Contributors, vii

1 Introduction, 1

*John WD McDonald, Andrew Burroughs, Brian, G Feagan and M Brian Fennerty*

---

## Part I: Gastrointestinal disorders

2 Gastroesophageal reflux disease, 19

*Naoki Chiba and M Brian Fennerty*

3 Barrett's esophagus, 62

*Constantine A Soulellis, Marc Bradette, Naoki Chiba, M Brian Fennerty and Carlo A Fallone*

4 Esophageal motility disorders: Achalasia and spastic motor disorders, 78

*Jason R Roberts, Marcelo F Vela and Joel E Richter*

5 Eosinophilic esophagitis, 93

*Elizabeth J Elliott*

6 Ulcer disease and *Helicobacter pylori* infection: Etiology and treatment, 102

*Naoki Chiba*

7 Non-steroidal anti-inflammatory drug-induced gastro-duodenal toxicity, 139

*Alaa Rostom, Katherine Muir, Catherine Dubé, Emilie Jolicoeur, Michel Boucher, Peter Tugwell and George Wells*

8 Acute non-variceal gastrointestinal hemorrhage: Treatment, 165

*Nicholas Church and Kelvin Palmer*

9 Functional dyspepsia, 190

*Sander Veldhuyzen van Zanten*

10 Celiac disease: Diagnosis, treatment and prognosis, 200

*James Gregor and Michael Sai Lai Sey*

11 Crohn's disease, 211

*Brian G Feagan and John WD McDonald*

12 Ulcerative colitis, 232

*Derek P Jewell, Lloyd R Sutherland, John WD McDonald and Brian G Feagan*

13 Pouchitis after restorative proctocolectomy, 248

*Darrell S Pardi and William J Sandborn*

14 Microscopic colitis: Collagenous and lymphocytic colitis, 257

*Johan Bohr, Robert Löfberg and Curt Tysk*

15 Drug-induced diarrhea, 267

*Bincy P Abraham and Joseph H Sellin*

16 Metabolic bone disease in gastrointestinal disorders, 280

*Ann Cranney, Alaa Rostom, Catherine Dubé, Rachid Mohamed, Peter Tugwell, George Wells and John WD McDonald*

17 Colorectal cancer in ulcerative colitis: Surveillance, 301

*Paul Collins, Bret A Lashner and Alastair JM Watson*

18 Colorectal cancer: Population screening and surveillance, 311

*Theodore R Levin and Linda Rabeneck*

19 Prevention and treatment of travelers' diarrhea, 324

*Herbert L DuPont*

20 *Clostridium difficile* associated disease: Diagnosis and treatment, 335

*Lynne V McFarland and Christina M Surawicz*

21 Irritable bowel syndrome, 355

*Alexander C Ford, Paul Moayyedi and Nicholas J Talley*

22 Ogilvie's syndrome, 377

*Michael D Saunders*

23 Gallstone disease, 385

*Laura VanderBeek, Calvin HL Law and Véd R Tandan*

24 Acute pancreatitis, 396

*Colin D Johnson and Hassan Elberm*

25 Obesity management: Considerations for the gastroenterologist, 415

*Leah Gramlich, Marilyn Zeman and Arya M Sharma*

## Part II: Liver disease

- 26 Hepatitis C, 437  
*Keyur Patel, Hans L Tillmann and John G McHutchison*
- 27 Hepatitis B: Prognosis and treatment, 448  
*Piero Luigi Almasio, Calogero Cammà, Vito Di Marco and Antonio Craxi*
- 28 Alcoholic liver disease, 465  
*Hélène Castel and Philippe Mathurin*
- 29 Non-alcoholic fatty liver disease, 475  
*Christopher P Day*
- 30 Hemochromatosis, 484  
*Gary P Jeffrey and Paul C Adams*
- 31 Wilson's disease, 493  
*James S Dooley and Aftab Ala*
- 32 Primary biliary cirrhosis, 508  
*Gideon M Hirschfield and E Jenny Heathcote*
- 33 Autoimmune hepatitis, 524  
*Michael MP Manns and Arndt Vogel*
- 34 Primary sclerosing cholangitis, 533  
*Nishchay Chandra, Susan N Cullen and Roger W Chapman*
- 35 Non-histological assessment of liver fibrosis, 554  
*Dominique Thabut and Marika Simon-Rudler*
- 36 Portal hypertensive bleeding, 562  
*Christos Triantos, John Goulis and Andrew K Burroughs*
- 37 Hepatic outflow syndromes and splanchnic venous thrombosis, 603  
*Marco Senzolo, Neeral Shah, David Patch and Stephen Caldwell*
- 38 Ascites, hepatorenal syndrome and spontaneous bacterial peritonitis, 619  
*Pere Ginès, Andrés Cárdenas, Vicente Arroyo and Juan Rodés*
- 39 Hepatic encephalopathy: Treatment, 636  
*Peter Ferenci and Christian Müller*
- 40 Hepatocellular carcinoma, 650  
*Massimo Colombo and Massimo Iavarone*
- 41 Fulminant hepatic failure: Treatment, 661  
*James O'Beirne, Nick Murphy and Julia Wendon*
- 42 Liver transplantation: Prevention and treatment of rejection, 685  
*Maria Pleguezuelo, Giacomo Germani and Andrew K Burroughs*
- 43 Liver transplantation: Prevention and treatment of infection, 724  
*Antoni Rimola and Miquel Navasa*
- 44 Management of HCV infection and liver transplantation, 740  
*Brett E Fortune, Hugo R Rosen and James R Burton, Jr*
- 45 Management of HBV infection and liver transplantation, 748  
*Evangelos Cholongitas and George V Papatheodoridis*
- 46 Liver biopsy, 762  
*Evangelos Cholongitas, Andrew K Burroughs and Amar P Dhillon*
- 47 Drug induced liver disease: Mechanisms and diagnosis, 771  
*Raúl J Andrade and M Isabel Lucena*

