutting the tissue from the block is that one can be more certain that the tissue assayed is the same as the tissue examined microscopically. The normal reference range for hepatic iron concentration

is 0–35  $\mu\text{mol/g}$  dry weight (<2000 micrograms/g). The hepatic iron index has therefore limited use with the advent of genetic testing. The commentary on liver biopsy reports that a hepatic iron index >1.9 confirms a diagnosis of genetic hemochromatosis should be strongly discouraged.

### Imaging studies of the liver

Magnetic resonance imaging (MRI) can demonstrate moderate to severe iron overload of the liver. The technology is advancing and it is possible that eventually it may become as precise as hepatic iron determination [26, 27]. Proponents of MRI have emphasized the non-invasive nature of the test for the diagnosis and alleviated need for liver biopsy. As previously discussed, the role of liver biopsy has now shifted from a diagnostic tool to a prognostic tool. It is likely that the presence of an elevated ferritin with a positive genetic test will satisfy the non-invasive clinician more than an MRI study. MRI can also demonstrate the clinical features of cirrhosis such as nodularity of the liver, ascites, portal hypertension and splenomegaly as well as hepatocellular carcinoma. These features can be more readily assessed by abdominal ultrasound at a lower cost.

### Genetic testing for hemochromatosis

A major advance, which stems from the discovery of the HFE gene, is the diagnostic genetic test. The original publication reported that 83% of a group of patients with suspected hemochromatosis had the characteristic C282Y mutation of the HFE gene. In this report, the gene was called HLA-H but this name was later changed to HFE [1]. The C282Y mutation is also reported as 845A in some laboratories, reflecting the base pair change rather than the amino acid change. Subsequent studies in well-defined hemochromatosis pedigrees reported that 90–100% of typical hemochromatosis patients had the C282Y mutation [28]. The presence of a single mutation in most patients was in marked contrast to other genetic diseases in which multiple mutations have been discovered (cystic fibrosis, Wilson's disease,  $\alpha$ -1-antitrypsin deficiency). A second minor mutation, H63D, was also described in the original report [1]. This mutation does not cause the same intracellular trafficking defect of the HFE protein and many homozygotes for H63D have been found without iron overload in the general population. Compound heterozygotes (C282Y/H63D) and H63D homozygotes (H63D/H63D) may resemble homozygotes with mild to moderate iron overload, particularly if a co-factor is present, for example NAFLD, HCV, or alcohol. However, these compound heterozygote (C282Y/H63D) patients usually have normal iron studies [9, 29].

The interpretation of the genetic test in several settings is shown in Box 30.1. The test may also be performed on DNA extracted from paraffin embedded tissue such as

**BOX 30.1** Interpretation of C282Y, genetic testing for hemochromatosis

**C282Y homozygote:** This is the classic genetic pattern that is seen in >90% of typical cases. Expression of disease ranges from no evidence of iron overload to massive iron overload with organ dysfunction. Siblings have a one in four chance of being affected and should have genetic testing. For children to be affected the other parent must be at least a heterozygote. If iron studies are normal, false positive genetic testing or a non-expressing homozygote should be considered.

**C282Y/H63D (compound heterozygote):** This patient carries one copy of the major mutation and one copy of the minor mutation. Most patients with this genetic pattern have normal iron studies. A small percentage of compound heterozygotes have been found to have mild to moderate iron overload. Severe iron overload is usually seen in the setting of another concomitant risk factor (alcoholism, viral hepatitis, NAFLD).

**C282Y heterozygote:** This patient carries one copy of the major mutation. This pattern is seen in about 10% of the Caucasian population and is usually associated with normal or mildly increased iron studies. In rare cases the iron studies are high in the range expected in a homozygote rather than a heterozygote. These cases may carry an unknown hemochromatosis mutation and measurement of body iron stores is helpful to determine the need for venesection therapy.

**H63D homozygote:** This patient carries two copies of the minor mutation. Most patients with this genetic pattern have normal iron studies. A small percentage of these cases have been found to have mild to moderate iron overload. Severe iron overload is usually seen in the setting of another concomitant risk factor (alcoholism, or viral hepatitis).

**H63D heterozygote:** This patient carries one copy of the minor mutation. This pattern is seen in about 20% of the Caucasian population and is usually associated with normal iron studies. This pattern is so common in the general population that the presence of iron overload may be related to another risk factor. Liver biopsy may be required to determine the cause of the iron overload and the need for treatment in these cases.

**No HFE mutations:** There are currently some newly recognized mutations associated with iron overload that are

being studied in research laboratories (ferroportin, transferrin receptor 2, hepcidin, hemojuvelin). There will likely be other hemochromatosis mutations discovered in the future. If iron overload is present without any HFE mutations, a careful history for other risk factors must be reviewed and liver biopsy may be useful to determine the cause of the iron overload and the need for treatment. Many of these cases are isolated, non-familial cases.

**Non-expressing C282Y homozygotes:** As genetic testing becomes more widespread an increasing number of persons have been found with the hemochromatosis gene without iron overload. Large-scale population studies in North America and northern Europe have demonstrated that approximately 50% of C282Y homozygous women and 86% of homozygous men will have an elevated ferritin. It is apparent that the prevalence of HFE mutations far exceeds the prevalence of biochemical iron overload and clinical symptoms attributable to hemochromatosis. Patients who are homozygous for the C282Y mutation should be considered at risk of developing iron overload, but if there are no abnormalities in transferrin saturation or ferritin in adulthood, it seems more likely that they are non-expressing homozygotes rather than patients who will develop iron overload later in life [36].

**Family studies in hemochromatosis:** Once the proband case is identified and confirmed with genetic testing for the C282Y mutation, family testing is imperative. Siblings have a one in four chance of carrying the gene and should be screened with the genetic test and serum ferritin. The risk to a child is dependent on the prevalence of heterozygotes in the community and is approximately 1 in 20 and much lower if the spouse is non-Caucasian. A cost-effective strategy now possible with the genetic test is to test the spouse for the C282Y mutation to assess the risk in the children. If the spouse is not a heterozygote or homozygote, the children will be obligate heterozygotes. This assumes paternity and no other gene or mutation causing hemochromatosis. This strategy is particularly advantageous where the children are geographically separated or may be under a different physician or health care system [37]. Genetic testing in general raises many perplexing questions, such as premarital testing, *in utero* testing, and paternity issues, which have not yet been tested in hemochromatosis.

liver explants. Studies of explanted livers have demonstrated that many liver transplant patients classified as hemochromatosis patients are negative for the C282Y mutation [30]. This suggests that those patients may have had iron overload secondary to chronic liver disease rather than hemochromatosis. Therefore any interpretation of iron reaccumulation post liver transplant for hemochromatosis must be done with caution and with the benefit of genetic testing.

Genetic discrimination has been a concern with the widespread use of genetic testing. A positive genetic test even without iron overload could disqualify a patient for health or life insurance. In the case of hemochromatosis, the advantages of early diagnosis of a treatable disease outweigh the disadvantages of genetic discrimination. Recent population studies have demonstrated that genetic discrimination is rare with hemochromatosis genetic testing [31].

*Genotypic-phenotypic correlation in hemochromatosis* If we define the presence of homozygosity for the C282Y mutation as a predisposition for the development of hemochromatosis, it provides for the first time a benchmark for the assessment of the phenotypic diagnostic tools that have been used for decades. In one study transferrin saturation, ferritin, hepatic iron index and iron removed by venesection were evaluated in *referred* putative homozygotes with a high pre-test probability of hemochromatosis. Ninety-five percent (122/128) patients were homozygous for the C282Y mutation. The hepatic iron index was >1.9 in 91.3% of these cases, transferrin saturation >55% in 90%, serum ferritin >300 micrograms/l in 96% of men and >200 micrograms/l in 97% of women, and iron removed >5g in 70% of men and 73% of women. Four homozygotes for C282Y had no biochemical evidence of iron overload. The sensitivity of the phenotypic tests in decreasing order was: serum ferritin, hepatic iron index, transferrin saturation and iron removed by venesection. Although the genetic test is useful in the diagnostic algorithm (see Figure 30.3), this study demonstrated both iron loaded patients without the mutation and homozygous patients without iron overload [17].

However, population-based studies have revealed a different clinical profile for C282Y homozygotes. It appears that many C282Y homozygotes will have no obvious symptoms related to iron overload and that 50% of women and 20% of men will have normal serum ferritin [1]. The biochemical clinical expression of hemochromatosis is illustrated in screening studies in Figure 30.2. The prevalence of signs and symptoms of hemochromatosis is more difficult to assess since there are not standardized criteria for their assessment. A recent study by Allen *et al.* suggested that 28% of male and 1% of female C282Y homozygotes from a population screening study had hemochromatosis related symptoms [32, 33]. A screening

study from Norway which utilized 149 liver biopsies, demonstrated cirrhosis in 4% of male and in none of the female C282Y homozygotes [12]. Only the presence of liver disease was significantly different between C282Y homozygotes and a control population in a screening study from San Diego, California [34]. Several studies have demonstrated that there is no increase in diabetes compared to control participants [1, 34, 35].

If an isolated heterozygote is detected by genetic testing, it is recommended to test siblings. Extended family studies are less revealing than a family study with a homozygote but more likely to uncover a homozygote than random population screening.

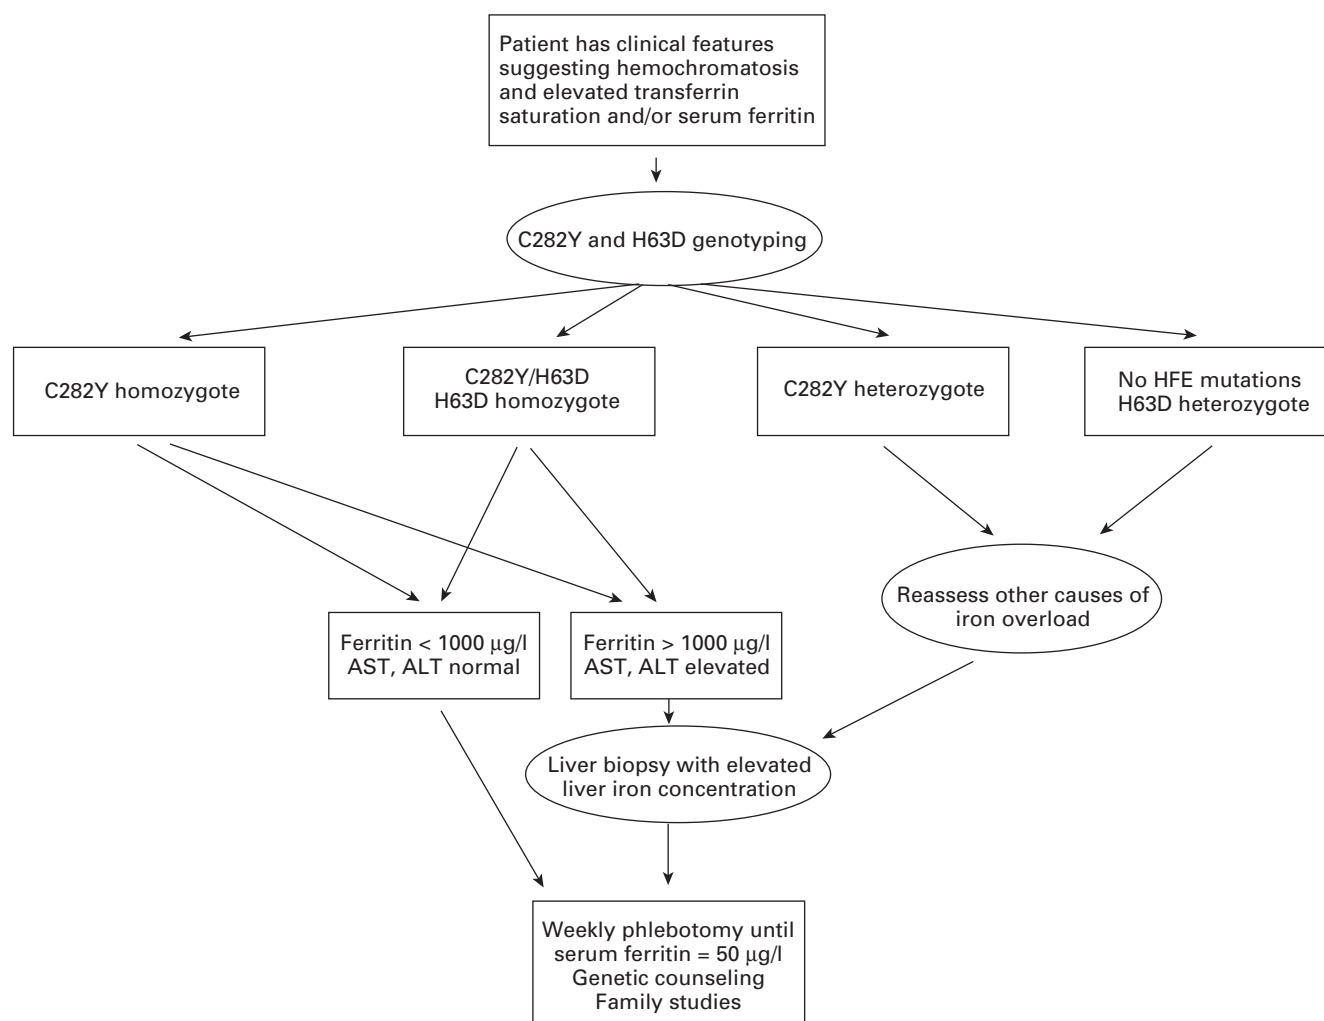

It is important to remember that there will be patients with a clinical picture indistinguishable from genetic hemochromatosis who will be negative for the C282Y mutation. Most of these patients will be isolated cases, although a few cases of familial iron overload (ferroportin, transferrin receptor 2 and hepcidin mutations) have been reported with negative C282Y testing [38]. A negative C282Y test should alert the physician to question the diagnosis of genetic hemochromatosis and reconsider secondary iron overload related to cirrhosis, alcohol, viral hepatitis, NAFLD or iron loading anemias. If no other risk factors are found, the patient should begin venesection treatment similar to any other hemochromatosis patient.

## Population screening

Soon after the development of the genetic test for hemochromatosis, it seemed that hemochromatosis would be an ideal disease for population screening. It seemed to have a high prevalence, could be detected with low-cost iron tests, confirmed by a specific genetic test and could easily be treated. Hemochromatosis meets many of the guidelines

**Figure 30.2** The percentage of C282Y homozygotes discovered in population screening studies that have an elevated serum ferritin (>200 ug/l in women, >300 ug/l in men).

established by the World Health Organization for screening (see Table 30.2). Large population screening studies have been done in North America, Europe and Australia using a variety of approaches and patient populations. A common finding is that there appear to be more genetic mutations than clinical illness. The natural history of untreated disease is the Achilles heel of screening for hemochromatosis. If the survival in untreated patients appears similar to control participants or treated patients, there is little rationale for identifying patients in the general population. Several epidemiological studies performed genetic testing for hemochromatosis many years after the initiation of the study and presented data on the serum ferritin and long-term survival of C282Y homozygotes and other genotypes that were followed for up to 25 years without treatment or awareness of their underlying condition (see Figure 30.4) [33, 39, 40]. A similar longitudinal study in type 2 diabetes found that there was no associa-

tion of HFE mutations or ferritin levels with all cause mortality or cardiovascular complications [41].

Universal screening is unlikely to be widely implemented, but selective screening in high-risk populations, such as men of northern European ancestry may be a preferred strategy. Other strategies include more intense physician and patient education about iron overload and extended pedigree studies. Screening patients with established causes of liver disease (e.g. HCV, HBV, autoimmune liver disease, etc.) for hemochromatosis is important as this will identify another co-factors causing liver damage and potentially fibrosis that is treatable.

### Treatment of hemochromatosis

Patients are initially treated by the weekly removal of 500ml of blood. Patients attend either a blood transfusion

**Table 30.2** Population screening for hemochromatosis.

WHO criteria for screening for medical disease	Phenotypic testing (serum iron, transferrin saturation, UIBC, ferritin)	Genotypic testing (C282Y mutation)
Is the disease an important health problem?	Yes (1 in 300)	Yes (1 in 200)
Is there an effective treatment?	Yes	Yes
Are there facilities for diagnosis and treatment?	Yes	Yes
Is there a presymptomatic stage?	Yes	Yes
Is the cost of screening reasonable?	Yes	If limited to few mutations
Is continuous case finding on an ongoing basis feasible?	Yes	Yes
Is there a suitable test?	Yes	Yes
Is the testing acceptable to the population?	Yes	Genetic discrimination?
Is the natural history of disease understood?	Natural history of untreated disease has not been well studied	Uncertain in non-expressing homozygotes
Is there agreement on whom to treat?	Yes, but the impact of treatment is difficult to assess	Yes

WHO; World Health Organization; UIBC: unsaturated iron binding capacity.

**Figure 30.4** The long-term survival in C282Y homozygotes (C282Y/C282Y) was not significantly different from patients with all of the other HFE genotypes in the ARIC study.

service, where red cells and plasma are used for transfusion, or an ambulatory care facility. The venesection is carried out by a nurse using a kit containing a 16-gauge straight needle and collection bag. Blood is removed with the patient lying flat over 15–30 minutes. A haemoglobin test is done at the time of each venesection. If the haemoglobin decreases to less than 100 g/l the venesection schedule is modified to 500 ml every other week. Serum ferritin is measured periodically (every three months in severe iron overload, monthly in mild iron overload) and weekly ven-

esections are continued until the serum ferritin is approximately 50 micrograms/l. Transferrin saturation often remains elevated despite therapy. Patients may then begin maintenance venesections three to four times per year. Iron reaccumulation is an inconsistent observation and many patients will go for years without treatment and without a rise in serum ferritin [41]. Chelation therapy is not commonly used for the treatment of hereditary hemochromatosis. The newest oral iron chelator, deferasirox, has been undergoing a clinical trial in hemochromatosis but its high

cost and potential side effects (GI side effects, elevation in serum creatinine) may limit its use to secondary iron overload.

There have been some studies, now, documenting reversal of fibrosis following iron depletion therapy [42, 43].

There are no randomized trials comparing venesection therapy to no treatment. Iron depletion before the development of cirrhosis can prevent cirrhosis and the development of hepatocellular carcinoma. Other disabling diseases such as arthritis, diabetes and impotence will likely be prevented. Therefore the goal is early detection and treatment before the development of cirrhosis.

### Introduction

Wilson's disease (WD) is a rare autosomal recessive genetic disorder of copper metabolism. Mutations in the copper transporter ATP7B result in the accumulation of copper in the liver because excretion in bile is defective. Accumulation of copper in the body results in tissue damage which particularly affects the liver and brain so that patients present with either hepatic and/or neurological disease. The prevalence of Wilson's disease is between 1:30,000 and 1:100,000. It was first described as a clinical syndrome in 1912 by Dr Kinnier Wilson. Until the development of oral copper chelators in the 1950s by Dr John Walshe, WD was uniformly fatal. In the majority of patients treatment halts disease progression and allows reversal of organ dysfunction, such that patients, although needing lifelong treatment, usually return to a normal life.

The understanding of the molecular genetics, cellular biology and pathogenesis of WD has advanced over the last twenty years. However, there is still a lack of universal consensus on the optimal treatment regimen, which by implication means that several are effective. There are very few randomized or comparative studies of therapy and current recommendations are based predominantly on observational data published over the last 50 years.

There is no single diagnostic test and evidence-based examination of the diagnostic approach shows that a combination of features is best used. Certain features allow a confident straightforward diagnosis of WD; ruling out WD (particularly in those with liver disease) may be challenging. Clinical issues include delayed diagnosis and deterioration during treatment.

### Physiological copper metabolism

Around 40% of dietary copper (intake being approximately 2–5 mg/day) is absorbed in the duodenum and upper jejunum. Absorbed copper passes in the portal vein to the liver. The copper is taken up across the sinusoidal aspect of the hepatocyte via the copper transporter 1 (CTR1) (Figure 31.1). This transporter is essential for healthy development and is thought to be the main mammalian process for the uptake of copper into cells [1]. Copper is potentially toxic in the cytoplasm; glutathione and metallothioneins are thought to bind copper, rendering it non-toxic. Another protein (ATOX1) is thought to deliver copper to ATP7B by a copper-dependent protein – protein interaction [2]. ATP7B transports copper into the trans-Golgi where it is incorporated into apoceruloplasmin to produce holoceruloplasmin.

When hepatic copper levels are high, ATP7B is expressed in cytoplasmic vesicles, allowing excretion of copper into bile. This process involves COMMD1 (previously called MURR1), a protein which interacts directly with ATP7B [3]. Copper toxicosis of Bedlington Terriers, where there is deficient biliary copper excretion, is a result of mutations in COMMD1 [3]. Studies in non-Wilsonian copper storage disorders in humans have, to date, shown no abnormality in this protein [4].

The evidence for the normal function of ATP7B is based on studies of the trafficking of this protein between different cellular compartments in response to the concentration of copper [5]. In HepG2 hepatoma cells cultured in medium with a low copper concentration ATP7B localized to the trans-Golgi network. With increased levels of copper there is redistribution of ATP7B to vesicles and thence to vacuoles. Immunohistochemical studies on human liver demonstrate punctuate immunoreactivity within the cell and localization also to the apical membrane adjacent to the bile canaliculus [6]. When the intracellular copper concentration is low or normal, ATP7B is found in the trans-Golgi

**Figure 31.1** Pathways of copper metabolism in the hepatocyte. See text for explanation (Cu=copper, CTR1=copper transporter1. MT=metallothioneins. GSH=glutathione. Cp=ceruloplasmin.) (reproduced with permission from Ala et al, *Lancet* 2007; **369**: 397–408)

network described above. With excess intracellular copper the ATP7B moves towards the canalicular pole of the hepatocyte.

Ceruloplasmin (Cp) is a member of the multi copper oxidase family of enzymes. It is also an acute phase protein. Cp itself is not essential for normal copper metabolism; it is for iron metabolism in which it is an important ferroxidase. It seems likely that the reason for the low Cp in WD is not the lack of hepatic expression of apoceruloplasmin (due to a low copper in the secretory pathway) but the change in the proportion of apo- to holoceruloplasmin in the circulation and the lower stability of apoceruloplasmin [7].

## Molecular pathogenesis

In WD there are mutations in the ATP7B gene. This gene was identified by three groups in 1993 [8–11].

The ATP7B gene is highly expressed in the liver, kidney and placenta. It encodes a transmembrane ATPase which is a copper-dependent P type ATPase.

Mutations in ATP7B are associated with lack of entry of copper into bile and into the Golgi. This leads to hepatic copper accumulation which, depending on its severity, leads to hepatic and neurological features of WD.

Mutations within the ATP7B gene variously affect the function of the ATP7B protein. The H1069Q mutation (which results in histidine to glutamate substitution at amino acid 1069) is the most common mutation found in patients of European origin. Studies on liver tissue from patients homozygous for this mutation with WD show that the ATP7B resided in the endoplasmic reticulum rather than the trans-Golgi network [12]. This mutation is associ-

ated with defective phosphorylation of ATP7B by adenosine triphosphate (ATP). This finding parallels the fact that the histidine 1069 is in a conserved motif within the ATP binding domain of ATP7B [13].

Techniques are now available for the analysis of various ATP7B mutations and show their effect on copper transport activity [14].

## Molecular genetics

### Phenotype/genotype relationship

Over 400 disease-related mutations in the ATP7B have been reported in WD ([www.wilsonsdisease.med.ualberta.ca/database.aspdatabase](http://www.wilsonsdisease.med.ualberta.ca/database.aspdatabase)). Most patients are compound heterozygotes. This makes phenotype/genotype correlation problematic.

In some populations, particular mutations predominate [15]. Because of this, screening of specific mutations may be fruitful. Thus, around 50–80% of patients with WD from Central, Eastern and Northern Europe carry at least one allele with the H1069Q mutation [15]. There is a wide range of mutations in the Mediterranean region and their frequency varies between different countries. In some countries, for example Sardinia and Spain, other particular mutations are common.

Studies of genotype/phenotype correlations of WD have been more made difficult by the large number of mutations that exist. Because of the prominence of the H1069Q mutation this has received most attention. Homozygosity for this mutation has been reported to correlate with late onset neurological disease in individual studies and in a meta-analysis [16]. There have been studies of genotype/phenotype associations with mutations in other genes but there is as yet no clinically applicable result [17].

### Family screening using genetics

Family screening for WD is covered later in this chapter. Clinical and biochemical tests should be done, but molecular genetics with identification of mutations is an invaluable tool. If both mutations are known in the index patient with WD, testing of indeterminate siblings for the same mutations will define whether or not they are either affected, heterozygote carriers or normal.

## Clinical manifestations

The clinical spectrum of manifestations of Wilson's disease is wide (Table 31.1). Patients can present acutely with liver failure, hemolysis or both. They may also present with chronic liver disease or neuro-psychiatric problems or a

combination of the two. Patients who present initially with neurological or psychiatric features tend to be older than those who present with clinical manifestations of liver disease or hepatic decompensation.

Classically, WD is recognized as presenting most often in children and young adults, and indeed it had been considered that it did not occur in individuals aged more than 40 years. However, it is now recognized that later presentation does occur, with a recent report of neurological presentation in a group aged 40–52, and hepatic presentation at up to 58 years of age [18]. This emphasizes the need to have WD within the differential diagnosis of patients with unexplained liver disease and particular neurological symptoms presenting anywhere from teenage years to the fifth decade, and beyond.

Most patients with central nervous system involvement are believed to have liver disease at the time of presentation but they may not be symptomatic from their liver disease. However, hepatic histology is not generally available for these patients because the diagnosis is usually established solely on the basis of the presence of Kayser Fleischer rings with a decreased ceruloplasmin concentration.

It is generally the case that those presenting with acute liver disease, even in the younger age group, already have cirrhosis. Deterioration at this stage appears to be based upon the toxic effect of free copper causing decompensation of liver disease [19], or hemolysis [20].

## Hepatic disease

### Pathology

In the early stages of the disease, diffuse cytoplasmic copper accumulation can only be seen with special immunological stains detecting copper. These are not routinely available. The early accumulation of cytoplasmic copper is associated with macrosteatosis, microsteatosis and glycogenated nuclei.

Ultra structural abnormalities (on electron microscopy) include enlargement and separation of the mitochondrial inner and outer membranes, with widening of the inter-crystal spaces, to increases in the density of granularity of the matrix, or presence of larger vacuoles. In the absence of cholestasis, these changes are regarded as pathognomonic of Wilson's disease.

These initial stages of WD progress to an intermediate stage which is characterized by periportal inflammation, mononuclear cellular infiltrates, erosion of the limiting plate, lobular necrosis and bridging fibrosis. These features may be indistinguishable from those of an autoimmune hepatitis [21, 22]. Mallory bodies are seen in up to 50% of liver biopsy specimens [23]. Cirrhosis almost invariably follows with either a micro-nodular or mixed macro-micro nodular pattern.

In patients with fulminant hepatic failure, parenchymal apoptosis, necrosis and collapse may be prominent, often, as already mentioned, on a background of cirrhosis [24]. One series of results of liver biopsy in WD showed cirrhosis in 54% of 83 patients with a hepatic presentation, and 41% in 34 with a neurological presentation [25].

Confirmation of excess copper histologically (rhodanine, rubeanic acid) may be helpful in diagnosis but if absent does not exclude Wilson's disease. The lack of immunoreactivity to copper binding protein (orcein stain) may occur because of the diffuse presence of copper in the cytoplasm and because of the stain's low sensitivity.

### Clinical features

Wilson's disease can present as fulminant hepatic failure. There is worsening coagulopathy and encephalopathy. There may be an associated Coombs' negative hemolytic anemia, when there is a substantial increase in serum total and free copper as well as a high urinary copper concentra-

tion. This complication is recognized as potentially leading to renal failure. Around 5% of patients present in this manner [26], with most patients being in the second decade of life, when KF rings may not yet be formed. Almost all such patients already have cirrhosis, although some might show evidence of massive necrosis with only bridging fibrosis, which clearly would progress to cirrhosis with time. Concentration of serum alkaline phosphatase is frequently low and this feature has led to the suggestion that a ratio of alkaline phosphatase concentration (in IU/L) to serum bilirubin concentration (mg/dl) is diagnostically useful. A ratio of less than 2 [27, 28] or 4 [29], may be diagnostic or very suggestive of Wilsonian fulminant hepatic disease.

In those with a more chronic hepatic presentation, the clinical picture can be similar to other forms of chronic hepatitis, which, as already noted, emphasizes the need for WD to be in the differential diagnosis of such patients.

Some patients present with an asymptomatic cirrhosis. These would have the usual clinical features, including spider nevi, splenomegaly, portal hypertension and ascites. Cirrhosis may be well compensated.

Hepatocellular carcinoma is very rarely associated with Wilson's disease, but as in other causes of cirrhosis it may occur [30, 31]. In a series of 11 patients reported (from a total cohort of 363) there were cholangiocarcinomas (three cases) and malignancies of uncertain origin (three cases) as well as three hepatocellular carcinomas [30].

If neurological features occur in patients with liver disease, they usually do so 2–5 years later [32].

## Eye changes

The classic finding in patients with WD is the Kayser Fleischer (KF) ring. KF rings are caused by the granular deposition of copper on the inner surface of the cornea in Descemet's membrane. They are most apparent at the periphery of the cornea. The upper pole is affected first. Although sometimes visible to the naked eye as a golden-brown ring on the periphery of the cornea, slit lamp examination by an experienced ophthalmologist is necessary to confirm the presence or absence of KF rings. Appearances indistinguishable from KF rings have also been seen in other forms of chronic liver disease, in particular chronic cholestasis, and cryptogenic cirrhosis [33].

Sunflower cataracts, also only visible by slit lamp examination, are brilliantly multi-coloured [34]. Interestingly, they do not impair vision.

Both of these findings disappear with successful medical therapy or after liver transplantation. The re-appearance in "the medically treated" patient suggests non-compliance with therapy [35].

Other less common ophthalmological findings include night blindness, exotropic strabismus, optic neuritis and optic disc pallor.

## Neurological and neuro-psychiatric disease

### Pathology

Histologically, there is an increase in astrocytes in the grey matter, associated with swollen glia, liquefaction, and appearances of spongiform degeneration. Neuronal loss is often accompanied by gliosis and active glial fibrillary protein. The characteristic astrocytes are Alzheimer type I and type II cells. Opalski cells are distinctive for WD [36]. These cells are thought to be derived from degenerating astrocytes [37].

### Clinical features

Neuropsychiatric signs are present in 40–50% of patients with WD [26].

The neurological changes have been classified as: (1) an akinetic-rigid syndrome similar to Parkinson's disease; (2) pseudosclerosis dominated by a tremor; (3) ataxia; and (4) a dystonic syndrome [38].

Subtle changes can appear before the characteristic neurological features. These include changes in behavior, deterioration of schoolwork or an inability to carry out activities that require good hand-eye coordination. There may be deterioration of hand writing and consequent micrographia – as in Parkinson's disease. Other neurological features include tremor, plasticity, lack of motor coordination, dysarthria, drooling and dystonia. Seizures, migraine, headaches and insomnia have also been reported. As well as behavioral changes already described, depression, anxiety and frank psychosis are seen [39].

Cognitive dysfunction in patients with WD may be present with neurological changes, often in the absence of detectable cortical changes or hepatic encephalopathy. This lends support to pathological changes of basal ganglia as being the primary cause in WD of cognitive deficit [40].

All patients with WD should have a neurological examination. Patients with obvious symptoms or signs need to be seen by a neurologist, preferably with a special interest in movement disorders, before treatment. A specific assessment tool with neurological features (based on that for Huntington's disease) has been used in clinical trials to assess patients [41]. However, a new Unified Wilson's Disease Rating Scale (UWDRS) has value in assessing disease severity [42].

### Imaging

Structural brain MRI for WD has shown widespread lesions in the putamen, globus pallidus, caudate, thalamus, mid brain, pons and cerebellum as well as cortical atrophy and

white matter changes. Broadly, these lesions show high signal intensity on T2 weighted images and low intensity on T1 scanning [43]. These changes tend to be more severe and widespread in patients with neurological WD [44], although MRI changes may be present in those without neurological symptoms or signs.

## Other clinical changes

There may be bone and peri-articular abnormalities, including osteomalacia, osteoporosis, spontaneous fractures, adult rickets, osteoarthritis, osteochondritis dissecans, chondrocalcinosis, subchondrial cyst formation and azure lunulae of the fingernails. The most common sites for skeletal and articular abnormalities are the knee joints and spine [45]. Myocardial copper accumulation can cause cardiomyopathy and arrhythmias although these are clinically rare [46].

Other rare extra hepatic/neural manifestations include hypoparathyroidism, infertility, repeated miscarriages [47] and renal abnormalities [48], including renal tubular acidosis with aminoaciduria and nephrocalcinosis.

## Diagnostic approach

Certain tests are essential when the possibility of WD has been raised. No single one of these on its own has 100% specificity or sensitivity for WD. A combination of features is necessary for a definitive diagnosis to be made [49].

The important observations or biochemical measurements used in the work-up of patients with suspected WD are: serum ceruloplasmin, serum total and free copper, ophthalmological examination (for KF rings); 24-hour urine excretion of copper, and measurement of liver copper content. One might add to this the presence of two mutations found on molecular analysis of the ATP7B gene, but since some of these may be polymorphisms caution is needed in making a diagnosis based on molecular analysis alone.

Other useful measures include: (1) urinary excretion of copper after penicillamine challenge (this test has been described and validated in the pediatric age group) [50]; (2) the presence of rhodamine staining on liver biopsy histology, if hepatic copper measurement has not been done.

There are potential problems with all the observations and measurements described above. Serum ceruloplasmin concentrations are well recognized to be normal in a proportion of patients presenting particularly with hepatic WD [51]. Urinary copper excretion can be increased in some other types of liver disease. The same is true for liver copper concentration, particularly in cholestatic disease.

However, if an individual with neurological symptoms consistent with Wilson's disease has Kayser Fleischer rings and a low serum ceruloplasmin concentration, the diagnosis is made. Kayser Fleischer rings are usually present in patients presenting with neurological Wilson's disease – 18 of 20 patients in one report [51].

In patients presenting with liver disease, diagnosis can be more difficult [51]. Roberts and Schilsky [49] have provided several valuable algorithms for the diagnostic approach for patients with different initial features suggesting WD. They provide specific recommendations on the basis of previous published work and the authors' experience in caring for pediatric and adult patients with WD.

To provide further help with the diagnostic route, Ferenci *et al.* [52] have proposed a scoring system (Table 31.2). Within this, clinical, biochemical, histological and molecular genetic data are allocated a score. The cumulative total gives an indication of the possibility of a particular individual having WD. This scoring system may be helpful if diagnosis of the disease is being considered [53]. The recent report of a group of pediatric patients as part of the analysis of the Euro Wilson's Group of patients gives some information on this scoring system [54].

## Liver function tests

Serum aminotransferase activity is in general abnormal in WD except at a very early stage. The rise in aminotransferase activity is often mild and does not necessarily reflect the severity of liver disease.

The ratio of alkaline phosphatase to serum bilirubin in mg/dl has already been discussed. This may be valuable in raising the possibility of WD in patients with fulminant hepatic failure but again is not 100% specific and may only be valuable in particular patient groups [55].

## Ceruloplasmin

A low serum ceruloplasmin concentration (normal range 0.2–0.5 g/l) should raise the question as to whether WD is a possible diagnosis. However, it should be emphasized that many patients presenting to a hepatology clinic can have a low ceruloplasmin, but in only a small fraction is WD diagnosed [56].

On the other hand, a low ceruloplasmin may be found in hypoproteinemic states due, for example, to the nephrotic syndrome, in copper deficient states (due to malabsorption) and in inherited diseases such as aceruloplasminemia [57]. In the latter two situations, the serum ceruloplasmin may be so low as to be undetectable by laboratory methods.

A normal serum ceruloplasmin in WD patients presenting with active liver disease is interpreted as due to an

**Table 31.2** Proposed scoring system for diagnosis of Wilson's disease (from Ferenci et al, 2003; ref 52).

	Score
<b>Clinical</b>	
Kayser Fleischer rings (slit lamp exam)	
present	2
absent	0
Neuropsychiatric symptoms suggestive of WD (or typical MRI features)	
present	2
absent	0
Coombs' negative haemolytic anemia (plus high serum copper)	
present	1
absent	0
<b>Laboratory results</b>	
Urinary copper (in absence of acute hepatitis)	
normal	0
1–2x upper limit normal	1
>2x upper limit normal	2
normal but > 5x normal after D-penicillamine challenge (2x 0.5 gm)	2
Liver copper concentration	
normal	–1
up to 5x upper limit normal	1
>5x upper limit normal	2
Rhodanine positive hepatocytes (only if quantitative Cu measurement not available)	
absent	0
present	1
Serum ceruloplasmin (nephelometric assay normal > 20 mg/dl)	
Normal	0
10–20	1
<10	2
<b>Mutation analysis</b>	
Disease causing mutations	
on both chromosomes	4
on one chromosome	1
none detected	0
<b>Suggested likelihood of WD as diagnosis from cumulative score:</b>	
4 or more:	highly likely
2–3:	probable, do more investigations
0–1:	Unlikely

acute phase reaction. The oral contraceptive may also falsely raise the ceruloplasmin.

A further confounding factor in the measurement of serum ceruloplasmin is the technique used. Most laboratories use an immunological reaction which measures both apo as well as holo ceruloplasmin. In WD it is the level in

particular of holo ceruloplasmin which is low. This would be measured more accurately by a biological method (oxidase activity), but this method appears only to be used in a small number of laboratories. Thus, the technology used for measuring ceruloplasmin may be responsible for the finding of normal levels in some patients with Wilson's disease, and also the variability between laboratories [58].

Steindl *et al.* found in their group of hepatic patients, that serum ceruloplasmin (measured immunologically) was low in only 65% of patients, but in patients with neurological or neuropsychiatric presentation, low ceruloplasmin was found in 85% [51].

These findings indicate that if the serum ceruloplasmin is low then other investigations are necessary in order to define whether this is related to WD or not. Conversely, in patients in whom WD has been suspected but who have a normal ceruloplasmin, other tests are required to investigate this further.

### Kayser Fleischer rings

Examination of the eyes using a slit lamp should be done by an experienced ophthalmologist. Steindl *et al.* found that Kayser Fleischer rings were found in 90% of patients with neurological and/or neuropsychiatric presentation and only 47% in those with hepatic disease [51]. Of ten asymptomatic siblings, only one had Kayser Fleischer rings.

### Urinary excretion of copper

Urinary copper is derived from the so-called free "non-ceruloplasmin bound" copper within plasma. In Wilson's disease 24-hour urinary copper excretion is increased; the threshold taken suggestive of disease is greater than 1.6 µmol/24 hour (100 µg/24 hour) [51, 59, 60]. The reference limits for normal 24-hour excretion of copper varies between laboratories, with many taking 0.6 µmol/24 hour (40 µg per 24 hours) as the upper limit of normal.

This limit seems to be a better threshold for diagnosis because sensitivity of detection of WD is increased. Strict precautions during collection to avoid contamination are necessary. The interpretation of 24-hour urinary copper excretion can be difficult because increased copper excretion may be seen in other types of liver disease, especially where there is severe liver injury. In addition, heterozygotes may also have intermediate levels of copper excretion.

Urinary copper output following penicillamine challenge has been found to be a useful diagnostic adjunct, particularly in the pediatric age group. The protocol used has been the administration of 500 mg of d-penicillamine at the start and again twelve hours later during a 24-hour urine collection. A copper excretion greater than 25 µmol/24

hours (1600 µg/24 hours) has been regarded as diagnostic for pediatric Wilson's disease [61]. The penicillamine challenge test for urinary copper excretion has been studied in adults and may be useful but less diagnostically so than in children [62]. **B4**

### Hepatic copper concentration

Accurate measurement of the liver copper concentration needs an adequate sample of liver biopsy (at least 1 cm of a 1.6 mm diameter core) [49]. The normal copper content of liver is less than 55 µg per gram dry weight. A hepatic copper concentration greater than 250 µg/gm dry weight is usual in homozygous WD. With some caveats this remains the best biochemical test for WD. Thus, the measurement of copper content in the liver is the most valuable diagnostic test in patients in whom other data are inconclusive. A normal liver copper concentration on an adequate sample of liver rules out Wilson's disease.

Diagnosis is sometimes only considered after liver biopsy has been done and when a sample has not been taken for copper estimations. Under these circumstances quantitative copper measurement can be done from tissue retrieved from paraffin blocks.

There has been discussion about the value of a liver copper measurement between 250 µg/gm dry weight and the upper limit of the normal range of 55 µg/gm dry weight. Values within this range do not exclude or define WD. Therefore results of hepatic copper concentration have to be taken in the context of the histological, clinical and biochemical data [63]. Specimens of liver with extensive fibrosis and few parenchymal cells may provide copper concentrations that are falsely low. Conversely, hepatic copper concentrations can be increased in patients with cholestasis, which may provide further confusion during the diagnostic work up.

### Molecular genetic analysis

Mutation analysis of ATP7B in individuals with a suspected diagnosis of Wilson's disease can be done to identify ATP7B mutations. Patients with neurological or hepatic disease sometimes have abnormalities of copper metabolism which do not reach the level of secure diagnosis for WD. For such individuals mutation analysis of ATP7B may be helpful. The finding of two mutations or homozygosity for a single mutation would be highly suggestive of the presence of WD. However, these data should be used in combination with the other clinical data. It is not yet known whether 100% of individuals carrying a mutation in the ATP7B gene on each chromosome 13 will develop WD if left untreated. A recent report suggests that this assumption may be challenged [64].

### Family screening using genetics

First degree relatives (siblings) must be screened for Wilson's disease. The probability of a sibling of an index case having WD is 25% and in their children approximately 0.5% (based on an estimated carrier frequency of 1 in 90). Screening should include liver function tests, serum ceruloplasmin and copper concentration, and urinary copper excretion. Depending on the outcome of these investigations, it may be necessary to have ophthalmological examination for KF rings and liver copper estimation.

Previously, haplotype analysis was done to identify siblings at risk. This involved using markers flanking the gene on chromosome 13 to be characterized so that it was then possible to identify siblings who had inherited the same two disease carrying chromosomes.

Molecular genetic analysis for mutations is now becoming more widely available. This will be useful for families in whom both mutations have been detected in the index patient, so that the presence or absence of these can be analysed in siblings. Siblings with a slightly low ceruloplasmin but without KF rings could be affected or carriers. Molecular genetic analysis is an alternative to hepatic copper quantitation to define their clinical status.

Parents of a child with WD have at least to be heterozygote carriers for this condition. Clinicians need to be alert to the rare possibility that one of the two parents is also affected.

Children of patients with WD are obligate heterozygote carriers. However, there is a 1 in 90 chance of the spouse being a carrier, which would result in a 50:50 chance of the child being susceptible. Thus, usually WD patients wish to know whether or not their children are affected. Children may be evaluated using biochemical tests (see below) and also, potentially, genetic screening. There is no evidence base for either approach and recommendations vary between specialists in this condition.

### Treatment

The majority of patients with WD are treated with copper chelators which promote copper excretion in the urine. An alternative approach in selected patients is zinc therapy, which results in reduced copper absorption (Table 31.3).

For patients with fulminant liver failure due to WD, or in those with hepatic decompensation unresponsive to medical treatment, liver transplantation is done (see later).

Wilson's disease is rare. It follows that there are very few randomized studies of therapy and therefore the evidence for the use of different therapeutic approaches is based upon publications describing the outcome in series of patients treated with particular regimens.

**Table 31.3** Treatment options for Wilson's disease.

Therapy	Mode of action	Pros	Cons	Notes
Penicillamine	Copper chelator <ul style="list-style-type: none"> <li>• urinary excretion</li> </ul>	Long experience Successful in majority of patients	Frequency of side effects <ul style="list-style-type: none"> <li>• immunological</li> <li>• neutropenia</li> <li>• proteinuria</li> <li>• neurological deterioration</li> </ul>	Used by many units despite side effects Need strategy if neurological or hepatic deterioration Efficacy reported in all patient groups
Trientine	Copper chelator <ul style="list-style-type: none"> <li>• urinary excretion</li> </ul>	Less experience than with d-penicillamine Most reported experience in patients intolerant of d-pen transferred to trientine Growing experience as first-line treatment	Some side effects but much fewer than d-penicillamine. Neurological deterioration reported but appears less than d-penicillamine Storage necessary in refrigerator (2–8°C)	Limited data as first-line treatment But increasing use as first-line treatment
Zinc salts	Induces metallothionein <ul style="list-style-type: none"> <li>• reduces absorption</li> </ul>	Few side effects Extent of experience mainly in asymptomatic and neurological patients	Speed of action Gastric intolerance in some patients (change formulation)	Initial treatment reported for asymptomatic/neurological disease; less data for hepatic Has been used post chelator as maintenance therapy
Tetrathiomolybdate	Copper chelator <ul style="list-style-type: none"> <li>• reduces absorption</li> <li>• biliary excretion</li> </ul>	Randomized study suggests low rate of neurological deterioration	Not generally available Some side effects	Investigational Need source for study and use
Albumin dialysis, MARS, plasmapheresis	Removes free copper and other toxins	Bridge to liver transplantation in acute liver failure/hemolysis	Not formally evaluated but case reports of success	Investigational but needs to be considered in acute liver failure/hemolysis
Liver transplantation	Replaces liver	Successful 80–90% Corrects metabolic defect (no WD treatment required) Life-saving	Timing Availability of donor	Only hope in certain patients

Wilson's disease was progressive and uniformly fatal until 1951, when the first chelating agent dimercaprol given intramuscularly was used. The clinical benefit of the orally active chelator penicillamine was reported by Dr John Walshe in 1956 [65]. This revolutionized treatment of the disease. Because some patients could not tolerate penicillamine, Walshe also developed trientine, another copper chelator, which was introduced in 1969 [66]. D penicillamine and trientine have remained the mainstay of chelation therapy. Ammonium tetrathiomolybdate (TTM), a copper chelator used for treating copper poisoning in animals, has been used historically and has been under investigation in the USA, particularly for treatment of patients with neurological disease [67].

Oral zinc therapy was first used in treatment in the early 1960s. It has been further studied particularly in Holland and the USA and as initial therapy has mainly been used for asymptomatic and pre-symptomatic patients. It has also been used as maintenance therapy after an initially period of treatment with a chelator [68].

Historically, the treatment of choice has been penicillamine. This drug does, however, have a range of side effects (see below) and there may be neurological deterioration in some patients after treatment is initiated. These issues have led to the suggestion that trientine may be an effective and safer alternative as initial treatment.

After chelation therapy, usually until clinical improvement has occurred, subsequent maintenance therapy may

either be with a reduced dose of chelator or alternatively zinc monotherapy. This choice depends on local experience, expertise and opinion.

Opinions differ as to the rationale and efficacy of treating with both chelator and zinc. These have to be given at separate times; taken together the activity of both would be expected to be compromised. The coordination of combination therapy thus needs very close control, which may be possible as an inpatient, but may suffer from compliance issues with timing at home.

## Penicillamine

Penicillamine is cysteine, doubly substituted with methyl groups. Copper is chelated by a free sulphhydryl group. After oral administration 40–70% is absorbed and is bio-available. More than 80% of the penicillamine absorbed is excreted in urine carrying with it chelated copper. Penicillamine may also induce metallothionein, a cysteine rich protein and endogenous chelator of metal.

Food reduces absorption by approximately 50%. Guidelines state that it is important that penicillamine is taken at least one hour before or two hours after eating, that is on an empty stomach [49]. However, Walshe has pointed out that studies with radioactive copper show better mobilization of copper when given before meals not after [69] and that penicillamine should always be given before meals. The target dose of penicillamine is 1000–1500 mg per day taken in 2–4 divided doses. **B4** Because of the concern of side effects, guidelines have recommended starting with a lower dose (250–500 mg per day) increasing by increments over several weeks [49]. This approach may increase tolerance to penicillamine. During the introduction of treatment it is necessary to monitor full blood count and urinary protein (using dipstix) regularly.

Adverse effects to penicillamine occur in 10–20% of patients and may be severe enough to necessitate withdrawal of the drug [37]. Side effects in the first 1–3 weeks include sensitivity reactions, with fever, rash, lymphadenopathy, neutropenia, thrombocytopenia and proteinuria [37]. If there are early immune side effects penicillamine should be discontinued immediately. Historically, reintroduction with steroid coadministration was used. However, with the availability of trientine, it seems more logical to withdraw penicillamine and introduce treatment with trientine, which has fewer side effects.

Later side effects of penicillamine include nephrotoxicity (a lupus-like syndrome) and bone marrow suppression (aplasia, thrombocytopenia).

Long-term use of penicillamine has been associated with skin complications, including progeriatric changes, elastosis perforans serpiginosa, and aphthous stomatitis [37]. Progeriatric changes are reported to occur with long-term

doses greater than 1000 mg a day – a reason for reducing to the maintenance dose as soon as feasible.

Penicillamine may affect pyridoxine metabolism. Supplementation (25–50 mg of vitamin B6 daily) is often prescribed, although the rationale is questionable [49]. Prescription is thought most important for groups at risk, in particular children, pregnant women and patients with malnutrition [70].

Data from Walshe in the UK, and Sternleib and Scheinberg in the USA have documented the clinical benefit of penicillamine in Wilson's disease [37, 71]. **B4** Hepatic function usually improves in patients with severe liver disease – that is those with high bilirubin, low albumin or prolonged prothrombin time with ascites or high Child Turcotte score. If patients deteriorate, the decision is whether to have a trial with a higher dose of penicillamine or consider working the patient up for liver transplantation.

In patients with WD and neurological changes, clinical and cerebral MRI improvement has been well documented [43]. Some studies [71, 72] report initial neurological deterioration in 20–50% of patients with a neurological presentation. In some cases this deterioration does not reverse [72].

## Trientine

Trientine has a polyamine structure. The copper is chelated by the formation of stable complexes with four constituent nitrogens in a planar ring. Although widely regarded as a weaker chelator of copper than penicillamine, Walshe has shown that as an initial treatment trientine may result in urinary copper excretion similar to that of penicillamine [73].

The initial dose of trientine is 1200–1800 mg per day in 2–3 divided doses. Again, it is critical for trientine to be taken at least one hour before, or two hours after food. In addition, it is critical to keep trientine refrigerated at around 4°C, since at room temperature over time, or higher temperatures, it becomes inactive. The maintenance dose of trientine is 900–1200 mg per day.

There are few reported side effects of trientine. Pancytopenia occurs rarely, and hypersensitive reactions and renal effects have not been reported. If copper deficiency develops because of excessive treatment with trientine, sideroblastic anemia and hepatic siderosis may occur. Neurological deterioration after treatment with trientine has been reported [74]; data suggest that this is less frequent than with penicillamine, but no direct comparisons have been made.

There are few data on the outcome with initial treatment with trientine in those with liver disease. Askari *et al.* [75] reported nine adults with severe liver disease identified over a ten-year period treated initially with trientine (1000 mg per day) in combination with zinc (150 mg per

day). One of the nine patients had hepatic encephalopathy. During treatment one patient developed mild neurological symptoms and was transferred to TTM and zinc. The remaining eight patients received trientine and zinc for at least four months. This was followed with maintenance zinc therapy. During the first twelve months of treatment prothrombin time, bilirubin and albumin concentrations were reported to return to normal and ascites disappeared. Over a follow-up of between twelve months and fourteen years, the benefit was maintained.

In one of the few randomized trials to have been done in WD, the efficacy of TTM was compared with trientine (both agents combined with zinc) in a series of patients with neurological Wilson's disease [74]. **A1d** In those treated with TTM 1 of 27 patients had neurological deterioration. This compared with 5 of 27 patients in the trientine group. As already pointed out, at present TTM is not available for routine prescription.

Results using trientine, mainly as a substitute for penicillamine after intolerance, have recently been reported in the pediatric age group and efficacy was shown [54]. **B4**

There is evidence now for the effectiveness of trientine in the treatment of patients with WD. Overall there are fewer side effects than with penicillamine and guidelines are now suggesting that trientine can be regarded as an acceptable alternative to penicillamine for initial treatment [49].

### Ammonium tetrathiomolybdate (TTM)

This drug forms a complex with copper and protein. When taken with meals these complexes are formed in the food and copper is excreted in stool. Thus, absorption is prevented. If TTM is taken between meals it is absorbed and complexes copper in blood with albumin. These complexes are metabolized by the liver and excreted in the bile [67].

As already noted, TTM is not currently available in England and only in investigational studies in the USA. The randomized trial of TTM against trientine has been referred to in the section on trientine [74]. **A1d** This study suggests that it is associated with less neurological deterioration. Three patients in the TTM group developed anemia or leucopenia; four had increased transaminases. These side effects resolved on dose reduction. More data are required to confirm the benefit of TTM, and it is unfortunate that this agent is not more widely available for study.

### Zinc

Oral zinc induces metallothionein in the intestinal cells which will then preferentially bind to intracellular copper in the duodenal enterocytes. Copper absorption is reduced. A small amount of copper is lost normally in the urine and

therefore without copper absorption there is negative copper balance.

The therapeutic dose of zinc in adults is 150 mg of elemental zinc. This is given in three divided doses. Since food interferes with absorption, zinc must be taken one hour before meals and more than two hours after meals, otherwise food would interfere with absorption. Untoward effects of zinc include dyspepsia. The timing of administration and different formulations, for example acetate, gluconate or sulphate may help.

Zinc has been reported as being therapeutically successful as a form of treatment in asymptomatic, pre-symptomatic affected family members of index cases with WD [68]. **B4**

In a group of patients with predominantly neurological WD followed up for a mean of twelve years Czlonkowska *et al.* reported that zinc was equally effective as penicillamine in their treatment [76]. **B4**

In patients with severe hepatic disease due to Wilson's disease, maintenance therapy with zinc after initial treatment with trientine was found to be effective [75].

### Vitamin E

Copper toxicity in part is due to lipid peroxidation of mitochondrial and other membranes. Experimentally this can be reduced by the administration of vitamin E, the levels of which may be lower in patients with WD [77]. Although currently, however, there is no evidence base to substantiate routine administration of vitamin E in patients with Wilson's disease, it may have a place in those with severe disease.

### Diet

Some foods contain a high concentration of copper and the recommendation has been in guidelines that they are generally best avoided [49]. Foods involved include chocolate, liver, nuts, mushrooms and shell fish.

### Current choice of medical treatment

Virtually all the data on the treatment options of WD are from clinical series of patients with only one randomized study in those with predominantly neurological disease [74]. Thus, strict recommendations (Table 31.4) are difficult and are predominantly dependent upon reported clinical series from specialist centers.

The choice between treatments depends upon the balance between their efficacy and their side effects. The evidence available shows that treatments available for Wilson's disease are effective for most patients. Clinical deterioration has been reported or alluded to in reviews for all treatments. Thus, none is reliably effective.

**Table 31.4** Considerations when choosing treatment for WD.**Initial treatment****General principles**

- Take advice if not experienced.
- Monitor closely for therapeutic effects and side effects.
- Have an alternative strategy if side effects/deterioration despite treatment.

**Hepatic presentation (compensated)**

- Trientine monotherapy appears acceptable and efficacious alternative to penicillamine. Zinc not used because of speed of therapeutic effect.
- Monitor liver function closely.

**Acute liver failure**

- Refer to liver transplant centre.
- May introduce chelator, vitamin E, nutrition.
- Calculate risk score (see text) on which to determine transplant listing.

**Neurological presentation**

- Review by movement disorder neurologist.
- Cerebral MRI.
- Chelators usually effective, but deterioration may occur (see text)
- Have strategy if deterioration with treatment.

**Pre-symptomatic WD**

- Use of chelator or monotherapy with zinc: experience with both.
- If not conversant, liaise with WD specialist.

**Maintenance therapy (after clinical stabilization with initial treatment)**

- Either reduce dose of chelator, or introduce zinc monotherapy.
- With both approaches close monitoring of patient (clinical symptoms and signs, LFTs, free Cu, urinary copper, KF rings).
- Watch for non-compliance (true for all phases of treatment).

Confounding issues evaluating treatments are that patients commence with different phases and patterns of clinical disease. In addition it is not always clear whether there has been treatment failure or lack of compliance.

Although penicillamine in many units remains the first choice of chelator for symptomatic patients, trientine has shown to be effective with fewer side effects. Combined chelation treatment with zinc has been used apparently with success but it is important to emphasize that there must be sufficient separation between taking of chelators and zinc.

For asymptomatic patients, although publications have suggested that zinc therapy is sufficient [68], patients in this group have also been treated with chelators successfully for many years.

There is no evidence or data to show whether for maintenance therapy, reduction of the dose of chelators is any less or more effective than zinc therapy alone.

For patients with hepatic disease who deteriorate despite what appears to be adequate treatment, and who are compliant with treatment, liver transplantation is a successful option. However, in patients with neurological deterioration the choices are more difficult.

Attempts to identify patients with a risk of neurological progression have been made. Studies of brain MRI changes may give hints [78], but evidence for a particular pattern being useful has not been substantiated.

Various approaches have been used to try and reduce the chance of neurological deterioration. Lower initial doses of chelators with gradual step-wise increase over the subsequent weeks have been suggested [49]. However, there is no evidence to suggest that this reduces the risk of neurological deterioration. In another report chelator was withdrawn temporarily, and subsequently reintroduced at a lower dose [78]. In a small number of patients this was thought to contribute to subsequent successful treatment.

As discussed earlier, data suggests that TTM is a useful initial treatment option with a lower risk of neurological deterioration [74, recently reviewed in 79].

In patients who deteriorate neurologically despite treatment with penicillamine, intramuscular use of dimercaprol has been associated with improvement [80].

## Monitoring

Clinical review of symptoms, signs and laboratory tests of liver disease are necessary at an interval appropriate to the severity of disease at the start of treatment. Similarly, neurological assessment ideally by a movement disorder neurologist should be done.

Measurements of serum copper and ceruloplasmin as well as 24-hour urinary copper excretion are valuable in showing reduction in free copper levels by treatment. They are also useful in showing whether there is compliance with medication.

The accepted target for non-ceruloplasmin bound copper is 5–15 µg/dl. The accurate calculation of non-ceruloplasmin bound copper (see below) is difficult since ceruloplasmin is almost universally measured immunologically. The problem with this method is discussed earlier. In addition, laboratories may report ceruloplasmin levels as being undetectable (<0.04 g/l, for example). It cannot be assumed however that there is no ceruloplasmin present. Estimation of free copper depends upon calculating the copper contained in the serum ceruloplasmin (3 µg/mg) and subtracting this from the total serum copper, after adjustment of the units (µg to µmol, dl to l, or vice-versa) as necessary (mol wt copper 63) [81].

The non-ceruloplasmin bound copper is an important measure in monitoring patients. It is also useful to see the

total serum copper falling with treatment. However, low levels may raise the question of whether there is copper deficiency due to therapy.

A 24-hour urine copper measurements should also be done. During chelation therapy an output of 3–8  $\mu\text{mol/l}$  (200–500  $\mu\text{g}$ ) denotes adequate treatment. Whether there is any advantage in measuring urinary copper after temporarily stopping chelating treatment for 48–72 hours is not evidence based. However, proponents of this approach would argue that copper excretion off treatment will give an indication of whether copper deficiency is occurring (when there will be low 24-hour urinary copper).

In some patients after years of treatment the 24-hour urine copper is surprisingly high. One explanation is that the patient restarts chelator after a period of non-compliance.

In patients taking oral zinc, urinary output of zinc as well as copper are measured. Twenty-four hour urinary zinc output of at least 2 mg per 24 hours has been suggested as indicative of a therapeutic level which would control copper metabolism in Wilson's disease [82]. If urinary zinc excretion on 150 mg of oral elemental zinc per day is not in this range, then questions regarding compliance, timing of treatment and formulation have to be raised. The dose of oral zinc can be adjusted in order to bring the urinary output of zinc in 24 hours into this "therapeutic" range.

## Prognosis

Long-term studies of survival in WD are difficult to interpret, and indeed the introduction of liver transplantation has improved outcome for those severely affected by liver disease. In a recent report of the cause of death in WD, the importance of early diagnosis is noted; delayed diagnosis was the principal cause of death, and the risk from poor compliance with treatment was emphasized [83].

## Pregnancy

A review of treatments used for WD in pregnancy has concluded that penicillamine, trientine and zinc are not associated with increased maternal or foetal risk when used during pregnancy [84]. Cessation of treatment has been associated with development of fulminant liver failure [85], and therefore compliance with treatment is important during pregnancy. It has been recommended that the dose of chelators be reduced during pregnancy, particularly the last trimester [49, 84]. The dose of zinc treatment is recommended to be maintained [49].

## Salvage treatment/bridge to transplantation in fulminant liver failure

Patients with WD may present with acute liver failure, often with hemolysis. Although listing for liver transplantation can be done immediately there may be a delay before a donor organ is available. For such patients case reports of plasma exchange, single pass albumin dialysis and MARS therapy have been published and reported in some cases to be beneficial [86–90]. Despite lack of clear evidence base, these approaches need to be considered as a potential life-saving bridge to liver transplantation.

## Liver transplantation

Liver transplantation is indicated for patients with acute fulminant hepatic failure (FHF) from WD. It is also indicated for patients with WD in whom medical therapy is ineffectual as defined by a failure to stabilize and prevent progressive hepatic insufficiency. This group includes a subset of who have neurological as well as hepatic disease, but the hepatic symptoms are predominant.

Transplantation of these individuals can be achieved by cadaveric donor [91–93] or living donor liver transplant [94], even if the donor is a heterozygous carrier.

One-year survival rates are 87–90% [91–94], results which compare well with those for other patient groups. The metabolic defect is corrected.

Scoring methods based on clinical features have an important role in the decision to list for transplantation. For children, the King's system uses serum bilirubin, international normalized ratio (INR), aspartate transaminase (AST) and white cell count at presentation [95]. A cutoff score of eleven gave a positive predictive value of 88% for death, and prospective evaluation in 14 patients predicted the need for transplantation. In adults the same scoring system performs well in predicting response to medical therapy in patients with decompensated chronic WD [96].

The clinical dilemmas in patients not responding to medical therapy are how to decide on the duration of an adequate treatment trial, and what is a true failure of medical therapy, so as to aid the decision to transplant. Given the lag between the initiation of treatment and measurable, objective clinical and laboratory response, which may be up to 6–8 weeks, the previous recommended interval for a medical trial was three months. While this three-month period is not an absolute requirement since some will deteriorate before this time has elapsed, careful observation is critical to detect those individuals for whom transplant may be more urgently needed. If the patient can be stabilized over this time period, there is at least hope for

the long-term utilization of medical therapy and avoidance of transplantation.

Individuals with long-standing neurological impairment from WD are unlikely to recover after transplantation, although improvement in severe neurological disease has been reported. In this group of patients the indication for transplantation must be considered carefully. The decision of whether to choose transplantation rather than medical treatment is complicated because of the significantly long period of time (up to four years) over which neurologically affected patients may improve whilst on medical therapy. The problem is that the time needed to determine whether medical treatment for neurological disease has failed, is probably longer than the window of opportunity for transplant to have prevented progression.

## Summary

(1) WD is rare, but an essential disorder to consider in patients with liver and/or neurological disease, since without treatment the condition is fatal.

(2) Once considered as a potential diagnosis, a group of clinical and laboratory investigations should be done. No investigation is 100% specific on its own. Diagnosis depends upon a combination of findings. A published scoring system has been proposed. Liver copper concentration is a gold standard. Mutation analysis of ATP7B, the gene involved, is more widely available as a clinical tool, and can play an important part in diagnosis.

(3) Screening of siblings of patients with WD is mandatory.

(4) Treatment of WD is based on a copper chelator (penicillamine or trientine), or zinc which inhibits absorption of copper. All may be effective but the clinical features of the patient are relevant to the choice. There is no universal consensus on a standard therapy.

(5) For patients with acute liver failure, liver transplantation is effective. A clinical scoring system aids selection for transplantation particularly in children.

(6) Supportive therapy for patients with acute liver failure/acute hemolysis includes plasmapheresis, albumin dialysis and MARS, as a bridge to transplantation, but there is no definitive evidence base for this.

## Introduction

Primary biliary cirrhosis (PBC) is the accepted name for a hepato-biliary disease characterized by a chronic non-suppurative granulomatous cholangitis of the interlobular and septal bile ducts [1, 2]. Epidemiological surveys have shown that the disease predominantly, but not exclusively, affects middle-aged women across all racial groups. In some studies the prevalence has been estimated to reach 1 in 1000 of women over 40 years old [3]. It is considered autoimmune in origin because overwhelmingly patients have serological evidence for specific anti-mitochondrial antibodies (AMA). Additionally, other autoimmune disorders are more frequent in those with this disease, and their relatives. The natural history of this chronic cholestatic disease is more variable than traditionally taught, reflecting a wide spectrum of presentation, but untreated progression is often to biliary cirrhosis. This is a result of chronic inflammation (piecemeal necrosis), ductopenia (a consequence of chronic granulomatous bile duct injury) and cholestasis (retention of bile acids).

## Diagnosis

The first descriptions of disease were in patients with a profound cholestatic hyperlipidemia and its accompanying pronounced skin xanthoma. With greater use of biochemical testing patients were identified prior to the onset of jaundice, and indeed now most patients are asymptomatic when diagnosed, with no significant fibrosis. The biggest diagnostic advance was made by Doniach and Walker who demonstrated that most individuals had non-organ and non-species specific mitochondrial antibodies, using the

then new technique of immunofluorescence [4, 5]. By the late 1980s, it was clear that the targets of the anti-mitochondrial antibodies were the E2 component of the pyruvate dehydrogenase complex and other members of the family of 2-oxo acid dehydrogenase enzymes located on the inner membrane of mitochondria. Understanding the antigens in greater detail led to better, and more specific assays for AMA using ELISA technology and/or immunoblotting; these confirm that an AMA test is positive in about 95% of patients with PBC [6]. However AMA-M2 is not restricted to PBC alone, with descriptions in the healthy population (~0.5%) [7, 8], in asymptomatic first-degree relatives of patients (as high as 13%) [9], in autoimmune hepatitis [10], hepatitic overlap syndromes [11], and transiently during acute liver injuries [12]. Additionally, of patients who have recurrent urinary tract infections, half test positive for anti-PDC-E2, most likely due to cross-reactivity with *E coli* mitochondrial antigens [13].

Careful assessment of liver pathology codified in greater detail the specific features of this disease, but whilst histological assessment has been very important in studying the progression of disease (and thus identifying risk factors for progression), and as a surrogate for treatment efficacy, its role in routine clinical care has become less prominent [14]. The characteristic lesion of PBC is lymphocytic destruction of the interlobular bile ducts within portal triads. Histological staging systems assess the degree of fibrosis, inflammation and/or bile duct damage. For example, in Ludwig's classification, stage 1 is defined by portal inflammation, and stage 2 is extension of the inflammation beyond the portal tracts into the surrounding parenchyma, with or without associated duct loss. By stage 3, fibrous septa link adjacent portal triads and stage 4 represents cirrhosis. The difficulty for any system is the sampling error inherent in percutaneous liver biopsy (e.g. it being difficult to agree what is an appropriate number of portal tracts that need to be sampled to be sure of adequate representation of cholestatic liver disease). Explant tissue has been used to demonstrate how variable a percutaneous biopsy can

actually be if relied upon to stage PBC [15]. Hence, when sections from 50 PBC liver specimens obtained at transplantation were examined only 10 (20%) samples had a consistent degree of fibrosis in all sections scanned. By contrast, the same fibrosis stage was assigned in 30 (60%) specimens examined using a simulated needle biopsy method. When the results obtained by the two methods were compared, there was a discrepancy of one or two stages in 32 samples. This discrepancy was the result of areas with a lesser degree of fibrosis in whole sections compared with a simulated needle biopsy specimen.

In present practice PBC is considered definite in the presence of all three of chronic biochemical cholestasis, anti-mitochondrial antibodies and typical pathology, but only probable if only two features are present [16]. However, in the correct context cholestasis with AMAs has been confirmed to be virtually diagnostic of PBC without recourse to biopsy [17]. Although asymptomatic individuals with PBC were reported by Sherlock in 1959 the natural history of such patients was more fully described by Long *et al.* in 1977 [18, 19]. Later it became evident that AMA positive subjects with normal liver biochemistry, undergoing serological tests because of the presence of another autoimmune disease, may also have the histological lesions of PBC on biopsy. A longitudinal follow-up study of 29 untreated patients assessed every year from first-detected AMA for a mean of 18 years showed that 24 (83%) developed cholestatic liver tests and 22 (76%) developed fatigue and/or pruritus. The median time to progression from AMA positivity to persistently abnormal liver enzymes was 5.6 years (range, 1–20 years) [20]. Whether all patients who test positive for AMA, particularly those who test positive by the more sensitive ELISA technology, will eventually develop clinical disease is unknown because such studies are yet to be performed. Indeed it seems improbable since the prevalence of AMA in the general population is so much higher than the prevalence of clinical disease, and the male: female ratio of those testing positive does not mirror that of the overwhelmingly female predominant PBC population as a whole [8].

It has also become clear with careful observation that 5% of patients have the clinical, biochemical, and histological features of PBC, as well as the same associated autoimmune diseases, but test repeatedly negative for AMA (by all modalities of testing) [21, 22]. These latter patients tend to be seropositive for antinuclear antibodies (ANA) or smooth muscle antibodies (SMA), often with high titers. The immunologic profile of PBC normally includes ANA and by indirect immunofluorescence is reported as commonly as 50% of the time. The immunofluorescence patterns for PBC-specific ANA are described as a perinuclear/rim-like or multiple nuclear dot pattern. The rim-like pattern results from autoantibodies directed against constituents of the nuclear envelope, including in particular

gp210, a 210-kd transmembrane glycoprotein of the nuclear pore complex. The multiple nuclear dot pattern is caused by autoantibodies against two autoantigens that colocalize: sp100 and promyelocytic leukemia protein. ANA reacting with gp210 occur in 10% to 40% of patients who have AMA positivity and in up to 50% of patients who have AMA-negative PBC and, therefore, are an appropriate second-line investigation in this group of individuals.

---

## Natural history

PBC is a chronic liver disease generally characterized by a slow progression but highly variable clinical course. More than half of patients diagnosed today are asymptomatic at diagnosis and one contemporary series showed how nearly 90% do not have fibrosis when first identified [23]. Some patients will still present jaundiced, or with intractable pruritus, but increasingly patients are generally investigated after the observation of an elevation in serum alkaline phosphatase (ALP) and/or total serum cholesterol, and this often results from a routine health screen. The diagnosis may also be made in patients with an associated autoimmune disease such as scleroderma, hypothyroidism or rheumatoid arthritis, in whom clinicians may routinely screen for PBC (usually with a combination of liver biochemistry and autoantibody screening).

An important question pertains to whether the natural history of the disease is unchanged when compared to prior studies and whether the widespread use of ursodeoxycholic acid (UDCA) explains the apparent change in severity of disease encountered, for example transplant rates for PBC have fallen markedly but this is not the case for PSC [24], and survival similarly appears improved for PBC but not PSC [25]. The Japanese have proposed a natural history model in which so called latent/early PBC (AMA-M2 positive with normal liver tests), passes on through to asymptomatic and then symptomatic PBC [26]. Patients with symptomatic PBC appear to have a more rapid progression to end-stage liver disease and have a worse prognosis than those with asymptomatic disease. Within this latter group, a further division has been suggested into those that develop portal hypertension (anti-centromere positive) and those that develop liver failure (anti-gp210 positive) [27]. How accurate these divisions are remains to be seen, and it perhaps reflects the lack of pathophysiological understanding of autoimmune liver disease that symptoms still play such an important part in classification. In the management of chronic viral hepatitis, the focus is on surrogate viremic endpoints (HBV DNA/HCV RNA) and symptoms do not register in natural history discussions. Conversely, the symptom often thought so “specific” for PBC, fatigue, is in fact also reported by those with other liver diseases [28].

The initial ten-year, follow-up report of asymptomatic disease suggested that 50% of asymptomatic patients became symptomatic over this period of time [19]. More recent studies with longer follow-up indicate that although asymptomatic disease tends to progress at a much slower rate than symptomatic disease, survival of both symptomatic and asymptomatic patients with PBC is significantly less than that of the general population [29, 30]. Mean survival for patients with symptomatic PBC is eight years whereas that for asymptomatic disease is closer to 16 years according to some authors [31]. One UK study suggested absolute survival was the same regardless of symptoms, although notably the cause of death in those who were asymptomatic was more commonly non-hepatic, and those without symptoms had less severe disease at diagnosis [32]. Information from the many randomized controlled trials (RCTs) of therapy in patients with PBC conducted over the past decades also confirms that the course of PBC is not the same for all patients. About one-third of asymptomatic patients develop symptomatic disease within five years. The other two-thirds may not develop symptomatic disease for much longer. A large study from Newcastle reported that 54% of patients with asymptomatic PBC do not die of their liver disease [33]. The age at diagnosis must be noted and may be relevant when trying to compare studies. One study that described asymptomatic patients included predominantly patients who were mostly older than 60 years old [20], and some reports show that the diagnosis of asymptomatic PBC tends to be made in patients who are between and two to ten years older than patients with symptomatic disease [34]. This relationship suggests that asymptomatic disease is not necessarily a precursor of symptomatic disease, but could also be a *form fruste* of symptomatic disease.

## Surrogate markers of outcome

As PBC is primarily a disease of the biliary system, when signs of failure of hepatocyte function develop, such as uncorrectable coagulopathy or jaundice, these usually indicate terminal disease, assuming there is no precipitant such as drug injury or a *de novo* autoimmune hepatitis. There are no symptoms present in patients with purely compensated disease which correlate with outcome, for example fatigue does not correlate with the severity of disease as judged by the height of the serum bilirubin or the Mayo risk score [35], and similarly, pruritus is not a marker of disease severity [36], in fact frequently diminishing as the disease progresses. In one report of symptom development in 770 patients who had PBC, ascites was present in 20% and bleeding varices in 10.5% after ten years of follow-up [33]. The outlook for patients who develop these complications is worse and new portal hypertension complicated by

ascites is usually a bad sign. In 143 patients who first developed ascites ( $n = 111$ ) or peripheral edema ( $n = 32$ ), the mean time to death was 3.1 years [37]. Occasionally, varices have been reported to develop in PBC before histologic cirrhosis can be documented (nodular regenerative hyperplasia or intense periportal inflammation) and this then carries a better prognosis [38].

Once a patient develops biochemical hyperbilirubinaemia, the natural untreated history of this disease is more predictable. The degree of hyperbilirubinemia has been shown to correlate extremely well with survival. This was shown prior to the introduction of liver transplantation and the height of the bilirubin was a valid marker of final outcome, that is, death. The liver insufficiency phase is characterized by worsening jaundice and is a preterminal phase: mean survival once the bilirubin is  $34 \mu\text{mol/l}$  is four years, and when the bilirubin reaches  $102 \mu\text{mol/l}$  mean survival is only two years [39]. This had formed the basis for guidance to refer patients with PBC for transplant once their bilirubin reaches  $100 \mu\text{mol/l}$ . Encephalopathy, when it occurs, is usually (but not always) during this phase. Pruritus, alkaline phosphatase, and cholesterol may all paradoxically improve in the preterminal stage. The introduction of UDCA therapy, which was demonstrated in early studies to reduce serum bilirubin levels [40], has been shown not to invalidate either the absolute serum bilirubin or the Mayo risk score as a prognostic marker [41]. What is less clear is whether the serum bilirubin in patients treated with UDCA remains a valid marker of survival in those with end-stage disease.

The identification of other surrogate markers of outcome remains extremely important in evaluating specific therapies in PBC, particularly as the mean survival time of this disease, in both symptomatic and asymptomatic patients, is long. As more and more asymptomatic patients (whose survival may be influenced by factors external to the liver) are included in drug trials, these trials will need to be very large in size and of long duration to evaluate the effect of therapy on survival effectively. Further, the risk scores discussed below may not necessarily be applicable to asymptomatic patients, since most are derived from cohorts of patients with moderate/severe disease, an exception being the study from Prince and colleagues [33].

More sophisticated risk scores designed to predict prognosis in patients with PBC have been developed. It is not surprising that serum bilirubin features in each of the scores described [42]. The most widely used composite score, the Mayo risk score, is popular because it does not require liver biopsy [43]. The components of the Mayo risk score, age, serum bilirubin and albumin, coagulation time, and the presence of fluid retention and/or use of diuretics, seem to be sufficient to accurately predict outcome in PBC. The Mayo risk score was first developed from a cohort of patients in a randomized trial, and validated for patients

who were not treated with a liver transplant for end-stage disease. The original Mayo risk score has been re-evaluated with extended follow-up and inclusion of a number of patients who progressed to receive liver transplantation [44]. In total, progression of primary biliary cirrhosis was studied in 312 patients who were seen at the Mayo Clinic between 1974 and 1984. Follow-up was extended to 1988, by which time 140 of the patients had died and 29 had undergone liver transplantation. These patients generated 1945 patient visits, which enabled the authors to study the change in the prognostic variables of primary biliary cirrhosis from the time of referral. The updated model was superior to the original model for predicting short-term survival (during the two years) after a patient visit. This study also confirmed that updating the model every time a patient is reviewed was statistically acceptable. Although the Mayo score is popular it should be noted that other investigators have also produced similar analyses on their own cohorts [33, 45]. When using risk scores in comparative studies it should also be borne in mind that patients presently may be less severe in their presentation than those included in original studies, and this may lead to an over estimate of mortality; further score validity is usually short (two years) and not long term. The MELD score is of value once the disease is advanced and provides an accurate tool for transplant evaluation since it is a reliable measure of short-term mortality risk [46]; in early stage disease it is clearly not particularly meaningful.

Recent attempts at survival analysis have looked to see if simple assessments of biochemical response to treatment may be useful clinically. Three studies stand out in this regard with particular utility for patients. Pares assessed the course and survival of patients with PBC treated with UDCA and compared this with the survival predicted by the Mayo model and the estimated survival of a standardized population [47]. There were 192 patients with PBC treated with UDCA (15 mg/kg per day) for 1.5–14 years. In this study a response to treatment was defined by an ALP decrease greater than 40% of baseline values or normal levels after one year of treatment. In the timeframe 8.9% of patients met the endpoint (died or fulfilled criteria for liver transplantation) and the observed survival was higher than that predicted by the Mayo model but lower than that of the control Spanish population. Just under two-thirds of patients responded to treatment, according to their definition and the survival of responders was significantly higher than that predicted by the Mayo model and similar to that estimated for the control population (but only if they were treated at an early stage of disease). In a similar vein the biochemical response to UDCA was correlated with long-term prognosis in PBC recently by a French group studying 292 patients [48]. Those showing ALP < 3 ULN, AST < 2 ULN, and bilirubin  $\leq 17 \mu\text{mol/l}$  after one year of UDCA had a ten-year transplant-free survival rate of 90% (95% CI:

**Figure 32.1** Survival without transplantation, according to the one-year biochemical response to UDCA. The thin curve represents survival of responders ( $n = 179$ ). The thick curve represents survival of non-responders ( $n = 113$ ). The survival of the control population (thin dotted curve) and the survival predicted for non-responders by the updated Mayo model (thick dotted curve) are indicated. The transplant free survival of responders was significantly higher than that of nonresponders ( $p < 0.0001$ ; RR, 0.4; 95% CI: 0.3–0.5) and similar to that of the control population ( $p = 0.8$ ). The transplant-free survival of non-responders was not different from that predicted by the updated Mayo model ( $p = 0.9$ ). Reproduced with the permission of the American Association for the Study of Liver Diseases [48].

81–95%), compared to 51% (95% CI: 38–64%) for those who did not (see Figure 32.1).

Huet *et al.* [49] have used a different approach, looking at portal hypertension in a study unlikely to be repeated because of its invasive nature. A total of 132 patients had portohepatic gradient and biochemical values measured at inclusion and every two years. After two years of treatment, a decreased or stable portohepatic gradient (hazard ratio, 4.64; 95% CI: 2.01–10.72) and normalization of AST level (hazard ratio, 2.89; 95% CI: 1.03–8.05) were predictive of better survival on multivariate analysis. Responders (defined as either stable or improved portohepatic gradient and normalized AST level at two years) had a 15-year survival similar to that of a matched local Canadian population.

Histology can be a hard endpoint, but only in the context of clinical trials where large numbers of biopsy specimens are available to offset the effect of sampling error. Transition rates between Ludwig histologic stages have been calculated using Markov modelling (namely that, given the present state, the future and past states are independent). In a large randomized trial of D-penicillamine, which was found to have no effect on histologic progression, the mean increase in histologic stage for PBC can be estimated to be one stage every 1.5 years. After four years, 31% of patients whose initial biopsy showed stage 1 had progressed to cir-

rhosis, and 50% of patients who started in stage 2 had progressed to cirrhosis [50]. An earlier study (on a relatively small number of patients) did indicate that patients who have liver fibrosis or cirrhosis on biopsy had a worse survival than those without fibrosis or cirrhosis [51]. On its own, presence or absence of cirrhosis is not a highly predictive surrogate marker for final outcome, that is, death, presumably because there are other features which factor into progression of disease. A detailed review of liver histology in PBC suggests that the presence of lymphoplasmacytic interface hepatitis is a marker of more rapidly progressive disease [52], and in another report of four cases, rapidly progressive bile duct loss, even in the absence of cirrhosis led to liver failure [53]. Corpechot described the progression toward cirrhosis in 183 UDCA-treated patients with PBC [52]. A total of 254 pairs of liver biopsy specimens collected during 655 patient-years were studied and the incidence of cirrhosis after five years of UDCA treatment was 4%, 12% and 59% among patients followed up from stages I, II and III respectively. At ten years, the incidence was 17%, 27% and 76% respectively. The median time for developing cirrhosis from stages I, II and III was 25 years, 20 years and 4 years respectively. The independent predictive factors of cirrhosis development were serum bilirubin greater than  $17\mu\text{mol/l}$ , serum albumin less than  $38\text{g/l}$ , and moderate to severe lymphocytic piecemeal necrosis. Validation of the importance of interface hepatitis is important, as are other potential factors (vascular supply to the liver, the presence of various inflammatory mediators and markers of tissue fibrosis). In the latest paper from France already discussed, independent predictive factors of death or transplant were baseline serum bilirubin level  $>17\mu\text{mol/l}$  (RR, 1.7), histologic stage  $\geq 3$  (RR, 1.5), interface hepatitis (RR, 1.9), and the absence of biochemical response (ALP  $> 3$  ULN or AST  $> 2$  ULN, or bilirubin  $> 17\mu\text{mol/l}$ ) (RR, 2.3) [48]. There is no good evidence that the AMA titer correlates with the course of PBC [54] (although it can fall with treatment [55]), but some groups have suggested specific anti-nuclear antibodies may delineate subtypes of PBC [27]. This, however, remains to be validated widely [56].

Aside from the increasing rarity of liver deaths from PBC, it has also become very difficult to use death as an endpoint, since most patients with decompensated PBC, if they have no contraindication, are referred for liver transplantation. As liver transplantation has become established for end-stage liver disease in particular, it has been used as a final outcome measure by many. Even transplant has some variability; however, certainly as some patients in the past have been transplanted for symptoms, different centers have longer waiting times, whilst factors such as blood group and body size can alter the duration of waiting. With the advent of scoring systems such as MELD, these issues will be largely addressed. Furthermore, perhaps because of therapy the rates of those patients with PBC

going to transplant continues to fall markedly [24]. Over a 12-year period (1995 to 2006) PBC and PSC transplant data of first-time liver recipients from the United Network for Organ Sharing database were collected. Although the absolute number of liver transplantations in the USA increased by an average of 249 transplants per year the absolute number of transplants performed for PBC decreased by an average of 5.4 cases per year. The absolute number of transplantations for PSC showed no statistical change.

---

### Therapeutic trial design: assessment of credibility

Understanding the limitations of the available evidence is essential for those interested in the evidence base for treatments of PBC. Numerous trials form the basis of the current treatment offered to patients. In evaluating such work a number of concerns arise for a disease such as PBC which is relatively uncommon and has a slow and varied natural history. To establish appropriate study size requires not only a large sample of historical data to chart the natural history of untreated disease but also pilot data, from which an estimate of the expected benefit can be calculated (sample size must also assess the frequency of adverse events). Historical data may not, though, always remain valid, for example the exclusion of chronic hepatitis C was only possible after approximately 1990, and patterns of presentation may change with time. The pivotal patient descriptions in the *New England Journal of Medicine* by Sherlock in 1973 clearly do not reflect those seen now [23, 57]. Recognized improvements in trial management have helped produce more robust data, with much thought given to careful trial design (e.g. double blinded, prior sample size calculation, stopping rules, crossover arms, and intention-to-treat analysis). The intention-to-treat principle is particularly relevant when carrying out statistical analysis of outcome to avoid as much bias as possible when interpreting the data. This means that all patients who are randomized need to be included in the final analysis, even though they may have been censored at a very early point in the trial because of untimely death, need to withdraw from the study, non-compliance, etc. Using the intention to treat principle allows for a very conservative analysis of the effectiveness of therapy, but permits assessment of the "real life" situation, that is, the generalizability of the study.

Meta-analysis can also overcome some concerns, particularly sample size, but many assumptions are made about inclusion and exclusion of studies, and original raw data is not always accessed. Additionally, meta-analysis is a tool to define the gaps in knowledge (and thus to help the design of better studies), rather than a true grading system for an intervention, meaning conclusions drawn may

reflect the quality and quantity of the evidence available as much as anything else. Variability in clinical practice, referral biases and varied ethnicity also generate difficulties as clinicians pool their patient resources. Finally, a major challenge relates to early detection of disease such that significant events, for example death or liver transplantation are unlikely to occur during any single trial. The use of surrogate markers (biochemical response, histological change, disease risk scores) as endpoints are by necessity employed, but their own origin and limitations need to be recognized as already discussed [58].

## Randomized controlled trials of treatment for primary biliary cirrhosis

### Immunosuppression

As the archetypal presumed autoimmune disease, inevitably immunosuppression has been evaluated as a therapy. Because the majority of patients with PBC are women and osteoporosis is prevalent (but not necessarily causally related to PBC [59–61]), corticosteroid therapy has for the most part been avoided. Trials of immunosuppressive therapy in PBC have employed azathioprine, cyclosporin, methotrexate, prednisolone, chlorambucil, thalidomide and, more recently, budesonide and mycophenolate mofetil. Neither of the two trials of azathioprine showed a beneficial effect of this drug on survival [62, 63]. The first trial had an inadequate sample size, lacked a placebo control group and predetermined stopping rules, and the results were not analyzed according to intention to treat. The second trial of azathioprine although much larger (248 patients), did not include a sample size calculation to assure that it had adequate power, and the withdrawal rate was greater than 20% in both the azathioprine and placebo groups. Despite randomization, the two groups were not stratified for factors known to influence survival and were not comparable at baseline. Only after employment of the Cox multiple regression analysis to adjust for these baseline differences was a benefit of treatment on survival observed. This difference in survival between the treatment groups could only be measured in months, which may not be clinically meaningful. Patients were followed for up to ten years, but the number of patients still being followed at that period was only nine in the azathioprine and none in the placebo group. It appears that the intention to treat principle was not used in the analysis, since 32 patients were excluded from the analysis because of incomplete data. Thus, the validity of the small benefit in survival can be further questioned. **A1d** Mycophenolate mofetil similarly has been disappointing, with no important clinical benefits, albeit in data from a single, small pilot study of 25 patients with PBC lasting one year [64].

Several small trials and one large trial (349 patients) of cyclosporin therapy have been published [65–68]. This trial ran into the same problems as had been encountered with the large azathioprine trial, that is, lack of comparability of the two treatment groups at baseline. Even though there were a similar number of deaths, 30 in the cyclosporin group and 31 in the placebo group, the authors concluded that survival was improved in the cyclosporin-treated patients. Renal impairment was observed in 9% and systemic hypertension in 11% of the cyclosporin-treated patients (1.7% and 1% in placebo-treated respectively). These two serious adverse effects in patients whose disease is relatively slowly progressive precludes the use of this drug in the long-term treatment of PBC. **A1d** Tacrolimus, a similar agent, has not been studied to date formally in PBC, neither has the other increasingly popular immunosuppressant, rapamycin.

Methotrexate was suggested to be of value in pilot studies [69, 70]. In one RCT of therapy sixty patients were recruited, 30 randomized to low-dose therapy (2.5 mg three times per week). At the end of six years, the serum bilirubin and Mayo risk score were higher in those receiving methotrexate, suggesting that the drug may be toxic in patients with PBC [71]. In a large NIH effort (placebo-controlled, randomized, multicenter trial comparing the effects of methotrexate plus UDCA to UDCA alone on the course of PBC) methotrexate when added to UDCA for a median period of 7.6 years had no effect on the course of PBC treated with UDCA alone [72]. **A1d** This study illustrates some of the difficulties of trial design: at the time of planning, it was anticipated that the five-year, transplant-free survival would be 83%, whereas the experience in this trial corresponded instead to a 94.5% five-year and 84.3% eight-year transplant free survival probability. The lower event rate meant that patients had to be followed for a longer time period, and this in turn probably contributed to a higher rate of patients discontinuing methotrexate. The authors calculated, using the log rank statistic to compare the distributions of time to an event in a randomized trial, that they needed to observe 88 events in order to have 90% power to detect a two-fold improvement in the risk of an event. With their calculations in a study that followed subjects for an average of eight years (with an expected 7% rate of death and 16% rate of transplant or death), this implied they needed to randomize a total of 1257 subjects when using the endpoint of overall survival, or 550 subjects when using the endpoint of transplant-free survival. If one then appreciates their recruitment reality, the enormous challenges for investigators planning future studies is clear: in this case investigators at 12 centers in the USA screened 535 patients for possible entry into the trial. At screening 393 of the 535 patients were determined to meet the defined inclusion criteria, and 385 patients went on to meet the screening inclusion and exclusion criteria. Three hundred

patients progressed to a pre-entry evaluation phase and ultimately 265 patients were randomized with equal probability in a double-blind fashion.

A small, three-year RCT of prednisolone has been done [73]. **A1d** A significant reduction in the serum bilirubin level (a valid surrogate outcome measure) was observed in treated patients, but osteoporosis in those who received corticosteroids worsened. However, a trial with a very small sample size of bisphosphonates in patients with PBC treated with corticosteroids indicates that etidronate significantly stabilizes bone mineral density in vertebrae of patients with PBC receiving corticosteroids [74]. Hence, it may be appropriate that corticosteroids be re-evaluated in the therapy of PBC now that patients can be given preventive therapies to reduce the complication of osteoporosis. Budesonide is an oral corticosteroid which is eliminated on first pass through the liver. Thus it was hoped that this agent could benefit patients with PBC without having a deleterious effect on bone mineral density. In the first small RCT by Leuschner *et al.*, improvement in liver biochemistry, IgM values and liver histology was observed in the few patients studied, most of whom had very early disease [75]. In a second study by Angulo *et al.*, no benefit was observed and the Mayo risk score increased significantly in those randomized to budesonide for a year and bone mineral density measurements deteriorated in the lumbar spine ( $p < 0.01$ ); it is likely that many of these patients had advanced PBC so that the benefit of the first-pass effect was lost [76]. Subsequent work from Finland has alluded to a histological benefit when combined with UDCA and the observation that interface hepatitis on baseline biopsy is predictive of outcome in PBC (as well as a failure to normalize transaminases with UDCA) does suggest that a subgroup may benefit from immunosuppression [77]. **A1d** Interest therefore remains in using budesonide adjunctively in those with more florid hepatitic features. However, Wolfhagen *et al.* in another small RCT involving 50 patients with PBC with suboptimal response to UDCA, treated patients with additional prednisone (30 mg/day tapered to 10 mg/day) and azathioprine (50 mg/day) [78]. There was no improvement in bilirubin. The trial was too small and of too short a duration to examine the effect on survival.

#### **A1d**

A small study of 13 patients randomized to 0.5–4 mg daily of chlorambucil (mean 2 mg daily) compared with placebo has been reported [79]. All treated patients developed some degree of bone marrow suppression and discontinuation of therapy was required in four. A 30% withdrawal rate due to drug toxicity indicates that this drug should not undergo further evaluation in patients with PBC. **A1d** A very small and short (six-month) RCT of 18 PBC patients taking thalidomide has been reported, showing little benefit of this treatment [80]. However, this study lacked adequate power to evaluate this form of

therapy in any meaningful way. No benefit on serum bilirubin was observed during the six months of treatment.

An alternative approach has been to use drugs that may not interfere with the primary cause, that is, immune-mediated bile duct destruction, but interfere with the progression of the disease, either by reducing fibrogenesis or by reducing cholestasis. Two potential antifibrotic drugs have been assessed: colchicine in four good studies [81–84] and D-penicillamine in many more [85–92]. The studies of colchicine therapy are interesting, but unfortunately all the size of the populations studied are small. A Cochrane Hepato-Biliary Group systematic review of randomized clinical trials for this agent included ten trials involving 631 patients, only four of which were high-quality [93]. No significant differences were detected between colchicine and placebo/no intervention regarding mortality (relative risk (RR), 1.21; 95% CI: 0.71–2.06), mortality or liver transplantation (RR = 1.00; 95% CI: 0.67–1.49), liver complications, liver biochemical variables, liver histology, or adverse events. **A1c** While the numerous trials of D-penicillamine demonstrated great interest, the results are also disappointing. Unlike patients with Wilson's disease, adverse effects of therapy were particularly common, resulting in a high withdrawal rate, similar to the experience with rheumatoid arthritis. This drug is not recommended for the treatment of PBC and a meta-analysis is consistent with this (including seven trials randomizing 706 patients) [94]. **A1c**

### **Reduction of cholestasis: ursodeoxycholic acid**

The prevailing view remains that UDCA improves the natural history of PBC [95], although the evidence for efficacy has been cumulative, is imperfect, and has been appropriately challenged as dogma [96, 97]. **A1a** Japanese researchers first isolated UDCA from bear bile in 1927; bear bile itself having a track record in traditional medicine as a choleric [98]. UDCA is the natural intestinal metabolite of chenodeoxycholic acid (7- $\beta$  epimer). In the 1960s patients with gallstones were found to have lower biliary levels of cholic acid and chenodeoxycholic acid, which led to trials of oral bile salt supplementation in hepatobiliary disease. UDCA is less hydrophobic and more hydrophilic than other bile acids, with apparently less toxicity towards the hepatobiliary epithelium. Its therapeutic mechanism of action includes expansion of the hydrophilic bile acid pool, a direct choleric effect (administration results in a bicarbonate-rich choleresis and modulation of biliary transporter proteins), anti-inflammatory effects (UDCA interacts with the glucocorticoid receptor *in vitro*) and anti-apoptotic effects on hepatic epithelia [99]. Cessation of therapy with UDCA leads to a return of abnormal liver biochemistry in those with PBC who respond, demonstrating that the initiating and perpetuating factors of PBC remain unresolved.

UDCA normally accounts for about 4% of bile acids but with pharmacotherapy UDCA becomes the predominant bile acid. Leuschner showed that when treating gallstones with UDCA in those with histologically confirmed HBsAg-negative chronic active hepatitis a fall in transaminases occurred [100]. In further work to investigate the dose-response relationship for UDCA, three different doses were given to patients with PBC, PSC and chronic hepatitis. This allowed Podda *et al.* to show that significant falls in liver biochemistry occurred at dosages of 4–5 mg/kg daily, but higher doses (8–10 mg/kg and 12–15 mg/kg) induced further improvements, with the changes correlated approximately with the enrichment of bile by UDCA [101]. Subsequent studies confirmed a correlation between the degree of bile enrichment and improvement in liver biochemistries and PBC Mayo risk score, and overall in PBC the data suggest that the optimum dose of UDCA if used should be 13 to 15 mg/kg per day, given as a single daily dose [40, 55, 102, 103]. UDCA at this dose is very safe, with minimal side effects: weight gain (approx. 3 kg in the first 12 months [104]), hair loss and, rarely, diarrhea and flatulence. Additionally, nothing suggests UDCA is teratogenic but it is usually stopped before and during the first trimester, and restarted subsequently, with there being a good safety profile from its use in intrahepatic cholestasis of pregnancy [105].

### Justification for the widespread use of UDCA

Many studies have attempted to demonstrate clinical efficacy for UDCA, particularly following initial studies showing a fall in bilirubin levels in patients with PBC, with most trials showing beneficial effects of UDCA on biochemical parameters in particular. With such a slow natural history any individual trial will inevitably lack the power to address endpoints such as death or liver transplantation. Additional criticism can be made for assuming that every patient benefits equally, that is, identifying and treating more patients with mild disease may be self-fulfilling if those patients were never destined to progress. Moreover whilst appealing to assume that the natural history of the disease is unchanged, the absence of a clear cut pathophysiological understanding means that such an assumption should not necessarily be considered correct.

The cumulative evidence that convinces most to prescribe UDCA, has nevertheless come from individual and pooled analysis. Of note the Mayo Clinic followed up patients with PBC treated with UDCA and have demonstrated a treatment-related prolongation in transplant free survival [106–108]. French cohorts with long-term follow-up similarly demonstrate survival benefit [109], and this was reiterated and furthered by a Spanish cohort including nearly 200 patients treated for a mean of 6.7 years [47]. Pathophysiologically early disease is most likely to respond to intervention before duct loss is established and fibrosis

present. In those with early stage disease, a biochemical response to UDCA (normalization or a 40% reduction from baseline) after one year was associated with a similar survival to the matched control population. In the Netherlands ter Borg and colleagues were able to show a survival benefit without transplant for low-risk patients compared to survival predicted by the Mayo risk model (which, as discussed, may not be a perfect risk score to employ in this case if the comparison group has predominantly early stage disease, as survival may be underestimated); moreover overall survival was nearly the same as for a control population [110]. **B4** A UK study that examined a large cohort not receiving UDCA did not, however, demonstrate differences in outcomes between treated and untreated patients [111]. A recent publication, as discussed, looked at defining the biochemical response a year after treatment, to identify UDCA-treated patients at risk of death or transplant and showed how UDCA responders had a ten-year, transplant-free survival rate of 90%, compared to 51% for those who did not [48]. **B4**

Three larger double-blind randomized trials used the same dose of UDCA (13–15 mg/kg per day), and thus the results have been analyzed according to an intention to treat principle [102, 107, 112, 113]. In two of these a composite “treatment failure” outcome measure was used, and in the third the percentage change in total serum bilirubin over two years was used as the primary outcome measure. Detailed sample size calculations and clear-cut predetermined definition of study duration were only described for this latter study. Few adverse effects of UDCA were reported and the withdrawal rate was less than 20% in all three studies. In two of the three trials, some patients initially randomized to placebo were switched to open label UDCA after the first 24 months, that is, the studies have a crossover design. However, the results were analyzed according to intention to treat (methodologically this can be criticized in studies with large crossover designs), so that those patients initially randomized to receive placebo and subsequently switched to receive UDCA remained in the placebo group for the purposes of analysis. Ultimately, then, this combined analysis of the three trials (548 patients) showed a one-third reduction in the risk of death or transplant, for patients with moderate to severe PBC, that is, UDCA therapy for up to four years led to an increase in time free of liver transplantation. Subgroup analyses did not show any benefit in patients who, at baseline, had a total serum bilirubin of less than 17–68  $\mu\text{mol/l}$  and/or stage I/II liver histology. These subgroup analyses do not prove that UDCA is ineffective in patients with asymptomatic and/or early disease, but they do suggest that clinical trials in such patients would require very large numbers of patients and would be required to be of such long duration to show any benefit of the treatment that they would not be feasible. One other concern raised was the observa-

tion that those patients crossed over to UDCA, continued to have a poorer clinical course. A further large trial (151 patients) employed a smaller dose (10–12 mg/kg body-weight daily) and a different preparation of UDCA [114]. After two years of treatment no difference in survival was seen, there being eight deaths in those randomized to UDCA and 12 in those randomized to placebo. Prolonged follow-up also showed no survival benefit [115].

### Meta-analysis findings

It should be pointed out that the pooled analysis of the three trials is not a systematic review or meta-analysis, but rather was done by pooling of results from three trials which were of similar design. This procedure differs from a systematic review or formal meta-analysis, which attempts to minimize bias by the consideration and inclusion of all relevant trials, justifies the exclusion of trials from the analysis, and explores heterogeneity between trials and the reasons for variation in results. A formal meta-analysis which demonstrates benefit from an intervention may also include a sensitivity analysis to indicate the number of unpublished or excluded trials of specified size with negative results which would be required to negate the results of the meta-analysis. Meta-analyses may suffer from the opposite weakness cited for the combined analysis of similar trials, that is, they may involve pooled analysis of trials which differ sufficiently in their design that they are not truly comparable. Accordingly, caution should be exercised in interpreting both combined analyses and meta-analyses. For PBC much debate has been generated because the various meta-analyses have been inconsistent. Some conclude no beneficial effect on the incidence of death and/or transplant, despite improvements in serum bilirubin, jaundice and ascites [96, 97]; thus, UDCA treatment offers no benefit. This contrasts with others showing that long-term treatment with the optimal dose of UDCA could improve survival free of transplant [116]. One needs to appreciate the varying, and often inadequate sample size and duration of several studies, as well as inclusion of data from trials using suboptimal doses. Both Goulis *et al.* and the Cochrane group have performed detailed analyses of the heterogeneous studies in which treatment periods ranged from as little as six months up to four years, the daily dose of UDCA ranged from 7.7 mg/kg to 15 mg/kg, and there was a wide range of disease severity. In addition, the Jadad scores for methodological quality were only  $\geq 4$  in five of the 16 trials. Sensitivity analyses for dose, length of study, and quality did not show differences in the first meta-analysis. The Cochrane group attempted to take these variations into consideration and observed a marginally significant effect of UDCA on liver transplantation only in the later period in which all the patients were treated with open label UDCA, but not in the original period in which patients were treated with

UDCA or placebo/no intervention. However, transplant is not a perfect endpoint, as already alluded to. Survival without transplant was not significantly influenced by UDCA therapy (see Figure 32.2).

Since not all placebo or non-intervention patients were eventually given UDCA (although the majority were), the evaluation of the non-randomized phases of these trials has intrinsic biases and lacks the appropriate basis for an intention-to-treat analysis. Of the 16 randomized clinical trials evaluating UDCA against placebo, nearly half of the trials had high risk of bias [97]. In all studies, the administration of UDCA was associated with an improvement of liver biochemistry. The latest updated Cochrane meta-analysis shows that overt ascites and obvious jaundice are less frequent in patients randomized to UDCA, but there was no difference in the number of patients with bleeding varices or hepatic encephalopathy. These data suggest that prolonged treatment with UDCA, started before onset of severe disease, may be required to exert a beneficial effect on the natural history of PBC; appropriately powered studies have not been performed to date, however, to definitively confirm the concept that patients with early disease benefit most from UDCA.

The meta-analysis that was confined to trials using an appropriate dose of UDCA ( $>10$  mg per kilogram of body weight per day) and with sufficient follow-up (at least two years) included a total of 1038 patients (522 who received UDCA and 516 who received placebo) [116]. Treatment with UDCA resulted in significant improvement in liver biochemical values. Histologic evidence of disease progression was similar for the two treatment groups, but subjects without evidence of fibrosis (stages I and II) who were treated with UDCA had slower disease progression than did subjects in the control group. A total of 160 patients who were treated with UDCA and 186 control subjects died or underwent liver transplantation. This difference was significant in a fixed-effect model (OR, 0.76; 95% CI: 0.57–1.00;  $p = 0.05$ ) but not in a random-effects model (OR, 0.77; 95% CI: 0.50–1.21;  $p = 0.30$ ). This particular analysis is open to criticism because of the difference seen between the fixed-effect and random-effects model.

### Osteoporosis

There are modest increases in both the absolute and relative fracture risks in people with PBC compared with the general population, with the excess risks similar in those with more severe disease [117, 118]. No effect of UDCA on bone mineral density was, however, demonstrated in the RCT of UDCA in PBC published by Lindor *et al.*, although the study may have lacked power [119]. A small study assessing bone mineral density and vertebral fractures in PBC patients randomized to cyclosporin A or placebo suggested that cyclosporin-treated patients have less bone loss and better biochemical parameters of bone remodelling

**Figure 32.2** Meta-analysis of ursodeoxycholic acid for primary biliary cirrhosis: outcome mortality or liver transplantation [97].

[120]. With regard to specific treatment of osteoporosis in PBC, a number of small trials have been performed. Etidronate was not shown to be beneficial whereas alendronate was well tolerated and did significantly improve bone density in a double-blinded randomized, placebo-controlled trial, including a total of 34 patients followed for one year [121, 122]. Estrogen therapy can be used safely (from the hepatic perspective) and there is limited data on its efficacy [123–125].

### Fatigue and pruritus

Although there are now some very sophisticated methods to measure these symptoms [126], none of the RCTs of therapy for PBC employed such instruments to monitor the effect of therapy. There are many anecdotal case reports of marked improvement and marked worsening of both fatigue and pruritus in patients receiving UDCA. Pilot studies of methotrexate have reported dramatic improvement in both fatigue and pruritus, but these uncontrolled

studies provide only weak evidence for benefit. The Newcastle group have reported a study of the CNS-acting drug modafinil in patients with PBC suffering from significant daytime somnolence and associated fatigue [127]. Open label modafinil therapy was associated, where tolerated by patients, with improvement in excessive daytime somnolence and associated fatigue in PBC, but clearly placebo-controlled trials are needed. Effective treatments for pruritus, a distressing symptom in PBC are more readily available [128]. Although randomized controlled data is limited [129], treatment approaches include cholestyramine [130, 131], rifampin [132], sertraline [133], opioid antagonists [134, 135] and plasma exchange or albumin dialysis [136–138].

### Histology

In the study by Pares *et al.* the apparent benefit of five years of UDCA therapy on liver histology in terms of stage of disease, progression of bile duct destruction and interface

hepatitis was significantly greater than that observed in those randomized to placebo [139]. The majority of patients included in this trial had early asymptomatic disease. Assessment of liver histology from the French multicenter study using the Markov model indicated that regression of cirrhosis was never seen, but that the progression to cirrhosis was markedly delayed in those who received UDCA [140]. It must be emphasized that follow-up liver histology was not available in all randomized patients, some refused to have a second biopsy, and more importantly, no second biopsy was obtained from those patients who died or required a liver transplant, that is, those whose liver disease clearly had progressed. Only 44% of patients had second biopsies available for evaluation. This factor introduces the potential for significant bias into observations concerning effect of both UDCA and placebo on histology. However, a further pooled study showed that two years of UDCA treatment reduced periportal necroinflammation and improved ductular proliferation; if UDCA was initiated at the earlier stages disease (I–II) it also delayed the progression of histologic stage [141].

#### Cost-effectiveness of ursodeoxycholic acid therapy in primary biliary cirrhosis

Cost-efficacy analyses are limited to one paper, which used data from two previously published trials, and determined the effectiveness of UDCA by comparing the annual reduction in the development of ascites, varices, variceal bleeding, encephalopathy, liver transplantation, and death between the treatment groups [142]. Average annual costs for each of these events were estimated based on literature and institutional data. Approximately twice as many major events occurred in the placebo group compared with the UDCA group. Based on the estimated annual cost of managing these events and the then annual costs of UDCA (\$2500), there was an annual cost saving per patient of \$1372. Compared with the placebo group, patients receiving UDCA had a lower incidence of major complications and lower medical care costs.

#### Recurrent PBC following liver transplantation

After around five years, perhaps approaching one in five patients transplanted for PBC will have histological evidence of recurrence [143]. Diagnosis needs to be carefully evaluated in view of the broad differential in transplant recipients, but disease progression is slow and retransplantation exceptional. Some data suggests lower recurrence with cyclosporin use as opposed to tacrolimus [144], and whilst UDCA appears to improve liver biochemistry, in the short term it does not alter histological progression [145].

### The future for therapy in primary biliary cirrhosis

Although most physicians will prescribe UDCA for patients with PBC, newer and more targeted therapies are needed. Specific targets may arise when there is a better biologic understanding of disease. The group of patients most appropriate for new agents would logically be those who fail to respond adequately to UDCA (around 40% of patients) and a number of agents are worthy of comment. The addition of bezafibrate (which may increase phospholipid translocation into the bile) has been investigated, but the results to date are early and a well-powered study is needed [146, 147]. Atorvastatin, with many anti-inflammatory properties beyond its lipid lowering effects, was recently shown not to be of value for PBC [148]. In view of the cloning of a human retrovirus from a cDNA library derived from PBC biliary epithelia cells, anti-retrovirals have been investigated, but convincing data is still awaited [149, 150]. More selective immunosuppression (e.g. rituximab) is also being studied. More specific approaches focusing on fibrosis modulation may eventually prove efficacious, for example rapamycin, angiotensin blockade, or adhesion molecule modulation. Finally, other ways of targeting the bile acid pathway are being pursued. Modifications to UDCA (e.g. nor-UDCA) may appeal [151], as well as interfering with nuclear hormone receptors [152]. The Farnesoid X receptor (FXR) is a bile acid-activated nuclear receptor highly expressed in both the liver and gastrointestinal tract. It has a role in regulating bile and cholesterol metabolism and FXR agonists (e.g. novel bile acids or small molecule agonists such as INT-747) may have a place in treating cholestatic liver diseases. The first ever genome wide association study in PBC published in 2009 [153] identified the IL-12 signaling axis as highly relevant to disease, and so rational therapy may now truly be on the horizon for patients.

## Introduction

Autoimmune hepatitis is a self-perpetuating necroinflammatory disease of unknown etiology, which is characterized by a loss of tolerance towards the patient's own liver tissue. If left untreated the disease leads to cirrhosis and liver failure. Since the recognition of immunologically based liver disease in the 1950s, efforts have been directed toward the development of tools for diagnosis, classification according to serological markers and clinical course, and distinguishing autoimmune hepatitis from other liver diseases.

In the early years diagnosis of autoimmune hepatitis was hampered by the lack of knowledge about the etiology of most acute and chronic liver diseases. The detection of hepatitis viruses and a better understanding of the etiology of other forms of liver disease allowed for the exclusion of patients with these disorders from studies of autoimmune hepatitis and a more accurate determination of prognosis and effects of immunosuppressive drugs. The characterization of distinctive autoantibodies and the identification of autoantigens led to a more specific diagnosis of the disease and to the ability to characterize distinct subclasses according to prognosis, treatment response and outcome.

---

## Features of autoimmune hepatitis

Autoimmune hepatitis is a syndrome which is characterized by a typical constellation of epidemiological, laboratory and clinical features: female predominance (female: male ratio 4:1), overrepresentation of the human leukocyte antigen (HLA) alleles DR3 and DR4, hypergammaglob-

ulinemia, circulating autoantibodies, response to immunosuppressive therapy and coexistence of extrahepatic autoimmune diseases. The disease is seen in all ethnic groups and at all ages [1–5]. The mean annual incidence of AIH among white Northern Europeans is ~2 per 100,000 inhabitants, and its point prevalence is ~17 per 100,000 [6].

## Clinical features

Although autoimmune hepatitis occurs mainly in young women, the disease may develop at any age and in either sex [5]. Patients with AIH frequently complain about non-specific symptoms such as fatigue, jaundice, nausea and abdominal pain at presentation, but the clinical spectrum is wide, ranging from an asymptomatic presentation to fulminant disease. Forty percent of patients present with acute hepatitis [7]. Fulminant liver failure may occur but is rare. Hepatomegaly is common and an enlarged spleen is palpable in 50% of patients. In some patients the disease progresses without major symptoms, and the diagnosis is not made until symptoms of severe liver disease are present. Amenorrhea occurs in women with severe hepatic inflammation.

Coexisting extrahepatic autoimmune diseases are frequently found in patients with autoimmune hepatitis. Whereas arthropathies and periarticular swelling of both large and small joints occurs in 6–36% of patients, arthritis with joint erosions is rarely seen. Additional clinical features are listed in Table 33.1.

The risk of hepatocellular carcinoma in autoimmune liver disease varies considerably between the different diseases PBC, PSC and AIH. Particular PSC can be complicated by cholangiocarcinoma, gallbladder carcinoma and hepatocellular carcinoma [8]. In contrast, the incidence of HCCs in patients with AIH was not well documented for a long time. However, several recent retrospective studies indicate that about 2% of AIH patients eventually develop HCCs [9–11]. Similar to other chronic liver diseases, cirrhosis is the *sine qua non* for HCC development in AIH.

### Serological features

Autoantibodies are an important tool for the diagnosis of AIH [12]. However, autoantibodies are not specific to AIH and their expressions can vary during the course of AIH [13]. Furthermore, a low autoantibody titer does not exclude the diagnosis of AIH and a high titer (in the absence of other supportive findings) does not establish the diagnosis. Importantly, autoantibodies do not cause the disease nor alter in titer in response to treatment (at least in adult populations); as such, they do not need to be serially monitored [12]. ANA, SMA and LKM are pivotal components for the diagnosis of AIH and should be first tested in suspicious patients [14]. ANA were the first autoantibodies to be associated with AIH and led Mackay to create the term “lupoid” hepatitis as early as 1956. ANA are the most non-specific marker of AIH and can also be found in PBC, PSC, viral hepatitis, drug-related hepatitis, and alcoholic and non-alcoholic, fatty liver disease [15, 16]. Additionally, serum ANAs have been reported to occur in up to 15% of the general healthy populations from different countries, increasing with age. SMA are frequently found in AIH, and are directed against components of the cytoskeleton such as actin and non-actin components, including tubulin, vimentin, desmin and skeleton [15]. They frequently occur in high titers in association with ANA and are, like ANA, present in a variety of liver and non-liver diseases such as rheumatic diseases. Antibodies to LKM were first discovered in 1973 by indirect immunofluorescence and are reactive with the proximal renal tubule and hepatocellular cytoplasm [17, 18]. They form a heterogeneous group and are associated with several immune mediated diseases, including AIH, drug-induced hepatitis, the autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED or APS-1), and chronic hepatitis C and D infection [15]. A 50kilo Dalton antigen of LKM-1 was identified as the cytochrome mono-oxygenase P450 2D6 (CYP2D6). LKM-3 antibodies are directed against family 1 uridine 5'-diphosphate glucuronosyltransferase (UGT1A), which belong to the drug metabolizing enzymes located in the endoplasmatic reticulum.

Patients who present without these antibodies may be tested for other, characterized autoantibodies. Antibodies against LC-1, SLA/LP, pANCA and the asialoglycoprotein receptor may be helpful to extend the diagnosis of AIH in these patients. Anti-LC1 antibodies are visualized by indirect immunofluorescence. However, their characteristic staining may be masked by the more diffuse pattern of LKM-1 antibodies. Therefore, other techniques such as ouchterlony double diffusion, immunoblot and counter-immunoelectrophoresis are also used for their detection. The antigen recognized by anti-LC1 was identified as formiminotransferase cyclodeaminase (FTCD) [19]. Contrary to most other autoantibodies in AIH, anti-LC1 seems to correlate with disease activity and may be useful as a marker of residual hepatocellular inflammation in AIH [20]. Anti-SLA/LP antibodies are detectable by radioimmunoassay and enzyme linked immunosorbent assays (ELISA) but cannot be detected by immunofluorescence [15]. Anti-SLA/LP antibodies are considered to be highly specific for AIH, in which they are detectable in about 10–30% of patients. In some patients, they are the only serological marker of autoimmune hepatitis. Screening of cDNA expression libraries identified a UGA tRNA suppressor as anti-SLA target autoantigen [21]. Several studies suggest that patients with anti-SLA/LP antibodies display a more severe course of the disease [22–25].

Additionally, antibodies against cardiolipin, chromatin and *Saccharomyces cerevisiae* have been described in AIH, which, however, do not define patients with a distinctive clinical phenotype [26–28].

There have been several proposals to classify AIH according to different antibody profiles. According to this approach, AIH type I is characterized by the presence of ANA and/or anti-SMA antibodies. AIH type II is characterized by anti-LKM-1 and with lower frequency against LKM-3 antibodies. AIH type III is characterized by autoantibodies against SLA/LP. AIH-2 displays a regionally variable prevalence, with only 4% in the USA and up to 20% in western Europe [18, 29]. Patients with AIH-II are younger at presentation, show a more severe course at onset and are more likely to progress to cirrhosis [30]. Both entities of AIH are characterized by a high incidence of other organ specific immune mediated diseases, for example autoimmune thyroid disease, which are not only detected in patients with AIH, but also in their first degree relatives.

### Histological features

Autoimmune hepatitis cannot be diagnosed by liver histology alone, since there are no pathognomonic histological features. Histology can only support the diagnosis and is used to classify disease activity (grading) and the degree of fibrosis (staging). There is a general agreement that bridging necrosis and multilobular necrosis should be

**Table 33.2** HLA alleles and autoimmune hepatitis.

HLA allele	Population	Adults/Children	# Pat.	#Contr.	Risk ratio

regarded as factors associated with a poor prognosis. Interface hepatitis, also known as piecemeal necrosis or periportal hepatitis, is the histological hallmark and plasma cell infiltration is typical [14, 30–32].

Up to 30% of adult patients have histological features of cirrhosis at diagnosis [5, 33]. Recent data indicate that only a small number of patients develop cirrhosis during therapy and that fibrosis scores are stable or improve in up to 75% patients [34]. However, it is important to note that the presence of cirrhosis at baseline significantly increases the risk of death or liver transplantation [5, 35]. Almost half of children with AIH already have cirrhosis at the time of diagnosis [36, 37]. In elderly patients a more severe histological grade has been reported, but the frequency of cirrhosis does not seem to be different from that in younger patients [38, 39].

### Genetic features

It is generally accepted that occurrence and probably the severity of autoimmune hepatitis is influenced by genetic factors. However, the heritable component of AIH is currently regarded as small. The most conclusive genetic association with autoimmune hepatitis is related to the major histocompatibility complex alleles. Among white northern European and Americans there is a well-recognized association between increased susceptibility to AIH and inheritance of HLA DR3 and HLA DR4 (later identified as DRB1\*0301 and DRB1\*0401 respectively) [40, 41]. HLA DR3 is the main susceptibility factor in white Caucasians, and HLA DR4 is a secondary but independent risk factor for the disease. Eighty-five percent of white patients with type I AIH from the USA and northern Europe have HLA DR3, DR4, or DR3 and DR4. Table 33.2 summarizes confirmed associations of HLA DRB1 alleles in AIH patients

from different populations [42]. Based on these data, different models have been created whereby genetic susceptibility and resistance to AIH is best related to specific amino acid sequence motifs within DRB1 polypeptides. Donaldson has suggested three different models: one, for type I AIH is dependent on histidine or other basic amino acid residues at position 13 of the DR $\beta$  polypeptide; the second is based on the amino acid residue LLEQKR at positions 67–72 of the DR $\beta$  polypeptide and the third model is based on valine/glycine dimorphism at position 86 [43].

HLA alleles associated with AIH confer not only susceptibility towards AIH but also appear to influence the course of the disease. Most strikingly, patients with the DRB1\*0301 were found to be younger at disease onset and have a higher frequency of treatment failure, relapse after treatment withdrawal and liver transplantation. Patients with DRB1\*0401 are at greater risk to develop additional autoimmune disorders, but are thought to be associated with milder disease, seen in older patients, which is easier to treat [41, 44, 45].

### Diagnosis

Because signs and symptoms of AIH are not specific, an international panel (the International Autoimmune Hepatitis Group (IAIHG)) established a consensus on diagnostic criteria, and its recommendations were published in 1993 [46], and revised in 1999 [14]. These criteria include clinical, laboratory and histological findings at presentation, as well as response to corticosteroid therapy and are in most cases sufficient to make the diagnosis of autoimmune hepatitis and to distinguish it from other forms of chronic hepatitis. Response to corticosteroids may help to clarify the diagnosis even in patients who lack other typical

features (see Table 33.3) [14, 30, 42, 47]. Additionally, a scoring system was established assigning points (both negative and positive) to specific findings to allow for the distinction between a definitive diagnosis and a probable diagnosis. Prior to corticosteroid treatment, a definitive diagnosis requires a score greater than 15; after treatment, a definitive diagnosis requires a score greater than 17.

The AIH scoring system was subsequently subjected to validation testing in several studies, which consistently showed that the sensitivity was very high (97–100%) but that the specificity for excluding AIH in patients with biliary disorders was markedly lower (44–65%) (see Table 33.3). The notable weakness of the original system in excluding cholestatic syndromes justified the subsequent revision to further downgrade cholestatic findings [14]. The new scoring system more precisely differentiated between biliary diseases and AIH, and application of the revised system in PBC and PSC patients revealed significantly less patients who scored for definite and probable AIH [48, 49].

However, the above-described criteria were primarily introduced to allow comparison of studies from different centers. Because these criteria are complex and include a variety of parameters of questionable value, the IAIHG decided to devise a simplified scoring system for wider applicability in routine clinical practice. A limited number of routinely available measurements were therefore selected to design the score. Liver histology (demonstration of hepatitis on histology is required), autoantibody titers, gamma-globulin/IgG levels, and the absence of viral hepatitis were found to be independent predictors for the presence of AIH (see Table 33.4) [50]. The score was found to have good sensitivity and specificity in a second validation set. Therefore a simple score based on four measurements may be sufficient to differentiate between patients with or without AIH, with a high degree of accuracy. However, additional studies are required to validate this score in patients with different chronic liver diseases.

## Treatment

The indication for treatment of AIH is based on inflammatory activity and not so much on the presence of cirrhosis. In the absence of inflammatory activity immunosuppressive treatment has only limited effects. An indication for treatment is present when aminotransferases are elevated two-fold, gamma globulin levels are elevated two-fold and histology shows moderate to severe periportal hepatitis. Symptoms of severe fatigue are also an indication for treatment. An absolute indication exists in cases with a ten-fold or higher elevation of aminotransferase levels, histological signs of severe inflammation and necrosis, and upon disease progression.

**Table 33.3** Scoring system for diagnosis of autoimmune hepatitis.

## Conventional corticosteroids and azathioprine

Three controlled trials provided evidence that corticosteroid therapy reduces mortality in autoimmune hepatitis, and this benefit was further substantiated by longer follow-up of the patients in one of these studies (see Table 33.5). The magnitude of the reduction of mortality produced by steroids can be estimated from the original analysis of the study of Cook *et al.* (control 55%, steroid 14%, absolute risk reduction (ARR) 42%, numbers needed to treat (NNT) = 3) and from the analysis conducted after ten-year follow-up

of the same patient groups (control 73%, steroid 37%, ARR 36%, NNT = 3) [51, 52]. **A1d**

Treatment with prednisone monotherapy or in combination with azathioprine remains the standard therapy for patients with AIH [53]. Both are equally effective and the decision for either strategy involves the consideration of patient profiles [54]. Data from the randomized trials and from uncontrolled studies suggest that the remission rate is approximately 80% with initial therapy [55]. About 9% percent of patients deteriorate despite compliance to treatment, 13% improve, but not to a degree to reach remission and 13% are intolerant to standard therapy [56, 57]. Long-term remission is maintained by low-dose corticosteroids alone or in combination with azathioprine (1–2 mg/kg body weight) or with azathioprine monotherapy [53]. **B4**

Controlled trials have not been performed in patients with mild asymptomatic autoimmune hepatitis. In these patients, who numerically far outnumber patients with severe liver disease, the role for steroid therapy remains unclear and the decision to treat must be weighed against the risk of medication. A recent study revealed that the overall survival and survival to liver related endpoints of asymptomatic patients who received no therapy was not different to that of the total cohort [5]. **B4** However, asymptomatic patients not receiving therapy require a close follow-up since 25% of this group subsequently developed symptoms [5].

Treatment withdrawal should not be attempted less than 2–3 years from the start of therapy to prevent early relapse. Drug withdrawal should be preceded by liver biopsy if a long-term biochemical remission is not documented. The rate of relapse depends on the degree of continuing inflam-

**Table 33.5** Effect of prednisone on mortality in randomized controlled trials of chronic autoimmune hepatitis (CAH).

Study	Patients	Steroid regimen	Control intervention	Mortality		
				Control	Steroid	p
Cook <i>et al.</i> (1971)	49 patients with CAH, 35 with cirrhosis; no previous steroids; 5 patients (4 in steroid group) excluded from analysis because of change in diagnosis	Prednisone 15 mg (3–72 months) attempts to withdraw after 1 month	"No specific treatment"	3/22	15/27	<0.01
Soloway <i>et al.</i> (1972)	35 <sup>a</sup> patients with chronic liver disease biochemically and histologically, 16 with cirrhosis	Prednisone 20 mg after 4 weeks tapering course from 60 mg (3 months to 3.5 years)	Placebo	1/18	7/17	<0.05
Murray-Lyon <i>et al.</i> (1973)	47 patients with chronic aggressive hepatitis, 33 with cirrhosis; approximately half had previous steroid or azathioprine	15 mg daily (up to 2 years); discontinued in 1 month if no improvement in liver function	Azathioprine 75 mg	1/22	6/25	N/A <sup>b</sup>

<sup>a</sup> Additional patients were randomized to receive prednisone 10 mg plus azathioprine 50 mg (14 patients), or azathioprine 100 mg (14 patients); see text.

<sup>b</sup> N/A, not available. Estimated probability of survival at two years: steroid 95%, azathioprine 72%.

mation and increases from 20% with complete resolution of hepatic inflammation to 50% with ongoing portal inflammation, and 100% with progression to cirrhosis or persisting periportal hepatitis. The rate of relapse after treatment withdrawal is as high as 80%. Those without relapse have to be regularly assessed by clinical parameters and liver biopsy, as the risk of relapse cannot be predicted reliably. Ongoing inflammation may exist without significantly elevated transaminases. Normal liver histology after two years of steroid therapy does not exclude relapse following treatment withdrawal.

### Budesonide

Budesonide, a non-halogenated glucocorticoid, is of particular interest for the treatment of AIH, because it has a 15-fold greater receptor binding capacity than prednisolone, and a high hepatic first-pass clearance, exceeding 90% of the orally administered dose. Several small studies suggested that budesonide might be an interesting alternative for immunosuppression, with fewer side effects than conventional glucosteroids. The potential benefit of budesonide was therefore evaluated in a phase 3 multicenter, multinational clinical study. In this study, patients with newly diagnosed AIH and no signs of cirrhosis were randomized to a six-month treatment period. Randomized patients received either prednisolone (dose: 40 mg for the first four weeks, and then tapered down to 10 mg/day in week nine; upon early biochemical remission start of tapering was allowed already at week three) or 3 mg budesonide tid. Upon biochemical remission budesonide dose was reduced to 3 mg bid. All patients received azathioprine at a dose of 1–2 mg/kg body weight. The primary endpoint was defined as biochemical remission, defined as AST and ALT within normal range without steroid specific side effects throughout the six-month treatment period (complete response). In this largest AIH-trial, ever conducted, 3 mg tid oral budesonide was superior to oral prednisone in inducing biochemical remission in AIH with significantly less steroid specific side effects, suggesting that budesonide is a valid alternative for conventional steroids in selected patients [58]. **A1d**

### Other immunosuppressive drugs

If standard treatment fails or drug intolerance occurs, alternative therapies can be considered. Several agents have emerged, especially from the transplantation setting, which might offer greater immunosuppression and which are better tolerated than prednisone and azathioprine. These include cyclosporine A, tacrolimus, cyclophosphamide, mercaptopurine, mycophenolate mofetil or deflazacort, which have been more or less successfully tested in several small studies with AIH patients [59–63]. **B4**

### Liver transplantation

Liver transplantation remains the only life-saving option in approximately 10% of AIH patients. The indication for liver transplantation in AIH is similar to that in other chronic liver diseases [64]. The disease accounts for about 4–6% of liver transplantation in the USA and Europe. Candidates for liver transplantation are usually patients who do not show early response at six months of treatment and who do not reach remission within three years of continuous therapy [65]. The long-term results of liver transplantation for AIH are excellent and well within the range of other indications for liver transplantation [66]. Studies published during past years indicate that the rate of recurrence of AIH ranges between 10–35%, and that the risk of AIH recurrence is perhaps as high as 68% after five years of follow-up [66, 67]. Prednisone alone or in combination with azathioprine remains the therapy for recurrent autoimmune hepatitis [68, 69]. Addition of rapamycin successfully treats patients with post-transplant hepatitis, not responding to treatment with increasing doses of prednisolone and addition of azathioprine or to calcineurin inhibitors [70].

**B4** Several follow-up studies indicate that patients with recurrent AIH are at risk of developing liver allograft cirrhosis, requiring re-transplantation. Some patients even develop recurrence of AIH within the second graft.

Development of *de novo* autoimmune hepatitis in patients who undergo transplantation for non-autoimmune liver disease is rare (2.5–3.4% of allografts) and predominantly occurs in children. [71–73]. Treatment with prednisolone and azathioprine is effective in these patients.

### Prognosis

Data on the natural progression of untreated disease are derived principally from papers published in the 1960s and 1970s, prior to the widespread use of immunosuppressives for AIH. The mortality in untreated autoimmune hepatitis in the placebo control groups of these early clinical trials was greater than 50% within 3–5 years of diagnosis [74, 75]. However, only cases with severe inflammatory activity or fibrosis were included in these early trials. Although the etiology of the chronic hepatitis was not certain, due to the lack of viral markers, the majority of patients in these trials appear to have been suffering from autoimmune hepatitis. However, it was impossible to exclude hepatitis C infection until the early 1990s. Verification of these data on naive patients in whom the diagnosis of hepatitis C has been excluded is not possible, since studies including untreated control groups or cohort studies of untreated patients can no longer be justified ethically.

Several studies have shown that up to 30% of adult patients have histological features of cirrhosis at diagnosis.

In one study on the natural history of AIH from the Mayo clinic, Roberts *et al.* found that the ten-year survival of patients with cirrhosis was similar to that of patients without cirrhosis at baseline (93%) [76]. In contrast, one recent study reported that patients with cirrhosis at baseline had poorer ten-year survival (61.9%; CI: 44.9–78.9%) than those without cirrhosis at presentation (94.0%; CI: 87.4–100%) ( $p = 0.003$ ) regardless of whether they presented with symptoms or whether they received immunosuppressive therapy [5]. **B4** Furthermore, patients with cirrhosis at presentation were shown to be more likely to die or develop complications of their liver disease during follow-up [35].

Almost half of the children with AIH already have cirrhosis at the time of diagnosis. Long-term follow-up revealed that only a few children can completely stop all treatment and about 70% of children receive long-term treatment [18, 36]. Most of these patients relapse when treatment is discontinued, or if the dose of immunosuppressive drug is reduced. About 15% of patients develop chronic liver failure and are transplanted before the age of 18 years.

In elderly patients, a more severe initial histological grade has been reported, but the frequency of cirrhosis does not differ from that in younger patients. At follow-up, about 30% of patients develop cirrhosis. Response to immunosuppression is similar in older and younger patients and up to 90% of older patients achieve remission. However, in a study from the UK 41% of the elderly patients with AIH received no immunosuppressive therapy and the prognosis was not worse than in younger, usually treated, patients [39, 77, 78]. **B4**

## Introduction

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease in which a progressive obliterating fibrosis of the intrahepatic and extrahepatic bile ducts leads to biliary cirrhosis, portal hypertension and eventually hepatic failure, and in addition 10–30% of patients will develop a cholangiocarcinoma. In comparison with some of the conditions discussed in this book, PSC is a rare disease. But the absence of large randomized clinical trials and meta-analyses in PSC does not prevent gathering the best evidence with which to attempt to answer the many questions posed by patients and clinicians about the etiology, diagnosis, prognosis and management of this disease. Inevitably, where good external evidence is lacking, personal clinical expertise may play a greater role in the decision-making process. This integration of clinical expertise and best available clinical evidence from systematic research constitutes the practice of “evidence-based gastroenterology”.

## Etiology

A number of causative agents have been implicated in the pathogenesis of PSC but no single hypothesis has provided a unifying explanation for all the clinical and pathological features of this disease. PSC is closely associated with inflammatory bowel disease (IBD), the majority (65–86%) of patients with PSC have coexistent ulcerative colitis and the prevalence of PSC in ulcerative colitis (UC) populations is between 2% and 6% [1–3]. In a patient with ulcerative colitis, abnormal liver function tests, particularly an elevated serum alkaline phosphatase, may be the first indica-

tion of this insidious condition. Magnetic resonance cholangiopancreatography (MRCP) and endoscopic retrograde cholangiopancreatography (ERCP) are diagnostic, demonstrating the diffuse multifocal strictures and dilatation giving rise to the characteristic “beaded” appearance. The precise etiology and pathogenesis of PSC is still not completely understood. This chapter sets out the evidence that immune mechanisms play a key role in the development of the disease.

## Autoimmunity

The 2:1 male to female ratio of patients with PSC and the relatively poor response of the disease to immunosuppression suggest that PSC is not a classic autoimmune disease. PSC patients do have an increased frequency of the HLA B8 DR3 DC2 “autoimmune” haplotype, in common with a number of organ-specific autoimmune diseases such as lupoid chronic active hepatitis, type I diabetes mellitus, myasthenia gravis and thyrotoxicosis [1–3]. PSC is also independently associated with a range of autoimmune diseases, diabetes mellitus and Graves’ disease being the most common. Saarinen *et al.* found that 25% of patients with PSC had one or more autoimmune disease, compared with 9% of patients with IBD alone [4].

## Autoantibodies

A wide range of autoantibodies can be detected in the serum of patients with PSC, clearly indicating an altered state of immune responsiveness or immune regulation. Although a few studies have demonstrated some correlation between particular clinical parameters and the presence of autoantibodies, there is presently insufficient evidence to make use of any of them in determining prognosis. Most are present at low prevalence rates and at relatively low titers (see Table 34.1).

Anti-neutrophil specific antibodies are commonly found in the sera of PSC patients, occurring in up to 88% of

**Table 34.1** Serum autoantibodies in primary sclerosing cholangitis.

Antibody <sup>a</sup>	Prevalence
Anti-nuclear antibody	7–77%
Anti-smooth muscle antibody	13–20%
Anti-endothelial cell antibody	35%
Anti-cardiolipin antibody	4–66%
Thyroperoxidase	7–16%
Thyroglobulin	4%
Rheumatoid factor	15%

<sup>a</sup> Antimitochondrial antibody is only rarely detected in PSC (<10%). This is useful in differentiating primary sclerosing cholangitis from primary biliary cirrhosis.

patients. The antineutrophil cytoplasmic antibodies (ANCA) associated with PSC are distinct from cANCA and classic pANCA in that they demonstrate a unique staining pattern on indirect immunofluorescence microscopy. These “atypical pANCA” are non-specific, with a prevalence of 33–88% in PSC, 40–87% in ulcerative colitis, and 50–96% in type I autoimmune hepatitis (AIH) [5]. Work by Terjung and Worman has demonstrated that the target antigen for atypical pANCA is a neutrophil envelope protein termed viz tubulin-beta isotype 5 and appears to be localized to the nuclear periphery [6]. It has been suggested that the anti-neutrophil antibody in PSC therefore be renamed pANNA (anti-neutrophil nuclear antibody).

Over recent years, several autoantibodies have been identified and implicated in the pathogenesis of PSC. The presence of autoantibodies to surface antigens expressed on biliary epithelial cells has been demonstrated in PSC. Preuss *et al.* evaluated the presence of serum autoantibodies to human recombinant sulphite oxidase (anti-SO) in a variety of chronic liver disorders, and observed the highest incidence in PSC patients [7]. Furthermore, antibody activity decreased significantly during ursodeoxycholic acid (UDCA) treatment. The specificity of glutathione S-transferase theta 1 (GSTT1) as a potential autoantigenic target was evaluated in PSC [8]. Reactivity against GSTT1 was found with PSC and IBD as well as some patients with other autoimmune pathology, indicating that this population of antibodies is neither specific nor a sensitive serologic marker for PSC, but the frequency was clearly higher in autoimmune patients than controls.

The importance of autoantibodies in the development of PSC remains unclear. To date there is no convincing model of the pathogenesis of PSC and it may be that these antibodies are simply a marker for an as yet undetermined immune dysregulation.

## Immunogenetics

Studies of genes encoding the key proteins in the immune system have contributed towards our understanding of the influence of the immune system on the development and progression of PSC.

PSC appears to be a “complex” disease in that it is not attributable to a single gene locus. Susceptibility to PSC is probably acquired through inheriting one of a number of patterns of genetic polymorphisms which together cause a predisposition to development of the disease.

## MHC genes

The major histocompatibility complex on the short arm of chromosome 6 encodes the HLA molecules which have a central role in T cell response and are highly polymorphic. The major histocompatibility complex (MHC) class I and class II regions encode the classical transplantation antigens of the HLA A, B, CW and DR, DQ and DP families. The class III region encodes a range of immune response genes, including those encoding tumor necrosis factor- $\alpha$  and  $\beta$  (TNF- $\alpha$  and  $\beta$ ), the heat shock protein family (HSP-70), complement proteins C2, C4A, C4B, Bf, and the genes encoding the MHC class I chain-related proteins, MIC $\alpha$  and  $\beta$  (MICA and MICB).

An association between the haplotypes HLA A1-B8-DR3, DR6 and DR2 and susceptibility to PSC are well documented, whilst the presence of HLA DR4 is protective [9]. A recent Norwegian study demonstrated that a gene in linkage disequilibrium with the D6S265\*122 microsatellite allele contributes to susceptibility to developing PSC in individuals carrying DR6 solely [10]. Furthermore, a possible protective effect of DR11 was observed. MICA\*008 homozygosity confers the strongest association with disease susceptibility. However, the MICA\*002 allele has been shown to be protective [10]. The technique of molecular genotyping has elucidated six key HLA haplotypes associated with PSC (see Table 34.2).

Karlsen *et al.* found that HLA associations found in PSC were mostly distinct from those seen in UC [11]. Also, no significant differences were observed between PSC patients with or without concurrent UC, suggesting that UC in PSC may in fact represent a distinct UC/IBD phenotype.

## Non-MHC immunoregulatory genes

A range of non-MHC immunoregulatory genes has been studied in relation to PSC. Cytotoxic lymphocyte antigen-4 (CTLA-4) is one of the differentiation antigens exclusively expressed on activated CD4+ and CD8+ T cells. It acts by binding to B7, the same ligand as CD28, thereby disrupting the crucial CD28-B7 interaction, one of the key co-stimula-

**Table 34.2** Key HLA haplotypes associated with primary sclerosing cholangitis (PSC).

Haplotype	Significance in PSC
B8-TNF*2-DRB3*0101-DRB1*0301-DQA1*0501-DQB1*0201	Strong association with disease susceptibility
DRB3*0101-DRB1*1301-DQA1*0103-DQB1*0603	Strong association with disease susceptibility
DRB5*0101-DRB1*1501-DQA1*0102-DQB1*0602	Weak association with disease susceptibility
DRB4*0103-DRB1*0401-DQA1*03-DQB1*0302	Strong association with protection against disease
MICA*008	Strong association with disease susceptibility

tory events in the initiation and progression of the T cell immune response. A CTLA-4 gene polymorphism has been associated with susceptibility to several autoimmune diseases, although its role in PSC is controversial, with a recent study failing to demonstrate any association [12].

Recent studies on non-HLA polymorphisms have produced conflicting data. An Australian study demonstrated that a 32 base pair deletion in the chemokine receptor-5 (CCR5-Delta 32) gene resulted in a non-functioning receptor, and that this was strongly associated with PSC [13]. In contrast, a Belgian study concluded that the mutation was in fact protective against PSC [14], whilst a third study failed to demonstrate any association with the deletion and PSC in 363 Scandinavian patients [15]. A subsequent study from the Belgian investigators observed that the -28G promoter polymorphism of the Regulation on Activation Normal T Expressed and Secreted (RANTES, a ligand of the CCR5 receptor) gene was significantly increased in PSC patients compared with IBD patients and healthy controls [16]. The authors hypothesized that the resulting inflammatory response in the gut predisposed to bacterial translocation through the bowel wall.

Intracellular adhesion molecule-1 (ICAM-1) mediates leucocyte adhesion and is found on proliferating bile ductules and interlobular bile ducts in patients with advanced PSC. Yang *et al.* have previously shown that K469E homozygosity for ICAM-1 is associated with protection against PSC in a cohort of British patients [17]. However, no such association was demonstrated in a larger Scandinavian study [18].

The end result of inflammation in PSC is periductal fibrosis. Genes involved in the regulation of the production and destruction of extracellular matrix are therefore also good candidate genes for study. One such family of genes is that

comprising the matrix metalloproteinases (MMPs). A promoter polymorphism of MMP-3 (stromelysin) has been shown to be associated with both susceptibility to PSC and progression to portal hypertension [19]. Wiencke *et al.* could not confirm this association in 165 Norwegian PSC patients [20]. However, the polymorphism was noted to be more prevalent in patients with concurrent PSC and UC in comparison to patients with PSC only.

Karlsen *et al.* found that the genetic polymorphisms conferring susceptibility to IBD (CARD15, TLR-4, CARD4, SLC22A4, SLC22A5, DLG5 and MDR1) did not play a role in the genetic predisposition to PSC in a large cohort of Scandinavian patients [21].

### Cellular immune abnormalities

The initiation and maintenance of the immune cascade is determined not only by MHC recognition but also by the presence of accessory cells and molecules to provide co-stimulatory signals and the production of cytokines to amplify or modify the immune response.

The cellular infiltrate at the site of tissue injury is probably more relevant than the circulating population. Although it is clear that there is a T cell predominant portal tract infiltrate in PSC, there is still some uncertainty regarding the relative importance of CD4+ and CD8+ cells in this infiltrate. The hypothesis that these T lymphocytes are involved in the pathogenesis of the disease (rather than simply being markers for its presence) is supported by evidence that these cells are functional. This evidence comes from studies of surface markers expressed on activated and memory T cells.

### T cells

Most T cells carry a T cell receptor (TCR) consisting of two disulphide-linked polypeptides, termed  $\alpha$  and  $\beta$ . A group of T cells carrying an alternative receptor, termed  $\gamma\delta$ , has been identified. The significance of  $\gamma\delta$  cells in the pathogenesis of PSC is therefore not clear although they might function by modulating  $\alpha\beta$  T cell activation or regulating antibody or autoantibody production from B cells.

Although T cell receptor gene rearrangements serve to generate genetic diversity, a particular V $\alpha\beta$  gene segment can play a dominant role in recognition of certain peptide-MHC complexes. Expanded T cell populations using restricted sets of T cell receptor V gene segments have been identified in areas of inflammation in diseases such as rheumatoid arthritis and Sjögren's disease. This suggests the presence of a specific antigen with the capacity of driving the production of T cells with this restricted V $\alpha\beta$  segment product [22, 23]. Studies from Broome *et al.* indicated that the hepatic, but not peripheral, T cells in PSC

preferentially have V $\beta$ 3 T cell repertoires [24]. An oligoclonal expansion was not demonstrated in this study, but oligoclonal T cell receptors which proliferate in culture with enterocytes and are cytotoxic to enterocyte cell lines *in vitro* have also been reported in PSC [25].

### Biliary epithelial cells

The biliary epithelial cell (BEC) is the target of immune attack in PSC, while at the same time appearing to be an active participant in the immune response. Normal biliary epithelial cells express only HLA class I and not class II antigens. However, the HLA class II antigens HLA-DR, DQ and DP have all been found to be expressed by the biliary epithelial cells of patients with PSC [26, 27]. These antigens have the potential to initiate an immune response by binding autoantigens or exogenous antigens and presenting the peptides to class II restricted T lymphocytes.

Xu *et al.* identified autoantibodies in 63% of PSC patients, which stimulated BECs to produce increased levels of the pro-inflammatory cytokine IL-6 and induce expression of CD44, the lymphocytic homing receptor [28]. The same group conducted a further study concluding that BECs played an integral role in their own destruction [29]. They demonstrated that stimulation of BECs with PSC IgG, induced the expression of Toll-like receptor (TLR) 4 and TLR9, extracellular signal-related kinase (ERK) 1/2, and transcription factors. Further stimulation of TLR-expressing BECs with lipopolysaccharide and CpG DNA resulted in the production of pro-inflammatory cytokines and chemokines. Nitric oxide, arising from BECs in response to cytokines, has been shown to cause ductular cholestasis and inhibit cholangiocellular bile formation [30]. Thus, cholangiocytes appear to play a significant role in the pathogenesis of PSC.

### Lymphocyte homing

Grant *et al.* have proposed the existence of an enterohepatic circulation of lymphocytes, whereby some mucosal T lymphocytes produced in the gut during active inflammation persist as memory cells capable of recirculation through the liver [31]. Under certain circumstances these gut-derived lymphocytes might become activated, resulting in bile duct inflammation. The migration of these T cells to the liver is mediated by the aberrant co-expression of endothelial cell adhesion molecules, including vascular adhesion protein-1 (VAP-1) and mucosal addressin cell adhesion molecule-1 (MAdCAM-1), and chemokines in both organs in patients with concomitant PSC and IBD. Eksteen *et al.* demonstrated that the chemokine CCL25, ordinarily confined to the gut, is up-regulated to the liver in PSC, where they recruit CCR9+ T cells by binding to MadCAM-1 [32]. In a second study, the same investigators propose that CXCR3, a chem-

okine receptor, promotes the recruitment of regulatory T cells (T regs) to inflamed tissue and CCR10 lymphocytes allow them to respond to the ligand CCL28 secreted by epithelial cells, resulting in the accumulation of CCR10+ T regs at mucosal surfaces [33]. This concept of dual homing lymphocytes helps to explain the observation that PSC runs a course independent of inflammation in the bowel and indeed can develop even after proctocolectomy. Furthermore, the evidence provides a possible explanation as to why patients with IBD develop extra-intestinal manifestations.

### Hepatobiliary transporters

Disturbance of the hepatocellular transport processes leads to an alteration of bile composition, impaired biliary secretion, and ultimately bile duct injury. Genetic variations of these transport systems may therefore play an important role in the pathogenesis of cholestatic liver diseases such as PSC.

The steroid and xenobiotic receptor (SXR) is a transcription factor that is involved in endogenous bile acid homeostasis. A Scandinavian study of 327 PSC patients demonstrated that functional polymorphisms of the SXR gene failed to confer susceptibility to the development of the disease. However, the gene variants did modify disease course [34]. Lithocholic acid (LCA) is a potentially toxic secondary bile acid that once sensed by the SXR, is detoxified via the increased transcription of the enzymes cytochrome P450 3A and sulfotransferase. A simultaneous up-regulation of the membrane transporters MDR1 and MRP2 results in the excretion of the LCA metabolites. A recent review suggests that deficiencies in these defence mechanisms are associated with the development of PSC and IBD [35].

The absence of phospholipids in the bile of multidrug resistant gene 2 knockout (Mdr2<sup>-/-</sup>) mice results in the development of hepatobiliary injury similar to PSC in humans [36]. Variations in Mdr3 gene, the human equivalent of the mouse Mdr2 gene, have not been observed in human PSC patients [37]. Studies evaluating the role of the cystic fibrosis transmembrane conductance regulator (CFTR) have reported conflicting results [10].

### Role of bacteria in the etiopathogenesis of primary sclerosing cholangitis

The coexistence of inflammatory colitis in around 75% of northern European patients with PSC has led to the hypothesis that the initiating step in this disease is the access of intestinal bacteria through an inflamed and leaky bowel wall, to the portal circulation. An abnormal immune response to bacterial antigens (possibly acting as molecular mimics for autoantigens) in an immunogenetically suscep-

tible host might be sufficient to precipitate the cascade of immune reactions detailed above.

Investigation of bacterial growth from human tissue is confounded by the bacterial contamination caused by intubation of the bile duct at ERCP. Several animal models, however, have been used to investigate this proposal. Wistar and Sprague-Dawley rats develop a pattern of hepatic injury somewhat similar to human PSC after artificially induced small bowel bacterial overgrowth, although a subsequent study in humans involving 22 PSC patients failed to confirm this association [38].

Previous studies have implicated *Helicobacter* species in the pathogenesis of PSC. More recently, Krasinskas *et al.* demonstrated an increase in the prevalence of *H. pylori* DNA detected in microdissected hilar hepatic ducts of PSC patients in comparison to controls [39]. However, direct infection of the biliary epithelium with a subsequent inflammatory response could not be confirmed.

### Hypotheses for the etiopathogenesis of PSC

A plausible unifying hypothesis for the etiopathogenesis of PSC has been put forward by Vierling [40]. This suggests that the initial insult is the reaction of an immunogenetically susceptible host to bacterial cell wall products entering the portal circulation through a permeable gut wall either due to colitis or possibly during episodes of intestinal infection. The resulting Kupffer cell (hepatic macrophage) activation would result in peribiliary cytokine and chemokine secretion attracting activated neutrophils, monocyte/macrophages, lymphocytes and fibroblasts to the site of infection. The resultant concentric fibrosis around the bile ducts could lead to ischemia and then atrophy of the biliary epithelial cell. The bile duct loss would then lead to progressive cholestasis, fibrosis and secondary biliary cirrhosis. This hypothesis does not explain why there is a relative paucity of patients with PSC and underlying Crohn's colitis, nor the association of PSC with stricturing of the pancreatic duct.

In conclusion, current evidence suggests that PSC is an immune-mediated rather than a classic autoimmune disease. Genetic analysis suggests a pivotal role for certain alleles of the MHC in determining susceptibility to the development of PSC, whilst the importance of non-MHC genes is not so clear-cut. The association with inflammatory colitis suggests that an abnormal immune response may be initiated in an immunogenetically susceptible host by the access of bacterial antigen, through a permeable gut wall, to the portal circulation. This bacterial antigen might then act as a molecular mimic of an autoantigen precipitating an immune reaction leading to PSC initiation. In addition, lymphocytes generated from the inflamed gut may enter the liver via the enterohepatic circulation resulting in bile duct inflammation with the eventual progression to

stricturing and scarring of the intrahepatic and extrahepatic bile ducts, peribiliary fibrosis and ultimately, cirrhosis. There are difficulties in determining which of the wide range of immune abnormalities identified in these patients, are causal and which are the consequence of tissue injury.

---

### Diagnosis

Characteristic cholangiographic features form the mainstay of PSC diagnosis. Over recent years, MRCP has become established over ERCP as the first-line investigation for the diagnosis of PSC. It confers several advantages, including complete visualization of the biliary tree, liver parenchyma and intra-abdominal organs, and planning for potential therapeutic options. Perhaps, most importantly, it negates the significant morbidity and mortality associated with ERCP. Furthermore, over recent years, several studies have demonstrated comparable sensitivities, specificities and diagnostic accuracies between the two modalities [41, 42]. In 2008, Weber *et al.* reported on the results of the largest comparative study to date and found that MRCP had a sensitivity, specificity and diagnostic accuracy of 86%, 77% and 83% respectively [43]. In a recent case-controlled analysis of 36 patients with PSC, interobserver agreement for diagnosing PSC was very good, but very poor in assessing disease severity [44]. Limitations of the investigation due to inferior spatial resolution include detecting PSC in cirrhotics or in the early stages of the disease, and also with the differentiation of cholangiocarcinoma. Two recent clinical decision models have demonstrated that the strategy of initial MRCP, followed by ERCP if required, is the most cost-effective approach to the work-up of patients with suspected PSC [45, 46]. Petrovic and colleagues raised the question as to whether the degree of biliary duct changes on MRCP correlated with patient survival [47]. Using the Mayo risk score as a survival model, they performed a retrospective study including 47 patients and found no such correlation.

There is some evidence that common bile duct wall thickening and layering demonstrated at endoscopic ultrasound (EUS) may be a useful adjunct in the diagnosis of PSC. However, a comparative prospective study with MRCP is required to determine its true value [48].

---

### Epidemiology, natural history and prognosis

Over recent years, emerging evidence suggests a change in both the epidemiology and natural history of PSC. Epidemiological data is scarce and tends to originate from centers with a specialist interest in PSC. The largest population-based cohort epidemiological study to date, compar-

ing 223 PSC patients with 2217 control patients, reported an incidence of 0.41 per 100,000 and a prevalence of 3.85 per 100,000 over a ten-year period in the UK [49]. As with previously published data, PSC was more commonly observed in middle-aged males, although only 50% of cases were associated with IBD. In comparison to the general population, there was a two-fold and three-fold increase in the risk of malignancy and mortality respectively. The authors also found a non-significant rise in incidence of PSC during the study period. Kaplan *et al.* reported an incident rate of 0.92 per 100,000 person years in the largest population-based study of PSC in Canada [50]. In contrast with previous findings, the investigators observed that the risk of developing PSC was similar in patients with UC and Crohn's disease. At least one coexisting autoimmune disorder was observed in 84% of patients, and autoimmune hepatitis overlap was evident in 10% of cases. A Swedish tertiary center observed a change in the clinical presentation amongst 246 PSC patients over a 20-year period, with more recently diagnosed patients, being older at diagnosis, presenting with fewer symptoms, and having a lower frequency of concurrent IBD [51]. Geographic variation also exists, with Japanese studies demonstrating lower incidences of both IBD and cholangiocarcinoma in patients with PSC [52].

The clinical course of PSC is quite variable; the disease is indolent in some patients and more rapidly progressive in others. However, a diagnosis of PSC should be considered in patients presenting with acute liver failure [53]. The natural history of PSC is described in a number of retrospective studies, with the median survival time from diagnosis to death or orthotopic liver transplantation (OLT) reported between 9.6 and 21 years [54, 55]. Differences in survival estimations may reflect the variation in the definition of onset and outcome. As there is no reliable marker of early disease in PSC the onset is difficult to identify clearly. Whether the onset is defined as the occurrence of the first symptoms consistent with PSC, as the time of the first abnormal liver function test, or as the time of diagnosis by ERCP, will result in differences in survival estimates. In retrospective studies details of distant events may be sparse and there is likely to be failure to recognize early signs and symptoms. Patients with late stage disease may predominate, while patients who die from rapidly progressive disease may be missed.

The ideal study of prognosis is prospective and follows patients from a defined point in the disease process, usually diagnosis. There have been no studies using such an inception cohort in PSC because the disease is rare and its slow progression makes a prospective study impractical. A large retrospective study published by Tischendorf *et al.* evaluated the natural history of 273 PSC patients and observed an estimated median survival time from diagnosis to OLT or death of 9.6 years [56]. This is lower in comparison to

previously published data, and may be explained by the higher prevalence of cholangiocarcinoma (13.2%), genetic and environmental factors, and the lower threshold for performing OLT as evidence-based practice evolves. Of the cohort, 39.6% proceeded to liver transplantation and 14.3% developed neoplasia affecting the hepatobiliary system. An elevation in serum bilirubin persisting longer than three months following diagnosis was identified as a novel poor prognostic indicator. Using a range of clinical, biochemical and radiological parameters, the authors constructed a prognostic model, which possessed the highest concordance index in comparison to the MELD score, revised Mayo score and Child-Pugh-score. Several prognostic models have been constructed with the aim of predicting survival and determining therapeutic strategies, and whilst they successfully predict the natural history of the disease in a cohort of PSC patients, they are less successful when applied to individual patients. The confounding factor is the development of hepatobiliary or colonic cancer.

### Cholangiocarcinoma

Cholangiocarcinoma (CCA) will develop in 10–30% of patients with PSC, with a cumulative lifetime risk of 10–15% [57]. The absence of predictive risk factors and the inability of conventional investigative modalities to differentiate between benign and malignant strictures, contributes to its dismal prognosis. Historically, the use of tumor markers has been limited by their lack of specificity. The benefit of tumor markers, either in combination, or with ERCP, has not been confirmed despite initial promising results. Recently, serum trypsinogen-2 has been found to be superior to several tumor markers, including CA19-9 and CEA, for differentiating patients with PSC and cholangiocarcinoma from patients with PSC alone [58]. Following an initial study describing <sup>18</sup>F-fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET) as a sensitive test for detecting cholangiocarcinomas in PSC patients two prospective studies have reported conflicting results [59]. In 2005, a study from Belgium concluded that FDG-PET was unable to distinguish malignant stenotic hilar lesions from inflammatory abnormalities [60]. Prytz *et al.* performed a blinded study in which 24 PSC patients listed for OLT, and without evidence of cholangiocarcinoma on USS, CT or MRI, underwent FDG-PET scanning [61]. The results were subsequently correlated with explant histology. The modality correctly identified three patients with cholangiocarcinoma but failed to detect one case of high-grade dysplasia.

A prospective study by Tischendorf and colleagues found that transpapillary intraductal ultrasound (IDUS) was superior to ERCP in discriminating between malignant and benign dominant bile duct strictures with a sensitivity,

specificity and diagnostic accuracy of 87.5% vs 62.5%, 90.6% vs 53.1%, and 90% vs 55% respectively [62]. Whilst endoscopic ultrasound (EUS) guided fine-needle aspiration is of value in analyzing suspicious biliary strictures, there have been no studies assessing its use in PSC patients. The use of endoscopic cholangioscopy has been investigated in two separate prospective trials as it permits direct visualization of the biliary tree and enables directed tissue sampling of abnormal areas. Tischendorf *et al.* concluded that cholangioscopy with directed biopsies was significantly more sensitive (92% vs 66%) and specific (93% vs 55%) than ERCP and subsequent brush cytology, in diagnosing malignant strictures [63]. In a second study cholangioscopic biopsies detected one out of three cholangiocarcinomas and excluded cancer in 31 patients at a median follow-up of 17 months [64]. Furthermore, approximately 25% of strictures could not be traversed, highlighting the need for more technically advanced miniscopes. Moreno Luna *et al.* demonstrated that advanced analysis of cytological specimens obtained at ERCP using fluorescent in-situ hybridization (FISH) and digital image analysis (DIA), increased the sensitivity for the diagnosis of malignancy over routine cytology in PSC patients with strictures [65].

To date, there is limited data on screening asymptomatic PSC patients for early CCA. Two separate studies have concluded that routine brush cytology at the time of ERCP improves the detection of early neoplastic changes [66, 67]. A study from the Mayo Clinic has proposed combining serum CA19-9 with an abdominal ultrasound scan at 12-monthly intervals as a useful screening/surveillance tool [68].

There is a paucity of data assessing the impact of UDCA on the development of CCA. Rudolph and colleagues evaluated the incidence rate of CCA in 150 PSC patients maintained on UDCA over an 18-year period [69]. Patients developed 0.58 CCA per 100 patient years in years 0–2.5, 0.59 CCA in years 2.5–8.5, and no CCA thereafter. These rates were lower than those of historical controls.

## Gallbladder disease

Gallbladder disease, including gallstones and polypoidal lesions, is common in patients with PSC, with two studies reporting a prevalence of 41% [70, 71]. In approximately 60% of cases, gallbladder polyps are malignant, and given the dismal prognosis of such lesions, annual evaluation of the gallbladder using ultrasonography has been recommended. Leung *et al.* reported that the size of a polyp could not reliably predict its malignant potential, therefore advocating the use of early cholecystectomy in patients with PSC and polypoidal lesions on imaging [72]. The interval and cost-effectiveness of this strategy has yet to be investigated.

Lewis *et al.* proposed that the metaplastic-dysplastic-carcinoma sequence could be applied to PSC-associated gallbladder cancers. The authors also observed a strong correlation between gallbladder neoplasia and biliary neoplasia, therefore supporting the concept of a “field effect” along the entire biliary tree in patients with PSC [73].

## Colonic neoplasia

An increase in the risk of colorectal dysplasia/cancer in patients with concomitant PSC and UC is generally acknowledged. Soetikno *et al.* conducted a meta-analysis that included 11 studies and reported a four-fold increase in the risk of patients with PSC and UC developing colorectal cancer compared to those with UC alone [74]. The predominance for right-sided colonic cancers has suggested a role for carcinogenic secondary bile acids, such as deoxycholic acid (DCA), in the pathogenesis of such tumors. Moreover, it has been demonstrated that UDCA inhibits deoxycholic acid-induced apoptosis by modulating mitochondrial transmembrane potential and reactive oxygen species production [75]. Subsequently, two studies demonstrated the apparent chemoprotective effect of UDCA against the development of colon cancer in patients with PSC and UC [76, 77]. More recently, a third trial failed to reveal a significant reduction in the incidence of dysplasia or cancer in those using UDCA. However, a reduction in cumulative overall mortality was observed [78].

Despite the lack of randomized controlled trials, there is a general consensus that annual surveillance colonoscopy should be performed in patients with coexistent PSC and UC. The same strategy should be adopted in those with concomitant colitis who have undergone OLT, as the risk of colorectal neoplasia remains high, and furthermore increases with time [79]. Although, the colorectal cancer risk in PSC patients with Crohn's colitis is unknown, regular surveillance is advocated.

In the future, it is envisaged that the detection rates of dysplastic lesions will improve with the advent of hi-tech imaging techniques, such as chromoendoscopy. The role of 5-aminosalicylates in chemoprevention remains unclear. Proctocolectomy with ileo-anal pouch formation is the preferred surgical management of PSC-associated colorectal malignancies as it avoids the complication of peristomal varices evident in patients with an ileal stoma [80]. A recent study observed a higher prevalence of mucosal atrophy in the pouches of patients with coexistent PSC and UC compared with UC controls, suggesting a higher risk of neoplastic transformation in the former group [81]. The incidence of pouchitis is also increased in patients with an ileal pouch-anal anastomosis and coexistent PSC [82].

### Small duct PSC

The results of three independent studies aimed at determining the natural history and long-term prognosis of small duct PSC (sdPSC) were published in 2002 and although they revealed similar results, they were limited by small patient size and relatively short follow-up periods [83–85]. Björnsson *et al.* extended the follow-up of the sdPSC patients reported in the original three studies and concluded that patients with sdPSC had a significantly better long-term prognosis than appropriately matched patients with large duct PSC over 13-year median follow-up period [86]. Of the 83 patients with sdPSC included in the study, approximately 23% either underwent liver transplantation or died, and this compared favorably to the large duct PSC group in which almost 50% developed similar outcomes. Patients with sdPSC had a significantly longer survival free of liver transplantation than patients with large duct PSC (13 years (IQR, 10–17) vs ten years (IQR, 6–14) respectively; hazard ratio, 3.04; 95% CI: 1.82–5.06;  $p < 0.0001$ ). In keeping with the findings reported in the original studies, 27.9% of the 68 patients who underwent repeated cholangiography progressed to develop large duct disease, with a median time of progression of 7.4 (IQR, 5.1–14) years. One patient with small duct PSC who proceeded to develop large duct disease was diagnosed with cholangiocarcinoma, although no malignancies were reported in those solely with small duct disease throughout the entire follow-up period. A significantly higher proportion of patients with sdPSC progressing to large duct PSC either died or underwent liver transplantation compared to those who did not progress (47% vs 15.6%,  $p < 0.004$ ). Importantly, recurrence of small duct disease was evident in the grafts of two patients who had undergone transplantation for end-stage liver disease secondary to sdPSC.

A recent study from the Mayo Clinic evaluated the influence of inflammatory bowel disease (IBD) and UDCA therapy on 42 patients with sdPSC over a median follow-up period of 4.8 years [87]. They observed a relatively low prevalence of IBD in this form of PSC (52%) although not all patients had undergone a colonoscopy in this retrospective cohort study. Interestingly, 27% had Crohn's disease with colonic involvement and this is in keeping with previously published data. Small duct PSC tended to be diagnosed earlier in patients with IBD as evidenced by a lower prevalence of signs of liver disease at presentation. This may be due to earlier detection of abnormal LFTs in patients undergoing active follow-up for their IBD. Concomitant IBD had no influence on long-term prognosis of sdPSC. Treatment with UDCA at a dose of 13–15 mg/kg failed to halt disease progression, although an improvement in liver biochemistry was observed.

### Autoimmune pancreatitis (immunoglobulin G4-associated cholangitis)

Autoimmune pancreatitis (AIP) is a recently described clinical entity characterized by stricturing of the pancreatic duct, focal or generalized pancreatic enlargement, a raised serum immunoglobulin G4 (IgG4) level, a lymphoplasmacytic infiltrate on biopsy, and a response to steroid therapy [88]. AIP in association with intra- and extrahepatic bile duct stricturing similar to those evident in PSC is termed autoimmune pancreatitis – sclerosing cholangitis (AIP-SC). Pancreatic abnormalities are not universally found, suggesting that IgG4-associated cholangitis (IAC) may be a more appropriate term to describe the condition [89]. Whether PSC and AIP represent different ends of the same disease spectrum or are separate clinical entities is of debate, although current evidence favors the latter (see Table 34.3).

The association between AIP and IBD is weak, with a small series from Europe finding UC or Crohn's disease in only 30% of patients with AIP [90]. Furthermore, no cases of cholangiocarcinoma in the presence of AIP have been reported to date. Whilst, no randomized trials of therapy in AIP have been conducted, corticosteroids have been shown to improve biliary structuring [91]. Differences in etiopathogenesis have also been observed. Zen *et al.* demonstrated that the over-production of T-helper (Th) 2 and regulatory cytokines resulted in a unique inflammatory disorder in AIP [92]. A recent study reported the almost exclusive detection of CXCR5- and CXCL13- positive cells in patients with AIP when compared to those with PSC [93].

### Elevated serum IgG4 in PSC

A study from the Mayo Clinic found an elevated serum IgG4 level ( $>140$  mg/dl) in 9% of their cohort of 127 PSC patients [94]. In comparison to PSC patients with normal IgG4 concentrations, the former group had significantly higher levels of ALP and bilirubin, in addition to higher PSC Mayo risk scores. An association with IBD was less likely in those with elevated IgG4 levels, although biliary and pancreatic involvement were similar in both groups. Although overall survival time was not different, the time to liver transplantation was significantly shorter (1.7 vs 6.5 years) in patients with elevated IgG4 levels, suggesting a more severe disease course. Whether this group of patients respond to corticosteroids in the same way as those with AIP is yet to be determined.

### Management of complications

As PSC slowly progresses to biliary cirrhosis and portal hypertension, complications may arise from chronic

**Table 34.3** Comparison of PSC and AIP-SC.

	PSC	AIP-SC
<b>Gender</b>	M:F = 2:1	Probably some male predominance
<b>Clinical presentation</b>	Usually insidious. Sometimes with obstructive jaundice secondary to cholangiocarcinoma.	Mild abdo/back pain. Sometimes with short history of obstructive jaundice due to CBD stricture
<b>Associated inflammatory bowel disease</b>	Yes	No
<b>Cholangiographic findings</b>	Diffuse changes throughout intra- and extrahepatic bile ducts. Abnormalities in pancreatic duct common.	Pancreatic duct strictures or narrowing. Often stricture of distal 1/3 of common bile duct. Intrahepatic duct changes less common.
<b>Blood chemistry data</b>	Often cholestatic but bilirubin usually near normal.	May be cholestatic. Bilirubin often high.
<b>Autoantibodies</b>	Atypical pANCA plus range of others.	Antibodies to carbonic anhydrase II plus range of others.
<b>Immunoglobulins</b>	IgG4 levels normal.	IgG4 levels usually elevated.
<b>Histology</b>	Absence of plasma cells positive for IgG4 on immunostaining.	IgG4 positive plasma cells present in bile ducts and portal tracts.
<b>Liver biopsy staging</b>	Range of Ludwig staging including higher stages e.g. III or IV.	Ludwig staging usually only I or II.
<b>Treatment</b>	Ursodeoxycholic acid +/-biliary drainage for dominant strictures	Systemic steroid therapy usually leads to complete resolution of symptoms and signs of disease. Occasionally patients relapse and require longer courses of steroids

cholestasis or chronic liver failure (as in PBC and other liver diseases) or complications specific to PSC such as biliary strictures and the development of cholangiocarcinoma. The general management of the complications of cholestasis is discussed elsewhere in this book. Given the unpredictable course of PSC, several investigators have sought to create simple, non-invasive means of predicting the development of advanced liver disease. In a cohort of 154 patients, an aspartate transaminase to alanine transaminase ratio (AST: ALT) of at least one was observed to be both an indicator of cirrhosis and a predictor for liver-related death/LT and liver-related death [95]. In a prospective study, Corpechot *et al.* demonstrated that using transient elastography as a measure of liver stiffness provided an accurate and simple means of assessing biliary fibrosis and histological stage in 28 patients with PSC [96].

### Management of complications specific to primary sclerosing cholangitis

Dominant biliary strictures may be treated endoscopically, either via balloon dilatation or the placement of a biliary stent. No randomized trials have compared the different endoscopic treatment options. However, balloon dilatation has become the preferred option as biliary stents are prone

to occlusion and therefore predispose to infection [97]. Stenting after dilatation provides no added value. Gluck *et al.* evaluated the survival of 106 PSC patients who underwent endoscopic therapy over a 20-year period and observed that patient survival at years three and four was significantly higher than that predicted by the Mayo Clinic natural history model for PSC [98]. In a 13-year prospective study Stiehl *et al.* studied the survival of 106 patients with PSC treated with 750mg UDCA daily and by endoscopic balloon dilatation of major dominant stenoses whenever necessary [99, 100]. Ten patients had a dominant stricture at entry and over a median follow-up of five years another 43 developed a dominant stenosis. This was not prevented by low dose UDCA treatment, but successfully treated by balloon dilatation in the majority, only five requiring temporary stenting. This combined approach of UDCA and endoscopic intervention significantly improved the survival compared with predicted survival rates. This was an uncontrolled study and provides only relatively weak evidence that UDCA and/or endoscopic therapy prolonged survival, although the results are promising. Where LT is precluded, as in biliary obstruction due to cholangiocarcinoma, endoscopic stenting is undoubtedly the best option for more distal lesions.

Selected non-cirrhotic PSC patients with dominant extrahepatic strictures may benefit from a bilioenteric bypass [101]. Extrahepatic biliary resection (EHBR) is also potentially effective in carefully selected non-cirrhotic patients. In 2008, Pawlik and colleagues published data on the perioperative morbidity and long-term survival of the largest cohort of patients ( $n = 77$ ) who had undergone EHBR over the longest follow-up period ever reported (median 10.2 years) [102]. Results were promising, with non-cirrhotic patients demonstrating three, five and ten-year survival rates of 89.6%, 83.3% and 60.2% respectively. This compared favorably with PSC patients who had undergone liver transplantation whose corresponding survival rates were 87.4%, 67.3% and 57% respectively. Furthermore, none of the patients treated with EHBR developed cholangiocarcinoma during the follow-up period. There was a striking contrast in short and long-term survival, with approximately 40% of cirrhotic patients dying within one year of surgery, compared to 5% in the non-cirrhotic cohort. A ten-year survival rate of only 12% was observed in cirrhotics. In addition, EHBR was also associated with low perioperative morbidity and mortality, and also a low rate of PSC-related hospital readmissions.

PSC patients with dominant biliary duct strictures are at increased risk of developing secondary bacterial infections necessitating the need for antibiotic therapy. Kulaksiz and colleagues conducted the first study to evaluate the role of fungal infections in patients with PSC [103]. In a prospective, non-randomized trial, 148 bile samples were obtained endoscopically from 67 consecutive patients. *Candida* species were isolated from eight (11.9%) patients and of these, seven had dominant strictures requiring multiple endoscopic dilatations and courses of antibiotics, suggesting these treatment modalities may have predisposed to colonization with the fungus. The efficacy of antifungal agents and the effect of *Candida* infections on the outcome of PSC patients after liver transplantation will need to be evaluated in future trials.

### Medical therapy – the prevention of disease progression

In both PBC and PSC the primary site of inflammation and damage is the biliary epithelium. When severely damaged or destroyed the bile ducts do not have the capacity to regenerate like hepatocytes, which are the primary target for injury in various parenchymal liver diseases. Given the finite number of bile ducts in the liver the natural history of PSC, like PBC, is that of progressive loss of functioning intrahepatic bile ducts (ductopenia). This ductopenia leads to a progressive and irreversible failure of hepatic biliary excretion. To delay and reverse this process physicians have tried a variety of agents, but in PSC, in

contrast to PBC, few randomized controlled trials have been done.

#### Ursodeoxycholic acid

This hydrophilic bile acid has become widely used in the treatment of cholestatic liver of all causes. UDCA appears to exert a number of effects, all of which may be beneficial in chronic cholestasis: a choleretic effect by increasing bile flow; a direct cytoprotective effect; an indirect cytoprotective effect by displacement of the more hepatotoxic endogenous hydrophobic bile acids from the bile acid pool; an immunomodulatory effect; and finally an inhibitory effect on apoptosis.

Using a labeled bile acid analog Jazrawi *et al.* demonstrated a defect in hepatic bile acid excretion, but not in uptake in patients with PBC and PSC, resulting in bile acid retention [104]. They observed an improvement of hepatic excretory function with UDCA in patients with PBC but only a trend towards improvement in the small number of patients with PSC. Not only is hepatic bile acid excretion affected by UDCA but so is ileal reabsorption of endogenous bile acids. The net result is enrichment of the bile acid pool with UDCA. Hydrophobic bile acids are more toxic than UDCA, which can protect and stabilize membranes.

Studies have demonstrated that long-term treatment with UDCA decreases aberrant expression of HLA class I on hepatocytes and reduces levels of soluble cell adhesion molecules (sICAM) in PBC patients. *In vitro* studies have shown that UDCA may alter cytokine production by human peripheral mononuclear cells. In PSC one study has shown that UDCA has been shown to decrease aberrant HLA DR expression on bile ducts [105]. However, a more recent study could not demonstrate any alteration in expression of either HLA class I and II or ICAM-1 on either biliary epithelial cells or hepatocytes [106]. The body of evidence suggests that UDCA does have some modulatory effects on immune function, but how important these are remains unclear.

Numerous studies have attempted to address the clinical efficacy of UDCA treatment in PSC. The majority have been uncontrolled studies in small numbers of patients. In a pilot study O'Brien *et al.* treated 12 patients with UDCA on an open basis over 30 months [107]. They documented improvement in fatigue, pruritus and diarrhea and significant improvement of all liver biochemical tests, particularly alkaline phosphatase, during the two UDCA treatment periods. Symptoms and liver biochemistry relapsed during a six-month withdrawal period between treatment phases. During UDCA treatment the amount of cholic acid declined slightly but the levels of other relatively hydrophobic bile acids did not change significantly.

In the first randomized double-blind controlled trial of UDCA in PSC Beuers *et al.* compared over a 12-month

period six patients who received UDCA 13–15 mg/kg bodyweight with eight patients who received placebo [108]. The majority of patients had early disease (Ludwig classification stages I and II). After six months a significant reduction in alkaline phosphatase and aminotransferases was achieved in the treatment group. A significant fall in bilirubin was only noted after 12 months. Using a multi-parametric score the UDCA-treated group showed significant improvement in their liver histology, mainly attributed to decreased portal and parenchymal inflammation. Unfortunately treatment did not ameliorate their symptoms.

Similar results were obtained by Stiehl *et al.* who randomized 20 patients to either 750 mg daily of UDCA or placebo [109]. However, in a larger randomized placebo-controlled trial of UDCA in PSC by Lindor *et al.* no benefit was demonstrated [110]. In this trial 105 patients were randomized to treatment with UDCA in conventional doses (13–15 mg/kg bodyweight daily) or placebo and followed up for up to six years (mean 2.9 years). Treatment with UDCA had no effect upon the time until treatment failure, defined as death, liver transplantation, the development of cirrhosis, quadrupling of bilirubin, marked relapse of symptoms or the development of signs of chronic liver disease. Furthermore, the significant improvement in liver biochemical tests seen in the treated group was not reflected by any beneficial changes in liver histology. **A1d**

In the early 2000s, two pilot studies were performed in order to investigate the efficacy of higher than conventional doses of UDCA in the management of patients with PSC. On the basis that the higher dose would provide adequate enrichment of the bile acid pool and enhance immunomodulatory effects, the Oxford group studied the efficacy of UDCA at a daily dose of 20 mg/kg in a double-blinded, placebo-controlled trial involving 26 patients over a two-year period [111]. The investigators reported significant improvements in most outcomes measured, including liver biochemistry, cholangiographic appearances and histological grade of liver fibrosis, in those randomized to the high dose UDCA. Symptomatic improvement was not evident. An open-label study from the Mayo Clinic reported a significant reduction in expected mortality at four years using the Mayo risk score in patients using UDCA at a dose of 25–30 mg/kg/day in comparison to those taking lower doses (13–15 mg/kg/day) or placebo [112]. A significant improvement of liver biochemistry was also noted. However, radiological and histological outcomes were not measured. In 2005, Olsson *et al.* published the findings of the largest placebo-controlled, prospective trial of high-dose UDCA to date [113]. During the five-year study period, 110 PSC patients received UDCA (17–23 mg/kg/day) and their results were compared with 109 patients in the placebo group. Although there was a trend towards increased survival in the UDCA-treated group, this was

statistically insignificant as the study was underpowered. There was no statistical difference between the two groups in symptom profile, quality of life or in the number of patients diagnosed with cholangiocarcinoma. The primary endpoint of the study was liver transplantation or death, and whilst the incidence of this was lower in the UDCA-treated group, it did not reach statistical significance (7.2% vs 10.9%, 95% CI: 12.2–4.7%,  $p = 0.368$ ). In all three studies, the higher doses were well tolerated. **A1c**

Cullen and colleagues conducted a double-blinded, randomized dose-ranging trial to determine whether further enrichment of the bile acid pool with UDCA would lead to additional benefits in outcome for PSC patients [114]. Thirty-one patients were randomized to treatment with 10 mg/kg, 20 mg/kg or 30 mg/kg daily of UDCA for two years. **A1d** As expected, higher doses of UDCA led to further improvements in liver biochemistry compared to more conventional lower doses. Greater reductions in the Mayo risk score were noted in patients who had received the higher doses of UDCA. No significant changes in liver histology among the three groups were observed, which was not surprising given the short follow-up period. Biliary enrichment of UDCA increased with increasing dose, and after two years of treatment biliary UDCA represented 65.6% of total bile acids in the 10 mg/kg group, 79.3% in the 20 mg/kg group, and 92.6% in the 30 mg/kg group. This is in contrast to the findings reported by Rost *et al.* who observed a plateau in bile enrichment after daily doses beyond 22–25 mg/kg. High-doses of UDCA were well tolerated, and in particular, exacerbations of diarrhea in those with underlying colitis were not reported [115]. However, a multicenter randomized trial from the USA comparing high dose UDCA (28–30 mg/kg) with placebo in PSC patients has been halted prematurely because of a higher incidence of adverse outcomes in the UDCA group [116] (see Table 34.4). Thus, at present, high dose UDCA cannot be recommended.

By virtue of its different physiological properties to standard UDCA, Fickert *et al.* investigated the therapeutic effects of 24-*nor*ursodeoxycholic acid (*nor*UDCA), a C<sub>23</sub> homologue of UDCA with one fewer methylene group in its side chain, using mutant drug resistant gene 2 knockout mice (Mdr2<sup>-/-</sup>) as an animal model for PSC [117]. Mdr2<sup>-/-</sup> mice that received a diet containing *nor*UDCA demonstrated a significant improvement in their liver biochemistry and histology, in comparison to mice that were fed UDCA. In addition, a marked reduction in hydroxyproline content and the number of infiltrating neutrophils and proliferating hepatocytes and cholangiocytes was observed in the *nor*UDCA group. Proposed mechanisms of action of *nor*UDCA include increased hydrophilicity of biliary bile acids, stimulation of bile flow with flushing of injured bile ducts, and induction of detoxification and elimination routes for bile acids.

**Table 34.4** Controlled trials of ursodeoxycholic acid in primary sclerosing cholangitis.

### Corticosteroids

Systemic and topical corticosteroid therapy has been evaluated in a number of small, often uncontrolled, trials, but there is no direct evidence to suggest that they are beneficial in PSC. Indeed, when PSC patients with coexistent UC are given corticosteroids for treatment of their colitis, this treatment appears to have little influence on the behavior of their liver disease. **B4** A recent finding that a rat model of cholangitis possesses fewer glucocorticoid receptors on hepatic T lymphocytes may explain the ineffectiveness of steroids in human PSC [120].

In one study, ten patients diagnosed by ERCP and liver biopsy with early PSC (elevated serum alkaline phosphatase, but none with biliary cirrhosis) were treated with

prednisone without a significant response [121]. In another uncontrolled pilot study ten patients with PSC, selected because they had elevated aminotransferases, were given prednisolone, and the majority responded with improvement in their biochemistry [122]. In a subsequent study Lindor *et al.* were unable to confirm these optimistic results [123]. They treated 12 patients with a combination of low dose prednisone (10 mg daily) and colchicine (0.6 mg twice daily). The clinical course of the treated patients was compared with a control group, but the study was not randomized. After two years no significant differences in the biochemistry and liver histology were detected between the two groups. In this study treatment did not alter the rate of disease progression or improve survival. The

absence of a beneficial response, and the suspicion that corticosteroid therapy enhanced cortical bone loss and hence the risk of developing compression fractures of the spine even in young male patients, led the authors to advise against empirical corticosteroid therapy in these patients. This conclusion was strengthened by the observation that spontaneous fractures in patients who have undergone liver transplantation occur almost exclusively in PSC patients who are already osteopenic at the time of transplantation [124].

Topical corticosteroids are usually administered through a nasobiliary drain left *in situ* following ERCP. The only controlled trial of nasobiliary lavage with corticosteroids from the Royal Free Hospital showed no benefit when compared with a placebo group [125]. Although the numbers were small, the bile of all the treated patients became rapidly colonized with enteric bacteria and a higher incidence of bacterial cholangitis was recorded in the treatment group.

More recent clinical trials have studied the possible benefit of budesonide, a second-generation corticosteroid with a high first-pass metabolism and minimal systemic availability. Unfortunately preliminary results both alone and in combination with UDCA have been disappointing [126, 127]. **A1d**

There is emerging evidence that corticosteroids may be of value in patients who have overlap syndromes between PSC and autoimmune hepatitis, and in the subgroup of PSC patients who have elevated immunoglobulin G4 levels [128].

### Other immunosuppressants

Despite the evidence that PSC may be an immune-mediated disease, there have been few randomized controlled trials of immunosuppressive agents containing sufficient numbers of patients with early disease. Immunosuppression is unlikely to be effective in patients with advanced liver disease and irreversible bile duct loss, and this may account for the disappointing results so far seen in PSC with these agents.

No controlled trials of azathioprine in PSC have been reported. In one case report two patients improved clinically on azathioprine but in another the patient deteriorated [129, 130]. The use of cyclosporine in PSC has been evaluated in a randomized controlled trial from the Mayo Clinic involving 34 patients with PSC and, in the majority, coexistent ulcerative colitis [131]. Treatment with cyclosporine reduced the symptoms of ulcerative colitis but had no effect on the course or prognosis of PSC [132].

**A1d** Follow-up liver histology after two years of treatment revealed progression in 9/10 of the placebo group but only 11/20 of the cyclosporine-treated group. This was not reflected by any beneficial effect on the biochemical tests. The prevalence of adverse effects was low; serious renal

complications were not reported. A combination of cyclosporine and prednisolone elicited a beneficial response in a 65-year-old man with PSC accompanied by pancreatic duct abnormalities [133].

### Methotrexate

After demonstrating a promising response to low dose oral pulse methotrexate in an open study involving ten PSC patients without evidence of portal hypertension [134], Knox and Kaplan carried out a double-blind, randomized placebo-controlled trial of oral pulse methotrexate at a dose of 15mg per week [135]. Twelve patients with PSC were entered into each group and followed up for two years. Although, a significant fall in the serum alkaline phosphatase by 31% was observed in those receiving methotrexate, there were no significant improvements in liver histology, treatment failure or mortality rates. **A1d** In a pilot study Lindor *et al.* found that methotrexate given in combination with UDCA to 19 PSC patients was associated with toxicity (alopecia, pulmonary complications), but showed no additional improvement in liver biochemistry compared with a control group of nine patients treated with UDCA alone [136].

### Tacrolimus

Preliminary results from a small pilot study evaluating the benefit of tacrolimus were encouraging, with all ten PSC patients displaying a marked improvement in their liver biochemistry, without the development of significant side effects [137]. Talwalker *et al.* conducted an open-label, phase 2 study, during which, 16 patients received tacrolimus at a dose of 0.05mg/kg twice daily for one year [138]. A considerable proportion (81%) of patients experienced drug-related adverse effects, with 31% developing toxicities necessitating withdrawal from the study. Of the eight patients who completed the year of treatment, significant improvements in median serum ALP and AST levels were observed. It has been suggested that the poor tolerability of the drug may limit its use in the future.

### Mycophenolate mofetil

Two studies failed to demonstrate a significant benefit of mycophenolate mofetil (MMF) in the treatment of patients with PSC. Sterling and colleagues reported results from a randomized-controlled study in which 25 patients received either UDCA (13–15mg/kg) alone or in combination with MMF at a dose of 1g twice a day [139]. After two years, no significant differences were demonstrated with respect to liver biochemistry levels, histological and cholangiographic appearances between the two groups. **A1d** An open-label study performed at the Mayo Clinic evaluated the efficacy and safety of MMF as a single agent in 30 patients with established PSC over a one-year period [140]. Although a statistically significant reduction in ALP levels was observed, there was no such improvement in the other liver

function tests or Mayo risk score. Furthermore, the drug was not well tolerated, with seven patients withdrawing from the study due to drug-related adverse effects. Both studies included a substantial proportion of patients with advanced fibrosis and therefore immune-mediated inflammation would be minimal, which may account for the lack of efficacy of MMF.

Cladribine, a nucleoside analog with specific antilymphocyte properties, has been used to treat a variety of autoimmune disorders. In a recent pilot study in PSC six patients with early disease were treated for six months and followed for two years. Whilst significant decreases were seen in peripheral and hepatic lymphocyte counts no significant changes were observed in symptom scores, liver function tests or cholangiograms [141].

### Anti TNF- $\alpha$ agents

Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) has been suggested to drive local inflammatory responses in PSC, and on this basis infliximab has been evaluated as a potential therapeutic agent. Hommes *et al.* conducted a double-blind, placebo-controlled study to assess the efficacy and safety of the chimeric monoclonal antibody in PSC patients [142]. Patients were randomized to receive infliximab (5 mg/kg) or placebo for 52 weeks. Patient enrollment was discontinued prematurely after results of an interim analysis failed to identify any clinical or histological benefit. Of ten patients enrolled, only seven patients (four infliximab and three placebo) completed the study through week 52. No apparent differences could be detected in alkaline phosphatase levels, histological parameters, or symptom scores and no serious drug-related adverse events were reported in either group. **A1d** Two other drugs with anti-TNF activity, etanercept and pentoxifylline, have been found to be ineffective in the treatment of PSC in separate pilot studies [143, 144]. **B4**

### Miscellaneous treatments

#### D-penicillamine

Increased hepatic copper levels are detected in all patients with prolonged cholestasis including those with PSC. This observation provided the rationale for the controlled trial of the cupruretic, D-penicillamine, performed by the Mayo Clinic [145]. Seventy patients were randomized to either D-penicillamine or placebo for 36 months. No improvement was observed on disease progression or overall survival in the treatment group. Major adverse effects, including pancytopenia and proteinuria led to the permanent discontinuation of penicillamine in 21% of the treated patients. **A1d**

#### Silymarin

Silymarin, a flavonolignan extracted from milk thistle (*Silybum marianum*), has shown promise in the treatment of

a variety of chronic liver disorders characterized by degenerative necrosis and functional impairment. It confers hepatoprotection through its antioxidant, immunomodulatory and antifibrotic properties. Angulo *et al.* performed an open-label pilot study in which 30 patients with PSC received silymarin 140 mg three times a day for one year [146]. A statistically significant improvement in ALP and AST levels was observed, and it appeared to be well tolerated, with only one patient developing diarrhea. Overall, 34% of patients demonstrated a  $\geq 50\%$  improvement or normalization of liver biochemistry. No significant change in serum bilirubin, albumin and Mayo risk score was demonstrated. Whilst the results are encouraging, further controlled trials with a larger sample size and extended follow-up period are warranted. **B4**

#### Colchicine

In the light of initial reports which suggested a positive trend of the antifibrogenic agent colchicine on survival in PBC and other types of cirrhosis, a randomized trial from Sweden compared colchicine in a dose of 1 mg daily by mouth in 44 patients with PSC with a matched placebo group of 40 patients [147]. At three-year follow up there were no differences in clinical symptoms, serum biochemistry, liver histology or survival between the two groups. The evidence, therefore, suggests that colchicine does not appear to have a role in the treatment of PSC. **A1d**

#### Bezafibrate

Kita *et al.* conducted a study to assess the efficacy of bezafibrate administered at a dose of 400 mg/day for one month in a variety of chronic liver diseases, including six patients with PSC [148]. In addition to a significant reduction in serum ALP and  $\gamma$ -GT, a decline in ALT was observed in the PSC subgroup. Further trials are warranted in order to evaluate the efficacy of bezafibrate in PSC. **B4**

#### Nicotine

In keeping with ulcerative colitis, there is a strong inverse relationship between PSC and cigarette smoking. This led Angulo *et al.* to test the hypothesis that oral nicotine might have a beneficial effect in PSC [149]. Eight non-smoking patients with PSC were treated with nicotine 6 mg four times daily for up to one year. Adverse effects were frequent, requiring cessation in three patients and no beneficial effects were seen. A transdermal nicotine patch trial in 11 patients also failed to demonstrate any improvement in symptoms or liver biochemistry [150]. **B4**

#### Probiotics

On the basis that substances originating from the inflamed gut lead to damage of the biliary tree in PSC, Vleggaar *et al.* conducted a double-blinded, placebo-controlled, crossover study to evaluate the efficacy of probiotics in PSC

patients with coexistent IBD [151]. Fourteen patients were initially randomized to receive treatment with probiotics or placebo for three months, and following a one-month washout period, a crossover was made. The investigators failed to observe any significant differences in symptoms or liver biochemistry between those treated with probiotics and those receiving placebo. **A1d**

### Combined therapy

In an important pilot study, the potential of combination therapy was explored by Schramm *et al.*, who treated fifteen patients with PSC [152]. All patients received low-dose UDCA (500–750 mg daily), prednisolone 1 mg/kg daily and azathioprine 1–1.5 mg/kg daily. After a median follow-up period of 41 months, all patients had a significant improvement in liver function tests. Seven patients had been previously treated with UDCA, but liver enzymes improved only after immunosuppressive therapy was added. More importantly, six out of ten with follow-up biopsies showed histological improvement and significant radiological deterioration was only seen in one of ten patients who had had ERCP. **B4**

### Orthotopic liver transplantation

For patients with advanced PSC, OLT is the only therapeutic option. In the absence of prognostic models capable of predicting the course of disease or the onset of complications in individual patients, the timing of OLT continues to be controversial [153]. With improving expertise and technology, five-year survival rates following liver transplantation have exceeded 80% [154]. This has been associated with an increase in the incidence of recurrent PSC (rPSC) within the allograft. Differences in diagnostic criteria and the use and timing of protocols applied to detect biliary strictures at various institutions have resulted in disparities in the reported incidence of rPSC. Furthermore, whilst MRCP provides a simple, non-invasive means of detecting PSC recurrence, the diagnosis of rPSC is challenging, particularly as indistinguishable biliary stricturing can occur due to chronic rejection, graft preservation injury, hepatic artery stenosis, biliary tract infection and the use of an ABO-incompatible allograft. Investigators from the Mayo Clinic have sought to resolve these issues by setting strict diagnostic criteria based on the existence of cholangiographic and/or histological features characteristic of PSC in the absence of any other apparent cause and occurring beyond the third month after transplantation [155].

A meta-analysis conducted by Gautam *et al.* demonstrated a recurrence rate of 17% in over 900 PSC patients [156]. The natural history of rPSC is unpredictable, although in three recent studies evaluating survival outcome and risk factors for recurrence, retransplantation was required in approximately one-third of all patients [157–159]. There was no significant difference in long-term survival between

recipients with rPSC and those with non-recurrent disease. In comparison with symptomatic PSC patients pre-liver transplant, those with rPSC had a better prognosis. Predisposing risk factors identified from these studies included the presence of UC post-transplantation (prior colectomy seemed to be protective), male gender, prolonged use of corticosteroid post-transplantation, acute cellular rejection (ACR), steroid-resistant ACR, HLA-DRB1\*08, and the presence of cholangiocarcinoma prior to liver transplantation. Recurrent PSC is likely to become more prevalent in the future, hence a better understanding of its pathogenesis and long-term outcome is essential (see Table 34.5).

Approximately one-third of patients will experience a deterioration in their IBD following OLT, despite the use of heavy immunosuppression [160]. Immunosuppressive regimens containing corticosteroids appear to prevent IBD exacerbation, whilst an increase in corticosteroid dose during a flare leads to a response in most patients [161]. Proctocolectomy is required in a minority of patients with medically-refractory colitis. In addition, PSC patients with a long duration of ulcerative colitis and pancolitis are at increased risk of developing colorectal cancer with reduced survival following OLT [162]. Long-term, post-transplant colonic surveillance is therefore recommended. The impact

**Table 34.5** Risk factors for PSC recurrence.

Reference	Risk factor
Jeyarajah <i>et al.</i> [164]	Recipient age Cytomegalovirus infection Recurrent acute cellular rejection (ACR)
Vera <i>et al.</i> [165]	Male gender Presence of intact colon after liver transplantation
Khettry <i>et al.</i> [166]	Gender mismatch
Abu-Elmagd <i>et al.</i> [167]	Coexistent IBD Recipient age
Brandsaeter <i>et al.</i> [168]	Steroid-resistant ACR
Kugelman <i>et al.</i> [169]	Monoclonal CD3 antibody (OKT3) therapy for steroid resistant ACR
Cholongitas <i>et al.</i> [158]	Presence of UC post-transplantation Prolonged use of corticosteroid post-transplantation
Alexander <i>et al.</i> [159]	HLA-DRB1*08 ACR
Campsen <i>et al.</i> [160]	Presence of cholangiocarcinoma prior to OLT

of OLT on the disease course of pouchitis is not clear. However, dysplasia within the pouch has been reported, therefore advocating the need for surveillance pouchoscopies [163]. *De novo* ulcerative colitis may develop post-OLT in those patients not receiving long-term steroids [161].

## Conclusion

Over recent years, substantial progress has been made in obtaining a better understanding of this rare yet important condition. The increasing use of MRCP has resulted in fewer patients being exposed to the complications of ERCP. Furthermore, it has enabled clinicians to diagnose PSC at an earlier stage, and consequently this has led to a change in the clinical presentation over the past decade. Advances in endoscopic, radiological and molecular techniques continue to be made, therefore expanding both diagnostic and therapeutic options, and perhaps most importantly, enabling the differentiation between benign and malignant strictures. Unfortunately, there is no established effective medical treatment for PSC. A recent study was suggested that high-dose UDCA may be harmful and should not be used for the treatment of PSC. Larger, prospective, placebo-controlled trials are required in order to determine the true efficacy and safety of previously evaluated and future medical therapies. Greater insight into the pathogenetic mechanisms involved in PSC would enable therapy to be targeted more specifically at the area of initial damage, namely, the biliary epithelium.

## Non-histological assessment of liver fibrosis

*Dominique Thabut and Marika Simon-Rudler*

UPMC Service d'Hépatogastroentérologie, Assistance Publique-Hôpitaux de Paris, Groupe Hospitalier Pitié-Salpêtrière, Université Pierre et Marie Curie, Paris, France

Management and prognosis of chronic liver diseases depend mainly on the amount of liver fibrosis. Therefore, assessment of liver fibrosis is crucial, not only to evaluate the severity of the disease, but also to monitor disease progression and treatment efficacy. Recent reviews recommend liver biopsy as the gold standard for the evaluation of fibrosis [1]. However, liver biopsy has several well-known limitations, that is, sampling error and intra/inter-observer variability [2–8], and risks, with a morbidity ranging from 0.3 to 0.6%, and a mortality of 0.05% [9]. Moreover, liver biopsy is costly. All these pitfalls have stimulated the search for new, non-invasive techniques for the assessment of liver fibrosis. There is a consensus that ideally, non-invasive methods should be easily repeatable, with minimal sampling error or observer variability, and be less expensive than liver biopsy. Assessment of liver fibrosis has been extensively evaluated during the past five years, with over 400 original articles. There are two categories of non-invasive tests: serum markers and methodologies related to liver imaging techniques, the most innovative of which being the measurement of liver stiffness by transient elastography. In this chapter we describe the main methods available for the detection of liver fibrosis, discuss their performance as a diagnostic test, their advantages and limits, and try to determine when and how to use them. We will focus on the most validated techniques that are available for clinical practice.

### Serum markers of liver fibrosis

#### Description of the different serum markers and indices

Serum markers can be direct or indirect. Several direct markers have been evaluated, measuring components of

extracellular matrix in the serum (e.g. hyaluronic acid, collagen IV, procollagen III, laminin, YKL-40) as well as enzymes and cytokines involved in the fibrogenetic and fibrolytic process (metalloproteases (MMPs) and tissue inhibitors of metalloproteases (TIMPs)). Indirect markers include markers of liver function and liver inflammation, and are generally routinely available tests, like prothrombin time, serum bilirubin, platelet count, transaminases, but also include apolipoprotein A1, and alpha2-macroglobulin. Taken separately, none of these markers are sufficiently discriminative to consider avoiding liver biopsy. However, combination of different serum markers considerably improves their performance. Therefore, algorithms combining the results of panels of markers have been developed in order to assess liver fibrosis. Before evaluating the performance of the different tests, one must know which stage of development the tests have reached. Indeed, some tests are still at the exploratory stage, which is the first phase of development of the test. Following this comes the very important validation step, either internal validation, or, even better, an external and independent validation. Before use of any test in clinical practice, an external and prospective validation of the test is mandatory. Also important is the formulation of pre-analytical and analytical recommendations, precautions required for use, and algorithms for false positive and false negatives. Lastly, there are steps concerning patents and commercialization.

To date, and since the publication of the first index, which was the PGA index, in alcoholic patients in 1991 [10], more than 30 indexes have been published. As well as PGA, 17 have been validated at least twice [11–26], and five are patented and on the market: FibroTest-FibroSure, ELF index, Fibrometer, FibroSpect II and HepaScore [11, 13, 16, 23, 26]. Table 35.1 describes the components of the 17 tests that were validated twice; 14 were derived and validated for chronic hepatitis C liver disease (HCV). The first commercialized test, and also the most validated, is the FibroTest-FibroSure [16]. The results of this test range from 0 to 1. FibroTest has now been validated in hepatitis C by

**Table 35.1** Summary of the 18 tests that have been validated at least twice for the diagnosis of liver fibrosis.

Test	Year 1st publication	Key leader	Components	Liver disease
PGA	1991	Poynard	PT, GGT, ApoA1	ALD
AP	1997	Poynard	Age, Plt	HCV

the original authors [27] and independent teams [13, 28–32], and also in other settings: HBV [33–35], NAFLD [36], HCV-HIV co-infection [37], alcoholic liver disease [38, 39], and in renal transplants and hemodialysed patients [40].

### Diagnostic performance of the different serum markers of fibrosis

The performance of a test can be studied with the Area Under the Receiving Operating Curve (AUROC), which reflects the specificity and sensitivity of the test, that is, its discriminatory power. However, one pitfall is that the liver biopsy, which is considered to be the gold standard, is not a perfect standard as it suffers inherent problems of sampling [2]. Another problem is the dichotomous categorization of liver biopsy, that is, mild versus significant fibrosis in the METAVIR scoring system (F0F1 vs F2F3F4), or if the test is aimed to detect severe fibrosis (F0F1F2 vs F3F4) or cirrhosis (F0F1F2F3 vs F4). However, grouping different stages may not be relevant [2]. These categories are descriptive and do not reflect an arithmetical progression of fibrosis in numerical terms, that is, F4 is not twice the amount of fibrosis as F2, and those categories which happen to have numbers and not names cannot be used as a continuous variable in a statistical analysis. Moreover, the AUROC will depend on the prevalence of each fibrosis stage in the population under study. For example, the AUROC for the detection of significant fibrosis will be higher if the population sampled is mainly composed of F0 and F4 patients, than of F1 and F2 patients [41]. Therefore, comparison of

different tests must be performed on the same population, and if this is not the case, comparison of AUROC provided by different studies makes no sense. Use of standardized AUROCs is a better way to assess comparisons [41] but has seldom been used.

A recent overview reported standardized AUROCs for the diagnosis of significant fibrosis (F2F3F4) of 0.84 (95% CI: 0.83–0.86) for FibroTest, without any differences amongst the different causes of liver disease [42]. This meta-analysis also compared FibroTest to the other patented biomarkers, and did not show any significant differences between the AUROCs of these markers for advanced fibrosis. **A1c** However, because of the limited number of patients included in the direct comparisons a clinically significant difference cannot be excluded, particularly between Hepascore with a smaller AUROC (0.04 difference) versus FibroTest and Fibrometer [42]. To date, in hepatitis C, two independent studies compared three of the five patented tests [30, 43], that is, FibroTest, Fibrometer and Hepascore. There was no difference between these tests, when considering the AUROC for the detection of significant fibrosis (F2F3F4), severe fibrosis (F3F4) or cirrhosis (F4). **A1d** For other etiologies of liver disease, there are no published comparisons of the diagnostic performance of the different tests.

Another way to compare these tests could be to compare their accuracy, or its opposite, the proportion of misclassified patients, for each stage of fibrosis. Then a Profile Performance Test can be established. Halfon *et al.* did this for FibroTest and Fibrometer [30]. In this study, with

similar accuracy between the two tests (71% and 72% all stages together,  $p = \text{ns}$ ), the FibroTest classified more F1 patients correctly, whereas the Fibrometer classified more F2 and F3 patients correctly [30]. These results have to be confirmed by other studies.

The study of discordant cases is of major importance when interpreting the results of a test. To date, FibroTest is the test for which discordant results have been the best studied. With Fibrotest there are well-described causes of false positives (hemolysis, Gilbert's syndrome and sepsis) and false negatives (inflammation). In an independent study, discordant results were attributed to FibroTest in 29% of cases (5% of entire population), 21% to liver biopsy, and in the remainder attribution was undetermined. Not surprisingly, the main reason for discordant results were patients with an intermediate stage of fibrosis [31]. However, the performance of liver biopsy in discriminating between two intermediate stages, can also be poor [2]. Although performing an entire liver biopsy is certainly the gold standard, a liver biopsy 15mm long (the median biopsy length in tertiary centers) is not. It has an AUROC of 0.82 between F1 and F2. That is, there are around 20% false positives or false negatives [2]. Therefore, a test with an AUROC of 0.66 (usually described as a "weak" value when using a true gold standard) between F1 and F2 has a relative AUROC versus the best AUROC possible of  $0.66/0.82 = 0.80$ , which can be considered acceptable for a non-invasive test. The size of liver biopsy is not solely responsible for discordance [44], but few studies have made evaluations with cohorts with optimal size biopsies.