Index, 787

The colour plate section can be found facing p. 266.

## Introduction

*John WD McDonald<sup>1</sup>, Andrew K Burroughs<sup>2</sup>, Brian G Feagan<sup>1</sup>  
and M Brian Fennerty<sup>3</sup>*

<sup>1</sup>Robarts Clinical Trials, Robarts Research Unit, University of Western Ontario, London, Ontario, Canada

<sup>2</sup>The Royal Free Sheila Sherlock Liver Centre, Royal Free Hospital, and University College London, London, UK

<sup>3</sup>Oregon Health and Science University, Division of Gastroenterology and Hepatology, Ontario Oregon, USA

Over the past three decades the emergence of evidence-based medicine (EBM) has had a substantial impact on clinical practice. In the first half of the twentieth century, diagnostic tests or treatments, usually based on a strong scientific rationale and experimental work in animals, were routinely introduced into clinical care without good scientific proof of efficacy in people. Some of these interventions, such as gastric freezing for the treatment of ulcers and penicillamine therapy for primary biliary cirrhosis, were ultimately shown to be ineffective and harmful [1, 2]. There is little doubt that the widespread acceptance by physicians of unproved treatments has been detrimental to the well-being of many patients.

Fortunately, the need for a more critical approach to medical practice was recognized. In 1948 the first randomized controlled trial (RCT) in humans was carried out under the direction of the British Medical Research Council [3]. Epidemiologists and statisticians, notably Sir Richard Doll and Sir Bradford Hill, provided scientific leadership to the medical community, which responded with improvements in the quality of clinical research. The use of randomized allocation to control for confounding variables and to minimize bias was recognized as invaluable for conducting valid studies of treatments. The initiation of these landmark experiments defined a new era in clinical research; the RCT soon became the benchmark for the evaluation of medical and surgical interventions. Gastroenterologists played an important part in these early days. In 1955, Professor Sidney Truelove conducted the first randomized trial in the discipline of gastroenterology [4]. He and his colleagues proved that cortisone was more effective than a placebo for the treatment of ulcerative colitis. As noted in Chapter 12, this treatment has stood the test of time. The ascendancy of the RCT was accompanied by a call for greater scientific rigor in the usual practice of clinical medi-

cine. Strong advocates of the application of epidemiological principles to patient care emerged and found a growing body of support among clinicians.

As the number of randomized trials grew to the point of becoming unmanageable, it was recognized that there was a need to provide summaries of the evidence provided by these trials for the use of practitioners, who frequently lack both time and expertise to consult the primary research. Busy clinicians may consult local experts, with the tacit assumption that they will make recommendations based on evidence. Liberati and colleagues provided evidence that this approach led to inappropriate care for many women with breast cancer [5]. Subsequently, convincing evidence became available through the work of Antman *et al.* and of Mulrow that the conventional review article and the traditional textbook chapter are seldom comprehensive, and are frequently biased [6, 7]. More recently, Jefferson reinforced this conclusion on the basis of a survey concerning recommendations for vaccination for cholera, which appeared in editorials and review articles [8]. He pointed out that authors of editorials and reviews frequently resort to the "desk drawer" technique, pulling out evidence with which they are very familiar, but failing to assemble and review all of the evidence in a systematic way.

In the UK, Archie Cochrane, as early as 1979, made a compelling case that there was a need to prepare and maintain summaries of all randomized trials [9]. Cochrane's challenge to the medical community to use scientific methods to identify, evaluate and systematically summarize the world's medical literature pertaining to all health care interventions is now being met. From its inception in 1993, the electronic database prepared by the volunteer members of the Cochrane Collaboration and published as the *Cochrane Library* has grown exponentially [10]. Systematic reviews and especially Cochrane reviews are now widely used by clinicians in the daily practice of medicine, by researchers and by the public. Accordingly, data from systematic reviews published in the *Cochrane Library*

are featured prominently in several chapters in *Evidence-based Gastroenterology and Hepatology*. Unfortunately, coverage in the *Cochrane Library* of topics in gastroenterology and hepatology is still far from complete.