The number of liver biopsies that could be avoided could also represent a target for comparing tests. However, one must be aware that the number of biopsies avoided depends on the specificity and sensitivity required of a test. For example, in the first publication of FibroTest by Imbert-Bismuth, which suggested a requirement of 95% specificity and 100% sensitivity for the diagnosis of significant liver fibrosis, only 46% of biopsies could be avoided [16]. Similarly, Parkes *et al.* arbitrarily defined the "inaccurate" zone of a marker when one "cannot reliably attribute test results" in comparison to tests with lower sensitivities/specificities at thresholds with positive predictive values  $< 90\%$ , and negative predictive values  $> 95\%$  [45]. Choosing these thresholds could be acceptable if a true gold standard existed. However, if this definition was applied to 15mm liver biopsies, the biopsy would be inaccurate in 40% of cases for a diagnosis between F1 and F2.

In summary, non-invasive tests for fibrosis are difficult to compare, and independent validations have not identified one as being better than any other. **B4** Tests have different profiles, and the overall proportion of discordant results between tests and liver biopsy is in the range of 20%, considering all fibrosis stages together.

## Limitations of serum markers

One of the main limitations of serum markers is their availability. The tests on the market are available, but not often reimbursed by health authorities or insurance companies. The reproducibility of some indirect components is not good, for example for platelet count. For FibroTest, as mentioned before, the interpretation should take into account the well-described causes of discordances: false positives because of hemolysis (decrease in haptoglobin and bilirubin), false negatives because of inflammation.

---

## Transient elastography

### Principles

Transient elastography measures the liver stiffness, using a device including an ultrasound transducer probe that is mounted on the axis of a vibrator [46]. Vibrations transmitted by the transducer induce an elastic shear wave propagating through the underlying tissues. Pulse-echo ultrasound acquisitions are used to follow the propagation of the wave and to measure its velocity, which is directly related to tissue stiffness: the stiffer the tissue, the faster the shear wave propagates. This procedure is non-invasive, painless, fast and easy to perform. Results are immediately available, are expressed as kilopascals, correspond to median values of ten validated measurements and range between 2,5 to 75 kPa [47]. The results of a transient elastography examination can be considered valid only when several conditions are fulfilled: the interquartile range (IQR), reflecting the variability between the different measurements, should not exceed 30% of the median value, and the success rate must reach 60%. An expert in the field should always perform the clinical interpretation of transient elastography [48].

### Diagnostic performance of transient elastography

As for serum markers, elastography was first validated in patients with chronic hepatitis C [49]. The diagnostic performance of transient elastography was fairly good, with AUROCs ranging from 0.79 to 0.83 for the diagnosis of clinically significant fibrosis, and 0.95 to 0.97 for cirrhosis [29, 49]. Cutoffs with optimal accuracy were proposed for each METAVIR fibrosis stage, which, however, differ between etiologies of liver diseases so that the diagnosis must be known for the correct interpretation. As for serum markers, a substantial overlap of stiffness values was observed between adjacent stages of fibrosis. However, as already mentioned, the diagnostic performance of liver biopsy when compared to the whole liver, is also far from

satisfactory. Transient elastography has also been validated in diseases other than chronic hepatitis C: chronic hepatitis B [50, 51], HIV-HCV coinfection [52, 53], NASH [54], alcoholic liver disease [55], cholestatic diseases [56] and liver transplant patients [57, 58].

In a recent meta-analysis, the sensitivity and specificity for the diagnosis of cirrhosis with transient elastography was very good (87% and 91% respectively) [59]. **A1c** However, there was significant heterogeneity that could be explained by a “cutoff effect”. Indeed, optimal cutoffs for cirrhosis remain variable, ranging from 10,3 kPa for hepatitis B to 17,3 kPa for cholestatic diseases with no consensus. Similar to serum markers, the AUROCs for transient elastography depend on the prevalence of cirrhosis in the different populations [41].

Transient elastography was compared to FibroTest in one study: the diagnostic performance measured by AUROCs was similar [29]. Looking at the discordant results between transient elastography and FibroTest, more false negatives were observed with elastography than with FibroTest [60]. However, FibroTest more frequently overestimated the fibrosis found in the liver biopsy. In another study, elastography had the best diagnostic performance for early detection of cirrhosis in patients with chronic hepatitis C [61].

### Limitations of transient elastography

Liver stiffness measurements can be difficult in overweight patients or in those with narrow intercostal space, and impossible in patients with ascites [48]. Recent studies suggest that liver stiffness is influenced by ALT flares, with a risk of overestimation of fibrosis. Reproducibility of liver stiffness is excellent with good inter- and intra-observer agreement [62], but this is less good in patients with low degree of fibrosis, or steatosis or with an increased BMI.

### Is there a way to optimize the performance of the tests?

The combination of different serum markers together with transient elastography result in much better estimation of the degree of fibrosis. Sebastiani proposed stepwise algorithms in patients with compensated chronic hepatitis C, by performing sequentially APRI, FibroTest and in the remaining patients liver biopsy. With this approach, liver biopsy could be avoided in 71% of cases with an accuracy of 93% [63]. The same approach was also suggested for chronic hepatitis B [35]. Castera proposed the combination of FibroTest and transient elastography, and significantly improved the performance compared to each non-invasive test alone, with an accuracy of 84% when combining the tests [29]. This is probably a very promising approach. The

most important point, when analysing results of non-invasive tests for the screening of liver fibrosis, is to consider their results according to the clinical setting, and to establish if there are clinical situations that may lead to discordant results. If there are such situations then repeat the tests after a few months in order to see if the discordant result remains or not.

---

### Can we expect more from non-invasive tests?

Non-expert physicians and patients aspire to having an almost perfect test, that is, more than 99% applicability and with less than 10% of false positive or false negative results. This is not possible, even with a liver biopsy [34]. A 25 mm non-fragmented biopsy is obtained in less than 50% of all large reported series [44], and the rate of false positives or negatives of such a 25 mm non-fragmented biopsy in one study was about 20%, for the diagnosis of advanced fibrosis, in comparison with the whole liver, which is a virtual gold standard [2]. Among the discordant results observed between biopsy and biomarker estimates of fibrosis, the cause of failure is frequently due to an inadequate biopsy size or interpretation [44, 64]. Therefore, it is far-fetched to expect to obtain an almost perfect biomarker with an AUROC greater than 90% for the diagnosis of advanced fibrosis. Hence, in France, clinical practice is evolving rapidly and a nationwide survey recently found that among 546 hepatologists, 81% used non-invasive biomarkers (FibroTest-ActiTest) and 32% used elastography (Fibroscan), with a dramatic decrease in the use of liver biopsy in more than 50% of patients with chronic hepatitis C, but with an increase in the number of patients treated [65]. A recent overview by French health authorities officially approved non-invasive biomarkers FT and FS as first-line estimates of fibrosis in patients with chronic hepatitis C, and recommended reimbursement by the social security system. Liver biopsy was only approved as second-line test in case of discordant results or non-interpretability of non-invasive markers [66].

---

### Correlation with clinical events and survival

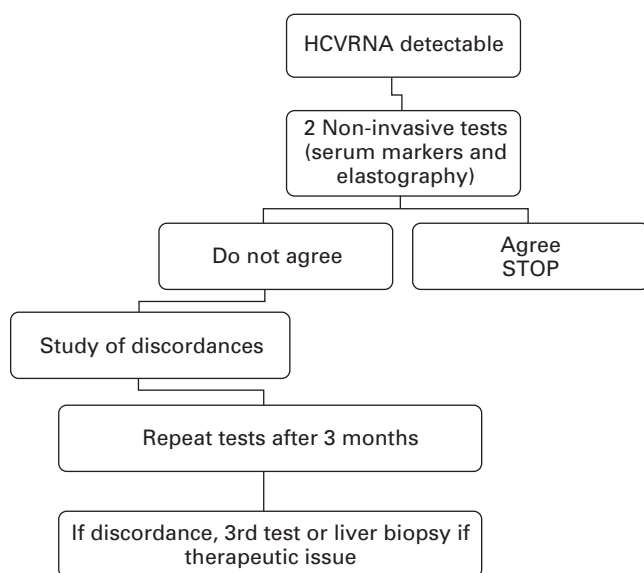

As liver biopsy is not a perfect gold standard, and as the non-invasive tests of fibrosis were constructed taking liver biopsy as the reference, the diagnostic performance of different non-invasive markers is difficult to interpret. Therefore, survival and clinical events related to liver disease could be considered as better endpoints to establish the clinical usefulness of these tests. One group of authors found serum markers to be correlated with survival and

survival without liver-related complications [64, 67], and others to response to antiviral therapy [68–70]. FibroTest and transient elastography results have also been found to correlate with the presence and degree of portal hypertension [71–75], although the relationship between elastography and esophageal varices is not good [61, 75, 76]. The ELF score was predictive of liver-related morbidity and mortality, with better sensitivity than liver biopsy [23]. However studies evaluating the prognostic value of non-invasive markers of fibrosis will need to compare these with established prognostic markers, such as hepatic venous pressure gradient, and Child-Pugh and MELD scores. Prognostic scores that are currently used in chronic liver disease rarely include histology in their formulae.

### Proposed algorithm for the prediction of liver fibrosis in HCV patients

As liver biopsy is an imperfect gold standard, an algorithm can be proposed which contains few indications for liver biopsy (see Figure 35.1). One starts with two non-invasive tests, and in case of discordant results, clinical causes of this must be evaluated. If none are found, then the tests should be repeated after a few months in order to see if the discordant result persists. If this persists and if the clinical findings do not help to resolve the issue, then liver biopsy or another test could be performed, particularly if a therapeutic decision depends on this. If this is the case, liver biopsy should be considered as complementary to the non-invasive markers, providing histological information at

**Figure 35.1** Proposed algorithm for detection of liver fibrosis in HCV patients.

baseline that can help integrate the results of the non-invasive tests.

### Conclusion

During the last five years, there has been a major improvement in the non-invasive diagnosis of liver fibrosis, especially for patients with chronic hepatitis C. Independent validations, assessment of preanalytical and analytical recommendations, and study of discordances are of major importance before considering using these tests in clinical practice. All the patented tests seem comparable to one another, and have good performance characteristics, which is also true of transient elastography. The most important issue is to consider the results of non-invasive tests in the correct clinical setting. Because liver biopsy, has its own inherent false positive and false negative results in terms of staging fibrosis (due to sample size and interpretation) any comparison with it cannot lead to establishing a perfect non-invasive marker. In France, where most of these markers have been developed, liver biopsy is no longer mandatory as a first-line test to stage fibrosis in HCV patients and indeed many current guidelines in other countries do not require a liver biopsy before starting therapy at least for genotype 2 and 3 infections. For other etiologies of liver disease, non-invasive staging of fibrosis still requires more validation. Further studies are needed on the prognostic value of these non-invasive tests, with appropriate validation of prognostic models. This involves not only good discrimination (AUROC), but good calibration, that is, the proportion of times the expected result is observed as being correct.

## Introduction

Portal hypertension is a major complication of chronic liver disease, most frequently cirrhosis, leading to the development of portosystemic collaterals, of which the most clinically significant are those that form gastroesophageal varices. Variceal hemorrhage is the most serious complication of portal hypertension and is still associated with a high mortality rate, although it has diminished over the past three decades, probably because of several new therapeutic approaches for the prevention and treatment of variceal bleeding. The therapeutic armamentarium for portal hypertensive bleeding has been considerably expanded by the introduction of pharmacological therapy with various vasoactive agents, the endoscopic ligation of esophageal varices and the covered transjugular intrahepatic portosystemic shunt (TIPS).

As a result, the number of randomized clinical trials dealing with the treatment of portal hypertension is ever increasing. However, most of the new treatments are inadequately or poorly evaluated in trials using heterogeneous criteria for the definition of their main endpoints and usually lacking adequate statistical power.

We evaluated randomized controlled trials for prevention of first bleeding, treatment of acute bleeding and prevention of recurrent bleeding from esophageal varices, using meta-analysis where applicable. The main endpoints selected for analysis were the following: (1) first bleeding episode (for primary prevention trials), or failure to control bleeding including very early re-bleeding (for trials of acute bleeding) or re-bleeding (for trials for prevention of re-bleeding); (2) mortality (short term or long term); and

(3) incidence of complications. Pooled estimates of efficacy are presented as pooled odds ratios (POR), obtained by the Mantel-Haenszel method (fixed effect model). We used a statistical evaluation of heterogeneity by  $\chi^2$  test to assess whether the variation in treatment effect within trials of the same group was greater than might be expected. We considered heterogeneity to be present if  $p < 0.05$ ; if so the calculation of POR was carried out by the DerSimonian and Laird method [1], which is recommended for meta-analysis of studies with significant heterogeneity.

## Prediction of the presence and development of esophageal varices

At the time of diagnosis, esophageal varices are present in 30% of patients with well compensated cirrhosis and 60% of patients with decompensated cirrhosis. Their size is reported to increase by 10–20% in the 1–2 years following their first endoscopic observation [2]. The presence of esophageal varices has been correlated to platelet count, the size of the spleen, the presence of ascites, albumin level, Child Pugh score, and the presence of spider nevi. Esophageal varices are formed if portal pressure exceeds 10–12 mmHg. However, not all patients in this group have varices at endoscopic examination. There have been efforts towards diagnosing varices without endoscopy using various indirect indices such as platelet count, albumin, spleen size, Child Pugh score, but without a final consensus as to whether these can substitute endoscopy [3–7]. Currently, there are no satisfactory non-endoscopic indicators for the presence of varices and consequently endoscopic screening is still the best practice to detect varices. The hepatic vein pressure gradient (HVPG) is presently the most reliable predictor of variceal development [8–11]. The recently developed PillCam ESO esophageal capsule has been shown to be an accurate diagnostic tool for the detection of esophageal varices and portal hypertensive gastropathy [12–15], but cannot substitute endoscopy unless this cannot be done. **A1c**

## Prevention of the development and growth of varices

Pre-primary prophylaxis is the term used for the prevention of varices. Beta-blockers reduce portal pressure by an average of 15–20%. The decrease of portal pressure is neither dependent on liver function nor the degree of initial portal hypertension or other systemic hemodynamic parameters. However, propranolol does not seem to affect the size of varices, although it reduces variceal pressure [16].

Two studies have addressed the role of beta-blockers in the progression of esophageal varices. In the first study Cales *et al.* [17] studied 206 cirrhotics with small varices or without varices; 102 patients received propranolol and 104 patients received placebo. After two years of follow-up the proportion of patients with large varices was 31% in the propranolol group compared with 14% in the placebo group ( $p < 0.05$ ). More recently, Merkel *et al.* compared nadolol (83 patients) with placebo (78 patients) with a mean follow-up of 60 months [18]. A significantly lower rate of esophageal varices enlargement in patients randomized to nadolol was observed and a significantly lower probability of variceal bleeding. Survival was not improved.

However, in a third study that randomized 213 patients without esophageal varices (minimal HVPG of 6mmHg) to receive either timolol (108 patients) or placebo (105 patients), beta-blockers did not prevent varices formation (39% and 40% respectively;  $p = 0.89$ ) [9]. **Ald** The majority of patients (88%) were Child A liver status and 12% Child B. Median follow-up was 54.9 months, while mean daily dose of timolol was 10.8mg. Serious adverse events were more common among patients in the timolol group ( $p = 0.006$ ). Varices developed less frequently among patients with a baseline HVPG  $< 10$ mmHg and among those in whom the HVPG decreased by more than 10% at one year. To date there is only one study with evidence that beta-blockers can reduce the progression of small to large varices in patients with cirrhosis [18]. However, taking into consideration the available data regarding the risk of bleeding in patients with small varices we consider that these drugs are a reasonable therapeutic option, particularly for patients with advanced liver disease, or living far from endoscopic units. **Ald**

## Risk of first variceal bleeding

Mortality of the first bleeding episode can be high, depending on severity of liver disease (10–30%). Hence the identification of patients with varices who will bleed, before they do so, is clearly important in order to offer effective prophylactic therapy to those who need it, and avoid it in those who do not, particularly if the therapy is invasive or costly. The risk factors for the first episode of variceal bleeding in

patients with cirrhosis are the severity of liver dysfunction, large size of varices (increased tension of the variceal wall), and the presence of endoscopic red color signs. The combination of these three factors is the basis of the North Italian Endoscopic Club (NIEC) index for the prediction of the first variceal bleeding [19]. It is important to realize that patients with small varices and grade C severity cirrhosis have comparable risk of first bleeding compared to patients with large varices and grade A severity cirrhosis, emphasizing the importance of liver dysfunction [20]. However, only a third of patients who present with variceal hemorrhage have the above risk factors [21]. Hence there is a need to define new predictive factors that could be combined in the NIEC index to improve its validity. The main interest has been the identification of hemodynamic factors that could more readily reflect the pathophysiological changes that lead to variceal bleeding. It is now well accepted that bleeding is extremely rare if HVPG falls below 12mmHg [8]. The severity of HVPG has been shown to be an independent risk factor for bleeding.

---

## Randomized controlled trials for prevention of first variceal bleeding

### Shunt surgery versus non-active treatment

There have been four prophylactic shunt trials [22–25], which were the first randomized controlled trials in portal hypertension, including 302 patients. A meta-analysis of these trials has been published [26]. Variceal bleeding was significantly reduced (odds ratio (OR) 0.31; 95% CI: 0.17–0.56) in the treated group, but survival was significantly worse (OR 1.6; 95% CI: 1.02–2.57). In addition, the risk of chronic or recurrent encephalopathy was significantly increased (OR 2.0; 95% CI: 1.2–3.1) in shunted patients. In view of the mortality data and the serious adverse effects, prophylactic shunt surgery has been abandoned worldwide. Moreover the advent of liver transplantation removes any rationale for prophylactic surgery of any kind in cirrhotic patients. **Ald**

Thus, the results of Inokuchi *et al.* from Japan, who compared devascularization procedures or selective shunts with non-active treatment [27], showing a significant reduction in bleeding risk and mortality with prophylactic surgery, are not clinically relevant today, over and above the issue of the method of randomization, which complicates the validity of the data.

### Sclerotherapy versus non-active treatment

The success of endoscopic sclerotherapy in the treatment of acute variceal bleeding led to extensive evaluation of sclerotherapy for the prevention of the first variceal bleed.

There are 21 trials [28–48], of which four are published in abstract form [42–45], including a total of 1922 patients. The main characteristic of these trials was the statistically significant heterogeneity ( $p < 0.001$ ) in the direction and size of the treatment effect on bleeding and death, so that meta-analysis cannot be interpreted correctly. The first trials reported promising results, with a reduction in bleeding rate, and in some a reduction in overall mortality [29, 35, 36]. However, they were of poor quality [49]. Subsequent larger trials did not confirm benefit and indeed some trials have suggested that prophylactic sclerotherapy is deleterious [40, 48]. In evaluating endoscopic sclerotherapy it must be remembered that it is an expensive and invasive treatment, which is associated with potentially serious complications. Hence prophylactic sclerotherapy would have to be clearly superior to no prophylactic treatment by a considerable margin before it could be recommended for widespread use. **Ala**

### Variceal ligation versus non active treatment

In recent years, endoscopic variceal ligation has replaced endoscopic sclerotherapy as the method of choice for the prevention of re-bleeding. In randomized trials and a meta-analysis, ligation was more effective than sclerotherapy in preventing re-bleeding, in part because it resulted in faster eradication of varices and had fewer complications [50]. For primary prophylaxis, ligation has been compared to no treatment in seven trials [51–57], four full papers [53, 54, 56, 57] (see Table 36.1). Meta-analysis of randomized trials shows that EVL reduced both the risk of first portal hypertensive bleeding (OR 0.25; 95% CI: 0.17–0.37) and mortality (OR 0.42; 95% CI: 0.29–0.60) compared to no treatment [57]. Some adverse effects of variceal ligation (retrosternal pain, dysphagia, etc.) were transient, but two patients died, one because of esophageal perforation related to the insertion of the overtube (although this is no longer necessary in current practice)[53], and others after postligation ulcer

bleeding [54, 58], raising concerns about iatrogenic bleeding [59].

### B-blockers versus non-active treatment

The optimal prophylactic treatment should be easy to administer, have relatively few adverse effects, and be reasonably effective. Drug therapy potentially fulfils these criteria best. In addition, drug therapy has the potential to protect against gastric mucosal bleeding, which accounts for a sizeable proportion of first bleeding episodes [67]. There are nine prophylactic trials using  $\beta$ -receptor blockade in cirrhotic patients with large varices comprising 996 patients; seven trials of propranolol [38, 44, 48, 61, 64–66], and two of nadolol [62, 63]; two of these as abstracts [44, 66] (see Table 36.2). One of the latter trials was an outlier, reporting a very low bleeding rate in non-treated patients [66]. This study causes statistically significant heterogeneity in the evaluation of first bleeding in a comprehensive analysis evaluating the effect of B-blockade therapy in the prevention of variceal bleeding. The heterogeneity disappears when this trial is excluded from the analysis [66]. There was a statistically significant bleeding risk reduction with  $\beta$ -blocker treatment when the outlier trial was included (OR 0.54; 95% CI: 0.39–0.74) or excluded (OR 0.48; 95% CI: 0.35–0.66). The number of patients needed to be treated (NNT) with  $\beta$ -blockers to prevent one bleeding episode was estimated to be 11. There was no heterogeneity in the evaluation of mortality ( $p = 0.19$ ). Mortality was reduced with  $\beta$ -blockers but not significantly so (OR 0.75; 95% CI: 0.57–1.06).

$\beta$ -blockers have been shown to be effective independently of cause and severity of cirrhosis, presence of ascites and variceal size in an analysis of individual patient data from four of the above trials [68]. However, bleeding may occur after stopping  $\beta$ -blocker therapy, suggesting that therapy should be maintained lifelong [69]. Finally, propranolol has been shown to prevent both acute and chronic

bleeding from portal hypertensive gastropathy in a single blind randomized study [67]. Adverse effects of  $\beta$ -blockers are usually reversible after discontinuation of the drug, and no fatal complications have been reported. **A1a**

### $\beta$ -Blockers versus nitrates and beta blockers

A randomized trial first published in 1996 [84] and further evaluated in 2000 [85] showed that nadolol and isosorbide dinitrate combined were more effective than nadolol alone for prevention of first variceal bleeding.

In this study [85] 146 patients with cirrhosis and known esophageal varices, but no bleeding, were treated for seven years. Sixteen in the nadolol group and eight in the combination group bled (logrank test,  $p = 0.02$ ). The cumulative bleeding risk was 29% and 12% respectively (95% CI for the difference 1–23%). Addition of isosorbide 5-mononitrate did not increase the incidence of liver failure, development of ascites or renal insufficiency; five patients requested discontinuation of nitrates due to adverse effects. However, the results of the most recent multicenter and larger randomized controlled trial are conflicting. In this study 349 cirrhotic patients with gastroesophageal varices were randomized to receive propranolol + placebo ( $n = 174$ ) or propranolol + isosorbide mononitrate (ISMN) ( $n = 175$ ) [86]. There were no significant differences in the one and two-year actuarial probability of variceal bleeding between the two groups (propranolol + placebo 8.3% and 10.6% respectively; propranolol + ISMN, 5% and 12.5% respectively). Survival was also similar. Adverse effects were signifi-

cantly more frequent in the propranolol + ISMN group, mainly due to a greater incidence of headache. The combination was otherwise safe and did not produce any deleterious effects on renal function.

$\beta$ -blockers effectively prevent variceal bleeding. Adding nitrates does not further decrease the low residual risk of bleeding in patients receiving propranolol. Current data do not support a recommendation for additive medication to non-selective  $\beta$ -blockers for primary prophylaxis of variceal bleeding. **A1d**

### Variceal ligation versus $\beta$ -blockers

There are 15 randomized trials comparing endoscopic band ligation of high risk esophageal varices to propranolol [58, 70–83] (see Table 36.3). In the first trial, Sarin *et al.* found that ligation was more effective than propranolol for prevention of bleeding (actuarial survival, propranolol 43%, ligation 15%,  $p < 0.05$ ) [71]. However, the rate of bleeding in the propranolol group was higher than has been observed in some other studies. This may be because of the lower mean dose of propranolol used (70 mg/day compared with 123 mg/day in previous studies). Alternatively, the difference in bleeding rates between groups may have occurred because of the relatively small number of patients studied and the resultant rather wide confidence intervals. The rate of bleeding in the propranolol group was the same as that in the non-treated group in a previous trial by the same authors in which the same selection criteria were used [53]. In the meta-analysis of the 15

**Figure 36.1** Primary prevention: Forrest plot of randomized trials of banding ligation of esophageal varices versus beta-blockers in primary prevention of variceal bleeding. Portal hypertensive bleeding. BB: beta-blockers; EBL: Endoscopic band ligation. Data are expressed as OR (95% CI) in a log scale.

studies variceal ligation significantly reduced the risk of first variceal bleeding compared with propranolol (POR 0.52; 95% CI: 0.38–0.72). However, the same meta-analysis did not find any difference in terms of mortality, with a trend in a favor of drug treatment (POR 0.94; 95% CI: 0.69–1.28), and iatrogenic bleeding due to ligation causing death [57, 59]. Recently Wang *et al.* reported similar efficacy of ligation to the combination of nadolol plus ISMN (see Figures 36.1 and 36.2) [87]. **Ala**

The conflicting results of these studies and the small number of patients randomized and events observed, as

well as the cost of endoscopic variceal ligation, do not provide sufficient evidence for recommending any change in the current practice of prescribing propranolol as the treatment of first choice for the primary prevention of variceal bleeding and using band ligation if there are contraindications or intolerance to beta-blockers. **Ala**

### Variceal ligation versus sclerotherapy

Variceal ligation was compared with sclerotherapy for the primary prevention of variceal bleeding in three small

**Figure 36.2** Primary prevention: Forrest plot of randomized trials of banding ligation of esophageal varices versus beta-blockers in primary prevention of variceal bleeding. Mortality. BB: beta-blockers; EBL: Endoscopic band ligation. Data are expressed as OR (95% CI) in a log scale.

studies [52, 60, 88] of which one was published only in abstract form [52]. The results were conflicting. One study indicated that sclerotherapy was more effective [88], the second that ligation was more effective [60], and the third that the two interventions are of similar efficacy [52]. Thus, it is not surprising that there is significant heterogeneity in the meta-analysis ( $p = 0.045$ ) for bleeding, and combining the data in a meta-analysis may not be justified. There was no significant difference for mortality (POR 0.84; 95% CI: 0.35–2.05).

## Conclusion

The data from prophylactic trials suggest that screening for varices in cirrhotic patients should be part of routine clinical practice, and if these are found, prophylactic treatment to prevent first variceal bleeding should be offered [89, 90]. Shunt surgery prevents bleeding but the increase in mortality and the long-term risk of encephalopathy make this treatment unacceptable. Prophylactic sclerotherapy should not be used as it is relatively ineffective, costly and potentially dangerous. The treatment of first choice is prophylactic  $\beta$ -blocker therapy; it is inexpensive, easy to administer, and effective for prevention of the first variceal hemorrhage and of bleeding from gastric mucosa. Primary prophylaxis with variceal ligation appears to be safe and may be a reasonable alternative for: (1) patients with contraindications to  $\beta$ -blockers; (2) patients who cannot tolerate or have no hemodynamic response to the drug therapy. However, it is unlikely to be a routine prophylactic treatment as it is much more expensive and less available than  $\beta$ -blockers and it will not prevent gastric mucosal bleeding [57]. The trend towards increased mortality with banding needs further observation, as increased mortality was seen with prophylactic sclerotherapy.

## Outcome of acute variceal bleeding

Acute variceal bleeding is a life-threatening complication in patients with cirrhosis and portal hypertension, with mortality that ranges from 10% to 40% [91]. Although overall survival is improving [1], because of new therapeutic approaches, mortality is still closely related to failure to control hemorrhage or early re-bleeding, which is a distinct characteristic of portal hypertensive bleeding and occurs in between 15% and 50% of patients in the first days to six weeks after admission [92].

HVPG has been shown to be prognostic for both survival and the course of acute bleeding. In 1986 Vinel *et al.* documented that short term prognosis in alcoholic cirrhotics with variceal bleeding was independently associated with portohepatic gradient measured within 48 hr of admission [93]. This was confirmed in a small study of 22 patients, in which the best cutoff for continued bleeding or early re-bleeding was HVPG > 16 mmHg [94]. Villanueva *et al.* showed that HVPG > 20 mmHg and a decrease  $\leq 10$  mmHg under vaso-active therapy were independent predictors of further bleeding [95]. An HVPG > 20 mmHg has been shown to correlate with important clinical outcomes, such as more difficulty in controlling acute variceal bleeding, more early re-bleeding, more blood transfusion need, more days in intensive care and increased hospital mortality [96]. Avgerinos *et al.* showed that HVPG > 16 mmHg was independently associated with death and/or early re-bleeding, evaluating HVPG measurements before and immediately after endoscopic treatment and every 24 hours for a five-day period [97]. Interestingly, there was sustained rise of portal pressure after sclerotherapy, but not band ligation. In addition, Vlachogiannakos *et al.* showed that somatostatin but not octreotide effectively prevents the post-

endoscopic increase of HVPG [98]. With the prognostic association of high HVPG with the course of bleeding (using vasoactive drugs and endoscopic therapy) and mortality, a randomized study showed that urgent TIPS in patients with HVPG > 20 mmHg, protected against continued or repeated bleeding and reduced mortality [96]. This study clearly demonstrated the therapeutic benefit of intervention based on HVPG measurement and validated the value of 20 mmHg HVPG as a cutoff. The question then arises about the applicability of measuring HVPG in this setting, which although accurate and reproducible, with little co-efficient of variation in measurement, and with few complications is not currently feasible outside a research setting [99].

Several studies have evaluated factors associated with failure to control bleeding and mortality. A consensus has determined that control of variceal bleeding spans the first five days and mortality is death within six weeks of onset of bleeding [89]. Ben-Ari *et al.* showed that in 385 cirrhotics treated initially with vasoactive drugs and then endoscopic therapy if bleeding continued or recurred (within five days) active bleeding at endoscopy (independent of the interval from onset of melena and/or haematemesis or the interval to admission to hospital), the severity of liver disease (mainly Child-Pugh grade C) as well as encephalopathy, platelet count and history of alcoholism were all independently associated with failure to control bleeding (internal validation of the model was performed) [100]. There were some interactions between variables in that active bleeding was associated with transfusion need and transfusion need was associated with Child-Pugh class, and shorter interval to admission. Interestingly a higher Child-Pugh score and increased mortality was independent of transfusion requirement. Independent factors associated with mortality within 30 days were failure to control bleeding within five days, raised bilirubin, encephalopathy, shorter interval to admission to hospital and plasma urea. Leclaire *et al.* evaluated prospectively 468 consecutive patients with cirrhosis and upper gastrointestinal bleeding (23.5% died during hospitalization) [101]. The independent factors associated with in hospital mortality were: presentation with hematemesis, bleeding starting in hospital, prothrombin time <40% (the strongest association, reflecting severity of liver disease), recent use of steroid drugs within seven days of bleeding, age >60 years and a concomitant hepatocellular cancer. Thomopoulos *et al.* retrospectively evaluated 141 patients with acute variceal bleeding (18.6% 6 week mortality) treated with somatostatin started before endoscopy and endoscopic ligation [102]. Early re-bleeding, Child-Pugh grade C and shock at admission were independent predictors of mortality at six weeks, whilst active bleeding and presence of infection (prophylactic antibiotics were not routinely used) were not adverse factors.

Lo *et al.* also found active bleeding to be independently associated with recurrent bleeding, but not mortality, although this was higher in the group with active bleeding at endoscopy [103]. In addition, the presence of hepatocellular carcinoma may alter the immediate prognosis [101, 104, 105] so that early imaging (large tumors will be detected by a bedside ultrasound) to detect HCC may alter the therapeutic algorithm, for example TIPS rescue therapy may not be indicated and only vasoactive and endoscopic methods applied. A concomitant portal vein thrombosis, whether due to tumor or not may also worsen prognosis as often bleeding is more difficult to control.

The use of prophylactic antibiotics should be standard therapy for patients with cirrhosis who have variceal bleeding [106]. The association with failure to control was shown prospectively [107], following a hypothesis that proposed infection as a trigger for bleeding [108], and the causal association was shown in two randomized trials [109, 110]. Antibiotics result in better control of bleeding and less early re-bleeding. **A1c** The prognostic models that assess control of bleeding should now be based in cohorts of patients who have had prophylactic antibiotics.

In a prospectively evaluated cohort of 117 patients with cirrhosis [111], HVPG was measured within 48 hours. As in a previous study HVPG > 20 mmHg was independently predictive of failure to control bleeding at five days, together with shock (systolic blood pressure at admission <100 mmHg) and non-alcoholic etiology of cirrhosis, giving an optimal discrimination using an AUROC curve with a c statistic of 0.79 [96]. However, removing HVPG, the model contained Child-Pugh class, shock at admission and non-alcoholic cirrhosis as independent associations with a c statistic of 0.8, that is, the same discriminatory capacity. The authors devised a simple point score which will be useful in clinical practice as it identifies a subgroup with 40% or more chance of failure to control variceal bleeding. Indeed the authors confirm what is already known clinically about these patients with difficult bleeding with the added data; this is associated with a higher HVPG [89]. This should intensify clinical research into more effective vasoactive regimens to lower portal pressure and treatment algorithms which will result in more effective therapy to control bleeding *ab initio*, for example early TIPS after diagnostic endoscopy, or first-line injection with glues at diagnostic endoscopy, or indeed the recently described self-expanding covered esophageal stent [112]. A randomized trial of early TIPS, reproposing a management scheme used by Orloff *et al.* with emergency porto-caval shunt [113].

Although survival following variceal bleeding has progressively improved [91, 114], it remains to be proven that "complete" or better control of bleeding with early TIPS or other measures over and above what is current practice after failed vasoactive drugs and endoscopy will result in

improved survival. In the large study by Ben-Ari *et al.* mortality in Child-Pugh grade C was independent of transfusion need, that is, of severity of bleeding [100]. Thus there may be an inexorable train of events which is initiated by bleeding in this group of patients, leading to death, independent of good control of bleeding. This concept of “going past the point of no return” is seen in the development of renal failure, despite the prompt resolution of sepsis (not associated with spontaneous bacterial peritonitis) in cirrhosis, where just over 20% of such patients have the complication of renal failure despite optimal treatment and resolution of the precipitating septic event [115].

Intravenous third-generation cephalosporins, compared to oral quinolones are a good option for prophylaxis in upper GI bleeding in cirrhosis being active against Gram-negative bacteria and non-enterococcal streptococci [116]. In addition, many cirrhotics receive quinolones already as prophylaxis for spontaneous bacterial peritonitis, and quinolone resistant bacteria are currently sensitive to cephalosporins. Current trials have started antibiotics after endoscopic diagnosis. Possibly the administration should be started at admission before endoscopy with the potential to increase therapeutic benefit.

The clinician should be aware that most clinical trials have focused on esophageal varices, with very few designed to evaluate therapy for gastric varices. Gastric varices may lead to more severe bleeding initially, and tend to re-bleed frequently [117]. The following sections refer to esophageal varices unless specified.

## Randomized controlled trials for the treatment of acute variceal bleeding

### Pharmacologic treatment

Vasoactive drug treatment is the only treatment that does not require sophisticated equipment or the skills of a specialist and is immediately available, even before the patient is admitted to hospital [118]. Furthermore, as evidence suggests that those patients with high variceal or portal pressure are likely to continue to bleed or re-bleed early, prolonged drug therapy that lowers portal pressure over days may be the optimal treatment [8, 119]. The vasoactive drugs that are currently used in the management of acute variceal bleeding are vasopressin, glypressin, somatostatin, octreotide and vapreotide. Vasopressin, which is a powerful vasoconstrictor, lowers portal pressure through the induction of smooth muscle contraction, particularly in splanchnic arterioles. However, the drug also causes systemic vasoconstriction which leads to serious side effects, such as cardiac arrhythmias, myocardial ischemia, mesenteric ischemia and cerebrovascular episodes, resulting in cessation of therapy in up to 25% of cases [120, 121].

Terlipressin is a synthetic analogue of vasopressin (triglycyl lysine vasopressin). It has an intrinsic effect as well as being converted *in vivo* into vasopressin by enzymatic cleavage of the triglycyl residues. This prolongs its biological half-life, so that a continuous intravenous infusion is unnecessary. Somatostatin has been used in the pharmacological treatment of variceal bleeding because it reduces splanchnic blood flow [122], portal pressure and azygous blood flow in patients with cirrhosis [123], although only the findings regarding the reduction in azygous flow are consistent. Bolus injections of somatostatin appear to have greater hemodynamic effects as compared with continuous infusion. Finally, octreotide has been reported to cause a reduction in portal pressure [124], and a transient decrease in azygous blood flow [125], but there are some studies that do not confirm these data, using similar or even greater doses of the drug [126].

## Randomized controlled trials of vasoactive drug treatment of acute variceal bleeding

### Drugs versus placebo

See Table 36.4.

### Vasopressin versus placebo

Vasopressin was compared with non-active treatment or placebo in four randomized controlled trials [121, 127–129], including only 157 patients. In two trials the intra-arterial route of administration was used [121, 129]. There was a significant heterogeneity in the evaluation of failure to control bleeding. There was a clear trend in favor of vasopressin but the result was not statistically significant by the Der Simonian and Laird method (POR 0.23; 95% CI: 0.05–1.02). Moreover there was no difference in mortality (POR 0.98; 95% CI: 0.47–2.1). Complications were reported in up to 64% of patients, which led to discontinuation of treatment in 25% of cases. In order to minimize the systemic complications of vasopressin, nitroglycerin has been added to the regimen. This drug is a powerful venous dilator, reduces the portal vascular resistance and improves myocardial performance. Three randomized controlled trials have compared vasopressin alone with vasopressin plus nitroglycerin (transdermally [120], sublingually [130], and intravenously [131]), including 176 patients. Failure to control bleeding was significantly less common with vasopressin plus nitroglycerin (POR 0.39; 95% CI: 0.21–0.72) but there was no difference in mortality (POR 0.94; 95% CI: 0.49–1.79). In two of the trials [130, 131], adverse effects were significantly reduced with the combination treatment. However, nitroglycerin, because of portocollateral shunting, bypasses the liver, and can cause significant sys-

temic effects. Hence, this combination therapy must be monitored very closely and is less applicable as an immediate therapy.

### Terlipressin versus placebo

The clinical efficacy of terlipressin has been evaluated in six randomized placebo-controlled studies [118, 132–136] including 388 patients. In two studies endoscopic sclerotherapy was employed at the initial diagnostic endoscopy [118, 133]. In one trial the drug was given while the patient was transferred to hospital. There was a statistically significant reduction in failure to control bleeding with terlipressin compared with placebo (POR 0.49; 95% CI: 0.33–0.75) and more importantly the same meta-analysis showed that terlipressin is the only vasoconstrictor that significantly reduces mortality (POR 0.51; 95% CI: 0.33–0.79). However, there is some criticism of these studies. The sample sizes were small, allowing a large type 2 error in the first three trials [132, 135, 136], and the evidence in the early administration trial [118] of the effect of terlipressin, given only

as three doses up to eight hours, does not readily explain the apparent benefit on mortality (only in group C patients) via an effect on the control of bleeding. **A1c**

### Somatostatin versus placebo

Three placebo-controlled trials of somatostatin exhibit divergent results [137–139]. The trials by Valenzuela *et al.* [139] and Gotzsche *et al.* [138] suggested that somatostatin was no more effective than placebo. Unfortunately both studies had a very long recruitment period, suggesting marked patient selection. Moreover, Gotzsche *et al.* did not evaluate the endpoint of failure to control bleeding [138], while Valenzuela *et al.* reported an extremely high response rate (83%) in the placebo group (the highest ever reported) [139]. In contrast, the study by Burroughs *et al.* reported a statistically significant benefit for somatostatin in controlling variceal bleeding over a five-day treatment period [137]. These differences in the reported results caused statistically significant heterogeneity ( $p = 0.006$ ) in the meta-analysis of the six studies which compare somatostatin

with placebo or inactive treatment [140–142]. There was a trend in favor of somatostatin but the result was not statistically significant by the Der Simonian and Laird method (POR 0.6; 95% CI: 0.21–1.65). There was no difference in mortality between the two treatment groups (POR 1.02; 95% CI: 0.64–1.61). **Alc**

Moitinho *et al.* evaluated a total of 174 patients with acute variceal bleeding who were randomized to receive somatostatin for 48 h: (A) one 250 µg bolus + 250 µg/h infusion; (B) three 250 µg boluses + 250 µg/h infusion; (C) three 250 µg boluses + 500 µg/h infusion [143]. The 500 µg/h infusion dose achieved a higher rate of control of bleeding (82 vs 60%,  $p < 0.05$ ), less transfusions ( $3.7 \pm 2.7$  vs  $2.5 \pm 2.3$  units,  $p = 0.07$ ) and better survival (93 vs 70%,  $p < 0.05$ ) than schedules A and B. Others have confirmed the above results using somatostatin 500 µg/h [144, 145]. **Ald**

### Octreotide versus placebo

There is only one double blind randomized trial of octreotide versus placebo ( $n = 262$ ) in the management of acute variceal bleeding, currently available only in abstract form [146]. In this study a continuous five-day infusion of 50 µg/hour octreotide, started as soon as possible after admission was not more effective than placebo, whether or not injection sclerotherapy was needed for active bleeding or drug failure. Infections were treated if suspected on clinical grounds and were similar in the two trial groups. Moreover, two other studies using octreotide (100 µg eight-hourly, subcutaneously) or placebo after the control of the initial bleeding episode failed to show any difference in early re-bleeding or mortality between the two treatment groups [147, 148].

### Drugs versus balloon tamponade

Six trials compared vasoactive drugs with balloon tamponade. The drugs were terlipressin in three studies [149–151], somatostatin in two studies [152, 153] and octreotide in one study [154]. Meta-analysis of these six trials showed that the drugs were as effective as balloon tamponade for prevention of failure to control bleeding (POR 1.04; 95% CI: 0.63–1.72) or death (POR 0.65; 95% CI: 0.36–1.16). **Alc** Sensitivity analysis showed that there was no difference according to the type of drug. However, the sample sizes were small and the endpoints not very clear, indicating that these results should be interpreted with caution. Tamponade, if used properly, provides good control of bleeding. However, the balloons should not be inflated for more than 12 hours and preferably less, and bleeding frequently recurs when the balloons are deflated. From the trial reports it is not always clear when efficacy is being assessed, for example during therapy or at the end of an interval of 24 hours after termination of drug therapy or tamponade. Whether the new expanding oesophageal

stent will replace tamponade will be known from RCTs [112].

### Drugs versus drugs

See Table 36.5.

#### Terlipressin versus vasopressin

Terlipressin was compared with vasopressin in five small, unblinded studies involving only 247 patients [155–158, 170]. In two studies, vasopressin was associated with nitroglycerin [157, 158]. Failure to control bleeding was less frequent with terlipressin, but the result was not statistically significant (POR 0.74; 95% CI: 0.36–1.14). There was no difference in mortality between the two treatment arms (POR 1.48; 95% CI: 0.85–2.57). More importantly, the complication rate was significantly lower with terlipressin even when vasopressin was combined with nitroglycerin. **Alc**

#### Somatostatin versus vasopressin

Somatostatin was compared with vasopressin in eight trials including 343 patients [159–165, 171]. Although these trials showed a trend in favor of somatostatin, the difference was not statistically significant (POR 0.74; 95% CI: 0.48–1.13). There was no difference in mortality between the two vasoactive agents (POR 0.97; 95% CI: 0.6–1.5). However, a statistically significant reduction in complications was observed in the group receiving somatostatin (POR 0.11; 95% CI: 0.07–0.19) as the mean complication rate was 51% with vasopressin and only 10% with somatostatin. **Alc**

#### Somatostatin versus terlipressin

Three studies have compared somatostatin with terlipressin involving 326 patients [166, 167, 172]. These studies showed that the two drugs were similarly effective in preventing failure to control variceal bleeding and death. Moreover, in one of these studies a significantly lower incidence of complications in the somatostatin group was reported [166]. **Alc**

#### Octreotide versus other drugs

The efficacy of octreotide treatment in comparison to other vasoactive drugs, for acute variceal bleeding, has not been adequately evaluated. Octreotide was found to be comparable to vasopressin in two low quality studies ( $n = 89$  in total) [168, 173], and to terlipressin plus nitroglycerin in another ( $n = 87$  patients) [169]. However, the sample sizes were small and the trials may have lacked power to show differences, and the endpoints are not very clear, indicating that these results should be interpreted with caution.

#### Somatostatin versus other drugs

In a single center randomized trial 62 cirrhotics with variceal bleeding were randomized to receive somatostatin

(n = 35) versus somatostatin plus nitroglycerine (n = 26) [174]. Similar proportions of patients achieved control of bleeding in the two groups (88.6% vs 92.3% respectively). The authors concluded that the addition of nitrates does not improve the control of bleeding or prevent early re-bleeding. **Ald**

### Recombinant activated factor VIIa

In a placebo-controlled double blind randomized trial, recombinant factor VIIa was safe but no clear-cut benefit in control of bleeding or mortality was seen [175]. More recently a randomized controlled trial assessed the efficacy and safety of rFVIIa in patients with advanced cirrhosis and active variceal bleeding [176]. At 31 hospitals in an emergency setting, 256 patients (Child-Pugh > 8; Child-Pugh B = 26%, C = 74%) were randomized equally to: placebo; 600 µg/kg rFVIIa (200 + 4x 100 µg/kg); or 300 µg/kg rFVIIa (200 + 100 µg/kg). The primary composite endpoint consisted of failure to control bleeding within 24

hours, or failure to prevent re-bleeding or death by day five. Administration of rFVIIa had no significant effect on the composite endpoint compared with placebo (p = 0.37). There was no significant difference in five-day mortality between groups; however, 42-day mortality was significantly lower, with 600 µg/kg rFVIIa compared with placebo (odds ratio 0.31; 95% CI: 0.13–0.74), and bleeding-related deaths were reduced from 12% (placebo) to 2% (600 µg/kg), but this was not associated with differences in control of bleeding. There is no evidence that recombinant activated factor VIIa improves outcome in acute variceal bleeding. **Alb**

### Randomized controlled trials of emergency sclerotherapy in the management of acute variceal bleeding

Injection sclerotherapy, first introduced in 1939 and “rediscovered” in the late 1970s, has been used for the control of

acute variceal bleeding over the past two decades. Paradoxically the best evidence for the value of sclerotherapy in the management of acute variceal bleeding has come from a more recently published study by the Veterans Affairs Cooperative Variceal Sclerotherapy Group [177]. In this study sclerotherapy, compared with sham sclerotherapy, stopped hemorrhage from actively bleeding esophageal varices (91% in sclerotherapy arm compared with 60% in sham sclerotherapy,  $p < 0.001$ , ARR = 29%, NNT = 3) and significantly increased hospital survival (75% vs 51%,  $p = 0.04$  ARR = 24%, NNT = 3). **AId**

Today it is generally accepted that sclerotherapy should be carried out at the diagnostic endoscopy, which should take place as soon as possible, because there is evidence that this is beneficial compared with delayed injection [178, 179]. No more than two injection sessions should be used to arrest variceal bleeding within a five-day period [92]. Several sclerosing agents have been used for injection, polidocanol 1–3%, ethanolamine oleate 5%, sodium tetradecyl sulfate 1–2% and sodium morrhuate 5%. There is no evidence that any one sclerosant can be considered the optimal sclerosant for acute injection, as it has been shown that a substantial proportion of intravariceal sclerosant ends up in the paravariceal tissue and vice versa. **B4** There is no evidence that one technique is better than the other. One of the main shortcomings of sclerotherapy is the risk of local and systemic complications, although this varies greatly between trials and may be related to the experience of the operator [180].

### Sclerotherapy plus drugs/balloon tamponade versus drugs/balloon tamponade

The five trials, three papers [181–183] and two abstracts [184, 185] comprised 400 patients (413 episodes): three used

vasopressin [181, 182, 184], one somatostatin [183] and one octreotide [185]. Treatment effect was evaluated within 24 hours up to 120 hours, except in one study at two weeks [181]. Specific definitions of failure to control bleeding are given in four [181–183, 185]; only three [181, 182, 186] report complications; blood transfusion was reported in four [181–183, 185]; three report less transfusion with sclerotherapy [181–183]; and one no difference [185]. Median quality score was 58 (49–68.5). Failure to control bleeding was reported: 214 episodes of variceal bleeding in the sclerotherapy and vasoactive drugs/balloon tamponade group and 199 in the vasoactive drugs/balloon tamponade alone. Failure to control bleeding was significantly more frequent without sclerotherapy, with pooled difference being 16.3% (95% CI: 8.7–23.9%;  $p = 0.0001$ ). **AId** The NNT was 6 (95% CI: 4–11). The publication bias assessment was 15 null or negative studies. The sensitivity analyses differed from the main meta-analysis as follows: abstracts alone showed no differences between trial groups. In only one study, octreotide added to sclerotherapy did not improve control of bleeding. Fewer deaths occurred with sclerotherapy combined with drugs than with drugs/balloon tamponade alone ( $Q$ ,  $p = 1.0$ ), with a 5.5% difference (95% CI: –1.8–12.7%;  $p = 0.138$ ) with no significant changes in the sensitivity analyses. Complications: reported in three studies [181–183] and two [181, 183] did not report per patient. A systematic evaluation was not possible (see Table 36.6).

### Sclerotherapy versus drugs

There are 15 studies comprising 1296 patients (1324 episodes), 11 papers [187–197] and four abstracts [198–201]; one used vasopressin [196], one used terlipressin [188], four used somatostatin [191–193, 198] and nine used octreotide [187, 189, 190, 194, 195, 197, 199–201]. Treatment effect

S: sclerotherapy; D: drugs; NR: not reported.

was evaluated at the end of drug infusion (12–168 hours). The efficacy of sclerotherapy was 83% (57–94%) in studies of 12–48-hour drug infusion [189–192, 194–196, 198–201] and 73% (68–83%) when 120–168 hours [187, 188, 193]. All except three trials [189, 199, 200] report complications. One study had less transfusion with sclerotherapy (units,  $2.1 \pm 0.41$  vs  $2.9 \pm 0.79$ ;  $p < 0.05$ ) [199], ten found no difference [187–195, 197], one study did not state [201], and three had no report [196, 198, 200]. Median quality score was 60 [51–73]. Considering failure to control bleeding, there was significant heterogeneity ( $p = 0.01$ ), but only in the magnitude and not in the direction of treatment effect; in only two were drugs better than sclerotherapy, but without reaching statistical significance [190, 201]. Excluding abstracts there was no heterogeneity ( $p = 0.4$ ). Failure to control bleeding was less frequent with sclerotherapy with a difference of 3.4% (95% CI:  $-1.8$ – $8.5\%$ ;  $p = 0.2$ ) with no change following sensitivity analyses. If all papers are considered then sclerotherapy was more effective, with a 5.9% difference (95% CI:  $1.5$ – $10.3\%$ ) ( $p = 0.008$ ). The other sensitivity analyses showed that octreotide in nine studies ( $p = 0.04$ ) and vasopressin (one study) as well as the combined group of somatostatin and octreotide were significantly worse than sclerotherapy. In the trials there were no differences between treatment groups considering only patients with cirrhosis, or abstracts, or somatostatin, or drug infusion more or less than 120 hours, or combined group of vasopressin and terlipressin or terlipressin alone. There were fewer deaths with sclerotherapy – 4.3% (95% CI:  $0.6$ – $8.1\%$ ) ( $p = 0.02$ ). **Ala** The NNT was 23 (95% CI:

12–157). The effect is not robust, as publication bias assessment was four null or negative studies. Sensitivity analyses did not change the main meta-analysis. Complications in 12 studies [187, 188, 190–198, 201] had significant heterogeneity ( $p = 0.0001$ ) and were less frequent with any drug 8.8% (95% CI:  $0.2$ – $15.6\%$ ;  $p = 0.01$ ) (see Table 36.7).

### Sclerotherapy plus drugs versus sclerotherapy alone

The eight trials, six papers [189, 202, 205–208] and two abstracts [203, 204] (the first with two treatment arms) comprised 1026 patients; four studies were placebo controlled [202, 203, 205, 206, 208]. Vasoactive drug was administered for 120 hours in six trials [202–206, 208] and 48 hours in two [189, 207]. The efficacy of sclerotherapy was 82.5% (81–84%) with 48 hour drug administration and 61.5% (36–77%) with 120 hours ( $p = \text{ns}$ ). In all studies but one the average units transfused were significantly less with combination therapy [189]. Median quality score was 60 (49.5–75). Failure to control bleeding was less frequent with sclerotherapy combined with drugs: 13.2% (95% CI:  $8.4$ – $18.1\%$ ;  $p < 0.0001$ ). **Ala** The NNT was 8 (95% CI:  $5$ – $15$ ). The publication bias assessment was 47 null or negative studies, that is, the result is very robust. In the sensitivity analyses, terlipressin did not have an advantage: there was no advantage of any drug added to sclerotherapy for 48 hours administration and no advantage of combined therapy when no placebo drug was used. The difference in mortality was 3.4% (95% CI:  $-0.4$ – $7.1\%$ ) in favor of combined therapy ( $p = 0.08$ ). Sensitivity

analysis showed that in placebo controlled trials in which drug was given for 120 hours the difference was 1.3% (95% CI: -3.3–5.8%), strongly suggesting no benefit in mortality despite benefit for control of bleeding. For complications, five studies had data but only two reported per patient [202, 205], with no statistical differences (see Table 36.8 and Figures 36.3 and 36.4).

### Sclerotherapy versus variceal ligation

The twelve trials, eight papers [209–216] and four abstracts [217–220], comprised 1309 patients. In seven trials only patients with cirrhosis were included [209–213, 216, 219]. The same ligating device (Bard Interventional Products, Tewksbury, Massachusetts) with an overtube was used in eight [209–212, 214–216]; in three this was not mentioned [217–219] and one used a six-shooter [220]. A definition of failure to control bleeding is stated in five [209, 210, 212,

213, 216]. The efficacy of sclerotherapy for initial hemostasis at the end of endoscopy was 95% (76–100%) compared with 97% (86–100%) with ligation EBL group ( $p = 0.4$ ). In only one [213] of documenting transfusion requirements [211–213, 215, 216, 218], was this less in the ligation group (units,  $4.5 \pm 1.8$  (0–12) versus  $3.2 \pm 1.2$  (0–6)  $p < 0.01$ ); in others there was no difference. Median quality score was 68.5 (50.5–79). Failure to control of bleeding: there was a difference favoring ligation -2.5% (95% CI: 0.4–4.6%) ( $p = 0.018$ ). **Ala** Sensitivity analyses did not show differences from the main metaanalysis, including an evaluation defining failure versus those in which there was no failure.

Regarding mortality, the percentage difference was 1.3% favoring ligation (95% CI: -2.3–4.9%,  $p = 0.46$ ). Sensitivity analyses did not show differences from the main metaanalysis.

In another recent trial [221] patients admitted with acute gastrointestinal bleeding and with suspected cirrhosis

received somatostatin infusion for five days. Endoscopy was performed within six hours and those with esophageal variceal bleeding were randomized to receive either sclerotherapy (n = 89) or ligation (n = 90). Therapeutic failure occurred in 21 patients treated with sclerotherapy (24%) and in nine treated with ligation (10%) (RR = 2.4, 95% CI: 1.1–4.9). However, in those with active bleeding there was no difference between ligation and sclerotherapy. Failure

to control bleeding occurred in 15% vs 4%, respectively (p = 0.02). Treatment group, shock and HVPg > 16 mmHg were independent predictors of failure. Side effects occurred in 28% of patients receiving sclerotherapy vs 14% with ligation (RR = 1.9; 95% CI: 1.1–3.5), being serious in 13% vs 4% (p = 0.04). Six-week survival probability without therapeutic failure was better with ligation (p = 0.01) (see Table 36.9 and Figures 36.5 and 36.6).

**Figure 36.5** Forrest plot of risk difference for control of bleeding in trials of sclerotherapy vs variceal ligation.

**Figure 36.6** Forrest plot of risk difference for mortality in trials of sclerotherapy vs variceal ligation.

### Ligation plus sclerotherapy vs ligation

There were 113 patients with either active bleeding or stigmata of recent bleeding from esophageal varices who were randomly assigned to receive ligation plus sclerotherapy, or ligation alone. Hemostasis of active bleeding was achieved at the time of the index treatment in eight of ten of the patients in the combined group (80%) and in ten of twelve of the patients in the ligation group (83%,  $p > 0.05$ ) [222].

### Ligation + terlipressin vs ligation + octreotide

In a recent randomized trial [223] 88 patients with cirrhosis with variceal bleeding allocated to terlipressin ( $n = 43$ ) or octreotide ( $n = 45$ ) successful hemostasis was achieved in 98% of patients. Early re-bleeding, which included re-bleeding within six weeks of therapy was seen in 28% of terlipressin group and 24% of octreotide group. The two treatments were equally effective for acute esophageal

variceal bleeding with regard to hemostatic effect and prevention of re-bleeding.

### Randomized controlled trials of emergency surgery in the management of acute variceal bleeding

Four randomized trials, carried out in the 1980s, compared sclerotherapy to emergency staple transection [224–226]. Failure to control bleeding was reported only in two of these studies, with divergent results. Teres *et al.* reported that efficacy of transection in their study was only 71%, the lowest in the literature, compared with 83% in the sclerotherapy arm [226]. In contrast, in the largest study by Burroughs *et al.*, a five-day bleeding-free interval was achieved in 90% of the patients who underwent transection (none re-bled from varices) compared with 80% in those who had two emergency injection sessions [227]. There was

no difference in mortality between the two treatment modalities. Cello *et al.* showed that emergency portacaval shunt was more effective than emergency sclerotherapy (followed by elective sclerotherapy) in preventing early re-bleeding (19% vs 50%) [228]. Hospital and 30-day mortality were not significantly different. **A1c** Finally, Orloff *et al.* in a small study, reported that portacaval shunt, carried out in less than eight hours from admission, was significantly better than medical treatment (vasopressin/ balloon tamponade) in the control of acute variceal bleeding [229]. Survival was also better in the patients who had shunts, but the difference was not statistically significant.

### Randomized controlled trials of other endoscopic therapies in the management of acute variceal bleeding

Two types of tissue adhesives (n-butyl-2-cyanoacrylate, Histoacryl and isobutyl-2-cyanoacrylate, Bucrylate) have been used for the control of variceal bleeding [230]. The adhesives potentially result in better immediate control of bleeding because they harden within seconds upon contact with blood. However, extra care must be taken to ensure that the adhesive does not come into contact with the endoscope and block suction and operator channels. This can be prevented if the adhesive is mixed with lipiodol to delay hardening. Moreover, the sclerotherapy needle must be carefully placed within the varix prior to injection, to avoid leak. A small randomized trial showed that cyanoacrylate was superior to conventional sclerotherapy with 3% ethanolamine oleate solution for control of bleeding and reduction of hospital mortality in Child-Pugh class C patients [231]. Two randomized controlled trials compared sclerotherapy alone with the combination of sclerotherapy and n-butyl-2-cyanoacrylate [232, 233]. The combined treatment was more effective than sclerotherapy alone in both studies. **A1c** Moreover, in two studies n-butyl-2-cyanoacrylate was compared with variceal ligation for the control of bleeding from esophageal [234] or esophagogastric varices [235]. The overall success rate for initial hemostasis of both treatment modalities was similar in these studies. **A1c** However, n-butyl-2-cyanoacrylate was superior to variceal ligation for the control of fundal variceal bleeding, but it was less effective for the prevention of re-bleeding (67% vs 28%). In a small randomized study [236], a biological fibrin glue (Tissucol) was more effective than sclerotherapy with polidocanol in the prevention of early re-bleeding and had a significantly lower incidence of complications. Finally, another study found that fibrin glue was as effective and safe as ligation for acute bleeding and for prevention of re-bleeding from esophageal varices, but had superior tissue compatibility [237]. More studies are necessary to confirm these data and examine the potential risks

of activating coagulation, systemic embolism and particularly transmission of infections with the human plasma-derived fibrin glue. The literature available on thrombin is limited. Bovine thrombin was effective in small series, but has been withdrawn due to its infection risk [238].

In addition, in a prospective randomized controlled trial [239], cirrhotic patients with acute or recent esophageal variceal bleeding were assigned randomly to percutaneous transhepatic varices embolization, PTVE (52 patients) or EVL (50 patients). During the follow-up period (median 24 and 25 months in the PTVE and EVL groups respectively) UGI re-bleeding developed in eight patients in the PTVE group and 21 patients in EVL group ( $p = 0.004$ ). Recurrent bleeding from esophageal varices occurred in three patients in the PTVE group and 12 in the EVL group ( $p = 0.012$ , relative risk 0.24, 95% CI: 1 0.05–0.74). Survival in these two groups was not significantly different.

An endoscopic detachable snare is another ligation device which has the advantage of allowing an unlimited number of ligations by reloading the nylon minisnare while the endoscope remains in the esophagus. The first prospective randomized trial showed that the mini snare performed equally well when compared with a multiple variceal ligator [240]. **A1d** In another study 50 patients with acute esophageal variceal bleeding were recruited: 25 were treated by elastic band ligation and 25 by endoloop ligation: re-bleeding 12% endoloop group and 28% ligation was not significantly different [241].

### Gastric varices

The incidence of bleeding from gastric varices varies between 3% and 30%, but in most series it is less than 10% [251]. Patients with gastric variceal hemorrhage bleed more profusely and require more transfusions than patients with esophageal variceal bleeding [252]. **B4** Moreover, these patients have a higher risk of re-bleeding and a decreased survival rate compared with patients bleeding from esophageal varices. The optimal treatment of gastric variceal bleeding is not known. Limited information is available on the role of vasoactive drugs in the control of gastric fundal bleeding and balloon tamponade has been used with little success. Use of standard sclerosants is associated with unacceptable re-bleeding, particularly from necrotic ulceration, as the gastric mucosa appears much more sensitive to this than the esophagus.

Because of this, alternative sclerosant agents have been evaluated. The tissue adhesives n-butyl-2-cyanoacrylate and isobutyl-2-cyanoacrylate, mixed with lipiodol to delay premature hardening, have been evaluated, and found to be efficacious in observational, studies [253]. Isobutyl-2-cyanoacrylate has been shown to be superior to ethanolamine, in a non-randomized study, achieving

hemostasis in 90% of 23 patients, as opposed to 67% of 24 patients ( $p < 0.005$ ) [254].

In a randomized controlled trial of 37 patients with isolated fundic varices (acute and recent bleeding) with follow-up of 15 months, cyanoacrylate glue was shown to be more effective than sclerotherapy with alcohol for variceal obliteration (100% vs 44%,  $p < 0.005$ ) [255]. There was a trend in favor of cyanoacrylate glue for the control of acute bleeding (89% vs 62%) and the need of surgical intervention (10% vs 35%), although both were statistically non-significant. Mortality was similar in the two groups. **Ald**

In another randomized trial [256] 48 patients received endoscopic band ligation (GVL) and another 49 patients received endoscopic n-butyl-2-cyanoacrylate injection (GVO). Both treatments were equally successful in controlling active bleeding (14/15 vs 14/15,  $p = 1.000$ ). More of the patients who underwent GVL had GV re-bleeding (GVL vs GVO, 21/48 vs 11/49;  $p = 0.044$ ). The two-year and three-year cumulative rate of GV re-bleeding were 63.1% and 72.3% for GVL, and 26.8% for both periods with GVO;  $p = .0143$ , log-rank test. Multivariate Cox regression indicated that concomitance with HCC (relative hazard: 2.453, 95% CI: 1.036–5.806,  $p = 0.041$ ) and the treatment method (GVL vs GVO, relative hazard: 2.660, 95% CI: 1.167–6.061,  $p = 0.020$ ) were independent factors predictive of GV re-bleeding. There was no difference in survival between the two groups.

In the study by Lo *et al.* cirrhotic patients with a history of gastric variceal bleeding were randomized to two groups [257]. The group receiving endoscopic obturation (group A) comprised 31 patients and the group receiving band ligation (group B) comprised 29 patients. Butyl cyanoacrylate and pneumatic-driven ligator were applied, respectively. Active bleeding occurred in 15 patients in group A and 11 patients in group B. Initial hemostatic rate was 87% in group A and 45% in group B ( $p = 0.03$ ). The sessions required to achieve variceal obliteration and obliteration rates were similar in both the groups. However, re-bleeding rates were significantly higher in group B (54%) than group A (31%) ( $p = 0.0005$ ). Nine patients of group A and 14 patients of group B died ( $p = 0.05$ ). Authors concluded that endoscopic obturation using cyanoacrylate proved more effective and safer than band ligation in the management of bleeding gastric varices.

However, reports of cerebral embolism, with tissue adhesives identified at postmortem as well splenic embolization and development of retrogastric abscesses, cause concern. Interest has therefore focused on thrombin. This is much easier to administer, and has been shown to provide good early hemostasis [258]. However, in all of these studies, re-bleeding rates have remained high. Hence, in patients with re-bleeding or uncontrolled bleeding from gastric varices, devascularization surgery or portosystemic shunting has been proposed. “Salvage” TIPS is very effective

in this situation, with more than 95% success rate for initial hemostasis and an early re-bleeding rate of less than 20% [251]. TIPS appears to be as effective for gastric varices as for esophageal varices.

Non-actively bleeding patients with fundal varices constitute a discrete population. The efficacy of cyanoacrylate in these patients is controversial and bleeding rates in this group can be relatively high. The Japanese experience with balloon-occluded transvenous obliteration as a prophylactic procedure in this patient population appears promising [259, 260]. TIPS, shunt surgery and, of course, liver transplantation are the only other therapeutic options for recurrent bleeding from gastric varices. The consensus at Baveno IV was to use endoscopic therapy with tissue adhesive (e.g. N-butyl-cyanoacrylate) [89]. Lastly, in a recent trial TIPS proved more effective than glue injection in preventing re-bleeding from gastric varices, with similar survival and frequency of complications [261].

## Uncontrolled variceal bleeding

The definition of uncontrolled variceal bleeding includes the continued/early variceal re-bleeding (within five days) despite two sessions of therapeutic endoscopy, continued variceal bleeding despite balloon tamponade and continued/early gastric or ectopic variceal bleeding despite vasoconstrictor therapy.

Predictive models indicate grade C patients with signs of significant bleeding are the patients at risk of failure. Balloon tamponade has most often been used to arrest life-threatening hemorrhage or if other measures fail. It has also been used in the absence of a definite diagnosis if bleeding from varices is strongly suspected. The usual tube is a modified four-lumen Sengstaken-Blakemore tube (SBT). The airway should be protected by an endotracheal tube under a short general anesthetic, as the risk of aspiration is very high, particularly in unskilled hands [262]. If blood is still coming up the gastric aspiration lumen, then varices are less likely to be the cause of blood loss, although gastric fundal varices are not always controlled by tamponade. In fact, whenever this occurs, if the position of the SBT has been checked and adequate traction applied, the diagnosis of variceal bleeding should be questioned, and emergency angiography performed.

In a recent report the use of self-expandable metallic stents was evaluated to arrest uncontrollable acute variceal bleeding (20 patients mean age 52, 8 Child pugh C) [112]. The patients had not been successfully managed with prior pharmacologic or endoscopic therapy. The stents were successfully placed in all of the patients and were left in place for 2–14 days. Bleeding from the esophageal varices ceased immediately after implantation of the stent in all cases. No recurrent bleeding, morbidity, or mortality occurred during

treatment with the esophageal stent. All of the stents were extracted without any complications after definitive treatment had been started.

### Randomized trials of TIPS

TIPS stops bleeding in a significant percentage of patients [263]. In uncontrolled studies TIPS is effective in stopping variceal hemorrhage [251, 264, 265], but there is still a high mortality [266]. Monescillo *et al.* evaluated variceal bleeders with HVPG  $\geq 20$  mmHg randomly allocated to receiving transjugular intrahepatic portosystemic shunt (TIPS; HR-TIPS group,  $n = 26$ ) within the first 24 hours after admission or not (HR-non-TIPS group) [96]. The HR-non-TIPS group had more treatment failures ( $p = 0.0001$ ). Early TIPS placement reduced treatment failure ( $p = 0.003$ ), in-hospital and one-year mortality ( $p < 0.05$ ). Overall TIPS remains a good choice as a rescue therapy although when it is not available staple transection of the esophagus could be considered [267]. **Ald** In another multicentre trial an early decision for PTFE-TIPS improved survival in high risk cirrhotic patients admitted with acute variceal bleeding [268].

New diagnostic and treatment algorithms of acute variceal bleeding are needed using known predictive factors of failure to control bleeding and mortality in order to identify the group of bleeders with poor outcome. In this group more effective vasoactive regimens, early TIPS after diagnostic endoscopy, and the use of self-expanding covered esophageal stents could be considered [269].

### Conclusion

The available data suggest that emergency endoscopic treatment with banding ligation or sclerotherapy, at the time of the initial diagnostic endoscopy, should be the gold standard for the management of the acute variceal bleeding episode. Sclerotherapy may be more applicable in some acute situations compared with ligation. A diagnostic endoscopy, with visualization unhindered by the ligation device, should be done first as varices may not be the source of bleeding. If ligation is to be used then this entails a double intubation and does lengthen the procedure.

Sclerotherapy is also significantly better than drug treatment alone and there is no need for further studies directly comparing sclerotherapy or ligation with one of the currently available drugs. However, the combination of sclerotherapy with a drug, given as soon as possible after admission is currently the best option. The drugs of choice for this combination are terlipressin (as mortality is reduced albeit in small placebo-controlled studies) and somatostatin (which has less side effects and has been successfully tested over five days). Further studies are needed to assess the role of tissue adhesives or fibrin glues in patients' unresponsive to vasoactive drugs or sclerotherapy.

The role of emergency TIPS as "salvage therapy" for uncontrolled bleeding from esophageal or gastric varices is now common practice but only certain centres can offer an emergency service. Randomized trials with other therapies such as esophageal stent should be performed.

### Prevention of recurrent variceal bleeding

Patients surviving the first episode of variceal bleeding are at very high risk of recurrent bleeding (70% or more) and death (30–50%). All patients who have previously bled from varices should have secondary therapy to prevent further variceal bleeding [89]. There is no role for an observational policy, as all randomized studies have shown active therapy to be better than observation alone. **Ala** Hence, in clinical practice the risk indicators of long-term re-bleeding are of less clinical value, than those for first variceal bleeding. However, severity of liver disease, continued alcohol abuse and variceal size have been associated with variceal re-bleeding.

A recent development has been the proposed use of hemodynamic indices to identify patients who are more likely to re-bleed. Two such indices have been reported, using the technique of hepatic venous pressure measurement as an indicator of portal pressure. From the analysis of the Barcelona-Boston-New Haven Primary Prophylaxis trial, it was concluded that variceal bleeding did not occur with an HVPG  $< 12$  mmHg, in patients with predominantly sinusoidal portal hypertension. However, with an HVPG  $> 12$  mmHg, the correlation between portal pressure and bleeding risk is inconsistent.

An hemodynamic index was proposed by Feu *et al.* [270]. Patients who had a percentage reduction of HVPG of 20% or more from baseline had a re-bleeding rate of 15% compared with 50% in those who did not achieve this hemodynamic target. Unfortunately, these HVPG targets are achieved in only about one-third of patients on  $\beta$ -blockers, hence the introduction of combined pharmacologic therapy. Several studies on secondary prevention have used hemodynamic monitoring during combination pharmacotherapy in their design. In these studies the target values are reached only in 45–60% of patients subjected to therapy with  $\beta$ -blockers and nitrates. Moreover, because most re-bleeding episodes occur within one month of the index bleed, early repeat HVPG measurements are needed in order to identify the nonresponders. However, the above approach has not been confirmed in one study [271]. A randomized study has shown greater likelihood of HVPG reduction with sequential monitoring of portal pressure but no reduction in rebleeding compared to combined ligation and nadolol without monitoring of HVPG [272].

There are several options including pharmacologic, endoscopic and surgical/radiological therapies.

## Randomized controlled trials for the prevention of variceal re-bleeding

### $\beta$ -blockers versus no treatment

A comprehensive meta-analysis of 12 trials comprising 769 patients [273–284] has been published [285]. The mean follow-up was  $21 \pm 5$  months. There was significant heterogeneity in the evaluation of re-bleeding ( $p < 0.01$ ). Treatment with  $\beta$ -blockers significantly decreased the risk of re-bleeding (Der Simonian and Laird method: POR 21%; 95% CI: 10–32%). The NNT with  $\beta$ -blockers to prevent one re-bleeding episode was 5. Survival was also significantly improved in patients treated with  $\beta$ -blockers. (Der Simonian and Laird method: POR 5.4%, 95% CI: 0–11%) although there was significant heterogeneity in this analysis ( $p < 0.01$ ). **Ala** The NNT to prevent one death is 14. Adverse events occurred in 17% of patients and were generally mild. No fatal complication has been reported with  $\beta$ -blockers.

The use of hemodynamic targets (20% reduction of HVPG and/or fall  $<12$  mmHg) to identify patients who are “non-responders” to pharmacological therapy could be a useful tool in the planning of treatment for secondary prevention of variceal bleeding. These patients could then be offered alternative therapy such as variceal ligation, or combination drug therapies, before they have further bleeding. The applicability of hemodynamic monitoring has been questioned [286], and non-responders have a 60% of re-bleeding [287].  $\beta$ -blockers in association with oral nitrates have been shown to induce a greater drop in portal pressure than  $\beta$ -blockers alone [288]. Other drugs that may work in combination with  $\beta$ -blockers include angiotensin-converting enzyme (ACE) inhibitors and angiotensin-II receptor antagonists [289],  $\alpha$ -adrenoreceptor antagonists like prazosin [290] and spironolactone [291], but problems with their adverse effects, particularly hypotension and lack of efficacy, preclude their use.

### $\beta$ -blockers plus nitrates versus $\beta$ -blockers alone

The rationale behind the use of combination therapy is that agents acting through different mechanisms may be additive or synergistic in terms of their benefit. In a recent randomized trial the addition of ISMN significantly improved the efficacy of propranolol alone in the prevention of variceal re-bleeding, but only after stratification according to age (i.e.  $<50$  years of age vs  $>50$  years of age;  $p = 0.03$ ), or after evaluation of prolonged follow-up (3 years;  $p = 0.05$ ) [292]. However, no significant difference was found in the overall rate of re-bleeding and survival. Moreover, more patients in the combination treatment group had to discontinue therapy due to adverse effects [293]. Similarly, no additional benefit from the combination

of  $\beta$ -blockers and ISMN was reported in an abstract [293]. **Ald** Of note is that in this study, a higher mortality was observed in the combination-therapy group. Recently, combination therapy and its effectiveness in preventing re-bleeding was assessed by hemodynamic monitoring. Although the number of patients studied was small ( $n = 34$ ) and the  $\beta$ -blocker dose was fixed (160 mg of long-acting propranolol) the investigators reported that the addition of ISMN increased the number of responders (HVPG  $< 12$  mmHg or  $>20\%$  from baseline value) from 38% to 59%, and these patients experienced less bleeding (10% vs 64% for non-responders;  $p < 0.05$ ) [294].

### Sclerotherapy versus no treatment

There are seven trials, including 1111 patients [182, 281, 295–299]. The re-bleeding rate was reduced in all studies except one [295]. Meta-analysis showed that the pooled odds ratio was significantly reduced (POR 0.63; 95% CI: 0.49–0.79). Mortality was also reduced significantly in the sclerotherapy arm (POR 0.77; 95% CI: 0.61–0.98). **Ala** However, complications were frequent and did not differ from those of prophylactic or emergency sclerotherapy.

### Sclerotherapy versus drugs

Eleven trials, involving 971 patients compared sclerotherapy with drugs (propranolol in ten studies [281, 300–307, 309] and nadolol plus ISMN in one study [308] for the prevention of recurrent bleeding (from any source, for example varices, portal hypertensive bleeding, or sclerotherapy ulcers) (see Table 36.10). There was a striking heterogeneity in the evaluation of re-bleeding ( $p = 0.004$ ): in five studies [281, 301, 305, 306, 308] re-bleeding was less frequent in patients randomized to drugs and in six studies in patients randomized to sclerotherapy [300, 302–304, 307, 309] the POR showed that there was no significant difference between the two treatment modalities (Der Simonian and Laird method: POR 0.88; 95% CI: 0.72–1.25). **Ala** There was no significant heterogeneity in the evaluation of survival ( $p = 0.15$ ). More patients randomized to sclerotherapy survived, but the result was not statistically significant (POR 0.95; 95% CI: 0.58–1.32). Moreover, the number of patients free of adverse events was significantly higher in the drug group compared with sclerotherapy group (POR 0.85; 95% CI: 0.65–1.11).

### Sclerotherapy plus drugs versus sclerotherapy

Twelve trials of sclerotherapy and drugs (eight propranolol [310–317], three nadolol [318–320] and one isosorbide-5-mononitrate [321] versus sclerotherapy alone, comprising 853 patients are summarized in Table 36.11). Theoretically the administration of drugs might prevent re-bleeding

before variceal obliteration. One problem with this group of studies is that only one study evaluated  $\beta$ -blockers after obliteration [313]. In the others, the drug was stopped at eradication. There was statistically significant heterogeneity caused by differences between studies both in the direction and in the size of the effect of treatment: three studies were in favor of sclerotherapy alone [314, 315, 320], while nine were in favor of sclerotherapy plus  $\beta$ -blockers [310, 313, 316–319, 321], statistically significant difference reported in three [312, 313, 321] POR showed that there was statistically significantly less re-bleeding in the combined treatment arm (Der Simonian and Laird method: POR 0.55; 95% CI: 0.35–0.86). There was no statistically significant heterogeneity in the evaluation of survival, with no signifi-

cant difference between the treatments treatments (POR 0.77; 95% CI: 0.5–1.1) (see Figures 36.7 and 36.8). **Ala**

Combination sclerotherapy plus subcutaneous octreotide was also compared with sclerotherapy alone for the prevention of early re-bleeding, as well as for long-term management of patients after variceal hemorrhage [322]. This last study showed significantly less re-bleeding and mortality rates in the combined treatment group. However, the possibility of a severe selection bias was raised due to the exceedingly high re-bleeding rates in the sclerotherapy group. Therefore the clinical efficacy of subcutaneous octreotide in reducing re-bleeding rates remain uncertain, despite the post-prandial increase in portal pressure being blunted by octreotide but not by propranolol.

### Sclerotherapy plus drugs vs drugs

In a single randomized trial 131 patients were randomly assigned to sclerotherapy plus propranolol with propranolol alone. Twenty-eight patients from the propranolol group but only 12 patients from the propranolol-plus-sclerotherapy group had recurrent bleeding from esophageal variceal rupture ( $p$  less than 0.01). The total number of blood units per patient with recurrent bleeding was slightly but not significantly more important in the propranolol group ( $8 \pm 7$ ) than in the propranolol-plus-sclerotherapy group ( $5 \pm 5$ ;  $p = 0.09$ ) [323]. **Ald**

### Sclerotherapy versus variceal ligation

Sclerotherapy does significantly decrease re-bleeding rates and mortality, but it has been associated with serious complications, the most common of which are esophageal stricture and bleeding from treatment-induced ulcers. Variceal ligation was developed with the aim to provide an endo-

**Figure 36.7** Secondary prevention: Forrest plot of randomized trials of sclerotherapy plus drugs versus sclerotherapy in secondary prevention of variceal bleeding. Variceal bleeding. SCL: sclerotherapy. Data are expressed as OR (95% CI) in a log scale.

**Figure 36.8** Secondary prevention: Forrest plot of randomized trials of sclerotherapy plus drugs versus sclerotherapy in secondary prevention of variceal bleeding. Mortality. SCL: sclerotherapy. Data are expressed as OR (95% CI) in a log scale.

scopic therapy at least as effective as sclerotherapy, but with fewer complications. There are 20 studies [209, 210, 212–218, 220, 242–249, 324, 325] ( $n = 1634$ ) comparing sclerotherapy to variceal ligation for the prevention of recurrent bleeding.

Thirteen studies included only patients with cirrhosis [209–213, 216, 242–244, 246–248, 324], six studies involved patients with cirrhosis or non-cirrhotic portal hypertension [214, 215, 218, 220, 245, 249], and one study included only patients with hepatic fibrosis due to schistosomiasis [217]. The sclerosing agent used was sodium tetradecyl sulfate (eight trials [210–213, 216, 242, 244, 324]), ethanolamine oleate (four trials [209, 217, 245, 248]) polidocanol (two trials [243, 246]) absolute alcohol (one trial [214]) and was not reported in five studies [215, 218, 220, 247, 249]. The same ligation equipment (Bard Interventional Products, Tewksbury, Massachusetts, USA) was used in all trials. All treatment sessions were done at intervals of 1–3 weeks. Meta-analysis showed that re-bleeding was significantly less common with variceal ligation than with sclerotherapy

(POR 0.53; 95% CI: 0.42–0.67), without significant heterogeneity amongst trials. **Ala** The NNT with variceal ligation rather than with sclerotherapy to prevent one re-bleeding episode is 10 (95% CI: 7–17). Publication bias assessment showed that 121 null or negative studies would be needed to render the results of the meta-analysis statistically non-significant. Variceal ligation was also associated with significantly lower mortality when compared with sclerotherapy as the result just reached statistical significance (POR 0.77; 95% CI: 0.59–0.99,  $p = 0.048$ ). Complications were also less common in patients treated with variceal ligation in all studies except one [209], although the size of the difference varied between studies, causing significant heterogeneity ( $p = 0.004$ ). Meta-analysis showed that the difference was statistically significant in favor of variceal ligation (Der Simonian and Laird method: POR 0.29; 95% CI: 0.19–0.44). In addition, the number of treatment sessions needed to achieve variceal obliteration was less with variceal ligation in all studies (2.7–4.1 sessions with variceal ligation compared with 4–6.5 sessions with sclerotherapy).

L, variceal ligation; L + S, variceal ligation plus sclerotherapy; NR, not reported.

There was no difference between the endoscopic modalities in the number of patients with varices obliterated (POR 1.23; 95% CI: 0.93–1.61), while the recurrence of varices was more frequent in patients treated with variceal ligation (POR 1.36; 95% CI: 0.96–1.92). **Ala** However, re-bleeding after initial eradication seems unusual especially if patients are in a regular endoscopic follow-up, and varices that recur are re-obliterated (see Table 36.12) [326].

### Variceal ligation versus variceal ligation plus sclerotherapy

To further improve the results achieved with variceal ligation, which requires between three and four therapeutic sessions for variceal eradication (and 25% of patients would have an episode of recurrent bleeding before completion of therapy), variceal ligation combined with low-volume sclerotherapy has been assessed. This could lead to more rapid eradication of varices than the use of variceal ligation alone. Sclerotherapy obliterates deeper paraesophageal varices that serve as feeder vessels for the submucosal vessels, whereas ligation can only be applied to submucosal varices.

Eight studies, involving 501 patients have tested this hypothesis: six were published as peer-reviewed articles [222, 325, 327–329, 331] and two as abstracts [330, 332] (see Table 36.12). Meta-analysis showed no significant differences between the two endoscopic treatments in the number of patients with varices eradicated (POR 1.32; 95% CI: 0.77–2.25), in re-bleeding (POR 0.93; 95% CI: 0.58–1.4) or deaths (POR 0.94; 95% CI: 0.57–1.55). However, complications were significantly higher from the combined therapy compared with variceal ligation alone (POR 2.71;

95% CI: 1.48–4.96). **Alc** Moreover, the number of sessions required to achieve eradication was greater in the combined therapy arm in all studies and significantly in one [325]. A detailed meta-analysis has been published [335].

Two other randomized studies investigated whether there was an additive effect of sclerotherapy for small varices (not amenable to variceal ligation) after the completion of repeated variceal ligation treatment. Bhargava and Pokharna reported that the combined treatment eradicated the varices in a significantly greater number of patients than variceal ligation alone, but they did not find any difference in re-bleeding [333]. In contrast Lo *et al.* reported that the combined treatment resulted in significantly less recurrence of esophageal varices and re-bleeding [334].

Finally, three studies of comparison between combined variceal ligation and sclerotherapy with sclerotherapy alone have been reported [330, 336, 337]. There was no difference in re-bleeding and mortality between the two treatment modalities in any of these studies. Moreover, this comparison is now redundant since sclerotherapy has been replaced by variceal ligation for the secondary prevention of variceal bleeding.

### Variceal ligation versus drug combination (β-blockers plus nitrates)

Six randomized controlled trials [186, 338–342] (two published as abstracts [338, 339], two using propranolol [339, 340] and the others nadolol), involving 719 patients, assessed the efficacy of variceal ligation versus drug combination of β-blockers (propranolol or nadolol) and nitrates (ISMN). We performed a meta-analysis including the updated results [342] of a previous trial [343]. There is no

**Figure 36.9** Forrest plot of randomized trials of variceal ligation versus  $\beta$ -blockers plus nitrates in secondary prevention of variceal bleeding. Variceal bleeding. EVL: variceal ligation; NSBB + I:  $\beta$ -blockers plus nitrates. Data are expressed as OR (95% CI) in a log scale.

**Figure 36.10** Forrest plot of randomized trials of variceal ligation versus  $\beta$ -blockers plus nitrates in secondary prevention of variceal bleeding. Mortality (EVL: variceal ligation, NSBB + I:  $\beta$ -blockers plus nitrates). Data are expressed as OR (95% CI) in a log scale.

difference in re-bleeding rate (REM, OR 0.98; 95% CI: 0.5–1.9). Importantly, regarding survival combined medical therapy is better than ligation (FEM, OR 0.72; 95% CI: 0.5–0.9). **Ala** One randomized trial has compared obliteration of n-butyl-2-cyanoacrylate versus propranolol, with no difference in re-bleeding rates nor survival, but with more complications with the adhesive injection (see Table 36.13 and Figures 36.9 and 36.10) [344].

### Variceal ligation plus drugs vs ligation

In a prospective randomized trial, a total of 122 patients with a history of esophageal variceal bleeding were randomized to receive EVL only (group A, 62 patients) or triple therapy (group B, 60 patients, ligation plus nadolol and sucralfate) [345].

After a median follow-up of 21 months, recurrent upper gastrointestinal bleeding developed in 29 patients (47%) in group A and 14 patients (23%) in group B ( $p = 0.005$ ). Recurrent bleeding from esophagogastric varices occurred

in 18 patients in group A and 7 patients in group B ( $p = 0.001$ ). Twenty-one patients in group A (50%) and 12 patients (26%) in group B experienced variceal recurrence after variceal obliteration ( $p < 0.05$ ). Treatment failure occurred in 11 patients (18%) in group A and in 4 patients (7%) in group B ( $p = 0.05$ ). Twenty patients from group A and 10 patients from group B died ( $p = 0.08$ ); 9 and 4 of these deaths, respectively, were attributed to variceal hemorrhage ( $p = 0.26$ ). The combination of ligation, nadolol and sucralfate (triple therapy) proved more effective than banding ligation alone in terms of prevention of variceal recurrence and upper gastrointestinal re-bleeding as well as variceal re-bleeding. **Ald** In another multicentre trial 80 patients randomized to receive EVL plus nadolol or EVL alone [250]. The variceal bleeding recurrence rate was 14% in the EVL plus nadolol group and 38% in the EVL group ( $p = 0.006$ ). Mortality was similar in both groups. The actuarial probability of variceal recurrence at one year was lower in the EVL plus nadolol group (54%) than in the EVL group (77%;  $p = 0.06$ ). **Ald**

### TIPS versus drug therapy

Escorsell *et al.* compared TIPS with drug therapy and found that the two-year re-bleeding rate was significantly lower in the TIPS group [346]. A total of 91 Child-Pugh class B/C cirrhotic patients surviving their first episode of variceal bleeding were randomized to receive TIPS ( $n = 47$ ) or drug therapy (propranolol + isosorbide-5-mononitrate) ( $n = 44$ ) to prevent variceal re-bleeding. Re-bleeding occurred in six (13%) TIPS-treated patients versus 17 (39%) drug-treated

patients ( $p = 0.007$ ). The two-year re-bleeding probability was 13% versus 49% ( $p = .01$ ). Encephalopathy was more frequent in TIPS than in drug-treated patients (38% vs 14%,  $p = 0.007$ ). Child-Pugh class improved more frequently in drug-treated than in TIPS-treated patients (72% vs 45%;  $p = 0.04$ ). The two-year survival probability was identical (72%). Medical therapy was less effective than TIPS in preventing re-bleeding. However, it caused less encephalopathy, identical survival, and more frequent improvement in Child-Pugh class with lower costs than TIPS in high-risk cirrhotic patients.

### TIPS versus sclerotherapy or variceal ligation and covered stents

Thirteen trials, involving 948 patients, compared TIPS with endoscopic treatment (with or without the addition of propranolol): nine with sclerotherapy [347–355] and four with variceal ligation [356–359] (one in abstract form [350]) (see Table 36.14). The median range of follow up was from 10 to 32 months. Re-bleeding was significantly less common in patients randomized to TIPS (POR 3.28; 95% CI: 2.28–4.72). However, there was a trend toward fewer deaths in the endoscopic treatment arm, although the difference was not statistically significant (POR 0.87; 95% CI: 0.65–1.17). **Ald** In addition, hepatic encephalopathy was statistically significantly more common in patients randomized to TIPS (POR 0.48; 95% CI: 0.34–0.67). These results are a mirror image of the surgical trials for the secondary prevention of variceal bleeding. However, an important difference is that the mean follow up was less than two years in all but two of these trials [354, 359], whereas the surgical shunt trials had a much greater average follow-up (3–4 years). As TIPS

Scl: sclerotherapy; NR: not reported; POR: pooled odds ratio; TIPS: transjugular intrahepatic portosystemic shunt; PSE: porto-systemic encephalopathy.

stenosis occurred in 50–70% of patients within the first year, this approach involves regular monitoring with Doppler/ultrasound, and repeat procedures for recanalization [359]. A similar conclusion was reached in a trial comparing TIPS to propranolol and ISMN in 91 patients with cirrhosis and a Child-Pugh score >7 [346]. TIPS, although effective in reducing re-bleeding did not improve survival, caused hepatic encephalopathy and had a worse cost-benefit profile than pharmacological treatment. However, current TIPS shunts are covered stents with a much reduced chance of dysfunction. Finally, in a recent trial patients who required TIPS for the prevention of esophageal variceal re-bleeding were randomized to either TIPS alone (n = 39, group 1) or TIPSS plus VBL (n = 40, group 2) [361]. In group 1, patients underwent long-term TIPS angiographic surveillance. In group 2, patients entered a banding programme with TIPS surveillance only continued for up to one year. There was a tendency to higher variceal re-bleeding in group 2, although this did not reach statistical significance (8% vs 15%; relative hazard 0.58; 95% CI: 0.15–2.33,  $p = 0.440$ ). Mortality (47% vs 40%; relative hazard 1.31; 95% CI: 0.66–2.61,  $p = 0.434$ ) was similar in the two groups. Hepatic encephalopathy was significantly less in group 2 (20% vs 39%; relative hazard 2.63; 95% CI: 1.11–6.25;  $p = 0.023$ ). Hepatic encephalopathy was not statistically different after correcting for sex and portal pressure gradient ( $p = 0.136$ ). Therefore, VBL with short-term TIPS surveillance is an alternative to long-term TIPS surveillance in the prevention of esophageal variceal bleeding. A covered stent was evaluated in a randomized trial of 80 patients with cirrhosis with uncontrolled bleeding (n = 23) or recurrent bleeding (n = 25), or refractory ascites (n = 32) who received either a polytetrafluoroethylene-covered stent (group 1: 39 patients) or the usual uncovered prosthesis (group 2: 41 patients) [361]. After a median follow-up of 300 days, five patients (13%) in group 1 and 18 (44%) in group 2 experienced shunt dysfunction ( $p < 0.001$ ). Clinical relapse occurred in three patients (8%) in group 1 and 12 (29%) in group 2 ( $p < 0.05$ ). Actuarial rates of encephalopathy were 21% in group 1 and 41% in group 2 at one year (not significant). Estimated probabilities of survival were 71% and 60% at one year and 65% and 41% at two years in groups 1 and 2 respectively (not significant). Thus, the use of polytetrafluoroethylene-covered prostheses improves transjugular intrahepatic portosystemic shunt patency and decreases the number of clinical relapses and reinterventions without increasing the risk of encephalopathy, and is the standard stent to be used.

### Endoscopic histoacryl obliteration vs propranolol and other studies

In a randomized study 41 patients with a first bleeding from esophageal (n = 31) or gastric (n = 10) varices were

after primary hemostasis with obliteration using Histoacryl® were randomly allocated either to undergo complete Histoacryl® obliteration of the remaining varices (group A, n = 21) or to long-term propranolol administration (group B, n = 20), for the prevention of re-bleeding [344]. No significant difference was observed between groups A and B with regard to the incidence of early re-bleeding (during the first 6 weeks; 5/21 and 3/20), bleeding-related deaths by six weeks (3/21 and 6/20), long-term re-bleeding (11/21 and 5/20), or overall number of deaths (9/21 and 9/20). The incidence of complications was higher in group A (10/21) than group B (2/20) ( $p < 0.03$ ). **Ald** In two trials treatment with ligation followed by argon plasma coagulation (APC) was superior compared with ligation alone [363, 364]. In another randomized trial 50 cirrhotic patients with esophageal varices randomized into two groups: endoscopic sclerotherapy (ES) (n = 25) vs EUS-guided sclerotherapy (EUS-ES) (n = 25)[365]. EUS-ES was as safe and effective as ES in variceal eradication. Recurrence tended to be less frequent and occurred later.

### Surgical shunts

The ideal patients for a decompressive surgical shunt, should be well compensated patients with cirrhosis, who have had troublesome bleeding, either failing at least one other modality of therapy (drugs or sclerotherapy), or had bleeding from gastric varices despite medical or endoscopic therapy, or who live far from suitable medical services. These shunts achieve an overall re-bleeding rate of 14.3% and a survival rate of 86%, but they may cause encephalopathy in 20.6% of patients (severe encephalopathy in 3%). The advent of TIPS has had a major impact on the need for these operations. Today, a common indication for a surgical shunt is in patients who have had TIPS, without major encephalopathy, but have had recurrent symptomatic TIPS dysfunction. In essence, they have had a non-surgical trial of shunting, and have selected themselves as good candidates. Small diameter portacaval H-graft or distal splenorenal shunts are probably the favored surgical option, as the portal vein is then still available should liver transplantation be required.

---

### Randomized controlled trials of surgical therapy

#### Total portacaval shunt versus selective distal splenorenal shunt

Selective distal splenorenal shunt (DSRS) was designed to reduce the incidence of hepatic encephalopathy and liver failure following total portacaval shunt (PCS) by partially maintaining portal liver perfusion while decreasing portal

blood flow to varices. Six trials, including 336 patients, compared PCS with DSRS [366–371]. A meta-analysis of these trials has been published [26]. There was no statistical significance in re-bleeding between the two surgical treatments (POR 0.88; 95% CI: 0.54–1.45). Patients with DSRS showed a trend toward less hepatic encephalopathy (POR 1.29; 95% CI: 0.76–2.17) and better long-term survival (POR 1.28; 95% CI: 0.82–2.01), but the differences were not statistically significant. **A1a** The calibrated small-diameter portacaval H-graft shunt (PCHGS) is effective in the control of variceal hemorrhage and has been associated with reduced hepatic encephalopathy when compared with total PCS [372]. **A1d**

### Surgery versus drugs

A randomized controlled trial including 119 patients compared the effectiveness of portal blood flow preserving procedures (selective shunts and the Sugiura-Futagawa operation),  $\beta$ -blockers and sclerotherapy for secondary prevention of variceal hemorrhage [373]. The re-bleeding rate was significantly lower in the surgical group compared with patients receiving drugs (16.6% vs 77.5%,  $p < 0.0001$ ) and survival was better for Child's A cirrhosis in all groups, but there was no significant difference between treatment groups considered as a whole. **A1d**

### Surgery versus sclerotherapy

DSRS was compared with sclerotherapy in four trials, involving 292 patients (see Table 36.15) [374–377]. A comprehensive meta-analysis of these studies, using individual patient data provided by the principal authors, has been previously published [378]. **A1a** Re-bleeding was statistically significantly reduced by DSRS (pooled relative risk (PRR) 0.16; 95% CI: 0.10–0.27). There was statistically significant heterogeneity in the evaluation of mortality, as the risk of death was increased in one study [376] and decreased in the other three [374, 375, 377]. The pooled relative risk was not statistically significant between the treatment modalities (PRR 0.78; 95% CI: 0.47–1.29). Chronic hepatic

encephalopathy was increased after DSRS but the difference was not statistically significant (PRR 1.86; 95% CI: 0.90–3.86). **A1a** The results of this meta-analysis are in accordance with the trial discussed above in which significantly lower re-bleeding rates were documented in the surgical compared with sclerotherapy group (16.7% vs 63%,  $p < 0.0001$ ), but no difference in mortality was observed [309]. However, this study was heavily criticized for the different exclusion criteria that were used in different treatment arms, the lack of information regarding cause of portal hypertension and differences in the surveillance endoscopy program. Finally, two trials [379, 380] (one an abstract [379]) have compared PCS with sclerotherapy in the elective treatment of variceal hemorrhage. Re-bleeding was significantly less in the portacaval shunt group. However, the incidence of hepatic encephalopathy was significantly increased with the surgical treatment and there was no difference in survival.

### Surgery versus TIPS

Recently Rosemurgy *et al.* extended the follow-up (median four years) of a previously published randomized trial comparing 8mm prosthetic H-graft portacaval shunts (HGPCS) with TIPS as definitive therapy for bleeding varices who failed non-operative management [381]. **A1d** The trial included 132 patients and shunting was carried out as an elective, urgent or emergency procedure. Placement of TIPS (non-covered stents) resulted in more re-bleeding (16% vs 3%), liver transplantations (7.5% vs 0%) and late deaths (34% vs 13.2%). According to a cost-benefit analysis carried out by the same group of investigators, TIPS was associated with much higher costs than HGPCS, due to subsequent occlusion and re-bleeding [382]. DSRS has also been shown to be superior to TIPS in terms of recurrent bleeding (6.25% vs 25.7%), encephalopathy (18.75% vs 42.86%) and shunt occlusion (6.25% vs 68.57%) in a comparative study with 67 patients with Child's A and B cirrhosis [383]. Finally Zachs *et al.* recently showed that in a population of Child's A cirrhosis, DSRS is a more cost-effective treatment than TIPS [384]. Given

the better results with covered stents it is likely that if TIPS is available, surgical shunts will be reserved for patients in whom TIPS cannot be placed for technical reasons.

## Conclusion

Pharmacological treatment with  $\beta$ -blockers is a safe and effective long-term treatment for the prevention of recurrence of variceal bleeding. The combination of  $\beta$ -blockers with isosorbide-5-mononitrate needs further testing in randomized controlled trials. The use of hemodynamic targets of HVPG response should be further evaluated for their applicability in clinical practice during pharmacologic therapy for the prevention of re-bleeding. If endoscopic treatment is chosen, variceal ligation is the modality of choice. The combination of simultaneous variceal ligation and sclerotherapy does not offer any benefit. However, the use of additional sclerotherapy for the complete eradication of small varices after variceal ligation should be further addressed in future trials. The results of randomized controlled trials comparing variceal ligation with pharmacologic treatment showed that combination treatment with non-selective  $\beta$ -blockers and nitrates and variceal ligation are equally effective. Combined endoscopic and pharmacological therapy gives the lowest re-bleeding rates but survival is no different. However non-selective beta-blockers also prevent other complications of cirrhosis [385–389] and so will be a fixed component of combination therapy. Finally, the use of TIPS for the secondary prevention of variceal bleeding is not supported by the current data, mainly because of its worse cost-benefit profile compared with other treatments. However, this conclusion is based on uncovered stents. Covered stents may be more effective, and are the stent of choice. There is a limited role for the selective surgical shunts (DSRS or HGPCS) in the modern management of portal hypertension. The ideal patient should have well compensated cirrhosis, have had troublesome bleeding, have failed at least one other modality of therapy (drugs or ligation), or have bled from gastric varices despite medical or endoscopic therapy or live far from suitable medical services, or for whom TIPS is not available.

## Summary

In conclusion, this critical review of the studies of treatment in portal hypertension has highlighted several issues with regard to the design of clinical trials and the analysis of the data that should be addressed in future trials. The quality of future trials will also be significantly improved if standardized definitions of critical endpoints (for example bleeding or re-bleeding episodes, treatment failure, etc.), agreed upon in consensus conferences are applied. This will aid the reduction of the heterogeneity

that is present in randomized controlled trials in portal hypertension and lead to better evidence for the optimal treatment options.

## Budd-Chiari syndrome

### Introduction

Budd-Chiari syndrome (BCS) is caused by obstruction of hepatic venous outflow at any level from the small hepatic veins to the junction of the inferior vena cava (IVC) with the right atrium in the absence of right heart failure or constrictive pericarditis [1]. It occurs in 0.2 per million inhabitants per year with a prevalence ranging from 1/1,000,000 of the general population in Eastern countries to 1/100,000 in Nepal [2–4]. The most common presentation is with ascites, but the range is from fulminant liver failure to asymptomatic forms. Obstruction of hepatic venous outflow is mainly caused by primary intravascular thrombosis, which may occur suddenly or repeatedly over time, accompanied by some revascularization accounting for the variable parenchymal hepatic damage and presentation. An important differential diagnosis is constrictive pericarditis or other obstructive cardiac causes. The prognosis of BCS is dictated by the rapidity of disease onset, the severity of liver dysfunction, anatomical sites of thrombosis and etiology.

### Staging the venous obstruction

Budd-Chiari syndrome is classified into four disease types according to the site of the venous obstruction and in addition to the presence or absence of portal vein thrombosis: hepatic vein obstruction/thrombosis without IVC obstruction/compression; hepatic vein obstruction/thrombosis with IVC obstruction (as a result of compensatory caudate lobe hypertrophy, or IVC thrombosis) [5]; isolated hepatic webs; isolated IVC webs. Concomitant portal vein throm-

bosis occurs about 15% of patients with BCS, and when extensive, may preclude shunting. Coexisting PVT is associated with a mean survival of one month compared with 6.3 years without PVT [6]. Moreover, five-year survival was reported to be 85% in non-PVT BCS patients versus 58% when PVT was present [7]. Medical or mechanical thrombectomy combined with TIPS is, however, changing this poor prognosis [8, 9]. Primary membranous obstruction of the IVC is a sequela of thrombosis, occurring without hepatic vein thrombosis and accounting for 60% of BCS patients in Asia [2, 10]. However this pattern has changed over time and IVC obstruction now accounts for a lesser proportion of cases in India [11].

Diagnosis is based on the demonstration of an obstructed hepatic venous outflow tract. Color and pulsed Doppler ultrasound has a diagnostic sensitivity of almost 80% and is the recommended first-line investigation [12]. CT scan or MRI, in addition, shows the typical diagnostic feature of patchy enhancement of hepatic parenchyma which is typical of all diseases involving perfusion defects of the liver. Three-dimensional contrast-enhanced magnetic resonance angiography has been shown to have similar sensitivity to hepatic venography which was considered the most accurate diagnostic imaging [13].

Although non-invasive imaging is sufficient for the diagnosis, hepatic venography is still useful to determine the extent of the thrombosis, as well as to measure caval pressures. In addition, the portal vein can be outlined by CO<sub>2</sub> portography. A transjugular liver biopsy and dilatation and/or stenting of hepatic venous and IVC webs can also be performed, as well as disruption of portal vein thrombus and placement of a TIPS [14]. If a TIPS procedure is planned and hepatic veins cannot be cannulated, the portal vein can sometimes be reached via a transcaval puncture [15].

Liver histology is of potential importance when thrombosis is limited to the small intrahepatic veins as well as to estimate liver reserve and potential reversibility of the liver injury when deciding whether shunting procedures will be

safe. However, sampling error is an under-studied but potentially important consideration in this setting.

### Functional staging and clinical presentation

A typical patient with BCS is female, about 35 years old, with underlying thrombophilia, and often taking oral contraception [3, 4]. BCS should be suspected in patients with acute abdominal pain; an enlarged liver, particularly with known thrombophilic disorders; or when fulminant liver failure is associated with ascites [16]. Chronic BCS should be excluded when there is refractory ascites, particularly if liver function tests are relatively normal [17]. Leg edema and venous collaterals on the trunk indicate IVC compression/thrombosis [10]. Ascitic fluid typically reveals a high serum-ascites albumin gradient and total protein above 25 g/l, that is, non-cirrhotic ascites.

The severity of presentation has led to a traditional classification of fulminant (5%) [18], acute (20%) [7], subacute or chronic BCS (60%) [17], with these proportions seen in reported series. However, the prognostic value of this classification has not been prospectively validated and several authors no longer recommend it to predict mortality [19–21]. Asymptomatic BCS accounts for about 15% of cases (no ascites or abdominal pain) and is usually diagnosed fortuitously, following investigation of slightly abnormal results of liver function tests [17]. The absence of ascites is attributed to long-standing, venous collaterals. In acute BCS, 58% of patients have histological evidence of chronic disease as recent thromboses compound previous subclinical thromboses [22].

Hepatocellular carcinoma appears to complicate BCS with an incidence similar to other chronic liver diseases. HCC developed in 11 of 97 patients in a recent cohort followed up for a mean of five years [23]. However, the incidence of HCC in patients with membranous IVC obstruction is reported to range from 25% to 47.5% [24].

### Etiology

A recent advance in the diagnosis of myeloproliferative disorders as aetiological factors in both Budd Chiari and splanchnic venous thrombosis is the identification of a mutation in the auto-inhibitory domain of a growth factor receptor kinase—the Janus tyrosine kinase-2 (JAK2) gene in myeloid cells, resulting in disinhibited kinase activity. This is a routine investigation in patients with Budd Chiari syndrome and splanchnic venous thrombosis, and the JAK2 mutation has been detected in 50–80% of patients with MPD, 37–45% of BCS patients, and 80% of BCS patients with MPD [28]. In the remaining patients bone marrow biopsy should be performed to exclude the diagnosis.

Amongst other acquired thrombophilic conditions, Behcet's disease is the leading cause of BCS in endemic

areas. Paroxysmal nocturnal hemoglobinuria is an extremely rare disease with a severe prognosis and a close association with BCS. The incidence of BCS during the course of the disease is about 35%. Flow cytometry on peripheral blood for detection of the CD55 and CD59 deficient clone is the current standard for diagnosis. Treatment therapies include monoclonal antibodies and bone marrow transplant.

The diagnosis of antiphospholipid syndrome is difficult due to the high prevalence of anticardiolipin antibodies in chronic liver disease. Using lupus anticoagulant as diagnostic criteria, a prevalence of antiphospholipid syndrome is seen in about 15% of BCS patients [4]. Other thrombophilic disorders are seen as a cause of BCS in 20%; the factor V Leiden mutation is commonly found [26]. However, the G20210A prothrombin gene mutation appears to be less over represented among BCS patients. Diagnosing protein C and S deficiency is not straightforward as reduced concentrations can be caused by impaired hepatic synthesis. However, a normal factor II concentration together with a 20% or more reduction of protein C or S can confirm the presence of true deficiency [29].

Oral contraceptive use is a risk factor for BCS, (particularly high estrogen content pills), related to heterozygosity or homozygosity for thrombophilic defects, including ones as yet unknown [30]. BCS in pregnancy (usually postpartum) is associated with estrogen changes, IVC compression and physiologic hyperfibrinogenemia. A summary of prevalence of BCS prothrombotic defects with suggested diagnostic panel is represented in Table 37.1.

### Prognosis and survival

The natural history of BCS is not well known, as most publications report on treated patients. Mortality rates have decreased over time [17, 31]. In 120 patients, five-year survival before 1985 was 50%, compared with 75% thereafter. Mortality is highest within two years of diagnosis and independent of treatment in one study, with 77%, 65% and 57% of patients surviving one, six and ten years respectively [31].

Clinicopathological factors, including treatment variables, derived from multivariable prognostic models are shown in Table 37.2 [7, 19–21, 31, 32]. In the largest cohort of 237 patients the severity of encephalopathy, ascites, serum prothrombin time and bilirubin resulted in defining three groups with statistically different five-year survival rates of 89%, 74% and 42% [7].

Histopathological features do not help to determine prognosis [7, 21, 31, 33]; in only one study of surgical shunts (n = 24) was advanced fibrosis associated with increased mortality [32]. Chronic histological changes accompanying an acute presentation of BCS resulted in lower survival compared to acute or chronic BCS [19].

IVC obstruction has a good short-term prognosis, but there is a lack of long-term data [2]. In Japan, patients with

obliterative cavopathy have a 25% mortality rate over 15 years; most die from variceal bleeding, liver failure and hepatocellular carcinoma [10].

## Treatment

### Medical therapy and management of complications

All patients should receive anticoagulation, unless contraindicated, starting with intravenous heparin, then warfarin, to maintain the international normalized ratio of at

least 2.5, if not higher. This treatment will control the disease in 10% of cases when the thrombosis is mild and prevent progression, although there are no randomized trials [17, 31, 34].

Fulminant BCS is usually associated with abundant necrosis that ideally requires liver transplantation. Even in the setting of immediate shunting (surgical or TIPS), hepatic regeneration will rarely take place and liver transplantation must be available as the liver failure may worsen [35]. In patients with acute BCS, early thrombolytic therapy

used within 72 hours from diagnosis and infused directly into the thrombosed hepatic vein for 24 hours, has had variable success [36]. Adjunctive angioplasty or stent placement may not be of further therapeutic benefit [37].

### Angioplasty

Short-segment obstruction or webs in hepatic veins or the IVC are treated successfully by balloon dilatation or intravascular stents. Membranous vena caval obstruction can be relieved initially in 90% of patients, but 20–30% will need additional angioplasty [38, 39]. Eapen *et al.* reported 94% and 87% survival at one and five years in BCS patients with mild disease, according to the Murad classification, who were treated only by radiological intervention at a single center [40].

Approximately half of all cases of rethrombosis are due to suboptimal anticoagulation therapy. When there is diffuse thrombosis of hepatic veins, angioplasty alone is only successful in 56% of patients, even with additional thrombolytic therapy. On the other hand, stents result in long-term patency rates of 80–90%, requiring further angioplasty in 50% [41]. Failure of thrombolysis or angioplasty and the presence of a diffuse hepatic vein thrombosis are indications for shunting.

### Portosystemic shunting

The therapeutic principle of portosystemic shunting is the conversion of the portal vein into an outflow tract (reversed portal flow), thus decompressing the sinusoids. Thrombosis or compression of the IVC maintains a high pressure in the intrahepatic IVC. Therefore a portacaval or mesocaval shunt will not provide decompression, whereas a shunt from the portal or mesenteric vein to the suprahepatic IVC or right atrium will be effective.

**Surgical shunts** Patients with a non-fulminant presentation of BCS and those without significant hepatic fibrosis who have a chronic presentation, can be considered for surgical shunting, providing the portal vein is patent. A side-to-side portal caval shunt (or meso-caval shunt) not only decompresses the liver, but also relieves ascites and eliminates the risk of variceal bleeding. A differential of 10 mmHg or more between the portal and intrahepatic IVC is considered essential [32]. A hypertrophied caudate lobe often makes the side-to-side portal caval shunt difficult to construct. Orloff *et al.* reported no technical failures, one operative death, 95% survival, a complete resolution of ascites and no encephalopathy in 60 patients, followed for a range of 3.5 to 27 years. Normal liver histology was found in 48% of patients, and stable fibrosis in the other patients, but cirrhosis did not regress. All shunts, with the exception of two patients who experienced late thrombosis, remained hemodynamically effective, despite some patients not receiving anticoagulation [42]. Contrary to this study,

another series reported a survival rate between 57–75% [35, 43] suggesting Orloff *et al.* either possessed greater experience or used more favorable selection criteria.

If the IVC is patent but severely compressed, a self-expanding stent can be placed in the intrahepatic IVC, followed by a surgical infrahepatic shunt [44]. Retrospective series have questioned the benefits of surgical shunts due to the lack of a survival advantage, independent of liver disease severity, the type of shunt (including TIPS), and the interval between diagnosis and procedure; an exception was patients with mild hepatic impairment (82% vs 68% survival at five years) [19, 21]. This lack of effect on survival could be explained by the average 25% hospital/perioperative mortality (range 0–30%) [35], and late shunt dysfunction/thrombosis [45]. Increased fibrosis at surgery was associated with higher mortality [32]. Some perioperative mortality can be attributed to acute hepatic decompensation, which is remedied only by emergency salvage liver transplantation.

Thus, shunting should be performed in a liver transplantation center where rescue therapy is possible. Moreover a TIPS procedure should be attempted before a surgical one, allowing a trial of shunting; if this fails, a liver transplantation is indicated. **B4**

**Transjugular intrahepatic portosystemic shunts (TIPS)** The use of TIPS has improved the management of BCS. TIPS avoids laparotomy, overcomes caudate lobe compression and occlusion of the IVC, with less periprocedure mortality than surgical shunting, particularly in patients with poor liver function. Using TIPS does not preclude subsequent surgical shunting or liver transplantation [14, 46–48]. With TIPS, the porto-caval pressure gradient should be normalized ( $\leq 6$  mmHg). In three series, mortality rates ranged from 9–30% during a mean follow-up of four years. Among 65 patients, seven died: one with fulminant liver failure (transplantation contraindicated), four with severe liver disease (acute on chronic presentation) and three with underlying hematological disorders.

Long-term patency, despite routine anticoagulation therapy, only averaged 50%, with 36–72% of patients needing reintervention. TIPS can be placed even if there is portal vein thrombosis [11]. Polytetrafluoroethylene-covered stents result in patency rates of 67% at one year compared with 19% with uncovered stents, a very low rate compared with other series [46]. A recent cohort study on 124 patients with BCS who underwent TIPS in six centers in Europe showed that TIPS was able to improve survival according to Rotterdam score prediction with five years survival of 71% in high risk patients [49].

TIPS should be considered as first-line therapy, if variceal bleeding occurs, for acute and chronic BCS and also in patients with fulminant BCS if a liver donor is not available within 2–3 days. **B4** A recent report demonstrated that

**Table 37.3** Liver transplantation for Budd-Chiari syndrome.

among five patients with FHF, TIPS allowed resolution of the disease in one, and acted as a bridge to liver transplantation within one month in three patients [50]. TIPS intervention should be managed carefully if the patient's liver reserve is sub-optimal and rescue liver transplantation should be available. **B4**

### Liver transplantation

In the remaining 10% of patients, when percutaneous angioplasty or TIPS fail, liver transplantation should be considered. Emergency liver transplantation is indicated for fulminant BCS, and has been used as a salvage procedure for fulminant liver failure induced by surgical shunting [35, 43, 51].

There are seven major transplant series, with more than ten patients each, totaling 162 patients (see Table 37.3), with survival rates between 50% and 95% with a mean follow-up of 4.5 years [35, 52–55]. Twenty patients (12%) had acute portal vein or hepatic arterial thrombosis, or late thrombosis, which was fatal in eight and resulted in retransplantation in eight. Despite anticoagulation recurrent BCS occurred in two of seven transplanted patients [56].

Recently a retrospective analysis of series from USA and Europe has shown a five-year survival rate of 80% [57, 58]. However, a TIPS was placed in only 4% of patients before transplant in the European series and anticoagulation was used in less than 60%. Recurrence of venous thrombosis or BCS occurred in about 10% of patients, confirming the need of anticoagulation.

Although almost all genetic thrombophilic disorders are cured by transplantation [43, 59], thrombosis still occurs and routine anticoagulation therapy is necessary. Careful monitoring is necessary as complications of anticoagulation were seen in 40% and in 17/197 (11%) after liver transplantation who had bleeding complications due to anticoagulation leading to two deaths in the European series [56].

In patients with myeloproliferative disorders, use of hydroxyurea and aspirin is safe and effective [60]. So far

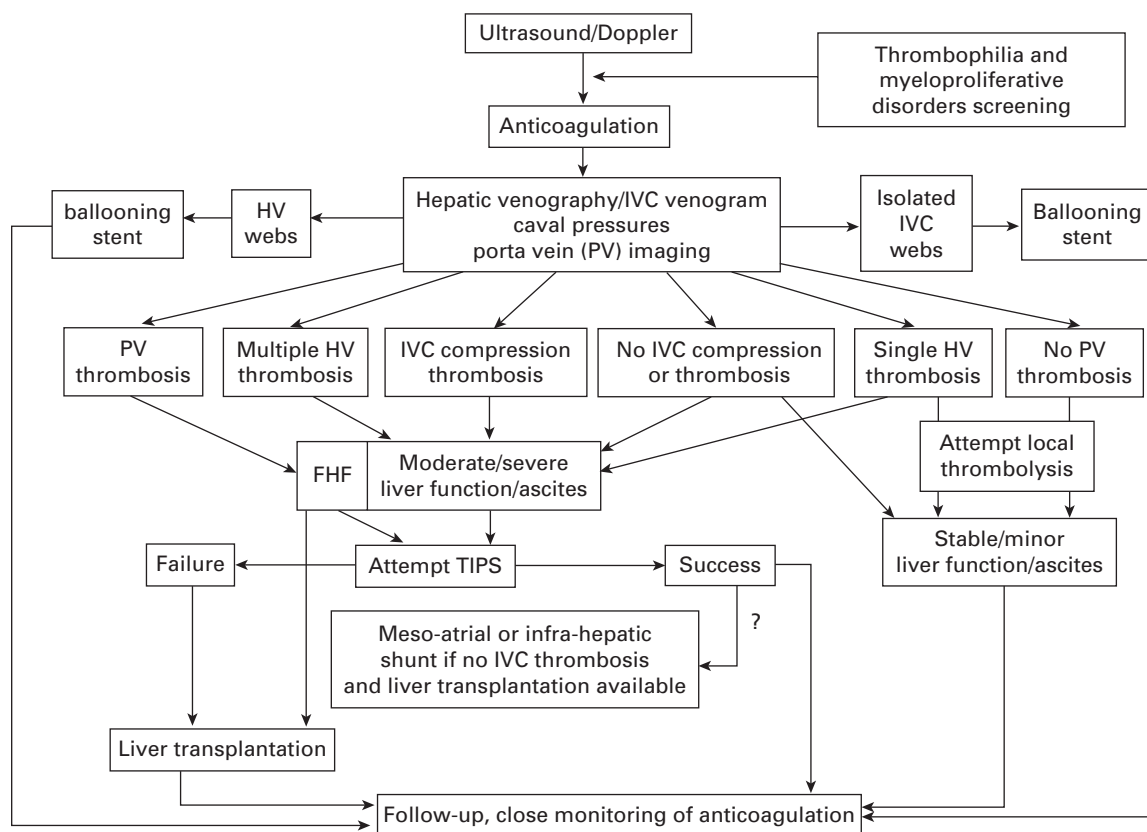

malignant transformation is anecdotal [54, 58]. A suggested algorithm of treatment for BCS is shown in Figure 37.1.

### Portal and splanchnic vein thrombosis

Splanchnic thrombotic disease has a wide spectrum of presentation and a wide range of severity. The disorders can be challenging and sometimes overlapping; appropriate management hinges on accurate diagnosis and especially on the broad distinction between cirrhosis-associated thrombotic disease and non-cirrhotic splanchnic venous thrombosis. The complexity of these cases, especially with non-cirrhotic acute PVT or cavernoma, usually warrants a multidisciplinary approach with involvement of both hematology and GI/hepatology, as well as other support services. Below, we have focused on portal vein thrombosis (PVT) and isolated splenic vein thrombosis (SVT), with emphasis on adult disease from a practical clinical perspective. Several recent reviews also offer excellent and comprehensive examination of the disorder [61–63].

#### Portal vein thrombosis (PVT): epidemiology

The exact annual incidence of PVT is not known although it is a common condition in most tertiary care centers. The difficulty in determining clear epidemiology of PVT results in part from its highly variable associations. In an autopsy series, PVT was discovered in 254 of 23,796 autopsies (1%) performed over a 12-year period from Uppsala Sweden [64]. Among those with PVT, 28% had cirrhosis (one-third with and two-thirds without hepatocellular cancer), 23% had primary hepatobiliary cancer (two-thirds hepatocellular cancer and one-third biliary), 44% had metastatic cancer, 10% had intra-abdominal infection or inflammatory conditions, 3% had myeloproliferative disease and 14% were without an apparent association. As discussed below, up to 20% of patients with cirrhosis develop portal thrombosis, which probably constitutes the single most common association encountered in liver centers. However, PVT in

**Figure 37.1** Flow chart in and management of Budd-Chiari syndrome.

cirrhosis is frequently discovered incidentally and, while it may result in liver atrophy and warrants a close examination for an associated hepatocellular cancer, it is a less urgent clinical situation than acute PVT in the non-cirrhotic patient in whom the presentation can be dramatic.

In all cases, additional diagnostic investigation is warranted and the risk-benefit of anticoagulation therapy needs to be carefully considered. However, as a result of the broad array of presentations and relatively low prevalence, controlled data treatment is limited and much of the literature, including two efforts at consensus or summary statements, are reflections more of experience and expert opinion than evidence-based on randomized trials [65, 66].

### Portal vein thrombosis: overview of clinical presentation and evaluation

The typical clinical presentation ranges from sudden onset of abdominal pain and ascites with acute PVT, to acute variceal hemorrhage in the setting of chronic PVT, to incidentally discovered cavernoma (cavernous transformation of the portal vein) found, for example, during an evaluation of low platelets due to hypersplenism and splenome-

galy. These clinical situations can present the clinician with diagnostic and therapeutic problems which need to be systematically worked through. For example, the presence of splenomegaly may be both part of PVT secondary to the thrombus and localized portal hypertension and also part of an underlying myeloproliferative disorder. Ascites can be seen even in patients without cirrhosis and its evaluation can be confusing (see below).

These studies, especially CT and MR, may also help to establish whether the thrombus is recent (absence of collateralisation) or chronic (presence of cavernous transformation.) Long standing portal vein thrombosis may result in irregularity of the liver outline, probably due to asymmetry of blood flow, resulting in the radiological appearance of cirrhosis-in these instances a biopsy is required, as the prognosis will be significantly altered by the histology.

The clinician then needs to exclude the presence of varices by endoscopy which then helps to weigh the risk-benefit of anticoagulation therapy. Laboratory tests should be performed to evaluate for hypercoagulable conditions and the history must be carefully explored to evaluate for any evidence of prior liver abnormalities, use of prothrombotic agents such as estrogen preparations, and prior

thrombotic disease, including family history and prior intra-abdominal inflammation. Detailed questioning is needed regarding any history of neonatal illness which would suggest possible umbilical vein cannulation, and any distant episodes of intra-abdominal illnesses which might suggest prior appendicitis or diverticulitis.

### Acute non-cirrhotic PVT

Acute, non-cirrhotic PVT is the least common cause of PVT but perhaps the most dramatic. Among 3655 liver disease patients recorded in a University of Virginia liver disease registry kept between approximately 1995 and 2004, 19 patients (0.5%) presented with this condition (unpublished observations). Although these patients have not yet been thoroughly evaluated about one-third of these had an underlying myeloproliferative disorder and another third had an identifiable pro-thrombotic condition. The most common presentation in our patients was abdominal pain and ascites, with intractable variceal bleeding in a minority. Similarly, Condat *et al.* observed significantly less gastrointestinal bleeding in acute PVT compared to cavernoma (see below) [67]. Bloody diarrhea may also be evident, especially if the thrombosis extends into the superior mesenteric vein distribution. Ascites can also be seen in one-third of patients with non-cirrhotic acute PVT [61]. Opening of portosystemic collaterals dissipates the portal hypertension and thus the ascites, although a transition to chylous ascites indicates rupture of the pressurized lymphatic vessels [68]. The ascites fluid characteristics may be difficult to interpret as the fluid (in non-chylous situations) derives from bowel edema rather than the typical liver-derived transudate as in cirrhosis [69].

Although 20–40% of patients have no identifiable underlying thrombophilic risk factors and there is a degree of regional variation, myeloproliferative disorders (polycythemia vera, essential thrombocythemia or myelofibrosis) are the most common identifiable causes of acute PVT, while specific factor abnormalities such as protein C, S or anti-thrombin III deficiency, factor V Leiden or prothrombin mutation, and anti-phospholipid abnormalities are associated risk-factor in the remaining cases [67, 70].

Myeloproliferative disorders underlie PVT more often than previously thought, and it is here that the test for the JAK2 mutation has been particularly eye-opening, as it has provided a non-invasive screening test for bone marrow disorders allowing one to select patients for the more invasive bone marrow biopsy [71]. This test probably should become a part of the routine laboratory evaluation of these patients but this remains to be determined. It should be considered if available.

Morbidity in acute PVT can be substantial, but prolonged survival in acute non-cirrhotic PVT is common. Consistent with our own experience, Janssen *et al.* reported ten-year

survival of 81% in this group provided that cirrhosis and underlying malignancy were excluded [72]. As discussed further below, long-term morbidity related to recurrent thrombi and/or transformation to cavernoma can be influenced by early anticoagulation, although controlled data is lacking, and the benefits must be weighed against the risk of severe portal hypertensive bleeding and other complications of anticoagulation.

### Portal cavernoma

This entity was first reported in 1869 by Balfour and Stewart to describe the post-thrombotic dilatation of the portal vein, which we now know to be commonly associated with prior and often unrecognized PVT. The term “cavernoma” was subsequently used by Köbrich in 1928 to describe the spongy appearance of the network of blood vessels in the portal vein location related to re-canalization of the thrombosis. Local infections (portal phlebitis, omphalitis), abdominal trauma and a history of prothrombotic disorders are implicated in the development of the PVT, but many cases remain unexplained. Cavernoma develops as the portal vein thrombus undergoes reorganization and remodeling into a network of collateral vessels which overcome the occlusion and restore, to a variable degree, hepatopedal blood flow. Cavernous transformation can occur rapidly even within 6–20 days and thus the presence of cavernoma, while usually suggesting chronicity, does not necessarily indicate a very distant event [73]. Hematemesis and splenomegaly are the most common presenting symptoms occurring in about 50% of these patients [74].

Portal biliopathy (biliary obstruction and stricturing) due to ischemia, duct compression by collateral vessels or possible local infection causes symptomatic disease in 4 to 24%, although abnormal cholestatic liver chemistries and cholangiographic abnormalities are much more common [75]. Treatment options include medical therapy with ursodeoxycholic acid, endoscopic therapy including biliary stenting, and in severe cases surgical or radiological shunting. In chronic cases, pre-operative decompression of the portal cavernoma is being explored to avoid life-threatening hemorrhage and other complications following surgical intervention [76]; decompression can be feasible by the placement of TIPS [77].

Strategies to avoid the complications of portal cavernomas have involved early anticoagulation, in cases with early diagnosis, to promote recanalization [67]. Long-term therapy is essential in those with an identified pre-thrombotic condition such as underlying protein C or S deficiency. However, intervention with anticoagulation requires careful exclusion and management of varices if present. It is also important to recall that portal cavernoma may be stable over many years, even without aggressive intervention, especially among patients presenting with

more indolent symptoms, which is also our experience. In such cases, we have typically used low-dose forms of anticoagulation provided varices have been excluded endoscopically.

### PVT in cirrhosis

Portal vein thrombosis (PVT) occurs in 10–20% of all cirrhotic patients, and conversely cirrhosis is responsible for about 20% of all cases of PVT [78]. Symptoms of acute abdominal pain, variceal bleeding, and ascites develop in 57% of cirrhotic patients with PVT [79]. Portal vein thrombosis in this setting can develop due to hepatic fibrosis and the resistance to blood flow (stasis), but there can also be many other factors, including a genetic predisposition to prothrombotic disorders, or abdominal infections, or local factors, for example pancreatitis [80]. Thrombosis can extend distally into right and left portal vein branches or proximally into the superior mesenteric vein (see Table 37.4). More often the thrombosis in the portal vein is incomplete and does not result in complete occlusion [81].

Complications of PVT in cirrhosis include splenomegaly, esophageal varices, gastric varices, and portal hypertensive gastropathy. PVT has traditionally been a contraindication to liver transplantation due to technical difficulties in intraoperative anastomoses. This situation has led to evaluation of a trial of anticoagulation in patients with cirrhosis and PVT [82]. However, monitoring anticoagulation in cirrhosis with an underlying coagulopathy is a challenge. Traditional measures such as INR (international normalized ratio) are of limited use because it is not only affected by oral anticoagulation medication, such as coumadin, but also factor deficiencies from hepatic dysfunction.

Low weight molecular heparins may be safer than oral anticoagulation in cirrhosis. Recently, repermeation was obtained in 50% of 38 patients with cirrhosis and portal vein thrombosis with only one episode of non-severe variceal bleeding [83].

Further study is clearly essential to determine the relative utility and the risk-benefit of this type of intervention. Surgical techniques involving thrombectomy and bypass

grafts also remain to be fully evaluated but should be used cautiously as these may be associated with high morbidity and mortality [84].

The use of transjugular intrahepatic portosystemic shunt is feasible in patients with portal vein thrombosis given the patency of intrahepatic portal branches, even in the presence of cavernous transformation and allows treatment of portal hypertensive complications when anticoagulation fails to prevent progression of thrombosis. Moreover TIPS allows the undertaking of thrombectomy in 50% of cases [85]. An integrated algorithm of treatment of portal vein thrombosis including easy anticoagulation and radiological treatments when progression of thrombosis or portal hypertensive complications occur could be the best option, but this needs to be prospectively explored. **B4**

### Portal vein thrombosis and hepatocellular cancer (HCC)

The incidence of PVT in patients with cirrhosis and hepatocellular carcinoma (HCC) has been found to be as high as 35% [86]. Indeed, the development of PVT in previously stable cirrhosis warrants a close evaluation for neoplasia. Hypercoagulability due to the underlying malignancy can explain the higher rate of PVT, but tumor invasion into the portal vein can also cause mechanical obstruction. Clinically, it can be difficult to discern between thrombosis or tumor invasion using current imaging modalities.

The concurrence of PVT and HCC imparts a severe prognosis. HCC without PVT has a median prognosis of 24 months, but when associated with PVT and possible portal vein tumor invasion, this drops to a dismal 2.7 months [87]. This striking difference may relate to tumor aggressiveness or possibly to limitations of therapeutic intervention. Several different techniques for HCC treatment are currently being used: percutaneous ethanol injection, radiofrequency ablation, transcatheter arterial chemoembolization, and glass radioactive microspheres. In the setting of PVT and compromised portal flow, extensive or multiple arterial embolization techniques can increase the risk of liver failure, but radioactive microspheres may offer the best risk-benefit ratio.

In experienced centers, super-selective, segmental drug delivery can avoid these complications but still has clinical limitations [88]. In addition, the diagnostic dilemma of thrombus versus tumor invasion, limited by current imaging techniques, usually precludes the possibility of liver transplantation. With tumor invasion into the portal vein, transplantation has limited success and is associated with rapid recurrence [89]. Together, these complex associations are indicative of the need for careful clinical investigation in patients suffering the triad of cirrhosis, HCC and PVT.

**Table 37.4** Grades of portal vein thrombosis (PVT).

Grade	Description
Grade 1 PVT	Thrombosis of intrahepatic portal vein branches
Grade 2 PVT	Thrombosis of right or left portal branches
Grade 3 PVT	Partial obstruction of portal vein trunk
Grade 4 PVT	Complete obstruction of portal vein trunk

Adapted from Nonami *et al.* [86].

### Isolated splenic vein thrombosis

Isolated splenic vein thrombosis presents most commonly with abdominal pain and UGI bleeding, frequently due to gastric varices, although there is regional variation in the major clinical manifestations and associated symptoms [70, 90]. Underlying malignancy (50%) and pancreatitis (15%) are the two most common predisposing factors although identifiable hypercoagulable states and myeloproliferative disorders can be present in a small minority (7%) in some series [70]. While intractable gastric variceal bleeding is the most serious complication, a natural history study from North Carolina indicates, surprisingly, that this occurs in only about 4% of SVT patients, in the setting of pancreatitis over a mean follow-up of 40 months [91].

From the perspective of gastric variceal bleeding, SVT is the cause in only about 10% of new onset GVB, with the majority being related to cirrhosis and portal hypertension without associated thrombotic disease [92]. Nonetheless, GV bleeding in the setting of SVT is challenging and associated with a high rate of recurrent bleeding following local therapy such as with cyanoacrylate injection. This may be due to the origin of GV in SVT from the short gastric veins rather than gastro-spleno-renal anastomoses as seen in cirrhosis. In our experience, most cases of such non-cirrhotic SVT complicate either local pancreatic or gastric cancer (50%), or chronic pancreatitis (50%) [92]. In the latter case, splenectomy, although lacking controlled data, is the optimal intervention [93]. **B4** In the former, palliative measures are more often appropriate.

Several unique circumstances can also be seen in this clinical scenario, such as pregnancy-related SVT [96]. Notably, bleeding due to pregnancy related splenic vein thrombosis can be treated with local injection of cyanoacrylate polymers as occurred in one case we have described [92]. Delivery was successful and post-partum endoscopic evaluation revealed no recurrence of the gastric varices.

### Anti-coagulation in portal vein thrombosis

Patients with a procoagulant disorder should be anticoagulated to prevent thrombus extension, or the development of de-novo thromboses. The concern is that patients with varices may bleed if anticoagulated. Yet the evidence suggests that the lethality of subsequent thrombosis is higher than that of bleeding [94]. Thus pragmatically, the approach should be: if pro-coagulant, and never bled, then anticoagulate. If pro-coagulant and previous variceal bleeding—then balance of risk may favour (brief) variceal obliteration and/or betablockers followed by anticoagulation.

The data on thrombolytic therapy in patients with acute portal vein thrombosis is peppered with anecdote and case

reports. Whilst outstanding results have been documented, catastrophic complications are also recognised (though usually less reported). A recent review suggested this should only be considered in those who are least likely to re-canalise with anticoagulant therapy—patients with ascites, acute splenic and portal vein thrombosis [95].

Current evidence favours early institution of heparin anticoagulation followed by warfarinisation whilst a search for precipitant factors occurs. Patients with an identified prothrombotic tendency, even in the presence of varices, should be anti-coagulated [97].

---

## Veno occlusive disease/sinusoidal obstruction syndrome

### Introduction

Hepatic veno-occlusive/sinusoidal obstruction syndrome (VOD/SOS) disease is a clinical syndrome characterized by hepatomegaly, ascites, weight gain and jaundice [98, 99]. It was first described in a patient who drank an infusion made with pyrrolizidine alkaloids.

Early histological abnormalities include sinusoidal congestion associated with centrilobular necrosis, and later fibrous obliterative lesions in the hepatic venules occur with histologic damage located to zone 3 of the acinus.

VOD is also associated with other toxins such as alcohol, oral contraceptives, toxic oil, terbinafine, or radiation injury. The first case associated with hematopoietic stem cell transplantation (SCT) was reported in 1979 [100]. Since then SCT has become the most important and frequent cause of VOD. In this setting diagnosis is made using the same clinical signs as for other etiologies. Other causes are infrequent but require exclusion. VOD after SCT is a part of the spectrum of multi organ syndromes which include idiopathic pneumonitis, diffuse alveolar hemorrhage, thrombotic microangiopathy and capillary leak syndrome.

The incidence of VOD after SCT ranges from 0 to 70%, dependent on the particular application of specific diagnostic criteria, the sample size and risk factors which are heterogeneous amongst different cohorts [101]. Currently, the incidence and severity of VOD after SCT is decreasing due to earlier timing of SCT in patients with leukemia, the use of non-myeloablative regimens and the decrease of HCV infection amongst transplant candidates [102]. However, the incidence of VOD remains high in patients undergoing aggressive chemotherapy regimens to eradicate cancer. New chemotherapeutic agents, in particular gemtuzumab and ozogamicin have been associated with a frequent occurrence of sinusoidal toxicity.

Veno-occlusive disease is also reported after other solid organ transplantation, particularly, kidney transplantation.

The largest series report an incidence of 2–5% (5/200 kidney transplants), mainly related to azathioprine toxicity. In liver transplant recipients the largest series reported an incidence of 1.9% (19/1023 liver transplants) clinical VOD, related to the number and severity of rejection episodes and azathioprine use. In contrast, reversible hepatic venule stenosis, including cases diagnosed histologically, is reported in 43% after liver transplantation and is mainly related to azathioprine [103].

Pathophysiology and histology

After SCT the high dose cytoreductive therapy used in patients who have a particular susceptibility, produces endothelial injury of both sinusoids and small hepatic venules (the latter only if the damage is more severe). Due to the inconspicuous presence of venular damage in patients with less severe VOD/SOS, and evidence from experimental models of the primary target being sinusoidal endothelial cells, the denomination of sinusoidal obstruction syndrome has been proposed to replace the term VOD.

The sinusoidal damage leads to activation of the coagulation cascade and clot formation. Fibrin-related plugs, intracellular fluid entrapment and cellular debris progressively occlude sinusoids, causing intrahepatic post-sinusoidal portal hypertension, responsible for the clinical signs of fluid retention (weight increase), hepatomegaly, ascites and jaundice. Usually fibrosis occurs several weeks after the onset of the disease. An early deposition of matrix metalloproteinases-2 has also been reported in the sinusoids. Several factors other than cytoreductive therapy contribute to the damage in VOD. Release of cytokines such as TNF-alfa, IL1 and 2 released due to the endothelial injury, but also due to cyclosporine given to patients with GVHD, have procoagulant activity. Immunological mechanisms have been implicated based on the observation of a lower incidence of VOD following T cell depleted and autologous SCT, and a higher incidence amongst mismatched transplants.

All these injuries cause depletion of glutathione from hepatocytes, resulting in increased sensitivity to zone 3 damage due to other compounds, which can further deplete this antioxidant compound, such as cyclophosphamide, busulfan and BCNU. In parallel with the decline in hepatic venous flow, nitric oxide (NO) levels in the hepatic vein decreases [104]. This change suggests that vasoconstriction related to NO depletion occurs, further incrementing the damage.

Clinical presentation and diagnosis

The classic presentation of VOD is characterized by the triad of weight gain caused by fluid retention, tender hepatomegaly and hyperbilirubinemia without any known cause [104, 105]. Usually this occurs within 10–20 days after

SCT when regimens containing cyclophosphamide have been used. With other regimens it occurs later on [106]. After liver transplantation VOD occurs over a wide interval, with a mean of nine weeks after transplant. Diagnosis is usually based on signs and symptoms, having ruled out other conditions which can mimic the disease, particularly after STC, such as viral infections and graft versus host disease, cholestatic secondary sepsis, heart failure and tumoral infiltration of the liver [107].

Nowadays, clinical criteria have been formalized in the Baltimore and Seattle criteria (see Table 37.5). The Baltimore criteria are more restrictive, and usually patients fulfilling these are diagnosed at a more severe stage of the disease [108].

Endothelial injury can be suspected even before the appearance of the clinical or other laboratory signs by finding elevated serum levels of PAI-1, procollagen III, and its precursor propeptide (P-III-P) [109]. Serum hyaluronic acid, vWF-cleaving protease ADAMTS13 and Ca-125 have also been evaluated as early markers of VOD.

Ultrasound of the liver and abdomen with Doppler examination is the first-line imaging investigation. Findings include the presence of ascites, hepatomegaly, attenuated hepatic veins and/or biliary dilatation. However, none of these signs are specific for the diagnosis and must be interpreted within the clinical context [110].

Pulsed Doppler ultrasound can suggest VOD on the basis of a decreased or reversed portal venous flow [111]. Significant elevation of the hepatic artery resistive index in duplex sonography may be a sensitive index of liver

Table 37.5 Diagnostic criteria of veno occlusive disease after SCT.

Seattle criteria
At least two of the three following criteria: within the first month after stem cell transplantation (SCT):
(1) Jaundice
(2) Hepatomegaly and right upper quadrant pain
(3) Ascites and/or unexplained weight gain
Baltimore criteria
Elevated total serum bilirubin (≥2 mg/dl) before day 21 after SCT and two of the following three criteria:
(1) Tender hepatomegaly
(2) Weight gain > 5% from baseline
(3) Ascites
Modified Seattle criteria
Occurrence of two of the following events within 20 days of SCT:
(1) Hyperbilirubinaemia (≥2 mg/dl)
(2) Hepatomegaly or right upper quadrant pain of liver origin
(3) Unexplained weight gain (> 2% of baseline bodyweight) because of fluid accumulation

damage related to VOD. In infants, a segmental portal flow reversal has also been shown to be strongly associated with early VOD [112].

### Hemodynamics and hepatic vein catheterization

The transjugular access is a safe route to perform measurement of the hepatic venous pressure gradient (HVPG) and liver biopsy [113]. The absence of a significant gradient ( $<6$  mmHg) along the hepatic veins and in the IVC can exclude anatomical causes of outflow obstruction. In one study 82% of patients with VOD had HVPG greater than 9 mmHg, but this was not found in those with GVHD. In another study an HVPG greater than 10 mmHg was significantly correlated with VOD (91% specificity and 86% positive predictive value) [114].

HVPG can be also helpful to determine prognosis, as patients who will survive with VOD have less severe portal hypertension. An HVPG greater than 20 mmHg is correlated with poor prognosis [98]. The transjugular access allows liver biopsy to be performed safely even if coagulation is impaired (without the need of blood product transfusion), which is often the case. Another advantage of TJLB is the possibility of performing multiple passes in different sites of the liver, which offers a theoretical advantage in diagnosing diseases with patchy distribution like VOD or hepatic venous obstruction syndromes [113].

### Prognosis and outcome

Bearman *et al.* have developed a model to estimate survival in patients with VOD based on a large cohort of SCT patients. Percentage of weight gained, bilirubin, ascites and peripheral edema were associated with worse survival. Severe VOD was associated with 98% mortality at day 100 after SCT (see Table 37.3). Moreover HVPG greater than 20 mmHg was confirmed as an independent prognostic marker of mortality [98].

Outcome of VOD after liver transplantation is reported by Sebahg *et al.* with 63% mortality (12 of 19 patients) in the largest series published. Because of the low incidence of this complication after LT, no specific prognostic factors have been evaluated, but clinical features derived from SCT groups could be used to assess severity of VOD after LT as well. Mortality after liver transplantation is related mainly to liver failure and development of renal insufficiency due to portal hypertensive complications [103].

### Therapy

#### Prevention

Treatment of VOD is primary supportive and spontaneous recovery is reported in 70–85% of mild forms after stem cell transplantation. However, as severe forms do not resolve

and given the paucity of effective therapies, prevention is a priority. The use of non-myeloablative regimens in patients with risk factors for VOD is now possible. Busulfan has been shown to be less hepatotoxic when administered intravenously rather than orally. The study of genetic polymorphisms of glutathione S transferase and TNF- $\alpha$  have been evaluated and allow identification of the patients at risk, but further studies are needed.

Prophylactic administration of ursodeoxycholic acid, being an antioxidant and antiapoptotic agent, has been evaluated in four randomized trials [115–118]. Two trials have shown a significant benefit of UDCA 600 mg daily in preventing VOD after SCT (VOD incidence 15% vs 40% and 3% vs 18.5%) [115, 117], but in the most recent two (one in combination with heparin) no benefit of UDCA administration per se or when added to heparin was seen. In the trial in which UDCA was given alone at the dose of 12 mg/kg daily, there was a decrease in overall mortality, with a decreased incidence of GVHD [116, 118].

Prostaglandin E1 is a vasodilator with protective properties for the endothelium and has antithrombotic activity. One non-randomized trial in which PGE1 was given in combination with heparin or heparin and tPA showed a lower incidence of VOD in the PGE1 group (12.2% vs 25.5%). However, the most recent prospective study, enrolling 24 patients using PGE1 alone, failed to show any advantage and was associated with severe toxicity in all [119].

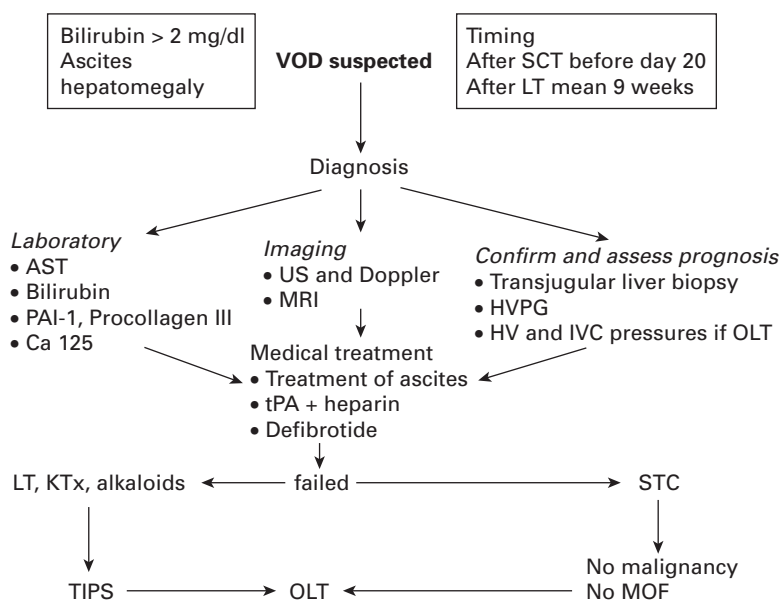

### Treatment

Treatment of the classical syndrome also includes supportive measure. Ascites is treated with sodium restriction, diuretics and paracentesis. Mechanical organ support may be needed when renal or respiratory failure develops. Correction of coagulopathy and prevention of infections in severe forms are often used to avoid bacterial translocation from the gut by intestinal disinfection.

Based on the histological presence of microthrombosis and fibrin deposition in the hepatic venules of patients with VOD, the principal specific therapy has been to promote fibrinolysis with or without anticoagulation [102]. To date, about 130 patients have been treated with tPA; the response rate is about 30% in the largest series, with the addition of concomitant heparin [120]. However, no response was seen amongst patients with MOF, renal or respiratory failure. Moreover, 24% developed severe bleeding. Thus, administration of antifibrinolytics and anticoagulants should be avoided in these patients, but conversely should be given early in the course of VOD. **B4**

Administration of ATIII and protein C or PGE1 have not been shown to be effective [121]. However, there is some evidence for the use of defibrotide. **B4** This is a polydeoxyribonucleic acid derived from porcine and bovine mucosa that has antifibrinolytic and antithrombotic properties; it also decreases leucocyte rolling and adherence to the

**Figure 37.2** Flow chart in diagnosis and management of veno-occlusive disease.

VOD: veno occlusive disease; SCT: stem cell transplantation; OLT: orthotopic liver transplantation; HVP: hepatic venous pressure gradient; HV: hepatic vein; IVC: inferior vena cava; KT: kidney transplantation; MOF: multi organ failure; TIPS: transjugular, intrahepatic, portosystemic shunt.

endothelium as well as decreasing thrombin generation and lowering circulating levels of PAI-1.

In the largest series published, treatment with 10–60 mg/kg/day infusion of defibrotide every six hours achieved a response rate of 36% and overall survival rate of 35% at 100 days after SCT, without adverse events [122].

The high mortality rate of VOD after liver transplantation leads to the need of specific therapy. In the only two patients treated with defibrotide for VOD after LT, only one survived [123]. No effective medical therapy has been reported.

Decompression of the engorged sinusoids by a transjugular, intrahepatic, portosystemic shunt can relieve portal hypertension and prevent renal failure in patients with VOD. The recent review on clinical practice guidelines for transjugular intrahepatic portosystemic shunt (TIPS) did not recommend TIPS for veno-occlusive disease (VOD). **B4** However, it was implied that VOD is only seen after SCT, whereas it can be seen in other settings, in which TIPS may offer a potentially useful treatment.

To date, 27 VOD patients treated with TIPS, have survived, 20% of the total. All but three (two with previous liver and one with previous kidney transplantation) had bone marrow transplantation [124, 125]. The most common causes of death usually occurring within one to three weeks following diagnosis were multi-organ failure (MOF), sepsis and hemorrhage, due to underlying hematological disease. The interval could influence the success of TIPS. If MOF is already present, patients are probably being treated too late. Earlier intervention may be worthwhile, but it needs formal assessment. Indeed, the causes of death in patients with VOD are usually renal and cardiopulmonary failure and sepsis, rather than liver

failure per se. In liver transplantation six patients with VOD have been treated with TIPS, one died, one was retransplanted, but information in these two patients about the course or the cause of liver failure or death were not reported. Thus, although TIPS is not recommended for patients with severe VOD, this may apply only to SCT patients in whom MOF conditions the prognosis. If a severe VOD is diagnosed in a liver transplanted patient and if medical therapy fails, a transjugular portosystemic shunt should be considered.

Liver transplantation has been reported anecdotically as a rescue therapy in patients with VOD after SCT not responding to medical therapy. Currently, 18 patients have been reported in the literature for transplantation due to VOD/SOS, with 13 deaths (72%), primarily due to infective complications [126]. The presence of malignancies and multiple organ failure (if VOD is advanced) contraindicates OLT. When VOD develops after liver transplantation itself, retransplantation can be performed as a rescue therapy as the liver is the only organ damaged. Previous placement of TIPS allows more time for the clinician to re-list the patients for OLT and it does not jeopardize subsequent OLT.

A flow-chart for the suggested diagnosis and management of VOD is shown in Figure 37.2.

### Introduction

Patients with cirrhosis frequently develop disturbances in body fluid regulation that result in an increase in the volume of extracellular fluid, which accumulates in the peritoneal cavity as ascites and in the interstitial tissue as edema [1]. Although the pathogenesis of ascites is incompletely understood, most available evidence indicates that fluid retention is the consequence of the homeostatic activation of vasoconstrictor and sodium-retaining systems triggered by marked arterial vasodilation mainly in the splanchnic vascular bed [2]. Marked abnormalities in the splanchnic microcirculation due to portal hypertension facilitate the accumulation of the retained fluid in the peritoneal cavity. Ascites is frequently complicated by abnormalities of renal function such as impaired ability to eliminate solute-free water and vasoconstriction of the renal circulation, which may lead to development of dilutional hyponatremia and hepatorenal syndrome respectively [1, 3]. Finally, coexistence of ascites and abnormalities in the host defense mechanisms against bacterial infection, which occur frequently in patients with advanced cirrhosis, accounts for the spontaneous infection of ascitic fluid, a condition known as spontaneous bacterial peritonitis [4, 5].

The aim of this chapter is to review, on the basis of available evidence, the efficacy of various therapeutic methods in the management of ascites, hepatorenal syndrome and spontaneous bacterial peritonitis in cirrhosis. The pathogenesis of these complications is briefly discussed to provide the reader with an understanding of the pathophysiological basis of the different therapeutic approaches. A comprehensive review of the pathophysiology of these disorders may be found elsewhere [1, 6].

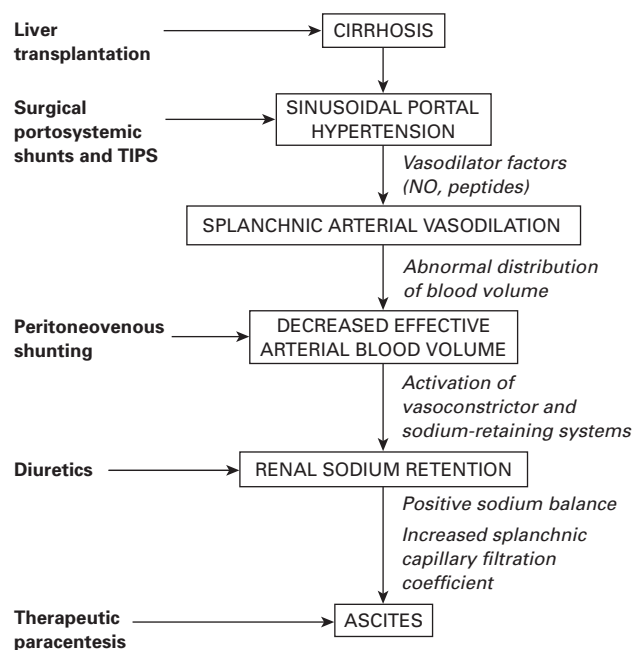

### Ascites

A large body of evidence indicates that in cirrhosis, sodium retention with subsequent ascites and edema formation, results from the action of neurohumoral factors on the kidney, which are activated during the homeostatic response to a disturbed systemic circulation (see Figure 38.1) [1, 2, 6, 7]. The initial abnormality is sinusoidal portal hypertension causing marked arterial vasodilation mainly in the splanchnic circulation. The mechanism of this vasodilation is not known, but may involve the increased synthesis/release of vasodilating substances, including nitric oxide and/or vasodilator peptides [2, 8]. Arterial vasodilation results in an abnormal distribution of blood volume, with reduced effective arterial blood volume (the blood volume in the heart, lungs and central arterial tree), sensed by the arterial receptors with subsequent renal sodium retention due to the activation of vasoconstrictor and sodium-retaining factors.

### Sodium restriction

In all diseases associated with generalized edema (cirrhosis, heart failure, renal failure), the amount of exogenous fluid retained depends on the balance between sodium intake and the renal excretion of sodium. Because sodium is retained iso-osmotically in the kidney, 1 liter of extracellular fluid is gained for every 130–140 mmol of sodium that is retained. If sodium excretion remains constant, the gain in extracellular fluid volume (and the consequent increase in weight) depends exclusively on sodium intake and increases proportionally to the amount of sodium in the diet. Nevertheless, because sodium excretion may be increased pharmacologically by the administration of diuretics, the sodium balance depends not only on sodium intake but also on the natriuretic response to the diuretics.

With this background, it seems reasonable that a reduction in sodium intake (low salt diet) will favor a negative

**Figure 38.1** Proposed pathogenesis of ascites formation in cirrhosis according to the arterial vasodilatation hypothesis and available therapeutic interventions (in bold).

TIPS: transjugular intrahepatic portosystemic shunt; NO: nitric oxide.

sodium balance and the elimination of ascites and edema. This was demonstrated in earlier studies and is supported by the common clinical observation that the management of ascites is more difficult in patients who do not comply with a low sodium diet [9, 10]. **C5 B4** Non-compliant patients usually require higher doses of diuretics to achieve resolution of ascites and are readmitted more frequently to hospital for recurrence of ascites. Surprisingly, however, an advantage of low sodium diet as compared with an unrestricted sodium diet in the management of ascites has not been demonstrated in randomized controlled trials [11–13]. **Ald** Nevertheless, it should be pointed out that in these studies most patients had mild sodium retention (urine sodium in the absence of diuretic therapy was close to sodium intake) and showed an excellent response to diuretic therapy (less than 5% of patients did not respond to diuretics).

Therefore, on the basis of available evidence, it can be concluded that in patients with mild sodium retention, restriction of dietary sodium is probably not necessary; the hypothetical benefit of low salt diet in the achievement of a negative sodium balance is overridden by the marked natriuretic effect of diuretics. In contrast, in patients with marked sodium retention, who usually have a less intense natriuretic response to diuretics compared with patients with moderate sodium retention, dietary sodium restriction (80 mmol of sodium per day) may facilitate the elimination of ascites and delay the reaccumulation of fluid. A

more severe restriction of sodium is not recommended because it is poorly accepted by patients and may impair their nutritional status. **C5**

### Therapeutic paracentesis

Therapeutic paracentesis has progressively replaced diuretics as the treatment of choice in the management of patients with cirrhosis and large volume ascites [14, 15]. This change in treatment strategy is based on the results of several randomized controlled trials comparing paracentesis (either removal of all ascitic fluid in a single tap or repeated taps of 4–6 liters/day) associated with plasma volume expansion versus diuretics [16–20]. **Ald** Because paracentesis does not affect renal sodium retention, patients should be given diuretics after paracentesis to avoid reaccumulation of fluid [21]. **Ald**

Two aspects concerning the use of therapeutic paracentesis in patients with cirrhosis and ascites deserve to be specifically discussed: (1) the population of patients with cirrhosis in whom therapeutic paracentesis should be used; and (2) the use of plasma expanders to prevent disturbances in circulatory function after paracentesis. While most physicians consider that therapeutic paracentesis is the treatment of choice for all patients with large volume ascites [14, 15], others believe that therapeutic paracentesis should be used only in those patients who show a poor or no response to diuretics [22]. Results of randomized trials indicate that therapeutic paracentesis is faster and in several trials was associated with lower incidence of adverse effects compared with diuretics (see Table 38.1) [16–20]. **Ald** Moreover, therapeutic paracentesis may have a better cost-effectiveness profile compared with diuretic treatment that can result in prolonged hospitalization. Therefore, on the basis of the available evidence, it seems clear that the use of therapeutic paracentesis should not be restricted to patients failing to respond to diuretics but should be considered the treatment of choice for all patients with large volume ascites (see Box 38.1).

The removal of large volumes of ascitic fluid is associated with circulatory dysfunction characterized by a reduction of effective blood volume [23–29]. Several lines of evidence indicate that this circulatory dysfunction and/or the mechanisms activated to maintain circulatory homeostasis have detrimental effects in cirrhotic patients. First, circulatory dysfunction is associated with rapid reaccumulation of ascites [29]. Second, approximately 20% of these patients develop hepatorenal syndrome and/or water retention leading to dilutional hyponatremia [23]. Third, portal pressure increases in patients developing circulatory dysfunction after paracentesis, probably owing to an increased intrahepatic resistance due to the action of vasoconstrictor systems on the hepatic vascular bed [27]. Finally,

<sup>a</sup>Differences in the rate of adverse effects among the studies may be due, at least in part, to differences in the populations of patients included.<sup>b</sup>Figures represent the number of patients developing the adverse effects compared with the total number of patients in each treatment group.**BOX 38.1** Recommendations for the management of patients with cirrhosis and large volume ascites [1]

- (1) Total paracentesis plus intravenous albumin<sup>a</sup> (8g/l of ascites removed). Patients can be treated as outpatients. Hospitalization is recommended for patients with associated complications (i.e. encephalopathy, bacterial infection, gastrointestinal bleeding).
- (2) After removal of ascitic fluid, start with moderate sodium restriction (80mmol/day) and diuretics, either aldosterone antagonists alone (i.e. spironolactone 50–400 mg/day) or in combination with loop diuretics (i.e. furosemide 20–100 mg/day). If patients were on diuretics before the development of large volume ascites, check compliance with sodium diet and diuretic therapy. Compliant patients should be given doses of diuretics higher than those given before paracentesis in order to prevent the recurrence of ascites. Non-compliant patients should be instructed to comply with therapy.
- (3) Consider liver transplantation.

<sup>a</sup>Although a survival benefit of albumin over other plasma expanders has not been demonstrated, albumin is more effective than other plasma expanders in the prevention of paracentesis-induced circulatory dysfunction when more than 5l of ascitic fluid are removed.

the development of circulatory dysfunction is associated with shortened survival [29].

The most studied effective method to prevent circulatory dysfunction is the administration of plasma expanders. A randomized trial has shown that albumin is more effective than other plasma expanders (dextran-70, polygeline) for the prevention of circulatory dysfunction as estimated by changes in plasma renin activity, probably owing to its persisting longer in the intravascular compartment [29]. **Alc** When less than five liters of ascites are removed, dextran-70, polygeline or saline show efficacy similar to that of albumin. However, albumin is more effective than these other plasma expanders when more than five liters of ascites are removed [29]. **Alc** Despite this greater efficacy, randomized trials have not shown differences in survival of patients treated with albumin compared with those treated with other plasma expanders [29–33]. Larger trials would be required to demonstrate a benefit of albumin on survival as well as on renal function. Table 38.2 shows the incidence of adverse effects observed in randomized trials comparing therapeutic paracentesis without plasma volume expansion or with three different plasma expanders in patients with cirrhosis and large ascites.

In summary, conclusive results from a randomized trial with adequate power to demonstrate a benefit of albumin

administration after therapeutic paracentesis on mortality are not available. However, the currently available data indicate that circulatory dysfunction after removal of large amounts of ascitic fluid is potentially harmful to patients with cirrhosis. Albumin appears to be the plasma expander of choice when more than five liters of ascites are removed.

## Diuretics

Diuretics eliminate the excess extracellular fluid presenting as ascites and edema by increasing renal sodium excretion, thus achieving a negative sodium balance. The diuretics most frequently used in patients with cirrhosis and ascites are aldosterone antagonists, mainly spironolactone and potassium canrenoate, drugs that selectively antagonize the sodium-retaining effects of aldosterone in the renal collecting tubules, and loop diuretics, especially furosemide, that inhibit the  $\text{Na}^+\text{-K}^+\text{-2Cl}^-$  co-transporter in the loop of Henle [34].

Despite the use of diuretics in clinical practice for more than 30 years, few randomized trials have been reported comparing the efficacy of different diuretic agents in the treatment of ascites [34–36]. In patients without renal failure, the aldosterone antagonist spironolactone at a dose of 150mg/day (increased to 300mg/day if there was no response) was shown in one randomized trial to be more effective than the loop diuretic furosemide at a dose of 80mg/day (increased to 160mg/day if there was no response) [35]. **A1d** This increased efficacy of aldosterone

antagonists has also been suggested in several studies [13, 37–40]. Based on these findings, aldosterone antagonists are considered the diuretics of choice in the management of cirrhotic ascites.

In clinical practice, aldosterone antagonists are frequently given in combination with loop diuretics. Theoretical advantages of this combination include greater natriuretic potency, earlier onset of diuresis, and reduced tendency to induce hyperkalemia. Two different regimens of diuretic administration have been proposed. In the first, the dose of aldosterone antagonists is increased progressively (usually up to 400mg/day of spironolactone) and loop diuretics (furosemide up to 160mg/day) are added only if no response is achieved with the highest dose of spironolactone. In the second, the two drugs are given in combination from the start of therapy. Both regimens are similar with respect to efficacy and incidence of complications. The only difference is that when the combination of spironolactone and furosemide is used from the beginning of therapy there is a more frequent need to reduce the dose of the drugs in responsive patients compared with the other stepwise regimen [41]. **Ald** Diuretic therapy is effective in the elimination of ascites in 80–90% of all patients, a percentage that may increase to 95% when only patients without renal failure are considered [13, 16–20, 35–40]. **Ald B4** The remaining patients either do not respond to diuretic therapy or develop diuretic-induced adverse effects that prevent the use of high doses of these drugs. This condition is known as refractory ascites [42]. These adverse effects

include hepatic encephalopathy, hyponatremia, renal impairment, potassium disturbances, gynecomastia and muscle cramps [34, 40–43]. The incidence of renal and electrolyte disorders and encephalopathy vary depending on the population of patients studied, and is higher in patients with marked sodium retention and renal failure (who require higher doses of diuretics) and lower in patients with moderate sodium retention and without renal failure. Although some of these complications may be unrelated to diuretic therapy and due to the existence of advanced liver disease [44], there is no doubt that diuretics are a major cause of these complications because their frequency is markedly lower if ascites is removed by therapeutic paracentesis (see Table 38.1). Spironolactone-induced gynecomastia is common and may be important enough to lead to the discontinuation of the drug in some patients. An alternative treatment for these patients is amiloride, although its potency is much lower than that of spironolactone [36]. **Ald** Eplerenone, a new aldosterone antagonist has fewer endocrine adverse effects compared with spironolactone and could be a good alternative to spironolactone in patients with spironolactone-induced gynecomastia [45]. However, its effectiveness in patients with cirrhosis and ascites has not been assessed. Finally, muscle cramps of variable intensity, sometimes severe, may also occur as an adverse effect of diuretics. Effective therapies for muscle cramps include quinidine (300 mg/day) [46], or albumin (25 g/week) [43]. Zinc sulfate (440 mg/day) also appeared effective in an uncontrolled study including a small number of patients [47]. **B4**

Because therapeutic paracentesis has replaced diuretics as the treatment of choice for hospitalized cirrhotic patients with large volume ascites in most centers, at present the main indications for use of diuretics in cirrhosis are as follows [15]:

- Treatment of patients with mild or moderate ascites or those with large volume ascites in whom paracentesis is not effective because of compartmentalization of ascitic fluid due to peritoneal adhesions.
- Treatment of patients with edema without ascites.
- Prevention of recurrence of ascites after therapeutic paracentesis.

### Peritoneovenous shunt

A peritoneovenous shunt is a device designed to transfer ascitic fluid from the abdominal cavity to the systemic circulation via an abdominal tube and a thoracic tube ending in the superior vena cava connected through a one-way valve. This device was used extensively in the 1970s and 1980s for the treatment of refractory ascites in cirrhosis. Although the system was pathophysiologically sound, its use declined progressively during the 1990s due to a high incidence of severe adverse effects, a high rate of obstruc-

tion, lack of demonstration of a significant survival benefit, and development of new procedures, such as the transjugular intrahepatic portosystemic shunt (TIPS) [48–54]. For all these reasons, this procedure is rarely used nowadays.

### Transjugular intrahepatic portosystemic shunt

TIPS was introduced in clinical practice in the 1990s for the management of refractory variceal bleeding, with the objective of creating a portosystemic shunt, without the need of surgery. The procedure consists of the placement of an intrahepatic stent between one hepatic vein and the portal vein using a transjugular approach [55]. It soon became evident that in patients with variceal bleeding and ascites treated with TIPS there was an increased natriuretic effect of diuretics, leading to the reduction or elimination of ascites in most patients. These beneficial effects of TIPS on ascites are similar to those reported in earlier studies in patients treated with surgical portosystemic shunts, especially side-to-side portacaval shunts.

A large number of uncontrolled studies have shown that TIPS is effective in preventing recurrence of ascites in patients with refractory ascites. This effect is due to reduction in the activity of sodium-retaining mechanisms and amelioration of renal function, which lead to an improvement of the renal response to diuretics [56–61]. **B4** The main disadvantages of TIPS include shunt stenosis or obstruction (up to 75% of patients develop stenosis within 6–12 months, leading to reaccumulation of ascites in most cases), but this has been reduced with covered stents. In addition, there is a high rate of encephalopathy due to the shunting of blood from the splanchnic to the systemic circulation [62, 63]. Other adverse effects include impairment in liver function, which is usually transient, hemolytic anemia and heart failure [55, 64]. Because of its efficacy and the paucity of good alternative therapies (except for that of repeated large-volume paracentesis with concomitant administration of intravenous albumin), TIPS became a widely used treatment for patients with refractory ascites during the 1990s despite the initial lack of randomized controlled trials comparing it with medical therapy.

Five randomized trials comparing uncovered TIPS versus repeated large volume paracentesis with concomitant intravenous albumin in patients with cirrhosis and refractory ascites have been published [65–69]. **A1c** The trials demonstrate that TIPS controls ascites effectively and is associated with a lower rate of ascites recurrence. The main results of these trials are summarized in Table 38.3. Although there are some discrepancies between the results of the trials these studies demonstrate the following:

- TIPS is clearly more effective than large volume paracentesis in the prevention of recurrence of ascites [65–69]. However, normalization of renal sodium homeostasis is

**Table 38.3** Complications and survival in randomized trials comparing transjugular intrahepatic portosystemic shunt (TIPS) and large volume paracentesis in patients with cirrhosis and refractory ascites.

<sup>a</sup>In all studies, except that of Rössle *et al.* [66] IV albumin (6–8 g/l ascites removed) was given routinely to all patients treated with paracentesis.

<sup>b</sup>Patients/total number of patients included.

NR: not reported; IV: intravenous.

not completely achieved and most patients treated with TIPS still require sodium restriction and diuretics during follow-up [67–68].

- TIPS reduces the risk of developing hepatorenal syndrome type 1 [67].
- TIPS is associated with an increased risk of severe hepatic encephalopathy and does not reduce significantly the risk of other complications of cirrhosis, such as gastrointestinal bleeding or spontaneous bacterial peritonitis [67, 68].

- There is a high rate of TIPS stenosis or obstruction that requires frequent intervention to maintain shunt patency [65–69].

- Hepatic encephalopathy after TIPS occurs in approximately 30–50% of patients [65–69].

- Despite better control of ascites and a reduction in the number of hospitalizations for ascites, TIPS does not appear to improve the quality of life compared with repeated large volume paracentesis with concomitant intravenous albumin [67, 68].

- The cost of TIPS is higher than that of conventional therapy with repeated large volume paracentesis and concomitant intravenous albumin [67].

- TIPS does not improve either overall or transplant-free survival compared with therapy with repeated large volume paracentesis with intravenous albumin [67, 68, 70].

A high quality meta-analyses of these randomized controlled studies concluded that TIPS is better at controlling ascites but does not improve survival compared with paracentesis [70]. **A1c** However, another recent meta-analysis that reviewed individual patient data of three trials indicates that TIPS significantly improves transplant-free survival of cirrhotic patients with refractory ascites [66, 68, 69, 71]. **A1c** Although meta-analysis using individual data seems a more reliable tool compared with standard meta-analysis, it cannot overcome deficiencies of individual studies, such as inclusion of patients who did not have refractory ascites in two of the studies [66, 69], use of large-volume paracentesis without albumin in one study [66], and use of TIPS as rescue therapy in a large proportion of patients treated with large-volume paracentesis in another study [69]. Until more information becomes available, the higher frequency of hepatic encephalopathy as well as the higher cost of TIPS compared with large-volume paracentesis plus albumin, in the context of a lack of survival benefit, leaves TIPS as a second-line therapy in the management of refractory ascites. The first line of treatment for refractory ascites is repeated large-volume paracentesis associated with albumin [14, 15]. TIPS placement may be an option for patients with preserved liver function (bilirubin < 3 mg/dl, serum sodium level > 130 mEq/l, Child-Pugh score < 12, model for end-stage liver disease (MELD) score < 18, aged < 70, without hepatic encephalopathy, central hepatocellular carcinoma, or cardiopulmonary disease.

The recommendations for the treatment of refractory ascites based on these conclusions are summarized in Box 38.2.

## Liver transplantation

Liver transplantation has become a frequent intervention for patients with advanced cirrhosis. Although randomized trials comparing liver transplantation with conventional

**BOX 38.2** Recommendations for the management of patients with cirrhosis and refractory ascites

- (1) Total paracentesis plus intravenous albumin (8 g/l of ascites removed). Repeat paracentesis during follow-up whenever needed. Patients can be treated as outpatients. Consider liver transplantation.
- (2) Patients should be on sodium restriction (80 mmol/day) and maximum tolerated doses of diuretics (up to spironolactone 400 mg/day and furosemide 160 mg/day). Check urine sodium under diuretic therapy. If urine sodium is greater than 30 mmol/day, diuretic therapy may be maintained because it may help to delay the recurrence of ascites. If urine sodium is lower than 30 mmol/day or diuretic treatment induces complications, diuretics should be withdrawn.
- (3) Consider the use of transjugular intrahepatic portosystemic shunt (TIPS) in patients with preserved liver function and with low acceptance of repeated total paracentesis or in those in whom paracentesis is not effective because of the presence of peritoneal adhesions.

medical therapy in patients with ascites are not available for obvious reasons, the 80% five-year probability of survival obtained in adult cirrhotic patients treated with liver transplantation in most centers is markedly greater than the expected 20% in non-transplanted patients with cirrhosis and ascites [72]. **B2**

Earlier recommendations suggested that ascites per se was not an indication for liver transplantation, and patients had to be considered for transplantation only when ascites was refractory to diuretic therapy or was associated with severe complications, such as spontaneous bacterial peritonitis or hepatorenal syndrome. However, with these guidelines a large proportion of these patients die while registered on the transplantation waiting list. This is because of the short survival associated with these conditions. The median survival time is less than one year for patients with refractory ascites and those recovering from spontaneous bacterial peritonitis, and is even shorter in patients with hepatorenal syndrome, particularly in those with the progressive form of this syndrome – type 1 – who have a median survival time of less than one month [50, 51, 73].

With the growing understanding of the natural history of ascites in cirrhosis, it is now known that a number of factors predictive of survival can be used to identify candidates for liver transplantation [74]. The most useful predictive factors are related to abnormalities in renal function and systemic hemodynamics and include:

- An impaired ability to excrete a water load (urine volume < 8 ml/min after a water load of 5% dextrose 20 ml/kg intravenous (IV)).

- Spontaneous dilutional hyponatremia (serum sodium < 130 mmol/l).
- Arterial hypotension (mean arterial pressure < 80 mmHg in the absence of diuretic therapy).
- Reduced glomerular filtration rate (even moderate reductions, as indicated by serum creatinine levels between 1.2 (106 μmol/l and 1.5 mg/dl (133 μmol/l) in the absence of diuretic therapy).
- Marked sodium retention (urine sodium < 10 mmol/day under a moderate sodium-restricted diet and in the absence of diuretic therapy).

Interestingly, in patients with ascites these parameters are better than liver function tests as predictors of prognosis [74]. Therefore, patients with one or more of these predictive factors have a poor survival expectancy and should be referred to transplant centers for evaluation. **B4**

The MELD score (Model for End-stage Liver Disease score, which includes serum bilirubin, international normalized ratio (INR) and serum creatinine) may be suitable for the evaluation of prognosis of patients with cirrhosis and ascites, as it includes a variable that estimates the degree of impairment of renal function [75]. In addition, many patients with advanced cirrhosis and refractory ascites may have low serum sodium (levels less than 130 mEq/l), which is an independent poor prognostic factor for outcome and survival. In fact both the MELD score and the serum sodium concentration are independent predictors of mortality. Thus, a new score incorporating MELD and serum sodium (MELD-NA) has been proposed, since serum sodium improves the prognostic accuracy of the MELD score in the prediction of survival in these patients [76, 77]. Nevertheless, the inclusion of serum sodium in a new score for survival prediction in cirrhosis has some limitations given that serum sodium is a very labile parameter. In addition, this new score needs to be validated in prospective studies.

## Hepatorenal syndrome

Hepatorenal syndrome is at the most severe end of the clinical spectrum of abnormalities of renal function in patients with cirrhosis and ascites [3, 6, 42, 78]. It may occur in two different clinical patterns [42, 78]. Type 1 hepatorenal syndrome is characterized by rapid and progressive impairment of renal function as defined by a 100% increase of the initial serum creatinine to a level greater than 2.5 mg/dl (221 μmol/l) or a 50% reduction of the initial 24-hour creatinine clearance to a level lower than 20 ml/min in less than two weeks; in some patients, this type of hepatorenal syndrome develops spontaneously without any identifiable precipitating factor, while in others it occurs in close chronological relationship with some complicating event, particularly in relation to bacte-

**BOX 38.3** Diagnostic criteria of hepatorenal syndrome

- (1) Cirrhosis with ascites.
- (2) Serum creatinine > 1.5 mg/dl (133  $\mu$ mol/l).
- (3) No improvement of serum creatinine (decrease to a level lower than 1.5 mg/dl–133  $\mu$ mol/l– after at least two days off diuretics and volume expansion with albumin (1 g/kg body weight up to a maximum of 100 g/day).
- (4) Absence of shock.
- (5) No current or recent treatment with nephrotoxic drugs.
- (6) Absence of signs of parenchymal renal disease, as suggested by proteinuria (>500 mg/day) or hematuria (<50 red blood cells per high power field), and/or abnormal renal ultrasound.

Adapted from Salerno *et al.* *Gut* 2007; **56**: 1310–1318.

rial infections such as spontaneous bacterial peritonitis [79].

Type 2 hepatorenal syndrome is characterized by a less severe and non-progressive reduction of glomerular filtration rate (at least in the short term); the main clinical consequence of this type of hepatorenal syndrome is refractory ascites.

Because of the lack of specific diagnostic tests, the diagnosis of hepatorenal syndrome is currently made according to several criteria, as proposed by the International Ascites Club, which are based on demonstration of a marked reduction in glomerular filtration rate (serum creatinine > 1.5 mg/dl in the absence of diuretic therapy) and the exclusion of other causes of renal failure that may occur in patients with cirrhosis (see Box 38.3) [42, 78].

For many years, no effective therapy existed for patients with hepatorenal syndrome, except for liver transplantation. Recently, several effective, new interventions have been introduced.

### Vasoconstrictors

A number of observational studies published in the 1990s showed that the administration of vasoconstrictor drugs to patients with cirrhosis and hepatorenal syndrome causes a marked improvement of renal function in a large proportion of patients [80–92]. **B4, C5** The rationale for the use of vasoconstrictors in patients with hepatorenal syndrome is to improve effective arterial blood volume by causing a vasoconstriction of the extremely dilated splanchnic vascular bed. The improvement in the arterial circulatory function leads to a suppression in the activity of vasoconstrictor systems and a subsequent increase in renal perfusion and glomerular filtration rate.

Two types of vasoconstrictor drugs have been used in patients with hepatorenal syndrome: vasopressin ana-

logues (terlipressin and ornipressin) and  $\alpha$ -adrenergic agonists (norepinephrine, noradrenaline and midodrine), which act on V1 vasopressin receptors and  $\alpha$ 1-adrenergic receptors, respectively, present in the smooth muscle cells of the vessel wall. The drug most frequently used in published studies is terlipressin, which is marketed in many countries for the indication of acute variceal bleeding in cirrhosis. In most studies terlipressin has been combined with intravenous albumin to further improve the arterial underfilling. Ornipressin is no longer available and there is limited information on the efficacy of  $\alpha$ -adrenergic agonists [89–92]. There are four randomized placebo controlled trials investigating the efficacy and safety of terlipressin and albumin in patients with hepatorenal syndrome [93–96]. **A1c** The information currently available on terlipressin can be summarized as follows:

(1) In uncontrolled trials, the administration of terlipressin improves renal function in 50–75% of patients [82–88]. Although there are no dose-efficacy studies, treatment is usually started with 1 mg/4–6 h IV, and the dose is increased up to a maximum of 2 mg/4–6 h after two days if there is no response to therapy as defined by a reduction of serum creatinine > 25% of pre-treatment values.

(2) Results from two large randomized placebo controlled studies indicate that treatment with terlipressin together with albumin is associated with marked improvement of renal function in approximately 40% of patients [93, 94].

**A1c** The overall population of patients treated with terlipressin and albumin in these two studies did not have an improved survival compared to that of patients treated with albumin alone. However, both studies showed that responders in terms of improvement of renal function after therapy had a significant (but moderate) increase in survival compared to non-responders [93, 94]. **A1c** A summary of the results of the four randomized studies are shown in Table 38.4 [93–96].

(3) In most studies, treatment with terlipressin is usually maintained until serum creatinine decreases below 1.5 mg/dl or for a maximum of 15 days. It is unknown whether the continued administration of the drug after the endpoint of 1.5 mg/dl of serum creatinine has been reached may cause a further improvement of renal function.

(4) The incidence of ischemic side effects requiring the discontinuation of treatment is approximately 10%. Some patients may develop myocardial ischemia, arrhythmia, intestinal ischemia or transient pulmonary edema during the first few days of therapy [82–88, 93–96]. Therefore, patients with HRS treated with terlipressin should be closely followed with cardiac monitoring, ideally in semi-intensive or intensive care unit, and if signs of cardiovascular disturbances develop, terlipressin should be discontinued promptly.

(5) A consistent finding in all studies is that the recurrence of hepatorenal syndrome after treatment withdrawal is

**Table 38.4** Response rate, survival, recurrence, and adverse effects in patients with cirrhosis and hepatorenal syndrome treated with terlipressin and albumin in randomized controlled trials.

uncommon (approximately 5–15% of patients) (Table 38.4). The explanation for this low recurrence rate is unknown. Treatment of recurrence is usually effective.

(6) The above observations refer mainly to type 1 hepatorenal syndrome, as the majority of patients included in the published studies were in this category. Although some reports suggest that vasoconstrictors also improve renal function in patients with type 2 hepatorenal syndrome, their efficacy in this setting remains to be confirmed [94].

### Transjugular intrahepatic portosystemic shunt

There is limited information on the effects of TIPS in patients with type 1 hepatorenal syndrome. Two uncontrolled studies reported that TIPS improves renal function in patients with this syndrome [97, 98]. **B4** Improvement in renal function after TIPS placement alone is slow and successful in approximately 60% of patients. Median survival after TIPS in patients with type 1 HRS ranges between

two and four months. Studies assessing TIPS for type 1 HRS have included patients with preserved liver function and excluded those with a history of hepatic encephalopathy, Child-Pugh scores  $\geq 12$  or serum bilirubin  $> 5$  mg/dl. The applicability of TIPS in patients with type 1 HRS is low because TIPS is considered contraindicated in patients with severe liver failure (high serum bilirubin levels and/or Child-Pugh score greater than 12) and hepatic encephalopathy, which are common findings in the setting of type 1 HRS. No studies have been reported that compared TIPS with vasoconstrictor drugs in patients with type 1 hepatorenal syndrome.

There have been no specific studies assessing the efficacy of TIPS in type 2 hepatorenal syndrome. However, in a subgroup analysis of patients with refractory ascites and type 2 hepatorenal syndrome included in one randomized trial, TIPS reduced the recurrence rate of ascites and the risk of progression from type 2 to type 1 hepatorenal syndrome, but did not improve survival compared to control patients treated with repeated therapeutic paracentesis with intravenous albumin [67]. **Ald**

### Other therapeutic methods

Hemodialysis or continuous hemodiafiltration are frequently used in the management of type 1 hepatorenal syndrome in many centers, particularly in patients who are candidates for liver transplantation, with the aim of preventing the complications associated with acute renal failure and maintaining patients alive until transplantation is done [99]. Complications during hemodialysis in these patients are common and include arterial hypotension, bleeding and infections. On the other hand, clinical or biochemical features indicating the need for renal replacement therapy, such as heart or respiratory failure, severe acidosis or severe hyperkalemia are uncommon, at least in early stages of type 1 hepatorenal syndrome. In contrast, these features are usually seen in patients with cirrhosis and acute renal failure caused by conditions other than hepatorenal syndrome, especially acute tubular necrosis due to septic or hemorrhagic shock and acute glomerulonephritis. Considering all these facts and the efficacy of measures aimed at improving circulatory function (especially vasoconstrictors), the use of hemodialysis or continuous hemodiafiltration in the management of patients with hepatorenal syndrome needs to be re-evaluated and perhaps used as a second-line therapy for those patients not responding to vasoconstrictors. Recently, a new method of dialysis, the extracorporeal albumin dialysis or molecular adsorbent recirculating system (MARS), a system that uses an albumin-containing dialysate that is used to remove albumin-bound and water-soluble toxic metabolites, has been reported to improve renal function and survival in a small uncontrolled study in patients with hepatorenal syndrome

[100]. **B4** These promising results, however, require confirmation.

### Liver transplantation

Liver transplantation is the only definitive treatment for patients with hepatorenal syndrome without contraindications to the procedure [101]. Even patients showing a complete response to vasoconstrictors or TIPS with normalization of serum creatinine have a poor prognosis if not transplanted [85, 86, 93, 94]. **B4 A1c** Main causes of death in these patients include liver failure and/or bacterial infections [85, 86]. Ideally, patients with hepatorenal syndrome should be prioritized for liver transplantation due to the high mortality rate; otherwise, most patients may die while awaiting liver transplantation. The implemented system of organ allocation in the USA based on the MELD score may be useful in this respect, because it includes serum creatinine in addition to parameters of liver function (bilirubin and INR) [75, 102]. Therefore, patients with hepatorenal syndrome usually achieve high values in the MELD score and may receive transplants within a short period of time. In addition to prioritization, these patients should probably be treated with vasoconstrictors, whenever possible, while awaiting transplantation in order to improve renal function and maintain life while they are on the waiting list. The reversal of HRS before transplantation may help patients not only reach transplantation, but also reduce the relatively high morbidity and mortality after liver transplantation characteristic of HRS [103, 104]. A small study indicates that patients with hepatorenal syndrome treated with vasopressin analogues before transplantation have a complication rate and short-term and long-term survival which are not different from those observed in transplant patients without hepatorenal syndrome [105].

### Dilutional hyponatremia

Patients with advanced cirrhosis often develop spontaneous dilutional hyponatremia due to impairment of the renal excretion of free water. This disorder always occurs in the setting of ascites with severe sodium retention, and most patients have poor or no response to diuretics [106]. In this condition, renal retention of solute-free water is disproportionate to that of sodium retained and serum sodium levels decrease despite the existence of increased total body sodium. Dilutional hyponatremia in cirrhosis is defined as a reduction in serum sodium concentration below 130 mEq/l in the setting of ascites and/or edema [106]. **C5** The impaired solute-free water excretion is due to high circulating levels of vasopressin (antidiuretic hormone) secondary to a hypersecretion of the hormone from the neurohypophysis triggered by a non-osmotic (vasoactive) stimulus [107, 108]. The clinical consequences of dilutional hyponatremia are incompletely understood,

but it has been linked to some neurological and non-neurological symptoms seen frequently in patients with advanced cirrhosis. Dilutional hyponatremia impairs the quality of life of patients with cirrhosis because it requires the restriction of fluid intake to a level similar to that of urine output in order to prevent a positive fluid balance that would lead to a further increase in total body water and impairment of hyponatremia.

There is no effective therapy currently available in clinical practice to treat spontaneous dilutional hyponatremia. Fluid restriction is effective in preventing further reduction of serum sodium concentration but usually is not followed by an increase in serum sodium. The administration of hypertonic saline solutions does not make much sense from a pathophysiological perspective, because total body sodium and extracellular fluid volume are increased in patients with dilutional hyponatremia. It invariably leads to marked increase in ascites and edema and has only modest effects on serum sodium concentration and therefore is not recommended. There are anecdotal reports of the efficacy of albumin infusions, but this remains to be proved in larger series [109]. **B4** In recent years, several orally active drugs, the so-called vaptans, that selectively antagonize the vasopressin V2 receptor (the receptor present in collecting duct cells in the kidney responsible for water reabsorption in the distal parts of the nephron), have been developed [108, 110]. **C5** The rationale behind the use of these drugs in patients with cirrhosis and dilutional hyponatremia is to selectively antagonize the effects of vasopressin in the kidney so that solute-free water excretion is increased, the abnormal water balance restored, the increased body water reduced, and serum sodium concentration normalized [108]. **C5** So far, the results of a few phase II and III studies in patients with cirrhosis have confirmed the beneficial effects of these drugs. Two multicenter, randomized, placebo-controlled trials evaluated the use of lixivaptan in cirrhotic patients with dilutional hyponatremia [111, 112]. **A1c** In these two studies this agent caused a dose-related increase in serum sodium levels and solute-free water clearance. Unfortunately, the drug caused significant dehydration in some patients at the effective doses in one study [111]. In the other study, which evaluated two doses of the drug versus placebo, a small amount of patients in each group was included and the effects of lixivaptan were only evaluated until serum sodium normalized, without information on long-term response [112]. A large multicenter randomized controlled study evaluating the use of tolvaptan in patients with euvolemic or hypervolemic hyponatremia (SIADH, congestive heart failure and cirrhosis) indicates that this agent is effective in raising serum sodium concentration when used for 30 days [113]. **A1c** In this study, a subgroup of patients with cirrhosis and dilutional hyponatremia were assigned tolvaptan or placebo in ascending doses according to response [113].

**A1c** There were no significant side effects compared to placebo. Tolvaptan rapidly improved serum sodium, fluid balance and caused significant weight loss in patients with cirrhosis and hyponatremia compared to placebo and markedly increased solute-free water clearance without adversely affecting renal function. In patients with cirrhosis and dilutional hyponatremia, normalization of sodium levels ( $>135$  mEq/l) occurred in 30% and 22% of subjects at days 4 and 30 respectively [113]. This agent therefore seems to be safe, effective and is likely to be promising in the treatment of dilutional hyponatremia. Another multicenter randomized study evaluated short-term use (14 days) of satavaptan at doses of 5 mg, 12.5 mg, 25 mg once daily in 110 patients with cirrhosis and hyponatremia receiving 100 mg of spironolactone [114]. **A1c** Satavaptan treatment was associated with improved control of ascites (measured by a reduction in body weight) and a reduction in abdominal girth. This beneficial effect on ascites was associated with improvements in serum sodium in all patients. A major side effect was thirst in the satavaptan group, and in a few patients a large volume diuresis of 5 liters or more in less than 24 hours. V2 receptor antagonists seem to not only improve ascites control, but also increase serum sodium in patients with cirrhosis, ascites and hyponatremia on diuretics.

Although a number of issues remain to be answered about the efficacy, clinical usefulness, tolerability, drug interactions and adverse effects of vaptans, they represent a powerful pharmacological tool for the management of patients with advanced cirrhosis and dilutional hyponatremia.

## Spontaneous bacterial peritonitis

Spontaneous bacterial peritonitis is a common and severe complication in cirrhotic patients with ascites characterized by infection of ascitic fluid with no apparent intra-abdominal source of infection [4, 5]. Spontaneous bacterial peritonitis is generally caused by Gram-negative bacteria from the intestinal flora, especially *Escherichia coli*. However, Gram-positive cocci, particularly *Staphylococcus aureus*, are being isolated with increasing frequency, mainly in hospitalized patients [115–117]. The diagnosis of spontaneous bacterial peritonitis is based on the demonstration of an absolute number of polymorphonuclear cells in ascitic fluid greater than  $250/\text{mm}^3$  [5]. **C5** The clinical spectrum is very variable and ranges from complete absence of symptoms to a classic clinical picture of peritonitis [4, 5, 118]. For this reason and because of its high prevalence, spontaneous bacterial peritonitis should be ruled out in patients with cirrhosis admitted to hospital with ascites, outpatients undergoing large volume paracentesis, and hospitalized patients who develop signs and/or symptoms suggestive

of peritoneal or systemic infection (i.e. abdominal pain, rebound tenderness, ileus, fever, leukocytosis, shock), hepatic encephalopathy or impairment in renal function [5, 118]. Cirrhotic patients with hydrothorax may also develop a spontaneous infection of pleural fluid that is pathogenically similar to spontaneous bacterial peritonitis and should be managed in a similar fashion [119].

## Therapy

Antibiotic therapy should be started whenever the polymorphonuclear count in ascitic fluid is greater than  $250/\text{mm}^3$  and before obtaining microbiological culture results [5]. **C5** Third-generation cephalosporins are the antibiotics of choice as initial empiric treatment for spontaneous bacterial peritonitis, because of their broad antibacterial spectrum, high efficacy and safety [5, 120–123]. **A1c** Resolution of infection occurs in up to 90% of patients. Cefotaxime (2 g/8–12 hours) has been the drug most commonly used in randomized trials, but other third-generation cephalosporins have similar efficacy [124]. **A1c** Cefotaxime has been shown to be more effective than other antibiotics, such as aztreonam or the combination of aminoglycosides plus ampicillin [120–125]. Amoxicillin-clavulanic acid is as effective as third-generation cephalosporins [126]. Quinolones (ofloxacin, ciprofloxacin) administered orally are also effective and may be an alternative to third-generation cephalosporins or amoxicillin-clavulanic acid except in patients who are severely ill (i.e. septic shock, severe renal failure) or with complications that may impair the absorption of the drug (gastrointestinal hemorrhage or ileus) [127]. **A1c** Given the increased frequency of Gram-positive cocci isolates in nosocomial spontaneous bacterial peritonitis, the empiric antibiotic treatment for this condition should probably include an antibiotic active against these bacteria, particularly *S. aureus*, until the results of ascitic fluid or blood cultures are available [115–117]. **C5** Antibiotic therapy is maintained until the complete disappearance of all signs of infection and decrease of polymorphonuclear count in ascitic fluid below the threshold value of  $250/\text{mm}^3$ . In most patients, resolution is achieved in a short period of time, usually less than six days.

The development of hepatorenal syndrome, which is one of the most common and severe complications of spontaneous bacterial peritonitis can be effectively prevented by the administration of albumin together with the antibiotic therapy [79, 128]. **B4** The incidence of hepatorenal syndrome is markedly lower in patients receiving albumin plus antibiotics compared with patients receiving antibiotics alone. The prevention of hepatorenal syndrome achieved by administration of albumin improves survival of these patients [128]. **B4** This may be particularly important for liver transplant candidates. The beneficial effect of albumin is probably related to its capacity to prevent the

**BOX 38.4** Recommendations for the management of spontaneous bacterial peritonitis

- (1) After diagnosis of peritonitis has been made ( $>250$  polymorphonuclear cells/ $\text{mm}^3$  in ascitic fluid), start with third-generation cephalosporins (i.e. cefotaxime 2 g/8–12 hourly intravenously or ceftriaxone 1 g/24 hours intravenously) or amoxicillin-clavulanic acid (500 mg/125 mg/8 hourly intravenously). In patients on antibiotic prophylaxis, third-generation cephalosporins are the treatment of choice. In nosocomial spontaneous bacterial peritonitis, consider the addition of an antibiotic active against Gram-positive cocci.
- (2) Give albumin 1.5 g/kg intravenously at the time of diagnosis of the infection and 1 g/kg 48 hours later.
- (3) Maintain antibiotic therapy until disappearance of signs of infection and reduction of polymorphonuclear cells in ascitic fluid below  $250/\text{mm}^3$ .
- (4) After resolution of infection, start long-term norfloxacin 400 mg/day per os (orally).

reduction in the effective arterial blood volume and subsequent activation of vasoconstrictor systems that occurs during the infection.

Recommendations for the management of spontaneous bacterial peritonitis are summarized in Box 38.4.

Hospital mortality in patients with spontaneous bacterial peritonitis was around 30% in most series published during the 1980s and 1990s. In the series that included patients treated with intravenous albumin, hospital mortality has decreased to 10–15% [128]. Advanced liver failure and associated complications (i.e. gastrointestinal hemorrhage, hepatorenal syndrome) are the main causes of death in these patients. As previously discussed, the most important predictor of survival in patients with spontaneous bacterial peritonitis is the development of hepatorenal syndrome during the infection [79, 128]. Long-term prognosis of patients who have recovered from an episode of spontaneous bacterial peritonitis is poor, and patients should be evaluated for liver transplantation. Recurrent spontaneous bacterial peritonitis is very common in these patients and constitutes a major cause of death [4].

### Prophylaxis

The identification of subsets of patients with an increased risk of developing spontaneous bacterial peritonitis has stimulated the search for interventions to prevent the development of this complication. Conditions associated with an increased risk of spontaneous bacterial peritonitis include: gastrointestinal bleeding, low protein concentration in ascitic fluid, advanced liver failure (high serum bilirubin and/or markedly prolonged prothrombin time), and past history of spontaneous bacterial peritonitis [4, 5]. Because

most episodes are caused by Gram-negative bacteria present in the normal intestinal flora, the rationale for the prophylaxis of spontaneous bacterial peritonitis has been based mainly on the administration of antibiotics that produce a selective decontamination of the gastrointestinal tract, with elimination of aerobic Gram-negative bacteria without affecting aerobic Gram-positive bacteria and anaerobes.

The efficacy of this approach has been demonstrated in patients with gastrointestinal hemorrhage and in patients who have recovered from the first spontaneous bacterial peritonitis episode (see Table 38.5) [129–136]. **A1c** In patients with gastrointestinal hemorrhage, the short-term administration of norfloxacin markedly reduces the incidence of spontaneous bacterial peritonitis or bacteremia as compared with patients not receiving prophylactic antibiotics [130]. In patients with advanced liver disease who are actively bleeding, intravenous ceftriaxone (1 g/day for seven days) is the preferred dose due to problems with oral absorption in this setting [133]. **A1c** Other effective approaches consist of the administration of parenteral antibiotics, such as ofloxacin or the combination of ciprofloxacin and amoxicillin-clavulanic acid [131, 132]. **B4** The absolute risk reduction in four trials of antibiotic prophylaxis in patients with gastrointestinal hemorrhage ranges from 9% to 23%. The results of a meta-analysis indicate that antibiotic prophylaxis in patients with gastrointestinal bleeding not only prevents infection but also improves survival [134, 135] **A1c**

Long-term norfloxacin administration is very effective in the prevention of spontaneous bacterial peritonitis recurrence (Table 38.5) [136]. This approach is effective and is recommended to prevent recurrence in patients who have recovered from an initial episode [5, 136]. **A1d** Antibiotic prophylaxis (norfloxacin, ciprofloxacin, or trimethoprim-sulfamethoxazole) also appears to be effective in the prevention of the first episode of spontaneous bacterial peritonitis (primary prophylaxis) in patients with low ascitic fluid protein ( $<10\text{--}15\text{ g/l}$ ), who have a high risk of developing spontaneous bacterial peritonitis (Table 38.5) [137–144]. **A1d** A recent randomized placebo controlled study showed that long-term treatment with norfloxacin (400 mg/day) in patients with advanced cirrhosis and ascites with low protein level ( $<15\text{ g/l}$ ) in the ascitic fluid was associated with a lower risk of development of hepatorenal syndrome compared to a control group of patients receiving placebo [144]. **A1c** Norfloxacin reduced the one-year probability of developing spontaneous bacterial peritonitis and hepatorenal syndrome, and significantly improved the three-month and the one-year survival compared with placebo [144]. **A1c** Additional randomized controlled trials involving larger numbers of patients with longer periods of follow-up are needed in order to determine the potential problems such as bacterial resistance and duration of therapy.

<sup>a</sup>Figures represent the number of patients developing spontaneous bacterial peritonitis during follow up compared with the total number of patients in each treatment group.

<sup>b</sup>Refers to antibiotic prophylaxis given to prevent the first episode of spontaneous bacterial peritonitis.

<sup>c</sup>Control group received norfloxacin 400mg/day po.

<sup>d</sup>The control group received norfloxacin only during hospitalizations, po, per os (orally).

## Acknowledgement

Some of studies reported in this chapter have been performed with the support of grants from the Fondo de Investigación Sanitaria- Ministerio de Ciencia e Innovación: Fondo de Instituto de Salud Carlos III, FIS08; PI080126.

Division of Gastroenterology and Hepatology, Medical University Vienna, Vienna, Austria

Because the pathogenesis of hepatic encephalopathy (HE) is unknown, no truly “specific” treatment exists [1]. Nevertheless, a variety of compounds have been introduced for treatment of HE (see Table 39.1). Some of these treatments are based on clinical observations, some on extrapolation of experimental data obtained in animal models of HE. Research on hepatic encephalopathy is hampered by the imprecise definition of this disabling complication of liver disease. In view of this, the Organisation Mondiale de Gastroentérologie (OMGE) commissioned a working party to reach a consensus in this area and to present it at the Eleventh World Congress of Gastroenterology in Vienna (1998). The working party continued its work thereafter and published their final report.

In summary, the working party has suggested a modification of current nomenclature for clinical diagnosis of hepatic encephalopathy (see Table 39.2), proposed guidelines for the performance of future clinical trials in hepatic encephalopathy, and felt the need for a large study to redefine neuropsychiatric abnormalities in liver disease, which would allow the diagnosis of minimal (= subclinical) encephalopathy to be made on firm statistical grounds [2]. These new definitions will be the basis to improve the design of clinical studies but cannot be applied to already published trials. Nevertheless, the new nomenclature was used in this analysis.

## Design of clinical trials in hepatic encephalopathy

A large spectrum of clinical conditions is summarized under the term “HE” and includes a variety of neuropsychi-

atric symptoms, ranging from minor, not readily discernible signs of altered brain function, overt psychiatric and/or neurological symptoms, to deep coma. Accordingly, the methods to quantify treatment effects and treatment endpoints are highly variable. Another variable is the treatment of control groups. Most studies compare a new drug to “standard treatment” (which by itself may be highly effective) such as oral lactulose, for which efficacy has not been demonstrated in a randomized placebo controlled trial for ethical reasons. However, in view of the natural history of HE, the inclusion of a placebo group in trials of new agents is highly desirable. In studies comparing a new drug with effective “standard treatment” demonstration of effectiveness of the new drug will require a very large sample size. Table 39.3 summarizes the appropriate study endpoints in various patient groups.

## Natural history of HE

The natural history of HE is not well studied. However, examination of the outcomes in the placebo treatment groups in nine randomized controlled trials (see Table 39.4) reveals that patients with grade III and IV HE may have recovery rates from 22% to greater than 90%. Therefore, in studies of new agents which lack controls, high response rates may be anticipated, and trials of new agents may require quite large numbers of patients to demonstrate benefits. In the short term mortality of patients with HE appears to be low if unstable patients are excluded. The course of patients with subclinical HE is unknown, and it is by definition impossible to detect clinical improvement in such cases. Studies of new agents with subclinical illness should focus on progression to more severe levels of HE. The grade of encephalopathy of patients selected for clinical trials may be expected to have a substantial influence on results.

## Methods to quantify

### Clinical assessment

The simplest assessment of HE is a description of the mental state, according to Conn [12], which grades HE in stages I–IV based on changes in consciousness, intellectual function and behavior. It does not include neurological changes or asterixis. The Glasgow Coma scale is useful in stages III and IV.

### The PSE (portal–systemic encephalopathy) index

In 1977 the "PSE index" was introduced in a trial comparing neomycin with lactulose and has been subsequently used by

**Table 39.2** Proposed nomenclature of hepatic encephalopathy [2].

HE type	Nomenclature	subcategory	subdivisions
A	Encephalopathy associated with acute liver failure		
B	Encephalopathy associated with portal-systemic bypass and no intrinsic hepatocellular disease.		
C	Encephalopathy associated with cirrhosis and portal hypertension/or portal-systemic shunts	Episodic hepatic encephalopathy	precipitated
			spontaneous <sup>a</sup>
		Persistent hepatic encephalopathy	recurrent mild
			severe treatment-dependent
		Minimal hepatic encephalopathy	

<sup>a</sup>Without recognized precipitating factors.

other investigators [13]. The main problem with this index is the inclusion of arterial ammonia estimations. Hyperammonemia is possibly a cause, but not a symptom or effect of HE. Measurements of arterial ammonia concentrations require serial arterial punctures. The scoring of actual arterial ammonia concentrations is arbitrary and not based on a sound statistical analysis. Furthermore, the other parameters of the PSE index – mental state, EEG and number connection tests (NCT) – are also graded by arbitrary units. No age-dependent normal values are used for NCT [14]. Finally, the PSE index does not discriminate between overt, mild or subclinical HE and has not been validated prospectively. In clinically overt HE the PSE index does not appear to be superior to simple clinical grading.