Several other clinical epidemiologists played important roles in the evolution of evidence-based medicine. Beginning in the 1970s, David Sackett encouraged practicing physicians to become familiar with the basic principles of critical appraisal. Criteria developed by Sackett and others for the evaluation of clinical studies assessing therapy, causation, prognosis and other clinical topics were widely published [11, 12]. His text, *Clinical Epidemiology: a Basic Science for Clinical Medicine*, co-authored by colleagues Gordon Guyatt, Brian Haynes and Peter Tugwell, introduced many physicians to the concepts of EBM [13]. In the USA, Alvin Feinstein called attention to the need for increased rigor in the design and interpretation of observational studies and explored the scientific principles of diagnostic testing [14, 15]. Among gastroenterologists, Thomas Chalmers, a strong, early advocate for the RCT [16], was responsible for introducing gastroenterologists and others to the importance of randomized trials in gastroenterology and hepatology and to the concept of systematic reviews and meta-analysis as means of summarizing data from these studies [17, 18].

Despite the opposition of some, the popularity of EBM continues to grow [19]. Although the explanations for this phenomenon are complex, one factor is that many practitioners recognize that ethical patient care should be based on the best possible evidence. For this, and other reasons, the fundamental concept behind EBM – the use of the scientific method in the practice of clinical medicine – has been widely endorsed by medical opinion leaders, patients and governments.

## What is evidence-based gastroenterology and hepatology?

Evidence-based gastroenterology and hepatology is the application of the most valid scientific information to the care of patients with gastrointestinal and hepatic diseases. Physicians who treat patients with digestive diseases must provide their patients with the most appropriate diagnostic tests, the most accurate prognosis and the most effective and safe therapy. To meet this high standard individual clinicians must have access to and be able to evaluate scientific evidence. Although many practitioners argue that this has always been the standard of care in clinical medicine, a great deal of evidence exists to the contrary. Wide variations in practice patterns among physicians have been documented for many treatments, despite the presence of good data from widely publicized RCTs and the promotion of practice guidelines by content experts. For example,

Scholefield *et al.* carried out a survey of British surgeons who were questioned regarding the performance of screening colonoscopy for colon cancer [20]. Although this study was done in 1998 (after publication of the results of the RCTs described in Chapter 18 which demonstrated a benefit of this practice), many of these physicians failed to make appropriate recommendations for screening patients at risk. What is the explanation for this finding? One possibility is that many clinicians rely for information on their colleagues, on local experts, or on review articles or textbook chapters that are not based on the principles of EBM.

Two important points about EBM should be emphasized. First, use of the principles of EBM in the management of patients is complementary to traditional clinical skills and will never supersede the recognized virtues of careful observation, sound judgment and compassion for the patient. It is noteworthy that many good doctors have intuitively used the basic principles of EBM; hence the promotion of such well-known clinical aphorisms as “go where the money is” and “do the last test first”. Knowledge of EBM enables physicians to understand why these basic rules of clinical medicine are valid through the use of a quantitative approach to decision making. This paradigm can in no way be considered detrimental to the doctor-patient relationship.

Second, although RCTs are the most valuable source of data for evaluating health care interventions, other kinds of evidence must frequently be used. In some instances, most obviously in studies of causation, it is neither possible nor ethical to conduct RCTs. Here, data from methodologically rigorous observational studies are extremely valuable. A dramatic example was the demonstration by several authors (quoted in Chapter 27) that the relative risk of hepatocellular carcinoma in chronic carriers of the hepatitis B virus is dramatically higher than in persons who are not infected. Although these data are observational, the strength of the association is such that it is exceedingly unlikely that a cause other than hepatitis B virus is responsible for the development of cancer in these people. Case-control studies are especially useful for studying rare diseases and for the initial development of scientific hypotheses regarding causation. The etiological role of non-steroidal anti-inflammatory drugs in the development of gastric ulcer was recognized using this methodology [21]. Finally, case series can provide compelling evidence for the adoption of a new therapy in the absence of data from RCTs, if the natural history of the disease is both well characterized and severe. An example is the identification of orthotopic liver transplantation as a dramatically effective intervention for patients with advanced liver disease.

Box 1.1 shows a generally agreed approach to ranking the strength of evidence that arises from various types of studies of health care interventions, and this system is used throughout the book. This ranking of evidence has

**Box 1.1** Grading of recommendations and levels of evidence used in *Evidence-based Gastroenterology and Hepatology*

**Grade A**

Level 1a

- Evidence from large randomized clinical trials (RCTs) or systematic reviews (including meta-analyses) of multiple randomized trials which collectively have at least as much data as one single well-defined trial.

Level 1b

- Evidence from at least one “All or none” high quality cohort study; in which *all* patients died/failed with conventional therapy and some survived/succeeded with the new therapy (e.g. chemotherapy for tuberculosis, meningitis, or defibrillation for ventricular fibrillation); or in which many died/failed with conventional therapy and *none* died/failed with the new therapy (e.g. penicillin for pneumococcal infections).