### Psychometric tests

Grading of HE does not allow the documentation of subtle changes. To quantify the impairment of mental function in mild stages of HE several psychometric tests have been evaluated [15, 16, 17]. Detailed psychometric testing is more sensitive in the detection of minor deficits of mental

**Table 39.3** Methods to assess treatment in various groups of patients with hepatic encephalopathy.

Study group	Treatment endpoint	Assessment of treatment effects	Natural history	Problems
Episodic HE, type C	Clinical improvement	Clinical grading, EEG, SEP	Well documented	High mortality, precipitating factors
Persistent HE, type C	Clinical improvement	Clinical grading, PSE index <sup>a</sup>	Well documented

<sup>a</sup>All patients were on neomycin.

HR, hepatorenal syndrome; RF, respiratory failure; MOF, multiorgan failure; BCAA, branched chain amino acids; MHE, minimal hepatic encephalopathy.

function than either conventional clinical assessment or the EEG [16]. However, the tests are cumbersome, and when applied repeatedly the reliability of most of them is adversely affected by the learning effect. Few are useful in routine practice. The most frequently applied test is the number connection test [14, 16]. This test is easily administered and the results can be quickly quantified. One important consequence of the application of psychometric tests in cirrhotic patients was the finding that even patients with apparently normal mental status have a measurable deficit in their intellectual performance [13]. These patients are usually referred to as suffering from “minimal HE” or

“stage 0 HE”. However, psychometric tests may overdiagnose minimal HE, because scores are usually not corrected for age [14, 18]. Furthermore, it is unknown whether abnormalities of test results correlate with impaired quality of life or performance in daily life [18]. On the contrary, the driving ability of patients with test results classifying them as “unable to drive a car” [15] was not different from that of healthy controls. A quality-of-life questionnaire (sickness impact profile (SIP)) detects the extent and frequency of deficits in daily functioning in patients without clinically apparent HE. From the 136 statements, five were selected as predictive of minimal HE [18].

A standardized prospectively developed test battery that includes the NCT A and B, the line tracing test, the serial dotting test and the digit symbol test was recommended by the working party to be used in future studies [2]. This test (PHES) can be applied at the bedside and performed within 10–20 minutes and examines visual perception, visuo-spatial orientation, visual construction, motor speed and accuracy, and is also sensitive against disturbances of concentration, attention and working memory. Each individual test and the whole battery has been standardized in a large group of healthy controls (including all ages). A composite score of the single test results was calculated. Each of the individual test results was scored 0 points in the  $\pm 1$  SD range from the mean. Thereby, subjects can achieve between +6 and –18 points. When a cutoff between normal and pathological results was set at –4 points, only 1 (0.9%) of the controls, 25% of cirrhotic patients without clinical evidence of HE, but all patients with grade I HE achieved pathological results. **B2** The test has a high specificity for HE as compared with other metabolic encephalopathies [19, 20].

### Electrophysiological tests

The simplest EEG assessment of HE is to grade the degree of abnormality of the conventional EEG trace. A more refined assessment by computer assisted techniques allows variables in the EEG such as the mean dominant EEG frequency and the power of a particular EEG rhythm to be quantified. Evoked responses (by visual, somatosensory, or acoustic stimuli) or event related responses, like the P300 peak after auditory stimuli, are sensitive to detect subtle changes of brain function and can be used for diagnosis of minimal HE [20].

### Critical flicker frequency

Retinal glial cells are involved in ammonia detoxification by glutamine synthesis. In patients with liver failure, they exhibit morphological changes similar to those observed in brain astrocytes, suggesting that retinal gliopathy could serve as a marker of cerebral gliopathy in patients with hepatic encephalopathy. These observations provided the rationale for the development of a visual test (the critical flicker/fusion frequency) for determining whether hepatic encephalopathy is present. Initial experience suggests that the critical flicker/fusion frequency may be a highly objective and sensitive measure of minimal hepatic encephalopathy [21, 22, 23].

### Diagnosis of minimal hepatic encephalopathy

One important consequence of the application of psychometric tests in patients with cirrhosis was the finding that even patients with apparently normal mental status have

some form of a measurable deficit in their intellectual performance, long-term memory, and learning capability [15, 24]. These patients are usually referred to as “minimal HE” or “stage 0 HE”. Up to 15% of patients with cirrhosis have minimal HE when defined by the presence of a prolonged NCT or an abnormal EEG [25]. Several approaches are being studied to evaluate for minimal hepatic encephalopathy. At present, none is used routinely in clinical practice.

One study comparing the Psychometric Hepatic Encephalopathy Score (PHES) with an EEG in 100 patients with cirrhosis found agreement in detection of MHE in only 73% [26]. The poor correlation may reflect differences in how these tests detect various features of MHE.

The Inhibitory Control Test (ICT) is a computerized test of attention and response inhibition that has been used to characterize attention deficit disorder, schizophrenia and traumatic brain injury. The subject is instructed only to respond to two alternating letters (X/Y) (called “targets”) and not to respond when they are not alternating (called “lures”). Lower lure responses, higher target responses, and shorter lure and target reaction times indicate good psychometric performance. A study comparing ICT to a psychometric battery of tests for MHE diagnosis in 136 patients estimated sensitivity for MHE to be 88% [27]. Patients with MHE had significantly higher ICT lures and lower targets compared to patients without MHE.

The PHES was compared with a comprehensive computerized assessment (Cognitive Drug Research [CDR]) of cognitive function in 89 patients with cirrhosis [28]. There was a high correlation between the two assessment methods. The MELD score correlated with PHES. In contrast, the CDR domains Continuity of Attention and Quality of Episodic Memory were significantly related to venous blood ammonia levels. There were marked deteriorations in the CDR composite scores representing Accuracy of Working and Episodic Memory after amino acid challenge to increase blood ammonia. Both PHES and CDRS returned to the control range after liver transplantation.

The Repeatable Battery for the Assessment of Neuropsychological Status (RBANS) measures a wide range of neurocognitive functions relevant to MHE. The test has been used in multiple clinical trials in the USA for a variety of neurologic disorders and in patients with advanced cirrhosis [29]. The RBANS has not yet been compared directly with the PHES, and its responsiveness to hepatic encephalopathy treatment is unknown.

A concern in patients with minimal hepatic encephalopathy is whether they are at increased risk for driving accidents. Studies evaluating this question have produced disparate conclusions. At least three reports concluded that 44–60% of patients with advanced liver disease (but without overt clinical signs of HE) were unfit to drive based upon the results of extensive batteries of neuropsychologic tests

[1, 21, 22]. In one study, for example, 40 patients with chronic liver disease and portal hypertension without clinical signs of portasystemic encephalopathy were given the same extensive psychometric tests typically used for expert reports on driving capacity [15]. Sixty percent of patients were considered to be unfit to drive, and 25% were considered to be questionable. The total driving score of patients with minimal hepatic encephalopathy was significantly reduced compared with controls or cirrhotic patients without minimal hepatic encephalopathy [30]. A later report found that patients with minimal hepatic encephalopathy had poor insight into their driving skills [31].

## Evidence-based medicine and hepatic encephalopathy

Evidence based medicine is a process of systematically finding, appraising, and using research findings as the basis for clinical decisions [32] based on the formulation of relevant questions concerning a patient's problem.

The answer to the question "Does treatment with specific drugs, compared to placebo, improve HE?" should be addressed separately for overt and subclinical HE. In the following sections we have identified the studies that attempt to answer this question and we have critically appraised the evidence for the most important treatment regimens. The magnitude of the treatment effect of various interventions has been assessed. This assessment is difficult in HE because of the use of different methods which are not readily comparable for quantifying the severity of this disease. The question of the clinical applicability and generalizability of the findings of randomized controlled studies in HE must be addressed in the context of the treatment and the grade of encephalopathy studied.

To identify all randomized controlled trials in HE, a Medline search was conducted using several terms. A total of 50 randomized trials had the endpoint "improvement of HE" and included more than ten patients per study group (see Table 39.5). In addition, two meta-analyses have been published [33, 34].

## Treatment of hepatic encephalopathy

### Clinically overt he (grade I–IV) in patients with cirrhosis

#### Supportive care and treatment of precipitating causes of HE

It is important to recognize that HE, acute and chronic, is reversible and that a precipitating cause rather than worsening of hepatocellular function can be identified in the majority of patients [1, 2]. These causes include gastrointes-

tinal bleeding, increased protein intake, hypokalemic alkalosis, infection, and constipation (all of which increase arterial ammonia levels), hypoxia, and the use of sedatives and tranquilizers. Patients with advanced cirrhosis may be particularly sensitive to benzodiazepines.

Treatment of these precipitating events is typically associated with a prompt and permanent improvement of HE. As a result, every attempt should be made to identify and to treat such precipitating events. This approach has never been tested formally but is based on common clinical experience. As judged from the outcomes observed in placebo groups of controlled studies (see Table 39.3) standard medical care is highly effective.

#### Enemas

Cleansing of the colon by enemas is a rapid and effective procedure to remove ammoniagenic substrates. The efficacy of enemas of 1–3 liters of 20% lactulose or lactitol solutions was proven in randomized controlled trials; a favorable response was noted in 78–86% of patients (ARR 0.4%, NNT = 2.5) [35, 36]. **A1d** Interestingly, enemas with tap water were ineffective, raising the possibility that colonic acidification rather than bowel cleansing was the effective therapeutic mechanism.

#### Nutrition

Patients with grade III–IV HE usually do not receive oral nutrition. In general, there is no need for parenteral nutrition if patients improve within two days.

Based on the "false neurotransmitter hypothesis", total parenteral nutrition with specific amino acid solutions has been proposed. A number of randomized controlled studies have evaluated the use of solutions with a high content of branched chain amino acids (BCAA) and a low content of aromatic amino acids (AAA). These studies differ with respect to the amino acid solutions used, the study protocols, patient selection and the duration of treatment, and are difficult to compare. The results have been conflicting, but most studies did not find any improvement in HE or any reduction in mortality in patients treated with BCAA [37, 38]. Although a meta-analysis revealed a significant trend toward improvement in these outcomes, it was concluded that further randomized controlled trials are needed [34]. At present, infusions of modified amino acid solutions should not be used in the standard treatment of patients with HE. **A1c**

There is no proven need for a specific diet for patients with HE. Although mentioned in all textbooks, the recommendation of a low protein diet in patients with advanced liver disease is not supported by good clinical or experimental evidence. On the contrary, in patients with alcoholic hepatitis, low protein intake is associated with worsening HE, while a higher protein intake correlates with improvement in HE [39]. The recommendations of the

**Table 39.5** Randomized trials with endpoint “improvement of HE”.

Test drug	Control				Total

<sup>a</sup>Usually includes lactulose or neomycin.

European Society of Parenteral and Enteral Nutrition (ESPEN) are that oral protein intake should not exceed 70 g/day in a patient with a history of HE; a level below 70 g/day is rarely necessary and minimum intake should not be lower than 40 g/day to avoid negative nitrogen balance [40]. **C5**

## Pharmacotherapy

### Flumazenil

Based upon the GABA-benzodiazepine hypothesis of the pathogenesis of HE, the benzodiazepine receptor antagonist flumazenil has been tested for treatment of HE in five randomized placebo controlled trials involving over 600 patients. Four were crossover trials, and one used a parallel group design. Flumazenil was superior to placebo in four of these studies (Table 39.5). In the only large double-blind, placebo controlled crossover trial 537 cirrhotic patients with grade III (265 patients) or IVa (262 patients) hepatic encephalopathy were randomized to receive intravenous flumazenil or a placebo over a 3–5 minute period [3]. Patients subsequently received the other study medication if they were still in grade III or IVa encephalopathy after the first study period. Treatment was begun within 15 minutes of randomization. Outcome measures included both a neurological score and a grading derived from con-

tinuous EEG recordings. Table 39.6 shows the results obtained by combining the scores from the initial and crossover period. Improvement of the neurological score was documented in 46 of grade III and in 39 of grade IVa patients during the combined flumazenil treatment periods and in 10 (Grade III) and 3 (Grade IVa) of the patients during placebo treatment periods. Improvement of the EEG score occurred in 73 (Grade III) and 57 (Grade IVa) patients during flumazenil treatment and 13 (Grade III) and 9 (Grade IVa) patients during placebo treatment. The effects of flumazenil were statistically significant ( $p < 0.01$ ).

**A1d** In the second study [41], 24 of 49 randomized patients were excluded from the final analysis, mainly due to inadequate benzodiazepine screening. However, flumazenil was superior to placebo even when the data were evaluated by intention-to-treat analysis; among the 25 patients who were not excluded, clinically relevant improvement was seen in 35% compared to 0% in patients given placebo.

**A1d** In the Canadian trial, very strict exclusion criteria resulted in the rejection of 56 of 77 potential patients [42]. Improvement in neurological symptoms was observed in 6 of 11 flumazenil treatment periods compared to 0 of 10 placebo periods; a few patients showed improvement in the EEG during both treatments. The beneficial effect of flumazenil was not related to the presence of identifiable benzodiazepines in the blood. **A1d** In the fourth positive study, drug effects were evaluated on continuous EEG recordings obtained before, during and ten minutes after a

bolus dose of the drug [43]. No patient improved on placebo; on flumazenil the EEG recording improved in 12 out of 18 cases (66%) and was associated with a short-lasting modest clinical improvement. **A1d** In the fifth study the response rate with flumazenil was greater than that observed with placebo, but the result was not statistically significant [44].

A meta-analysis of all published trials involving a total of 641 patients showed that flumazenil induces clinical and electroencephalographic improvement of HE in patients with cirrhosis [46]. Taken together, these studies suggest that some patients with severe HE will experience clinical improvement when flumazenil is added to standard treatment. **A1c**

## Antibiotics

Neomycin has been used as standard treatment of HE for almost 40 years. Surprisingly, there is no evidence that

neomycin is effective. The only randomized placebo controlled study found no benefit of neomycin compared to standard treatment alone [12]. Based on this negative study and the potential for serious adverse effects of this drug, neomycin should not be prescribed for this condition. **A1d** The combination of neomycin with lactulose was not superior to placebo [33]. **A1d** Other antibiotics including paromomycin, metronidazole, vancomycin [47] but there is no evidence supporting their efficacy but are better tolerated. Rifaximin was introduced for treatment of HE about 15 years ago [48, 49]. In a prospective randomized controlled trial two doses of rifaximin were compared for treatment of HE, but this prospective trial unfortunately did not include a control group. A dose of 1200 mg/d appeared to be most effective [50]. Rifaximin was then compared to lactitol in a prospective randomized, double-blind, double-dummy, controlled trial. The overall efficacy of both drugs in episodic HE type was similar (81.6 and 80.4% improved on rifaximin and lactitol, respectively) but rifaximin was

associated with a more profound decrease of serum ammonia levels [51]. In a metaanalysis rifaximin was at least equally effective as and in some studies superior to nonabsorbable disaccharides and antimicrobials in relieving signs or symptoms observed in patients with mild-to-moderately severe hepatic encephalopathy [52]. A recently published randomized controlled trial showed rifaximin 550 mg tablets significantly reduced the risk of overt hepatic encephalopathy (HE) recurrence over a six month period, maintaining remission more effectively than placebo [53]. Additionally in this study, treatment significantly reduced the risk of hospitalization for HE. Future clinical trials should focus on using standardized methods of evaluating mental status and limiting enrollment to patients with mild-to-moderate, episodic, persistent, or minimal hepatic encephalopathy. **A1c** Well-designed studies are needed to fully delineate the efficacy of rifaximin and other pharmacologic treatments for patients with hepatic encephalopathy.

## Disaccharides

Synthetic disaccharides (lactulose, lactitol, lactose in lactase deficiency) are currently the mainstay of therapy of HE. The dose of lactulose (45–90 g/day) should be titrated in every patient to achieve two to three soft stools with a pH below 6 per day. Lactitol has been evaluated in a number of clinical trials. It appears to be as effective as lactulose, is more palatable, and may have fewer adverse effects [33, 54]. **A1d** In patients with lactase deficiency, lactose has

most of the same effects as the synthetic disaccharides in the colon [55, 56].

The efficacy of these disaccharides is considered to be beyond doubt, although only one a properly conducted placebo controlled trial has been performed [12, 55]. Approximately 70–80% of patients with HE improve on lactulose treatment, a response rate comparable to that observed in patients treated with neomycin [10, 11]. Treatment is usually well tolerated, and the principal toxicity is abdominal cramping, diarrhea, and flatulence. Nevertheless, in view of the questionable efficacy of neomycin, the efficacy of oral lactulose or lactitol for treatment of clinically overt HE has to be questioned. The first placebo controlled trial (with a crossover design) involved just seven patients, of whom [57] only two had clinical symptoms. One patient improved on lactulose. This result is clearly not significant, and the trial lacked adequate power. The second trial reported only the outcome of 14 of the 26 randomized patients [58]. In another prospective trial 90 patients with cirrhosis and minimal hepatic encephalopathy (MHE) were randomly assigned in a 1:1 ratio to receive treatment (lactulose) for 3 months (n = 31) or no treatment (n = 30) in a non-blinded design. Psychometric performance by number and figure connection tests parts A and B, picture completion, and block design tests and HRQOL by the Sickness Impact Profile (SIP). The mean number of abnormal neuropsychological tests decreased significantly in patients in the treated group compared with patients in the untreated group (multivariate analysis of variance for time and treatment,  $P = 0.001$ ). The mean total SIP score improved among patients

**Table 39.7** Randomized controlled trials of lactulose for hepatic encephalopathy.

	N	design	Lactulose (g/day)	Control	standard Tx	Outcome measures	Baseline characteristics	result
Elkington [56]	7	crossover	67	sorbitol	40 g protein	NH <sub>3</sub> , PSE, EEG	not given, 2 pts. overt HE	no difference
Simmons [57]	26	RCT	60	glucose	40 g protein	HE grade	not given, all overt HE	? no difference, data of 12 pats not given
Dhiman [59]	26	RCT	30–60	—		N abnormal $\psi$ -tests	Only MHE control group worse	L better than control group, no difference to baseline!
Watanabe [60]	36	RCT	27	—	40 g protein	N abnormal $\psi$ -tests	Only MHE	?
Horsmans [61]	14	RCT	60	lactose	60 g protein	N abnormal $\psi$ -tests	Only MHE control group worse	L better than control group, no difference to baseline!
Sharma [72]	140	RCT	30–60			Recurrent HE	Pts-recovered from HE	L better than no Tx
Prasad [58]	90	RCT	90			N abnormal $\psi$ -tests	Only MHE	L better than no Tx

MHE: minimal HE;  $\psi$ -tests: psychometric tests.

in the treated group compared with patients in the untreated group. [59] The interpretation of the three new studies [60, 90, 91] performed within the last five years is difficult due to the definitions used to document the effect of therapy. A recent trial studied consecutive cirrhotic patients who recovered from HE. Patients were randomized to receive lactulose or placebo [61]. Of 300 patients with HE who recovered, 140 (46.6%) met the inclusion criteria and were included. Primary end point was development of overt HE. All patients were assessed by psychometry (number connection test A and B, figure connection test if illiterate, digit symbol test, and object assembly test), critical flicker frequency test, and blood ammonia level at inclusion. Twelve (19.6%) of 61 patients in the lactulose group and 30 (46.8%) of 64 in the placebo group ( $P < 0.001$ ) developed HE over a median follow-up of 14 months (range, 1–20 months). Readmission rate due to causes other than HE (lactulose vs placebo: 9 vs 6) and deaths (5 vs 11) in 2 groups were similar. This is the first RCT which proves that lactulose is more effective than placebo. In contrast to oral lactulose administration, the efficacy of lactulose or lactose enemas is beyond any doubt (see above).

### L-ornithine-L-aspartate

Ornithine and aspartate increase ammonia removal. In cirrhotics, ornithine aspartate infusions prevented hyperammonemia after an oral protein load in a dose-dependent fashion [62]. In a randomized, placebo-controlled trial of patients with HE, ornithine aspartate (20g/day given intravenously over four hours for seven days) improved fasting and postprandial blood ammonia levels compared to placebo treated patients [4]. There was also symptomatic improvement (assessed by psychometric tests and the PSE index) in patients with grade I or II HE, but no effect was observed in those with minimal HE. A smaller placebo-controlled study also found benefits of oral ornithine-aspartate (18g/day) with no adverse effects [63]. In a randomized controlled study from Mexico oral administration of lactulose or L-ornithine-L-aspartate to Mexican patients with cirrhosis and hyperammonemic encephalopathy significantly reduced serum ammonia levels in study groups and additionally improved mental status parameters, number connection test, asterix scores, and EEG activity in the group receiving L-ornithine-L-aspartate [64]. The results of this study are encouraging, and a confirmatory trial is needed. A recent meta-analysis came to the same conclusions [65]. **A1c** In patients with acute liver failure, L-ornithine-L-aspartate was ineffective [66].

### L-Carnitine

L-carnitine is a natural substance involved in regulating substrate flux and energy balance across cell membranes. Carnitine has beneficial effects in different pathologies and prevents acute ammonia toxicity [67–69]. Several mechanisms have been suggested to explain its efficacy on ammonia toxicity, most importantly the interaction with NMDA-receptors [70]. A recent randomized, placebo-controlled trial in 150 patients with minimal to mild HE showed that on a 90-d treatment with 2g L-carnitine/BID fasting serum ammonia levels decreased and psychometric tests improved with a significant difference to patients receiving placebo [71]. In a continuation of their studies a randomized, double-blind, placebo-controlled study administering Acetyl-L-carnitine (ALC) in 125 cirrhotic patients with MHE was conducted [72]. Patients in group A were treated with ALC and in group B with placebo for 90 days. Minimal hepatic encephalopathy was diagnosed with the Trail Making Test (TMT), Symbol Digit Modalities Test (SDMT) and Auditory Verbal Learning Test (AVL) and cognitive function with the Mini Mental State Examination (MMSE). After 90 days in group A treated with ALC, there were decreases in prothrombin time, bilirubin serum levels, AST, fasting, and psychometric tests improved. No significant differences were observed in EEG in either group of patients treated with ALC or placebo. The benefits of ALC in comparison with placebo are demonstrated in greater reductions in serum ammonia levels, as well as in improvements of neuropsychological functioning. A systematic review of the literature assessing the use of carnitine in the treatment of HE identified three high-quality human trials for review. Analysis of the selected carnitine trials compared to currently accepted therapies suggests that L-acyl-carnitine is promising as a safe and effective treatment for HE, and further trials of this drug are warranted [73]. **A1c**

### Benzoate

A different approach to elimination of ammonia is the use of benzoate. Benzoate reacts with glycine to form hippurate. For each mole of benzoate, one mole of waste nitrogen is excreted into the urine. In a prospective, randomized double-blind study of 74 patients with acute HE, sodium benzoate (5g bid) was compared with lactulose [74]. Treatment effects were evaluated using the PSE index, visual, auditory and somatosensory evoked potentials, and a battery of psychometric tests. The improvement in encephalopathy parameters and the incidence of adverse effects were similar in the two treatment groups. **A1d** In view of the unknown efficacy of lactulose, a confirmatory placebo controlled trial is needed.

## Acarbose

Theoretically, the inhibition of intestinal disaccharidases should induce malabsorption of disaccharides and increase delivery of undigested carbohydrates to the colon. Acarbose (AO-128, an inhibitor of alpha glycosidase that is approved for treatment of diabetes mellitus) inhibits alpha-glucosidases that convert carbohydrates into monosaccharides. It also promotes the proliferation of intestinal saccharolytic bacterial flora at the expense of proteolytic bacterial flora producing mercaptans, benzodiazepine-like substances and ammonia. Their reduction could improve HE. A double-blind, randomized, controlled trial was performed in 35 cirrhotic patients with PSE. Patients were given a two-week treatment consisting of AO-128 (2mg three times daily) or an identical placebo. Efficacy of treatment was assessed by the PSE index (PSEI) in weekly intervals. More patients receiving AO-128 than patients receiving placebo showed >40% improvement in the PSEI (83% vs 35%;  $p < 0.05$ ). The mean stool pH decreased from  $5.8 \pm 0.3$  to  $5.5 \pm 0.3$  ( $p < 0.004$ ) after AO-128 treatment, whereas no changes were observed in the placebo group. The EEG and nitrogen balance did not show changes in any of the two groups. An improvement was seen in the NCT performance after AO-128 (from grade 2.0+/-1.04 to grade 1.25+/-0.87;  $p < 0.05$ ). Seven patients treated with AO-128 developed diarrhea, as compared with none in the placebo group ( $p < 0.05$ ) [75]. To further test this hypothesis a randomized controlled crossover trial involving 107 cirrhotic patients with diabetes mellitus and grade 1 to 2 HE was performed [76]. Treatment was associated with a reduction in blood ammonia blood levels and improvement in HE. **A1d**

## Modification of colonic flora (probiotics and prebiotics)

Alteration of gut flora (either with probiotics or with prebiotics such as fermentable fiber) has been associated with improvement in HE in pilot studies [77–79]. Such therapy appears to lower blood ammonia concentrations possibly by favoring colonization with acid-resistant, non-urease producing bacteria associated with MHE in 50% of patients [78]. Treatment with fermentable fibres alone was also of benefit in a substantial proportion of patients. A small trial demonstrated a significant rate of MHE reversal and excellent adherence in cirrhotics after probiotic yogurt supplementation with potential for long-term adherence [80]. In an open label randomized controlled study in patients with MHE, probiotics and lactulose were equally effective to improve the test employed to measure MHE [81]. **A1d** In a further study in 125 patients with cirrhosis and HE were randomized either to a treatment with Bifidobacterium+fructo-oligosaccharides (FOS) or lactulose for 60 days.

Bifidobacterium+FOS-treated patients compared with lactulose-treated patients showed a significant improvement of psychometric tests and a decrease of fasting ammonia levels at end of the study (82).

## Molecular adsorbent recirculating system (MARS)

Extracorporeal albumin dialysis (ECAD) using molecular adsorbent recirculating system (MARS) may improve severe HE in patients with advanced cirrhosis via the removal of protein or non-protein-bound toxins. A prospective, randomized, controlled, multicenter trial of the efficacy, safety and tolerability of ECAD was conducted in such patients [83]. Patients were randomized to ECAD and standard medical therapy (SMT) or SMT alone. ECAD was provided daily for six hours for five days or until the patient had a two-grade improvement in HE. HE grades (West Haven criteria) were evaluated every 12 hours using a scoring algorithm. The primary endpoint was the difference in improvement proportion of HE between the two groups. A total of 70 subjects (median age, 53; 56% male; 56% HE grade III; 44% HE grade IV; median model for end-stage liver disease (MELD) 32 (11–50) and CPT 13 (10–15)) were enrolled in eight tertiary centers. Patients were randomized to ECAD + SMT ( $n = 39$ ) or SMT alone ( $n = 31$ ). Groups were matched in demographics and clinical variables. The improvement proportion of HE was higher in ECAD (mean, 34%; median, 30%) versus the SMT group (mean, 18.9%; median, 0%) ( $p = 0.044$ ) and was reached faster and more frequently than in the SMT group ( $p = 0.045$ ). Subjects receiving ECAD tolerated treatment well, with no unexpected adverse events. The conclusion was that the use of ECAD may be associated with an earlier and more frequent improvement of HE (grade III/IV). Because this five-day study was not designed to examine the impact of MARS on survival, a full assessment of the role of albumin dialysis awaits the results of additional controlled trials. The shortcomings of this trial do not allow us to recommend its general use [84].

## Persistent HE type C

Patients with HE that is refractory to standard therapy are rare. Most have surgical shunts or a large diameter transjugular intrahepatic portosystemic shunt (TIPS). Due to the small number of such patients, there are no controlled studies. Case reports on individual patients describe successful approaches by narrowing or closure of the shunt, protein restriction together with BCAA supplementation, supplementation of zinc and thiamin, and the use of bro-

mocriptin and oral flumazenil. The only controlled study was performed in 37 hospitalized patients with documented severe protein intolerance [85]. Addition of BCAA to the diet enabled the daily protein intake to be increased to up to 80 g without worsening of cerebral function. **B4** Many control patients who received casein as a protein source deteriorated after increasing dietary protein intake. No benefit of BCAA supplementation was observed in protein-tolerant patients.

In protein-intolerant patients vegetable proteins appear to be better tolerated than proteins derived from fish, milk or meat. In three controlled studies a vegetable diet was better tolerated than a diet which also included meat [86, 87]. **A1d** Other studies did not show these favorable effects [88]. **B4** The beneficial effects of a vegetable diet on the protein tolerance of patients with HE cannot be explained by the amino acid compositions of the proteins alone [89].

## Minimal HE

Although the number of patients with minimal HE is large, good clinical studies are rare. Even among experts, there is no agreement on how to define minimal HE or whether minimal HE even exists. Efficacy of treatment is judged by the improvement of psychometric tests or of electrophysiological measurements (see Table 39.6). The clinical relevance of these outcomes is uncertain. Substances that improved responses in psychometric tests in randomized trials include lactulose [59, 90, 91], modification of colonic flora to increase lactobacilli [79, 80], ornithin aspartate [5], and oral BCAA [92, 93].

## Prevention of HE

The occurrence of HE is a problem after TIPS insertion [94]. Although most clinicians administer prophylactic treatments after TIPS placement, the frequency of episodes of overt HE was about 10% per month. **B4** The manifestation of HE before TIPS and/or reduced liver function were identified as independent risk factors.

## Summary of recommended treatment of hepatic encephalopathy in clinical practice

### Treatment of episodic he type C

Treatment of episodic HE type C involves two steps. The first is to identify and to correct precipitating causes:

- gastrointestinal bleeding
- sedatives or tranquilizers
- infections

- hypovolemia, hypoxia, electrolyte imbalance, hypoglycemia

The second step is initiation of measures to lower blood ammonia concentrations using:

- lactulose enemas
- ornithine aspartate IV
- parenteral or enteral nutrition, if patient is unable to eat
- flumazenil if the patient has been given benzodiazepines

## Chronic therapy

Chronic management of the patient with recurrent episodic HE type C requires individual adjustment of treatment. The titration of protein tolerance after an episode of HE should permit the design of an individual diet for each patient. Limitation of protein intake is reasonable in some patients, but protein restriction should be avoided if possible, since it will lead to negative nitrogen balance. In protein-intolerant patients, vegetable proteins are better tolerated than proteins derived from fish, milk, or meat. The supplementation of a low protein diet with branched chain amino acids should be considered. Additionally, patients may benefit from zinc and thiamin supplementation. The long-term benefit of all other treatments (including lactulose and neomycin) is uncertain. The need for treatment of minimal HE is not established and unproven therapy should be administered in the context of randomized controlled clinical trials.

## Introduction

Hepatocellular carcinoma (HCC) is the fifth most common cancer worldwide and the third most common cause of cancer mortality, with an estimated worldwide prevalence of 632,000 cases [1]. Accounting for about 90% of all primary liver cancers, HCC is unique in that it develops in the background of well-recognized risk factors that are responsible for marked variations of the tumor prevalence and clinical presentation, worldwide. Sequential scrutiny of the cancer registries has demonstrated important variations in the temporal trends of HCC incidence, with some evidence for an increase in incidence in resource-rich countries [1]. In these regions molecular epidemiology investigations have predicted a further rise in HCC incidence and mortality rates in the next decades due to the accumulation of patients with chronic liver diseases who are expected to develop HCC.

## Early diagnosis

Early diagnosis of HCC is feasible through surveillance of patients at risk, who are readily identifiable. Surveillance is feasible since the test adopted, abdominal ultrasound (US), is user friendly and acceptable to the population, while it has high diagnostic accuracy. Moreover, the diagnostic tests and recall procedures have been standardized, while early cancer definition also incorporates suitability for potentially curative treatments [2, 3]. The term "very early tumor" has been recently defined to indicate a <2 cm nodule with an indistinct nodular pattern and a hypoattenuated vascular pattern on contrast imaging; this has a

better prognosis than same size nodules which have a distinct nodular pattern but are hypervascular on imaging and infiltrating at histology [4]. The disparity in outcomes between patients diagnosed with an early HCC compared to those with a more advanced tumor strongly supports screening for HCC.

## Population to be screened

Patients with cirrhosis and carriers of hepatitis B virus (HBV) and hepatitis C virus (HCV) are the target population for screening (see Table 40.1) [2, 3, 5, 6].

Cirrhosis is the leading cause of HCC worldwide, the risk of HCC increasing in parallel with disease severity. The annual rate of conversion of virus-related cirrhosis to liver cancer is approximately 3%, but with important regional variations (from 1.5–2% in Europe to 3–8% in Asia) [2]. HCC risk can further increase in the presence of co-factors known to accelerate progression of HCC like aflatoxin B<sub>1</sub> in HBV carriers, and alcohol consumption, iron and obesity in HCV carriers [5]. In many developed countries diabetes and non-alcoholic steato-hepatitis have emerged as important risk factors for cryptogenic cirrhosis and HCC in patients lacking HBV or HCV, while transition from cirrhosis to HCC is accelerated in livers expressing histopathological markers of increased cell proliferation or cell dysplasia, independently of etiology. Age cutoffs have been indicated for starting surveillance of African and Asian patients, since the risk of HCC increases in parallel with ageing, viremia and severity of the underlying liver disease [7]. It is still uncertain whether surveillance programs are improved by patients' stratification by clinical and histological scores. By combining sex, age and serum  $\alpha$ -fetoprotein (AFP) levels, patients with compensated cirrhosis can be stratified in categories at increasing risk for the tumor. The lowest risk group (1.5% rate per year) included women younger than 53 years of age with normal AFP levels compared to men older than 53 year of age with

**Table 40.1** Groups of patients for whom surveillance is recommended by the European (EASL), American (AASLD) and Japanese (JSH) Associations for the Study of the Liver.

Guidelines	Target population	
	Chronic hepatitis B or C	Cirrhosis
EASL 2001[3]	HBV: not specified HCV: histological	Child-Pugh A and B Child-Pugh C if liver transplant available
AASLD 2005 [2]	HBV, non cirrhotics: ALT + DNA + and specific age cut-offs for ethnic groups	All etiologies A <sub>1</sub> AT, AIH, NASH (?)
JSH 2008 [5]	Increased HCC risk: sex, age, alcohol	Very high risk: HBV/ HCV

high AFP levels who are at the highest risk (10%) for developing HCC [8]. In cirrhotic patients with mixed etiology, sex, age, disease severity and liver cell dysplasia identified a subset of patients with an exceedingly high (72%) risk of developing HCC during a follow-up of three years [9]. In Spain, similar criteria of disease severity (excluding cell dysplasia) led to the identification of cirrhotic patients at high risk (30.1%) and those at low risk (2.3%) of developing HCC during four years of surveillance [10]. Patients with severe co-morbidities and those with advanced liver disease (Child-Pugh C class patients), who do not have criteria for curative therapies, should not enter surveillance programs. Moreover, surveillance programs should be restricted to individuals >30 years and those <75 years of age, due to the low risk of cancer in younger people, while the older ones would not have significant benefit if diagnosed with a HCC. However, these criteria for selection are not evidence-based and may not be appropriate for all geographical areas. Importantly, patient stratification by risk level does not change selection of patients for surveillance, since the growth rate of tumors is the only variable which influences the outcome of screening. **B4**

Epidemiological, clinical and experimental studies have established a strong link between chronic infection with HBV virus and HCC. This virus agent, in fact, is responsible for both genotoxic lesions of the liver cells and tumor promotion through increased liver cell proliferation associated with persisting hepatitis. Importantly from a clinical point of view, HBV does not necessarily require the step to cirrhosis to be oncogenic [11]. In a prospective cohort study in Taiwan, the risk of HCC in 3454 HBsAg carriers was 102 times greater than in 19,253 non-carriers [12]. **B4** However, the carriers at especially high risk for developing HCC were those with actively replicating HBV (HBsAg<sup>+</sup>/HBV

DNA<sup>+</sup>) and those with cirrhosis, thus underlying the pathogenic relevance of virus persistence, liver inflammation and long duration of infection. The important role of virus replication in HCC has a solid basis: HBsAg seropositive carriers have six-fold greater risk of HCC (60.2 vs 9.6) than HBsAg negative carriers, after adjustment for age, sex, infection with hepatitis C, cigarette smoking and alcohol use [7]. In the HBsAg negative carriers, the risk of HCC is higher in patients with serum HBV-DNA >13 pg/ml than in those with undetectable (<2.5 pg) HBV-DNA [7]. In a prospective study of 3653 infected Chinese patients followed for more than ten years, a strict correlation was demonstrated between ≥10,000 copies/ml HBV-DNA at baseline and increased risk of HCC, again after adjusting for sex, age, cigarette smoking, alcohol consumption, HBsAg, ALT levels and cirrhosis at study entry. **B4** The study also provided evidence of reduced HCC risk in patients with spontaneous reduction of HBV-DNA levels during follow-up, though several concerns were raised on the methodology and conduct of the investigations [13]. In another prospective study in Taiwan, the risk of HCC correlated in an additive manner with HBV viremia and the genotype C of HBV, the latter being associated with higher levels of viremia [14]. **B4** In two studies in mainland China, an association was demonstrated between increased risk of HCC, viremia, cirrhosis, core promoter and precore mutations, and genotype C of HBV, all thought to reflect independent predictors of HCC that ultimately may interact to boost hepatocarcinogenesis [15, 16]. The potential pathogenic role of genotype C was also confirmed in Japanese patients with HCC [17]. In certain geographical areas, however, environmental factors play a more important co-carcinogenetic role in HCC than host or virus factors. In China and Africa, development of HCC in HBV carriers is strongly boosted by exposure to dietary aflatoxin, which cooperates with HBV in causing irreversible genetic damage to the infected liver cells [18, 19]. In Qidong, China, even modest levels of aflatoxin exposure tripled the risk of HCC in HBV infected men [20]. Aflatoxin does not seem to play any appreciable role in the West, but systematic investigations on this risk factor are lacking. Finally, the frequent report of family clusters of HCC has suggested the possible existence of increased susceptibility to the carcinogenetic effect of HBV in family members, after adjustment for relevant environmental risk factors for HCC [21]. The identification of the above predictors of HCC in HBV carriers has been instrumental in the definition of the epidemiological profile of the HBV population to be targeted by screening programs aimed at early diagnosis of HCC [2]. Healthy carriers may develop HCC, but are at substantially lower risk, and often distinguishing between clinical subsets of HBsAg carriers may be difficult unless the patients are periodically assessed with laboratory or histological investigations [22]. The strong link between HBV and HCC has

been further confirmed by the decrease of HCC that has been observed among Taiwanese children since the start of mass vaccination of all newborns against HBV [23]. The AASLD indicates surveillance for non-cirrhotic HBV-carriers with signs of liver inflammation, like elevated serum ALT values and  $>10^3$  HBV-DNA, following the demonstration of the pathogenetic importance of HBV replication in HCC.

Patients with porphyria cutanea tarda, genetic hemochromatosis,  $\alpha$ -1-antitrypsin deficiency, tyrosinemia and hypercitrullinemia are also at high risk for HCC. Patients with glycogenosis types I and III, Wilson's disease and hereditary fructose intolerance may also develop HCC, but are at substantially lower risk [24]. HCC has also developed in patients with autoimmune hepatitis and primary biliary cirrhosis, probably reflecting treatment-related improvement in patient survival. HCC was also found in 64% of 160 Japanese patients and in 48% of 101 South African black people with Budd-Chiari syndrome [25, 26]. However, in these studies the possible role of other unidentified carcinogens could not be excluded.

Screening tests

Ultrasound is the method of choice for screening, since it has adequate sensitivity, specificity, positive and negative predictive values [3]. Based upon studies of tumor volume doubling time, six months has been selected by most experts in the West as the ideal interval of screening with US, whereas in the Far East, the three-month interval for screening is largely adopted. In Italy, a study in hemophiliacs chronically infected with hepatitis C virus demonstrated similar efficacy of 6-month and 12-month intervals of screening in the identification of potentially curable HCC [27]. In France, a multicenter study in patients with compensated cirrhosis showed that increasing the frequency of US examinations every three months did not increase the accuracy of screening whereas it resulted in increased costs to treat patients with false-positive results [28].

The serum assay AFP is no longer considered for screening by AASLD and EASL due to the high rates of false positive and false negative results in patients with chronic liver disease. Whether other serum markers like des-gamma carboxy-prothrombin (DCP) and fucosylated AFP (AFP-L3) should be incorporated into surveillance for HCC, is debatable [2]. A DCP value of 150mAU/ml had a better positive predictive value for differentiating early HCC from cirrhosis than an AFP value of 13ng/ml (92% vs 54%) [29]. The AFP-L3 variant with high affinity to lens-culinaris, is more specific for HCC than total AFP too, but differences among studies in assay methods, cutoff values chosen as diagnostic for HCC, and case mix with respect

to early tumors, do not allow for a definitive evaluation of the accuracy of this marker [29].

The recall policy

An abnormal screening test needs to be confirmed by either a US-guided liver biopsy or imaging-studies [3]. In patients with cirrhosis and a liver nodule detected during screening/surveillance, HCC can be diagnosed by imaging techniques without the need for a histological examination (see Table 40.2) [30]. CT scan, MRI and contrast-enhanced US serve the purpose whenever arterial enhancement of the nodule is demonstrated and followed by wash-out of contrast in the delayed venous phase [31]. The accuracy of radiological diagnosis, however, is tumor size dependent: the diagnosis is attained in all nodules  $>2$ cm in diameter with one imaging technique only, whereas nodules between 5 and 20mm in size escape diagnosis in two-thirds of the cases despite application of two imaging techniques [30]. Liver nodules not accurately diagnosed by imaging will require histological examination with a liver biopsy or close monitoring with US carried out at three-month intervals (enhanced follow-up). The risk of seeding should be considered as a complication of biopsy: in 41 papers specifying the total number of patients biopsied, the median risk of seeding was 2.9% (range 0–11%) for biopsy group, being lower (0.61–1.4%) in therapeutic percutaneous procedures [32]. The radiological diagnosis of HCC is complicated by false positive results in the presence of artero-venous shunts and macroregenerative nodules with dysplastic liver cells. Currently, dysplastic macronodules can be discriminated from early tumors by morphological criteria based on exclusion of microscopic stromal invasion [33].

Table 40.2 Radiological diagnosis of hepatocellular carcinoma in patients with cirrhosis according to the guidelines of EASL and AASLD [2, 3, 29].

Imaging techniques	Contrast-enhanced US, contrast-enhanced spiral CT and gadolinium-enhanced MRI
1–2 cm nodule	Two imaging techniques showing hyperenhanced nodule in the arterial phase and hypoenhanced nodule in the portal phase (wash-out)
$>2$ cm nodule	one imaging technique
Prospective validation	89 patients with a 5–20 mm nodule
Sensitivity	33%
Specificity	100%
Pos Pred Value	100%
Neg Pred Value	42%

Immunostaining for GPC-3, and structural and functional analysis of the genetic profile of the nodules may also distinguish between macronodules and tumors [4, 34]. Falsely negative nodules at contrast imaging are also a problem when searching for very early tumors, accounting for approximately 20% of all 1–2 cm in size HCCs [33].

### Is liver-related mortality reduced by screening?

In the last decade, more than 50% of all patients in Japan have been diagnosed with a TNM I/II tumor compared to the 1980s, when only a minority of the patients with a HCC were diagnosed in the early stage [35]. In a national survey of 554 members of the AASLD, the vast majority of responders indicated that patients with cirrhosis were routinely screened using US [36].

A surveillance program of semi-annual determinations of AFP in HBV carriers in Alaska led to the identification of curable HCC in 40% of the affected patients, a fact that was perceived as beneficial since prior to AFP screening programs the case-fatality rate for HCC in Alaskan natives was 100%, with an average survival of three months [37].

**B4** A randomized controlled study conducted in Shanghai area using abdominal US and serum AFP every six months among individuals with chronic hepatitis and other risks for HCC, showed a reduction in the mortality rates in the screened versus unscreened population (83.2 vs 131.5 per 100,000 inhabitants) [38]. **A1d** The study, however, has limitations in the design and conduct, because the proportion of patients with cirrhosis is unknown, transplantation was not included among the radical therapies and the compliance of the population to the program was suboptimal (58%) (see Table 40.3). Notwithstanding all these limitations, the RCT in Shanghai confirms the importance of

early diagnosis for improving HCC-related mortality in the community.

In cirrhotic patients attending hospital facilities, the HCC-specific mortality rates were reduced in patients with HCC detected during surveillance, most likely due to improvements in both detection and treatment. In a re-analysis of 112 cirrhotic patients with HCC detected during a hospital-based surveillance program, the survival rates were improved in patients who were treated for a liver cancer which had developed during the previous five years of surveillance compared to previous intervals (90% vs 55%,  $p = 0.0009$ ) (see Table 40.4) [7]. **B3** Increased survival was attributed to a significant reduction in the mortality rates of treated patients (from 34% to 5%,  $p = 0.003$ ), due to wider application of curative treatments and improved selection of patients undergoing surgical or ablative treatments. In Taiwan between 1989 and 1998, there was a significant increase in survival among 3345 patients with a HCC during the previous five years (from 29% to 35%), that was only in part (34%) due to advancement in medical care, but mostly (66%) attributable to early detection [39]. **B4**

### Is surveillance in patients with cirrhosis cost-effective?

The economic consequences of HCC surveillance strategy are poorly appreciated, due to the lack of randomized trials evaluating moderators of treatment outcome, like compliance, heterogeneity and etiology of liver disease and treatment effectiveness that may impact on cost-effectiveness of surveillance. Patient compliance is an important variable of surveillance, as 1–15% of all patients failed to comply with clinic-based surveillance programs in Europe and

**Table 40.3** A population-based screening for HCC: the importance of early diagnosis for improving HCC-related mortality[38].

Findings	Screened group (pp x yr = 38,444)	Control group (pp x yr = 41,077)
HCC occurrence		
Cases	86	67
Early cancer	39	0
Total incidence (per 100,000)	223.7	163.1

Japan (reviewed by Thompson Coon 2007 *et al.*) [40], compared to the 42% of the population enrolled in a study in Shanghai [38]. Cost-effectiveness of screening is largely influenced also by the heterogeneity of the natural history of tumor disease, the annual risk of HCC ranging from 1% in HBV patients to 5–8% in some patients with compensated cirrhosis due to HCV [5]. Since the cost for tumor detected is inversely proportional to the tumor incidence, screening is considered worthwhile in populations with equal or greater than 1.5% incidence of HCC. In population-based screening programs with HCC incidence lower than 1.5%, the low cost-effectiveness of surveillance is counterbalanced by the high numbers of targeted individuals with a preserved liver function, who have more chances of receiving curative treatments compared to patients enrolled in clinic-based surveillance programs. Finally, since cost-effectiveness of surveillance largely depends upon the outcome of treatments, studies like the Shanghai program which lack access to liver transplantation, do not inform about cost-effectiveness of surveillance in the West, where liver transplantation is a first option for selected patients with cirrhosis and a small tumor. In the absence of randomized trials, decision analysis (Markov modeling) has provided the best means to estimate cost-effectiveness of HCC surveillance in this patient population. A cost-effectiveness ratio represents the cost for life-year saved compared to a cost-utility ratio, which describes the cost per quality-adjusted life-year (QALY) saved. Surveillance programs in which cost-utility ratios are measured at less than US\$ 50,000 × QALY are thought to be cost-effective (see Table 40.5) [41].

## Treatment of patients with cirrhosis and HCC

The success of HCC treatment largely depends on staging accuracy, that is, the clinical classification of disease severity aimed to establish prognosis and select the adequate treatment for the best candidates. The Barcelona Clinic Liver Center (BCLC) classification for HCC has been endorsed by EASL and AASLD as standard of care for patients with cirrhosis, since it links tumor stage with treatment strategies (see Table 40.6). The compelling evidence that surveillance improves treatment of HCC is due to its ability to improve detection of small, treatable tumors.

### Early HCC

Survival of patients with compensated cirrhosis and an early HCC reaches up to 70–75% at five years after resection, transplantation or percutaneous interstitial treatments in carefully selected candidates (see Tables 40.7, 40.8, 40.9). Patients with a very early tumor, that is, well differenti-

ated, less than 2cm in size with an ill-defined nodular pattern at US, show the best survival rates and the lowest recurrence rates after either resection or percutaneous ablation [51]. While percutaneous ablation of HCC with alcohol (PEI) or radiofrequency (RF) likely are equally effective for treating ≤2cm tumors, patients with 3–4cm tumors, who are at increased risk of local recurrence, benefit more from RF than from PEI [47–53]. **A1d** However, most studies comparing RF to PEI are underpowered, lack estimates of overall survival at five years and do not account for patients unfit for RF who could receive PEI only. Further, RF had greater reported mortality (0.5%) and complication rates (8.9%) than PEI. Overall, limited hepatic resection is superior to local ablative therapies in cirrhotic patients with 2–5cm HCC who have moderate portal hypertension (<10mmHg HVPG) [46]. The database of the Liver Cancer Study Group of Japan, including 8010 patients with compensated cirrhosis treated by resection and 4037 patients treated by PEI, all with a less than 5cm HCC, showed survival figures at five years of 58% vs 39% respectively [54]. Recently, acetic acid demonstrated a higher necrotizing power than ethanol and percutaneous acetic acid injec-

**Table 40.6** The Barcelona Clinic Liver Cancer (BCLC) staging classification for hepatocellular carcinoma.

Stage	Performance status	Tumor volume number and invasiveness	Child-Pugh	Expected survival
(A) Early <sup>a</sup>	0	Single <5 cm or 3 nodules <3 cm each	A and B	50–75% at 5 yr
(B) Intermediate	0	Large/multinodular	A and B	16 months
(C) Advanced	1–2	Vascular invasion and/or extrahepatic spread	A and B	6 months
(D) End stage	3–4	Any of the above	C	<3 months

<sup>a</sup>The early stage is further stratified in: (A1) performance status (PS) 0, single <5 cm, no portal hypertension (HTN) and normal bilirubin; (A2) PS 0, single <5 cm, portal HTN and normal bilirubin; (A3) PS 0, single <5 cm, portal HTN and elevated bilirubin; (A4) PS 0, up to 3 <3 cm Child-Pugh class A–B.

**Table 40.7** Outcomes of liver transplantation in cirrhotic patients with a single small tumor or less than three small tumors (Milan criteria).

HVPG: hepatic venous pressure gradient.

tion (PAI) seemed to have a better local control and improved survival rate than PEI in two randomized trials [55, 56]. However, two other studies found similar outcome of PEI vs PAI for treating small HCC [57, 58].

In principle, orthotopic liver transplantation is the treatment of choice for a patient with either a small HCC or patients with multiple nodules, as long as they are within the so-called Milan criteria (single nodule ≤5 cm or 3 nodules ≤3 cm without portal invasion) and have no contraindications for liver transplantation [42]. **B2** While liver

transplantation cures both the tumor and the underlying cirrhosis, it is limited by the paucity of donors, the risk of severe recurrence of HCV and the lack of validated adjuvant treatments to prevent the risk of HCC recurrence.

Indeed, both resection and ablation of HCC are almost invariably complicated by tumor recurrence, which may reach up to 75% at five years. Early recurrence refers to HCC occurring in the first two years after partial/total resection or local ablation as a consequence of pre-treatment spread of neoplastic cells, while late recurrence (>2 years) are *de novo* primary tumors developing in the cirrhotic liver [59]. In patients with cirrhosis and a <5 cm HCC treated with hepatic resection or local ablation early recurrence is predicted by non-anatomical resection of the tumor, microscopic vascular invasion by tumor cells and high pre-therapy levels of serum AFP. In these patients, late recurrence (>24 months) is predicted by the grade of hepatitis activity, number of tumor nodules and gross tumor classification [59]. Unfortunately, preoperative prediction of early recurrence is difficult due to sampling errors with needle-biopsy and the lack of universally accepted cutoff values of serum AFP for selecting patients to hepatic resection. Since the clinical heterogeneity of HCC is governed by heterogeneity of the molecular pathways, transcription analysis of HCC cells has been applied to the prognosis in patients undergoing hepatic resection.

**Table 40.9** Radiofrequency ablation and ethanol injection for the treatment of HCC 3–4 cm in size.

Author	Selection	Treatment	2-year local recurrence	3-year survival
Lencioni 2003 [47]	1 nodule ≤5 cm	PEI (n = 50)	38%	73%
	≤3 nodules ≤3 cm	RF ablation (n = 52)	<b>4%</b>	81%

		RF ablation (n = 70)		60%

<sup>a</sup> PAI: Percutaneous acetic acid injection.

At least three HCC subsets have been identified linked to chromosome stability/instability and progenitor cell-like molecular signature, the latter having a very high risk of recurrence and short survival after resection compared to patients with molecular signatures predictive of less invasive tumor phenotype [60, 61].

The effectiveness of adjuvant therapies in reducing HCC recurrence following resection or local ablation is not evidence-based [62]. In the transplantation setting, the adoption of stringent criteria for listing (Milan criteria) and prioritization of patients to liver transplant have resulted in a satisfactory balance between survival and recurrence rates. Because restricting priority to HCC candidates within Milan criteria (TNMI and II) only, may impose an unreasonable “punishment” on some patients with larger tumors who may benefit from liver transplantation, transplantation of patients with a tumor beyond Milan criteria has been attempted, but with uncertain cost-effectiveness ratio despite accurate preoperative selection with imaging. The recurrence rates in patients with a radiological preoperative tumor exceeding TNM I/II are invariably higher than those in patients within Milan criteria, whereas expanding listing to include patients exceeding Milan criteria with better tumor grading, is challenged by the high risk of sampling errors with preoperative liver biopsy [63, 64]. Major obstacles to new guidelines for expanding listing beyond Milan, are that the analysis of the explanted livers has invariably demonstrated tumor understaging by preoperative imaging, lack of intention-to-treat data on survival and limited (<20%) incremented number of patients beyond Milan criteria selected by expanded criteria. This,

together with the lack of studies comparing the outcome of liver transplantation in patients within Milan versus those beyond Milan, makes the issue of expanded criteria for transplantation still unsolved. A recent multicenter retrospective study enrolling 1112 patients transplanted with HCC exceeding Milan criteria, showed a five-year overall survival of 71.2% for those patients who fell within the up-to-seven criteria (HCC with seven as the sum of the size of the largest tumor and the number of tumors) without microvascular invasion [65]. Bridge treatments with chemoembolization (TACE) or RF are likely to reduce the risk of drop-outs from the waiting list due to tumor progression and the risk of post-transplant recurrence, as well. Cost-effectiveness analysis using a Markov model suggested a survival advantage for neoadjuvant bridge therapy, that is, between listing and grafting, in patients within Milan criteria with waiting times exceeding six months [66]. However, a meta-analysis of 12 studies provided no evidence for a benefit with bridge TACE [67], while treatment response to repeat TACE could be a selection criterion for transplant candidacy independently of tumor stage at presentation [68]. There are controversial results in published studies; however, in those centers where the waiting-list time is longer than six months, the RFTA is usually adopted to reduce the risk of HCC progression [69].

### Intermediate HCC

These patients have a heterogeneous clinical condition, ranging from multiple small tumors to a single >5 cm

nodule in size or a combination of nodules exceeding Milan criteria. The standard of care is arterial chemoembolization with doxorubicin, mitomycin or cisplatin as antitumoral drugs, which achieves partial responses in up to 50% of patients and significantly delays tumor progression. The best candidates are patients with better preserved liver function (Child-Pugh A) and small esophageal varices. In a meta-analysis of seven trials including a total of 516 patients, comparing embolization versus conservative management, survival benefits were obtained in two studies, the median survival for intermediate HCC cases treated with chemoembolization being 20 months as compared to the 16 months of the untreated patients (see Figure 40.1) [70–76]. **A1c** It is noteworthy that the two randomized studies showing greater survival for patients treated with chemoembolization versus untreated patients, enrolled patients with advanced stage of HCC, too. One major issue with this loco-regional treatment of HCC is the lack of standardization in the schedule of treatments, particles used for embolization, the selectivity of embolization and the antineoplastic drugs, as well as the lack of clear-cut criteria for patient selection [77]. Indeed RCT of chemoembolization (TACE) versus embolization alone (TAE) show no difference [77]. A preliminary study suggests that TACE with drug-eluting beads containing doxorubicin provides objective response rates of approximately 70%, with negligible systemic toxicity [78]. Internal radiation with  $^{131}\text{I}$ -labelled lipiodol or Y-90 is under investigation following promising results in patients with advanced HCC [79, 80]. An international study of adjuvant therapy with the multikinase inhibitor Sorafenib in patients with intermediate HCC treated with chemoembolization, is planned.

## Advanced HCC

After many years of unsuccessful clinical trials demonstrating a lack of efficacy for standard anticancer chemotherapy and hormones the multikinase inhibitor Sorafenib, blocking tumor cell proliferation and angiogenesis, was shown to possess anti-tumor activity in patients with advanced HCC [62, 81]. In a multicenter study in the USA, Europe and Oceania, Sorafenib at oral daily doses of 800mg, improved patients' survival from 7.9 months to 10.7 months, with a prolongation of the median time to progression to 5.5 months from 2.8 months of placebo-treated patients [82]. In a similar trial conducted in Asia-Pacific Sorafenib was superior to placebo in terms of both overall survival and time to progression [83]. **A1d** Efficacy and tolerability of treatment with Sorafenib are guaranteed in patients with well preserved hepatic function (Child-Pugh A), whereas limited data exists in patients with Child-Pugh B status. One major problem in the management of patients receiving targeted anti-cancer therapy with Sorafenib is that only a minority (3%) of the treated patients ultimately achieved a significant (partial) tumor shrinkage as defined by the Response Evaluation Criteria in Solid Tumors (RECIST) criteria, thus emphasizing the need for new response markers to direct therapy in clinical practice.

## End-stage HCC

These patients have a dismal course (less than three months' survival) requiring best supportive care only, including

**Figure 40.1** Chemoembolization in the treatment of intermediate HCC two-year survival vs conservative management.

analgesics, steroids and antibiotics when spontaneous bacterial peritonitis occurs.

## Treatment of patients with normal livers

Hepatic resection is the primary option for the few patients with an HCC which develops in normal livers with well-preserved function. In two case series, the cumulative five-year survival for 128 such patients in two centers treated with hepatic resection was approximately 45%, compared with 12–26% for the 51 treated with orthotopic liver transplantation [84, 85]. The good results with hepatic resection probably depended on the absence of cirrhosis, which allowed for extensive resection of the liver without affecting survival. The poor results with liver transplantation probably reflected bias in patient selection, for example transplantation may have been done in patients with advanced HCC who were judged to be unsuitable candidates for resection.

## Introduction

Intensive care medicine has developed as a specialty over the last 50 years since the introduction of positive pressure ventilation. Major growth in the size and scope of the specialty has occurred in the last few decades in response to the need to support failing organ systems in critically ill patients and many new techniques and methods have been introduced into routine practice. However, due to the relatively small numbers and heterogeneity of patients and conditions in single centers, the majority of methods used have been introduced without the evidence of benefit from controlled clinical trials.

The same problems have hindered the development of an evidence base for the management of fulminant liver failure and much of the current management of this condition has derived from current practice in general and neuro-intensive care. Recently, the development of collaborative groups in the USA and Europe has led to the performance of multicenter randomized trials specifically designed to address the major deficiencies in the current evidence base.

The management of fulminant hepatic failure can be split into two main headings: (1) general supportive care and (2) therapies aimed at managing the failing liver and its complications.

## Definition

In 1970 Trey and Davidson introduced the term fulminant hepatic failure (FHF) to describe a syndrome of rapidly progressing liver failure in which encephalopathy follows

the onset of symptoms within eight weeks in someone without previous liver disease [1]. This definition is still used today; however, it has become clear that this definition is too broad and that subgroups exist. Both etiology and speed of progression to encephalopathy from the onset of jaundice can be used to define subgroups. This is important, as both factors have been shown to be independent predictors of prognosis (Figure 41.1) [2]. Interestingly, it is the hyperacute group that have the best chance for spontaneous recovery, although it also carries the highest risk of cerebral edema [2, 3].

## Etiology

FHF has many causes, worldwide, viral hepatitis is by far the most common cause. Within the UK, paracetamol (acetaminophen) self-poisoning has been the most frequent cause of FHF over the last fifteen years. However, recent epidemiological data from the major UK liver units suggest that the incidence of paracetamol induced FHF is falling. In 1998 legislation was introduced in the UK limiting the amount of paracetamol that could be sold over the counter. This appears to have reduced the morbidity and mortality associated with paracetamol self-poisoning [4], more so the most serious paracetamol self-poisoning. However, this effect has not been noticed in all areas of the country and some studies have shown no effect of legislation on the incidence and outcome of paracetamol poisoning [5, 6].

The reduction in presentation following paracetamol hepatotoxicity in the UK is at odds with recent data from the USA. Once thought to be a rare cause of FHF in the USA, recent data show an increasing incidence of paracetamol hepatotoxicity, which now accounts for 42% of all cases of FHF prospectively reported to the US Acute Liver Failure Study Group [7]. Within this cohort the majority of cases were unintentional overdoses. In both the UK and the USA the second most common cause of FHF is seronegative or FHF of indeterminate cause [8]. Despite intensive

**Figure 41.1** Speed of onset according to etiology (note that the majority of paracetamol poisoning would appear in the hyperacute group [2]).

research in this area the etiology or etiologies in this group, as the name suggests, remain unknown.

### Pathogenesis

FHF is not a disease but a syndrome, with a severity proportional to the degree of hepatic necrosis and the degree of the systemic response to this injury. FHF causes profound physiological derangement, characterized by encephalopathy, vasoparesis [9], and coagulopathy. As the syndrome progresses, cerebral edema [10] and renal failure are prominent and there is impaired immunity, with increased susceptibility to infection and subsequent multiple organ failure [11].

The rate of progression of FHF can be unpredictable in the hyperacute group. The syndrome typically evolves over several days, but deep coma can occur within hours. The mainstay of treatment in FHF is supportive while the decision to proceed to hepatic transplantation is being considered.

The cause of death in FHF can be split into two main groups; those with cerebral edema who die of brain ischemia or brain stem herniation, and those who succumb to sepsis and multiple organ failure. In a recent study of FHF patients listed for transplantation the major cause of death was multiple organ failure, with only 5% of patients succumbing to death directly related to intracranial hypertension [12]. This is at variance with previous surveys of cause of death in ALF, which showed a much higher incidence of cerebral deaths [13]. The reasons for this change are not clear, but better general ICU care and specifically the use of osmotherapy are likely to have been responsible for this change.

**Figure 41.2** Improving survival in FHF.

### Intensive care management versus ward management

There have been no controlled clinical trials comparing intensive care with ward management, but considering the almost 100% mortality before the adoption of modern intensive care units, it seems likely that intensive care management reduces mortality [14]. Patients with grade III and IV encephalopathy should be intubated, ventilated and managed within an intensive care unit. The use of high-dependency areas for patients with liver failure and lower levels of coma is to be encouraged [15].

### Management in a liver unit

Survival rates for FHF have increased markedly since the introduction of liver transplantation as a therapeutic modality for patients predicted to have a low rate of survival with medical management alone. Survival rates for FHF with medical therapy alone in cases that progress to grade III or IV encephalopathy are poor, varying between 10 and 40% depending on etiology. With the introduction of orthotopic liver transplantation (OLT) as a therapeutic option for patients with FHF, survival rates have increased to 80% at one year [16], and although not subjected to a randomized controlled trial it stands to reason, therefore, that the optimal management of patients with FHF should occur in liver units with ready access to a liver transplant program (see Figure 41.2).

FHF is a rare syndrome which can evolve rapidly; it is therefore crucial that patients predicted to have a severe course are identified early to allow safe and timely transfer to a liver unit. Criteria have therefore been developed to help advise peripheral hospitals when patients with FHF should be transferred to a liver unit (see Box 41.1) [17]. These criteria are based on clinical judgment and have not been subjected to a controlled clinical trial.

**BOX 41.1** Transfer criteria

INR > 3.0  
 Prothrombin time in seconds greater than the time in hours  
 since the overdose (for paracetamol poisoning)  
 Any evidence of encephalopathy  
 Hypotension following fluid resuscitation  
 Evidence of a metabolic acidosis  
 Hyperlactemia  
 Bilirubin > 300 µmol/L  
 Renal failure

## General supportive management

### Fluid resuscitation and circulatory management

Patients with FHF develop marked hemodynamic changes. Vasodilatation can be profound and is invariably accompanied by a compensatory increase in cardiac output [18]. This distributive shock, with relative hypovolemia, causes hypotension despite the increased cardiac output. Prognostic criteria such as acidosis, serum lactate and renal function should therefore only be assessed following adequate resuscitation, as there can be marked improvement in these following fluids.

The choice of resuscitation fluid in FHF is not clear. As yet there have been no randomized studies performed to specifically address this question. Colloid solutions provide greater volume expansion for a given volume transfused compared to crystalloids and were traditionally favored for resuscitation in critically ill patients until the publication of a meta-analysis of 30 randomized controlled trials in 1998, which suggested that albumin may increase mortality [19]. This publication led to a change in practice in many centers, although the methodology of the review was heavily criticized. A large randomized controlled clinical trial has since been performed in 7000 patients, comparing 4% human albumin solution and normal saline for the resuscitation of critically ill patients. This study found no difference in the primary endpoint of mortality between albumin and saline, but in subgroup analysis there was an increase in mortality in brain-injured patients receiving albumin, which needs to be subjected to further study [20]. **A1a** Despite the apparent safety of albumin, it is clear that its use has declined as a resuscitation fluid, with only 7% of units in a large European survey using albumin for resuscitation [21]. In practice, most patients will receive a mixture of colloid and crystalloid for resuscitation and no clear evidence-based recommendation can be given as to which crystalloid or colloid is appropriate in FHF patients. Balanced salt solutions are associated with less risk of hyperchloremia, may have an advantage over saline and are recommended for patients undergoing surgery. Recent data suggests that

starch-based colloids may increase the incidence of renal failure and need for renal replacement therapy, especially with increasing doses and it would seem logical to limit the use of this colloid [22].

The hemodynamic changes associated with FHF are fairly predictable. As stated above, profound systemic vasodilatation is followed by a compensatory increase in cardiac output. Blood pressure is often low despite aggressive fluid resuscitation. Endpoints in resuscitation are difficult to define and so the use of some sort of monitor of both cardiac preload and cardiac output can be used to observe response to interventions. There is little evidence to suggest any technique is superior to any other and so local experience should dictate which techniques are used. The use of static measures of preload and therefore adequacy of resuscitation, such as central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP) can be unreliable and are better supplemented by dynamic measurements, which are better at predicting the response to volume resuscitation in the critically ill. Measurement of stroke volume variation (SVV), pulse pressure variation (PPV) and even the cardiac output response to passive leg raising have all been found to be useful in predicting the response to transfused volume [23–25].

Despite 20 years of clinical trials, the role of the pulmonary artery catheter (PAC) in the management of the critically ill patient is still not settled and remains controversial. In 1996 Connors found in a retrospective case control study that the use of PAC in the initial management of critically ill patients during the first 24 hours appeared to increase mortality and costs [26]. Since that study, two randomized trials examining the clinical utility of PAC have been published. The first study (PAC-Man) reported the outcome of critically ill patients randomized to management with a PAC or no PAC/other cardiac output monitor. There were no differences in hospital mortality between the groups and the conclusion of the study was that PAC did not affect survival in critically ill patients. However, in the PAC group there was a 10% incidence of non-fatal complications [27]. **A1d** In a *post hoc* analysis of the same study, no difference could be found between PAC and other forms of cardiac output monitoring: suggesting that this form of invasive hemodynamic monitoring was either ineffective or that the information produced was not being interpreted correctly [28]. The use of PAC within a rigid treatment algorithm was examined in a recent randomized trial in patients with acute lung injury. In this randomized study of 1000 patients, the role of PAC compared to a central venous catheter within a fluid liberal or conservative management strategy was assessed. No overall mortality difference was seen in any of the groups and in particular no benefit of PAC insertion was seen [29]. **A1c** Taken together, data from these trials suggest that the PAC has no role in the routine management of critically ill patients and the

decision to insert a PAC must be made on a case-by-case basis.

During the early 1970s, it was first suggested that during critical illness a pathological supply-dependency line is seen (see Figure 41.2) [30]. This was proposed because of markedly increased resting oxygen consumption noted in critical illness associated with systemic inflammation. Oxygen delivery increases to meet the demand and it was noted that survivors had higher oxygen transport parameters than non-survivors did. It was also noted that if oxygen delivery was increased, by fluid resuscitation and/or inotropic drugs, oxygen consumption increased as well, suggesting that covert tissue hypoxia exists and that this may be the cause of multiple organ failure.

Work by Bihari and Gimson in the 1980s suggested the presence of a pathological supply-dependency for oxygen in patients with FHF. The patients with FHF who failed to survive had both a lower baseline  $\text{VO}_2$  than survivors and greater increases in  $\text{VO}_2$  following infusion of epoprosteronol, suggesting a greater oxygen debt [18]. However, since then the whole premise of this argument, that there exists a pathological supply dependency in critical illness, has been questioned because of the inevitable increase in calculated oxygen consumption when delivery is increased due to mathematical coupling [31]. Furthermore, it is clear that not all patients with critical illness have pathological oxygen supply dependency. Early studies evaluating the use of strategies to increase oxygen delivery to supranormal levels in an attempt to decrease organ failure did not succeed and in some reports were actually harmful [32]. From other studies done earlier in the course of septic shock, however, it appears that the early (i.e. less than six hours) institution of a protocol to increase oxygen delivery reduces mortality [33]. The interpretation of the above data with relevance to FHF must be cautious. However, given the similarities between FHF and septic shock it would seem reasonable to assume that early vigorous volume resuscitation is appropriate, but routine targeting of supranormal oxygen delivery should be avoided.

Adrenaline and noradrenaline are effective agents and are frequently employed to improve MAP in FHF, commencing at  $0.1 \mu\text{g}/\text{kg}/\text{min}$ . Both of these agents have been shown to improve MAP, significantly the addition of epoprosteronol (a microcirculatory vasodilator) to noradrenaline increases oxygen delivery while maintaining MAP [34]. Epinephrine, like other beta agonists has deleterious effects on intermediary metabolism if used over a period of time. These effects include hyperlactemia and hyperglycemia. This is related partly to the effect of epinephrine on glycolysis within skeletal muscles [35]. Norepinephrine does not have these effects and so is recommended on current evidence.

Blood pressure is important in maintaining flow to essential organs. What pressure is acceptable in FHF is

unknown. However, cerebral autoregulation is disturbed in FHF, making cerebral blood flow directly proportional to cerebral perfusion pressure [36]. This implies that hypotension will result in cerebral ischemia, which may be a factor precipitating brain swelling in FHF [37], and that hypertension will result in cerebral hyperemia and increased ICP. Although, as discussed later, targeting a specific blood pressure to maintain cerebral perfusion in the face of cerebral edema is often futile and probably unnecessary [38]. **B4**

Alternatives to norepinephrine or epinephrine to maintain blood pressure, such as terlipressin or vasopressin, have not been systematically evaluated in FHF. Terlipressin is widely used in patients with chronic liver disease and hepatorenal syndrome and has been used in catecholamine refractory septic shock [39–41]. Whilst it is evident that terlipressin is effective at reducing the need for catecholamines in septic shock states its use in patients with FHF may be compromised by its effects on cerebral blood flow and intracranial pressure. Shawcross *et al.* showed in a small study of six FHF patients with grade 4 encephalopathy, that a single dose of terlipressin (0.25 mg) caused a significant increase in cerebral blood flow (CBF) from a median of 69 (range 48–83)  $\text{ml}/100\text{g}/\text{min}$  to 81 (range 62–97)  $\text{ml}/100\text{g}/\text{min}$  ( $p = 0.016$ ) accompanied by a significant increase in intracranial pressure (ICP) from a median of 15 mmHg (13–18) to 20 mmHg (16–23), which was sustained for three hours post terlipressin administration. There was no significant change in systemic hemodynamics to explain these findings and the authors hypothesized that terlipressin affected CBF via an interaction with cerebral V2 receptors [42]. In a separate study, the effect of terlipressin (1 mg bolus) was examined in ten patients with FHF. The effects on intracranial pressure, cerebral blood flow and cerebral perfusion pressure were compared to norepinephrine. Surprisingly, given the findings of the previous study, the authors found that a 1 mg dose of terlipressin did not increase ICP or CBF despite increasing cerebral perfusion pressure (CPP) through increases in mean arterial pressure. **B4** When the effect of increasing the rate of norepinephrine infusion was studied, there were significant increases in both CBF and ICP. The findings of this study show that terlipressin can increase CPP without increasing CBF, suggesting that terlipressin restored cerebral blood flow autoregulation through an unknown mechanism [43]. The reason for these disparate findings is not clear and highlights the need for further studies in this area.

## Mechanical ventilation

Intubation of the trachea and mechanical ventilation is indicated for several reasons in FHF but not usually for hypoxemia [18]. As patients progress from grade II to

grade III encephalopathy, decreasing consciousness can lead to airway compromise with the risk of aspiration. Grade III encephalopathy is often characterized by agitation and aggressive behaviour. Sedation in these patients is required to allow appropriate monitoring and treatment, but requires intubation and ventilation. In patients at risk of intracranial hypertension it is common practice to target a partial pressure of CO<sub>2</sub> of between 4 and 5 kPa; this minimizes the risk of increased cerebral blood flow due to increases in CO<sub>2</sub>. Controlled trials have shown there to be no benefit from routine hyperventilation in FHF in terms of prevention of intracranial hypertension [44]. **A1d**

As opposed to other causes of systemic inflammatory response syndrome, the lungs are *relatively* spared early in the course of FHF. However, a proportion of patients progress to multiple organ dysfunction in which lung disease is prominent [45].

The normal lung can tolerate “conventional” ventilation with physiological tidal volumes and low levels of positive end expiratory pressure (PEEP) for extended periods without apparent harm. The situation is different for damaged lungs and particularly so in patients with acute respiratory distress syndrome (ARDS). There is increasing evidence that mechanical ventilation in the setting of ARDS can increase lung injury and negatively impinge on outcome. Ventilator induced lung injury (VILI) encompasses a wide spectrum of damage, consisting of conventional barotrauma, pneumothorax, pneumomediastinum and alveolar damage, and increasing pulmonary edema [46]. Recent controlled clinical trials have shown improvements in mortality with a protective ventilatory strategy [47, 48]. **A1d** A recent consensus conference has recommended certain steps to minimize damage to the lungs during mechanical ventilation [49]. **A1c**

- Minimize the inspired oxygen level and take aggressive steps to do this if the inspired fraction is greater than 0.65.
- Recruit alveoli by increasing PEEP. The amount of PEEP necessary to prevent cyclic opening and closure of alveoli is approximately 10–15 cmH<sub>2</sub>O.
- Minimize high airway pressures. Transalveolar pressures should not exceed 25–30 cmH<sub>2</sub>O. This corresponds to an end inspiratory static (plateau) pressure of 30–40 cmH<sub>2</sub>O.
- Prevent atelectasis by employing larger breaths periodically to re-expand collapsed units during tidal ventilation with small tidal volumes.

Patients who spontaneously recover from FHF or who are transplanted may need mechanical ventilation for a prolonged period of time and often require tracheostomy to facilitate weaning from the ventilator. A recent prospective study has shown that the percutaneous approach is safe in patients with liver disease, even with refractory coagulopathy and should be the method of choice [50]. **B4**

## Sedation and paralysis

Patients with acute hepatic failure requiring mechanical ventilation are deeply encephalopathic. The need for sedation varies between patients and should be tailored individually, the primary aim being relief from pain and tolerance of the ICU environment and interventions. Mechanical ventilation is usually tolerated with minimum amounts of opiate and little if any hypnotic agent. The effect of sedation should be continuously evaluated to ensure that aims are achieved and over sedation avoided, although it should be noted that scoring systems, for example the six-point Ramsay scale have not been validated in FHF and are difficult to interpret in the setting of hepatic encephalopathy [51]. Deep sedation is unnecessary and will only add to cardiovascular depression and prolong recovery in patients with impaired liver function. There are no randomized data to support the use of one sedative agent over another in the routine management of FHF, but Propofol may have some advantage over benzodiazepines as it has been used to reduce ICP in brain-injured patients and may reduce cerebral blood flow through the reduction in cerebral metabolic rate for oxygen [52, 53]. These considerations, however, have to be contrasted with the need to prevent surges in intracranial pressure during routine nursing care; supplemental sedation or small doses of non-depolarizing neuromuscular blocker may be useful during suctioning of the patient’s trachea.

The issue of paralysis in FHF should be considered. It had been common practice to paralyze all ventilated patients with FHF whilst at risk from cerebral edema. However, there have not been any controlled clinical trials comparing paralysis or not in FHF, and, for that matter, in any other branch of intensive care medicine. A recent retrospective review of 1030 patients with acute traumatic brain injury showed that ICU stay and infectious complications were higher in the group who received routine paralysis [54]. **B4** Anecdotal reports have also suggested an association between long-term paralysis and a necrotizing myopathy, in patients with asthma, that may prolong ICU stay and impinge adversely on outcome [55]. Thus, there is no indication for routine paralysis in FHF. **B4**

## Nutrition in FHF

There are no randomized trials concerning nutrition in FHF, but in common with other critical illnesses FHF is characterized by increased energy requirements and given that the majority of patients will be sedated and ventilated, this energy must come from supplemental feeding [56]. Initially, the majority of FHF patients will be fed nasogastrically with standard enteral formulae as per international guidelines [57]. **A1c** The enteral route, if available, is always superior to the parenteral route, assuming that adequate

feed can be given. There is no difference between gastric and post-duodenal feeding in terms of adequacy of feeding or infectious complications and therefore, if tolerated, nasogastric feeding is appropriate [58, 59]. In patients who fail gastric feeding and have residual feed volumes, consideration can be given to prokinetic agents, such as metoclopramide or erythromycin. These drugs are highly effective at stimulating gastric motility and reducing nasogastric aspirates, but the effect can be short-lived and placement of feeding tubes beyond the pylorus is often required [60]. Feeding should be instituted within 24 hours of admission to the intensive care unit and in the initial phases of the illness should be no more than 20–25 kcal/Kg BW/day increasing to 25–30 kcal/Kg BW/day in the recovery phase [57]. **A1c** Despite a theoretical risk of worsening encephalopathy in FHF, due to the administration of protein, there is no data to support routine protein restriction. In practice, most patients will tolerate protein intake of 1–1.5 g/kg/day without complication. Renal failure is a common complication of FHF and the majority of patients will require renal replacement therapy (RRT) during the course of the illness. RRT can cause reductions in important trace elements and vitamins such as copper, selenium, thiamine and vitamin E, and therefore consideration should be given to trace element and vitamin supplementation during FHF, especially if complicated by renal failure requiring RRT [61]. Some vitamins such as vitamin C and vitamin E have important antioxidant properties and supplementation with these vitamins has been studied in general critical care populations with some benefits [62, 63]. The use of immuno nutrition (feeds supplemented by compounds such as arginine, glutamine and fish oil) has not been studied in FHF. Individual trials have shown benefit in some subsets of critical care patients and glutamine supplementation is considered a standard of care in parenterally fed patients [64]. **B4** Further studies are needed in this area, particularly in relation to FHF.

Hypoglycemia is a feature of advanced liver failure due to lack of gluconeogenesis from the failing liver. Whilst it is not uncommon for FHF patients to require administration of glucose containing solutions to maintain blood glucose levels, many patients will need insulin to control elevated blood glucose levels. In 2001, Van den Berghe reported a reduction in mortality in surgical ICU patients treated with intensive insulin therapy to maintain blood glucose levels between 4.4 and 6.1 mmol/l [65]. This approach has not been evaluated in FHF patients and there is concern that such tight glycemic control may predispose to adverse events related to hypoglycemia. A larger study has recently been published concerning blood glucose levels in critically ill patients. This study actually showed a significantly increased mortality in patients with tight glucose control compared to a more liberal regimen [66].

**A1c**

## Stress ulcer prophylaxis

Many small randomized controlled clinical trials over the past 20 years have looked at the prevention of stress ulceration. While the incidence of stress ulcer has fallen over this period, the cause of this decline is unclear. It is probably the result of both improved resuscitation and the widespread use of stress ulcer prophylaxis. The most recent large study estimates the incidence of clinically important stress ulcer bleeding to be about 3% in general ICU patients [67].

Stress ulceration is probably the result of ischemic injury to the gastric mucosa, and adequate resuscitation is the single most important factor in its prevention. Apart from good general ICU care, there have been two broad approaches to reducing the incidence of stress ulceration: decreasing the acidity of the stomach with the use of antacids, H<sub>2</sub>-blockers, or proton pump inhibitors; and the use of sucralfate, a cytoprotective agent. The role of acid suppression in encouraging an increase in bacterial overgrowth and the ensuing micro-aspiration of colonized pharyngeal fluid, thus promoting the development of hospital-acquired pneumonia, has led to the comparison of the ulcer, pneumonia and mortality rates between the two methods.

Recently, several meta-analyses have attempted to resolve the uncertainty regarding efficacy on one hand and adverse effects of the drugs on the other [68, 69]. After combining their efforts, the two main groups of investigators published a meta-analysis which included all relevant published and unpublished randomized clinical trials [70]. The meta-analysis demonstrated similar efficacy for H<sub>2</sub>-blockers and sucralfate for the outcome of reduction in stress ulceration bleeding, but an increase in the incidence of pneumonia and an excess mortality in the H<sub>2</sub>-blocker group. **A1a** A more recent trial conducted by some of the same authors suggests a significantly higher rate of stress ulceration with sucralfate compared to ranitidine, without any difference in pneumonia or mortality rates [70]. **A1d**

The aim of stress ulcer prophylaxis is to increase the pH of the gastric lumen and therefore reduce acid related damage. Therefore, it would seem logical that proton pump inhibitors would be more efficacious in preventing bleeding. In randomized controlled trials proton pump inhibitors appear to cause more durable increases in gastric pH, but evidence that they are more effective in preventing clinically significant GI bleeding than H<sub>2</sub> receptor antagonists is lacking, although adverse events were similar between groups [71, 72]. **A1c**

FHF was excluded in most of the trials comparing sucralfate to pH-altering drugs and was not included in the meta-analysis. It is therefore difficult to make firm conclusions. Patients with FHF tend to fall into the high-risk group by virtue of both being ventilated and having a coagulopathy.

The balance of evidence suggests that pH-altering drugs such as H<sub>2</sub>-blockers or proton pump inhibitors provide the best defense against stress ulceration, but that this may be offset by an increased incidence of pneumonia. Current guidelines on the management of septic shock advise the use of either H<sub>2</sub> RA or proton pump inhibitors for the prevention of bleeding and it would appear reasonable to extrapolate this guidance to patients with FHF [73]. **B4**

### Infection, prophylactic antibiotics and selective decontamination of the digestive tract

Patients with FHF are prone to infection. Early studies of FHF patients reported an incidence of bacterially proven infection in 80% of patients and fungal infection in 30% [11]. Initial analysis of isolates from infected FHF patients showed that the most frequently cultured organism was coagulase negative staphylococcal species [74]. However, it is clear from more recent studies that the epidemiology of infection in FHF patients has changed. In a recent retrospective review of over 200 patients with FHF Karvellas *et al.* have reported that whilst 34% of patients will at some point develop bacteremia during ICU admission, this occurred later in the course of the illness (median time to bacteremia ten days) than in the original studies. Moreover, the most frequently cultured organisms were Gram-negative organisms such as *E. Faecium*, *Klebsiella* spp. and Vancomycin resistant enterococcus [75]. The underlying reasons for this change in epidemiology are not clear, but the widespread use of prophylactic antibiotics in patients with advanced liver failure must have an impact on the timing of the development of infection and the prevalence of resistant strains such as *Acinetobacter* spp.

The predisposition to infection displayed by FHF patients is multifactorial. These patients often have multiple vascular access devices and may undergo prolonged ventilation and renal replacement therapy, all of which are well-known risk factors for the development of bacteremias in the critically ill [75, 76]. In addition to risk factors related to interventions, patients with FHF also appear to have important immunological defects which predispose to infection and have a prognostic importance. Neutrophils from patients with FHF have been shown to be deficient in killing and phagocytic ability; defects which are reversed *in vitro* by the administration of G-CSF [77, 78]. Recently, Antoniadou *et al.* have characterized the function of monocytes from patients with acetaminophen induced liver failure. Monocytes are important orchestrators of the immune response, (and) have a critical role in protection from infection and show marked deactivation in patients with FHF from acetaminophen [79]. In particular, the density of surface HLA-DR on monocytes was shown to have prognostic ability in reference to acetaminophen induced FHF patients [80].

Inflammation induced by infection also appears to impact upon the severity of hepatic encephalopathy. The presence of components of the systemic inflammatory response syndrome (SIRS) appears to predict the severity of HE. The mechanism for this interaction is incompletely understood but it appears to be due to increased cerebral blood flow [81].

Because of the high incidence of infection and the underlying immunological defects in FHF, the use of prophylactic antimicrobial agents has been investigated. Both parenteral antibiotics and the use of selective decontamination of the digestive tract (SDD), in combination and individually, have been studied.

Intravenous antibiotics, if given prophylactically will reduce the incidence of infection in patients with FHF to approximately 20% [82, 83]. **B4** However, the use of prophylactic antibiotics has not been shown to improve outcome or reduce the length of stay in patients with FHF [83]. The role of SDD is less clear and has not been evaluated in controlled trials compared with placebo or intravenous antibiotics alone in FHF. Rolando reported that SDD used in combination with intravenous antibiotics provided no additional benefit [82–84]. **B4**

The most recent systematic review of randomized controlled trials of antibiotic prophylaxis in intensive care units was published in the Cochrane database of systematic reviews [85]. This systematic review evaluated 32 RCTs, which included 5639 unselected general ICU patients. Selected groups, for example patients with FHF, were excluded from the review. Pooled estimates of the 16 RCTs testing the effect of the SDD and systemic antibiotic combination indicate a significant reduction of both respiratory tract infections (OR 0.35; 95% CI: 0.29–0.41) and total mortality (OR 0.80; 95% CI: 0.68–0.93) (Figure 41.3). **A1a** The number needed to treat to prevent one infection is five, and the NNT to prevent one death is 23. When the data on the effect of SDD alone compared to control were pooled from the 16 available trials, a marked reduction in respiratory tract infections was demonstrated (OR 0.56; 95% CI: 0.46–0.68) but no corresponding effect on overall mortality (OR 1.01; 95% CI: 0.84–1.22) was found (Figure 41.4).

Although prophylactic intravenous antibiotics have been shown to reduce the number of proven infections in FHF, improvements in outcome have not been demonstrated. SDD on its own has not been shown to reduce infection or improve outcome in FHF. **B4** There is also a risk of promoting the emergence of multiply resistant organisms within intensive care units by the blanket use of broad spectrum antimicrobials. SDD selects for an increase in Gram-positive organisms, especially methicillin resistant staphylococcus (MRSA) and vancomycin resistant enterococcus (VRE). In a large single center randomized trial the use of SDD was not associated with the development of resistant strains such as VRE and MRSA. However, a follow-up study

suggested that SDD promoted the development of extended spectrum beta-lactamase producing strains [86, 87]. Future research should be aimed at determining the cost-effectiveness of SDD, with inclusion of estimates of the effects of the emergence of resistant microorganisms. However, for the individual patient the evidence in favor of the use of prophylactic antimicrobials is compelling.

## Management of cerebral edema

Hepatic encephalopathy (HE) is always present in FHF and although the pathogenesis has not been fully elucidated, considerable evidence points to a central role for ammonia as a major factor. The ammonia hypothesis is supported by extensive animal data and clinical studies correlating the level of ammonia with onset and severity of intracranial hypertension (ICH) [88–90]. Recent studies have suggested a role for infection and inflammation in the pathogenesis of HE, with evidence that the molecular mediators of infection and inflammation may act synergistically with ammonia to produce HE [81, 91–93].

Infection is a common precipitant of HE in both chronic liver disease and FHF. Large studies have demonstrated the role of the systemic inflammatory response syndrome (SIRS) and infection in the progression and severity of HE and other complications of liver failure [75, 92–94]. ALF is an inflammatory state and increased levels of the pro-inflammatory cytokines TNF- $\alpha$ , IL-6 and IL-1  $\beta$  can be demonstrated, especially in patients with raised ICP. The generation of these pro-inflammatory cytokines may be due to activation of the immune system by infection and also release from the necrotic liver [91].

The generation of cerebral edema in HE is dependent on blood ammonia, with entry into the brain increased in ALF, and serum levels > 150–200  $\mu\text{mol/l}$  found to predict intracranial hypertension [89, 90]. Ammonia is detoxified in the brain by formation of glutamine in astrocytes from amidation of glutamate. Glutamine accumulation in the astrocyte causes osmotic swelling, and cellular dysfunction through induction of oxidative stress and mitochondrial permeability transition [95, 96]. Indeed inhibition of glutamine synthetase ameliorates brain edema and improves the survival in animal models of ALF [97]. Astrocytic swelling thus contributes to the elevation of ICP in addition to the other component of intracranial hypertension in FHF, which is increased cerebral blood flow (CBF), although this has not been consistently demonstrated. Vascular autoregulation within the brain is defective in patients with ALF, with uncoupling of blood flow and cerebral metabolic rate [36, 98]. Cerebral hyperemia has been shown to be contributory to an increase in ICP in animal models based on portocaval anastomosis and ammonia infusions [99], and an increase in cerebral blood flow has been shown in some

human studies in ALF [100], but not in others [37, 101]. Indeed, studies have shown a wide variation in cerebral blood flow in patients with ALF and an increase in cerebral lactate production has been shown, indicating possible ischemia that may induce cerebral swelling [37]. Recent work has shown that in patients with elevated ICP, CBF was increased and associated with the presence of SIRS criteria, markers of inflammation (C-reactive protein, white cell count) and elevated levels of the pro-inflammatory cytokines TNF- $\alpha$  and IL-6. Moreover, patients who developed surges in ICP also had associated increases in CBF and inflammatory markers [102]. The blood brain barrier is thought to remain intact in ALF and thus it seems unlikely that circulating cytokines can have a direct effect on cerebral function, although a recent small series has shown net efflux of inflammatory cytokines from the brain, suggesting that the blood brain barrier may be impaired in some way as has been shown in experimental animals [91, 103].

The above studies lead to the proposal of a “two hit” hypothesis, whereby the initial event in the precipitation of HE is raised ammonia levels consequent upon liver failure, which causes astrocyte swelling and cellular dysfunction, setting the stage for the worsening of ICP via increased cerebral blood flow in the setting of a concurrent inflammatory state.

## Intracranial pressure monitoring

The use of intracranial pressure (ICP) monitors in FHF has not been subjected to a randomized controlled trial. As with any monitor used in critical illness, finding a positive outcome related to their use is difficult. At best, studies have suggested they may help with the management of patients with raised ICP. One study using historical controls suggested greater interventions associated with their use, and assuming the interventions were appropriate, this may be of benefit. The duration of survival from the onset of grade IV encephalopathy was significantly greater in the ICP monitored group (median 60 vs 10 hours,  $p < 0.01$ ), although overall survival was unchanged [104]. Blei *et al.* performed a postal survey of complications in 262 patients from liver transplant centers across the USA [105]. Epidural transducers were the most commonly used devices and had the lowest complication rate (3.8%); subdural bolts and parenchymal monitors (fiberoptic pressure transducers in direct contact with brain parenchyma and intraventricular catheters) were associated with complication rates of 20% and 22% respectively. Fatal hemorrhage occurred in 1% of patients undergoing epidural ICP monitoring, whereas subdural and intraparenchymal devices had fatal hemorrhage rates of 5% and 4% respectively. They concluded that epidural transducers were the safest form of monitoring even if not the most accurate. A similar survey of 25 centers

contributing to the US Acute Liver Failure Study Group was recently performed by Vaquero *et al.* [106]. In this study, only 27.7% of patients with grade III or IV encephalopathy had an ICP monitor placed. Patients with ICP monitoring were more likely to be younger and be listed for liver transplantation. There was considerable heterogeneity amongst centers regarding the frequency of use and the type of monitor used. In this study subdural monitors were used most commonly. Similar to the earlier study by Keays *et al.* the use of ICP monitoring was associated with more interventions such as mannitol, barbiturate and vasopressor administration. There was no difference in survival or neurological outcome between the two groups, although only patients who underwent transplantation were compared. Complications of insertion were seen in 10% of patients, all of these events being related to intracranial bleeding. In three patients intracranial bleeding was clinically insignificant, but in two patients bleeding may have contributed to mortality. Whilst the complication rate appears to be lower than the previous study by Blei *et al.* (10% vs 20% bleeding rate), the use of recombinant factor VII was more frequent, suggesting that aggressive control of coagulation does not protect from bleeding when using subdural or parenchymal monitors. The issue of coagulation is highlighted in a recent report of a protocolized approach to FHF management, which reported intracranial bleeding in 3 of 22 patients treated with platelet, fresh frozen plasma and cryoprecipitate infusions, in addition to recombinant factor VII and desmopressin administration prior to insertion [107]. Another use of ICP monitoring is to determine if transplantation may be rendered futile by a poor neurological outcome. A cerebral perfusion pressure (mean arterial pressure minus intracranial pressure) of less than 50mmHg has in the past been considered a contraindication for OLT [108]. This was because of concern regarding cerebral ischemia resulting in poor neurological outcome. Recent reports of patients with CPPs of less than 50mmHg in which full neurological recovery has taken place have called this practice into question. Davies reported four patients with fulminant hepatic failure who developed prolonged intracranial hypertension (>35mmHg for 24–38h) that was refractory to standard therapy and associated with impaired cerebral perfusion pressure (<50mmHg for 2–72h) [38]. All survived with complete neurological recovery.

In the absence of randomized trial evidence showing benefit of ICP monitor insertion, the decision to use this form of monitoring must be taken on a case-by-case basis. There are currently multiple interventions that can be used to lower a raised ICP and only with knowledge of the ICP can the cerebral perfusion pressure (MAP-ICP) be calculated and manipulated. However, the risk of monitor insertion is not insubstantial and not all patients will develop intracranial hypertension. Risk factors for the development

of intracranial hypertension are now well described and it would seem appropriate to offer this form of monitoring to those most at risk, such as those with sustained high ammonia levels, renal failure or high vasopressor requirements, especially if young and hyperacute in presentation [89]. **B4**

## Radiological assessment

CT scanning, since its introduction into routine clinical practice, has become a standard investigation in any patient with suspected intracranial pathology. In FHF, correlation between ICP measurements and pressures predicted by CT imaging have been generally poor [109]. As little information is gained in relation to the difficulty associated with transporting these very sick patients to the CT scanner, a decision regarding the need for a CT must be carefully considered. CT may be of help if there is any diagnostic difficulty as to the cause of the coma or if a complication of ICP bolt insertion is suspected.

Functional radiology with single photon emission tomography SPECT scanning has been used to assess regional cerebral blood flow in patients with FHF, but it is difficult to see this being used clinically [110].

## Monitoring of cerebral oxygenation

ICP and CPP monitoring are used to infer the adequacy of cerebral perfusion and oxygenation. The direct monitoring of cerebral oxygenation and blood flow are appealing. Instead of inferring the adequacy of cerebral perfusion and oxygenation from clinical signs and pressure measurements they provide direct evidence for the ongoing viability of the brain.

Methods used for the estimation of cerebral oxygenation include the sampling of jugular venous blood for oxygen saturation and products of metabolism such as lactate. A brain that is affected by limitation of supply will extract more oxygen from the arterial blood. This will result in a reduction in venous oxygen saturation. Jugular venous saturation of less than 55% suggests an ischemic brain, and steps can be made to improve the blood flow to the brain, either by increasing blood flow, decreasing ICP or reducing the metabolic demands of the brain. High JV saturation >85% may represent a hyperemic brain and steps can be made to reduce cerebral blood volume if ICP is raised. Very high JV saturation is often seen as a terminal event and may represent a complete loss of oxygen extraction by the brain.

Direct estimates of cerebral oxygenation can be achieved by the insertion of a probe into the brain parenchyma to either measure the partial pressure of oxygen or, if a microdialysis is used, to measure extracellular metabolic products [111]. Microdialysis has produced data that

offers insights into the pathogenesis of hepatic encephalopathy, but as yet can only be considered a research tool [112–114]. Non-invasive methods of measuring cerebral oxygenation and blood flow include near infrared spectroscopy, transcranial Doppler and SPECT scanning. A small study of FHF patients showed that near infrared spectroscopy can detect changes in cerebral blood flow, but further work comparing to conventional monitoring is needed [115]. A study of transcranial Doppler measurements of the middle cerebral artery in FHF showing detectable changes in Doppler signals in relation to changes in MAP, and CPP has recently been reported, but as yet appears to lack the precision for decision making in this critical area [116].

Validation of non-invasive methods of monitoring cerebral function are ongoing, but controlled trials showing improvement in outcome are lacking.

### Treatment of intracranial hypertension

Current guidelines recommend the reduction of intracranial pressure when it exceeds 20–25 mmHg [117]. Apart from adjuvant therapies, such as optimizing patient position to facilitate venous drainage via the jugular vein [118], two approaches can be used to facilitate reductions in ICP: namely osmotherapy and modulation of cerebral blood flow. Osmotherapy initially with urea and then mannitol has been used for many years to treat cerebral edema associated with traumatic brain injury. Canalese *et al.* showed that 1 g/kg of mannitol was an effective treatment for established intracranial hypertension in FHF and that dexamethasone was ineffective for prevention [119]. Since then, the same workers have shown that 0.5 g/kg of mannitol is as effective [120]. **B4** They suggest that boluses should be delivered rapidly to achieve maximum effect. Hypertonic saline has been used for many years in neurosurgical and trauma patients as osmotherapy of raised ICP [121–123]. A study of hypertonic saline as osmotherapy in FHF has been conducted. In this small randomized trial patients with FHF and grade III or IV encephalopathy received standard medical therapy or standard medical therapy plus an infusion of 30% saline to maintain serum sodium levels between 145–155 mmol/l. All patients were undergoing ICP monitoring. There was a significant reduction in ICP in treated patients compared to controls and more control patients had episodes of ICH characterized by elevations of ICP > 25 mmHg. This study was not powered to show differences in outcomes such as survival, but establishes the efficacy and safety of moderate induced hyponatremia to control ICP [124]. **A1d**

Hyperventilation decreases ICP by inducing cerebrovascular vasoconstriction; this reduces cerebral blood volume. It has not been shown to be any advantage in the long term in controlling ICP in FHF [44]. **B4** A short-term period of

hyperventilation in patients with raised ICP unresponsive to osmotherapy may be tried, while monitoring jugular venous saturation to assess cerebral oxygenation.

Barbiturates decrease cerebral metabolic rate via their anesthetic action and cause cerebral vasoconstriction. They have been used as agents to prevent secondary brain damage in traumatic brain injury. However, myocardial depression and hypotension with a possible compromise in cerebral perfusion pressure have limited the enthusiasm for routine use. There have not been any randomized controlled clinical trials evaluating barbiturate infusions in FHF. Forbes *et al.* investigated the role of thiopentone infusions in 13 patients with FHF in an uncontrolled study [125]. The overall survival rate of 5 out of 13 was claimed to be better than expected, but it is difficult to come to any conclusions from these data. Prolonged recovery and hypotension limit the use of thiopentone in FHF, although it may be tried when all else fails. A study in traumatic brain injury found barbiturate infusion to be of no additional benefit to acute hyperventilation [126].

Hypothermia has been investigated extensively in patients with traumatic brain injury. Initial enthusiasm for the technique in small trials was tempered with the publication of a large multi-center trial that failed to show an improved outcome, but also demonstrated an increase in complications, including bleeding and infections [127]. This is in contrast to ischemic injury following cardiac arrest, where improved survival has been shown [128]. Recently, moderate hypothermia has been reported as a rapid effective measure in reducing ICP in ALF, although there are no controlled trials [129]. **B4** Hypothermia may have a beneficial effect on the ICP in ALF by multiple mechanisms, such as decreasing ammonia extraction and reducing the cerebral metabolic rate. However, the main mechanism responsible seems to be modulation of CBF and the restoration of cerebral autoregulation to arterial pressure [130]. Hypothermia, however, may have deleterious effects on coagulation and infection and therefore cannot be recommended as routine therapy at the current time; however, a currently ongoing multicenter study will clarify the role of hypothermia.

Indomethacin is a non-steroidal anti-inflammatory drug which is also a potent cerebral arteriolar vasoconstrictor and has been used to treat sustained intracranial hypertension in patients with traumatic brain injury [131, 132]. Experimental and clinical studies indicate that indomethacin reduces ICP primarily by decreasing CBF and therefore, it may have value in the management of patients with elevated ICP in FHF with evidence of hyperemia. The use of indomethacin to control ICP in FHF has been reported in case reports and a small series [133]. Twelve patients with FHF and intracranial hypertension were studied with microdialysis, jugular venous oximetry and transcranial Doppler before and after the administration of a single

bolus of indomethacin. ICP was reduced from 30 (7 to 53) to 12 (4 to 33) mmHg ( $p < 0.05$ ) and there were improvements in CPP. Importantly, there was no evidence of brain ischemia as evidenced by unchanged jugular venous oxygen saturation and brain lactate concentration [134]. Further studies on the role of indomethacin for ICP treatment in FHF appear warranted.