Level 1c

- Evidence from at least one moderate sized RCT or a meta-analysis of small trials which collectively only has a moderate number of patients.

Level 1d

- Evidence from at least one RCT.

**Grade B**

Level 2

- Evidence from at least one high quality study of non-randomized cohorts who did and did not receive the new therapy.

Level 3

- Evidence from at least one high quality case control study.

Level 4

- Evidence from at least one high quality case series.

**Grade C**

Level 5

- Opinions from experts without reference or access to any of the foregoing (for example, argument from physiology, bench research or first principles)

appeared in a number of publications; we have chosen to reproduce it from *Evidence-based Cardiology*, along with the system used by its editors, Yusuf *et al.*, for making recommendations on the basis of these levels of evidence [22]. As mentioned in Box 1.1, throughout this book recommendation grades appear as **A** or **A1a**.

## Clinical decision making in gastroenterology and hepatology

Clinical decision making by gastroenterologists usually falls into one of the following categories:

- Deciding whether to apply a specific diagnostic test in arriving at an explanation of a patient's problem, or determining the status of the patient's disease.
- Offering a prognosis to a patient.
- Deciding among a number of interventions available for managing a patient's problem. In this category, the first question is “Does a given intervention do more good than harm?” The second is “Does it do more good than other effective interventions?” The third is “Is it more or less cost-effective than other interventions?”

A comprehensive approach would incorporate many different types of evidence (e.g. RCTs, non-RCTs, epidemiologic studies and experimental data), and examine the architecture of the information for consistency, coherence and clarity. Occasionally, the evidence does not completely fit into neat compartments. For example, there is strong (A1a) evidence through very large randomized trials that fecal occult blood testing on an annual or semi-annual basis modestly reduces mortality from colon cancer in a population at average risk for this disease. The evidence that direct examination of the colon at intervals of five to ten years results in even greater benefit has been derived only from case control studies (B3). Physicians, patients and policy advisers should have both levels of evidence available to make informed decisions.

Recommendation grades appear either within the text, for example **A** and **A1a** or within a table in the chapter.

The grading system clearly is only applicable to preventative or therapeutic interventions. It is not applicable to many other types of data such as descriptive, genetic or pathophysiological.

## Application of a diagnostic test

*Example: A four-year-old child is experiencing diarrhea and has a positive family history of celiac disease. Should a serological test for antiendomysial antibody (EMA) be done?*

Chapter 10 includes an extensive treatment of this topic with a summary of studies (see Table 10.1) that included various groups of patients with a greater or lesser probability of having celiac disease (ranging from patients with gastrointestinal symptoms to patients in whom celiac disease was suspected on clinical grounds). Several studies listed in Table 10.1 and the study of Cataldo *et al.* [23] are relevant to this patient.

When evaluating this test the reader may wish to adopt the approach of Kitching *et al.* for deciding on the clinical usefulness of a diagnostic test (Figure 1.1) [24].

The criteria listed in Figure 1.1 for validity of a diagnostic test were clearly met in Cataldo's study. In Chapter 10 Gregor and Say explore the utility of the test and point out that tests with high positive likelihood ratios (LR > 10) and

- **Are the study results valid?**

- 1 Was there an independent blind comparison (or unbiased comparison) with a reference (“gold”) standard of diagnosis?
- 2 Was the diagnostic test evaluated in an appropriate spectrum of patients (like those seen in the reader’s practice)?
- 3 Was the reference standard applied regardless of the diagnostic test result?

- **What are the results?**

Cataldo F, Ventura A, Lazzari R *et al.* Antiendomysium antibodies and celiac disease: solved and unsolved questions. An Italian multicentre study. *Acta Paediatr* 1995;**84**:1125–31.

A study of IgA endomysium antibodies (EMA) in 1485 children with gastrointestinal disease (688 with celiac disease confirmed by intestinal biopsy)

Results for antiendomysial antibody (EMA) test			
	No. of patients with biopsy proven celiac disease		
	Present	Absent	Totals
EMA positive	645	20	665
	a	b	a+b
EMA negative	c	d	c+d
	43	777	810
	a+c	b+d	a+b+c+d
Totals	688	797	1485

Sensitivity =  $a/(a + c) = 645/688 = 0.94$

Specificity =  $d/(b + d) = 777/797 = 0.97$

Likelihood ratio (positive result) =  $\text{sensitivity}/(1 - \text{specificity}) = 0.94/(1 - 0.97) = 31$

Likelihood ratio (negative result) =  $(1 - \text{sensitivity})/\text{specificity} = (1 - 0.94)/0.97 = 0.06$

Positive predictive value =  $a/(a + b) = 645/665 = 0.97$

Negative predictive value =  $d/(c + d) = 777/810 = 0.96$

**Figure 1.1** Approaches to evaluating evidence about diagnosis.

low negative likelihood ratios ( $LR < 0.1$ ) are generally considered to be clinically useful. The EMA test clearly falls into this category. The authors draw attention to the fact that the probability that a specific patient actually has celiac disease (based on a positive test), or does not have it (based on a negative test), also depends on the pretest odds of the patient having the disease (see Table 1.1).

If the child in question, whose pretest likelihood of celiac disease is estimated to be 8%, has a negative test it may be concluded that the child almost certainly does not have celiac disease; on the other hand, if the child has a positive test, the likelihood of him or her having celiac disease is still only 65%.

As Gregor and Alidina point out, the implications of misdiagnosis must be considered carefully. In the circumstance of a positive test in the child with non-specific symptoms the physician and the child’s parents should consider whether it is now reasonable to proceed to intestinal biopsy to confirm the diagnosis, rather than recommending a gluten-free diet, presumably for life. If a search for other clinical or laboratory clues reveals that celiac disease is very likely to be the correct diagnosis, the pretest likelihood may

**Table 1.1** The anti-endomysial antibody (EMA) test for celiac disease. Dependence of post-test likelihood of celiac disease on pretest likelihood, assuming positive  $LR = 31$ , negative  $LR = 0.06$ .

Pretest likelihood of celiac disease	Post-test likelihood with a positive EMA test (%)	Post-test likelihood with a negative EMA test (%)
8% (non-specific symptoms, positive family history)	65	0.5
50% (more specific symptoms)	97	6
0.25% (population screen)	8	0.02
Data from Chapter 10.		

be as high as 50%. This would raise the post-test likelihood to 97%. The physician and parents may be comfortable accepting the diagnosis and proceed to a trial of a gluten-free diet, rather than subjecting a young child to intestinal biopsy. This is an excellent example of how a skilled clinician must integrate the principles of evidence-based medicine with traditional clinical skills and judgment.

## Offering a prognosis

*Example: A 50-year-old woman with recently diagnosed celiac disease, has learned at a meeting of the local celiac society that patients with celiac disease have a substantial increase in the risk of developing a number of cancers and that this cancer risk is reduced by strict adherence to a gluten-free diet.*

Chapter 10 describes the types of study which are relevant to determination of prognosis and discusses the strengths and weaknesses of case-control and cohort studies.

Gregor and Alidina point out that certain case-control studies which reported very high mortality and malignancy rates may have been subject to selection bias (inclusion of particularly ill or refractory patients) and measurement bias (patients with abdominal symptoms being more likely to undergo investigations such as small bowel biopsy which may lead to a diagnosis of celiac disease). They refer to a British study in which a cohort of patients with celiac disease was assembled and followed for ten years. This design attempts to minimize the biases that are inherent in the case-control studies. Table 1.2 shows that the risk of certain cancers is increased compared to the risk in the general population. Table 1.3 shows that strict adherence to a gluten-free diet significantly reduced this risk and may have eliminated the excess risk for several of the identified cancers.

**Table 1.2** Cancer mortality in 210 patients with celiac disease at the end of 1985.

On the basis of this evidence it is reasonable to advise the patient that her disease does carry with it an increased risk of certain relatively uncommon cancers and that adherence to a strict gluten-free diet appears to minimize this increased risk.

## Recommendations concerning therapy

We have provided examples of how evidence concerning the use of diagnostic tests and prognosis can be analyzed and incorporated into clinical practice. Most chapters in this book deal more extensively with evidence concerning therapy and rely heavily on data from randomized trials and meta-analyses.

*Example: Should a 28-year-old woman who has had an uncomplicated resection of the terminal ileum for Crohn's disease receive maintenance therapy with an S-aminosalicylate (ASA) product? Prior to the surgery she had had steroid-dependent disease and had failed treatment with both azathioprine and methotrexate.*

A search of the literature for placebo-controlled randomized trials of 5-ASA for maintenance of remission in patients with a surgically induced remission of disease would reveal several trials. The largest published trial is that of McLeod and colleagues, who randomized 163 adult patients to receive either 3 g/day of 5-ASA or a placebo following surgery [26]. The primary outcome of interest was the recurrence of active Crohn's disease as defined by the recurrence of symptoms and the documentation of active disease either radiologically or endoscopically. At

<sup>c</sup>p < 0.001.

- **Are the results valid?**

- 1 Was the assignment of patients to treatment really randomized (and the randomization code concealed)?
- 2 Were all patients who entered the study accounted for at its conclusion?
- 3 Were the clinical outcomes measured blindly?

- **Is the therapeutic effect important?**

- 1 Were both statistical and clinical significance considered?
- 2 Were all clinically important outcomes reported?

- **What are the results?**

McLeod RS, Wolff BG, Steinhart AH *et al.* Prophylactic mesalamine treatment decreases postoperative recurrence of Crohn's disease. *Gastroenterology* 1995;109:404–13.