*N*-acetylcysteine (NAC) has been shown to reduce clinical signs of intracranial hypertension in patients with FHF following paracetamol hepatotoxicity [135]. NAC treated patients had a lower incidence of cerebral edema (10/25, 40%) than was observed in control patients (17/25, 68%;  $p = 0.047$ ; 95% CI for difference in incidence: 2–54) [135].

**A1d**

### Anticonvulsant therapy

The incidence of clinical seizure activity in FHF has not been reported but it is likely that sedative and paralysing agents mask it during mechanical ventilation. Ellis and colleagues recently reported the incidence of subclinical seizure activity and the effect of the anticonvulsant phenytoin in FHF. With the use of a cerebral function monitor they found an incidence of 32% in the control group. The occurrence of seizure activity likely increases the risk of developing cerebral edema. The use of phenytoin reduced the incidence of subclinical seizure activity although not significantly. The incidence of cerebral edema in the patients that received an autopsy was significantly higher in the control group [136]. **A1d**

### Renal failure

The incidence of acute renal failure associated with FHF is high; up to 70% of all patients develop renal failure (defined as urine output of less than 300 ml/24 hours and a serum creatinine of greater than 300 mmol/l in the presence of adequate intravascular filling) [10]. The etiology of renal failure in FHF is multifactorial, with both pre-renal and renal components. Relative hypovolemia and hypotension contribute to pre-renal causes. Disordered renal vascular autoregulation, present in sepsis, may also exist in the hyperdynamic circulatory failure of FHF, making renal blood flow directly dependent on blood pressure. Direct renal toxicity in patients with FHF secondary to paracetamol poisoning contributes to the very high incidence of renal failure in this group of patients [10]. The contribution of the hepatorenal syndrome, or functional renal failure in the presence of FHF, is difficult to quantify and it probably represents one end of a continuum of disordered renal function from the hepatorenal syndrome to acute tubular necrosis [137].

### Renal protection

There is no proven preventative strategy against the development of renal failure, or treatment, that will shorten the duration of established renal dysfunction in FHF.

Dopamine has agonist activity at all adrenergic receptors, depending on concentration. Dopamine at a so-called “renal dose” ( $<5 \mu\text{g/kg/min}$ ) augments renal blood flow and increases urine volume and sodium excretion in animals and healthy humans. In FHF and other forms of distributive circulatory failure an increase in renal blood flow has been difficult to show [138]. There is now good evidence that dopamine does not prevent renal failure in critically ill patients [139]. **A1d** It has been suggested that dopamine may exacerbate renal dysfunction by delivering a sodium load to an already ischemic renal medulla [140]. The term “low-dose” dopamine has been questioned because of the wide variation in plasma concentration in critically ill patients [141], and because of significant effects on other organ systems, specifically anterior pituitary and immune function [142].

Other strategies, including frusemide, aminophylline and fenoldopam infusions have not been shown to prevent renal failure in the critically ill. Atrial natriuretic peptide, while showing promise in animal models, has not been shown to be useful in the clinical setting in early human trials [143].

The magic bullet in the prevention of renal failure in FHF remains elusive and so what is left is the maintenance of intravascular volume and an adequate perfusion pressure. Despite this, extra-corporeal support is common.

### Renal replacement therapy

While the incidence of renal failure in FHF remains high and attempts to prevent or treat it remain poor, renal replacement therapy has become a major part of the routine management. Proving that renal replacement therapy improves outcome is difficult as no randomized controlled trials have been done, but it can be assumed that it has contributed in part to the improvement in mortality figures over the last 30 years.

The type of replacement has been investigated in critically ill patients. It has been shown that intermittent forms of therapy cause more hemodynamic compromise than continuous forms of therapy. This has been examined in FHF. Davenport *et al.* investigated the effect of various modes of renal replacement therapy in 30 consecutive patients referred with both fulminant hepatic and acute renal failure [144]. Continuous forms of therapy were associated with more hemodynamic stability during the first hour of treatment [145]. **B4** Intracranial pressure remained stable during the continuous modes but increased significantly during intermittent machine hemofiltration [146].

The adequacy of renal replacement therapy must be considered. Patients with FHF often have severe metabolic acidosis and rapidly progress to anuria. They are markedly catabolic and serum concentrations of creatinine rise rapidly. Urea is notably low in FHF. The rate of ultrafiltration in critically ill patients has been investigated recently. It has been shown that, in general, modest increases in ultrafiltration rates are associated with an improved outcome overall [147]. **B4**

There is no evidence base for recommendations on when to start renal replacement therapy RRT in FHF. In general, conventional indications for the institution of RRT in critically ill patients should be adhered to, but given that hemofiltration and dialysis both reduce serum ammonia levels there may be a role for the early institution of RRT in patients with very high ammonia levels who may be at risk of ICH [148, 149]. Most liver centers use bicarbonate based buffers as replacement fluid, as lactate containing fluids may elevate the serum lactate causing interference with prognostication. Anticoagulation of the extracorporeal circuit could predispose to bleeding and in coagulopathic patients the use of epoprostenol or no anticoagulation can be considered.

### Critical illness related corticosteroid insufficiency

Critical illness related corticosteroid insufficiency (CIRCI) appears to be common in heterogeneous populations of critically ill patients. Low levels of cortisol and inadequate response to adrenocortical stimulation have identified patients with a poor prognosis. The mechanism of CIRCI is not completely understood and may be due to decreased production of cortisol, corticotrophin releasing hormone or due to increased resistance to the cellular effects of cortisol [150]. Studies of the effect of corticosteroid replacement in the critically ill have produced conflicting results, but use of moderate doses of hydrocortisone (200–300 mg/day) appears to show benefit in ARDS, community acquired pneumonia and caused quicker resolution of shock in vasopressor dependent patients [151–153]. **B4** Recently, Harry and colleagues [154] investigated the serum cortisol levels and the response to SST in 45 patients with acute hepatic dysfunction (AHD). Abnormal tests were common, occurring in 62% of patients. Those who required noradrenaline (NA) for blood pressure support had a significantly lower increment (median, 161 vs 540 nmol/l;  $p < 0.001$ ) following synacthen compared with patients who did not. The increase was significantly lower in those who fulfilled liver transplant criteria compared with those who did not. There was an inverse correlation between increment and severity of illness (Sequential Organ Failure Assessment,  $r\ 0.63$ ;  $p < 0.01$ ) [154]. The same authors also investigated the effect of corticosteroid therapy (300 mg hydrocortisone/

day) in 20 vasopressor dependent patients with acute liver failure (ALF) or acute chronic liver failure (ACLF) and compared these to a historical control group of patients not treated with steroids. The use of steroids was associated with reduction in vasopressor doses but no survival benefit. Notably, the incidence of infection was higher in the corticosteroid treated group, especially with resistant organisms such as methicillin resistant staphylococcus aureus (MRSA) [155]. **B4**

Further controlled trials are needed and it remains to be seen if there will be any benefit from the replacement of steroids in patients with FHF.

## Specific therapies

### N-acetylcysteine (NAC) in paracetamol poisoning and other etiologies

Paracetamol poisoning is the single largest cause of FHF in the UK, accounting for between 50 and 60% of cases seen [156]. NAC can prevent hepatic damage following paracetamol poisoning. Smilkstein *et al.* evaluated the time interval from poisoning to treatment with NAC in relation to the incidence of hepatic damage as defined by increased transaminase values. NAC was found to be most effective when given during the first eight hours following ingestion. More recent data suggest that NAC is effective when given up to 72 hours after ingestion with a decrease in the occurrence of grade III/IV encephalopathy, cerebral edema, hypotension requiring inotropic support, and mortality, when compared to untreated controls [135, 157]. **A1d**

The mechanism of action of NAC in patients with established hepatic necrosis is unclear. Improvements in oxygen transport parameters have been shown with its use in patients with FHF due to paracetamol poisoning and FHF due to other etiology [158]. This, however, has been questioned recently [159]. A benefit in terms of a hemodynamic effect of this agent is seen when it is used in conjunction with epoprostenol. The beneficial effects may be attributable to a repletion of glutathione status and/or the antioxidant properties of NAC. NAC is also a sulphhydryl donor and this may be beneficial in patients in whom sulphhydryl groups may be oxidized, impairing microcirculatory function. Infusion of NAC has been shown to increase serum cGMP with no change in atrial natriuretic peptide, suggesting it may indeed have a role in the nitric oxide pathway in patients with acute liver failure [160].

Recently, a randomized controlled multicenter from the US acute liver failure study group examining the role of NAC in non-paracetamol ALF has been reported. This placebo-controlled study of 173 patients found no difference in overall survival between the two groups (70% survival NAC vs 66% placebo). However, there was significant

benefit for NAC in terms of transplant-free survival compared to placebo (40% vs 27%), but this benefit was only seen in patients with lower grades of encephalopathy (grade I and II) [161]. **A1d**

### **Blood purification: dialysis, plasmapheresis, hemofiltration, sorbant hemoperfusion and artificial hepatic support**

To support the acutely failing liver effectively there has to be a thorough understanding of the functional role of the liver in body homeostasis. The liver is a complex organ with many functions, in addition to the metabolic functions of the hepatocyte, which make up two-thirds of its mass. The remaining third is made up of other cell types including the Kupffer cells and endothelial cells. These other cells are important in many of its functions, including the immunological activity of the liver.

There are two main components to the pathophysiology of FHF. The metabolic mass theory, which states that there is a functioning mass of hepatocytes under which end organ dysfunction will occur, leading to the manifestations of FHF and ultimately death. The toxic liver hypothesis states that it is the toxins produced by the failing liver itself that are the cause of the syndrome of FHF. The truth probably lies somewhere in between and so any extracorporeal system has to both clear the serum of any toxins produced by the failing liver and maintain the metabolic and, if possible, the other functions of the native liver. Established FHF will lead inexorably to multiple organ failure and ultimately death in the majority of patients managed with medical therapy alone and so some kind of liver support, to maintain organ function is very attractive while waiting for definitive surgical treatment or regeneration and recovery. There are two main types of blood purification systems available. These are either biological or non-biological approaches.

Experience with extracorporeal systems designed to clear the blood through physiochemical means alone consist of dialysis, sorbant hemoperfusion, hemofiltration and plasmapheresis, and combinations of the above. More recently, extracorporeal dialysis against 20% albumin has been employed with the commercially available MARS (molecular absorbent recirculation system) [162].

Early work with hemodialysis showed improved coma scores in patients with chronic liver disease. With increasing pore size and improving biocompatibility with polyacrylonitrile (PAN) membranes the hope was to improve middle-molecule clearance. No improvement in mortality in FHF was shown [163]. Hemoperfusion involves the adsorption of lipophilic chemicals onto activated charcoal or synthetic resins. Again, early studies suggested an improvement in coma scores [164], but controlled studies failed to show an improved outcome with treatment [10]. **A1d**

Plasmapheresis or the exchange of plasma by fresh-frozen plasma (FFP) has theoretical advantages over other forms of blood cleansing regimens in that it removes both low molecular weight molecules and the higher molecular weight middle-molecules both bound and unbound. The Copenhagen group have been studying high volume plasmapheresis with exchanges of 11/hour for three consecutive days [165]. Their studies suggest an improvement in hemodynamics and improved CPP but no reduction in ICP. They also noted a decrease in Glasgow Coma Score, decreased INR and reduced serum bilirubin [165]. Improvement in mortality has yet to be shown with the technique although the results of a randomized clinical trial are awaited with interest. The MARS system is an extracorporeal circuit in which 20% human albumin solution is dialyzed against the patient's blood. The albumin within the circuit binds protein bound molecules, including bilirubin and bile acids, from the patient [162]. MARS therapy has been proposed as a liver support device in the management of FHF. The evidence for effect is limited to case reports and small case series with heterogeneous patients, but some success has been reported, including the improvement of coma scores [166]. A recent report of the use of MARS in 113 FHF patients showed increased survival without transplantation (66%) compared to historical controls (40%), but the retrospective design of the study and the differing baseline characteristics of the patients make interpretation of this data difficult [167]. In contrast, in a center which used MARS routinely for the management of FHF the majority of patients died in the absence of liver transplantation despite the use of MARS for extended periods of time [168]. **B4** The results from a French multicenter study of MARS in FHF are eagerly awaited.

Bioreactors containing hepatocytes have been the basis for biological extracorporeal support systems. These remain experimental and confined to clinical trials. Experience with the systems so far suggests few problems with biocompatibility, but there are few data to suggest an improvement in clearance or synthesis by the artificial liver. The systems at the present time are divided into those utilizing porcine hepatocytes or immortalized hepatoblastoma cell lines. The ELAD system comprises a continuous system using a hepatoblastoma cell line. A randomized study utilizing this system, assessing biocompatibility, showed an improvement in galactose clearance at six hours, but no other measured variables were significantly different between the treatment and control groups [169].

#### **A1d**

Recently, a randomized multicenter study has been published reporting the effects of the Hepatassist® bio artificial liver (BAL) support device in ALF and primary non-function of hepatic allografts [170]. This device incorporates a bioreactor comprising  $7 \times 10^6$  cryopreserved porcine hepatocytes housed within hollow fibres. The extracorporeal

circuit includes an oxygenator and a charcoal column. The circuit is perfused with plasma generated by a conventional plasmapheresis machine. This study enrolled 171 patients, 24 with primary non-function and 147 with acute or sub-acute liver failure. Patients were randomized to standard of care or treatment with the bio artificial liver, with treated patients receiving an average of 2.9 treatments. The commonest reason for the cessation of treatment was a liver becoming available for transplantation. The overall survival between the treated and non-treated groups was not significantly different, although when the data was analyzed to account for the impact of transplantation upon survival there appeared to be a survival benefit for acute and sub-acute liver failure patients at 30 days. [161] **A1d**

### Temporizing hepatectomy

The toxic liver theory of FHF has led to the introduction of temporizing hepatectomy in an attempt to regain hemodynamic control or a reduction in ICP in patients on the super-urgent transplant list. There have been several published case reports of successful liver transplantation following a prolonged anhepatic state. Ringe *et al.* presented the results of 30 patients who underwent hepatectomy (and temporary portacaval shunting to provide an outflow of the transected portal vein) between 1986 and 1993 [171]. Improvement in hemodynamic parameters was seen in 17 of the 30 patients following hepatectomy, with liver transplantation occurring 6–41 hours later (the effect on ICP was not stated). It is impossible to draw conclusions from these anecdotal data. Temporizing hepatectomy has been criticized because of removing the option to perform an auxiliary transplant. Temporizing hepatectomy may have a role in severe liver trauma, with uncontrollable bleeding and primary graft non-function where there is no hope of recovery.

## Liver transplantation

### Prognostic factors in fulminant hepatic failure and orthotopic liver transplantation

Hepatic transplantation in FHF has not been and never will be subjected to a controlled clinical trial. However, patients with FHF due to causes other than paracetamol poisoning who undergo transplantation have a 65% two-month survival rate [16], compared to 20–25% for patients managed with maximal medical therapy alone [172]. **B4** The survival without transplantation after paracetamol poisoning is higher than with FHF from other causes.

The task for the medical staff looking after patients with FHF is to decide which of these patients will not survive

without liver transplantation. The decision needs to be made as early as possible because there exists a “window period” during which a successful outcome can be expected [173]. Following paracetamol poisoning, time from ingestion to transplant was significantly longer in non-survivors following transplantation [16].

In order to make an informed decision regarding the likelihood of spontaneous recovery from FHF an understanding of the natural history of the disease is necessary. Because FHF is a rare syndrome, these data have only become available over the past 20 years, since the introduction of liver failure units around the world.

Poor prognostic markers developed from analysis of large databases from these liver units have been refined into clinically usable indications for transplantation. O’Grady *et al.* developed criteria from a database of 588 patients presenting to King’s College Hospital liver unit (see Box 41.2) [156]. The time course of the illness is important. It has been known for many years that the time to encephalopathy from the onset of symptoms is important prognostically, the “hyperacute” patients having a better prognosis than the “sub-acute”. Etiology and age are important in that different criteria were developed for FHF caused by paracetamol poisoning. The extremes of age are associated with a poor prognosis. A high serum creatinine and bilirubin were associated with a poor prognosis, as were prolongation of coagulation parameters [156]. Following paracetamol poisoning no particular prognostic cutoff level of INR has been found, but it has been noted that a rise of the INR from day three to day four is associated with a 7% survival as compared to a 79% survival in those whose INR fell from day three to four [157]. Metabolic acidosis following fluid resuscitation was found to be

#### BOX 41.2 King’s College Hospital prognostic criteria

In *non-paracetamol induced* liver failure  
 Prothrombin time > 100 seconds (INR > 6.5)  
 Or  
 pH < 7.3  
 Or any three of the following:  
 Age < 10 years  
 Age > 40 years  
 Seronegative hepatitis (non A, B, C, E, F), halothane or other drug reaction  
 Duration of jaundice > 7 days before encephalopathy  
 Prothrombin time > 50 seconds (INR > 3.5)  
 Bilirubin > 300 µmol/l  
 In *paracetamol induced* FHF  
 pH < 7.3 (following fluid resuscitation)  
 Or the coexistence of:  
 Prothrombin time > 100 (INR > 6.5), creatinine > 300 µmol/l and grade III or worse encephalopathy

highly specific for a poor outcome in paracetamol poisoning. A serum pH persistently less than 7.3 has become an independent transplant criterion regardless of grade of encephalopathy [156]. **B4** The metabolic acidosis seen in FHF is often associated with a raised whole blood lactate concentration. This hyperlactatemia is caused by both an increased production, but also by decreased clearance by the liver [174, 175]. Prolonged high blood lactate concentration in critical illness other than FHF is associated with poor prognosis. The relationship between whole blood lactate and prognosis in FHF has been investigated recently. Bernal and colleagues showed that a post-resuscitation lactate concentration of greater than 3.0 mmol/l can predict death with similar accuracy to the King's criteria, but earlier in the course of the illness. The addition of post-resuscitation lactate concentration to the KCH criteria increased sensitivity from 76% to 91% and lowered the negative likelihood ratio from 0.25 to 0.10 [176]. **B4**

The importance of lactate in the prognosis of ALF secondary to paracetamol overdose has been reflected by its inclusion as a criteria for registration on the UK superurgent liver transplant scheme. Other recent variations to the classic King's criteria have recently been adopted in the UK. Patients who are deteriorating in terms of mean arterial pressure, ICP or oxygenation can be listed for urgent liver transplantation if they fulfill two out of the three classical criteria in an attempt to increase the sensitivity of the King's criteria. The level of pH as the sole criteria at which a patient can be listed has been reduced to 7.25, reflecting improved and earlier renal support, whilst at the same time a lactate of greater than 3.5 mmol/l has become a single criterion for urgent registration.

A French group performed multivariate analysis of data from 115 patients with fulminant hepatitis B and found that a low factor V following the onset of grade III encephalopathy was the strongest predictor of a poor outcome (see Box 41.3) [177].

Both the King's and the Clichy criteria are in common use around the world. Following the publication of the King's College Hospital data the criteria were evaluated retrospectively in a French liver unit. Eighty-one non-transplanted patients with non-paracetamol induced acute liver failure were studied. The mortality rate was 0.81. The predictive accuracies, respectively on admission and 48 hours

before death, were 0.80 and 0.79 for the King's criteria and 0.60 and 0.73 for the Clichy criteria. The positive and negative predictive values, 48 hours before death, were 0.89 and 0.47 for the King's criteria and 0.89 and 0.36 for the Clichy criteria respectively. The low negative predictive values (0.36 and 0.47) indicated that neither of these could identify a subgroup with a low risk of death [178]. The additions to the King's criteria have yet to be subjected to external validation but these studies are ongoing.

While the above study compared prognostic criteria in non-paracetamol induced FHF, two recent studies compared general ICU scoring systems, the Acute Physiology and Chronic Health Evaluation (APACHE) scores, and the King's criteria for urgent liver transplantation [16, 179]. Mitchell *et al.* prospectively evaluated the APACHE II system in patients with FHF due to paracetamol poisoning. The study aimed to see whether the APACHE system is able to provide an accurate risk of hospital death in patients with paracetamol induced FHF or identify those patients needing transfer for possible hepatic transplantation and compared this to the King's College Hospital transplant criteria. A total of 102 patients were studied. An APACHE II score of >15 had the ability to predict death, which was similar to that of the King's criteria (sensitivity 82% and 65% respectively; specificity 98% and 99% respectively) when evaluating those patients who were transplanted as "deaths". An APACHE II score of >15 was able to identify four more patients than the King's criteria on the first day of admission. The calculated risk of death according to the APACHE II score, using the original drug overdose coefficient, was poorly calibrated. This is probably due to the lower incidence of potentially life-threatening drug overdoses in the original calibration population. From these data the crude APACHE II score may be able to identify non-survivors at an earlier stage than the King's College Hospital criteria.

Delays in listing patients for transplantation and in organ procurement result in further patient deterioration. This altered status results in the withdrawal of patients from the urgent list. Withdrawal of patients is based on clinical experience. However, several authors have analyzed the outcome from transplantation in FHF to help define contraindications to transplantation on the basis of poor outcome after transplantation. Devlin *et al.* used APACHE III data to look at 100 patients transplanted for FHF [16]. They found that in the paracetamol group at the time of transplantation, APACHE III score and serum bilirubin were significantly higher in the non-survivors. In the non-paracetamol group, serum creatinine, organ system failure scores, and APACHE III scores were significantly higher in the non-survivors. Bernal *et al.* studied the use of liver transplantation and the application of King's College Hospital transplant criteria in 548 patients presenting to the liver failure unit with severe paracetamol poi-

#### **BOX 41.3** The Clichy criteria in viral FHF

Coma or confusion  
and  
Factor V < 20% if under 30 years of age  
or  
Factor V < 30% if over 30 years of age

soning [180]. Of 424 patients who did not fulfill criteria, 28 (7%) died. Of 124 who fulfilled the criteria, 68 (55%) were listed for transplant, and 44 underwent transplantation. Thirty-three of the transplanted patients left hospital. Of the 80 patients who satisfied criteria but were not transplanted, nine survived to leave hospital. The reasons why patients who satisfied criteria were not listed were multiple organ failure and cerebral edema. These reasons also applied to the patients listed but withdrawn before a graft was available. In contrast to the report of Devlin *et al.*, the authors were unable to identify any preoperative factors predictive of death in the transplanted group. This suggests that patients unlikely to survive with a transplant are recognized and subsequently removed from the list. However, graft factors (identified by early markers of graft function, INR and AST) were also significantly worse in the non-survivors.

### Auxiliary OLT and regeneration

Auxiliary partial orthotopic liver transplantation holds potential advantages over conventional orthotopic liver transplantation in the setting of FHF. It has been known for many years that survivors from FHF often return to full health with normal or only slightly abnormal livers. The liver has great powers of regeneration and this has led to the introduction of partial liver transplantation in the hope of native liver regeneration and the eventual withdrawal of immunosuppression. A multicenter European study reported the results of 30 patients who underwent auxiliary transplantation for FHF [181]. After 3 months, 19 of the 30 patients survived; 13 had resumed normal native liver function with interruption of immunosuppression. The indications are not well defined, but the survivors of immunosuppression were aged less than 40 years and had FHF secondary to viral hepatitis and paracetamol poisoning.

A more recent study reported the outcomes of patients who underwent auxiliary grafting for FHF at a single center, 49 patients received an auxiliary graft, overall survival was 77% and over 50% of patients were able to be weaned from immunosuppression. Sequential post-transplant biopsies of native livers showed excellent regeneration, especially in patients transplanted for acetaminophen hepatotoxicity, where 100% native liver recovery was noted in survivors [182].

## Introduction

Liver transplantation (LT) has evolved rapidly over the past four decades. It may seem logical to consider LT recipients as a homogeneous group of patients who should be managed using universally applicable protocols, but they are a heterogeneous group of individuals, with different predisposing factors and co-factors for the development of rejection [1]. However, appropriate therapeutic approaches should be generated on the basis of evidence. In this chapter we attempt to elucidate the following:

- Do the severity, timing and number of episodes of acute cellular rejection affect prognosis?
- Is it possible to predict which patients will develop clinically significant acute rejection?
- Can immunosuppression be tailored to the individual patient?
- What is the evidence from randomized controlled trials that supports the choice of an immunosuppressive agent?
- Is it possible to withdraw immunosuppression or to change to less toxic immunosuppression?
- What is the influence of immunosuppression on HCV (hepatitis C virus) recurrence after LT?
- Does immunosuppression have a role in preventing HCC recurrence after LT?

During the past 25 years LT has become the standard therapy for acute and chronic liver failure of all etiologies. Nowadays most patients and liver grafts survive beyond the perioperative period, achieving one-year and ten-year survival rates of 90% and 65–80% respectively [2, 3]. In addition to longer survival, most LT recipients experience improved quality of life, including resumption of active

employment and reproductive capacity [4–8]. Despite these advances, LT faces several major challenges. Long-term outcome of patients is becoming the main concern for clinicians who have to deal with the side effects of immunosuppressant drugs in the long term. These include opportunistic infections that affect up to 50% of recipients, contributing to mortality in approximately 10%, and an increased incidence of *de novo* malignancy as a consequence of immunosuppression. In addition, complications arise from direct drug toxicity such as hypertension, renal dysfunction, induction of diabetes and dyslipidemias and rarely nodular regenerative hyperplasia of the liver, in patients receiving azathioprine [9–12]. The most important complication is the development of nephrotoxicity due to calcineurin inhibitors. In a series from Birmingham, 4% of patients surviving one year or more developed severe chronic renal failure, with a mortality of 44% in this group [13]. In a study on 36,849 LT recipients the cumulative incidence of chronic renal failure after LT at 12, 36 and 60 months was  $8.0 \pm 0.1$ ,  $13.9 \pm 0.2$  and  $18.1 \pm 0.2$  percent respectively [14]. In another series 6.9% had renal dysfunction within one year and 4.7% after one year, defined as a creatinine  $>1.8$  mg/dl for two weeks or more [15]. Moreover, the nephrotoxic effects, hypertension and hyperlipidemia of some immunosuppressive agents have been implicated in the pathogenesis of chronic allograft loss [16]. These problems have stimulated the re-evaluation of the ability of some patients to tolerate their liver graft without the need for long-term immunosuppression (operational tolerance), or with greatly reduced immunosuppression (prope tolerance) with the benefits derived from the return of natural immunity and reduction in drug-related toxicity [17–22].

However, at present the “manipulation” of the immune system to induce tolerance and thus significantly reduce or eliminate immunosuppression is not yet clinically viable [23–25]. Therefore, the vast majority of LT recipients need to take lifelong immunosuppressive therapy and this situation will not change until more reliable methods for

predicting and monitoring tolerance in individual patients are developed [21, 22].

## Acute allograft rejection

### Definition of rejection

Viewed from a biological perspective, the recipient's immune system is activated after transplantation but, because of the baseline immunosuppressive therapy, only some recipients will have clinical manifestations of this [26]. An important distinction has to be made between histological changes of cellular rejection, which may be seen in the absence of any significant clinical or biochemical abnormalities (biological rejection), and those accompanied by clinical signs of graft dysfunction (clinical rejection). However, abnormalities of liver function tests are almost universally present, and symptoms absent, so in the vast majority of the cases, the distinction between clinical and biological rejection, as defined above, can rarely be made in clinical practice.

### Acute cellular rejection

Cellular rejection was defined in 1995, by an international panel of experts, as "inflammation of the allograft elicited by genetic disparity between the donor and recipient, primarily affecting interlobular bile ducts and vascular endothelia, including portal veins and hepatic venules and occasionally the hepatic artery and its branches" [26].

### Clinical and laboratory findings

Most cases occur in the early postoperative period within 30 days. Late cases are usually associated with non-compliance of immunosuppressive therapy. A major problem is that the incidence varies according to whether rejection is defined on the basis of *clinically significant* rejection or simply on the basis of *histological abnormalities* or a *combination* of the two.

Clinically significant rejection occurs in approximately 50% of patients, whereas histological abnormalities can be seen in up to 80% of protocol biopsies performed at the end of the first week following transplantation [27].

Several reports have clearly indicated that standard liver tests, when elevated, have a low sensitivity and specificity for rejection and show only a weak correlation with the severity of histopathological findings [28, 29]. Various markers have been studied in an attempt to seek a specific indicator of graft rejection [30]. However, although markers of immune activation, such as peripheral eosinophilia, serum intercellular adhesion molecule (ICAM)-1 and interleukin (IL)-2 receptor are elevated, there is considerable overlap with other conditions (including sepsis and reper-

fusion injury) and none of these markers has been adopted into routine clinical practice.

Graft eosinophilia has been identified as an independently associated feature of acute cellular rejection in LT [31]. The absence of peripheral eosinophilia predicted the absence of moderate/severe histological rejection in one study [32]. However, as yet this has not been validated in other centers. Eosinophilia cannot be used to predict or to assess the response to corticosteroids for the treatment of acute rejection [32]. Therefore, liver histology remains the gold standard for the diagnosis of acute rejection [33–35].

### Histopathological features

The three main histopathological features are:

- A predominantly mononuclear but mixed portal inflammation, containing blast-like or activated lymphocytes, neutrophils and eosinophils (graded 1 to 3).
- Subendothelial inflammation of portal or terminal hepatic veins (or both) (graded 1 to 3).
- Bile duct inflammation and damage (graded 1 to 3).

In general, at least two of the above histopathological findings and biochemical evidence of liver damage constitutes the minimal diagnostic criteria for hepatic rejection. The diagnosis is strengthened if >50% of the ducts are damaged or if unequivocal endothelitis of the portal vein branches or terminal hepatic venules can be identified (see Table 42.1).

Early studies of the liver allograft rejection were focused mainly on inflammatory changes occurring in portal tracts,

**Table 42.1** Banff schema for grading of acute liver allograft rejection.

Overall grade <sup>a</sup>	Criterion
Indeterminate	Portal inflammatory infiltrate that fails to meet the criteria for the diagnosis of acute rejection
Mild	Rejection infiltrate in a minority of the triads that is generally mild and confined within the portal spaces
Moderate	Rejection infiltrate that expands most or all of the triads
Severe	As for "moderate" but with spillover into periportal areas and moderate to severe perivenular inflammation that extends into the hepatic parenchyma and is associated with perivenular hepatocyte necrosis

<sup>a</sup>Verbal descriptions of mild, moderate and severe acute rejection could also be labeled as grades 1, 2 and 3 respectively.

but also recognized the presence of inflammation involving hepatic venous endothelium and surrounding liver parenchyma [36–38]. During the Eighth Banff Conference on Allograft Pathology in 2005, the term *central perivenulitis* emerged to describe a spectrum of inflammatory regions of the liver that are in most cases thought to be a manifestation of liver allograft rejection. In cases in which perivenular inflammation occurs within the first weeks of LT and is associated with characteristic portal tract changes, the diagnosis of rejection is straightforward [39]. However in cases where portal inflammation lacks typical features of ACR the term *isolated central perivenulitis* should be used [40]. Krasinkas *et al.* demonstrated that isolated central perivenulitis is a common finding in late post-transplant biopsies and that most cases are probably related to rejection and are associated with a worse outcome compared to cases of purely portal-based rejection [40]. In 2004 Lovell *et al.* found that patients with centrilobular alterations in their first post-transplant biopsy ( $n = 15$ ) developed chronic rejection more frequently (60% vs 30%;  $p < 0.04$ ) and subsequent episodes of acute rejection (53% vs 25%;  $p < 0.04$ ) when compared to patients who did not have centrilobular alterations ( $n = 20$ ) [41].

### Grading and staging

In 1997, an international consensus on a common grading system for acute allograft rejection was achieved and subsequently it has been prospectively tested and proved to be simple, reliable and clinically relevant [42–44].

According to this Banff schema, which represents a merger and simplification of many previously published studies (see Table 42.1), there are two main components: the first is a global assessment of the overall rejection grade (indeterminate, mild, moderate, severe), the second involves scoring the three specific features of rejection semiquantitatively to produce an overall Rejection Activity Index (RAI) [45].

Datta-Gupta *et al.* showed that graft eosinophilia was an independent diagnostic marker of acute cellular rejection and it was included in the scoring system developed at the Royal Free Hospital [31].

### Role of liver biopsy and indication for treatment

The use of liver biopsy in the early post-transplant setting depends on each center's policy. Nowadays there is less uniformity regarding the use of protocol liver biopsies. This is mainly for two reasons: risks associated with the procedure and doubts about the usefulness of these biopsies to guide therapy, particularly amongst patients with normalizing transaminase values and other biochemical values [46]. However, to date, no large series has described a substantial risk associated with percutaneous liver biop-

sies in transplant recipients [46–48], and greater use of transjugular liver biopsies improves the applicability and does not increase the complication rate compared to percutaneous biopsies [49, 50].

Although it is accepted that liver histology is the gold standard and is essential for the diagnosis of acute cellular rejection, controversy continues to arise over the indications for treatment of rejection. The implication of this is that if treatment is not going to be given, why do a liver biopsy? Specifically, there is the question of the patient who has histological features of acute cellular rejection on protocol liver biopsy, with static or improving graft dysfunction. Some studies suggest that there is spontaneous resolution of mild rejection without biochemical dysfunction [51, 52]. However, abnormal liver function is more usual, and liver function tests are seldom normal at 5–7 days post-transplantation when protocol biopsies are usually done.

Bartlett *et al.* reviewed the literature concerning the natural history of acute cellular rejection, comprising 1566 patients, all of whom had protocol biopsies: 331 (21%) patients had evidence of acute histologic rejection with “normal or normalizing liver function tests” [53]. The majority (91%) of these patients did not receive adjuvant immunosuppression, and only 4% developed chronic rejection. **B3** Given these results, the authors concluded that withholding adjuvant immunosuppression from patients with histologic acute cellular rejection with “normal or normalizing liver function tests” is safe, thus not supporting the practice of protocol liver biopsies. However, the study has several limitations: the retrospective nature of the analysis of a heterogeneous group of studies, the lack of definition of “normal or normalizing liver function tests” and the lack of evaluation of histological severity of acute cellular rejection in patients without “biochemical graft dysfunction”. Before abandoning protocol biopsies, a hard look needs to be given to the evidence supporting this approach, and well designed prospective studies are necessary [54].

A further issue is that even severe histological rejection, and not only mild rejection, may resolve spontaneously and only rarely does this lead to graft loss [1, 55]. There is now evidence that the development of early rejection which responds to treatment has no negative long-term effects and may even be associated with lower risk for later immunological complications [44, 56]. Thus, the more fundamental question is how much rejection is not harmful, and therefore complete suppression of rejection is not a goal in managing immunosuppression.

### Prognostic factors

Do the severity, timing and number of episodes of acute cellular rejection affect prognosis?

### Number of episodes

In an abstract, Wiesner *et al.* evaluating a LT database with 870 patients followed for a median of three years, showed that the number of episodes of acute rejection and the histological severity were significantly associated with chronic rejection ( $p < 0.001$ ) [57]. Dousset *et al.* prospectively evaluated 170 LT patients and showed that there was no difference in graft function between patients with a single episode of acute rejection ( $n = 56$ ) and those without rejection ( $n = 84$ ) [58]. Among patients treated for a single episode of acute rejection, late hepatic function was not influenced by the severity of acute rejection, or by the response to corticosteroids. In contrast, patients with more than one acute rejection episode ( $n = 30$ ) had significant impairment of liver function tests (aspartate aminotransferase (AST)  $p < 0.05$ ; alanine aminotransferase (ALT),  $p < 0.001$ ; alkaline phosphatase,  $p < 0.01$ ), lower dye clearances ( $p < 0.01$ ), and more severe histological damage ( $p < 0.001$ ). The authors concluded that a single episode of acute rejection does not impair long-term hepatic function, whereas recurrent episodes can lead to damage to the liver allograft.

### Severity

McVicar *et al.* described a group of patients who had focal rejection in the hepatic allograft biopsy defined as lymphocytic infiltration involving less than 20% of portal tracts [59]. In the follow-up of patients showing focal or mild rejection, only six (15%) patients subsequently developed abnormal liver function tests and required treatment with additional immunosuppression for acute cellular rejection, suggesting additional immunosuppression is not needed in these patients, and close follow-up would identify the small number requiring therapy [56]. **B4**

In Birmingham, during follow-up of 151 patients to assess the effect of not treating mild acute rejection (protocol seven-day biopsies), 97 had histologically mild rejection, 50 had biochemical dysfunction and received prednisone for three days, while the remaining 47 cases with stable biochemistry had no additional treatment. Fifty-four patients with no rejection were included for comparison. The outcome at three months in all three groups was similar [27]. **B4**

Wiesner *et al.*, using the Liver Transplantation Database in a cohort study of 762 consecutive adult LT recipients, examined the association of histological severity of acute rejection and overall patient outcome [44]. They showed, using univariate analysis, that acute rejection overall, including mostly the milder grades, was significantly associated with an increased patient survival (relative risk (RR) 0.71,  $p = 0.05$ ) and a trend toward improved graft survival. Moreover, adjusting for other risk factors such as age and renal insufficiency revealed no significant decrease in survival among patients who had rejection. These findings

were similar to those of Fisher *et al.* who analyzed nine studies (comprising a total of 1473 patients), and found that there was no correlation between mortality and incidence of treated acute cellular rejection [60]. **B4**

These findings in LT are in contrast to renal transplantation in which acute rejection is significantly associated with decreased patient and graft survival. Why acute cellular rejection in LT recipients is not associated with decreased patient and graft survival remains unexplained. It is possible that acute rejection in the setting of controlled alloreactivity exerts a tolerizing effect, making the graft less susceptible to further immunological attack. However, it should be noted that successful treatment for cellular rejection occurs in nearly all cases. Thus, the correct interpretation of the finding reported above is that the occurrence and successful treatment of acute cellular rejection does not influence survival in LT patients, but it does imply that abolishing early cellular rejection need not, and indeed, should not be a goal of initial immunosuppression. This may eliminate the WOFIE period to provide some tolerance to the graft [17, 21, 22].

### Timing

As regards timing of acute cellular rejection, there is no firm consensus to define what is early or late rejection. In three different studies the timing and the outcome varied according to the definition of each center.

In a retrospective multi-center analysis of 623 LT, the cumulative incidence of biopsy proved rejection was 59% for early episodes ( $< 6$  months) and 21% for late episodes ( $= 6$  months). Patient and graft survival did not differ significantly between those who experienced an early acute rejection episode and those who did not ( $p = 0.49$  and  $p = 0.13$  respectively). Furthermore, these parameters did not differ significantly between recipients who experienced a late acute rejection episode and those who did not (patient survival  $p = 0.18$  and graft survival  $p = 0.20$ ) [57].

Wiesner *et al.* analyzed 762 consecutive adult LT recipients (Liver Transplantation Database) and found 367 (48%) who developed at least one acute cellular rejection episode within the first six weeks post-transplantation (occurring at a median time of eight days) [44]. Multivariate analysis indicated that acute cellular rejection was not significantly associated with mortality but there was a trend to better survival (RR 0.78,  $p = 0.25$ ) and re-transplantation free survival (RR 0.86,  $p = 0.44$ ). **B4** However, severe rejection doubled the risk of death or re-transplantation compared to mild rejection. Using proportional hazards modelling, in the same study, seven factors were identified as independently associated with an increased incidence of early acute hepatic allograft rejection: younger recipient age, lack of renal impairment, lack of edema, higher AST levels, fewer human leukocyte antigen (HLA) DR matches, longer cold ischemic times and older donors.

Mor *et al.* retrospectively reviewed 375 LT, and defined late onset acute cellular rejection as that which occurred after six months [61]. There were 315 episodes of early acute cellular rejection in 226 patients, and 31 episodes of late acute cellular rejection in 26 patients. Low cyclosporine levels appeared to account for 58% of these late episodes. Most episodes of rejection responded to pulse corticosteroids, and chronic ductopenic rejection arose in only two patients. There was no difference in survival between patients experiencing early and late rejection.

Anand *et al.* reviewed late onset acute cellular rejection, defining it as rejection recognized after the first 30 days post-transplantation [62]. They evaluated 717 patients who had undergone transplantation in Birmingham between 1982 and 1994: 59 (8%) patients had 71 episodes of late rejection. They, too, found that the most common precipitating event was low levels of calcineurin antagonists, and that most acute episodes of rejection in this timeframe were responsive to standard therapy. However, in contrast to Mor *et al.* [61], Anand found that 16 (27%) of 59 patients developing late onset rejection progressed to chronic ductopenic rejection and graft loss. Delayed response to an earlier episode of acute rejection, and centrilobular necrosis or bile duct loss at the time of diagnosis of late rejection, were associated with high risk of progression to chronic rejection and graft loss.

These results regarding timing, severity and number of episodes of early acute cellular rejection indicate that attempts to reduce the incidence of early acute rejection to very low levels in LT is neither necessary nor appropriate. Second, knowledge of the pathways of rejection and tolerance suggest that increased immunosuppression will inhibit the development of donor-specific tolerance, increase the incidence of immunosuppressive-related complications and result in poorer outcome [21, 22, 24]. Indeed, it is probably better not to treat certain mild, acute or other rejection episodes, and this practice is commonplace in some centers. However, randomized controlled trials are needed to provide evidence supporting this approach and to define thresholds for treatment.

### Prediction of acute rejection

Is it possible to predict which patients will develop clinically significant acute rejection?

Data from Birmingham show that there is a lower incidence of acute rejection when there is no evidence of immune involvement in the pathogenesis of the original liver disease, for example fulminant hepatic failure from paracetamol [1, 63]. In contrast, in patients transplanted for primary biliary cirrhosis and sclerosing cholangitis, in which immune-mediated damage of bile ducts is a feature of the original disease, acute rejection occurs more frequently and there is more frequent progression to ducto-

penic rejection. **B4** In 63 patients reported by Hayashi *et al.* patients with autoimmune hepatitis had more acute rejection than patients with alcoholic cirrhosis (81% vs 46.8%,  $p < 0.001$ ) regardless of the type of immunosuppression, and steroid-resistant rejection also occurred more frequently in patients with autoimmune liver disease than in patients with alcoholic liver disease (38.1% vs 12.8%;  $p = 0.003$ ) with a trend towards more chronic rejection (11.1% vs 2.1%) [64]. **B4** However, there was no difference in allograft or patient survival at one and three years. Berlakovich *et al.* evaluated 252 LT patients: those who had undergone LT for alcoholic cirrhosis ( $n = 60$ ), hepatoma ( $n = 91$ ) and posthepatic cirrhosis ( $n = 59$ ) had less acute rejection and less need of rescue therapy than patients who had received LT for cholestatic disease ( $n = 42$ ) [65]. The cumulative rates of acute rejection episodes per patient per month at six months, when 94% of all acute rejection episodes occurred, were: 0.45 for alcoholic cirrhosis, 0.55 for post-hepatic cirrhosis, 0.65 for hepatoma and 1.0 for cholestatic disease. **B4**

The group which has been consistently shown to have a lower incidence of acute and chronic rejection is chronic hepatitis B. This might reflect the underlying defect in cell-mediated immunity, which allowed the patients to become chronically infected with the virus in the first place [66, 67].

Farges *et al.*, in a retrospective analysis of 330 patients who were LT recipients for chronic liver disease, found that acute rejection (48% at one year) and chronic rejection (10% at three years) were comparable in patients who had undergone LT for primary biliary cirrhosis, sclerosing cholangitis, autoimmune cirrhosis and hepatitis C cirrhosis [66]. However, the incidence of acute (but not chronic) rejection was significantly lower in patients who had undergone LT for alcoholic cirrhosis (29% at one year), or hepatitis B virus (HBV) cirrhosis (21% at one year) and the latter also had lower chronic rejection (0% at three years).

**B4** Thus, some groups of patients can receive less immunosuppression. In particular, as HBV replication is potentiated by immunosuppression, it is also beneficial to reduce immunosuppression in these patients. However, Wiesner *et al.*, using multivariate analysis, showed that the six-week incidence of acute rejection in a cohort of 762 consecutive adult LT recipients was not dependent on the underlying disease [44].

Neuberger *et al.* showed that the percentage of patients with severe acute rejection at the liver biopsy performed seven days after the transplantation was higher among patients transplanted for HCV-related liver disease (69%) compared to other etiologies [1].

Although it is difficult to draw firm recommendations from these studies, most centers tend to lessen maintenance immunosuppression for HBV, HCV cirrhosis, alcoholic liver disease and hepatoma and/or use early steroid withdrawal, from the outset. Conversely, patients with

autoimmune hepatitis, primary biliary cirrhosis, or primary sclerosing cholangitis may need steroid maintenance and heavier initial immunosuppression.

Gomez-Manero *et al.* reviewed 133 transplanted recipients to identify predisposing factors for early ( $\leq 45$  days after LT) acute rejection [68]. No protocol liver biopsies were performed. Younger recipients, those with better hepatocellular liver function (Child A) and those who underwent transplantation for liver disease other than alcoholic cirrhosis, had a greater risk for early acute rejection. Combining these three variables, they developed a mathematical model to allow prediction of the individual risk of each patient. **B4** In our center we retrospectively evaluated a cohort of 470 LT patients who received protocol biopsies, looking at the presence of predictive factors for the absence of acute cellular rejection, during the first three months after LT. We found that the absence of rejection was associated with pre-transplant need of renal support, higher INR (International Normalized Ratio) level and a "healthy" appearance of the graft [69].

In summary, different studies have aimed to identify patients with a greater risk for developing acute rejection, but with some exceptions, they have been limited to a small number of patients and focused on a limited number of risk factors, and the results have been frequently contradictory. For this reason there is no consensus about the majority of factors predisposing to the occurrence of acute rejection after LT.

## Immunosuppression in liver transplant recipients

### Choice of an immunosuppressive agent

What evidence is there from randomised controlled trials to support the choice of an immunosuppressive agent?

#### Calcineurin inhibitors

Calcineurin inhibitors are still the cornerstone of immunosuppressive regimens. Both cyclosporine (CsA) and tacrolimus (Tac) bind to cytoplasmic receptors (cyclophilin and FK-binding protein 12 respectively), and the resulting complexes inactivate calcineurin, a pivotal enzyme in T cell receptor signaling. Calcineurin inhibition prevents IL-2 gene transcription, thereby inhibiting T cell IL production [70].

Regimens based on CsA resulted in one-year graft survival rates that exceeded 70%, but graft rejection still remained a cause of re-transplantation and death. Tac was superior to the old formulation of CsA (Sandimmune) for preventing acute rejection in three RCTs [71–73]. However, no significant benefits in mortality or graft loss were found. Thereafter, the microemulsion formulation of CsA (CsA-

ME) (Neoral) was developed improving absorption, generating new trials versus Tac [74]. Monitoring two-hour post-dose CsA levels ( $C_2$ ) has advantages over conventional trough CsA blood levels (pre-dose) ( $C_0$ ) [75].

The best evidence for comparison of the two CNI is derived from a meta-analysis of 16 RCT (nine multi-centers), including 3813 patients (1899 randomized to Tac and 1914 to CsA) (see Table 42.2) [71–73, 76–90]. The earliest three trials compared Tac with the original oil-based formulation of CsA, in the other studies CsA-ME was used [71–73].  $C_0$  was used in all RCT but one, which used  $C_2$  monitoring [89]. Prednisone was used as concomitant medication in all trials except one [83]; azathioprine (AZA) was used in nine trials (it was given only in the CsA group in four) and mycophenolate mofetil was used in four trials. The duration of the studies reached 12 months in 14 trials, and in the other two only six (77), and three months [85]. Immunosuppression with Tac reduced mortality by 15% at one-year post-LT (RR 0.85; 95% CI: 0.73–0.99), reduced graft loss by 22% (RR 0.78; 95% CI: 0.68–0.79), rejection by 18% (RR 0.82; 95% CI: 0.76–0.88) and steroid-resistant rejection by 43% (RR 0.57; 95% CI: 0.49–0.66). **Ala** New-onset diabetes occurred at a 27% higher rate with Tac (RR 1.27; 95% CI: 1.12–1.44).

The reduction in mortality associated with Tac was maintained when subanalyses of HCV patients were performed (RR 0.85; 95% CI: 0.73–0.99). **Alc** No significant differences were found in need for dialysis, or serum creatinine levels one year after LT or in the incidence of lymphoproliferative disorders. Thus, treating 100 patients post-LT with Tac instead of CsA would avoid death in two patients, graft loss in five, rejection in nine and steroid-resistant rejection in seven. Discontinuation of treatment was more frequent in patients with CsA than with Tac (RR 0.57; 95% CI: 0.49–0.66). **Ala** Neither the formulation of CsA (oil-based vs microemulsion) nor the method to guide its dose ( $C_0$  vs  $C_2$ ), affected the outcomes, although only one study used  $C_2$  monitoring.

The updated TMC study, giving data three years after randomization reported that 23.6% of patients in the Tac group and 26.2% in the CsA group had died [91]. Re-transplantation rates were 4.6% (Tac group) and 12.1% (CsA group). The primary endpoint (combined frequency, whichever occurred first, of death, re-transplantation or treatment failure for immunological reasons), was still significantly less frequent in the Tac group than in the CsA-ME (RR 0.75; 95% CI: 0.60–0.95). However, the combined endpoint of death or re-transplantation rate was not statistically different between groups. Discontinuation of CsA was more frequent than Tac (56.4% vs 33.9%,  $p < 0.01$ ). In the Tac group, a total of 62.1% of patients were alive at three years, with the original graft and still on their allocated medication, compared with 41.6% in the CsA group ( $p < 0.001$ ).

**Table 42.2** Randomized trials of tacrolimus vs cyclosporin included in the meta-analysis.

Author	Year	Groups	n	Immunosuppression		Results			
				Dose	Blood levels to maintain	Other agents	Minimum follow-up (months)	BPACR (%)	Patient mortality (%)
Fung	1991	Tac CsA-OB (C <sub>0</sub> )	41 40	0.1 mg/kg → 0.15 mg/kg 4 mg/kg → 8 mg/kg		Steroids Steroids	12	9.8 30	7.3 17.5

<sup>a</sup> Trials in which protocol biopsies were performed after transplantation: US study: days 7–28–360; Fisher *et al.*; only in HCV positive patients: month 12–24–36; Zervos *et al.*; month 12–18; Rolles *et al.*; days 5–10; Therapondos *et al.*; day 7; Martin *et al.*; month 3–12.

Tac: tacrolimus; CsA: cyclosporin; CsA-OB: cyclosporin, oily-based formulation; CsA-ME: cyclosporin, microemulsion formulation; AZA: azathioprine; MMF: mycophenolate mofetil; ATG: antithymocyte globulin; ALG: antilymphocyte globulin; BPACR: biopsy proven acute cellular rejection.

The five-year post-randomization surveillance of the Spanish multicenter RCT demonstrated no differences in overall survival (CsA-ME 76% vs Tac 66%,  $p = 0.18$ ), re-transplantation (CsA-ME 8% vs Tac 10%,  $p = 0.73$ ) or acute rejection rates (CsA-ME 33% vs Tac 26%,  $p = 0.8$ ) [92]. However, the proportion of patients switched from CsA-ME to Tac was significantly higher (CsA-ME to Tac 29% vs Tac to CsA-ME 8%,  $p = 0.01$ ), mainly due to lack of efficacy of allocated therapy. Both groups had similar occurrence of side effects, except for hyperglycemia, which was more frequent in the Tac group (CsA-ME 9.8% vs Tac 26.5%,  $p = 0.04$ ), while CsA-ME had a higher rate of severe adverse events or prolongation of hospitalization (CsA-ME 94% vs Tac 64%,  $p < 0.05$ ). In this study  $C_0$  monitoring was used.

However, in some of these trials, methodological aspects such as risk of bias in the sequence generation, baseline imbalance of the clinical factors, as well as the additional use of AZA in the CsA group and not Tac group, and the absence of defining diagnosis of rejection, suggest some caution in interpreting the magnitude of the difference between CsA and Tac.

In addition, several changes have occurred in the clinical practice since the design of these trials, such as the adoption of the  $C_2$  monitoring for CsA and the fact that AZA is now rarely used in primary immunosuppression regimens.

CNI-induced nephrotoxicity has a component of reversible renal vasoconstriction. Eventually tubulointerstitial chronic fibrosis and irreversible change result, but the interval between reversible and irreversible changes is variable [93]. Withdrawal of CNI during early stages of renal dysfunction results in improvement of renal function, but the optimal moment for conversion is not clear, although it is likely to be within six months of LT [94].

*Therapeutic drug monitoring of cyclosporine* Therapeutic monitoring of CNI is essential. CsA has a narrow therapeutic index, and an extremely variable pharmacokinetic profile and a strong pharmacodynamic linkage between desired and adverse effects.

An expert group has recommended  $C_2$  monitoring of CsA as optimal single-time point for monitoring [95]. LIS2T is an RCT that compared CsA-ME with  $C_2$  monitoring vs Tac [96], stratifying patients according to HCV status. Patients received either CsA-ME ( $n = 250$ ) or Tac ( $n = 245$ ) with steroids and some with AZA (41% CsA and 43% Tac). The primary outcome was the incidence of biopsy proven acute rejection within three months after LT: 26% CsA-ME vs 24% Tac ( $p = ns$ ). The six-month survival rate was 89% (CsA-ME) vs 88% (Tac) ( $p = ns$ ); the six-month graft loss rate was 4% (CsA-ME) vs 5% (Tac) ( $p = ns$ ). The sub-analysis of patients receiving dual or triple therapy with AZA whether with CsA-ME or Tac showed similar acute rejection rates, also between HCV-positive and HCV-

negative recipients. However, among HCV-positive patients death or graft loss at six months was significantly higher in the Tac group (15%) than in the CsA-ME group (6%) ( $p < 0.05$ ). Tolerability and safety were comparable, other than a higher incidence of diabetes mellitus (14% vs 7%,  $p < 0.02$ ) and diarrhea (29% vs 14%,  $p < 0.001$ ) in patients treated with Tac. Patients undergoing living-donor transplantation ( $n = 39$ ) in the LIS2T study showed similar results in terms of acute rejection, overall survival and graft loss between both treatments [97].

Thereafter, further surveillance in the LIS2T study with follow-up data available in 90% of patients, confirmed equivalent outcomes in trial groups as regards patient survival (85% CsA-ME vs 86% Tac), graft survival and rejection at 12 months after LT [98]. In HCV-positive patients, death or graft loss were more frequent in Tac patients (16% Tac vs 6% CsA-ME,  $p < 0.03$ ), despite HCV recurrence being similar. However, the mean time to histological diagnosis of HCV recurrence was significantly longer with CsA-ME than with Tac ( $100 \pm 50$  days vs  $70 \pm 40$  days;  $p < 0.05$ ). More patients required medication for hyperglycemia in the Tac group, regardless of diabetic status at baseline.

Annual costs were lower for CsA-ME with  $C_2$  monitoring than for Tac ( $\$5432 \pm 2091$  vs  $\$8291 \pm 3948$  respectively,  $p = 0.001$ ) in an RCT [99]. However, the annual pre-transplant and one-year post-transplant drug costs, and costs of concomitant medications were similar. Interestingly, this trial found no significant differences between Tac and CsA-ME- $C_2$  therapies in terms of one-year patient survival, early acute rejection and incidence of metabolic disorders (diabetes mellitus, hypertension and hyperlipidemia). Opposite to the previous study, Shenoy *et al.* found that recurrent HCV occurred less frequently in Tac treated patients than in CsA-ME treated ones (21% vs 61%;  $p = 0.04$ ), despite earlier recurrence (Tac  $72 \pm 42$  days vs CsA-ME  $145 \pm 43$  days,  $p = 0.006$ ) [99]. These data from a single industry sponsored study show that CsA-ME- $C_2$  provides at least equivalent immunosuppression to Tac, with similar costs, but the beneficial effects on HCV shown in the first study have not been substantiated [98].

*Dosage of cyclosporine* CsA is usually administered orally as two doses every 12 hours in LT patients. However, some patients have difficulty in achieving therapeutic  $C_0$  or  $C_2$  levels. To address this and to minimize adverse effects, conversion to once daily dosing of CsA-ME ( $75 \pm 15$  mg/day) was evaluated in 68 maintenance LT patients ( $4 \pm 1.3$  year after LT) with abnormal renal function [100]. The  $C_2$  levels ranged  $748 \pm 105$  ng/ml, without rejection episodes (although protocol biopsies were not done) and with improvement in renal function. Similar results were obtained in a non-randomized trial including 14 patients who underwent living-donor LT [101].

A randomized trial evaluated 60 post-LT patients with renal dysfunction to receive twice-daily CsA-ME vs conversion to once-daily equal dose vs conversion to once-daily reduced dose (to yield a  $C_2$  level 25–35% lower than the post-conversion  $C_2$ ) [102]. After conversion,  $C_0$  did not change, whereas  $C_2$  nearly doubled and the AUC increased by 29%. Moreover, once-daily dosing was associated with a trend to lower nocturnal mean arterial blood pressure. Thus, it has been suggested that reduction of 25–30% in the dose should be considered when conversion to once-daily dose is performed.

**Therapeutic drug monitoring of tacrolimus** Tac whole-blood trough concentration ( $C_0$ ) is routinely used to monitor therapy in most centres. As for CsA,  $C_0$  does not accurately reflect systemic exposure over the first 12 hours after dosing, for example patients with similar  $C_0$  Tac concentrations can have very different AUC due to the wide intra- and inter-subject variability in Tac pharmacokinetics [103]. Moreover, as for CsA there is no clear association between  $C_0$  concentrations and clinical outcomes. Clearance of Tac in patients in the early post-LT period is influenced by hematocrit and serum albumin, as well as concurrent medications such as diltiazem and fluconazole [104]. Thus, hypoalbuminemia and anemia, two of the most frequent clinical conditions in liver recipients, may increase the Tac clearance.

The relationship between the dose of Tac, trough concentration (enzyme linked immunosorbent assay, ELISA) and selected clinical endpoints (acute rejection, nephrotoxicity and other toxicities) were examined in a prospective multicenter study, which confirmed a poor correlation between the daily dose (mg/kg per day) and the steady-state whole-blood concentration. It suggested that to minimize nephrotoxicity without increasing the risk of rejection, it is necessary to maintain trough Tac blood concentration below 15 ng/ml [105].

In a recent study in which  $C_0$  was confirmed to be sub-optimal to monitor Tac therapy,  $C_4$  or  $C_6$  were found the best single timepoints [106]. However this study was developed and validated in patients more than six months post-LT, and thus it cannot be extrapolated to the early post-LT period when the risk of rejection is greatest and when Tac pharmacokinetics may fluctuate widely.

To improve Tac monitoring, measurement of calcineurin activity (CNA) has been proposed, and evaluated in peripheral blood mononuclear cells from 14 patients at 0, 2, 3, 4, 6 and 9 hours after Tac intake on days 8, 21 and 90, post-LT [107]. The time of maximal inhibition of CNA was reached four hours after Tac intake; this could be a means to improve Tac monitoring during the early phase post-LT, but it is difficult to envisage widespread applicability.

**Dosage of tacrolimus** A multicenter four-period crossover study showed that conversion from Tac twice a day to a

modified extended release (XL) formulation administered once-daily in the morning, led to equivalent exposure at a steady state [108]. There was less intrasubject variability with XL compared to Tac. The two-year post-conversion surveillance showed that the mean Tac whole blood trough concentration ranged from 6.2 to 6.6 ng/ml over the two years after conversion and most patients did not require dose adjustment; patient and graft survival at was 98.6% with an acute rejection rate of 5.8% [109]. Adverse effects were similar to those observed in historical cohorts with twice-a-day Tac.

**Tacrolimus rescue for acute cellular rejection** Two studies have demonstrated that Tac at levels of 15–20 mg/dl are effective as rescue therapy for steroid-resistant acute rejection in patients on CsA-based therapy [75, 110]. Moreover, a pilot study suggested that increasing Tac dosage (increments of 1–2 mg every one or two days with trough Tac blood levels of 15–20 ng/ml), and continued low doses of steroids could be considered as treatment for early acute rejection episodes (biopsy proven), including severe grades of rejection [111]. **B4** However, these higher doses of Tac (>15 ng/ml) are associated with renal dysfunction in the long-term, so that the cost-benefit of this strategy versus steroid therapy requires evaluation [105].

In summary, CNI-based immunosuppression, particularly Tac, improves the long-term graft survival in post-LT patients but renal dysfunction is frequent (9.5%) and this can worsen survival and lead to renal transplantation [13]. Reduction in CNI dosage often does not resolve this problem and suspension of CNI is often associated with increased rejection. Better use of CNI, and/or substitution with effective immunosuppressive agents without nephrotoxicity is required. The use of AZA, mycophenolate mofetil (MMF) and sirolimus with lower doses of CsA or Tac is the most commonly used strategy, as use of these agents as single drugs increases rates of rejection and graft loss [112].

### **Antimetabolites: azathioprine and mycophenolate mofetil**

Azathioprine is a prodrug form of 6-mercaptopurine which inhibits T cell activation, reduces antibody synthesis and decreases the circulating monocytes and granulocytes [113]. AZA alone is relatively effective in the prevention of rejection but has very little effect upon an established immune response [114].

Mycophenolate mofetil is a selective inhibitor of the *de novo* pathway of purine biosynthesis, thereby providing more specific and potent inhibition of T cell and B cell proliferation than AZA. It has been used for both treatment and prevention of rejection in combination with CNI (see Table 42.3) [115].

**Table 42.3** Randomized trials on MMF in liver transplanted patients.

Author	Year	Groups	Immunosuppression				n
			Dose MMF	Interval since LT	Other agents	BPACR (%)	
Fischer	2000	MMF	1 g bid	No interval	CsA + Ster + ATG	19.4	31
		AZA			CsA + Ster + ATG	40.6	32

		AZA			CsA + Ster	47.7	287
Schlitt	2001	MMF + CNI withdrawal	1 g bid	76 m (median)	± Ster	21.4	14
		CNI		90 m (median)	± Ster	0	14
Reich	2005	MMF + CNI discontinuation	1.5 g/d	16.5 m (mean)	Ster	30.0	20
		MMF + reduction 50% CNI dose		12.9 m (mean)	Ster	11.1	18
Reggiani	2005	MMF	0.75 g/d followed	No interval	Tac	75 <sup>a</sup>	12
		MMF + steroids	by 0.5 mg/d		Tac	16.7	7
Pageaux	2006	MMF + reduction ≥50% CNI dose	2–3 g/d	62.4 m (median)	± Ster	0	27
		MMF + standard CNI		68.4 m (median)	± Ster ± AZA	3.4	29
Ciccinati (Beckebaum)	2007 (2004)	MMF + low dose CNI	1 g bid	67.2 (mean)	± Ster	0	21
		MMF + full dose CNI		64.8 (mean)		0	11

<sup>a</sup>Only trial in which protocol biopsies were performed (at day 7 after transplantation). This trial was stopped due to a high incidence of acute rejection in the study group.

MMF: mycophenolate mofetil; Ster: steroids; CNI: calcineurin inhibitors; Tac: tacrolimus; CsA: cyclosporin; AZA: azathioprine; ATG: antithymocyte globulin; BPACR: biopsy proven acute cellular rejection; LT: liver transplantation.

MMF (1–1.5 g twice daily) was superior to AZA (1–2 mg/kg/d) in preventing biopsy proven acute rejection in the first six months post-LT in two RCTs, but patient and graft overall was not improved [115, 116]. **Ald** Compared with AZA, MMF has fewer myelotoxic and hepatotoxic adverse effects, but has more gastrointestinal upset including diarrhea, which affects 30% of patients but usually resolves with reducing the dose [117]. The two agents should never be used together. MMF is teratogenic and 3% of patients develop neutropenia [114]. Opportunistic infections are not significantly increased in comparison to AZA treatment. Monitoring of blood levels is not usually required. Retrospective analysis of large series of liver recipients (n = 15,133) reported better patient and graft survival, as well reduced late acute rejection rates in patients treated with MMF in addition to Tac and steroids, compared with Tac and steroids alone, again just showing that increased immunopotency results in less rejection [118, 119].

An enteric-coated formulation of mycophenolate sodium (EC-MPS) has been developed to reduce the gastrointestinal side effects by delaying mycophenolic acid (MPA, the active metabolite of MMF) release until the small intestine. Bioequivalence has been shown in renal transplantation for both pharmacokinetics [120–122], and RCT [123]. In LT EC-MPS use is limited [124, 125].

MMF has been successfully used as rescue therapy in 38 of 47 (80.9%) liver recipients with acute steroid resistant rejection, in 5 of 8 (62.5%) patients with chronic rejection, in 52 of 60 (86.7%) patients with chronic graft dysfunction and in 46 of 59 (77.9%) patients with CNI-related nephrotoxicity [126]. An RCT including 30 liver recipients who received Tac plus MMF vs Tac plus MMF plus steroids (MMF 750 mg bd for all), showed a higher rate of biopsy proven acute rejection in the former group (75% vs 17%,  $p < 0.002$ ), with similar toxicity [127]. However early acute rejection did not affect graft or patient survival. As previously mentioned, this study unfortunately did not evaluate equipotent regimes in terms of immunosuppression and just showed that more immunosuppression results in less rejection.

To date there is no clear evidence that combination of MMF with CNI improves graft or patient survival compared to CNI and steroids or AZA. Its role may be more as a renal-sparing agent. When administered to reduce the CNI dose in patients with impaired renal function or as monotherapy, acute rejection episodes occurred in 9–38% of cases after CNI withdrawal [128–130], which was more frequent when withdrawal occurred within six months [131] or 12 months [132] after LT in two RCTs, with rates of 50% [131] and 60% [132]. Later withdrawal was safe in

a retrospective review of 45 patients with renal dysfunction, treated at a median of 45 months after LT, either with MMF as monotherapy (n = 16), or in combination with low dose of CNi [133]. Therapeutic trough levels were deliberately kept < 5 ng/ml or CsA < 50 ng/ml. Acute cellular rejection was documented in only 6% with MMF monotherapy, and serum creatinine values decreased, more so in the monotherapy group compared to the combination group. Similarly, another non-controlled but prospective study introduced MMF 7.7 ± 4.3 years after LT in 49 patients with CNi-associated chronic renal failure (14 Tac, 35 CsA) [134]. Creatinine clearance increased significantly after CNi reduction (from the baseline level of 42.9 ± 14 ml/min to 48.8 ± 17 ml/min after one year and 58.4 ± 20 ml/min after three years, p < 0.0001). No acute or chronic rejection was reported. **B4**

A trial randomized 28 post-LT patients on CNi treatment (CsA or Tac) with impaired renal function (defined as >20% decline in renal function with creatinine level 1.8–4 mg/dl and/or creatinine clearance 20–60 ml/min) either to discontinuation or 50% reduction of CNi dose [129]. Both groups received MMF 1.5 g twice daily and steroids. Improvement of 15% or more in glomerular filtration rate (GFR) occurred in 64% of patients with CNi suspension and in 50% of patients with CNi dose reduction, and GFR remained stable in 36% and 37% respectively in a *per protocol* analysis. Mild or moderate rejection occurred in 30% with CNi discontinuation and in 11% with CNi dose reduction. However, no comparison was made with full dose of CNi. The same strategy was evaluated in an RCT in 32 post-LT patients who received MMF followed by stepwise reduction of CNi (n = 21) or continued CNi therapy (n = 11) [135]. Serum creatinine levels and BUN decreased significantly with MMF at three months (p < 0.01) and GFR increased (p < 0.001), and the lipid profile, blood pressure and transaminase levels also improved after introduction of MMF. No rejection episodes were observed. **Ald** However, the follow-up for some patients was very short.

Pharmacokinetic data have shown that peak concentrations and bioavailability with IV MMF are more than twice those of oral MMF, which may provide immunological advantage, but this has not been evaluated [136, 137].

Therapeutic drug monitoring of MMF is effective in preventing acute rejection in kidney and heart transplantation [138, 139]. Some evidence suggests that MPA concentrations (its active metabolite) could be used for predicting acute rejection in LT recipients [140]. However, routine monitoring of MMF has not been widely performed and dose adjustments are usually performed based on adverse effects. It is common practice to use 2 g/day or less in some LT studies rather than the 3 g/day in the renal transplant registration studies. There is great inter-individual variability of MPA pharmacokinetics, and as in the case of CsA and Tac, measurement after dosing of MMF may have a

stronger correlation with AUC, than C<sub>0</sub> monitoring [141–144]. Subtherapeutic values of MPA measured as C<sub>0</sub> and AUC have been found in approximately two-thirds of patients during the first days after LT and in one-third at months 3 and 6 post-LT, but the clinical associations with this are unclear [145].

#### mTOR inhibitors: sirolimus and everolimus

These are inhibitors of the mammalian target of rapamycin (mTOR). Their immunosuppressive activity is primarily related to the blockade of interleukin-2 and interleukin-15 induction of proliferation of T and B cells, and their synergism with other drugs such as CsA, Tac or MMF allows new combinations of therapy (see Table 42.4).

Cell growth and angiogenesis are also linked with mTOR activity; mTOR inhibition decreases HCC growth [146]. Recurrence of HCC after LT has become an important problem due to a longer recipient survival under chronic immunosuppression. Data from uncontrolled clinical studies and case reports suggest mTOR inhibitors may delay onset or reduce recurrent HCC [147–149]. A large randomized trial is taking place to clarify this issue (clinicaltrials.gov identifier NCT 00328770).

**Sirolimus** Sirolimus (rapamycin) is a macrocyclic lactone with similar structure to Tac, but its mechanism of action and adverse effect profiles are quite different. Sirolimus (SRL) blocks signal transduction in T-lymphocytes and inhibits cell-cycle progression from G1 to S phase, but does not inhibit calcineurin [150, 151].

While AZA and MMF often are used in conjunction with CNi inhibitors, since their use as single agents increases rates of rejection and graft loss [112], SRL is a promising alternative that may be equivalent to CNi in preventing graft rejection [152–154]. The adverse effects of SRL include dose-dependent hyperlipidemia, thrombocytopenia, anemia, leukopenia, with the absence of neurotoxicity, nephrotoxicity and diabetogenesis, but it has adverse effects on wound healing [155]. Risk of oligospermia in young male patients has also been reported [156].

**Sirolimus as primary immunosuppression** An international trial comparing SRL with Tac and steroids (n = 110) vs Tac and steroids alone (n = 112) in LT patients was suspended in phase II due to an increase of hepatic artery thrombosis in the SRL group (5.5% vs 0.9%) [157]. This has not been seen in non-randomized studies, but a formal warning remains on the drug information sheet [158, 159].

The first report only comprised 15 patients treated with SRL alone, or SRL plus CsA-ME, or SRL plus CsA-ME plus steroids [160]. Patients on triple therapy had no rejection, while 28% and 75% of those with dual and monotherapy, respectively had rejection. A retrospective study compared three groups: SRL alone (n = 28), SRL plus CIN (n = 56)

**Table 42.4** RCT on mTOR inhibitors in liver recipients.

Author	Year	Groups	n	mTOR inhibitor			Other agents	ACR (%)
				Dose	Blood levels at 12 months	Time from LT (months)		
Shenoy	2007	SRL conversion	20	3 mg/d (5 mg load)	6.7 ± 3 mg/dL (mean ± SD)	6–132	± AZA ± MMF ± Ster	5
		Continued CIN	20			12–144 (range)	± AZA ± MMF ± Ster	5
Watson	2007	SRL conversion	13	2 mg/d (no loading dose)	7.3 (3.8–9.9) ng/mL (median – range)	36	± AZA ± Ster	15.4
		Continued CIN	14			60 (median)	± AZA ± Ster	0
Levy	2006	Everol 1 g	28	N/A	N/A		CsA + Ster	32.1
		Everol 2 g/d	30				CsA + Ster	26.7
		Everol 4 g/d	31				CsA + Ster	25.8
		Placebo	30				CsA + Ster	40.0

Protocol biopsies were not performed in any of the three trials. In the Levy *et al.* trial, histological diagnosis of rejection was required, but not in the Shenoy *et al.* trial. The definition of ACR was not stated in the Watson *et al.* trial.

SRL: sirolimus; Everol: everolimus; MMF: mycophenolate mofetil; Ster: steroids; CIN: calcineurin inhibitors; CsA: cyclosporin; AZA: azathioprine; ACR: acute cellular rejection; LT: liver transplantation.

and CNI alone (n = 101) [161]. One-year patient and graft survival rates and histologically proven acute cellular rejection rates (no protocol liver biopsies) were not significantly different. The mean creatinine at one month was similar despite being higher in the SRL group at the time of transplantation.

Trotter *et al.* reported that low dose SRL plus CNI and minimal dose of steroids (three-day taper), resulted in less acute rejection rates than historical controls (treated with CNI plus 14-day tapered prednisone (30% vs 70%;  $p < 0.01$ ) [162]. Steroid-resistant rejection decreased by 90%. **B4** However, as in many studies the interpretation of these data is difficult as no protocol biopsies were done. McAlister *et al.* reported 56 patients who received low-dose Tac and SRL (target: trough levels, 5 and 7 ng/ml respectively) with prednisone up to six months after transplantation [159]. The biopsy proven acute cellular rejection rate was 14%, approximately 50% lower than historical controls. No patient had steroid-resistant rejection. Pridohl *et al.* reported patients transplanted for acute liver failure with triple immunosuppression (SRL, Tac and steroids); acute rejection and steroid-resistant rates were 14% and 0% respectively [163]. Some authors have suggested that SRL should be used in combination with low dose Tac to minimize adverse effects from either drug, whilst avoiding an increased risk of rejection [164, 165].

Dunkelberg *et al.* reported 170 LT recipients treated with SRL (2 mg/day) as part of primary immunosuppression [158]. One-year patient (93%) and graft survival rates (92%) were not different from historical controls (95% and 89%

respectively). The acute rejection rate and use of OKT3 (monoclonal antibody against CD3, muromonabCD3) was significantly lower in SRL-treated patients (14%) versus controls (39%), similar to a previous report [162]. However, the proportion of patients needing OKT3 was very high, both in the controls and SRL-treated groups, so that the precise immunosuppressive endpoints are difficult to compare with other publications. Hepatic artery and wound complications in SRL-treated patients were similar to historical controls.

Further studies are needed to assess the value of SRL as primary immunosuppression after LT, either as a single agent or in combination with other agents.

**Conversion from CNI to sirolimus** Chronic renal dysfunction occurs in approximately 18% of LT recipients by five-year post-LT and several patients develop end-stage renal disease which shortens patient survival [14]. In contrast to CNI, neither nephrotoxicity nor neurotoxicity has been described with SRL [155], so that it has been used in liver recipients with renal dysfunction, in order reduce or stop CNI, as well as for neurotoxicity or chronic rejection.

The first RCT assessing CNI withdrawal and replacement with SRL allocated 40 liver recipients with CrCl between 40–80 ml/min, to receive either SRL or continued CNI [166]. The mean SRL concentrations at one, three and twelve months were  $9 \pm 3.1$ ;  $7.7 \pm 1.9$  and  $6.7 \pm 3$  mg/dl respectively, with a mean dose throughout of 3 mg/day. Early improvement in CrCl was seen at one and three months in SRL patients: 75 ml/min SRL vs 61 ml/min con-

trols,  $p = 0.024$  at one month and 75ml/min SRL vs 56 ml/min controls,  $p = 0.012$  at three months. However, at 12 months the difference was not significant: 72ml/min SRL vs 58ml/min controls,  $p = 0.09$ . **Ald** This could be because the conversion was too late, at a mean of 4.4 years after LT. The incidence of acute rejection was 5% in both groups and there was no significant difference in lipid profile.

Similarly, another RCT allocated 27 liver recipients with GFR < 65ml/min, to remain on CNI therapy (86% Tac, 14% CsA) or to switch to SRL based immunosuppression [94]. Renal function was measured by the change in  $^{51}\text{Cr}$ -ethylenediaminetetraacetic acid GFR (delta GFR). The median time from LT to randomization was three years (0.88–7.4). The median whole blood SRL concentrations were 6.3ng/ml at three months and 7.3ng/ml at 12 months. Tac median 12-hour trough concentrations were 7.7 at three months and 7ng/ml at 12 months. Mean CsA concentrations at three and twelve months were 86 and 107 and 147ng/ml. Conversion to SRL led to a modest but significant improvement in renal function at three months after conversion, but the difference was not significant at one year. **Ala** No significant differences in serum creatinine were found. No acute rejection was diagnosed in patients with CNI, while it occurred in two patients (15%) on SRL. Adverse effects were similar except for rash and hypercholesterolemia requiring new statin therapy in the SRL group.

These data suggest that conversion to SRL can be done safely and provide adequate immunosuppression without increased incidence of rejection, graft loss or infection in LT recipients. However, there is no evidence as yet for long-lasting renal improvement. Moreover it is not clear if Tac dosing was reduced to a minimum as therapeutic concentrations could still be measured in blood. Multicenter randomized trials including larger groups, in particular, with much earlier conversion intervals, minimal Tac dosing, as well as longer follow-up, are needed to address the benefit of conversion to SRL. Lastly, the hypercholesterolemia induced by SRL may affect cardiovascular risk despite use of statin agents.

**Everolimus** Everolimus is a rapamycin derived compound with improved bioavailability and shorter half-life than SRL (18–35 hours vs 60 hours). Experience with everolimus in liver recipients is more limited than that with SRL. It has lower rates of acute rejection than those seen with AZA in heart transplants and similar to MMF in kidney transplants and may result in less cytomegalovirus infection [167, 168]. It inhibits the growth of human Epstein-Barr virus-transformed B lymphocytes *in vitro* and *in vivo*, so it may be optimal when treating post-transplant lymphoproliferative diseases or for prevention [169]. CsA increases exposure to everolimus.

Levy *et al.* performed a randomized placebo-controlled trial evaluating everolimus combined with CsA (target trough level of 150–400ng/ml) and prednisone in liver recipients [170]. Three different doses of everolimus were compared: 0.5mg bid ( $n = 28$ ) vs 1mg bid ( $n = 30$ ) vs 2mg bid ( $n = 31$ ) vs placebo ( $n = 30$ ). Biopsy proven acute rejection episodes were: 39.3% (0.5mg); 30% (1.0mg); 29% (2mg) vs 40% placebo, all non-significant. Rejection was three-fold higher when levels were  $\leq 3\text{ng/ml}$ . Overall graft and patient survival rates and renal dysfunction and its severity were similar across groups. However, the small sample size and high drop-out rates prevent robust conclusions. Larger RCTs are required.

### Anti-CD3 pan-T cell (orthoclone OKT3)

Muromonab-CD3 (OKT3) is a monoclonal antibody with defined specificity to the CD3 receptor of T cells, thus inactivating both naive and activated cytotoxic T cells. It has been used to prevent acute rejection and to reduce CNI dosage [171, 172]. It was the first monoclonal antibody preventing liver graft rejection. Re-exposure to OKT3 can result in lower efficacy due to the development of antimurine antibodies. There is increased risk of developing post-LT lymphoproliferative disorders and its use is associated with worse recurrence of HCV.

Randomization of 52 LT patients to receive either CsA + AZA + steroids or AZA + steroids + OKT3 followed by conversion to CsA at 14 days, showed lower incidence of acute rejection within two weeks after LT (41% vs 72%,  $p < 0.02$ ) as well as better renal function in the OKT3 group [173]. Nevertheless, long-term follow-up showed similar rejection rates at 30 days post-LT and similar renal function at 6, 12 and 24 months [174]. **Ald** A trial comparing OKT3 ( $n = 44$ ) vs a IL-2 receptor antibody (LO-Tact-1) ( $n = 43$ ) vs no induction ( $n = 42$ ) in liver recipients on treatment with CsA, AZA and steroids, showed that both agents significantly reduced acute rejection with fewer CMV infections in the LO-Tact-1 group [175]. These results, as well as improved use of current immunosuppressives, make OKT3 less likely to be used as induction therapy.

### Interleukin-2 receptor blockers: daclizumab and basiliximab

T-lymphocytes play a central role in the initiation and progression of the rejection response. Activated T-lymphocytes secrete IL-2 that acts in an autocrine and paracrine fashion to drive the response forward, and produces more IL-2 receptors (IL-2R). As only activated T-lymphocytes express IL-2R, blocking this receptor with a monoclonal antibody provides a highly selective approach to prevent rejection [176]. Daclizumab and basiliximab are chimeric and humanized antibodies that act on a receptor subunit, which is expressed only on activated T-lymphocytes, thus selectively inhibiting their proliferation. However, due to

**Table 42.5** Randomized trials on IL-2 blocker in liver transplanted patients.

Author	Year	Groups	n	Dose IL-2 blocker	BPACR (%)
Boillot	2005	Daclizumab + Tac	351	2 × 2 mg/kg IV pre-reperfusion – 1 mg/kg between day 7–10	25.4
		Tac + Ster	347		26.5
Yoshida	2005	Daclizumab + Low Tac + MMF + Ster	72	2 mg/kg IV 4 h post-LT – 1 mg/kg IV day 4	23.2
		Full Tac + MMF + Ster	76		27.7

		Basiliximab + CsA + Ster	90		38.1
Llado	2006	Basiliximab + CsA	96	20 mg IV day 0 and 4	18
		Basiliximab + CsA + Ster	102		13

<sup>a</sup>Only trial in which protocol biopsies were performed (at month 12 after transplantation).

MMF: mycophenolate mofetil; Ster: steroids; CsA: cyclosporin; AZA: azathioprine; BPACR: biopsy proven acute cellular rejection; LT: liver transplantation.

some redundancy within the IL-2R complex, which permits the IL-2R signalling despite the use of these antibodies, they have to be used together with other agents, such as CNI (see Table 42.5).

A pilot study evaluated the daclizumab (1 mg/kg IV, immediately pre- and post-operatively and four more doses at two-week intervals), combined with MMF and steroids, without use of CNI [177]. The study was stopped after the first seven liver recipients due to a 100% incidence of acute rejection, with 57% being steroid resistant. In contrast, retrospective analysis of 25 patients receiving the same therapy but with CNI had a rejection rate of 36% [24].

Considering the sequence of events in graft rejection in LT [24], immunosuppression with IL-2R blockers could play a role at the very beginning, leaving the introduction of CNI to a point when these agents can be introduced without excessive risk of infection or renal dysfunction, that is, monotherapy with IL-2R blockade for the first to second week and then monotherapy with CNI or other drugs.

**Daclizumab** A multicenter randomized trial assessed daclizumab as a steroid avoiding agent in 347 patients receiving Tac plus steroids against 351 patients on steroid-free regimen with Tac following daclizumab induction (follow-up three months) [178]. Acute rejection proven by biopsy that required treatment was similar, as well as graft and patient survival. The daclizumab group had less corticosteroid-resistant acute rejection (6.3 vs 2.8% respectively,  $p = 0.027$ ), less diabetes mellitus and CMV infection, without increased renal toxicity. **Ald**

In a multicenter, pilot study, 102 liver recipients were treated with daclizumab (2 mg/kg within six hours follow-

ing transplant and 1 mg/kg on day 7), MMF and Tac [179]. Acute rejection proven by biopsy was 9.8% at six months (none graded as severe) and 11.8% after 12 months. Patient and graft survival rates at six months were 96% and 95% respectively. Infections, hypertension, diabetes mellitus and hypercholesterolemia occurred in 22%, 37%, 14% and 2% of patients respectively. **B4** Thus, a steroid-free regimen using daclizumab, MMF, and Tac may prevent the occurrence of acute rejection without decreasing safety.

An RCT compared renal function in liver recipients treated with daclizumab (2 mg/kg IV within four hours postoperatively and 1 mg/kg IV on day 4 postLT) and delayed low-dose Tac (starting day 4–6) ( $n = 72$ ), vs those treated with standard Tac regimen without induction ( $n = 76$ ) [180]. Both groups also received MMF and tapering steroids. The GFR was significantly better in the daclizumab group during the first week after LT, but this was not maintained during the 12 months follow-up. **Ald** Patient survival and acute rejection rates were similar. Therapy with daclizumab and delayed CNI may not have long-term benefits.

A large series of 209 LT patients receiving daclizumab induction (2 mg/kg intraoperatively and 1 mg/kg on day 5 post-LT) was compared with 115 patients without induction therapy [181]. Despite the delayed initiation of CNI in the daclizumab group, there was less acute rejection within six months (25% vs 39%;  $p = 0.01$ ). Moreover, patients on daclizumab with pre-LT creatinine levels  $>1.5$  mg/dl showed sustained improvement of renal function, while it worsened in those without daclizumab. However patient and graft survival and the chronic rejection rates were not significantly different, again questioning whether long-

term benefit accrues. **B4** Currently, daclizumab has been withdrawn from the market.

**Basiliximab** Calmus *et al.* evaluated 101 patients treated with basiliximab (20mg dose on day 0 and 4) in conjunction with CsA (adjusted according to therapeutic levels), AZA (1.5mg/kg per day), and steroids (tapering from 200mg/day to 5mg/day) [182], and compared these with a historical cohort derived from Multicentre International Study in Liver Transplantation of Neoral (MILTON) [183]. One-year patient and graft survival rates were 90.1% and 88.1% respectively. Biopsy-confirmed ACR with basiliximab was 22.8% and none was severe. Malignancies, infections or other adverse effects were not increased. Rejection episodes were more frequent in HCV positive compared to HCV negative patients (29% vs 20%,  $p = \text{ns}$ ). **B3** Basiliximab in association with Tac and steroids similarly prevented ACR in live donor liver recipients, with a rejection-free probability of 93.5% within three months and 93.8% patient survival rate at three years [184, 185]. Neuhaus *et al.* reported an RCT comparing basiliximab ( $n = 188$ ) or placebo ( $n = 193$ ) in addition to CsA and steroids [186]. There were no protocol biopsies, but clinically suspected rejection was confirmed by liver biopsy. Within six months, acute rejection rates were 35.1% basiliximab and 43.5% placebo ( $p = \text{ns}$ ). Rejection rates in HCV positive patients were slightly more in basiliximab treated patients (39.1% vs 36.2%,  $p = \text{ns}$ ). Complications including infections were similar. **Ald** The greater rejection rates in HCV positive patients might result from false positive reporting linked to histological similarities between recurrent hepatitis C and acute rejection [187]. However, caution is needed in HCV infection, as adjuvant IL-2R antibodies combined with MMF in the early peritransplantation period was associated with early recurrence of hepatitis C and more rapid histological progression of disease in another study [188].

An RCT evaluated 198 liver recipients (45% HCV-positive) treated with basiliximab as induction therapy with CsA as maintenance immunosuppression, 102 of whom received steroids and 96 were steroid-free [189]. Biopsy-proven ACR, patient and graft survival, and infection rates were similar, including in HCV versus non-HCV subgroups. Diabetic patients in the steroid group had significantly more bacterial infections. The incidence of *de novo* hypertension and hypercholesterolemia was comparable at six months. **Ald**

In another multicenter trial treated initially with basiliximab, CsA and steroids were allocated to receive maintenance therapy either with CsA and steroids ( $n = 90$ ) or steroid withdrawal at day 14 ( $n = 84$ ) [190]. Biopsy-confirmed rejection and treated acute rejection by six months was higher in the steroid-free group (38.1% vs 24.4%,  $p = 0.03$ ). Metabolic complications were similar.

These results were also similar at 12 months follow-up. Acute rejection was easily controlled in most patients and did not affect graft survival. **Ald**

Non-randomized studies suggest basiliximab induction may allow delay in introducing CNI and reduced CNI dosage, thus improving renal function as well as reducing acute rejection. A prospective study included adult living donor LT (LDLT) recipients assigned to either basiliximab induction (Tac delayed until renal function improved;  $n = 27$ ) or conventional immunosuppression without basiliximab (Tac started on the first day post-LT;  $n = 18$ ) [191]. Patients in the induction group were in worse condition pre-LT and had a higher blood loss and transfusion. The serum creatinine levels at the second and third months post-LT were lower in the induction group ( $p < 0.05$ ). Renal insufficiency (an increase of  $\geq 0.5\text{mg/dl}$  in serum creatinine over the baseline value, or an increase of  $>50\%$  over baseline, or a reduction of 50% in calculated creatinine clearance, or need for dialysis) at the third month post-LT was lower in the induction group (26% vs 67%,  $p = 0.007$ ). Acute rejection at six months, as well as infections and diabetes mellitus were similar, and the median cholesterol level was lower in the induction group (152mg/dl vs 196mg/dl,  $p = 0.03$ ). **B3** However, the lack of randomization, the small number of patients and the short follow-up, negate robust conclusions. The same considerations pertain to 31 patients (94% chronic hepatitis B carriers) treated with basiliximab with steroid withdrawal 24 hours after LT and reduction of Tac dosage, which showed similar findings compared to historical controls [192].

### Anti-thymocyte globulin

Anti-thymocyte globulins are heterologous preparations consisting of polyclonal anti-lymphocyte antibodies. A rabbit derived polyclonal antibody (RATG) was shown to be an effective immunosuppressive agent in LT [193]. The role of RATG in LT has been evaluated as a CNI sparing agent [194], or to delay CNI administration in patients with renal dysfunction [195], to reduce or eliminate steroid use [196], or to avoid maintenance immunosuppression [197]. Moreover, its ability to selectively deplete T cells has been used for both prophylaxis and treatment of acute cellular rejection *per se*.

In conjunction with steroids, RATG reduced rejection without increasing infectious complications or malignancy [193, 198]. Eason and colleagues randomized 71 liver recipients to induction therapy with either RATG ( $n = 36$ ) or steroids ( $n = 35$ ) with maintenance Tac and MMF, with or without prednisone [196]. The rate of biopsy proven rejection was not significantly different: 20.5% RATG vs 32% steroids. However, the RATG group had less rejection needing steroids ( $p = 0.01$ ), without increased complications, in particular cytomegalovirus infection, diabetes and HCV recurrence. A follow-up of these patients and data on

additional patients undergoing steroid-free OLT confirmed these results [199]. **Ald**

Starzl *et al.* reported using RATG (5mg/kg) as pre-treatment therapy in 82 solid organ transplant recipients (17 LT) followed by minimum use of post-transplant immunosuppression (Tac monotherapy during the first four months, then spaced Tac therapy) [198]. Graft survival rates were 89% at one year and 88% at 13–18 months. RATG enabled 57.5% of recipients with surviving grafts to be maintained with spaced doses of Tac monotherapy from four months. **B4**

A retrospective analysis of 198 liver recipients, 118 receiving RATG and delayed initiation of CNi, and 80 receiving no antibody and early initiation of CNi, showed that delayed CNi initiation with RATG significantly improved serum creatinine levels and GFR, with similar patient and graft survival [200]. Overall infection and cytomegalovirus infection rates were significantly lower with RATG, with less early biopsy-proven acute rejection (16% vs 26%,  $p = 0.08$ ). Another comparison between 129 liver recipients with CNi immediately after LT vs 262 with CNi after initial short-term RATG induction, showed that by one year acute rejection rates were significantly lower in RATG treated patients (14.5% vs 31.8%,  $p = 0.0008$ ) [201]. Again, serum creatinine levels and GFR were better in the RATG group, with no additional harmful effects. Undesired side effects occurred at a similar rate in both groups. **B3**

Use of a three-day ATG induction therapy regimen after LT has been promoted as it results in no more rejection than a ten-day course, while reducing the adverse effects, especially lethal infection [202].

### Anti-CD52 (alemtuzumab)

New protocols of tolerogenic preconditioning have been developed using alemtuzumab (Campath-1H) and low doses of CNi. Alemtuzumab is a humanized monoclonal antibody directed against the CD52 antigen, a pan T, B and natural killer cell, and monocyte markers [203]. It rapidly depletes lymphocytes, monocytes and other cells without affecting neutrophils and hematopoietic stem cells. The depleted cells begin to re-emerge gradually during a period of six months without returning to baseline levels. This activity is believed to prevent an aggressive lymphocytic immune response after transplantation and allow a more gradual engagement of the host immune system under low conventional immunosuppression. This regimen of host conditioning prior to transplantation, followed by minimum post-transplant immunosuppression could increase the chance of developing tolerance [21, 22, 204–207].

The most extensive experience with the use of alemtuzumab in solid organ transplantation has been done in kidney transplantation [17, 208], as well as intestinal and multivisceral transplantation [209], in which treatment with

Campath-1H and low dose of CNi has shown encouraging results.

The outcome of 77 liver recipients treated with Campath-1H and low dose Tac, with steroid-free maintenance, compared with 50 patients treated with Tac and steroids (HCV patients excluded), showed no differences in patient and graft survival, while rejection-free survival was higher in the Campath-1 group: 51% vs 65% at 12 months,  $p = 0.009$  [23, 210]. Tac-related nephrotoxicity and mean creatinine levels were higher in the control group ( $p = 0.0001$  and  $p < 0.05$  respectively). **B3** No differences in viral infection rates were found. Thus, Campath-1 may be at least as effective, as Tac and steroid regimens, with less renal toxicity, but long-term follow-up is needed, especially with regard to risk of malignancy.

A similar study evaluated 76 liver recipients (50% HCV positive) treated with Campath-1 induction and low-dose Tac compared to 84 patients (31% HCV positive) receiving standard immunosuppression [211]. No differences in rejection or patient and graft survival were found at one year. However, HCV positive patients did significantly worse than those who were HCV negative, both in the induction and the control group. Moreover increased HCV viral replication was worse with Campath-1. **B3** Until now, optimal dose of Campath-1 and ideal combinations of maintenance immunosuppression remain to be determined and the effect on HCV recurrence documented. Its use as a primary treatment for rejection has not been studied. Randomized-controlled trials addressing these issues need to be performed.

### Ursodeoxycolic acid

Ursodeoxycholic acid (UDCA) is a hydrophilic bile acid which may improve parenchymal function in cholestatic states and possibly slow the progression of primary biliary cirrhosis [212, 213]. Additionally, UDCA reduces the expression of major histocompatibility complex (MHC) class I antigens in patients with primary biliary cirrhosis and therefore may have immunomodulatory effects on T cell-dependent liver damage [212–214]. During acute cellular rejection, MHC class I and II antigens are expressed on hepatocytes, although these are not primary target cells. Cholestasis itself may induce an increased expression of MHC class I antigens on hepatocytes, which can lead to lymphocyte CD8<sup>+</sup>-dependent cytotoxicity [215]. Based on these theoretical considerations, UDCA might decrease acute cellular rejection episodes in LT patients.

There are seven randomized controlled trials involving 335 liver recipients which evaluated UDCA or tauro-UDCA for prevention of acute allograft rejection (see Table 42.6) [216–222].

All seven trials failed to demonstrate that UDCA prevented the occurrence of acute rejection, confirmed by a

**Table 42.6** Randomized trials on ursodeoxycholic acid in liver transplanted patients included in the meta-analysis.

Author	Year	Groups	n	Immunosuppression			Results	
				Dose UDCA	Duration UDCA (First dose- Maintenance)	Other agents	ACR (%)	Patient Mortality (%)
Sama	1991	UDCA	20	600 mg/kg	5–7 d after LT – 6 months	Steroids + CsA	65.0	25.0
		No treatment	20			Steroids + CsA	65.0	30.0

		No treatment	15			Steroids + AZA + CNI	58.8	11.8

<sup>a</sup>Trials in which protocol biopsies were performed after liver transplantation: Keiding *et al.*: days 7–21–90–365; Barnes *et al.*: day 7 and month 3.

UDCA: ursodeoxycholic acid; TUDCA: tauro-ursodeoxycholic acid; CNI: calcineurin inhibitors; CsA: cyclosporin; AZA: azathioprine; ACR: acute cellular rejection.

meta-analysis of six trials [223]: acute cellular rejection (RR 0.89; 95% CI: 0.74–1.08), mortality, re-transplantation or steroid-resistant rejection were not improved. **Ala**

Assy *et al.* [224] performed a further RCT evaluating whether UDCA decreased rejection after total immunosuppressant withdrawal, in 26 liver recipients, free of rejection while on immunosuppressive agents for a minimum of two years after LT. They were randomized to UDCA (15 mg/kg) (n = 14) or placebo (n = 12) followed by sequential withdrawal of their immunosuppression over several months. Rejection and its severity were no different: UDCA 43% vs control 75% (p = 0.09) nor in the severity of the rejection. **Ald**

### Granulocyte-colony stimulating factor

Studies in animal models as well as clinical trials have demonstrated significant benefits of human recombinant granulocyte-colony stimulating factor (G-CSF) for the treatment of infections in bone marrow recipients, while the experience in solid organ transplantation is more limited. G-CSF used for the first 7–10 days resulted in less acute rejection in 37 liver transplant recipients, compared with historical controls (n = 49) receiving the same immunosuppressive protocol (22% vs 51%). This could be related to a significant reduction in serum TNF levels, which may

be a key player in allograft rejection [225, 226]. However, a subsequent multicenter randomized placebo-controlled trial comprising 194 patients did not confirm reduced infection rates and biopsy proven rejection was more common in the G-CSF treated group compared with placebo (30% vs 19%) [227]. **Ald**

### New immunosuppressive agents

Leflunomide is a member of malononitrilamide family which targets the *de novo* pathway of pyrimidine biosynthesis and thus inhibits T and B cell proliferation. A retrospective review of the use of leflunomide was carried out in 8 liver and 45 kidney transplant recipients [228]. CNI were stopped completely in four liver recipients and reduced by 65% in another patient. No evidence of acute rejection developed in any of these liver (or kidney) transplant patients.

FK778, a synthetic derived from leflunomide, has been developed to reduce the extended half-life of leflunomide (6–45 hours vs 15–18 days) [229]. Studies in LT are awaited.

FTY 720 is a unique immunosuppressive agent that not only inhibits lymphocyte proliferation, but also results in a redistribution of lymphocytes into lymph nodes and out of circulation. This ability of FTY 720 to impair effector T cell homing is achieved without affecting induction or

expansion of memory responses, suggesting that it may leave tolerizing interactions intact [230]. Studies in human LT are awaited.

Janus kinases (JAK) are intermediaries between cytokine receptors and STAT, which result in activation of the immune cells. JAK-3 may be an excellent target for clinical immunosuppression due to its requirement for signaling by multiple cytokines. JAK3/STAT inhibitors in animal models lead to immunosuppression to prevent rejection, without inducing many of the side effects observed with other current therapies [231]. Human studies are awaited.

### The future immunosuppression in liver transplantation

Future immunosuppressive strategies will be designed to help the development of tolerance of the allograft, selectively stimulating and/or minimally suppressing the recipient's immune reaction. Studies of the current immunosuppressive agents suggest two ways in which this goal might be attained. First, CNi dosage minimization or even avoidance will continue to be the focus of future studies, to avoid adverse effects and too much rejection. Second, use of new selective immunosuppressive agents which do not depress tolerizing mechanisms or even enhance them, while avoiding side effects, need to be developed [21, 22]. Both approaches need an easy method to assess immunopotency of the immunosuppressive agents and/or a measure of tolerance. The surrogate markers of blood concentrations of immunosuppressives in current use relate more to avoiding toxicity than to issues of rejection or tolerance. These new assays would allow personalized medicine, by individual tailoring doses of immunosuppressive therapy, depending on "day-to-day" immune status.

## Weaning immunosuppression

### Steroid withdrawal and steroid avoidance

Steroids have been the cornerstone of immunosuppressive regimens since the inception of solid organ transplantation. In the past two decades immunosuppressive protocols have evolved driven by a deeper understanding of immunological events after transplantation, and more focus has been placed on minimizing the multitude of side effects and toxicities associated with a long-term therapy with steroids (renal function, infectious risk, loss of bone density, diabetes, hypertension, hyperlipidemia, etc.). The trend has been to use fewer steroids for maintenance therapy. In 2000, a series showed safe withdrawal from the third post-operative month, but the duration of steroid use after LT and the potential role of complete steroid avoidance remain uncertain [232].

Studies evaluating steroid-withdrawal and steroid avoidance in LT are heterogeneous, especially with regards to the interval at withdrawal (1 day–9 months). The major-

ity of protocols utilize regimens based on MMF in conjunction with Tac and the proportion of studies using CsA is lower compared to those using Tac. However, many protocols utilize antibody induction agents such as daclizumab, basiliximab and rabbit-derived antithymocyte globulin, thus increasing immunopotency.

**Steroid withdrawal** Steroid withdrawal based on Tac-containing regimens showed comparable patient and graft survival to protocols using maintenance immunosuppression with steroids; one study found that histology-proven acute rejection was less with steroid withdrawal compared to a steroid regimen (6% vs 27%;  $p = 0.001$ ) [192, 233, 234]. Infection was less amongst patients who underwent steroid withdrawal (0% vs 18%;  $p = 0.001$ ) and two studies showed significant reduction in the onset of diabetes mellitus amongst patients who stopped steroids (Table 42.7) [192, 234]. **B3**

Pageaux *et al.* evaluated the impact of steroid withdrawal based on a CsA-based regimen in 174 patients, randomized to receive CsA and prednisolone ( $n = 90$ ) or CsA and placebo ( $n = 84$ ) [190]. Histologically proven acute rejection at six months was significantly more frequent among patients without steroids than patients on prednisolone (38.1% vs 24.4%;  $p = 0.03$ ). However, patient and graft survival were similar between the two groups, as well as infection rate, diabetes and hypertension. **Ald**

Greig *et al.* evaluated the safety and efficacy of early steroid withdrawal, comparing 71 patients treated with Tac to 72 patients treated with CsA-ME. They found that patients on Tac had a statistically significant better patient and graft survival (97% and 97%) compared to patients on micro-CsA (89% and 86% respectively) [86]. Acute rejection occurring during the first year was similar (35% with Tac and 43% with micro-CsA), and no chronic rejection developed during this period, presumably because of the short follow-up. **B4**

**Steroid avoidance** Several studies have evaluated the safety and efficacy of steroid avoidance in liver transplanted patients (see Table 42.8) [127, 178, 189, 196, 235–247].