Randomized controlled trial in which 163 patients with Crohn's disease who had all visible disease resected were randomized to receive mesalamine (Pentasa) 3 g daily or a placebo for a median period of 34 months. Primary outcome was recurrent Crohn's disease defined by recurrence of symptoms and radiographic or endoscopic documentation of recurrence.

	Recurrent Crohn's disease		Risk (%)	ARR (%)	RRR (%)
	Yes	No			
5-ASA	27	60	31	10	24
Placebo	31	45	41	–	–

ARR, absolute risk reduction; RRR, relative risk reduction.

- **Are the results relevant to my patient?**

- 1 Were the study patients recognizably similar to my own?
- 2 Is the therapeutic maneuver feasible in my practice?

**Figure 1.2** Elements of a valid and useful randomized trial.

the end of the follow-up period (maximum duration 72 months, median duration 34 months), 31% of patients who received active treatment remained in remission compared with 41% of those who received a placebo ( $p = 0.031$ ); 5-ASA was well tolerated. A low proportion of patients developed adverse reactions in the control and active treatment groups. One patient treated with 5-ASA developed pancreatitis that was attributed to the study drug. The results of this study can be evaluated using the guidelines described in Figure 1.2, which is modeled after the approach of Kitching *et al.* [24].

### Are the results of this study valid?

A review of the methods section of the article confirms that an appropriate method of randomization was employed (computer-generated in permuted blocks), which insured concealment of the randomization code [26]. Furthermore, inspection of the baseline characteristics of the treatment and control groups shows that they are well balanced with respect to such confounding variables as the time from

surgery to randomization. This information further supports the legitimacy of the randomization process. Assessment of the method of randomization is important, because non-randomized designs are especially vulnerable to the effects of bias. Studies which employ “quasi-randomization” schemes such as allocation to treatment according to the day of the week or alphabetically by the patient's surname have been shown to consistently overestimate the treatment effect identified by RCTs that employ a valid randomization scheme [27, 28]. However, it may be noted that 87 patients were randomized to 5-ASA, compared with only 76 patients in the control group. This observation raises the concern that the analysis might not have been done according to the “intent to treat” principle which specifies that patients are analyzed in the group to which they were originally assigned, irrespective of the treatment that was ultimately received. The use of this strategy reduces the possibility of bias, which might occur if investigators selectively withdrew from the analysis patients who had done poorly or experienced toxicity. For this reason, the intent to treat principle yields a conservative estimate of the true benefit of the treatment. However,

detailed review shows that in this study the discrepancy in patient numbers occurred because five patients who were randomized to the active treatment group withdrew consent prior to receiving the study medication and were not included. Thus, it appears that the analysis was based on the intent to treat principle.

Approximately 10% of patients in both treatment groups had incomplete follow-up. Methodologically rigorous studies have a very low proportion of patients for whom data are missing. This issue is important, since patients who are lost to follow-up usually have a different prognosis from those for whom complete information is available. If there is incomplete follow-up data for a substantial proportion of patients then the results are uninterpretable [29].

Turning to an assessment of the outcomes in this study, both the patients and investigators were unaware of the treatment allocation. Blinding is used to reduce bias in the interpretation of outcomes. This is especially important when a subjective outcome is evaluated [30]. In this study, objective demonstration of recurrent disease (endoscopy and/or radiology) was required in addition to the more subjective measure of the introduction of treatment for recurrent symptoms. Thus, the reader can be satisfied that the primary outcome measure was both clinically meaningful and objectively assessed.

Finally, the data analysis and results should be examined. A great deal of useful information can be obtained by reviewing the assumptions that were used in the sample size calculation. In this study, which analyzes a difference in proportions, the investigators had to define four variables: the alpha (type 1) error rate, the beta (type 2) error rate, the expected proportion of patients who would be expected to relapse in the placebo group, and the minimum difference in the rate of relapse which the investigator wished to detect. In this publication these parameters are easily identified. The rate of symptomatic recurrence was estimated to be 12.5% per year and it was anticipated that treatment with 5-ASA would reduce this rate by 50% to an absolute value of 6.25% per year. In contrast to the expected 50% relative risk reduction which was anticipated, the three-year actuarial risk of recurrence was 26% in the treatment group compared to 45% in the group that received 5-ASA ( $p = 0.039$ ). Therefore, the relative risk reduction  $((45-26\%)/45\% = 42\%)$  is slightly lower than the figure which the investigators considered to be clinically meaningful. Furthermore, the probability of a type 1 error is described as a one-tailed value of  $p = 0.05$ . This implies that one-tailed statistical testing was used to derive the  $p$  value of 0.039. The use of one-sided statistical testing raises legitimate concerns regarding the statistical inferences made in the study [31]. It is inappropriate to hypothesize that 5-ASA therapy could only be beneficial, given that the drug can cause diarrhea and colitis [32]. For these reasons, uncer-

tainty exists regarding both the clinical and statistical interpretation of these data.