No study found statistically significant differences in patient and graft survival comparing steroid-free and steroid inclusive regimens, but these studies are heterogeneous with a range of evaluation time between three months and five years, and often evaluated increased immunosuppression in the steroid free groups. **B4**

Two studies found statistical differences in biopsy-confirmed acute rejection rates [127, 235]: 24.3% with steroids vs 39.4% without ( $p = 0.04$ ) [235], and 16.7% steroids vs 75% no steroids ( $p = 0.002$ ) by Reggiani *et al.* [127]. In contrast, Varo *et al.* reported patients on steroids having a higher acute rejection rate compared to patients on steroid-free regimen (11.5% vs 26.6%;  $p = 0.01$ ) [240].

Patients following regimens without steroids experienced a lower incidence of infections (28% vs 52%;  $p = 0.03$ ) [242], a lower diabetes mellitus rate (7% vs 43%;  $p = 0.02$ ) [237], and a lower incidence of hypertension (25% vs 44%;  $p = 0.006$ ) [189] after LT compared to those using steroids.

**B4** Segev *et al.* performed a systematic review of 19 individual studies and 11 updates of these, comparing steroid-free to steroids-based protocols in liver transplanted recipients [248]. There was no difference in survival, graft loss or infection rates. There was a significant reduction in serum cholesterol, risk of CMV infection and HCV recurrence in the steroid-free group. However, the heterogeneity, short-term follow-up and relatively small size of many randomized controlled trials included in this meta-analysis and the lack of evaluating steroid dosage make the conclusions less robust. **A1c** Moreover, since in 19 individual studies, nine had replaced steroids with another immunosuppressive agent (one basiliximab, five daclizumab, one thymoglobulin and two MMF) and six studies had administered perioperative steroids (one or two doses) to the steroid-free arm, the real impact of steroid-free regimens on outcome after LT has not been evaluated properly.

However the data available on steroid withdrawal and/or steroid avoidance in LT recipients, do show at least comparable results to maintenance immunosuppressive protocols including steroids. **B3** Thus, steroids can be either avoided completely or withdrawn without significant sequelae. However, the long-term consequences of steroid avoidance remain unclear. Long-term follow-up studies are needed to explore more fully the benefits of steroid withdrawal and/or steroid avoidance in liver transplanted patients, particularly those transplanted for HCV related cirrhosis.

### Total withdrawal of immunosuppression

The main aspiration of transplant clinicians is the acceptance of the graft by the recipient without any long-term pharmacological help [17, 21, 22]. Long-term survivors following LT recipients are often systematically and excessively immunosuppressed. Consequently, drug weaning is an important management strategy, providing it is done gradually under careful physician surveillance. Only a few studies have reported cohorts with total withdrawal (see Table 42.9).

In 1998 Devlin *et al.* evaluated 18 adults with uneventful post-LT follow-up and showed that it was possible to either completely withdraw (5/18 patients) or significantly reduce (9/18 patients) maintenance immunosuppression to levels previously considered subtherapeutic [18]. Parameters associated with successful drug withdrawal were transplantation for non-immune-mediated liver disorders, fewer donor-recipient HLA A, B and DR mismatches, and low incidence of early rejection. In 13/18 immunosuppression was recommenced due to elevated

liver function tests, but only 4 out of these 13 patients had a histologically proven acute rejection. In a recent update of this study one patient out of the five successfully withdrawn from immunosuppression, developed chronic rejection and required re-transplantation, while in another patient immunosuppression was restarted due to low-grade rejection [249]. **B4**

Takatsuki *et al.* described 63 living donor LT recipients receiving Tac: 26 were entered in an elective program of withdrawal, while in the remaining 37 withdrawal was due to serious complications of immunosuppression [250]. In 24 patients, 6 from the elective cohort, Tac was stopped with a median drug-free period of 23.5 months. Rejection occurred in 16 patients (25.4%) after a median interval of 9.5 months, but all episodes were treated by reintroducing Tac or with short courses of steroids. In a later update of this study, the number of patients included in elective weaning increased to 67, with almost similar results (23.8% success and 12% acute rejection) [251]. **B4**

Contrasting with previous results, Eason *et al.* only achieved immunosuppression withdrawal in 1 of 18 patients (5.5%) but 11 of 18 (61%) had rejection [252]. These poor results were probably due to weaning immunosuppression just six months after transplantation, much earlier than in other studies. **B4**

UDCA did not prevent rejection after total immunosuppression withdrawal [224].

The role of liver cell chimerism and the role of donor bone marrow cell (DBMC) infusion were evaluated in immunosuppression withdrawal programs [253, 254]. Pons *et al.* achieved complete immunosuppression withdrawal in 3 out of 9 (33%) liver recipient patients [253]. Liver endothelial cell chimerism was studied in five patients and it was not associated with immunosuppression withdrawal.

Tryphonopoulos *et al.* reported similar patient and graft survival, comparing patients who received DBMC and patients who did not [254]. Rejection episodes were significantly lower in the DBMC group in the first two years, but overall there was no significant difference. Successful weaning was achieved in 20 patients out of 104 (19%), without difference between groups. **B4** Two patients developed chronic rejection and one required re-transplantation. These data confirmed previous results by Rolles *et al.*, who showed, in a randomized controlled study, that donor-specific bone marrow infusion has no benefit in inducing tolerance in patients undergoing LT [255]. **A1d**

Tisone *et al.* evaluated weaning immunosuppression in 34 HCV positive patients with recurrent allograft disease [256]. Complete and permanent immunosuppression withdrawal was achieved in 23.5%, with 35.2% rejecting during tapering, and another 41.2% developed rejection within eight months. Weaned patients showed stabilization or improvement of histological fibrosis, lower necroin-

flammation and improved liver function after a mean follow-up of 45 months. Low blood CSA trough levels during the first post-transplant week and initial steroid-free immunosuppression were found to be independent predictors of sustained weaning, suggesting this subgroup had less propensity for rejection. **B4**

### Immunosuppression in recipients with HCV related cirrhosis

Hepatitis C (HCV)-induced cirrhosis is a leading indication for LT [257]. HCV re-infection after LT occurs in virtually all patients transplanted for HCV-related liver disease [258, 259]. Histological evidence of chronic HCV infection develops in 50% to 90% of patients by 12 months after LT [260], and cirrhosis occurs in about 20% of patients within five years after transplant [257, 258, 261]. Several studies have evaluated host and viral factors that might be associated with the severity of HCV recurrence. Among host factors, immunosuppression is one of the major factors that accounts for accelerated HCV recurrence and it has been an area of extensive research and controversy [262].

In a recent multi-center international survey, the prevalent immunosuppressive strategies in LT for hepatitis C were evaluated among 81 LT programs worldwide. The most common regimen used (41%) was based on triple therapy (Tac, MMF and steroids). Concerning the use of steroids, 7.4% of programs used steroid-free protocols, 11% discontinued steroids within a week, 56% within three months and 98% within the first year. When US-programs and non-US programs were compared, CsA was used significantly more among non-US programs (35.6% vs 2.8%) and the duration of steroid therapy was significantly shorter in US programs (10.8 vs 29.4 weeks) [263].

### Steroids

Although the data on increase of HCV viral loads due to steroid boluses are convincing, the effects of steroid maintenance are still controversial [264, 265]. The link between steroid therapy and viral replication after LT in HCV recipients prompted many centres to advocate steroid therapy withdrawal. However, robust data are limited as to the efficacy of this approach. A rapid reduction in steroid dosage may be harmful for HCV recurrence [266]. **B4**

The direct effect of dexamethasone and prednisolone on HCV replication has been investigated using an *in vitro* replicon model. At clinically relevant concentrations (1–10 nM) treatment with both dexamethasone and prednisolone did not enhance, but resulted in a slight reduction of HCV replication. This minor reduction of HCV replication was confirmed by RT-PCR, showing more than 41% reduction in HCV-RNA levels [267].

In a recent study HCV patients transplanted between 2001 and 2004 (n = 90) were compared to a historical group

of HCV patients transplanted before the introduction of dual initial immunosuppression (CsA or Tac plus steroids) and slow steroid tapering (1999–2000) (n = 52) [266]. The historical cohort showed a significantly higher rate of severe disease (48%) compared to patients transplanted between 2001 and 2004 (29%). Among patients more recently transplanted the proportion on triple or quadruple regimens (10% vs 25%; p = 0.001) and the number of boluses of methyl-prednisolone were less (4 vs 11; p = 0.002) and the duration of maintenance prednisone was longer (350 days vs 249 days; p < 0.0001) [266]. **B4** These data confirm a previous study by Samonakis *et al.*, who found that short-term maintenance steroids ( $\leq 6$  months) and AZA were associated with less fibrosis progression [268]. **B4** This was further suggested by Vivarelli *et al.*, who compared rapid tapering of steroid (from 25 mg (day 6 to day 30 post-LT) to 15 mg (day 31 to 45), 10 mg (day 46 to 60) 5 mg (day 61 to 75), 2.5 mg (day 76 to 90)) and withdrawal at day 91 after LT (group A) to slow tapering (from 25 mg (day 6 to day 30 post-LT) to 15 mg (day 31 to 90), 10 mg (day 91 to 180), 7.5 mg (day 181 to 270), 5 mg (day 271 to the end of first year), 2.5 mg) and withdrawal 25 months after LT (group B) [269]. At 12 months after LT the rate of advanced fibrosis was higher in the group A compared to group B (42.1% vs 7.6%). Moreover, one and two-year advanced fibrosis-free survivals were 65.2% and 60.8% in group A and 93.7% in group B (p = 0.03 and p = 0.02 respectively). **B4**

In a recent randomized trial 103 liver transplanted patients for HCV cirrhosis were randomized to Tac (0.1 mg/kg/day) either alone or with AZA (1 mg/kg) and prednisolone (20 mg daily tailing off to zero by 3–6 months) [270]. There were no differences in short-term or overall survival between the two treatment arms and, despite more rejection episodes, the group that had maintenance low dose steroids for between three and six months had slower progression to Ishak stage 4 (23% vs 44%; p = 0.044). **Ald**

Filipponi *et al.* compared patients on steroid maintenance versus steroid-free regimens in HCV liver transplanted patients [235]. At 12 months after LT there was no significant difference with regard to liver fibrosis and viral loads. However, in patients treated with steroids the anti-viral treatment failure rate was significantly higher, but the biopsy proven acute rejection rate was significantly lower. **B4** Steroid avoidance was also evaluated in a prospective, randomized, multicenter trial comparing 312 patients randomized to three arms: (1) Tac and steroids; (2) Tac, steroids and MMF; and (3) daclizumab induction, Tac and MMF. Patient and graft survival did not differ significantly among treatment arms; freedom from HCV recurrence at one year was 62%, 60% and 67% in the three groups respectively; freedom from rejection was significantly higher in patients treated with corticosteroid-free immunosuppression compared to those exposed to steroids. Long-term

follow-up is not yet available [271]. Kato *et al.* randomized HCV positive liver transplanted patients to receive Tac and daclizumab, or Tac and steroids during 1999–2001 and Tac plus MMF and daclizumab or Tac plus MMF and steroids during 2002–2005 [272]. No statistically significant difference was found in mean fibrosis stage between the various treatment arms, either averaging across the two time periods or during these periods themselves. Patients on steroid free-regimens experienced a lower rate of diabetes mellitus (10% vs 45%;  $p = 0.01$ ) and wound infections (6% vs 31%;  $p = 0.01$ ). In a recent meta-analysis on steroid avoidance in LT, HCV recurrence was assessed heterogeneously (biopsy-proven (Ishak score)  $n = 1$ ; biopsy-proven (Ishak  $\geq 8$ )  $n = 1$ ; biopsy proven (fibrosis, score NS)  $n = 2$ ; biopsy-proven reinfection  $n = 2$ ; biopsy-proven  $n = 2$ ; biopsy-proven and biochemical abnormalities  $n = 1$ ; biopsy-proven with high LFTs and HCV-RNA  $n = 1$ ; biopsy-proven and HCV-RNA  $n = 1$ ; not specified  $n = 1$ ), HCV recurrence was lower with steroid avoidance and although no individual trial reached statistical significance, meta-analysis demonstrated this effect (RR 0.90; 95% CI: 0.82–0.99,  $p = 0.03$ ). However, there was considerable clinical heterogeneity. Data on fibrosis progression and on steroid dose and withdrawal were not reported [248].

### Calcineurine inhibitors

In a recent meta-analysis by Berenguer *et al.* including five randomized control trials (1995–2006) comparing Tac based vs CsA-based immunosuppression in HCV-infected liver transplant recipients, no statistically significant differences for mortality, graft survival, biopsy proven acute rejection, corticoreistant acute rejection or fibrosis cholestatic hepatitis were found [273]. These data confirm previous single center evaluations of differences between CsA and Tac showing no histological differences in HCV recurrence at 12 months nor overall survival rates (90) and no differences in HCV-RNA levels, serum transaminases, histological grading of portal inflammation and fibrosis [274]. **Ala**

CsA has recently been found to have an antiviral effect on HCV [275–281]. CsA has been shown to have a suppressive effect on the HCV replicon RNA level and HCV protein expression in an HCV sub-genomic replicon cell culture system. CsA also inhibited multiplication of HCV genome in a cultured human hepatocyte cell line infected with HCV [275]. This anti-HCV activity is independent of its immunosuppressive and cytotoxic function. Moreover Nakagawa *et al.* found that Tac does not suppress HCV replication [276]. However, despite the clear antiviral effect of CsA *in vitro*, there is still controversy about the effect of CsA on HCV-replication *in vivo*, in the setting of clinical organ transplantation. In a study, ten patients with chronic hepatitis C who did not respond to IFN therapy and who had elevated serum ALT values for at least six months

were treated with CsA for three months (dose increased at one month intervals from 1.5–2 to 2–3 and 3–4 mg/kg/day). Serum ALT levels gradually decreased in all but one patient; however, serum HCV-RNA titers did not change in any patient throughout the study period [282].

On the basis of current data, it is not possible to conclude that CsA by itself has a profound effect on viral replication or on the course of HCV recurrence after transplantation [283].

In contrast, there are also cohort studies that show advantages using CsA-based regimen compared to Tac-based ones [98, 266, 277, 284–286]. Berenguer *et al.* found that the interval from LT to acute hepatitis was shorter in patients on Tac regimen compared to those on CsA (59 days vs 92 days;  $p = 0.02$ ) [266], and that one of the variables associated with a higher probability of developing cirrhosis was induction therapy with Tac [284]. Levy *et al.* found that the mean time to histological diagnosis of hepatitis C recurrence was significantly longer with CsA-based regimen ( $100 \pm 50$  days) than with Tac ( $70 \pm 40$  days) even if the rate of histologically-proven HCV recurrence rate was similar between the two groups [98]. In an update study based on the same cohort of patients Shenoy *et al.* confirmed earlier recurrence in the Tac group ( $72 \pm 42$  days vs  $145 \pm 43$  days,  $p = 0.006$ ) but found that recurrent HCV occurred less frequently in Tac treated patients than in CsA-ME treated ones (21% vs 61%;  $p = 0.04$ ) [99]. Median time from LT to initiation of antiviral therapy was longer in CsA group compared to Tac group ( $4.9 \pm 1.1$  year vs  $2.6 \pm 1.2$  years) [277].

In another study, three-year actuarial risk of fibrosis stage 2 (METAVIR scoring system) was 66% with CsA and 90% with Tac [285]. The relationship between progression of liver fibrosis and histological necroinflammation in HCV recipients was evaluated in 55 patients transplanted for HCV liver disease between 1993 and 2002, retrospectively stratified in three different 40-month periods of transplantation. In a multiregression analysis, Tac at dose to maintain serum concentration of 5–10 ng/ml was a major factor associated with three-year fibrosis progression rate in HCV-transplanted patients [286]. However this was based on only ten patients.

A more interesting set of data is the potential influence of CsA on the efficacy of antiviral therapy in transplant recipients. Firpi *et al.* reported 115 patients in whom co-treatment of CsA with low-dose IFN $\alpha$  resulted in greater inhibition of HCV replication in comparison with the effects of CsA or IFN $\alpha$  alone [277]. A higher SVR rate was achieved in CsA based immunosuppression compared to Tac based regimens (46% vs 27%;  $p = 0.03$ ) when evaluated retrospectively. Inoue *et al.* observed higher SVR rate among patients with chronic HCV treated with IFN- $\alpha 2b$  in combination with CsA compared to the group with IFN alone (55% vs 32%;  $p = 0.01$ ) [287]. **B4**

CsA taper in association with MMF compared to unchanged immunosuppression with CsA was associated with a marked progression of allograft fibrosis (66% vs 0%), a slight increase of aminotransferases and HCV viral loads ( $372 \pm 280 \times 10^3$  IU/ml vs  $124 \pm 245 \times 10^3$  IU/ml). On the other hand renal function improved significantly in the group with MMF and CsA taper [288].

Margarit *et al.* randomized 35 HCV-positive liver transplanted patients to Tac monotherapy (n = 20) and dual therapy (Tac and steroids) (n = 15) [238]. HCV recurrence, diagnosed as elevation of liver enzymes together with histologic confirmation from liver biopsy, was seen in 17/20 (85%) patients on Tac-monotherapy and in 14/15 (93%). No difference in fibrosis score (Ishak classification) ( $2.77 \pm 2$  vs  $3.27 \pm 1.8$ ) and survival rate at one, three and five years after LT (89%, 83% and 61% vs 81%, 61% and 61%) was seen between the two groups. A comparison was also made between the 12 HCV patients who received no steroids at all (only-Tac) and the 23 patients who received steroids either from the beginning or to treat rejection (only-Tac-Ster). Fibrosis score (Ishak classification) was significantly lower in only-Tac group compared to the only-Tac-steroid group ( $1.78 \pm 1$  vs  $3.73 \pm 1.94$ ;  $p = 0.005$ ). Patient survival rate at one, three and five years after LT was no different between groups (92%, 92% and 73% only-Tac vs 78%, 61% and 51% only-Tac-steroids). **Ald**

Tac monotherapy (n = 27) in a randomized comparison with triple therapy (Tac, AZA and steroids tapered with six months) (n = 29), resulted in less severe graft hepatitis C with Tac triple therapy ( $p = 0.0044$ ), despite a higher histological rejection rate (70% vs 86%) and more steroid resistant rejection episodes (10% vs 18.5%) [245, 270]. **Ald**

### Azathioprine and mycophenolate mofetil

Antimetabolite immunosuppressants such as AZA and MMF have some common features with ribavirin, an antiviral drug which has been shown to enhance the activity of interferon in the treatment of HCV. Both ribavirin and MMF inhibit the inosine monophosphate dehydrogenase that has been shown to have *in vitro* antiviral properties against flaviviruses [289]. Moreover, ribavirin and three metabolites of AZA are processed to monophosphate nucleotides by inosine monophosphate dehydrogenase [290]. These data suggested the possibility that these immunosuppressive agents might also inhibit the hepatitis C virus replication. However, potential beneficial effects of MMF and AZA on HCV recurrence have not been documented in the literature [291].

*Azathioprine* Stangl *et al.* used the Bovine viral diarrhea virus (BVDV), a *Flaviviridae* virus closely related to HCV, to test the potential antiviral effects of AZA and MMF [292]. At doses that achieved similar cytotoxicity, AZA decreased BVDV replication ten times more than MMF. The inhibi-

tion of BVDV by AZA was not related to its cytotoxicity and the effect of AZA on a HCV replicon was at least as large as that of ribavirin.

Several studies (1996–2008) have reported on the impact of AZA on the severity of HCV recurrence [268, 284, 286, 293–299]. Most (70%) found that severity of HCV recurrence was decreased using AZA [268, 284, 294–296, 298, 299], whereas three studies showed similar severity in HCV recurrence whether AZA was used or not [286, 293, 297]. **B4** However, no study showed that AZA was associated with increased severity of recurrent HCV.

Patients treated with AZA containing immunosuppressive regimens reported by Hunt *et al.* experienced less recurrence (35.2% vs 77%;  $p < 0.005$ ) and fibrosis progression (5.8% vs 37.5%;  $p = 0.014$ ) than those without AZA [294]. Berenguer *et al.* evaluating pre-transplantation and early post-transplantation variables associated with a high risk for severe HCV related disease post-transplantation, found that one of the risk factors associated with severe disease was a short duration induction (<6 months) with AZA (RH 2.22; 95% CI: 1.37–3.60;  $p = 0.001$ ) [284, 295]. In other studies, the use of AZA was associated with a lower risk of allograft failure and lower mortality (OR 0.3; 95% CI: 0.16–0.64; OR 0.32; 95% CI: 0.12–0.79) [268, 298].

A randomized, multicenter and prospective clinical trial randomized 180 liver transplanted patients to dual therapy (Tac and steroids, n = 92) and triple therapy (Tac, steroids and AZA, n = 88). Considering the HCV-positive subpopulation (n = 85) the use of AZA was associated with a lower rate of acute rejection (20% vs 48%;  $p = 0.008$ ), but with no difference in graft and patient survival. Data on recurrent HCV was not reported [300].

A direct comparison between MMF and AZA in HCV-positive liver transplanted patients was evaluated by Wiesner *et al.* [115]. In 565 randomized patients, 278 (HCV+, n = 27) received CsA, steroids and MMF (1g twice daily IV for four to ten days, followed by oral 1.5g twice daily) and 287 (HCV-, n = 27) CsA, steroids and AZA (1.0 to 2.0mg/kg/d IV followed by oral administration). A significant reduction in the incidence of acute hepatic allograft rejection or graft loss in the MMF group compared with the AZA group (30.6% vs 41.4%;  $p < 0.04$ ) was seen at six months after LT. The incidence of HCV recurrence, defined histologically and in the presence of HCV-RNA, was 18.5% in the MMF group and 29.1% in the AZA group at six months after LT, but no long-term data is available.

However, a prospective crossover study reported that MMF, used as a substitute of AZA, led to an increase in viral load but it was not associated with an increase in ALT level [301]. Recently Kornberg *et al.* performed a prospective study revealing contrasting early and delayed results [302]. Twenty-one patients received quadruple induction CsA-based immunosuppression, augmented by MMF

( $n = 12$ ) or by AZA ( $n = 9$ ). In the MMF group recurrent disease was diagnosed earlier than in the AZA group ( $50 \pm 35$  vs  $35 \pm 35$  weeks), but patients under MMF had less severe allograft fibrosis at diagnosis of disease recurrence (Ishak-Knodell) ( $1.5 \pm 0.5$  vs  $2.2 \pm 1.2$ ). However, stage of fibrosis significantly increased in the MMF-group during six months of antiviral treatment compared to the AZA-group ( $1.5 \pm 0.5$  vs  $2.3 \pm 0.5$ ;  $p = 0.04$ ).

*Mycophenolate mofetil* Firpi *et al.* randomized 30 patients to four mycophenolate dose regimens (1000mg twice daily, 500mg twice daily, 250mg twice daily or a matched oral placebo twice daily) for eight weeks, and showed that no subject became virus negative or had a one-log decrease in virus level [291]. The mean change in HCV-RNA level at week 4 and 8 compared with baseline was +19% and +10% respectively.

Wiesner *et al.* evaluated retrospectively 3463 patients who underwent LT for HCV-related liver disease, and assessed the impact of MMF on long-term outcomes comparing patients who were discharged from the hospital on Tac-based immunosuppression with or without MMF [119]. Patients treated at discharge with MMF, Tac and steroids had significantly increased four-year survival (79.5% vs 73.8%;  $p = 0.002$ ) and graft survival (74.9% vs 69.5%;  $p = 0.024$ ) and lower rate of acute rejection after discharge (defined as treatment for acute rejection or acute rejection as the cause of graft failure) (27.3% vs 32.1%;  $p = 0.047$ ). However, MMF did not show convincing histological improvement of HCV recurrence. **B4** The combination of MMF (500–2000mg/day) and Tac taper (target level 50% starting) over two months, was assessed in a retrospective case-control study comparing 40 patients with histologically proven HCV recurrence after LT to 40 non-MMF HCV positive liver transplanted patients (Tac  $n = 29$ , CsA  $n = 8$ , Tac + AZA  $n = 1$ , CsA + steroids  $n = 1$ ). MMF in combination with CNI taper showed a positive effect on fibrosis progression, graft inflammation and ALT levels [296].

### Anti-lymphocyte preparations

Anti-lymphocyte antibody preparations such as OKT3 to treat steroid-resistant acute rejection impact on the progression of HCV recurrence. Cholestatic hepatitis is associated with very high serum viral load, and a strongly associated risk factor is associated with high levels of immunosuppression, mainly pulses of methylprednisolone and/or OKT3 therapy [295, 303–306]. **B4**

Induction immunosuppression has not been a common practice in LT but is now being used in recipients with compromised renal function as it can diminish the need to delay introduction of calcineurin inhibitor and as part of partly tolerizing regimens [21, 22, 197]. De Ruvo *et al.* compared thymoglobulin induction plus Tac monotheapy

( $n = 22$ ) to Tac plus steroid immunosuppression without induction ( $n = 30$ ) [307]. Patient survival and acute rejection rates did not differ. HCV recurrence was similar (54.5% vs 60%), but in the thymoglobulin group mean time to histologic recurrence was shorter ( $121 \pm 54.3$  days vs  $205 \pm 127$  days;  $p = 0.04$ ), despite lower HCV-RNA loads (mean peak:  $12.4 \pm 14.1$ MEq/ml vs  $19.2 \pm 14.3$ MEq/ml;  $p = 0.02$ ). The fibrosis score (Ishak score) was not significantly different between the two groups ( $0.85 \pm 0.8$  vs  $1.54 \pm 1.3$ ). **B3**

Induction therapy with either anti-CD25 monoclonal antibodies or rabbit antithymocyte globulins (RATG) resulted in good patient and graft survival, with acute rejection in 37.5% of patients treated with RATG and 20% in patients treated with anti-CD25. The rates of HCV recurrence, as defined on virological and biological criteria and confirmed by liver histology, were 80% in the anti-CD25 group and 56.25% in the RATG group, but with no reporting on severity or timing of recurrence [308]. Ramirez *et al.* compared induction with an anti-IL2 receptor inhibitor basiliximab to a historical group of 46 recipients on Tac-based immunosuppression [309]. In those with basiliximab induction, 43 of 46 patients (93.4%) remained rejection free during follow-up and the patient and graft survival rate at two years was 93.5%; histological HCV recurrence rate was 24%. The historical controls had a rejection rate of 31%, with lower patient and graft survival (71.7% and 69.5%) and a higher histological HCV recurrence rate (71%). Alemtuzumab (anti-CD25) was used by Marcos *et al.* in 38 HCV positive recipients, patient and graft survival at one year after LT were 71% and 70% versus 65% and 54% under conventional treatment [211]. Only 6% of the HCV positive recipients pre-treated with alemtuzumab developed first rejection during first four months after transplantation compared to 30% in the conventional group. However, HCV positive patients did significantly worse than those who were HCV negative, both in the induction and the control group. **B4** Moreover increased HCV viral replication was worse with alemtuzumab, but there was no data on histological recurrence.

In conclusion, studies on impact of immunosuppression regimens on post-transplantation outcome in HCV positive recipients support the idea that any dramatic change in immunosuppression as rapid withdrawal or alteration in the level or type of suppression (i.e. corticosteroids boluses and OKT3 use) are deleterious for recurrence. There may be a beneficial effect of low dose slow tapering of steroids and maintenance AZA. More randomized studies are needed to confirm these findings. A possible mechanism for these effects is that rapid change in immunosuppression enables a vigorous immune response and killing of HCV-infected hepatocytes, which despite lowering the overall HCV load in the liver, results in extensive fibrosis [305, 310].

## Chronic ductopenic rejection

### Definition

Chronic or ductopenic rejection is mainly an immunologic injury to the allograft and can result in irreversible damage to the bile ducts, arteries and veins. The pathogenetic mechanism is obscure and the role of histocompatibility and viral agents is unclear. Mast cells seem to be important effector cells [311]. Its incidence at five years after transplantation has decreased from 10–15% in the 1980s to 3–5% in current recipients [312]. This may be due to a better recognition and control of acute and early phases of chronic rejection, but there may be other reasons, such as improvements in preservation solutions.

### Clinical and laboratory findings

The natural history is poorly understood. Many cases occur following unresolved acute cellular rejection episodes. Chronic rejection in liver allografts shares risk factors and morphological characteristics with chronic rejection seen in other solid organ transplants, but there are also substantial differences. It has a relatively rapid onset, usually within several months, but it can occur weeks after transplantation, often following a progressive course. The peak incidence of graft failure from chronic rejection is 2–6 months post-transplantation and it progressively decreases with time [313]. Most cases require re-transplantation within the first year. Chronic rejection presenting after one year post-transplantation is “late onset chronic rejection” which presents more insidiously and may have different histological features [314].

However, despite its progressive course, in some cases it is potentially reversible, a quality that has been attributed to apparently unique immunologic properties and remarkable regenerative capabilities of the liver [315].

The diagnosis is clinically suspected when a patient develops progressive cholestasis and an increase in canalicular enzymes [26]. The early transition from acute to chronic rejection may be associated with an elevation in AST levels, which along with bilirubin concentrations, are associated with graft failure from chronic rejection. As with acute rejection, the clinical and biochemical manifestations of chronic rejection are non-specific and therefore the diagnosis also requires histological confirmation.

Theruvath *et al.* evaluated 924 liver transplants (median follow-up of 66 months), in whom histologically proven chronic rejection occurred in 2.1% [316]. Primary sclerosing cholangitis and a history of acute rejection were variables associated with an increased risk for development of chronic rejection. **B4** Wiesner *et al.* evaluated 870 consecutive primary liver transplant recipients and found that

autoimmune liver disease was an independent risk factor for developing chronic rejection [44]. **B4**

### Histopathological features

Two main histologic features are considered diagnostic: damage or loss of small ducts (less than  $60 < \mu\text{m}$  in diameter) in more than 50% of the portal tracts, (there needs to be specific cytokeratin staining of biliary epithelium) and foam cell obliterative arteriopathy of large and medium sized arteries [26]. Recently it has been recognized that distinct early histopathological changes presage disappearance of bile ducts in the form of a parenchymal inflammatory reaction. The early recognition of this “hepatitic” phase may be of fundamental importance. It could indicate the need for increased or altered immunosuppressive therapy [317]. In the past it may have been mistakenly diagnosed as superimposed hepatitis leading to an inappropriate reduction of immunosuppression, which could exacerbate the chronic rejection.

Bile duct loss in more than 50% of portal tracts and absence of necroinflammatory activity, represent late histopathologic changes, the classic textbook description, but these changes are late in the evolution of the process and are likely to be irreversible. Diagnosis at this stage may be useful in deciding when to list a patient for re-transplantation; additional immunosuppressive therapy is unlikely to be of any benefit and may do harm by increasing the risk of infection prior to transplantation.

### Grading and staging

There is a tentative scheme for grading chronic rejection proposed by the National Institute of Diabetes, Digestive, and Kidney Disease (see Box 42.1) [318].

### Treatment

Treatment is dependent on the stage at which the process is diagnosed. Cases of early chronic rejection may respond to increased dosage of Tac, which is the only effective rescue therapy, documented by different centers, resulting in a 70% graft survival at one-year follow-up. Patients who have a serum bilirubin level less than 10 mg/dl at the time of conversion to Tac and who develop chronic rejection more than 90 days after transplantation, have the best response [319]. **B4** The combination of mycophenolate mofetil with sirolimus has also been reported in an animal model to be effective in chronic rejection. Sirolimus may help to reduce arterial intimal thickening which is believed to be a pathophysiological root cause of chronic rejection [320]. **C5** However, the safety and benefit of sirolimus alone for chronic rejection is currently unknown.

**BOX 42.1** NIDDK definitions of grades far chronic rejection, and for rejection uncertain for chronicity (indefinite for bile duct loss)

Rejection, uncertain for chronicity (indefinite bile duct loss)

No complicating lobular changes

Lobular changes, including one of the three findings:

- Centrilobular cholestasis
- Perivenular sclerosis
- Hepatocellular ballooning
- Necrosis and dropout

Chronic rejection

Early or mild

Bile duct loss, without centrilobular cholestasis, perivenular sclerosis, or hepatocyte ballooning or necrosis and dropout

Intermediate/moderate

Bile duct loss, with one of the following four findings:

- Centrilobular cholestasis
- Perivenular sclerosis
- Hepatocellular ballooning
- Necrosis and dropout

Late or severe

Bile duct loss, with at least two of the four following findings:

- Centrilobular cholestasis
- Perivenular sclerosis
- Hepatocellular ballooning
- Necrosis and dropout

a Bile duct loss >50% of triads.

NIDDK, National Institute of Diabetes, Digestive and Kidney disease.

Neff *et al.* in a retrospective review of 21 transplant recipients with clinical and histological diagnosis of chronic rejection treated with sirolimus (0.07 mg/kg) and Tac (serum level 8–14 ng/dl), showed an improvement in the bile duct to hepatic artery ratio and total bilirubin levels. However, a large number of patients experienced drug-related side effects and were unable to tolerate therapy [321]. **B4**

Re-transplantation remains the best treatment for chronic rejection associated with severe biochemical cholestasis and advanced bile duct loss, which is usually unresponsive to immunosuppression. The recurrence rate of chronic rejection is as high as 90%, although it is not clear if some characteristics, for example early re-transplantation, are predictive factors for recurrence [322].

Recently it has been recognized that some cases of advanced chronic rejection have recovered spontaneously, or with the use of additional immunosuppression. In some of these cases, follow-up liver biopsies have shown a per-

sistent paucity of bile ducts without other histological features of chronic rejection. Ductopenia has also been noted as an incidental finding in protocol biopsies taken at annual review from patients who are clinically well, with no previous biopsies suggesting chronic rejection. These findings suggest that some patients may suffer permanent duct loss as a result of rejection, but that sufficient ducts remain to allow the graft to function normally. Because of these observations and the risks associated and logistical difficulties with a second transplantation, the decision to re-transplant should only be made when a confident diagnosis of irreversible and progressive graft damage is established.

## Liver transplantation: Prevention and treatment of infection

*Antoni Rimola and Miquel Navasa*

Liver Unit, Institut de Malalties Digestives i Metabòliques, Hospital Clinic, IDIBAPS, CIBEREHD, Barcelona, Spain

Early studies reported that 50–80% of patients developed infection after liver transplantation and that this complication was a major cause of death, especially during the first postoperative year, with a rate of infection-related mortality of around 20% [1–6]. Little information is available on the incidence of infection after liver transplantation in more recent years. However, due to progressively implemented preventive strategies against infection, especially opportunistic infections, it is likely that infectious complications have become less frequent. As an example, in our institution the incidence of infection decreased from 83% in the period 1988–1990 to 42% in the period 2001–2003 [7]. This, coupled with the improvement in the diagnosis of infection, has reduced the mortality secondary to infection, as shown in several recent prospective clinical trials on the efficacy and safety of different immunosuppressive regimens in which the short and mid-term infection-related mortality was less than 10% [8–10]. Nonetheless, infection remains a common and relevant complication in liver transplantation, requiring appropriate prophylactic and therapeutic measures, as summarized in this chapter. Since the rationale for these measures not only arises from the particular characteristics of each infection but also from the risk factors for and the time of occurrence of the different types of infection, these two aspects are also addressed in this chapter. As the spectrum of infection and its prevention and treatment have experienced important changes over time, this chapter is mainly focused on current practice.

### Risk factors for infection

All liver transplant recipients have two risk factors for infection: the major abdominal surgical procedure of trans-

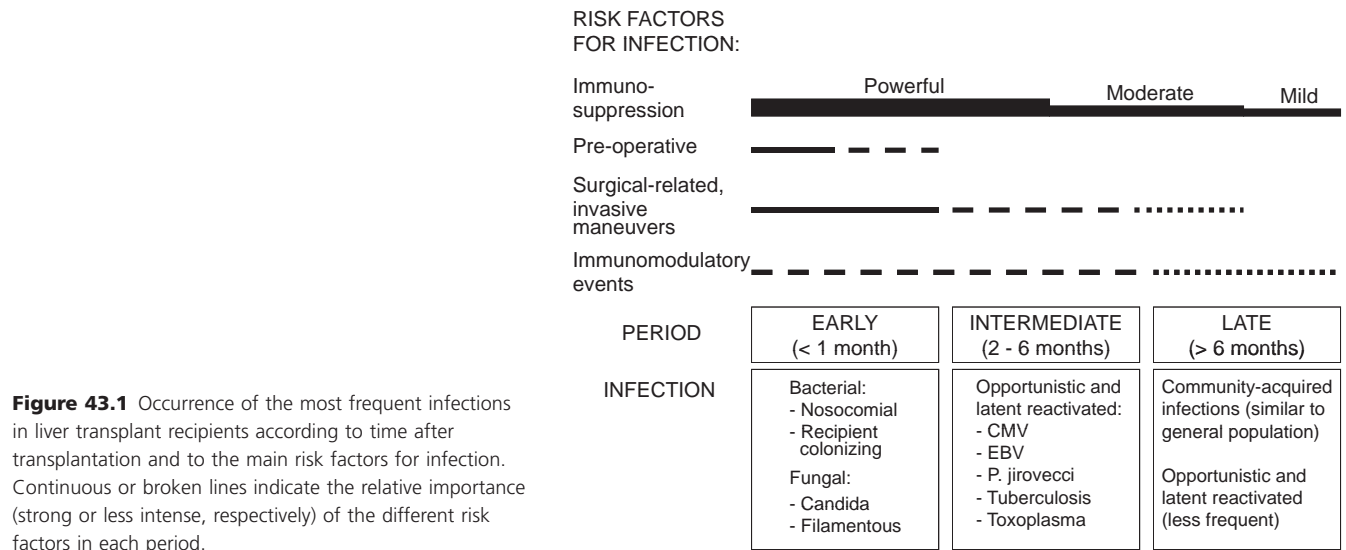

plantation and the administration of immunosuppressive treatment. In most cases powerful immunosuppression is administered during the early postoperative period, the phase with the greatest risk of rejection. Subsequently, immunosuppression is gradually reduced until the end of the first or second postoperative year, when immunosuppression is stabilized at a low grade of immune suppression. Other circumstances common in liver transplant recipients are also risk factors for infection by increasing the so-called “net state of immunosuppression” [11]. The most relevant of these circumstances are listed in Table 43.1. Apart from these general risk factors, there are also specific risk factors for the different types of infection, which will be addressed in the sections dealing with these infections.

### Time of infection occurrence

Classically, three different periods have been defined according to the predominant types of infection in each period: the first postoperative month, from month two to month six, and beyond six months (see Figure 43.1) [11–15].

During the first postoperative month, the most frequent infectious complications are bacteremia, pneumonia and surgical site infection, predominantly caused by nosocomial bacteria and recipient colonizing bacteria. Fungal infections are also relatively common. Despite the high grade of immunosuppression during this period, opportunistic infections are infrequent, with the exception of herpes simplex, probably because immunosuppression requires some time to promote the clinical expression of most opportunistic infections. Infections derived from the graft donor, although potentially serious, are also uncommon [16].

Characteristically, opportunistic infections and reactivated latent infections emerge during the intermediate period, from months two to six. Classical pathogens in this

**Table 43.1** Circumstances affecting the net state of immunosuppression in liver transplant recipients (adapted from reference 11).

Pharmacological immunosuppression
Invasive manoeuvres compromising muco-cutaneous barrier integrity:
Intravenous lines
Tracheal intubation
Reoperation
Bladder catheterization
Underlying immunomodulatory conditions (pre- and/or post-operative):
Very advanced liver disease
Metabolic:
Renal failure
Diabetes mellitus
Malnutrition
Multiple organ failure
Viral infection:
Cytomegalovirus
Epstein-Barr virus
Hepatitis C virus

period include cytomegalovirus (CMV) and other herpes group viruses, *Pneumocystis jirovecii* (formerly, *P. carinii*), other fungi (variable according to fungal geographical distribution), and protozoa (mainly *Toxoplasma* and *Leishmania*). Infections caused by mycobacteria, *Listeria* spp. and *Nocardia* spp. can also be observed. Although beyond the scope of this chapter, recurrence of hepatitis C virus should also be mentioned because this complication represents a major problem in liver transplantation.

Beyond month six post-transplantation, and coincidentally with a progressive reduction of immunosuppression

and little requirement of re-hospitalization, the risk of infection drastically decreases, becoming similar to that in the general population. During this late period, most infections are community acquired, although opportunistic infections can also occur.

This spectrum of infection occurrence can be altered due to a variety of reasons, with important overlap between the periods. For example, biliary and graft vascular problems can persist beyond the early postoperative period, with the subsequently prolonged risk of infection related to these surgical complications. The need to maintain long-term immunosuppression due to late-onset or persisting rejection is associated with an increased risk of opportunistic infections and latent infection reactivation throughout the time under potent pharmacological immunosuppression. Finally, the persistence or *de novo* appearance of immunomodulatory events, such as chronic renal failure or severe recurrence of pre-transplant liver disease (particularly, hepatitis C), can modify the risk of infection during the intermediate and late post-transplant periods.

## Bacterial infection

### Incidence and special risk factors

Bacterial infections are the most frequent infectious complications in liver transplant recipients and predominantly occur during the early postoperative period. The commonest bacterial infections in this period are surgical site infection, bacteremia and pneumonia. In most studies, the development of bacteremia and pneumonia has been associated with increased risk of mortality [17–22]. Surgical site infection, although not greatly influencing survival, increases hospital resource utilization and cost [23, 24]. In

recent reports, the mean incidence of surgical site infection, involving the incision wound and intra-abdominal organ-space infections (namely, localized or diffuse peritonitis, cholangitis, infected biloma and hepatic abscess), is approximately 25%, ranging from 5% to 40% [23–33]. Bacteremia has also been reported with variable frequency, between 9% and 36% [19, 28–30, 33–36]. In a recent prospective, multicenter study involving 16 Spanish centers and including 1012 liver transplantations followed up to two years, the incidence of the bloodstream infections (caused by bacteria in 96% of the cases) was 10% [22]. In this study, most bloodstream infection episodes were catheter-related (30%), secondary to surgical site infection (24%) and, to a lesser extent, to pneumonia (6%), whereas the primary source of bacteremia was not identified in 34% of cases. Similar sources of bacteremia have been found by other authors [18, 36, 37]. A 7–28% incidence of pulmonary infections has been reported in recent series [17, 19, 21, 28–30, 33, 35, 38–42]. Other types of infection, such as urinary tract or central nervous system infections, are much less frequently observed [13].

Aside from the general risk factors for infection previously mentioned, other factors specifically favor bacterial infection in liver transplant recipients. Prolonged surgery or reoperation, increased perioperative transfusion, living donor liver transplantation and biliary anastomosis with choledochojejunostomy predispose to surgical site infections [25, 26, 43, 44]. Specific risk factors for bacterial pneumonia are prolonged mechanical ventilation, persistent non-infectious pulmonary alterations and living donor transplantation [19–20, 39]. Rejection and prolonged hospital stay are risk factors for bacterial infections in general [35, 37, 40, 45]. In children, low weight and low age have been associated with increased risk of bacterial infection

[30]. The type and intensity of pharmacological immunosuppression does not clearly influence the risk of bacterial infection, although mTOR inhibitors (sirolimus and everolimus; also called proliferation signal inhibitors, PSIs) may favor surgical-site infections by impairing wound healing [46].

In later post-transplant periods, bacterial infections are much less frequent and are mainly limited to community-acquired infections, especially pneumonia and urinary tract infections [16, 47–49], and to infections related to persisting biliary and arterial complications [32, 33, 50, 51]. Liver transplant patients are slightly more susceptible to some intracellular bacteria, such as *Listeria* spp., *Legionella* spp., and *Nocardia* spp. [47, 52]. The negative impact of late bacterial complications on the survival of liver transplant patients is low or very modest [53–58].

### Causative organisms

Organisms causing bacterial infections in liver transplant patients during the early postoperative period correspond to environmental bacteria (transmitted from contaminated persons or equipment) and recipient endogenous bacteria [2, 3, 12, 13, 15, 17, 19–22, 24–28, 34, 36, 45, 59–61], summarized in Table 43.2.

Occasionally, other pathogens, such as *Legionella* spp., can transiently acquire special relevance [62–64]. Anaerobes are a rare cause of infection in liver transplant patients [35, 29, 30, 61], although *Clostridium difficile* colitis has been reported as being relatively prevalent in some centers [2, 43]. A substantial proportion of surgical-site and, to a lesser extent, pulmonary infections are polymicrobial. In pneumonia, the isolation of different organisms can correspond to either true polymicrobial infections or subsequent super-

**Table 43.2** The commonest microorganisms responsible for major bacterial infections in the early postoperative period following liver transplantation. Only data from recent studies (published from 2000 onwards) are included [17, 19–22, 24–26, 28, 34, 36, 59–61].

Surgical-site infections		Bacteremia		Pulmonary infections	
General type	Most frequent <sup>a</sup>	General type	Most frequent <sup>a</sup>	General type	Most frequent
Gram+ cocci: 40–56%	<i>Enterococcus</i> spp. <i>Staph. aureus</i> CN staphylococcus	Gram+ cocci: 32–75%	CN staphylococcus <i>Enterococcus</i> spp. <i>Staph. aureus</i>	Gram+ cocci: 0–42%	<i>Staph. aureus</i> <i>Streptococcus</i> spp.
Aerobic Gram– bacilli: 44–53%	<i>E. coli</i> <i>Klebsiella</i> spp. <i>Pseudomonas</i> spp.	Aerobic Gram– bacilli: 25–59%	<i>E. coli</i> <i>Klebsiella</i> spp. <i>Pseudomonas</i> spp.	Aerobic Gram– bacilli: 48–100%	<i>Pseudomonas</i> spp. <i>Klebsiella</i> spp. <i>S. maltophilia</i>
Polymicrobial: 17–48%		Polymicrobial: 4%		Polymicrobial: 10%	
				Unidentified: 30%	

<sup>a</sup> In some institutions, *Acinetobacter baumannii* is also very prevalent.  
CN: coagulase-negative.

infections by pathogens resistant to the current antibiotic therapy [17, 20]. As expected, causative organisms in pneumonia cannot be identified in a significant percentage of cases because the microbiological diagnosis frequently requires bronchoscopy with bronchoalveolar lavage, which is not always performed before starting antibiotic therapy [20, 38, 40, 62].

In late periods of liver transplantation, the most frequent bacterial complications are community-acquired pneumonia, mainly caused by *Streptococcus pneumoniae*, *Haemophilus influenza* and *Mycoplasma*, and urinary tract infections, mainly caused by Gram-negative bacilli [47, 13, 35, 49]. Other late bacterial infections are cholangitis related to persistent biliary complications, mainly caused by enterobacteria and *Pseudomonas* spp. [33], and hepatic abscess secondary to vascular complications, caused by a variety of organisms including Gram-positive cocci, Gram-negative bacilli and anaerobes [51]. Liver transplant patients can also develop tuberculosis. However, since this complication has special characteristics, its prevention and treatment will be addressed separately at the end of this section.

### Multi-drug resistant bacteria

A world-wide problem during the last decades has been the progressive emergence of bacteria resistant to multiple antibiotics. The most relevant multi-resistant bacteria in liver transplant patients are shown in Table 43.3 [19, 22, 24, 26, 29, 33, 59, 60, 65–67].

Methicillin-resistant *Staphylococcus aureus* (MRSA) is a frequent cause of early postoperative infection following liver transplantation. Nasal carriage of MRSA (acquired pre- or postoperatively) is associated with an increased risk of MRSA infection [68–72]. MRSA strains are usually susceptible to the glycopeptide antibiotics vancomycin and teicoplanin.

The prevalence of vancomycin-resistant enterococci (VRE) follows a variable geographical distribution, being high in most centers from the USA [65, 71, 73], and low in

most European countries [29, 74, 75]. Bowel colonization, acquired pre- or post-transplant, is the major source of VRE infection [71, 76]. Linezolid and daptomycin are active against most VRE [77, 78].

Among the enteric Gram-negative bacilli, *Escherichia coli* and *Klebsiella pneumoniae* are the organisms most commonly producing extended-spectrum beta-lactamase (ESBL), although other enterobacteriaceae strains can also express ESBL [79]. In general, ESBL-producing enterobacteria are susceptible to carbapenems (imipenem, meropenem and ertapenem) [80, 81].

*Pseudomonas* spp. are the most relevant multi-resistant non-fermentative Gram-negative bacilli in liver transplant patients. Other multi-resistant members of this family with increasing importance for liver transplant patients are *Acinetobacter baumannii* and *Stenotrophomonas maltophilia*. Tigecycline is habitually active against *A. baumannii* and *S. maltophilia* [82]. *S. maltophilia* is also highly susceptible to cotrimoxazole [83].

Several authors have found a direct association between mortality and VRE colonization and infection by some multi-resistant organisms [22, 65, 71, 76].

### Prevention

In theory, infection can be prevented by strategies reducing risk factors for infection and those reducing the infective capacity of potentially pathogenic organisms. However, risk factors for infection are either not susceptible to improvement (i.e. the severity of pre-transplant liver disease) or have experienced little change over the last years. Only two surgical and anesthetic approaches should be mentioned. One is the attempt to decrease the operative hemorrhage, an important risk factor for early bacterial complications, by the use of temporary portocaval shunting [84], the reduction of both central venous pressure and plasma transfusion [85], or the administration of aprotinin [86]. The other is the immediate tracheal extubation after

**Table 43.3** Multi-resistant bacteria in liver transplant patients with bacterial infections.

Bacteria	Mechanisms of multi-resistance	Percentage of multi-resistant organisms (average and range)	References
<i>Staphylococcus aureus</i>	Methicillin resistance	67% (16–100%)	19, 22, 26, 33, 60, 65, 66
<i>Enterococcus</i> spp.	Vancomycin resistance	10% (0–50%)	26, 29, 33, 60, 65, 67
Enteric Gram-negative bacilli	ESBL production <sup>a</sup>	27% (9–60%)	22, 24, 33, 60, 65, 67
Nonfermentative Gram-negative bacilli	Multiple mechanisms <sup>b</sup>	15% (10–47%)	22, 65

<sup>a</sup>ESBL (extended-spectrum beta-lactamase) producing organisms resistant to penicillins, cephalosporins and aztreonam.

<sup>b</sup>*Pseudomonas* spp. (the most representative organisms of this group) resistant to at least three of the following antibiotics: beta-lactams, carbapenems, aminoglycosides, or quinolones. Other relevant pathogens are *Acinetobacter baumannii* and *Stenotrophomonas maltophilia*.

surgery ("fast track" policy) to reduce the risk for pneumonia [87]. Nevertheless, the impact of these strategies on the incidence of bacterial infection is uncertain. At present, therefore, prevention of bacterial complications in liver transplant patients is almost exclusively based on interventions on the microbial flora.

### Peri-operative antibiotic prophylaxis

Although controlled studies on this topic are lacking (namely, prophylaxis versus no prophylaxis), peri-operative antibiotic prophylaxis is the standard practice to prevent surgical-site infections as well as other bacterial infections during the very early post-operative period. However, due to the marked differences from one center to another regarding the predominant causative organisms, no specific prophylaxis can be universally recommended. Furthermore, the paucity of prospective, comparative studies on different antibiotic regimens adds important difficulties. The only exception is a study comparing cefazolin and amoxicillin-clavulanate, in which no difference in the rate of surgical-site infection was observed between the two regimes [24]. Unfortunately, these two antibiotic regimes were suboptimal because around 40% of isolated organisms were resistant to the administered agents. **A1d** Thus, only general rules for peri-operative antibacterial prophylaxis can be made.

The appropriate antibiotic agents must be selected according to the local microbial epidemiology and the susceptibility of the most prevalent organisms at each center [88]. The most currently used antibiotics are third and fourth generation cephalosporins, frequently administered in association with other agents, especially those active against *Enterococcus* spp., such as ampicillin or amoxicillin (with or without clavulanate) [20, 25, 33, 65, 70, 75, 89, 90]. Other antibiotic combinations involve quinolones, antipseudomonal penicillins, or aztreonam [25]. One dilemma is the prophylactic use of antibiotics active against multi-resistant bacteria, because it seems judicious to reserve these often last-line antimicrobial agents for treatment [91]. In this setting, only the prophylactic administration of vancomycin or teicoplanin could be reasonable in centers with a high prevalence of MRSA [70, 91–93]. In contrast, the prophylactic administration of antibiotics active against VRE, such as linezolid, or ESBL-producing enterobacteria, such as carbapenems, is uncommon even at institutions with a high prevalence of these microorganisms.

Peri-operative antibiotic prophylaxis is routinely initiated immediately prior to transplantation and prolonged throughout the operation, although in some centers prophylaxis is extended to the first postoperative 24 hours or longer [33, 65, 70, 88, 89, 93].

Although the risk of donor-derived bacterial infection is low and the impact on patient and graft survival is usually negligible, the antibiotic prophylaxis in the recipient is

usually adapted to the organisms responsible for the donor infection and its duration prolonged for five to ten days [17, 94–96].

### Selective bowel decontamination and administration of probiotics and prebiotics

Since a high proportion of early infections are caused by bacteria of intestinal origin, selective decontamination of the digestive tract with nonabsorbable antibiotics has been used in different centers. However, few randomized, prospective, controlled trials have properly assessed the efficacy of this strategy [97–101]. Decontaminating regimens in these studies included gentamicin or tobramycin, polymyxin or colistin, and amphotericin or nystatin, administered orally for a variable period of time. In one study an oral paste with antimicrobial agents was also administered [100]. A reduction of infections caused by Gram-negative bacilli was attained in most treated groups, although the global rate of early bacterial infection was not significantly different, as emphasized in a recent meta-analysis [102].

**A1a** Survival was not influenced by the use of selective digestive decontamination. Therefore, the potential benefit of this type of prophylaxis is uncertain and it cannot be routinely recommended [45]. **A1a**

In two randomized trials, a marked reduction was achieved in the incidence of early infection caused by enteric bacteria with the prophylactic administration of a combination of living lactic acid bacteria (probiotics) and bioactive fibers (prebiotics), but clinical outcomes were not significantly different [103, 104]. **A1d**

### Prophylactic measures for multi-drug resistant bacteria

General measures include hand hygiene and barrier precautions, which are applicable for all these organisms [45, 105, 106]. Based on the association of nasal carriage of MRSA with infection by this organism [68–72], periodical pre- and post-operative screening for MRSA and nares decolonization with mupirocin application have been proposed in liver transplant candidates and recipients [69–71, 107]. Unfortunately, one study showed that this policy was not effective as it did not prevent postoperative MRSA infection and was followed by a frequent recurrence of nasal MRSA colonization [108]. **B4** Since other sites of colonization may be important, skin cleansing with chlorhexidine has also been postulated for a better control of MRSA [109, 110], as well as for VRE [111], but no study has evaluated these measures in liver transplant patients.

### Antibiotic prophylaxis for invasive procedures

The diagnosis and treatment of biliary complications, especially stenosis, frequently require endoscopic cholangiography. Bactobilia, that is, the bacterial colonization of bile, has been found with a very high incidence in liver

transplant patients with biliary stenosis, stents or previous papillotomy [112]. **B4** On the other hand, in a large series of patients undergoing ERCP, the only factor predisposing to cholangitis was liver transplantation [113]. Based on these data, antibiotic prophylaxis for ERCP is recommended in liver transplant patients [114]. Piperacillin-tazobactam and imipenem provide adequate coverage [112]. Although, to the knowledge of the authors of this chapter, there are no studies on the risk of cholangitis in patients undergoing percutaneous cholangiography, it seems advisable to follow the same recommendation as for ERCP.

In one study, liver biopsy was associated with sepsis when this procedure was performed in liver transplant patients with choledochojejunostomy [115]. For the authors of this study, antibiotic prophylaxis at the time of liver biopsy may be appropriate in this high-risk subgroup of patients, but biliary obstruction was not categorically excluded at the time of biopsy.

For surgical re-intervention very early after transplantation, the same peri-operative antibiotic prophylaxis as for liver transplantation appears adequate. For surgical interventions in later periods, the general guidelines for non-transplant patients undergoing surgery [116] seem sufficient, although the type of antibiotics to be administered should be adapted to the liver transplant patient condition (i.e. grade of immunosuppression) and local microbial epidemiology. **B4**

## Treatment

Antibiotic treatment should be started whenever a liver transplant patient develops either signs strongly suggesting infection (mainly significant fever), signs of sepsis or a well documented localized infection. Nevertheless, it is important to note that not all febrile episodes in liver transplant recipients correspond to infection [18]. When the need for treatment is defined, and after blood and other relevant site cultures are taken, antibiotic therapy is empirically initiated, without knowledge of the causative organisms and their *in vitro* susceptibility. Empirical therapy should be selected on the basis of different factors, particularly the site of the suspected infection and the local predominant pathogens and their susceptibility patterns. Other important factors are the time since transplantation, recent antibiotic administration, and the colonization status of the patient, if known. At each institution, protocols for empirical treatment of bacterial complications should be periodically revised and adapted to the changes in epidemiology and *in vitro* susceptibility of predominant organisms.

According to the commonest pathogens during the early period after transplantation (see Table 43.2), the most frequently used agents in the empiric therapy are third and fourth-generation cephalosporins, piperacilli-tazo-

bactam and quinolones [13, 117–119]. The administration of glycopeptides (vancomycin or teicoplanin) and carbapenems (imipenem, meropenem or ertapenem) can be justified in patients with sepsis and hospitalized in centers with a high incidence of MRSA and ESBL-producing Gram-negative bacilli, respectively [66, 118]. Once the responsible bacteria are identified and susceptibility tests are available, further adjustments may be required, consisting of either the withdrawal of superfluous antibiotics or the adequate antimicrobial changes if resistant organisms are isolated. Information on the adequacy of the initial empirical treatment is scarce in liver transplant patients with bacterial infection, although some authors have reported around 20% of failure [20, 61, 117]. However, the effectiveness of the initial empiric therapy does not seem to influence the final outcome provided the antibiotic therapy is rapidly modified according to the microbiological results, as also described in non-transplant populations [120–122]. **B4**

In later periods after transplantation, community-acquired pneumonia and urinary tract infection, the commonest bacterial infections in this postoperative phase [16, 47–49], are treated according to standard protocols in each center for immunosuppressed patients. Specific antibiotic therapy is administered for infections caused by infrequent but characteristic organisms, such as *Listeria* spp. and *Nocardia* spp. [47, 52].

## Special considerations

Surgical or percutaneous drainage is often required for the treatment of infections arising in devitalized anatomic sites, such as infected abdominal cavity collections or hepatic abscess [32, 36, 51]. Treatment of cholangitis secondary to biliary stenosis must include the endoscopic, radiological or surgical resolution of the stenosis [50]. The removal of IV lines is mandatory in catheter-related bacteremia [66].

Antibiotic treatment of pneumonia, especially in early stages following liver transplantation and in patients with mechanical ventilation, can be difficult because the responsible organisms are not identified in approximately 50% of episodes [20, 38]. Polymicrobial pneumonia, caused by more than one bacteria or bacteria combined with non-bacterial microbes, such as fungi, cytomegalovirus or *P. jirovecii* may represent an added difficulty for treatment [17, 20]. Although the empiric treatment of pneumonia attains a positive response in a relatively high proportion of patients, in patients who impair regardless of this therapy, invasive diagnostic procedures, such as fiberoptic bronchoscopy with bronchoalveolar lavage or lung biopsy, must be performed [20, 38, 62]. **B4** In spite of an aggressive diagnostic approach, the etiology of pneumonia can only be established on necropsy basis in some patients.

Since most liver transplant patients receive calcineurin inhibitors (tacrolimus or cyclosporine) as immunosuppres-

sive drugs, the potential capacity of different antibiotics to increase the risk of toxicity of calcineurin inhibitors must be taken into consideration [14]. Aminoglycosides can increase the risk of nephrotoxicity, and they should be avoided if possible [123]. Since imipenem may enhance the risk of seizures, particularly in patients with renal function or neurological impairment [124], the administration of other carbapenems (meropenem or ertapenem) may be more appropriate in patients treated with calcineurin inhibitors. Pharmacokinetic interactions of several antibiotics with calcineurin inhibitors metabolized by the hepatic cytochrome P-450 have been described [125, 126]. Rifampicin and nafcillin induce the metabolism of calcineurin inhibitors, with risk of rejection due to low levels of these immunosuppressants, whereas macrolides reduce their metabolism, with the consequent increased risk of toxicity. In patients who necessarily have to receive these antibiotics, a careful monitoring of blood levels of calcineurin inhibitors is mandatory. Since proliferation signal inhibitors (PSIs, also named mTOR inhibitors: sirolimus and everolimus) are also metabolized by the cytochrome P-450 [127, 128], it is likely that similar drug interactions can also occur.

## Tuberculosis

The incidence of tuberculosis in liver transplant recipients is around 1–2% in developed countries and 10–15% in endemic regions, which is much higher than that in the general population in the respective countries [129]. Reactivation of latent tuberculosis is considered the main mechanism for active tuberculosis in transplant recipients, which predominantly occurs within the first postoperative year [130, 131]. Approximately half of the patients have pulmonary disease, whereas the other half present with extrapulmonary or disseminated tuberculosis [130, 131]. Aggressive investigations are often required for the diagnosis, and, in some patients, the definitive diagnosis can only be established after a positive response to empiric treatment.

## Prevention

In patients receiving kidney transplantation, and, by extension, in patients with extra-renal transplantation, there is the general recommendation to administer antituberculous chemoprophylaxis with isoniazid for the first 9–12 postoperative months in transplant recipients with a past history of tuberculosis and/or pre-operative positive tuberculin test [88, 132–134]. **B4** However, regardless of the excellent efficacy of this strategy [130], prophylaxis with isoniazid in liver transplant patients with a positive tuberculin test is challenging for two reasons. First, a positive skin test without other additional risk factors is rarely associated

with latent infection reactivation [88]. As an example, in a study by our group, none of 73 patients with a pre-transplant positive tuberculin test developed post-transplant tuberculosis regardless of not receiving isoniazid prophylaxis [135]. In contrast, in the same study, tuberculosis was diagnosed in 2% of 279 patients with a negative tuberculin test; the incidence was especially high (10%) in patients with a past history of tuberculosis and untreated with isoniazid prophylaxis, thus suggesting that anergic patients with possible latent tuberculosis were very prone to develop latent infection reactivation. Second, an important concern for generalized isoniazid prophylaxis in liver transplant recipients with a pre-transplant tuberculin skin positive test is the high incidence of isoniazid hepatotoxicity, ranging from 17% to 41%, which can outweigh the possible benefit of this strategy [130, 135]. For these reasons, although there are no controlled studies on this issue, the general feeling is to limit isoniazid prophylaxis to patients with a history or chest X-ray evidence of past tuberculosis, particularly if it has been inadequately treated, or to patients with a positive skin test and additional risk factors (recent tuberculin conversion, non-Caucasian ethnicity or regional endemicity, and excessive immunosuppression) [88, 134]. **B4** In the remaining cases, surveillance and treatment of active tuberculosis, if it develops, seem sufficient. Alternative prophylactic regimes, particularly the combination of a quinolone and ethambutol, can be administered in the case of previous isoniazid administration forming part of inadequate antituberculous therapies or in the case of liver graft alterations precluding isoniazid treatment or making it hazardous. Another possibility is to administer prophylaxis while patients are on the waiting list for liver transplantation, although this strategy has been rarely explored [136].

## Treatment

The most recommended standard treatment for active tuberculosis in the general population is the combination of rifampicin, isoniazid, pyrazinamid and ethambutol for two months, followed by an additional four-month therapy with rifampicin and isoniazid [137, 138]. In transplant recipients, the length of treatment is extended up to 12 months in pulmonary disease and up to 18 months in extrapulmonary disease [139–143]. **B4** However, this therapeutic regime cannot be accomplished in a substantial proportion of patients due to hepatotoxicity, with an average incidence of around 30–40% [131, 130, 141, 144]. In patients with hepatotoxicity or significant liver graft alterations, the most hepatotoxic combination of rifampicin with isoniazid and/or pyrazinamide is usually withdrawn or avoided, and non-hepatotoxic or less hepatotoxic regimes, including ethambutol, quinolones, and rifabutin combined with isoniazid or pyrazinamide, are administered with satisfactory results [140, 142, 145].

## Viral infections

### Cytomegalovirus

Cytomegalovirus (CMV) belongs to the human herpesvirus family and is a significant opportunistic pathogen in liver transplantation. Infection by CMV is defined as the isolation of CMV or the detection of viral proteins or nuclear acids in whatever fluid or tissue of the organism [146, 147].

The clinical spectrum of CMV infection is very wide, from an asymptomatic infection to a lethal disease [147, 148]. Infection with CMV is classified as asymptomatic or symptomatic. An asymptomatic infection is defined by the detection of either the antigen pp65 of CMV in the leucocytes or the DNA of CMV in plasma, blood or leucocytes by PCR, without symptoms of the infection and without affecting organs [143, 149]. Symptomatic infection or CMV disease may manifest as a febrile viremic illness often associated with leukopenia and thrombocytopenia (CMV syndrome) or as an organ-specific disease, such as colitis, hepatitis and pneumonia. In case of organ involvement, the diagnosis can be established by histopathologic or cytological changes suggestive of CMV disease, particularly intranuclear inclusions and positive immunohistochemistry. In most cases, CMV disease occurs at weeks four to six after transplantation.

### Risk factors

CMV infection can be primarily acquired from the graft or from transfused blood products in patients lacking pre-existent CMV-specific immunity or can result from reactivation of latent virus or superinfection with a new strain [146, 150–152]. The risk of developing CMV infection and disease after liver transplantation is related to the donor and recipient CMV serostatus. Seronegative recipients of grafts from seropositive donors (D+/R–) are at the highest risk, with an incidence of infection of up to 80% and an incidence of disease of up to 60% in the absence of anti-CMV prophylaxis [151]. Seronegative patients who receive an organ from a seronegative donor (D–/R–) are considered at the lowest risk, although CMV infection can still develop from blood products, particularly if they receive unscreened pool of platelets [150]. Seropositive recipients have an intermediate risk, with an incidence of CMV disease of approximately 20% when the donor is also seropositive (D+/R+) and 10% when the donor is seronegative (D–/R+) [151]. Re-transplantation, antilymphocytic antibodies, and high levels of immunosuppressants are also risk factors for CMV infection.

### Prophylaxis

Prophylaxis of CMV infection is the administration of anti-CMV treatment prior to the detection of active CMV repli-

cation, usually for the first three post-operative months. There are two strategies of prophylaxis: universal prophylaxis, when it is administered to all transplant recipients, and targeted prophylaxis, when it is only administered to high-risk patients [153]. Oral valganciclovir is the most commonly used antiviral agent for prophylaxis of CMV in liver transplant patients. A number of reports have documented the efficacy of this strategy [153–159], with CMV disease development in only 15–30% of the D+/R– patients who received valganciclovir prophylaxis [160, 161]. **B4** The other potential benefit is the reduction of the indirect effects of CMV infection, including graft loss, fungal infection and even bacterial infection [160–163]. Potential risks are cost, toxicity, CMV resistance to ganciclovir, and the possible development of late onset CMV disease [164]. These risks have questioned universal prophylaxis and even targeted prophylaxis in favour of pre-emptive therapy. Prolonged prophylaxis beyond the month three and CMV infection monitoring after prophylaxis cessation have been proposed [162].

### Preemptive therapy

Preemptive therapy is the administration of anti-CMV treatment after the detection of active CMV infection but prior to the development of symptomatic disease. With this strategy, transplant recipients are carefully monitored for early evidence of viral replication by using CMV antigenemia assay or PCR for detection of viral DNA, followed by preemptive therapy at the first positive result. Some authors use a specific quantitative threshold value as an indicator for the initiation of antiviral medication in seropositive transplant recipients, but begin treatment in high risk recipients whenever any level of CMV antigenemia or viral DNA becomes detectable [159]. Valganciclovir is also the drug of choice for preemptive therapy. Recent studies have shown its efficacy in D+/R–, pointing again to the advantages of preemptive therapy over targeted prophylaxis [161, 162, 164]. **B4** However, more studies are needed to validate these findings.

### Therapy

The recommended treatment of a proven or suspected CMV infection is the IV administration of ganciclovir, an inhibitor of the CMV DNA polymerase [165]. In mild to moderate CMV disease, the duration of treatment is usually 14–21 days, although the best strategy is to stop the therapy when two weekly negative CMV tests (antigenemia or PCR) are achieved [151]. In many cases, oral valganciclovir can be used to complete the treatment after an initial period of IV administration of ganciclovir and when clinical symptoms have resolved. In a recent trial, oral valganciclovir has been as effective as IV ganciclovir in the treatment of non-severe CMV disease [166]. **A1d** The duration of the treatment in compartmentalized disease, that is, organ

involvement with minimally detectable or undetectable viremia, is more challenging. The most important adverse effect of ganciclovir and valganciclovir is bone marrow suppression. In case of severe bone marrow toxicity or ganciclovir resistance (very rare in liver transplant recipients), foscarnet is the best alternative treatment. Nephrotoxicity is the most important adverse effect of foscarnet [165].

### Epstein-Barr (EBV) virus

In liver transplantation, EBV infection is usually primary in children, whereas reactivation is the predominant mechanism for infection in adults [167]. Symptomatic EBV infection mainly consists of fever, leukopenia, lymphomonocytosis or thrombocytopenia, although approximately the half of patients present with atypical symptoms and signs [146]. However, the most important consequence of EBV infection in solid organ transplant recipients is its association with the development of post-transplantation lymphoproliferative disease.

### Post-transplantation lymphoproliferative disease

The association between EBV and post-transplant lymphoproliferative disease (PTLD) has been recognized since the early days of transplantation, although not all cases can be attributed to EBV [168–171]. The major pathogenic mechanism for PTLD is the insufficient EBV-specific cytotoxic T-cell control on EBV-driven B-cell proliferation [171]. PTLD, a systemic process involving both nodal and extranodal tissues, ranges from an infectious mononucleosis-like reactive plasmacytic hyperplasia to a lymphoma [172]. The incidence of PTLD in liver transplant recipients is around 2%, although children are particularly exposed, with an incidence approximately three times as high [173]. Poly- and monoclonal anti-lymphocyte antibodies and maintenance immunosuppression with azathioprine are major risk factors for PTLD, although doses of maintenance azathioprine used in liver transplantation are lower than in other solid organ transplants [174]. High EBV load may also be a risk factor, and this has led some authors to postulate that preemptive antiviral therapy and reduction of immunosuppression on the basis of viral load monitoring could be indicated to prevent EBV-associated PTLD [174, 175]. However, the efficacy of such a prophylaxis strategy is uncertain. Treatment of PTLD includes reduction of immunosuppression if possible, chemotherapy and anti-B-cell antibodies (rituximab) when PTLD has evolved to lymphoma, and surgical resection and radiotherapy in patients with tumor masses. Administration of interferon, immune globulin and anti-EBV treatment with acyclovir or ganciclovir are other potential therapies, although their efficacy is unproven [143, 174].

## Other herpesvirus

### Herpes simplex virus

Herpes simplex virus (HSV) infection, commonly caused by reactivation of a latent infection, predominantly involves mucosal surfaces [13]. Disseminated forms are rare. Treatment and prophylaxis is based on the administration of acyclovir or valacyclovir.

### Varicella zoster virus

Localized cutaneous zoster, secondary to a reactivation of latent varicella zoster virus infection, occurs with an incidence of approximately 5–10% in solid-organ transplant recipients [143]. Primary infection, although very rare in adults, can be more aggressive with severe organ involvement. Acyclovir and valacyclovir are the most used agents for treatment of varicella zoster virus infection [143].

### Human herpesvirus 6 and 7

After the primary infection, human herpesvirus (HHV) type 6 and type 7 remain latent in the host and can reactivate after transplantation and cause varied clinical manifestations, such as fever, cutaneous rash, pneumonitis, encephalitis, hepatitis and myelosuppression [176]. Although the incidence of HHV 6 and 7 infection is low [177], the interest for these pathogens or copathogens in transplant recipients is increasing due to the possibility of indirect effects: association with CMV disease, increased risk of opportunistic infections, and graft dysfunction and rejection [171, 176, 178]. Antiviral agents active against CMV are also active against HHV-6.

### Human herpesvirus 8

Human herpesvirus 8 (HHV-8) causes Kaposi's sarcoma, as well as primary effusion lymphoma (PEL) and many cases of multicentric Castleman disease (MCD) [179, 180]. Other co-factors, mainly immunosuppression, are also necessary. Current treatment options of Kaposi's sarcoma are limited to reduction in immunosuppression and chemotherapy [146]. Although an important reduction in HHV-8 replication by valganciclovir has been recently reported in non-transplanted patients [181], antiviral medication in combination with chemotherapy has been rarely investigated in the setting of organ transplantation [180, 182]. Interestingly, the conversion to PSI immunosuppressive drugs has been followed by regression of Kaposi's sarcoma in kidney transplant patients [183, 184]. **B4** Therefore, PSIs provide a potential treatment option in the management of post-transplant Kaposi's sarcoma.

## Fungal infections

Systemic fungal infections are a significant cause of morbidity and mortality in solid organ transplant recipients.

**Table 43.4** Specific risk factors for fungal infections (in addition to the general factors for infection shown in Table 43.1).

Pre-transplant period:
Steroid therapy
Hemodialysis, hemofiltration
Fungal colonization ( <i>Aspergillus</i> )
Re-transplantation
Intra-operative period:
Prolonged and difficult surgical intervention
Important blood product transfusion
Combined liver-kidney transplantation
Early post-operative period (<30 days):
Hemodialysis, hemofiltration
In all periods:
Broad-spectrum antibacterial therapy
Prolonged stay at the intensive care unit
Prolonged mechanical ventilation
Parenteral nutrition

The incidence of fungal infections after liver transplantation has been reported in the range of 7–42%, with *Candida* spp. and *Aspergillus* spp. as the most common pathogens [185, 186]. Other fungi (i.e. *Cryptococcus neoformans* or spp.) are much less frequently detected. Mortality rate has been reported as high as 92–100% for invasive aspergillosis and 70% for invasive candidiasis. The incidence of invasive fungal infection (but, unfortunately, not its related mortality) has decreased over time in most transplant centers due to the improvement in surgical technique and postoperative care, the use of low-dose steroid or even steroid-free immunosuppressive regimes, and the identification of risk factors for invasive fungal infection which has led to antifungal preemptive therapy [185–187]. Table 43.4 shows the specific risk factors for fungal infection, which should be taken into consideration to indicate antifungal prophylaxis [185–189].

### Antifungal prophylaxis

Both universal and preemptive strategies have been attempted in the prevention of fungal infection. Nystatin was initially used to prevent *Candida* mucositis, and fluconazole or other azole agents are routinely administered in most centers. Furthermore, targeted or preemptive antifungal prophylaxis has been increasingly used once risk factors for fungal infection became known. A recent meta-analysis of six studies on antifungal prophylaxis (study drugs: fluconazole, itraconazole and liposomal amphotericin B, alone or in combination, for five days to ten weeks) showed a beneficial effect of such a prophylaxis on morbidity and

mortality attributable to fungal infections [188]. Compared to controls, patients who received prophylaxis had fewer fungal infection episodes, due to a decrease in both invasive and superficial infections (69% and 73% relative risk reduction respectively). Fungal infection-related mortality also experienced a 72% relative risk reduction in the prophylaxis groups. In contrast, antifungal prophylaxis did not affect the need of empiric treatment for suspected fungal infections, the incidence of invasive *Aspergillus* infection and overall mortality. Patients receiving prophylaxis showed an increased proportion of episodes of non-*albicans* *Candida*, mainly *Candida glabrata*. Overall, the conclusion of this meta-analysis is that the benefits of universal antifungal prophylaxis are evident but limited and should be balanced with the disadvantages, particularly the selection of azole-resistant *Candida* spp.

In a recent study, liposomal amphotericin B versus fluconazole prophylaxis targeted to high-risk liver transplant subjects (two or more risk factors) attained similar rates of invasive fungal infection [189]. However, the incidence of invasive fungal infection in both arms was lower than that previously reported in untreated high-risk patients. The two antifungal prophylactic regimes were well tolerated. Another recent, prospective, multicenter, noncomparative, open-label trial, evaluating the prophylactic use of caspofungin in adult liver transplant recipients at high risk for invasive fungal infection [190], showed that only 2 out of 71 patients developed mucor and *Candida albicans* surgical infections, and this occurred 41 and 19 days after the end of prophylaxis, thus indicating that caspofungin was highly effective. Caspofungin was well tolerated in general, but it was associated with drug-related altered liver function requiring therapy discontinuation in 8% of patients.

Universal prevention against *Pneumocystis jirovecii* is followed at most centers, with excellent results since infection by this fungus has been virtually eradicated [45, 143]. In liver transplantation, the administration of low-dose cotrimoxazole for the first six to nine postoperative months is the first-option prophylaxis. Beyond this period, prophylaxis could be indicated in patients receiving powerful immunosuppression. Cotrimoxazole prophylaxis is also effective against *Toxoplasma gondii*, a protozoa which can also cause infection in liver transplant recipients [45]. In patients in whom cotrimoxazole cannot be given or is discontinued early due to toxicity, aerosolized pentamidine or oral dapsone are adequate alternatives.

### Treatment of invasive fungal infections

Invasive fungal infection is associated with a poor outcome, especially when the infection is diagnosed late. Therefore, early diagnosis and treatment are highly recommended. Microbiological, histological, radiological and molecular

tests are necessary for the diagnosis [191, 192]. Antifungal treatment can be empirically initiated in patients with signs of infection not responding to adequate antibacterial treatment, provided appropriate tests to detect fungal infection are performed, but results are not available yet [192].

Invasive *Candida* spp. infection is treated with fluconazole or itraconazole, unless the patient was receiving azole prophylaxis or azole-resistant non-*Candida albicans* is isolated (i.e. *Candida glabrata*). In these cases, amphotericin B or caspofungin are the recommended drugs [193]. Invasive aspergillosis is usually treated with amphotericin B, voriconazole or caspofungin, alone or in combination, mainly according to the severity of the infection and the response to the initial therapy [192, 194]. However, the management of invasive aspergillosis is a challenging issue. Reduction in immunosuppression, if possible, is also recommended.

## Management of HCV infection and liver transplantation

*Brett E Fortune, Hugo R Rosen and James R Burton, Jr*

University of Colorado, Denver, Colorado, USA

### Introduction

Hepatitis C virus (HCV) is the leading indication for liver transplantation (LT) worldwide. With recurrence of HCV being universal and a significant percentage developing severe allograft fibrosis, recurrent HCV infection represents one of the most significant issues facing the transplant physician today. HCV in the transplant setting is most challenging given the limited applicability and reduced tolerability of antiviral therapy and lower rates of response in comparison to the non-transplant setting.

### Natural history of recurrent HCV

Recurrence is immediate and universal with viral levels after 1–3 months post-LT, often being twenty-fold greater than in the pre-LT period [1]. The natural history of recurrent HCV after LT is accelerated compared to HCV infection in the non-transplant setting. Between 20–40% of patients transplanted for HCV develop allograft cirrhosis in five years compared to less than 5–20% at 20 years in the non-transplant setting [2–4]. Once cirrhosis develops, decompensation (variceal bleeding, ascites, hepatic encephalopathy) occurs in 25–67% within three years, compared to ~10% in immunocompetent HCV patients with cirrhosis [3–5]. Once decompensation develops after LT, outcome is very poor, with <10% surviving three years. Despite this accelerated course, a third of patients will demonstrate minimal fibrosis at five years [6]. Although short-term studies have shown patient and graft survival is similar for patients undergoing LT for HCV compared to other indications, analysis of the United Network for Organ Sharing (UNOS) database revealed significantly diminished sur-

vival five years after LT in HCV-positive patients compared to HCV-negative patients (56.7% vs 65.6%;  $p < 0.05$ ) [7].

Fibrosing cholestatic HCV infection occurs in approximately 5% of patients transplanted for HCV diagnoses. It is characterized by a rapidly progressive cholestatic hepatitis which typically develops one to three months post-LT, resulting in graft failure in three to nine months [8]. Typically very high HCV RNA levels are seen with serum bilirubin levels >6g/dl and alkaline phosphatase levels greater than five times the upper limit of normal with normal cholangiogram. The pathogenesis is likely immunologically different from typical HCV-induced allograft failure with preferential Th2 cytokine production by intra-hepatic lymphocytes being implicated [9, 10]. Treatment focuses on minimizing immunosuppression and viral suppression with indefinite use of interferon based antiviral therapy [11].

### Factors associated with severe HCV recurrence

A number of factors have been associated with severe HCV recurrence that affects both patient and graft survival. Table 44.1 outlines these donor, viral and transplant factors. Given the detrimental effects of treating acute cellular rejection with corticosteroids [12–14], suspicion for rejection in HCV patients should always be confirmed with liver biopsy. Differentiating recurrent HCV alone from recurrent HCV and rejection can be challenging [15]. Mild rejection may be treated without steroids by increasing calcineurin inhibitors or addition/increase of mycophenolate mofetil [16, 17]. The long-term effects of this approach are unknown. How best to handle maintenance immunosuppression is a hotly debated topic. Despite numerous pieces of literature on the role of immunosuppression and the effects on recurrent HCV, no clear conclusions can be drawn.

## Treatment of recurrent HCV

The treatment of HCV after LT has improved significantly over the past decade, with the best results obtained with utilizing pegylated interferon (peginterferon) with ribavirin, which this review will focus on primarily [18, 19]. Trials utilizing standard interferon and ribavirin have been reviewed separately [20]. The timing of antiviral therapy has played a major variable in studies investigating efficacy of treatment. Several treatment strategies have been proposed for managing recurrent HCV, with goals to prevent or slow disease progression (see Table 44.2). Rates of sustained virological response (SVR; HCV RNA undetectable six months after stopping therapy) are far less than those achieved in immunocompetent HCV-infected patients (overall 20–30%). There are a number of factors contributing to lower virological response rates to antiviral therapy in liver transplant patients (see Table 44.3) with similar

predictors of virological response as in non-transplant HCV infection. Possible predictors of SVR include early virological response (EVR, >2 log drop in HCV RNA at 12 weeks), infection with genotype 2, adherence to therapy and baseline viremia [18]. Primary treatment endpoints include histological response, graft survival and patient survival. While typically the major indication for treatment is driven largely by allograft damage, significant psychological and social factors of the patient play a role in withholding antiviral therapy in some cases.

## Pre-transplant antiviral therapy

Pre-transplant antiviral therapy is an attractive approach in which those with undetectable HCV RNA going into transplant may eliminate the risk of developing recurrent HCV. In some cases when patients achieve SVR from this regimen, they may completely avoid transplantation altogether. A recent review shows that up to two-thirds of patients who obtain SVR prior to liver transplantation will remain free of HCV in the post-transplant setting. This rate is lower for patients without achievement of SVR [21].

**Table 44.1** Risk factors associated with severe HCV recurrence.

Category	Factor
Donor factors	Donor age >40yrs Prolonged cold ischemia time Female sex Living donor liver transplant experience (<20 cases)
Viral factors	HCV genotype 1 in some studies High viral load at liver transplantation
Transplant factors	CMV infection Diabetes mellitus Higher average daily steroid use Treatment of acute cellular rejection with: Corticosteroid boluses OKT3 use

**Table 44.3** Contributing factors leading to lower response rates to antiviral therapy in liver transplant patients.

- High HCV RNA levels post-LT
- High prevalence of genotype 1, previous non-responders to antiviral therapy
- Presence of immunosuppression
- Poor clinical status and tolerability, especially early post-LT
- Cytopenias as result of immunosuppression requiring dose reduction and use of growth factors
- Renal insufficiency limiting dose of ribavirin on account of its associated risk of hemolytic anemia

**Table 44.2** Antiviral treatment strategies for recurrent HCV.

Treatment strategy	Timing of antiviral therapy	Advantage	Disadvantage
Pre-transplant	Prior to LT	Eliminate or reduce risk of recurrent HCV Potential to avoid LT	Low virological response Limited tolerability and potential for serious adverse effects
Preemptive	Early post-LT	Relatively low HCV RNA levels Minimal or no histological disease	Maximal immunosuppression Higher risk of rejection and infection
Established disease	Diagnosis of acute hepatitis or established and/or severe disease	Lower immunosuppression Improved clinical status and better tolerance Lower risk of rejection	High HCV RNA levels More advanced fibrosis

Unfortunately, this is a difficult group to treat given low response rates due to the high prevalence of genotype 1 and underlying cirrhosis and its associated side effects (e.g. leukopenia, thrombocytopenia).

One of the largest studies of pre-transplant antiviral therapy by Everson *et al.* described their experience with a low accelerating dose regimen (LADR) of primarily non-pegylated interferon and ribavirin and its efficacy for HCV clearance prior to transplant [22]. A total of 124 patients (70% genotype 1 and 63% having Child-Pugh class B or C) were treated, with 24% achieving SVR (13% genotype 1 and 50% non-genotype 1). Twelve out of 15 (80%) of patients who were HCV RNA negative going into transplant remained HCV RNA negative at least six months after LT.

Three comparative studies of peginterferon in liver transplant candidates (although included patients were not necessarily already considered or placed on transplant listing) have been reported [23–25]. DiMarco *et al.* reported results of 102 patients (67% treatment naive) randomized to receive peginterferon  $\alpha$ -2b monotherapy or peginterferon plus ribavirin (800 mg) for up to 52 weeks (treatment was stopped if HCV RNA was not undetectable at 24 weeks) [23]. Overall, SVR was 19.6% in the peginterferon and ribavirin group and 9.8% in peginterferon monotherapy group ( $p = 0.06$ ). Not surprising, response rates for non-genotype 1 were higher than for genotype 1 (66% vs 11%,  $p = 0.001$ ). Discontinuation was 27% in the peginterferon and ribavirin group and 41% in the peginterferon group. Helbling *et al.* randomized 124 naive patients to either peginterferon  $\alpha$ -2a plus standard dose ribavirin (1000–1200 mg) or peginterferon plus low dose ribavirin (600–800 mg) for 48 weeks [24]. SVR was 50% with the standard dose ribavirin group compared to 38% for the lower dose group ( $p = 0.153$ ). Both groups had similar rates of treatment discontinuation. Finally, in a nonrandomized controlled trial, the first to specifically assess the effect of antiviral therapy on liver function in patients with decompensated HCV cirrhosis, Iacobellis *et al.* compared 66 patients treated with peginterferon  $\alpha$ -2b and ribavirin (800–1000 mg) to 63 controls (no treatment). Twenty percent of the treatment group achieved SVR [25]. The study had similar discontinuation rates for the treatment group as observed in prior studies and survival was not different between the two groups, but a *post hoc* analysis showed a survival benefit in the treated group. An important finding in this study was a decreased incidence of decompensation (ascites, hepatic encephalopathy) in the treated group compared to the controls during follow-up. However it did not translate into increased survival in the treated patients.

In summary, pre-transplant antiviral therapy should be strongly considered in patients with cirrhosis who have Child-Pugh scores  $\leq 7$  or Model for End-Stage Liver Disease (MELD) scores  $\leq 18$  [8]. (MELD score =  $10 [0.957 \text{Ln} (\text{serum creatinine}) + 0.378 \text{Ln} (\text{total bilirubin}) + 1.12 \text{Ln}$

(INR) + 0.643].) **B2** A special group that should be strongly considered for antiviral therapy while awaiting transplantation are patients with well compensated liver disease upgraded on the transplant list solely for an indication of hepatocellular carcinoma, especially if they are non-genotype 1. **B4** Our program attempts to make these patients HCV RNA negative on treatment for at least two months before proceeding with either cadaveric or living donor transplantation. However, it is important to emphasize that the majority of HCV-infected patients without hepatocellular carcinoma will not be optimal candidates for antiviral therapy by the time they have moved up on the transplant list, due to their disease severity.

---

## Preemptive antiviral treatment

Preemptive treatment refers to early antiviral therapy days to weeks after LT, before the development of histological recurrence. A number of theoretical advantages exist with this approach in that patients have lower HCV RNA levels and lack histological disease. However, from a clinical standpoint, treatment at this time is most challenging due to poor clinical status, cytopenias from maximal immunosuppression, and higher rates of rejection and infection in the early transplant period. Only about 60% of LT recipients are eligible for preemptive therapy, with the need for dose reduction occurring in up to 50% of treated patients [26]. A recent meta-analysis found no studies of preemptive therapy that satisfied inclusion for analysis [19]. In summary, the efficacy of preemptive anti-viral therapy remains to be defined and should only be considered in patients undergoing retransplantation for rapidly progressive HCV recurrence [8].

---

## Treatment of established disease

Given the lack of efficacy and limitations of preemptive therapy, many transplant centers have opted to delay treatment until significant recurrent disease is verified. By taking this approach, treatment is focused on those likely to achieve benefit with antiviral therapy, avoiding unnecessary toxicity and side effects in those without significant disease recurrence. Two general approaches have been used to treat established disease. One approach initiates antiviral treatment at the diagnosis of acute recurrent hepatitis utilizing liver biopsy to exclude other causes for elevated liver enzymes, such as rejection. The second approach followed by most transplant centers is to initiate antiviral therapy when clinically significant evidence of recurrence exists. This latter approach utilizes protocol and/or clinically indicated liver biopsies reporting both the grade and stage of recurrent disease.

**Table 44.4** Published of controlled trials utilizing peginterferon and ribavirin for treating recurrent HCV vs no treatment.

Author year	Type of Study	# of Patients	Antiviral Regimen	Duration (weeks)	SVR	Histological Response <sup>a</sup>	Genotype 1 (%)
Castells, 2005	NRT	48	(1) PEG-IFN (1.5 mcg/kg/wk) + Riba (600–800 mg/d) for 24 wks + 24 wks if RNA neg (2) No treatment	24–48	(1) 33% (2) 0%	NR	100
Bizollon, 2007	NRT	48	(1) PEG-IFN (1.5 mcg/kg/wk) + Riba (800–1000 mg/d) (2) No treatment	48	(1) 30% (2) 0%	(1) 100% (2) 24%	85
Carrion, 2007	RCT	54	(1) PEG-IFN (1.5 mcg/kg/wk) + Riba (800–1200 mg/d) (2) No treatment	48	(1) 48% (2) 0%	(1) 74% (2) 30%	79

NRT: nonrandomized trial; RCT: randomized controlled trial; Riba: ribavirin; SVR: sustained virological response; NR: not reported.

<sup>a</sup>Defined as fibrosis stabilization (same fibrosis stage) or fibrosis improvement (reduction of  $\geq 1$  fibrosis stage).

Protocol liver biopsies in patients transplanted for HCV may be useful given the potential for significant fibrosis progression and has largely become standard of care [8]. Since fibrosis progression is not linear over time, possibly progressing more rapidly in the first post-LT year, the 12-month liver biopsy has the ability to stratify fibrosis progression. Those developing severe disease recurrence within the first transplant year are at a high likelihood of progressing to cirrhosis and should be considered for antiviral therapy [14, 27]. Furthermore, the absence of fibrosis 12 months post-LT is associated with excellent cirrhosis-free survival [14]. The measurement of hepatic venous pressure gradients (HVPG; wedged hepatic vein pressure minus free hepatic vein pressure) appears to be a useful tool in assessing disease severity in recurrent HCV [28]. HVPG measurements  $\geq 6$  mmHg in one study [29], or  $\geq 10$  mmHg in another study [5], at one year post-LT have been shown to be extremely accurate in predicting clinical decompensation over liver biopsy. The same group has also shown good correlation between HVPG measurements and histological response with antiviral therapy [30]. In summary, patients with fibrosis stage  $\geq 2$  out of 4, severe inflammation (grade 3 or 4), evidence of significant hepatic dysfunction (elevated bilirubin, prolonged prothrombin time), or HVPG gradients  $\geq 6$  should be strongly considered for antiviral therapy [5, 8] **B4**

### Controlled trials of peginterferon and ribavirin

The current standard of care for treating established recurrent HCV is pegylated interferon and ribavirin therapy. Multiple studies using various study designs and endpoints have been performed to evaluate the efficacy of established disease therapy after transplantation, with end-

points consisting of SVR, histological improvement, and allograft and patient survival. It appears that there is no significant correlation between success of antiviral therapy and the interval of time from transplant and start of antiviral therapy. There are only three comparative studies of peginterferon and ribavirin in treatment of established recurrent HCV (see Table 44.4 and Figure 44.1) with only one randomized study [30–32].

Castells *et al.* studied 24 patients receiving peginterferon  $\alpha 2b$  (1.5 mcg/kg/wk) and ribavirin (600–800 mg/day) for 48 weeks (if HCV RNA undetectable at 24 weeks) and 24 consecutive untreated controls [30]. All patients were genotype 1 and treatment was initiated for acute recurrent HCV confirmed on biopsy (mean four months after LT). Growth factors (filgrastim and darbepoetin alpha) were given and anemia and leukopenia occurred in 71% and 96% of cases respectively. Overall SVR was 33% in the treatment group and 0% in controls. One patient developed acute cellular rejection in the treatment group (two in the control group) that resolved with adjusting immunosuppression. No histological follow-up was reported in this study. On univariate analysis, SVR was associated with absence of corticosteroid administration to treat rejection ( $p = 0.01$ ), presence of early virological response (EVR  $> 2$  log drop in HCV RNA at week 12) ( $p = 0.002$ ) and absence of cytomegalovirus infection ( $p = 0.001$ ). **B2**

Bizollon *et al.* studied 27 patients with established recurrent HCV (median ten months after LT) receiving peginterferon  $\alpha 2b$  (1.5 mg/kg/wk) and ribavirin (800–1000 mg/d) for 48 weeks and compared them to 21 consecutive untreated controls [31]. Seventy nine percent were genotype 1 and some had previous treatment post-LT with non-pegylated interferon and ribavirin. Filgrastim was not used, but erythropoietin alpha was given. SVR was 30% in

**Figure 44.1** Forest Plot of sustained virological response and histological response rates in comparative studies of pegylated interferon and ribavirin versus no therapy in patients transplanted for HCV related cirrhosis with recurrent disease.

Tx: treatment.

Adapted from Xirouchakis E *et al.* Pegylated-interferon and ribavirin in transplant candidates and recipients with HCV cirrhosis: systemic review and meta-analysis of prospective controlled studies. *J Viral Hep* 2008; **15**: 699–709.

treatment group and 0% in controls. Two patients in the treatment group and one in the control group had acute cellular rejection. Patients completing treatment had improvement (65%) or stabilization (35%) of fibrosis 24 weeks after completing treatment. All eight patients achieving SVR had improvement in histology. Based on univariate analysis, the use of cyclosporine ( $p = 0.03$ ) and early virological response ( $p = 0.02$ ) were associated with SVR.

## B2

Carrion *et al.* have published the only randomized study to date [32]. In this study, 54 patients with mild HCV recurrence (F0–F2) at least six months post-LT were randomized to either peginterferon  $\alpha 2b$  (1.5 mcg/kg/wk) and ribavirin (800–1200 mg/day) for 48 weeks or no treatment. Filgrastim and darbepoetin were used to treat neutropenia and anemia respectively. Eighty-five percent were genotype 1 and treatment was initiated a mean of 16 months post-LT. Overall SVR in the treatment group was 48%. Histological response (improvement or stabilization six months after completing antiviral therapy) was seen in 74% of the treated compared to 30% of controls with all patients achieving SVR having a histological response. Biochemical response (normalization of ALT) on multivariate analysis independently predicted fibrosis improvement or stabilization. Hepatic venous pressure gradient also correlated with progression of fibrosis. **A1d**

## Graft survival

Bizollon *et al.* in a retrospective study analyzed the effect of SVR on graft survival in 80 patients treated for recurrent HCV at least six months after transplant with nonpegylated interferon and ribavirin [33]. Erythropoietin was utilized. Overall SVR was 42%. In those achieving SVR, 82% had either stabilization or improvement in fibrosis compared to

26% in those not achieving SVR ( $p < 0.001$ ). Among responders without cirrhosis at inclusion, none developed cirrhosis at the end of follow-up. In the one patient with cirrhosis at inclusion, no decompensation or hepatocellular carcinoma occurred. In nonresponders, 9 of 48 (19%) developed cirrhosis after a mean of 32 months. Four of the nine developed decompensation, with three being retransplanted a mean of seven months following diagnosis of cirrhosis.

Veldt *et al.* performed a larger study to investigate treatment benefits on graft survival [34]. In this retrospective cohort study, 78 patients treated predominately with peginterferon ( $n = 61$ ) in combination with ribavirin ( $n = 69$ ) were compared to 81 contemporary untreated patients, to assess graft survival. As treated patients may have been selected on the basis of medical compliance, mean immunosuppression levels were compared during the first month after transplant, between treated and untreated patients, as a measure for previous treatment compliance; no statistical differences were seen. Patients with severe recurrence resulting in graft failure or death within six months of transplant were not evaluated. Erythropoietin was utilized in this study. Seventy-four percent of treated patients had stage  $<2$  compared to 82% in control group ( $p = 0.82$ ). Overall SVR was 34%. A difference in graft survival was shown for patients treated within six months of HCV recurrence ( $n = 40$ ) compared to those not treated within this time period (log rank  $p = 0.002$ ). **B2**

## Patient survival

Two studies specifically focused on the effect of antiviral therapy on overall survival [35, 36]. Picciotto *et al.* prospectively analyzed the long-term effect of SVR on survival in 61 patients naive to treatment receiving peginterferon

(1 mcg/kg/wk) with ribavirin (600–800 mg) [35]. No patients received erythropoietin or filgrastim. Overall SVR was 28%. The group achieving SVR had an improved survival compared to those not achieving SVR ( $x^2 = 6.9$ ;  $p < 0.01$ ). **B4** Berenguer *et al.* performed a larger study to investigate effect of antiviral therapy on survival by comparing those receiving antiviral treatment ( $n = 89$ ; 31 treated with interferon and ribavirin and 58 treated with peginterferon and ribavirin) with untreated contemporary controls ( $n = 75$ ) [36]. Overall SVR was 37%. At seven years after transplant, 74% of the treatment group were alive versus 62% in the control group ( $p = 0.04$ ). They also saw higher five-year survival among the SVR group versus the nonresponder group, 93% versus 69%,  $p = 0.032$ ). **B2**

### Risk of acute cellular rejection and alloimmune hepatitis

A potentially serious and controversial complication of antiviral therapy in transplant patients is rejection. Concern exists that pegylated interferon may be associated with an increased risk of rejection because of its extended half-life. Three uncontrolled studies of pegylated interferon and ribavirin yield conflicting results, with no cases of rejection in two studies, and a rate of 25% in another [37–39]. Although rates of rejection were not significantly different in these trials, the trend for acute rejection was observed and cannot be dismissed [40]. However, controlled trials of pegylated interferon monotherapy as prophylactic therapy and for treatment of established disease showed no difference in rejection rates between treated and control patients [41]. Additionally, a recent randomized controlled trial of peginterferon and ribavirin for established disease reported no significant risk of rejection with treatment [32]. No clear association with antiviral therapy and development of chronic rejection exists. Moreover, data from the University of Colorado and other centers suggest that close monitoring of calcineurin inhibitor levels are necessary during antiviral therapy as a greater proportion of antiviral responders experienced a greater reduction in immunosuppression levels than nonresponders [42]. This is presumably due to improved hepatic function leading to enhanced biotransformation and lower immunosuppression levels [43]. This decrease in immunosuppression levels may play a key role in predisposing these patients to rejection.

Another potential complication from antiviral therapy is *de novo* autoimmune (or more appropriately alloimmune) hepatitis (AIH). Several case reports have observed patients with the development of worsening allograft function and found to have biopsy findings consistent with AIH [44–46]. The theory for this occurrence is based on the immunomodulatory properties of peginterferon/interferon therapy. One case series found a positive predictive factor

to be the use of anti-lymphocyte antibodies as induction for immunosuppression and protection from AIH with the use of G-CSF [45]. Unfortunately, due to small populations, it is difficult to determine the clinical significance of these findings, but AIH as a potential complication of peginterferon-based therapy cannot be dismissed. There should be a high suspicion for this condition in patients on antiviral therapy who have worsening liver enzymes in the setting of an undetectable HCV RNA. Treatment revolves around stopping antiviral therapy and modification to immunosuppression regimen.

### Retransplantation for allograft cirrhosis

For patients who either fail or do not tolerate antiviral therapy, the only option for those developing allograft failure from recurrent HCV is retransplantation. Retransplantation, regardless of indication may conflict with the mandate to avoid futile transplantation in that retransplantation is associated with a 20–30% reduction in survival and 40–50% higher costs compared to primary transplantation [47]. A recent US multicenter study of retransplantation for HCV found that 30% of patients with graft failure from recurrent HCV are not considered for retransplantation and only half of those who are evaluated are eventually relisted [48]. Furthermore, of those who are eventually listed, 80% die while waiting for retransplantation. The current MELD allocation system designed to transplant the “sickest first” may not favor patients needing retransplantation [49]. In the above mentioned multicenter study, MELD scores greater than 30 were associated with poor survival following retransplantation [47].