---

### **Are the results of this valid study important?**

To assess the importance of this result it is necessary to quantify the magnitude of the treatment effect. How the evidence is presented may influence both physicians and patients in making choices. The most basic means of expressing the magnitude of a treatment of fact is the absolute risk reduction (ARR), which is defined as the proportion of patients in the experimental group with a treatment success minus the proportion of patients with this outcome in the control group. In this instance the annual rate of relapse in the placebo-treated patients was 15% (success rate of 85%) compared with 8.7% (success rate of 91.3%) in those who received the active treatment. This yields an ARR of 6.3%. The number needed to treat (NNT), the number of patients with Crohn's disease who would have to be treated with 3 g/day of 5-ASA to maintain remission over a year, can be calculated as the reciprocal of this number, and is 16. Alternative ways of describing effectiveness include calculating the observed relative risk reduction ( $RRR = 63/15$ ) of 42%, or even stating that about 90% of patients respond to maintenance therapy, ignoring the substantial placebo effect which is evident. The evidence presented as the ARR or NNT, rather than the numbers which show the treatment in a more favorable light, may still lead the physician to recommend this form of treatment and cause the patient to choose to accept this strategy over no intervention. However, the expectations of the physician and patients are likely to be more realistic than they may be if the physician accepts and promotes in an uncritical way the information that 90% of patients who receive 5-ASA maintenance therapy will remain in remission over one year [33].

---

### **Are these results applicable to my patient?**

Following an assessment of the validity of the evidence using the criteria described in the preceding paragraphs, it is necessary to decide whether the conclusions of the study are relevant and important to the individual patient. An initial step is to evaluate the demographic characteristics of the patients in the RCT and compare them to those of the patient in question. If the patient for whom maintenance therapy is being considered is similar to the patients who were evaluated in the trial, it is reasonable to assume that she will experience the same benefit of therapy and is at no greater risk for the development of adverse drug

**Figure 1.3** Interventions for prevention of post-operative recurrence of Crohn's disease.  
Source: Doherty G, Bennett G, Patil S, Cheifetz A, Moss AC. Interventions for prevention of post-operative recurrence of Crohn's disease. In: *Cochrane Database of Systematic Reviews* 2009, Issue 4. Art. No.: CD006873. DOI: 10.1002/14651858.CD006873.pub2.

reactions. Alternatively, this patient may have characteristics that make it unlikely that a benefit from 5-ASA will be realized. For example, if the patient had residual active Crohn's disease it would be difficult to generalize the results of the study of McLeod *et al.*, since the patients in this trial had resection of all visible disease prior to study entry [26].

At this point, if we accept that the results are generalizable to our patient example, the relative risks and benefits of the therapy must be weighed and the patient's preferences should be considered. Evaluation of the data reveals that the trial was methodologically rigorous and evaluated an important outcome. However, it is doubtful whether conventional statistical significance was demonstrated. This raises the question of whether the observed differences between the treatment groups might have occurred by chance. Furthermore, the magnitude of the treatment effect is relatively small. In presenting to the patient the benefit of an annual reduction in the risk of recurrence of 6.3% it is also necessary to consider the cost and inconvenience of taking medication for an asymptomatic condition. One observation in favor of recommending the treatment is that the risk of serious toxicity with 5-ASA appears to be low.

Because there is a degree of uncertainty concerning the true benefit of 5-ASA maintenance therapy based on analysis of this single RCT, it would be prudent to review additional published data. A meta-analysis of 5-ASA therapy has been published [34]. Meta-analysis, the process of combining the results of multiple RCTs using quantitative methods, is an important tool for the practitioner of EBM. Pooling the results of multiple RCTs increases statistical power and thus may resolve the contradictory results of individual studies. Combining data from RCTs statistically also increases the precision of the estimate of a treatment effect. Moreover, the greater statistical power afforded by meta-analysis may allow insight into the benefits of treatment for specific subgroups of patients. These properties

are particularly relevant to the case under consideration, given the previously identified concerns.

The meta-analysis summarized data from 15 RCTs which evaluated the efficacy of 5-ASA maintenance therapy in 1371 patients with quiescent Crohn's disease. Patients were randomly assigned to receive either 5-ASA or placebo for treatment periods of 4–48 months. Although 5-ASA was superior to placebo in 13 of the 15 studies, the results of only two trials were statistically significant. Separate analyses were done using data from the four trials that included patients with a surgically induced remission (see Figure 1.3) in distinction to those that evaluated patients after a medically induced remission. Sensitivity analyses assessed the response to therapy in specific subgroups of patients. The overall analysis concluded that 5-ASA has a statistically significant benefit; the risk of symptomatic relapse in patients who received 5-ASA was reduced by 6.3% (95% confidence interval –10.4% to –2.1%, 2 p = 0.0028), which corresponds to an NNT of 16. Importantly, the greatest benefit was observed in the four trials that evaluated patients following a surgical resection. In these studies there was a 13.1% reduction in the risk of a relapse (95% CI: –21.8 – –4.5%, 2 p = 0.0028), which corresponds to an NNT of 8. No statistically significant effect was demonstrable in the analysis, which was restricted to the patients with medically induced remission.