### Summary

Based on available data, treatment of established disease recurrence (moderate fibrosis; stage  $\geq 2$ ) appears to be the most efficacious approach to managing recurrent HCV. **A1d B2** The primary goal of therapy should be SVR using full dose combination therapy with peginterferon and ribavirin and utilizing growth factors if necessary to minimize dose reduction and discontinuation. If SVR is not attainable, histological and overall graft and survival benefit appears to correlate with antiviral treatment. A number of unanswered questions remain in the management of recurrent HCV. The optimal basal immunosuppressive regimen for HCV patients remains to be defined. The optimal length of antiviral therapy post-LT and role of maintenance peginterferon is not known. Given the accelerated natural history of recurrent HCV, limitations of antiviral therapy and poor outcome with retransplantation, there is an urgent need for safer and more effective therapies. New

antiviral therapies currently under investigation may have a promising role in managing these difficult patients by shortening treatment course and/or improving antiviral response rates. Unfortunately these new drugs will be used in combination with peginterferon and ribavirin, thus not avoiding many of the potential side effects seen in treating patients post-transplant. Additionally, the interactions of these new medications with current immunosuppressive medication remain to be defined.

## Management of HBV infection and liver transplantation

*Evangelos Cholongitas<sup>1</sup> and George V Papatheodoridis<sup>2</sup>*

<sup>2</sup>Department of Internal Medicine, Athens University Medical School, Hippokration General Hospital, Athens, Greece

Hepatitis B virus (HBV) related chronic liver disease is a frequent indication for orthotopic liver transplantation (LT) in the Far East and the Mediterranean countries. Post-transplant HBV recurrence, which was almost universal in the era of no immunoprophylaxis or its short-term use, usually has an aggressive course resulting in graft loss, if left untreated [1–3]. Therefore, the HBV management is crucial for a satisfactory long-term outcome of HBV transplant patients.

HBV related liver disease was considered to be a relative or even absolute contraindication for LT in many centers, until the introduction of long-term hepatitis B immune globulin (HBIG) use in the early 1990s, which significantly decreased the post-transplant HBV recurrence rate and improved prognosis in this setting [4]. During the last decade, new antivirals, mainly nucleos(t)ide analogues, have been used, either as monotherapy or in combination with HBIG, in an effort to further improve the post-transplant outcome, treat HBIG failures, and/or reduce the need for the expensive HBIG preparations [5]. The HBV management in transplant patients can be divided into the pre-transplant, prophylactic post-transplant and therapeutic post-transplant approach [5]. In addition, the management of recipients who receive grafts from anti-HBc positive donors is discussed, as these recipients are at risk of iatrogenic HBV infection.

### Pre-transplant approach

The pre-transplant approach is based on antiviral therapy in order to lower the viral load and achieve serum HBV-DNA undetectability by sensitive assays at the time of LT

and thus to prevent post-transplant HBV recurrence [5]. Sometimes, the clinical improvement of HBV patients on the waiting list during or following effective antiviral therapy may even result in postponement or obviate the need for LT. Only two oral agents, lamivudine and adefovir dipivoxil, are currently licensed for use in patients with either chronic hepatitis B (CHB) or HBV decompensated cirrhosis, while three additional oral agents, entecavir, telbivudine and tenofovir disoproxil fumarate have been licensed for the treatment of CHB but not of HBV decompensated cirrhosis as yet. Interferon-alfa, which was the only available anti-HBV therapeutic option until the late 1990s, is usually contraindicated or causes intolerance and therefore cannot be used in patients with decompensated cirrhosis. The pre-transplant approach is usually combined with prophylactic post-transplant therapy [5].

### Lamivudine

Lamivudine, a cytosine analogue, was the first agent that could be widely used in the pre-transplant period revolutionizing the management of such patients. Lamivudine is generally well tolerated even in severely ill cirrhotics and has a good safety profile with rare and generally mild side effects. Lamivudine, at a daily dose of 100mg, has been shown to stabilize or even improve liver function sometimes resulting in withdrawal of patients from transplant lists [6, 7]. **B4** Unfortunately, the improvement or stabilization of liver function is often not sustained over time, since the prolongation of lamivudine therapy is associated with progressively increasing rates of lamivudine resistance often followed by virologic and biochemical breakthroughs [6, 7]. **B4** Lamivudine resistance is usually associated with the emergence of a mutation at position 204 within the YMDD motif of the major catalytic region C of the HBV polymerase gene (substitution of methionine with valine (rtM204V) or with isoleucine (rtM204I)), often in combination with another mutation at position 180 within the region B (substitution of leucine with methionine (rtL180M))

[8]. Lamivudine resistance usually emerges after the first six months with cumulative rates of 15–25% at the end of first year and >60–65% at the end of fourth year of lamivudine therapy [9].

Breakthroughs during lamivudine therapy have a risk for severe exacerbation of liver disease, which may result in rapid development of liver failure and patient death [10]. Moreover, pre-transplant HBV viremia even when due to YMDD mutants has been associated with increased probability of post-transplant HBV recurrence [11, 12], poorer outcome after LT and lower hepatocellular carcinoma (HCC) recurrence-free post-transplant survival in patients with HCC before LT [13]. Thus, transplant centers may be reluctant to perform LT in HBV cirrhotics with viremia irrespective of the type of HBV strains [14]. Another important issue is that the emergence of lamivudine resistance may have a negative impact on the efficacy of and the probability of resistance to other anti-HBV agents [9]. For all these reasons, lamivudine monotherapy is no longer considered an appropriate first-line therapy for pre-transplant HBV patients. **B4**

### Adefovir

The availability of adefovir, an acyclic nucleotide analogue of adenosine esterified with two pivalic acid molecules that is effective against both wild and lamivudine resistant HBV strains, was initially used in order to ameliorate the consequences of lamivudine resistance [9]. The use of adefovir monotherapy as first-line treatment in HBV-pretransplant patients has not been adequately evaluated. In CHB, adefovir monotherapy is associated with lower rates of resistance compared to lamivudine, but resistance may emerge in the second year and develop in up to 30% of cases treated with adefovir for five years [15]. Adefovir resistance is related to the emergence of a mutation at position 236 (substitution of asparagine with threonine, (rtN236T)) and/or at position 181 (substitution of alanine with valine or threonine (rtA181V or rtA181T)) of the HBV polymerase gene [16]. Another issue with adefovir monotherapy is that this agent, at least in the licensed 10mg daily dose, is not very potent, resulting in residual viremia in approximately 80% of HBeAg-positive and 50% of HBeAg-negative CHB patients [9]. In addition, it may have some potential for nephrotoxicity. For these reasons, adefovir monotherapy was not considered as an attractive option for patients with HBV decompensated cirrhosis, in whom complete inhibition of viral replication should be achieved [17]. Because of the suboptimal profile of both lamivudine and adefovir monotherapy in HBV pre-transplant patients, *ab initio* use of lamivudine and adefovir combination has been recommended for such cases in several guidelines, despite the lack of strong data on efficacy and safety for such a strategy [18]. **B4**

### Entecavir

Entecavir, a carboxylic analogue of guanosine, is a potent and selective anti-HBV agent that has been approved relatively recently for the treatment of CHB [9]. In nucleos(t)ide naive patients with HBeAg-positive or HBeAg-negative CHB, entecavir (0.5mg daily) has greater potency than lamivudine and adefovir and a very good resistance profile with <2% cumulative five-year resistance rate [9, 19]. Entecavir was also reported to have the same good efficacy and safety profile in the subgroup of naive patients with advanced fibrosis or cirrhosis [20]. Given the absence of nephrotoxicity and its overall good safety profile in combination with the high efficacy and low resistance risk, entecavir is expected to be a first-line option for the treatment of nucleos(t)ide naive patients with HBV decompensated cirrhosis. It should be noted, however, that entecavir is not yet approved for the treatment of such patients, as relevant data are lacking.

### Telbivudine

Telbivudine, another nucleoside analogue (L-deoxythymidine) that was approved recently for the treatment of CHB, is more potent than lamivudine but it also selects for mutations in the YMDD motif similar to those conferring lamivudine resistance (mainly rtM204I) [9]. In nucleos(t)ide naive CHB patients, telbivudine resistance starts to emerge within the first year (sixth to twelfth month) and increases during the second year of therapy. The telbivudine resistance rates were 4.4% and 2.7% at the end of first year and 21.6% and 8.6% at the end of the second year of therapy in HBeAg-positive and HBeAg-negative CHB respectively [21]. The absence of residual viremia (HBV-DNA < 400 copies/ml) at six months of telbivudine therapy is associated with low two-year probability of resistance [9]. Given its unfavourable resistance profile compared to other anti-HBV agents such as entecavir and tenofovir, the place of telbivudine monotherapy in the treatment of HBV pre-transplant patients will be unclear, even if the agent is approved for use in this setting.

### Tenofovir

Tenofovir, the second acyclic nucleotide analogue of adenosine, is the most recently approved agent for the treatment of CHB. It is administered orally as tenofovir disoproxil fumarate, which is a prodrug with good oral availability and is a potent agent for the treatment of both nucleos(t)ide naive and lamivudine resistant CHB [22–24]. Tenofovir has not been licensed for treatment of decompensated cirrhosis, but there are a few case reports with successful tenofovir use in such cases [25]. However, since tenofovir may be potentially nephrotoxic, both its efficacy

and safety should be tested in proper trials before its wide use in pre-transplant patients. To date, there is no evidence of resistance in CHB patients treated with tenofovir for 72 weeks, but more long-term data are lacking [22–24]. **B4** Due to the great potency and the possible high genetic barrier of this agent, long-term tenofovir resistance rates are expected to be low. If its safety in decompensated cirrhosis is confirmed, tenofovir will be a first-line option for the treatment of nucleos(t)ide naive patients with HBV decompensated cirrhosis. Thus, the results of a current trial, in which tenofovir, entecavir and tenofovir plus emtricitabine are compared in patients with HBV decompensated cirrhosis, are awaited.

### Management of HBV resistance

Patients with decompensated cirrhosis under antivirals should be monitored carefully for virologic response and possible virologic breakthroughs, with serum HBV-DNA testing at least every three months [18]. In CHB, any virologic breakthrough (increase in serum HBV-DNA by  $\geq 1 \log_{10} \text{iu/ml}$  above nadir after an early virological response) is considered in practice as viral resistance, if drug compliance is confirmed [18]. **B4** In decompensated cirrhosis, however, stricter criteria of response should be applied and any detectable viremia should be considered as a treatment failure, regardless of resistance and breakthroughs, signalling the need for treatment modification.

Lamivudine resistance represents the most common problem of HBV resistance because of the longer use and the poor resistance profile of lamivudine. Adefovir was the first agent used as rescue therapy for lamivudine resistance. The addition of adefovir to ongoing lamivudine therapy instead of the substitution of lamivudine with adefovir is the preferred option for lamivudine resistant CHB [9]. In pre-transplant HBV cirrhotic patients with lamivudine resistance, the addition of adefovir results in biochemical, virologic and liver function improvement [26, 27]. In particular, in a large study with 226 HBV patients on the waiting list with lamivudine resistance, the addition of adefovir achieved HBV-DNA undetectability in 59% of cases, without adefovir resistance during the first 48 weeks [27]. **B4** Moreover, alanine aminotransferase (ALT), albumin, bilirubin and prothrombin time normalized in 77%, 76%, 60% and 84% of the 226 patients respectively [27]. Despite the addition of adefovir, however, a significant proportion of patients (41% at 48 weeks and 35% at 96 weeks) maintained detectable serum HBV-DNA, which is not an acceptable result for current day practice.

Entecavir monotherapy (1 mg daily  $\geq 2$  hours before or after meals) has worse potency and higher resistance rates in lamivudine resistant than naive patients [9]. In particular, the cumulative entecavir resistance rate has been reported to be 6%, 15%, 36%, 46% and 51% at year 1, 2, 3,

4 and 5 years of entecavir therapy respectively [19]. **B4** Entecavir resistance requires selection of two lamivudine resistant mutations (rtM204V/I and rtL180M) and at least one additional substitution at positions 169, 173, 184, 202 or 250 of the HBV polymerase gene (rtI169T, rtV173L, rtT184G, rtS202I or rtM250V) [28]. Thus, entecavir resistance requires three mutations in nucleoside naive patients and only one additional mutation in patients with pre-existing lamivudine resistance. These findings have made entecavir a less attractive long-term therapeutic option for HBV patients with lamivudine resistance [9]. As there is cross-resistance between lamivudine and telbivudine, telbivudine is not expected to be effective in lamivudine resistant patients.

Tenofovir is effective against lamivudine resistant strains and is a more potent anti-HBV agent compared to adefovir [29]. Therefore, it is currently expected to become the treatment of choice for patients with lamivudine resistance. Whether switching to tenofovir or addition of tenofovir to ongoing lamivudine is the optimal and the more cost-effective approach for using tenofovir in patients with lamivudine resistance is not yet clear [29]. However, it seems safer to add in tenofovir considering the experience gained with adefovir, particularly in patients with decompensated cirrhosis.

There are no clear data for the treatment of patients with resistance to other anti-HBV agents, particularly in pre-transplant patients. Generally, resistance to an agent of one class (nucleosides: lamivudine, entecavir, telbivudine; nucleotides: adefovir, tenofovir) usually eliminates or reduces the activity of other agents of the same class due to partial or complete cross-resistance. This is well documented for lamivudine, telbivudine and entecavir, but it seems to be also the case, at least partly, for adefovir and tenofovir. Thus, in case of resistance to a nucleoside, a reasonable approach would be to add a nucleotide and vice versa. In particular in pre-transplant patients, in whom complete inhibition of HBV replication is absolutely desirable, entecavir and tenofovir (the most potent agent of each class) are expected to become the agents of choice, whenever approved. Of course, the most effective treatment of resistance is its prevention by starting treatment with agents that are potent and have a high genetic barrier [28].

---

## Prophylactic post-transplant approach

### Immunoprophylaxis alone

The efficacy of HBIG is associated with the pre-transplant type of liver disease (e.g. fulminant HBV infection, HBV and HDV co-infection) [30], viremic status and dose and duration of HBIG treatment, while the most widely

accepted recommendations for HBIG prophylaxis depend mainly on the pre-transplant viremic status [31]. Patients with detectable HBV-DNA by conventional hybridization assays, who may be transplanted only after clearance of HBV-DNA by lamivudine, are treated with more aggressive HBIG protocols compared to non-viremic patients [31, 32]. **B4** However, several practical questions about the ideal duration, but also about dosage, frequency and mode of HBIG administration remain to be answered [5].

HBIG may only rarely lead to eradication of HBV and therefore there is need for indefinite HBIG prophylaxis, which is an extremely expensive approach. The most cost-effective approach seems to be the individual tailoring of HBIG administration according to serum anti-HBs levels [5, 31], which is time-consuming [30]. Cheaper HBIG preparations for intramuscular administration have also been tried [33–35], as they have similar pharmacokinetic properties with intravenous preparations [36]. Interestingly, subcutaneous HBIG administration is under investigation, but no relevant long-term data are currently available [37].

Besides the high cost, long-term HBIG administration may also have some local or systemic side effects, while there is a progressively increasing risk of escape HBV mutants [8, 31]. Since the clinical significance of such HBV escape mutants has not been clarified, there is no consensus about continuation of HBIG therapy, or not, after their emergence [31], but most centers probably stop HBIG administration [5].

Another strategy aiming at cost reduction has been the substitution of HBIG with HBV vaccination. However, data on the efficacy of vaccination are rather conflicting and therefore greater numbers of patients and longer follow-up periods are required before definite conclusions can be drawn [38–42].

### Prophylactic post-transplant monotherapy with nucleos(t)ides analogues

Lamivudine monotherapy, before and prophylactically after LT, gave promising short-term results [5]. However, it was subsequently shown that the efficacy of such a policy declines over time with frequent development of virologic breakthroughs and HBV recurrence in 35–50% of cases at two years post-transplant and severe clinical outcomes in some patients [43–48]. Thus, such an approach has been abandoned not only in liver transplant but also in HBsAg-positive renal allograft recipients.

There are no studies on the efficacy of monoprophyllaxis with the newer nucleos(t)ides analogues. However, based on the data in pre-transplant setting, it is expected that adefovir monoprophyllaxis will also be associated with emergence of adefovir-resistant mutants in post-transplant patients. Entecavir, which is a more potent agent with very

low resistance rates in nucleoside naive cases and without risk for nephrotoxicity, seems to be a more attractive option for monoprophyllaxis in post-transplant patients. However, entecavir should be avoided in patients with previous lamivudine resistance, which should preferably be treated with adefovir or tenofovir. Tenofovir is more potent and cheaper than adefovir having better resistance profile, but its use may also have a risk for renal dysfunction, particularly in patients receiving nephrotoxic immunosuppressive therapy. Finally, telbivudine monotherapy has moderate resistance rate and therefore does not seem to be a good option for post-transplant patients. Thus, entecavir seems the most attractive monoprophyllaxis option in the post-LT HBV setting, followed by tenofovir, particularly in cases with previous lamivudine resistance. However, well-designed studies are needed to determine the optimal monoprophyllaxis approach, if any. For now, the combination of HBIG (at least for a short period) and one nucleos(t)ide appears to be the most reasonable post-transplant approach, but monoprophyllaxis with one of the new nucleos(t)ide analogues cannot be excluded in the future, particularly in patients with low risk of recurrence.

### Prophylactic post-transplant combined approach

Post-transplant prophylactic combination of HBIG and lamivudine was tried in order to improve the efficacy of post-transplant prophylaxis and/or reduce cost. The efficacy of such a combined regimen has been shown to be superior compared to the efficacy of prophylaxis with any of the two agents alone. A recent meta-analysis of six studies showed that HBIG plus lamivudine, compared to HBIG alone, was associated with 12-fold, 12-fold and 5-fold reduction of HBV recurrence, HBV-related death and all-cause post-transplant mortality respectively [49]. **Ala** In 36 studies of HBIG and lamivudine combination identified in the literature, post-transplant HBV recurrence was observed in only 95 (6.3%) of 1493 patients during a mean follow-up of 6–96 months (see Table 45.1) [12, 13, 32–34, 48, 50–79]. It should be noted that 11 of the 95 patients with post-transplant HBV recurrence had developed YMDD mutants during pre-transplant lamivudine therapy [12, 48, 57, 64, 68, 69, 76], while HBIG and/or LAM had been discontinued when HBV recurrence occurred in another 19 patients [51, 54, 57, 71, 75]. One particularly important aspect in favor of the combined HBIG and lamivudine prophylaxis is that such an approach was used in patients with high pre-transplant viremia levels (>50% of cases had HBV-DNA detectable by hybridization assays) and achieved low HBV reinfection rates at a reduced cost. Moreover, a relatively low HBIG dosage [12, 33, 34, 58, 63, 66, 67], similar to the recommended dosage for non-viremic HBV transplant patients [31], and/or intramuscular HBIG

<sup>a</sup>Plus 70,000 IV during the first seven days in two HBV-DNA positive patients.<sup>b</sup>Five patients, who died within one month after LT from unrelated to HBV causes, were not included in this survival estimation.<sup>c</sup>One patient received 80,000 IU of HBIG during the first month, while another patient received only 2000 IU of HBIG during the anhepatic phase and four IM injections of 650 iu each within the first six months after LT.<sup>d</sup>Thirteen patients received higher HBIG dosage (10,000 IU IV daily for seven days, 10,000 IU IV weekly for one month, and then 10,000 iu IV monthly for several years before conversion to IM HBIG.<sup>e</sup>Post-transplant LAM was added when HBIG administration changed from IV to IM (16 months median follow-up after the onset of LAM).<sup>f</sup>No HBV recurrence in 18 patients with undetectable pre-LT HBV-DNA during 70 months of follow-up.<sup>g</sup>All patients received LAM plus adefovir (10 mg/day) from day 8.<sup>h</sup>No patient with YMDD mutants.<sup>i</sup>Two patients had transiently positive HBsAg (one was under adefovir due to LAM resistance pre-LT).<sup>j</sup>One patient had detectable HBV-DNA (YMDD mutants), but none had clinical HBV recurrence.

preparations were usually used [13, 33, 34, 48, 50, 51, 58, 70, 72, 75, 79], or HBIG was even discontinued after a certain period [56, 57, 69, 73]. Therefore, the prophylactic post-transplant combination of HBIG and lamivudine preceded by short-term pre-transplant anti-HBV therapy is the currently recommended approach [5]. **B4** In the near future, the newer nucleos(t)ides analogues are expected to replace lamivudine in the post-transplant prophylaxis as well, probably leading to use even less HBIG.

The optimal post-transplant prophylaxis for patients who develop YMDD mutants in the pre-transplant period might be different than that for patients without such HBV strains. In total, seven studies have focused on patients with YMDD mutants pre-LT showing that only 4.2% (6/143) of patients developed post-OLT HBV recurrence during a mean follow-up of 19–36 months (see Table 45.2) [27, 67, 77, 80–83]. **B4** The triple combination of HBIG, lamivudine and adefovir was used in most patients (55% of 134 cases) with available data [73], while fewer (45%) were treated with HBIG plus lamivudine or HBIG plus adefovir or adefovir plus lamivudine. Of the six cases with post-LT HBV recurrence, two developed in patients under HBIG plus lamivudine and adefovir and four in patients under HBIG plus lamivudine (two had stopped HBIG and two did not receive adefovir pre-transplant and transplanted with

HBV-DNA > 5 log<sub>10</sub> copies/ml) [27, 67]. Tenofovir instead of adefovir is expected to offer better results in this setting. The *ab initio* use of potent antivirals with a high genetic barrier is definitely preferred in the transplant setting and particularly in cases with pre-existing evidence of viral resistance, as the risk of multi-drug resistance is higher than in non-transplant cases [84].

One relatively recent strategy of the prophylactic combined approach has been the withdrawal of HBIG administration after a certain period followed by maintenance lamivudine alone [85]. The first results of two small randomized trials were encouraging, with no HBV recurrence after 12–17 months under lamivudine monoprophyllaxis [86, 87]. However, longer follow-up showed that 20% of patients eventually experienced recurrence of HBV at seven years [75], which might have been related to poor compliance [75], or premature discontinuation of HBIG [86]. **B4** Indeed, HBV recurrence was not observed in any of 16 patients who continuously received HBIG for two years and then switched over to lamivudine monotherapy for an additional period of up to 27 months [88]. The latter findings were confirmed by a more recent retrospective study with median follow-up of 40 months after HBIG discontinuation [89]. These data suggest that the combination of HBIG plus lamivudine might be replaced by

lamivudine monotherapy after ≥ 24 months post-transplant in selected HBV transplant patients with low risk of HBV recurrence, although stronger data are needed before the wide use of such a strategy. **B4**

Given the poor resistance profile of lamivudine monotherapy, the replacement of HBIG and lamivudine combination with lamivudine and adefovir combination after the first few post-OLT months was also evaluated [73, 79, 90]. In the first relevant randomized study, 34 patients under low-dose intramuscular HBIG plus lamivudine for ≥12 months were randomized to continue the same treatment or switch to adefovir plus lamivudine [79]. At a median of 21 months post-switch, there was no case of disease recurrence (one patient in the switch group became HBsAg positive but remained HBV-DNA negative), while the switch approach was associated with substantially lower cost and better patient quality of life [79]. **Ald** In another recent study, 19 patients who were under adefovir plus lamivudine before LT, received low dose intramuscular HBIG, lamivudine and adefovir for only one week post-LT, followed by adefovir plus lamivudine without any case of HBV recurrence after 12 months of follow-up [90]. However, larger studies with longer follow-up are needed for definitive conclusions about this approach. Finally, the use of newer, more potent antivirals, such as entecavir or tenofovir, in order to early and safely discontinue HBIG certainly deserves to be evaluated.

## Therapeutic post-transplant approach

Therapeutic post-transplant approach is used in cases with HBV recurrence despite previous post-transplant prophylaxis. Given the immunosuppressive therapy taken by all post-transplant patients, the high levels of HBV replication and the risk for rapid progression of liver disease in such cases, the primary targets of treatment of post-transplant HBV recurrence are the control of liver disease and stabilization of graft function [5]. Generally, the principles of treatment in post-transplant HBV recurrence resemble those in the pre-transplant setting. In the pre-lamivudine era, interferon-alfa was a common option, but now its role has almost disappeared due to both low efficacy and low but possible theoretic risk of graft rejection [5]. Lamivudine has been frequently used in cases with recurrence despite HBIG prophylaxis, but it will be inactive in cases with lamivudine resistance [5]. Again, the main disadvantage of long-term lamivudine monotherapy is the progressively increasing rates of resistance exceeding 50% at three-years of therapy in transplant patients [91–95]. The emergence of such HBV mutants is associated with rapid development of advanced histologic lesions and even liver failure and death in some HBV transplant patients [94, 96, 97]. Thus, lamivudine is not an appropriate option for the treatment of HBV transplant patients. **B4**

<sup>a</sup>LAM plus ADV.<sup>b</sup>ADV plus LAM in 1, LAM plus famciclovir followed by ADV in one, LAM plus famciclovir in one and LAM alone in three patients.<sup>c</sup>ADV monotherapy.

Adefovir added to ongoing lamivudine therapy has been shown to be effective in transplant patients with lamivudine resistance, achieving significant improvements of serum HBV-DNA and transaminases levels (see Table 45.3) [27, 32, 47, 74, 98–102]. In the largest study, including 241 patients with lamivudine-resistant recurrent HBV infection, the addition of adefovir achieved HBV-DNA undetectability in >95% of cases (94% with HBIG and 100% without HBIG administration) with a cumulative resistance probability of 2% at 144 weeks (see Table 45.3) [27]. **B4** Tenofovir has also been reported to be effective in patients with post-transplant HBV re-infection and lamivudine resistance [32]. Since tenofovir is more potent and has a better therapeutic ratio compared to adefovir, it is expected to become the nucleotide of choice for such post-transplant patients. Entecavir might be also used in patients with post-transplant HBV re-infection because of its great potency, high genetic barrier and absence of nephrotoxicity, particularly in cases without lamivudine resistance. Entecavir has been tried in some transplant patients with adefovir [103] and lamivudine resistance [104], but the high probability of resistance with long-term entecavir in non-transplant patients with lamivudine resistance discourages its use in similar post-transplant cases [19].

### Anti-HBc positive donors

The current efforts to overcome the organ shortage include the use of marginal liver grafts, such as those from anti-

HBc positive donors. Unfortunately, the “occult” HBV infection in the donor liver may be reactivated in the recipient due to post-LT immunosuppressive therapy leading to *de novo* HBV infection. The most reasonable approach is to direct anti-HBc positive grafts to recipients with HBV related liver disease, as they will require life-long anti-HBV prophylaxis anyway. However, due to organ shortage, HBsAg-negative patients may also receive these grafts. The post-LT outcome of HBsAg-negative recipients of grafts from anti-HBc donors has been evaluated in 30 studies published as full papers (see Table 45.4) [105–134]. *De novo* HBV infection developed in 27% (82/300) of HBsAg-negative recipients who received no anti-HBV prophylaxis, this being significantly more frequent in HBV naive than anti-HBc positive recipients (12/123 or 10% vs 70/177 or 40%,  $p < 0.001$ ). In the anti-HBc positive group, *de novo* infection developed less frequently in cases with anti-HBs positivity compared to no anti-HBs positivity (1/67 or 1% vs 5/37 or 14%,  $p = 0.021$ ) [105, 106, 109–111, 113, 114, 121, 124–128, 130, 132, 133]. Anti-HBV prophylaxis reduced *de novo* HBV infection rates in both anti-HBc positive (4%) and HBV naive recipients (9%) [108, 112, 114–116, 118–125, 127, 128, 130, 131, 134]. In particular, *de novo* HBV infection rate was 23%, 5% and 0% in HBsAg-negative recipients under HBIG, lamivudine and their combination, respectively [105, 108, 112, 114–116, 120, 121, 124, 125, 128, 130, 131, 134].

Whether HBIG may be safely discontinued after a certain period or monoprophylaxis with a new nucleos(t)ide analogue with low resistance rates, are effective strategies in

six studies with inconsistent data on the serological HIV status of donors and/or recipients are not included [107, 110, 116, 122, 123]. Of 7050 HIV infection unknown anti-HBs status under HBIG+LAM prophylaxis among 18 recipients with past HBV infection or HBV naive under HBIG+LAM (122); (2) 0/1 anti-HBc positive recipient (unknown anti-HBs status) under HBIG+LAM prophylaxis; (3) 2/12 recipients with past HBV infection or HBV naive under no anti-HBV prophylaxis [107]; (4) 15/16 anti-HBc positive recipients (unknown anti-HBs status) under no anti-HBV prophylaxis during 111 months of follow-up [129]; (5) 3/28 recipients with unknown HBV status under HBIG+LAM [117]; (6) 2/14 recipients with unknown HBV status under HBIG plus vaccination [118].

*De novo* HBV infection also developed in (1) 0/3 anti-HBc positive recipients (unknown anti-HBs status) under LAM during 20 months of follow-up<sup>a</sup> [134];

(2) 0/1 anti-HBc positive recipient (unknown anti-HBs status) under HBIG during 11 months of follow-up<sup>b</sup> [114];

(3) 1/25 anti-HBc negative and anti-HBs positive recipients under LAM plus vaccination during 57 (33–85) months of follow-up<sup>c</sup> [119].

all, or in subsets, of such transplant patients remains to be determined. Pre- and post-transplant HBV vaccination has also been evaluated in this setting [105, 106, 108, 114–116, 118–121, 124, 125, 128, 131, 134], but further studies are required before safe conclusions can be drawn. For now, successful pre-LT vaccination does not appear to provide satisfactory protection from *de novo* post-LT HBV infection [105, 106, 108, 114–116, 121, 124, 125, 128, 131, 134]. However, HBV vaccination should be offered to all naive HBV LT candidates, even though additional anti-HBV prophylaxis might be required in cases of LT with anti-HBc positive grafts. If *de novo* post-LT HBV infection develops, antiviral treatment (see therapeutic post-transplant approach) is mandatory.

## Introduction

Since the introduction of the 1-sec Menghini needle technique in the early 1950s, liver biopsy (LB) has become the commonest procedure performed in clinical hepatology and remains an important tool in the differential diagnosis and therapeutic decision-making in patients with clinically diagnosed acute and chronic liver disease. Other indications include the evaluation of cholestatic liver disease (primary biliary cirrhosis, primary sclerosing cholangitis), the diagnosis and follow-up of treatment of heritable disorders (hemochromatosis, Wilson's disease), and LB may be helpful in identification of systemic inflammatory or granulomatous disorders [1–5]. LB is useful in evaluating otherwise unexplained abnormalities of liver function tests, particularly in patients with fever of unknown origin [1–5]. In patients with non-alcoholic fatty liver disease (NAFLD), imaging techniques are sensitive for detecting fatty liver (especially moderate to severe steatosis) [6–9], but they cannot distinguish simple steatosis from steatohepatitis and they cannot measure the degree of fibrosis [8, 10–12]. Thus, LB can confirm the diagnosis of NAFLD and identify the severity and the extent of fibrosis. Other indications for LB include the diagnosis of drug-induced liver damage and the diagnosis of neoplastic and other mass lesions, as well as conditions such as sarcoidosis and hematologic diseases. Finally, in the liver transplantation setting, LB is essential for diagnosis of acute or chronic rejection, recurrence of the primary disease, and characterization of additional intercurrent disease.

However, LB only represents approximately 1/50000 of the total liver mass [13] and several studies have stressed this limitation, evaluating the optimal size of a liver speci-

men and the impact of heterogeneity and intra- and inter-observer variation on the histopathological interpretation of LB.

The status of LB is being challenged by non-invasive markers for the evaluation of fibrosis, both serum markers and types of transient elastography [14], but in reality LB and non-invasive surrogates are complementary investigations [15]. Furthermore, recent studies have tried to determine optimal standards for length and number of complete portal tracts for accurate evaluation of grading and staging in chronic viral hepatitis [16, 17].

Percutaneous (PLB) and transjugular (TJLB) liver biopsy are the two main techniques. Laparoscopic LB is more invasive [18]. The needles used can be considered large, that is, an external diameter  $\geq 1.0$  mm (14–19 G) and thin when  $< 1.0$  mm ( $\geq 20$  G) [19]. Suction (Menghini) or cutting (Trucut) needles are the most used.

## Liver biopsy and its histological interpretation in chronic viral hepatitis

Although LB is an invasive procedure and should only be performed if it can offer significant and accurate diagnostic information, it is considered a key component during the initial work up of patients with chronic hepatitis C (CHC), and histopathology is the “gold standard” for assessing changes after antiviral therapy [20]. Although serological markers (anti-HCV) and HCV-RNA are very reliable for CHC diagnosis, LB is considered mandatory for grading (necroinflammatory activity) and staging (fibrosis) in most CHC patients [21, 22]. LB can also reveal unsuspected additional diagnoses, complications of treatment and progression/regression of CHC. LB is useful for evaluation of steatosis and siderosis, which may affect both the natural history and response to antiviral therapy [23–27]. However, LB is not considered necessary before starting antiviral therapy in CHC patients with genotype 2 [21], and is currently being debated in CHC patients with persistently

normal aminotransferase levels [28–31]. In chronic hepatitis B (CHB), LB is also a useful tool, because it provides important information concerning the severity of liver damage and the decision to treat [32]. In patients with e-antigen positive CHB, LB is recommended for those with elevated ALT/AST twice the upper limit of normal, while it is considered mandatory in the majority of patients with e-antigen negative CHB [32]. Regardless of the accepted utility of LB in identifying active HBV disease, the distinction between histologically inactive/active levels of inflammation and insignificant/significant fibrosis for the purposes of making therapeutic decisions has never been formally investigated.

Several histopathological scoring systems have been developed in order to facilitate the comparison between different trials and to standardize histopathological observations of hepatitis. Although there are many such systems [33–36], all of them produce values for various categories of inflammation (grade) and fibrosis/architectural disruption (stage), and in fact they “score” (i.e. categorize) similar histological features. In the Knodell “histological activity index” system (HAI) [33], each of four histopathological axes of assessment (piecemeal/bridging necrosis, lobular inflammation, portal inflammation and fibrosis/architectural change) is assessed separately and assigned a “score”, which is in fact a “numerical” shorthand symbol for a descriptive category. None of the scores, in any of the scoring systems is actually a measurement, or a real number in the arithmetical sense. Currently, the most widely used histopathological scoring system is the “Ishak” [34], which assesses fibrosis in seven categories ranging from normal to cirrhosis and so has potentially more discriminant descriptive power than the “Knodell”. The METAVIR scoring system was designed for HCV chronic hepatitis specifically [36]. All of the histological stage scoring systems are a composite evaluation, and attempt to describe architectural changes as well as fibrosis, and all of the systems have several drawbacks [37]. The most common error in evaluating fibrosis is to use the stage scores as numerical data, such that stage 2 is considered to comprise twice the amount of fibrosis as stage 1. In fact fibrosis measurement is the only way to quantitate collagen (e.g. different cirrhotic livers would all score 6 in the Ishak staging system, but might contain vastly different amounts of collagen) [37]. The proper measurement of collagen may be essential in some studies (e.g. to establish the effects of antifibrotic therapy), and then appropriate methodology (e.g. with image analysis rather than histological scoring) must be used [37]. On the other hand, specific measurement of LB collagen alone cannot address the issue of hepatic architectural disruption and nodularity per se, so that for routine diagnostic purposes histopathological examination may not only be sufficient, but is superior. If both evaluations can be performed, additional diagnostic and prognostic

benefits may ensue [38]. Collagen proportionate area measured using Sirius red stained sections, with digital image analysis computerized techniques, correlates with hepatic venous pressure gradient and allows histological gradation of fibrosis in cirrhotic liver [38].

## Different approaches of liver biopsy

### Percutaneous liver biopsy

Percutaneous liver biopsy (PLB) is the commonest and quickest LB procedure [39]. It is commonly undertaken as a day case procedure. It is performed under local anesthesia with lidocaine, with the patient holding breath in expiration and it lasts just a few seconds [19, 40]. After biopsy, many physicians use a short observation period because most of the complications occur during the first few hours after the procedure [39, 41, 42].

Although PLB is considered a safe procedure, major and minor complications occur in up to 6% of patients and in 0.04–0.11% can be life threatening [13, 42, 43]. The most common complications include pain, hemorrhage (intra-peritoneal bleeding, hematoma (intrahepatic or subcapsular) and hemobilia), infection, pneumothorax and inadvertent puncture of other intraabdominal organs. The complication rate is related to technical and patient factors. **B4** Technical factors include: (1) the experience of the operator who performs the procedure (less complications especially for those units performing more than 100 biopsies per year) [44–46]; (2) the use of ultrasonography (US) either before or the time of LB [47–49]; (3) the size of biopsy needle (less complications for the fine-needle); and (4) the use of more than one pass [46, 50–54]. Patient factors (high risk group) include: (1) the nature of the underlying liver disease (the presence of cirrhosis and tumor increase the complication rate) [54]; and (2) impaired coagulation beyond current safe limits [42], that is, platelet counts less than 60000/mm<sup>3</sup> and INR > 1.6. Patients with chronic renal insufficiency (serum creatinine greater than 1.5 mg/dl) are also considered at high risk: they usually receive desmopressin 15–30 minutes prior to the procedure [42].

Pre-liver biopsy US helps to detect focal hepatic tumors (benign or malignant), cysts, ascites, intrahepatic biliary dilatation or hepatic anatomical variation. Regarding the impact of US guidance on complication rate, recent evidence suggests that real time US guidance, compared to US guidance in order only to identify the puncture site, does not give any advantage regarding safety or size of liver specimen [55]. Both approaches decrease minor and major complications [47–49], particularly the risk of hemorrhage [56], but there is no clear evidence of this benefit [57, 58], compared to the blind approach, where the liver is percussed. Routine use of US for diffuse liver disease is still

debated and has not been established to be cost-effective related to time in hospital [48, 56, 59]. The lower bleeding rate under US guidance may be related to the use of fewer passes used to obtain an adequate sample [46, 51]. US does help the operator to avoid puncture of adjacent important structures [60, 61]; US changed the biopsy site in 21 (12.7%) of 165 patients in a prospective study [60]. The use of US may be especially important in obese patients, those with cirrhosis and patients with chronic obstructive pulmonary disease [56]. Although blind PLB is more commonly performed, it was found that US guidance was used by 56% of gastroenterologists and hepatologists in France [53]. In addition, Angtuaco *et al.* randomly sent questionnaires involving 260 members of the American Association for the Study of Liver Diseases and found that 75% had performed liver biopsies under US guidance [62]. Post-biopsy US is not routinely needed; usually it is performed in the presence of possible complications.

Although fine-needle PLB should be avoided for grading and staging in chronic viral hepatitis patients, guidance fine-needle PLB (via US or computed tomography) is considered particularly useful for diagnosis of hepatocellular carcinoma (HCC) [18, 54]. Indeed, histopathology is often the only way to establish or exclude HCC and to differentiate malignant from dysplastic or benign (degenerative) lesions arising from a background of cirrhosis [63, 64]. Using current guidelines for diagnosis of HCC [65], biopsy is limited to tumors between 1–2 cm diameter [66, 67], which do not have both arterial hypervascularity and portal venous washout. However, there is the risk of malignant seeding [68]. A recent review showed the median seeding rate to be 2.29% for biopsy alone and 0.95% when associated with ablation techniques [69]. **B4** This was confirmed by another review, where the risk of malignant seeding with biopsy alone was estimated at up to 2.7% [70].

#### **B4**

Plugged PLB is performed through a sheath following embolization of the biopsy track and it is used in patients with impaired blood coagulation. Plugged PLB is easier and quicker than TJLB (15 min vs 41 min respectively) and thus, it is recommended in cases of coagulopathy when TJLB approach is not available or has been performed unsuccessfully [71].

### **Menghini versus Tru-cut technique in PLB**

It is considered that the Tru-cut needle produces larger and less fragmented samples compared to the suction needle [4, 47, 54], particularly in patients with advanced fibrosis or cirrhosis [72], but in our recent systematic review on the quality of PLB, we found that the Menghini technique yielded significantly longer samples ( $19.9 \pm 6.6$  mm) compared to Tru-cut ( $14.3 \pm 3.2$  mm,  $p = 0.016$ ), but without a significant difference in the mean number of complete portal tracts (CPT) (7.3 vs 6.9,  $p = 0.8$ ). **B4** This could be

explained by the fact that the Tru-cut needle provides a maximum length of sample determined by the notch in the needle shaft (usually 20–25 mm) whereas with Menghini needle the length depends on the force of aspiration and operator experience. Finally, there are conflicting results regarding the relative safety of these two techniques: a retrospective study reported a higher rate of major complications with the Tru-cut needle as a result of its longer intrahepatic phase [18, 54], but another prospective study found no significant difference in complication rates related to the type of needle used [73]. **B4**

### **Quality of PLB for accurate histological interpretation**

Diagnostically, PLB of  $\geq 15$  mm length has been considered necessary for accurate diagnosis in chronic liver disease [74]; a review also concluded that six to eight complete portal tracts (CPT) should be present for precise diagnosis [13]. However, with the increasing need to assess fibrosis in chronic viral hepatitis, larger liver samples are needed to reliably assess grading and staging. Holund *et al.* [75] were the first to study the optimal specimen size for accurate assessment of necroinflammation and fibrosis. The studies of Colloredo *et al.* [16] and Bedossa *et al.* [17] established the minimum size for reliable scoring of LB for chronic viral hepatitis. In the first study 161 LB from CHC and CHB patients were evaluated, finding that a specimen of at least 20 mm long (of a 1.4 mm diameter, that is, 17 gauge biopsy) and/or containing  $\geq 11$  CPT was necessary for reliable assessment of grading and staging in chronic viral hepatitis [16]. Inadequate small samples tend to underestimate the degree of disease grade and stage. **B2** In the second study the adequacy of LB samples was assessed using image analysis in 17 surgical specimens taken from CHC patients [17]. A 25 mm long specimen (of a “virtual” 1 mm diameter biopsy) was the minimum length for reliable staging [17]. **B4** Indeed, the CPT number is the most suitable parameter to compare different kinds of liver biopsy specimens (e.g. percutaneous versus transjugular, or Menghini versus Tru-cut, or using different needle sizes) [76].

Although the recommendation that an adequate LB should have 11 or more CPT, or be longer than 20–25 mm for the assessment of chronic viral hepatitis, has been accepted rapidly as the optimal standard, there are several additional considerations. An important implication of these studies is that more than one pass is likely for most PLB, in order to achieve an adequate liver sample size [16, 17]. Indeed, the mean length and number of CPT in series of PLB reported in the literature was  $17.7 \pm 5.8$  mm and  $7.5 \pm 3.4$  respectively, which are less than the optimal standard [76]. Interestingly, in the same review, US guidance and more experienced operators were important factors for the length of PLB, but not for the number of CPT [76]. Thus,

based on documented series of PLB in the literature, the average length and number of CPT of PLB are both below the current optimal criteria for accurate histological interpretation [16, 17]. Therefore, more than one pass is likely to be needed, but this increases the risk of complications with PLB, making the minimum requirement for optimal PLB unrealistic and potentially more dangerous for the patient [46, 50, 51, 53]. **B4**

### Evaluation of heterogeneity and inter-observer variation in histopathological hepatitis scores in PLB using the new sampling standard

The minimum requirements for a LB reported above in relation to sampling heterogeneity in diffuse liver disease and inter-observer variability, are very important [16, 17]. Interestingly, there was no significant sample variability (that is, no there was significant difference in stage or grade between synchronous R and L lobe samples) in only one study in which the liver samples were on average >20mm long and thus adequate [77]. Conversely, Siddique *et al.* found a  $\geq 2$  point difference in Knodell scores of paired (two separate R lobe samples, via the same puncture site, with 4–5 portal tracts in each) HCV liver biopsies in 69% (total necroinflammatory score) and 21% (fibrosis score) of the pairs of biopsies [78]. Clearly inadequate samples are likely to give variable results, while adequate samples will give more reproducible results.

Regarding intra- and inter-observer variability, Rousselet *et al.* confirmed the influence of length and number of portal tracts on inter-observer agreement, at least between academic versus non-academic histopathologists and the available data from the literature shows that the agreement between histopathologists increases with the length and number of portal tracts in PLB [79]. **B2**

### Transjugular liver biopsy

Transjugular liver biopsy (TJLB) was first described experimentally in 1964 and it has been used in clinical practice since 1970. TJLB is usually used when there are contraindications to PLB, that is, in patients with massive obesity, gross ascites and severe coagulopathy [13, 45, 80]. However, in recent years, the use of TJLB has expanded to other patient groups, such as liver transplant recipients in the early post transplantation period [81, 82], patients with acute liver failure [83, 84], and those with congenital clotting disorders [85, 86]. The main advantage of TJLB is that there is no penetration of Glisson's capsule and, therefore, bleeding is extremely rare [13, 18, 45, 87]. Moreover, hepatic venography, hepatic venous pressure gradient (HVPG) measurements and portography with CO<sub>2</sub> can be performed concomitantly [18, 45]. Interestingly, HVPG might be a better endpoint than histology for the assessment of

therapeutic benefit of antiviral therapy and thus the transjugular approach may be the first choice in these cases [88].

The mean procedure time of TJLB is estimated to be 40.6 (15.5–48) minutes [80]. Initially, TJLB was performed by aspiration technique (Menghini); this resulted in excessive fragmentation and small specimens making diagnosis difficult [89, 90]. The development of a standard and, later, automated Tru-cut needle improved its effectiveness without increasing complications [91, 92]. At our center we use a quick-core 19G Tru-cut needle. Indeed, minor complications may be more frequent with Menghini TJLB needle, possibly related to the difficulty in controlling the depth of puncture [80]. **B2** Tru-cut needles give better samples (longer and more adequate for histological diagnosis) than Menghini needles (median length: 14.5mm vs 9.5mm respectively,  $p = 0.008$ ) [80]. **B2**

The total complication rate is 7.1% [80]. Minor complications are reported in 6.6% and include abdominal pain, supraventricular arrhythmias and complications from the neck. The latter are significantly less under ultrasound guidance [80]. Major complications occurred in 0.6% and include hepatic hematoma and intra-peritoneal hemorrhage. The latter is the most common major complication (0.2%) as a result of capsular perforation. This occurs particularly in patients with small livers, but it can be detected and treated during the procedure by injecting gelatin or coils at the site of leakage [93]. Death occurred in 0.09% of TJLBs due to intraperitoneal hemorrhage (0.06%) or ventricular arrhythmia (0.03%). Pediatric compared to adult series showed significantly higher total complication rates [81]. **B4**

### Quality of TJLB for accurate histological interpretation

Adequate biopsy specimens are crucial for accurate histological interpretation [16, 17], but TJLB specimens have been said to give smaller and more fragmented specimens, compared to PLB [13, 94]. However, a review of TJLB series reported in the literature showed that the mean length and number of CPT with TJLB after an average 2.5 passes were  $12.8 \pm 4.5$  mm and  $6.8 \pm 2.3$  respectively [80]. **B2** In addition, TJLB with three passes using Tru-cut needle gives comparable liver biopsy specimens to PLB (mean length and number of CPT were  $22 \pm 7$  mm and  $8.7 \pm 5$  respectively) without any serious complications [82]. **B2** TJLB with four passes provided liver specimens with a significantly greater number of CPT, compared to three passes TJLB (median: 9 vs 8,  $p = 0.04$ ) [95], without an increase in complications compared to a previous series [93]. **B2** In addition, four passes, compared to three passes, more often produced specimens of adequate length ( $\geq 25$  mm: 50% vs 35%,  $p = 0.026$ ) with more CPT ( $\geq 11$ : 40% vs 26%,  $p = 0.027$ ) [95]. **B2** Thus, at least four passes with TJLB should be

performed when liver specimens are needed for histopathological hepatitis grading and staging.

These data showed that TJLB gives comparable specimens to PLB, but as for PLB, optimal quality criteria for grading and staging are not universally obtained. However, in contrast to the risks of percutaneous biopsy with multiple passes, TJLB allows multiple passes (to obtain adequate samples) [46, 50, 51, 96], with far less likelihood of increasing complications [93, 97]. Therefore, TJLB could be an alternative and safe approach to obtain an adequate size of samples for reliable assessment of liver histology.

Heterogeneity of liver disease and inter- or intra-observer variation have been evaluated in only one study [98]: three cores of TJLB allowed a more accurate histological interpretation, compared to one or two cores of TJLB. **A1d**

Another advantage of TJLB is the opportunity to measure hepatic venous pressure gradient. This is particularly useful if the patient has cirrhosis, as it has prognostic significance [99], but it can also be used as an indirect marker of fibrosis [81, 88, 100].

### Laparoscopic and endoscopic liver biopsy

Diagnostic laparoscopy with LB is a safe and very efficient procedure, which can be performed under local anesthesia with conscious sedation and allows the visualization of the liver surface and can yield a larger amount of tissue (wedge biopsy) compared to the other techniques [18]. However, wedge biopsy in patients with diffuse liver disease, may overestimate the extent of fibrosis (staging) because of the exaggerated tissue changes that are observed in subcapsular tissue [101]. Therefore, during laparoscopy, needle biopsy samples of deeper tissue should be obtained for accurate staging. Laparoscopic LB should also be considered when both coagulation abnormalities and focal liver lesions are present [45], as well as for tumor staging and diagnosis of peritoneal disease. Laparotomy has the same advantages with laparoscopy, but is a more invasive procedure and with a higher rate of complications. In fact, the surgical approach is usually performed after accidental discovery of a focal or diffuse liver lesion during routine surgery [46].

Finally, in a recent study, De Witt *et al.* have proposed the endoscopic US-guided fine needle biopsy as an alternative, safe and sensitive procedure for the diagnosis and staging of liver metastases and mass lesions, since it was able to detect the presence of liver malignancy in 41% of patients with a previously negative evaluation [102].

---

### “Histological” assessment without liver biopsy

LB is an invasive procedure, requires hospitalization for at least a few hours and it is associated with low but signifi-

cant morbidity and mortality rates. Thus, it is not suitable for repeat testing to assess progression of liver disease. In addition, to achieve the new standards for optimal LB (20–25 mm length and 11 CPT) the patients will require more than one pass using a standard PLB, increasing the risk of complications. The question has been asked as to whether LB can be regarded as “the gold standard” for staging and grading of diffuse liver diseases when risks of biopsy, inadequate sampling, intra- and inter-observer error are taken into account [103].

Many studies have evaluated non-invasive markers (NIM). There are two types of NIM [104]. The first is based on serum markers: direct and indirect [105]. The indirect NIM may be simple, such as Fibroindex (AST, platelet count, gamma globulin) [106], and APRI index (AST/platelet count) [107], or more complex and expensive such as Fibrotest (a<sub>2</sub>-macroglobulin, haptoglobin, gamma globulin, apolipoprotein, bilirubin) [108], and PGAA index (a<sub>2</sub>-macroglobulin,  $\gamma$ GT, apolipoprotein A1, prothrombin time) [109]. Direct NIM are more expensive and are based on measurement of extracellular matrix in serum [110]. The second category of NIM are methodologies related to liver imaging techniques [105], such as transient elastography (FibroScan), which is based on ultrasound technology [111]. Some scores combine direct and indirect NIM (e.g. Fibrometer), while the accuracy of single NIM has been increased using them in algorithms (e.g. Fibrotest with Fibroscan) [110, 112].

Unfortunately, all these non-invasive tests are currently unable to distinguish different stages of fibrosis and are considered less reliable, compared to LB [113, 114]. The non-invasive tests are not measurements of fibrosis, and the studies that attempt to validate non-invasive tests generally compare them to histopathological stage scores, which are not liver fibrosis measurements either. Initially, studies had compared NIM with sub-optimal LB (<20–25 mm length and/or containing <11 CP), but more recent studies have overcome this drawback [115]. Furthermore, all NIM have been compared with categorical variables, that is, the stage scores, and only one study has evaluated NIM with histological digital analysis of collagen, which is a quantitative measurement of liver fibrosis [116]. Finally, several issues are as yet not clear, such as the effect of necroinflammation on NIM measurements [115], the role of NIM in the liver transplantation setting [117], and in liver diseases other than chronic viral hepatitis, such as NAFLD and PBC/PSC [118].

NIMs may become an important tool for follow-up of fibrosis, using LB as the initial diagnostic assessment. The latter should be performed to obtain optimal LB specimens. TJLB techniques offer the possibility of safely obtaining ideal liver biopsy samples on repeated occasions, which is very important, particularly in clinical trials, where the efficacy of antiviral therapies is being assessed.

### Introduction

The liver is central to the biotransformation of virtually all drugs and foreign substances and, hence, an adverse hepatic reaction is a potential complication of nearly every medication that is prescribed. The list of drugs capable of inducing liver damage increases from year to year [1–5], and in the last decades this also included several herbal remedies [6–10], and dietary supplements [11, 12]. Indeed, drug-induced liver disease (DILI) is an increasing health problem, accounting for >50% of cases of acute liver failure in Western countries [13], and for the 4–10% of cases of jaundiced patients taken as a whole, admitted to a general hospital [14–16]. Moreover, a recent study suggests that roughly 1% of medical inpatients develop DILI during the course of hospitalization [17].

The overall frequency of DILI was assessed in a community-based study performed in France over a three-year period, which found an annual incidence of 14 cases per 100,000 inhabitants [18]. To be included as true cases in this study the patients had to have symptoms, so this latter figure is probably an underestimation of the actual number of cases that occurred. In addition, this figure was 16 times as high as the number notified to the French network of pharmacovigilance, revealing the main drawback of spontaneous reporting systems, which is under-reporting.

The frequency of DILI associated with specific drugs is unknown. At best, scattered data for the numerator (total number of affected subjects) are available for some medica-

tions, but information on the denominator is derived mainly from prescribing data (as a surrogate for data on number of persons and time of exposure); however, this does not accurately reflect the population exposed. Nevertheless, the frequency of unpredictable hepatotoxicity associated with the use of a given medication is suggested to be around 1 per 10,000 to 1 per 100,000 exposed individuals [19, 20]. In two large databases of DILI cases prospectively recorded, the Spanish and American Registries of hepatotoxicity, which are not restricted to specific agents and can be regarded as representative of clinical practice, antibacterial agents, non-steroidal anti-inflammatory drugs and central nervous system agents were reported to rank as the main compounds incriminated in DILI [21, 22]. In both databases, amoxicillin-clavulanate was the single agent most frequently responsible for DILI.

An important currently unresolved difficulty is that the diagnosis of DILI is not standardized, relying largely on the circumstantial evidence of exposure to a drug or herbal product and its relationship to the start of symptoms, the effect of discontinuation of the suspected toxic substance on outcome, and the exclusion of other causes of liver disease (see below). The rare occurrence of DILI, together with the lack of specific diagnosis have an important impact in terms of epidemiological data concerning the problem and is a barrier for progress in the understanding of the mechanisms involved.

### Mechanisms

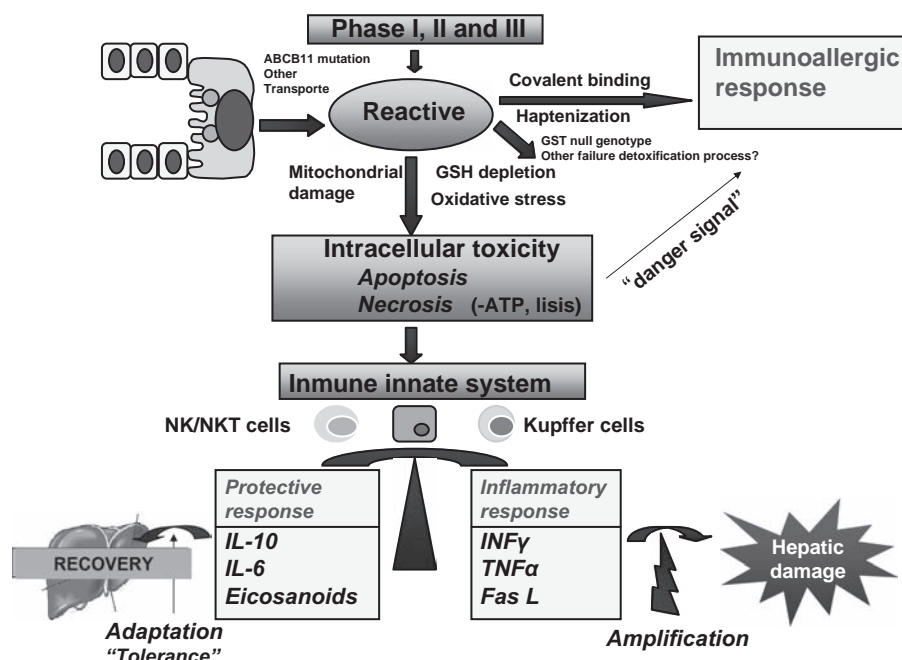

Hepatotoxicity directly related to the dose of a compound is the hallmark of *intrinsic* “dose-dependent” type A adverse drug reactions. Acetaminophen (paracetamol) is in practical terms the only marketed drug whose capacity of producing liver injury is closely related to the total dose consumed. On the contrary, *idiosyncratic* DILI, which represents the majority of DILI in clinical practice, is typically

Supported partly by research grants from the Agencia Española del Medicamento, Fondo de Investigación Sanitaria FIS PI 07/0980 and EC07/90910 and Boehringer-Ingelheim, Barcelona.

**Figure 47.1** Pathways of chemical injury in the liver (upstream mechanisms) and their modulation by the immune system (downstream mechanism). GSH: Glutathione; GST: glutathione-S-transferase.

a non-predictable (not based on the pharmacology of the drug) type B adverse drug reaction. Idiosyncratic reactions cannot be usually predicted from preclinical studies. They are classified as immunoallergic (hypersensitivity features present), or metabolic, although this is more an arbitrary division and overlap between categories can occur. The classical concept of idiosyncratic DILI includes the lack of a clear dose relationship. That said, it has been recently re-emphasized that even in allergic adverse drug reactions, a dose threshold is required, as these reactions are very rare when the dose of any drug is less than 10 mg per day [23]. Actually, 77% out of 598 cases of idiosyncratic DILI included in a Swedish database occurred in patients taking drugs at daily dose of at least 50 mg (higher doses), 14.2% at doses of 11–49 mg (intermediate doses), and only 9% at doses equal or less than 10 mg (lower doses) [24]. Furthermore, it has also been pointed out that most drugs, that either have been withdrawn from the market, or have received a black box warning due to hepatotoxicity were prescribed at daily doses greater than 50 mg/day [25].

A recent definition states that idiosyncratic reactions are toxic responses determined by individual susceptibility to (host) factors that increase the penetrance and expressivity of the intrinsic toxicity of a drug (or a drug metabolite) [26]. Indeed, development of DILI is a complex, multi-step process in which the toxic potential of the drug, genetic and acquired factors, as well as individual deficiencies in the adaptive processes, that limit the extent of the injury, determine the susceptibility to the rare occurrence of idiosyn-

cratic hepatotoxicity (see Figure 47.1) [27]. Thus, most patients tolerate the drug without adverse liver effects or there is a background of mild, and often transient, asymptomatic liver injury (i.e. statins, isoniazid), indicating an adaptation to the drug and further tolerance. Therefore, the combination of susceptibility factors coupled with drugs that (due to variation in handling between different phases of drug metabolism, detoxification, and transport) reach a threshold for exposure to drug or toxic metabolites, enhances the risk of idiosyncratic hepatotoxicity.

Several mechanisms and pathways may be involved in DILI. Most frequently, damage is initiated through the formation of reactive drug metabolites that can be directly toxic or induce immune reactions [28, 29]. In other instances drugs can impair mitochondrial function, which may decrease fat oxidation (causing fat accumulation) and/or energy production leading to cell death [30, 31]. Also parent drugs or reactive drug metabolites, either through direct toxicity or immune reactions, may open the mitochondrial permeability transition pore, which subsequently results in necrosis or apoptosis [32]. A unifying hypothesis that involves underlying genetic or acquired mitochondrial abnormalities as a major determinant of susceptibility for a number of drugs that target mitochondria and cause DILI has been proposed [26]. The mitochondrial hypothesis requires gradually accumulating and initially silent mitochondrial injury in heteroplasmic cells, which then reaches a critical threshold and abruptly triggers liver injury. This is consistent with the fact that, typically, idiosyncratic DILI

is delayed (by weeks or months). New animal models (e.g. the Sod2+/- mouse) provide supporting evidence for this concept [26]. However, genetic analyses of DILI patient samples are ultimately needed to provide evidence for this proof-of-concept [26].

In drug-induced immune-mediated hepatic injury, the drug reactive metabolites trigger an adaptive immune response directed against the drug-modified liver components, resulting in acute or chronic liver damage. Advances in the understanding of the pathogenesis of hepatotoxicity are hampered by the fact that no satisfactory animal models for idiosyncratic DILI have been developed. Recent evidence in experimental acetaminophen hepatotoxicity clearly indicates that the balance between the pro- and anti-inflammatory mediators determines the susceptibility and severity of liver injury [33]. Conceivably, these insights could be extrapolated to idiosyncratic DILI in humans, particularly the role of the innate immune system and cell-death pathways.

## Risk factors

Most of the risk factors that have been identified are the ones which influence drug disposition and metabolism. Incomplete information in case reports has precluded analyses of drug-related, environmental risk factors and clinical presentation profiles, which, however, can be obtained in large cohorts of patients with DILI [21, 22, 34–37]. Known risk factors are, nevertheless, poorly predictive of hepatotoxicity, and in many instances of DILI no risk factor can be identified [38].

## Environmental factors

There are several *environmental factors* that appear to operate in determining individual susceptibility.

### Age

Elderly patients are more vulnerable to DILI. In particular, increased age is a susceptibility factor for developing hepatotoxicity to antituberculous drugs [39]. Older age has also been implicated in amoxicillin-clavulanate induced cholestasis [40, 41]. In contrast, valproic acid and erythromycin hepatotoxicity are more common in childhood [42]. Older age, rather than being a predisposing factor to DILI, seems to have an impact on the phenotypic expression of toxic liver damage, strongly favoring the appearance of a cholestatic pattern of injury [21, 43].

### Gender

Women are more susceptible than men to most forms of DILI [18, 44–46]. For instance, autoimmune hepatitis triggered by drugs is seen almost exclusively in women [47],

and diclofenac hepatotoxicity has been reported more frequently in women with osteoarthritis [42].

However, new epidemiological data have challenged this traditional belief, showing a similar sex distribution in DILI cases [21, 48], with a higher prevalence of female gender only at younger ages [43]. Yet, female gender is considered to be a risk factor for developing fulminant liver failure [21], and female sex accounted for 76% of patients presenting with drug-induced acute liver failure in the USA who were transplanted [49]. Similarly to age, gender may influence the clinical presentation of DILI as women are over represented in the hepatocellular type of injury [43].

## Chronic alcohol consumption

A history of alcohol intake was considered to be a general risk factor for idiosyncratic DILI, and as such scores 1 + point in the standard clinical scale for assignation of causality developed by experts, the CIOMS (Council for International Organizations of Medical Sciences) or RUCAM (Roussel Uclaf Causality Assessment Method) scale [50]. However, for most of the drugs capable of inducing hepatotoxicity there is no evidence for a role of alcohol in potentiating toxicity. In practical terms, chronic alcohol intake increases the risk of developing liver fibrosis during methotrexate therapy, enhances acetaminophen hepatotoxicity by inducing cytochrome P-450 (CYP) 2E1 (with generation of higher levels of the reactive metabolite and depletion of glutathione stores), as well as susceptibility to liver damage from isoniazid, halothane and cocaine [42].

## Concomitant drugs

These are capable of modulating the hepatotoxic potential of other drugs through CYP or hepatic transport system induction, inhibition or substrate competition. In addition, concomitant medication with hepatotoxic potential may further increase the risk [51]. Concurrent use of anticonvulsants which induce drug metabolism greatly increases the risk of hepatotoxicity due to valproate [42]. The concurrent use of isoniazid and rifampicin, a potent microsomal inducer, enhances the risk of isoniazid hepatotoxicity [52].

## Underlying disease states

Controversy exists as to whether pre-existing liver disease is a susceptible factor for the development of hepatotoxicity. The presence of chronic hepatitis B, hepatitis C infection or co-infection with human immunodeficiency virus (HIV) increases the risk of isoniazid hepatotoxicity or elevated transaminases on HAART (highly active antiretroviral therapy) [53]. The increased susceptibility exhibited by HIV patients suggests a role for cytokine imbalance [54]. Rifampicin is more hepatotoxic when used for control of itching in patients with primary biliary cirrhosis [55].

Obesity, diabetes mellitus type 2 and insulin resistance are known risk factors for steato-hepatitis, and have also been shown, along with psoriasis, to increase the risk of developing liver fibrosis during methotrexate therapy [56].

### Genetic risk factors

Idiosyncratic hepatotoxicity is not predictable based either on the pharmacology of the drug or the dose administered, even when confounding variables such as environmental factors are taken into account. On the other hand, recurrence of liver injury with re-exposure to the drug often occurs under different clinical circumstances, indicating that susceptibility to hepatotoxicity could depend principally on host genetic factors [57]. Association studies have sought for single nucleotide polymorphisms (SNPs) in candidate genes, which are those presumably involved in drug bioactivation/detoxification processes as well in the immune response (see Table 47.1).

The reactive metabolite hypothesis states that most DILI instances would result from the production of reactive metabolites [20, 28, 29, 58, 59], which accumulate within the hepatocyte to levels that exceed a critical threshold. Once this threshold is crossed the damage is initiated. In liver, CYPs are more abundant in the centrilobular (zone 3) than periportal regions. Therefore, centrilobular necrosis, which represents one typical histological feature of serious acute drug-induced liver injury, may indeed indicate that drug metabolizing enzymes have a major role in pathogenesis. Only anecdotal reports suggest a role of CYP 450 polymorphisms in hepatotoxicity. For example, CYP2D6 deficiency is associated with perhexiline hepatotoxicity [60], and may occur in up to 10% of Europeans [61]. CYP 2C19 deficiency was suggested to be associated with Atrium (a phenobarbitone containing combination preparation) liver injury [62]. However, 60 patients with DILI caused by drugs known to be substrates of CYP2C9 and CYP2C19, showed a similar prevalence of allelic variants to those in other European populations, and there were no patients exhibiting very low enzyme activity with CYP2C9 \*3/\*3 and CYP2C19 \*3/\*3 genotype [60]. These data suggest that CYP2C9 and CYP2C19 genetic polymorphisms might not be a predictable potential risk factor for DILI. Indeed, variant genotypes of CYP, associated with lower enzyme activity could not account for higher susceptibility to DILI, as an intact or even enhanced enzyme activity (determined by environmental rather than genetic factors) seems to be required for the formation of reactive metabolites.

An alternative possibility is that reactive metabolites may not undergo detoxification, either because they are poor substrates, or because of failure of detoxification enzyme function (due to genetic polymorphisms). Phase II enzymes are known to be polymorphically expressed. The major Phase II genes implicated in hepatotoxicity are

N-acetyltransferase 2 (NAT2) and the glutathione S-transferases M and T (GSMT and GSTT).

In Chinese patients on antituberculosis therapy, carriers of NAT2 genotypes which are associated with slow acetylation, had four-fold risk of developing isoniazid-induced hepatotoxicity [63]. Regular monitoring of serum aminotransferase was thus suggested in slow NAT2 acetylators receiving isoniazid treatment [64]. The same authors showed that subjects with CYP2E1 *c1/c1*, were 2.5 times more likely to develop hepatotoxicity when compared with the other genotypes. The odds ratio for hepatotoxicity increased to 7.4 when CYP2E1 *c1/c1* was combined with slow acetylator status [65].

Oxidative stress induced by the reactive metabolites or reactive oxygen species generated by drugs, may be the final common pathway underlying DILI. Individual vulnerability to a drug might then not be closely related to the rate of parent drug metabolism, but related to deficiencies in the detoxification process, or in drug transporters which ultimately determine the level of exposure to the reactive metabolite. In this regard, glutathione S-transferase (GST), a major phase II family of conjugation enzymes, prevents the binding of reactive metabolites to cellular proteins and modulates the by-products of oxidative stress, catalyzing the conjugation of electrophilic moieties to glutathione [66].

The importance of GST as a general detoxification mechanism in DILI is underlined by the fact that it acts for a variety of metabolites derived from aflatoxin, acetaminophen, benzo(a)pyrene, bromobenzene, or felbamate, and other substances [67–72]. In humans, the activity of the cytosolic GSTs M1 ( $\mu$ ) and T1 ( $\theta$ ) are polymorphically expressed due to complete *GSTM1* and *GSTT1* gene deletions, that occur in homozygosity (null genotypes) in 50%, and 10–25% of Caucasian subjects respectively [73]. A significant association with *GSTM1-GSTT1* null genotype was found in Japanese patients with troglitazone induced DILI [74], and in a cohort of French [75], but not British patients [76], with tacrine-induced DILI. An association with *GSTM1* (but not *GSTT1*) null genotype, was also identified in Indian patients with antituberculosis drug-induced hepatotoxicity (52% vs 24% in controls,  $p < 0.05$ ) [77], and in Chinese patients with antituberculosis drug-induced hepatotoxicity, (2.23 fold-increased risk) [78]. Taken together, and consistent with studies in animal models, these findings point to a role for these enzyme activities as a general protective mechanism against hepatotoxicity. This hypothesis was tested in a study involving 154 patients with a diagnosis of DILI due to an array of medications. Carriers of double *GSTT1-M1* null genotypes were 2.70 times more likely to develop hepatotoxicity, when compared with non-carriers. The odds ratio for DILI patients receiving antibacterials, and NSAIDs were 3.52 and 5.61 respectively. Patients with amoxicillin-clavulanate hepatotoxicity had a 2.81-fold increased risk. There was a

statistically significant predominance of women in the combined null genotype ( $p < 0.001$ ) [79].

The Manganese Superoxide Dismutase (MnSOD) is also a critical determinant of cellular defence against toxic insult to the liver. A study including 115 subjects with DILI (63 with antituberculosis hepatotoxicity) showed that those with a variant C allele (genotype T/C or C/C) of *MnSOD* had an increased risk of hepatotoxicity compared to those with *MnSOD* T/T genotype, considering all drugs together (adjusted OR: 2.44), but also in the sub-category of antituberculosis drugs (adjusted OR: 2.47) [78].

The functions of ATP-Binding-Cassette (ABC) transporters, which determine the excretion or accumulation of certain reactive metabolites, make them obvious candidate genes in the identification of susceptible individuals to develop DILI. In a study a single nucleotide polymorphism in exon 13 of *ABCB11*, 1331T > C (V444A), which is associated with decreased hepatic BSEP expression, was significantly more frequent in drug-induced cholestasis than in hepatocellular injury, or in the control population [80]. In contrast, carriers of the *ABCB11*, 1331T > C polymorphism were found to have a two-fold increased risk of developing toxic hepatocellular damage in a cohort of 188 Spanish DILI patients [81].

With the availability of increasing information on new polymorphisms and their functional significance, it is currently feasible in some cases to perform genotyping for different polymorphisms concomitantly. A study involving 24 patients with diclofenac-induced liver injury showed that simultaneous possession of variant of UDP-glucuronosyl-transferase (that mediates the glucuronconjugation of diclofenac to a paradoxically reactive metabolite acyl-glucuronide) the *UGT2B7\*2* allele (associated with increased activity), and the *ABCC2* (that transports the glucuronide to the biliary canaliculus), C-24T variant (associated with reduced activity) was more common in DILI patients compared with controls. Haplotype distributions for *CYP2C8* (which plays a role in the metabolism of diclofenac to 5-hydroxydiclofenac) were also significantly different in patients with hepatotoxicity [36]. Interestingly, in this study, 21% of the community control population was positive for both the “at-risk” *UGT2B7* and *ABCC2* genotypes [36]. It is clear that the incidence of serious hepatotoxicity is much lower than these figures. Indeed, genetic polymorphisms of drug metabolism, although increasing the risk of DILI, do not explain why all patients with a given polymorphism do not develop DILI when treated with the relevant drug.

## Immunological factors

Once hepatic cells become stressed by the toxic insult, the response of the innate and acquired immune system

(downstream events), appear to determine whether liver injury subsides or progresses to clinical disease (see Figure 47.1) [27].

Variations in the production of immunoregulatory cytokines (genetic polymorphisms) such as IL-10 and IL-4 have also been reported to contribute to the susceptibility to diclofenac hepatotoxicity [82]. The observed polymorphisms, resulting in low IL-10 and high IL-4 gene transcription, could favour a Th-2 mediated antibody response to neoantigenic stimulation associated with disease susceptibility.

As the increased susceptibility related to these downstream events may be less drug-specific than those involved in the accumulation of reactive metabolites, it might be possible to group cases of DILI associated with a heterogeneous group of drugs. In a cohort of 146 patients with DILI the analysis of three polymorphisms: -1082G/A, -819C/T, and -592C/A in the *IL-10* gene promoter, did not reveal any association with the predisposition to develop hepatotoxicity. However, the low IL-10 producing haplotype was more prevalent in DILI patients coupled with the absence of peripheral blood eosinophilia [83]. All cases with serious DILI outcome carried low or intermediate IL-10 producing haplotypes and had normal or low eosinophil counts. [83] Indeed, low IL-10 producing haplotype, leading to a reduced or absent rise in peripheral eosinophil count, could be a marker of an unfavorable outcome of DILI, supporting the concept of accelerated Th1 T-cytotoxic response.

## HLA genotyping

Major histocompatibility complex molecules (i.e. class I and II HLA molecules) participate in antigen presentation to immunocompetent cells and in the regulation of the immune response. Significant association has been reported between *DRB1\*1501-DRB5\*0101-DQB1\*0602* haplotype and cholestatic hepatitis related to amoxicillin-clavulanate [84]. Also a genome-wide association study using 866,399 markers in 51 cases of flucloxacillin DILI and 282 controls matched for sex and ancestry showed an association peak in the major histocompatibility complex (MHC) region with the strongest association ( $P = 8.7 \times 10^{-33}$ ) seen for rs2395029[G], and other SNPs all of which are a part of an extended MHC 57.1 haplotype present in <4% of Europeans, which is associated to hypersensitivity to abacavir [85]. However, even in cases of DILI with no evidence of allergy, such as those induced by ximelagatran (hepatocellular type, delayed in latency, no eosinophilia), using a wide genome screen approach, a strong genetic association between elevated alanine aminotransferases (ALT) and the HLA class-II alleles *DRB1\*07* and *DQA1\*02* was also recently shown, suggesting a possible immune pathogenesis. Consistent with this hypothesis, immunological

studies suggest that ximelagatran may have the ability to act as a contact sensitizer, and hence be able to stimulate an adaptive immune response [86].

A large cohort of cases with drug-induced liver disease due to variety of agents with a wide range of manifestations may be suitable in the evaluation of the effect of genetic factors on the phenotype expression of hepatotoxicity [87]. The *HLA DRB1\*15* and *DQB1\*06* alleles of the class II HLA system participate in increased susceptibility to the development of a cholestatic/mixed pattern in drug-induced liver injury, thus providing indirect evidence about the immunoallergic nature of this specific pattern of damage and explaining, at least in part, why a given drug may cause different patterns of liver damage [87].

### Diagnostic approach and tools for causality assessment

The phenotypic expressions of DILI may present in several ways (clinical and pathological) that resemble known forms of acute and chronic liver disease; the severity ranges from sub-clinical elevations in liver enzyme concentrations to acute liver failure. Mainly, drugs tend to induce acute hepatitis, cholestasis or a mixed condition (see Table 47.2) [47].

Liver histology (although not very specific and, at best, “compatible with”) is still the ideal tool for defining the pattern of liver damage. However, since a liver biopsy specimen is often not available, the pattern of drug-related liver injury is, from a practical standpoint, classified according to laboratory data [88, 89]. The classification scheme was proposed by CIOMS [88] and recently updated by the Food and Drug Administration Drug Hepatotoxicity Committee (see Table 47.3) [89].

The acute hepatocellular (cytotoxic, cytolytic) type of liver injury is the most common expression of hepatotoxicity and it is observed with many drugs (see Table 47.4) [21, 22]. Patients with acute hepatocellular injury related to drugs are at risk of acute liver failure. The presence of combined increases in ALT and bilirubin levels in DILI reflects a substantial loss in hepatocellular function and potential for liver failure [90]. **B4** These parameters are considered a specific indicator of severe hepatotoxic potential of a drug. In patients with acute drug-induced hepatitis the presence of jaundice is the most significant predictor of mortality/liver transplantation. The observation by Hyman Zimmerman, known as “Hy’s rule” [47], predicts a mean mortality (or its surrogate marker, liver transplantation) of 10% (range 5–50%) for jaundiced patients with acute toxic hepatocellular damage. Hy’s rule has been validated in large case series from Spain and Sweden in which analysis of pooled data showed that other variables such older age,

DILI clinical issue	Key point	To be remembered
<b>Presentation</b>	<ul style="list-style-type: none"> <li>DILI may resemble any acute and chronic liver disease.</li> <li>Acute hepatocellular presentation predominates.</li> </ul>	<ul style="list-style-type: none"> <li>Hypersensitivity features occur in less than a quarter of patients.</li> </ul>
<b>Prognosis</b>	<ul style="list-style-type: none"> <li>Female sex, hepatocellular damage and high bilirubin levels on presentation are risk factors for the development of fulminant hepatic failure.</li> <li>Cholestatic/mixed damage is more prone to chronicity.</li> </ul>	<ul style="list-style-type: none"> <li>Classification of damage by biochemical criteria is useful to stratify prognosis.</li> </ul>
<b>Diagnosis</b>	<ul style="list-style-type: none"> <li>Relies largely on exclusion of other causes of liver injury.</li> <li>Rules for assigning causality in DILI do not substitute clinical judgment.</li> <li>The “signature” (consistent clinical, pathologic and latency presentation) for a given drug may be variable.</li> </ul>	<ul style="list-style-type: none"> <li>CIOMS/RUCAM scale provides a framework to guide diagnosis in DILI, and adds consistency and reproducibility to clinical judgment.</li> <li>Complexity of CIOMS/RUCAM scale precludes its implementation in routine clinical practice.</li> </ul>

**Table 47.3** The classification of the type of liver damage according to the Council for International Organizations of Medical Sciences (*J Hepatol* 1990, **11**: 272) and recently updated by the Food and Drug Administration Drug Hepatotoxicity Committee ([www.fda.gov/cder/livertox/presentations2005](http://www.fda.gov/cder/livertox/presentations2005)).

Hepatocellular: Increase >3N ALT or when  $R \geq 5$   
 Cholestatic: Increase >2N AP or when  $R \leq 2$   
 Mixed: Increase >2N ALT and AP or  $2 < R < 5$   
 $ALT \times N$   
 $R =$   
 $AP \times N$

N: Upper limit of normal; BC: Conjugated bilirubin; BT: Total bilirubin;  
 ALT: Alanin-aminotransferase; AP: Alkaline phosphatase.

**Table 47.4** Drugs and compounds predominantly associated with hepatocellular or cholestatic damage.

Hepatocellular damage	Cholestatic damage
Acarbose	Amoxicillin clavulanic acid
Allopurinol	Azathioprine
Amiodarone	Captopril, enalapril, fosinopril
Amoxicillin, Ampicillin	Benoxaprofen
Anti-HIV:	Bupropion
(didanosine, zidovudine, protease inhibitors)	Carbamazepine
Non-steroidal anti-inflammatory drugs	Carbimazole
(ibuprofen, diclofenac, piroxicam, indometacin)	Cloxacillin, dicloxacillin
Asparaginase	Clindamycin
Benzazepam	Ciprofloxacin, norfloxacin
Bromfenac	Contraceptive steroids
Chlormethiazole	Cyproheptadine
Cocaine, Ecstasy and amphetamine derivatives	Diazepam, Nitrazepam
Diphenytoin	Erythromycins
Disulfiram	Estrogens
Ebrotidine	Gold compounds, penicillamine
Fluoxetine, paroxetine	Herbal remedies:
Flutamide	(Chaparral leaf ( <i>Larrea tridentata</i> ), Glycyrrhizin, Greater celandine
Halothane	( <i>Chelidonium majus</i> ))
Herbal remedies	Irbesartan
((Chaso and Onshido, Herbalife®	Lipid lowering drugs:
Germander ( <i>Teucrium chamaedrys</i> ), senna Pennyroyal oil, kava-kava ( <i>Piper</i>	(atorvastatin, fluvastatin)
<i>Methysticum</i> ), Camellia <i>sinnensis</i> (green tea), Chinese herbal medicines))	Macrolide antibiotics
Leflunomide	Mirtazapine
Lipid lowering drugs:	Penicillin G
(lovastatin, pravastatin)	Phenothiazines (chlorpromazine)
Isoniazid	Raloxifen
Ketoconazole	Rofecoxib, Celecoxib
Mebendazole, albendazole, pentamidine	Rosiglitazone, pioglitazone
Mesalazine	Sulfamethoxazole-trimethoprim
Methotrexate	Sulfonylureas:
Minocycline	(Glibenclamide, Chlorpropamide)
Nitrofurantoin	Sulindac
Nefazodone	Terbinafine
Omeprazole	Tamoxifen
Pemoline	Tetracycline
Pyrazinamide	Ticlopidine, Clopidogrel
Risperidone	Thiabendazole
Ritodrine	Tricyclic antidepressants:
Sulfasalazine	(Amitriptyline, Imipramine)
Telithromycin	
Terbinafine	
Tetracycline	
Tolcapone	
Topiramate	
Trazodone	
Troglitazone	
Trovafloxacin	
Valproic acid	
Venlafaxine	
Verapamil	
Vitamin A	
Ximelagatran	

female gender and AST levels were independently associated with a poor outcome [21, 38]. **B4** Further analysis of the Swedish database, has found that there was also a significant linear relationship between daily dose and the outcome of death/liver transplantation (2%, 9.4% and 13.2% in <10, 11–49, and >50mg/day groups respectively,  $p = 0.03$ ) [24]. **B4** On the contrary, it has recently been suggested that eosinophilia accompanying DILI may be associated with a better short-term prognosis [91, 92]. Actually, none of the patients included in the Spanish Registry with idiosyncratic DILI who died, evolved to liver failure, or required a liver transplantation had eosinophilia, whereas this feature was found in the 23% of the patients with milder outcomes [21]. **B4** Of note is that the height of transaminases in acute hepatocellular DILI lacks prognosis significance. Indeed, a decrease in liver enzymes after drug withdrawal in patients with severe DILI may reflect rather than a clinical improvement, a limited hepatic reserve associated with impending liver failure [90]. Moreover, if acute injury is superimposed on underlying liver disease, monitoring liver function tests may be difficult to interpret. For example, if advanced cirrhosis is present, the severity of liver injury may be underestimated by the height of the serum ALT measurements [93].

Acute cholestatic injury is caused by many drugs, including anabolic and contraceptive steroids, which characteristically produce DILI with minimal or absent accompanying inflammation. Other medications, which include amoxicillin-clavulanate, macrolide antibiotics and phenothiazine neuroleptics, typically cause variable degrees of portal inflammation and hepatocyte necrosis, in addition to marked cholestasis, which is predominantly centrilobular (see Table 47.4) [42, 47].

In mixed hepatic injury, the clinical and biological picture is intermediate between the hepatocellular and the cholestatic patterns, and features of either type may predominate. By definition, the ALT/AP ratio is between 2 and 5 (see Table 47.3). When faced clinically with a mixed hepatitis picture, the gastroenterologist should always suspect and seek a potentially hepatotoxic medication, since this type of injury is far more characteristic of drug-induced hepatotoxicity than of viral hepatitis [47]. Almost all drugs that produce cholestatic injury are also capable of inducing a mixed pattern.

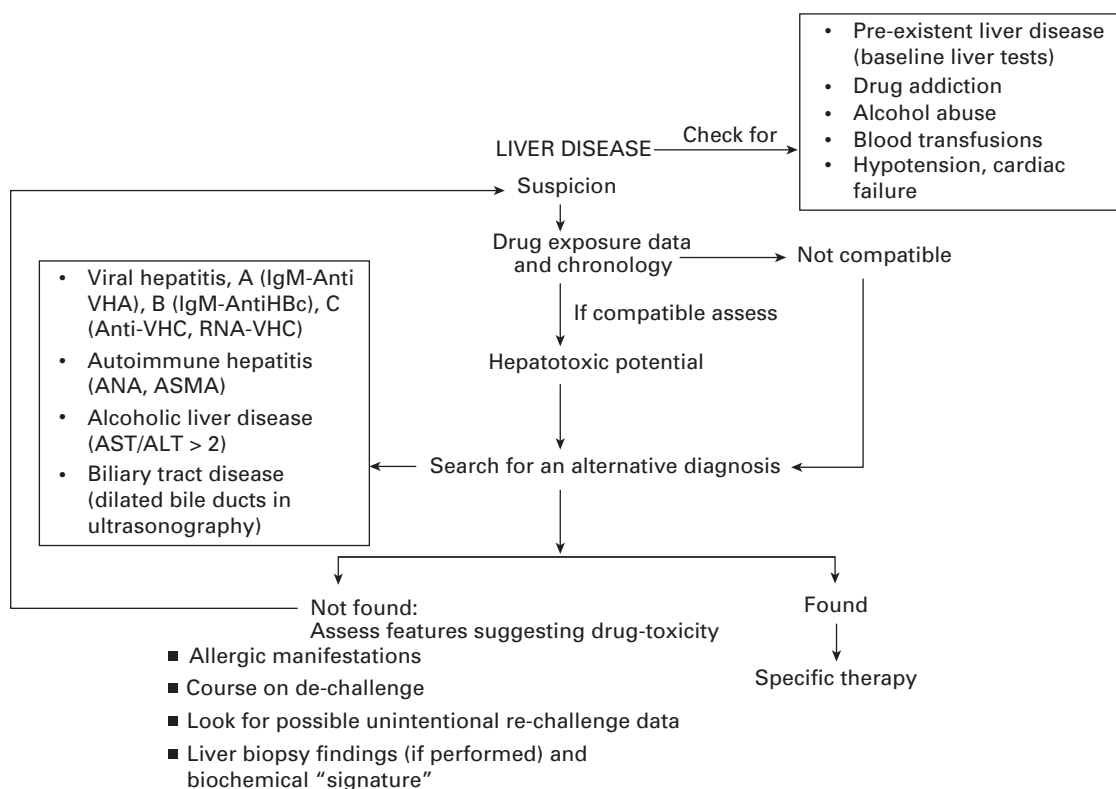

Drug-induced acute cholestatic and mixed lesions progress less frequently to acute liver failure than the hepatocellular type. However, their resolution is generally slower, with a higher likelihood towards chronicity in one study (9% vs 4% respectively;  $p < 0.031$ ) [94]. In contrast, in the hepatocellular pattern with jaundice at presentation, the severity of chronic lesions was greater (higher incidence of cirrhosis and chronic hepatitis) [94, 95]. Cardiovascular and central nervous system drugs are the main groups leading to chronic liver damage [94]. Of the

whole population included in the Spanish Registry, 5.6% of patients had biochemical evidence of chronicity [94], a figure similar to that reported in the Swedish population (6%), even though the majority of the patients included in this latter study were identified in an outpatient basis and had mild to moderate DILI [96]. A higher prevalence of chronicity (14%) has been reported in the analysis of the first 300 patients enrolled in the cooperative group Drug Induced Liver Injury Network in USA [22]. Further studies on the natural history of DILI are ongoing.

The diagnosis of DILI remains a challenge because, except for the very rare circumstance in which an unintentional positive re-challenge may confirm the putative involvement of a drug, the evidence that is usually collected is often circumstantial. It is often based on subjective impressions from previous experiences, and can lead to inaccurate diagnosis [97]. At present, the diagnosis of DILI is complex and not standardized, and is made with varying levels of confidence, relying largely on exclusion of other causes of liver disease and identification of a signature pattern of disease manifestations, in relation to starting and stopping of the suspected drug or herbal medication [98]. The process is time-consuming and delays clinical diagnosis; at least until other possible causes of liver disease have been excluded. It has been considered as the Achilles heel in the field of hepatotoxicity. Confounding features include multiple drugs prescribed, lack of information on doses consumed, as well as the stop and start dates [99]. A careful “step-by-step” approach is outlined in Figure 47.2 [100].

This issue has important implications not only for practicing clinicians, but also for conducting research into the risk factors, mechanisms and natural history of DILI, and from a medico-legal and drug regulation/development standpoint [101]. The use of causality assessment methods does add some consistency to the diagnostic process, by translating the suspicion into a quantitative score and by providing a framework that emphasizes the features that merit attention in cases of suspected hepatic adverse reaction (see Table 47.2) [102].

A controversial issue is the role of liver biopsy in the diagnosis of DILI. Indeed, since there are no histological findings specific for toxic damage, liver biopsy should not be performed routinely for this indication [103]. Furthermore, a liver biopsy specimen which is often taken several days after the clinical presentation of the symptoms, when the pathological features are beginning to wane, may generate perplexity and confusion in cases in which chronological sequence criteria are critical and when exclusion of alternative causes appear to incriminate the drug [104]. Currently, a reasonable approach for performing a liver biopsy in patients with suspected DILI is restricted to some specific situations: (1) the patient may have an underlying liver disease and, hence, it is difficult to ascribe the picture to the candidate drug or to a

**Figure 47.2** Algorithm for step-by-step approach to a suspected case of drug-induced liver disease.

recrudescence of the disease [104]; (2) to characterize the pattern of injury with those drugs that had not been previously incriminated in hepatotoxicity [1, 3, 105]; and (3) for identifying more severe or residual lesions (e.g. fibrosis) which could have prognostic significance. For instance, in some chronic variants of hepatotoxicity, clinical and laboratory features poorly reflect the severity of the liver injury [105], and a liver biopsy may clarify its true magnitude. Furthermore, severe bile duct injury during cholestatic hepatitis has been shown to be predictive of clinical evolution into chronic cholestasis [106], and, in a retrospective study, the presence of fibrosis in the index liver biopsy was related to the development of chronic liver disease [107].

Prompt recognition of potentially hepatotoxic drugs as the cause of liver injury is the most important aspect in the management of hepatotoxicity. It is of paramount importance as immediate stoppage appears to decrease the risk of progression to acute liver failure or chronic liver injury [94, 95]. The fact that the diagnosis of hepatotoxicity still relies upon careful history taking (completeness of data and accuracy) and a correct interpretation of the patient's clinical manifestations and laboratory data, should not be underestimated. An approach to diagnosis following clinical judgment, that closely depends on physician's skill, and that is not standardized, results in categories of causation that can be defined as drug-related (e.g. acetaminophen

over dosage, cases of positive re-challenge), clearly non-drug related (an alternative explanation found, negative de-challenge) or possibly drug-related (temporal sequence, possible competing cause, de-challenge positive) [104]. This last judgment in which subjectivity prevails and in which there is no strong argument for confirming or ruling out drug causality represents the majority of situations in clinical practice. Consequently, agreement among physicians who evaluate a given case of drug-suspected hepatotoxicity may differ strongly, and indeed has been shown to lead to inaccurate diagnosis [97].

To ascertain the putative role of a drug on the basis of quantitative criteria, clinical and laboratory data are assessed with probabilistic approaches (based on Bayesian statistics) and algorithms or clinical scales. The qualities usually required for a diagnosis scale are reproducibility and validity. Reproducibility ensures an identical result regardless of who the user is, and when the scale is used. Validity means the method is able to distinguish between cases where the drug is responsible and cases where it is not [104]. It is worth noting that none of the things that are currently measured have proven to be reliable in assessing causality for drug-induced liver injury. Therefore, more convincing evidence of validity is difficult to obtain in the absence of a unanimously accepted "gold standard" defining "truth" (see Table 47.2).

The first method developed in the area of DILI and, at present, the most prominent adjudication system in use by experts/researchers/sanitary authorities is CIOMS or RUCAM (Roussel Uclaf Causality Assessment Method) scale, which provides a standardized scoring system, in which the limits and content of most criteria were decided by consensus, among experts, on the basis of organ-oriented characteristics [50]. The parameters are outlined in Table 47.5. The time to onset and course criteria vary according to whether cases present with hepatocellular or cholestatic/mixed liver injury, since the latter may occur after a longer post-cessation interval and resolve much more slowly. The CIOMS/RUCAM scale provides a scoring system for seven axes in the decision strategy in which the answers correspond to weighted numeric values that are summed to give a total score. The scores are translated into categories of suspicion: definite or highly probable (score >8), probable (score 6–8), possible (score 3–5), unlikely (score 1–2) and excluded (score (</= 0). This method was originally validated using cases of drug-induced liver disease with known positive re-challenge (the major type of evidence recognized as demonstrating the role of a drug), and the system performed well when these cases were assessed, based on data prior to re-challenge, or when concomitant drugs were included [98]. This tool has the advantage of providing a framework that emphasizes topics that need to be addressed in cases of suspected hepatic adverse reaction, in order to improve the consistency of judgments. The major drawback is its complexity. It requires training and is less efficient when a user is unfamiliar with the format. The scale may seem cumbersome and while reading across the page, care needs to be taken not to misunderstand the questions, otherwise careless errors can be made [102]. Hence, it is not generally used by practicing physicians, who presumably find it confusing and difficult to apply.

A simpler but also organ-specific method, the Clinical Diagnostic Scale (CDS) (also called the M&V scale), was developed and tested by Maria and Victorino from Portugal [108]. In contrast with the CIOMS/RUCAM scale, the M&V scale includes questions that apply only to immune-allergic hepatitis. Furthermore, there are differences in the periods allowed for the end of treatment and the onset of liver injury and for the disappearance of liver abnormalities after withdrawal of treatment, as well as different criteria to define drug injury. The CDS/M&V scale is classified using five ratings: >17, relationship definite; 14–17, probable; 10–13, possible; 6–9, unlikely; <6 excluded. The CDS/M&V scale was validated using real and fictitious cases of immunoallergic drug-induced liver injury immunological mechanism (high percentages of positive immunological tests in cases classified as definite or probable), and was compared with the external standard or experts' classification.

The merits of the CIOMS/RUCAM scale and the CDS/M&V scale were compared in a population of 215 patients reported to a Registry [109]. Causality in this population was verified by three experts as drug-induced (185), or as non-drug caused (30 cases). Complete agreement between the CDS/M&V scale and the CIOMS/RUCAM scale was obtained in only 42 cases (18%). The CDS/M&V scale, classified only about one-third of the cases as probable or definite, and tended to underestimate the probability of causality. It was not unexpected, due to the arbitrary weights given to relevant assessment criteria, that the performance of the M&V scale was poor in drug injury with long latency periods (i.e. amoxycillin/clavulanic acid), evolution to chronicity after withdrawal (cholestatic pattern), or death (due to the lack of de-challenge data). On the contrary, the best agreement between scales was found for idiosyncratic immunologic DILI cases.

The need for more accurate and simple tools in drug hepatotoxicity has lead investigators to evaluate the performance of the Naranjo Adverse Drug Reactions Probability Scale (NADRPS), which is not liver specific but valuable in the overall evaluation of adverse drug reactions [110]. The attractive aspect of the Naranjo scale is its simplicity (see Table 47.5). The NADRPS involves ten “yes”, “no” or “unknown or non-applicable” questions. The adverse drug reaction is assigned to a probability category, on the basis of the total score as “definite”  $\geq 9$ , “likely” = 5–8, “possible” = 1–4, “unlikely”  $\leq 0$ . In comparison with the CIOMS scale assessing a cohort of 225 cases of suspected DILI, the Naranjo scale had a low sensitivity and negative predictive value and it was neither reproducible nor valid for evaluating drug hepatotoxicity, and thus its use for this purpose is not recommended [111]. Indeed, the Naranjo algorithm was designed for evaluation of adverse drug reactions related to pharmacological actions of the drugs, and hence has questions such as “drug concentrations and monitoring”, “dose relationship”, “placebo response”, which are clearly not relevant to idiosyncratic DILI.

However, limitations of the CIOMS/RUCAM scale have also been highlighted [90, 99, 112], such as the poor definition of the components needing to be answered, poor diagnostic capability when two drugs are given with the same temporal sequence, and the arbitrary weighting and selection of important validation criteria, such as the cutoff age point, known relevant risk factors and better estimates of temporal chronology. All of these are taken into consideration for each case under evaluation (see Table 47.5). Indeed, a recent report has shown a low reliability of the RUCAM instrument, and, moreover, poor agreement among experts in the analysis of 40 well-defined DILI cases [113]. Each case was adjudicated by three reviewers, each working independently. After an interval of at least four months,

**Table 47.5** Scores for individual axes of most commonly used diagnostic scales.

CIOMS/RUCAM		Maria & Victorino/CDS		Naranjo	
Axis	Score	Axis	Score	Axis	Score
<b>Chronological criteria</b> (according to type of liver damage: hepatocellular or cholestatic/mixed)		<b>Chronological criteria</b>		Previous reports on ADR	+1 to 0
Time to onset of the event		From drug intake until onset event		Onset of the ADR after drug administration	+2 to -1
Suggestive	+2	4 days to 8 weeks	+3		
Compatible	+1	Less than 4 days or more than 8 weeks	+1	Improvement of ADR after drug withdrawal or antagonist	+1 to 0
From drug withdrawal until onset event		From drug withdrawal until onset event			
Compatible	+1	0 to 7 days	+3	Positive rechallenge	+2 to -1
Course of the reaction		8 to 15 days	0		
Highly suggestive	+3	More than 15 days	-3	Presence of alternative causes	+2 to -1
Suggestive	+2	Normalization of laboratory values			
Compatible	+1	Less than 6 mo (cholestatic) or 2 mo (hepatocellular)	+3	Positive rechallenge with placebo	+1 to -1
Against the role of the drug	-2				
Inconclusive or not available	0	More than 6 mo or 2 mo	0		
<b>Risk factors</b>				Toxic drug levels in biological fluids	+1 to 0
Age(≥50y)	+1 to 0	<b>Other causes</b>

CIOMS: Council for International Organizations of Medical Sciences; RUCAM: Roussel Uclaf Causality Assessment Method; CDS: Clinical Diagnostic Scale; SPC: Summary Product Characteristic; ADR: adverse drug reaction.

With CIOMS/RUCAM, score ≤ 0, diagnosis of excluded; 1–2 unlikely; 3–5, possible; 6–8 probable; >8 highly probable or definite.

With Maria & Vitorino/CDS, score > 17, definite; 14–17, probable; 10–13, possible; 6–9, unlikely; <6, drug hepatotoxicity excluded.

With Naranjo Adverse Drug Reaction Probability scale, score ≥ 9 diagnosis of definite; 5–8, likely; 1–4 possible; ≤0, doubtful.

cases were re-adjudicated by the same reviewers. Test-retest differences ranged from -7 to +8 with complete agreement in only 26% of cases. On average, the maximum absolute difference among the three reviewers was 3.1 on the first occasion and 2.7 on the second, although much of this variability could be attributed to differences between the enrolling investigator and the external reviewers. Under the best-case scenario, the test-retest reliability among the site principal investigators was only 0.65, while the inter-rater reliability among the external reviewers, was unacceptably low at 0.46. The authors concluded that the mediocre reliability of the RUCAM is problematic for future studies of DILI [113].

It would be important, nevertheless, to accommodate all relevant information into an ideal scoring system and to eliminate low impact items. This is now feasible with the use of large datasets of cases. Clinicians attribute a crucial value to the presence of clinical signs of hypersensitivity, which is not a domain in the scale. Besides, when liver biopsy findings are available, they should be taken into account for the evaluation of alternative causes, and also to reach a definitive diagnosis if an eosinophilic hepatic infiltrate, centrozonal damage (highest content of cytochrome P450), granulomas and microsteatosis are evident. Furthermore, assessment of known genetic risk factors for hepatotoxicity could be further evaluated. Indeed, a computerized scale that could integrate in a dynamic way all available knowledge with regard to the given drug and its signature in a particular patient population would be of great value. A modified RUCAM/CIOMS instrument termed DWW-J (Digestive Disease Week-Japan) has been proposed [115]. In this approach, the indirect evidence of immunoallergy such as eosinophilia, or a positive *in vitro* lymphocyte stimulation test, were weighted; no case in which the temporal criteria did not fall within the accepted limits was excluded, and the domain regarding concomitant drugs was deleted [114]. The performance of the DWW-J scale was then evaluated in 127 DILI cases and 46 controls with 423 putative drugs. As compared with CIOMS the modified scale showed a higher sensitivity but a poorer specificity [115].

International consensus is needed to agree upon common definitions, diagnostic criteria, terminologies and instruments to assess the causality in DILI and it is now feasible by the concerted actions of several investigators working in this area [21, 22, 35, 37]. Hopefully, a new instrument will be developed to improve the consistency, accuracy and objectiveness in causality assessment in hepatotoxicity. Such a goal, will allow better planning and interpretation of genetic studies and this, in turn, will enhance knowledge and research into the mechanism underlying DILI.