**Are the results of this meta-analysis valid and reliable?**

Figure 1.4 provides some useful guidelines for the interpretation of overview analyses. It is important that a comprehensive search strategy be adopted since publication bias, the selective publication of studies with positive results, is an important threat to the validity of meta-analysis [35]. This criterion was met. Camma and colleagues' review of the literature was extensive and not limited to English lan-

- Are the results of this overview valid and reliable?
  - 1 Is it an overview of randomized trials of treatments?
  - 2 Does it include a methods section that describes:
    - (a) finding and including all the relevant trials?
    - (b) assessing their individual validity?
    - (c) using valid statistical methods that compare “like with like” stratified by study?
  - 3 Were the results consistent from study to study?
  - 4 Are the conclusions based on sufficiently large amounts of data to exclude a spurious difference (type 1 error) or missing a real difference (type II error).
- Are these applicable to your patient?
 Differences between subgroups should only be believed if you can say “yes” to all of the following:
  - 1 Was it hypothesized before the study began (rather than the product of dredging the data), and has it been confirmed in other, independent studies?
  - 2 Was it one of just a few subgroups analyses carried out in this study?
  - 3 Is the difference both clinically (beneficial for some but useless or harmful for others) and statistically significant?
  - 4 Does it really make biologic and clinical sense?

**Figure 1.4** Approaches to evaluating evidence concerning overviews.

Reproduced from Yusuf S *et al.*, eds. *Evidence-based Cardiology*. BMJ Books, London, 1998 [22].

guage publications. The investigators also searched review articles, primary studies and abstracts by hand. Quality scores were used to evaluate the validity of the individual studies and a sensitivity analysis was done which assessed the effect of trial quality on the result. No important change in the overall result was noted when studies of lower quality were excluded from consideration. However this type of analysis was not carried out in the analysis of the subgroups of four trials (411 patients) which evaluated 5-ASA after a surgically induced remission.

One of the included studies, that of Caprilli *et al.*, which involved 95 patients, showed a greater benefit for 5-ASA than any other trial, medical or surgical, which has been performed [36]. An important methodological deficiency of this RCT was the failure to conceal the treatment allocation from the investigators. Since these physicians were aware of the treatment assignment, and the definition of relapse used required clinical interpretation, it is possible that the 27% reduction in the risk of relapse identified is an overestimation of the true treatment effect. Accordingly, the inclusion of the results of this study in the subgroup analysis of the surgical studies may overestimate the true benefit of 5-ASA. Furthermore, Camma *et al.* did not include an additional trial by Lochs *et al.*, which was only available as a preliminary report at the time the meta-analysis was done [37]. This study, which is the largest RCT to evaluate 5-ASA following surgery, assigned 318 patients to receive either 4 g of active drug or a placebo for 18 months. Although Camma and colleagues described this study as “confirming” a benefit of 5-ASA after surgery, the results are not impressive. Only a 6.9% reduction in the rate of relapse was observed in patients who received the active treatment (24.5% 5-ASA com-

pared with 31.4% placebo). This difference was *not* statistically significant.

This example underscores the importance of updating systematic reviews as new information becomes available, which is the approach of the Cochrane Collaboration, but not of reviews in conventional publications. When the data provided by Lochs *et al.* were aggregated with those of the other trials, the overall estimate of benefit for 5-ASA was less (ARR 4%, NNT 25) [38]. On the basis of these data it can be concluded that 5-ASA may be an effective maintenance therapy following surgery, but the magnitude of the treatment effect is modest at best.

Chapter 11 includes a meta-analysis performed as part of a Cochrane review that also supports this conclusion (see Figure 1.3).

---

### Are these results applicable to our patient example?

The meta-analysis of surgical trials by Camma *et al.* provides important information to the clinician who must decide whether or not to offer patients 5-ASA for maintenance therapy. The concern regarding statistical significance raised by the critique of the McLeod study has been reduced. It seems likely that the beneficial effect of 5-ASA following surgery is real. However, although the majority of the criteria outlined in Figure 1.4 have been met, the issue of clinical relevance remains. The most optimistic estimate of the size of the treatment effect, derived from the meta-analysis, is an NNT of 8. However, given the possibility of bias in the study of Caprilli *et al.*, a more conservative estimate could be based on the data of Lochs and

colleagues from the single large randomized trial which yielded an NNT of 15, or from the revision by Sutherland of Camma's meta-analysis that yielded an ARR of only 4%, and an NNT of 25.

In presenting this information to the patient the following points should be emphasized.

- The existing data suggest that 5-ASA is not effective, or at the most, very marginally effective.
- The annual risk of relapse following surgery is relatively low without treatment.
- 5-ASA therapy is safe.
- The cost of 5-ASA therapy is approximately US\$70 per month.
- To derive a benefit from the treatment the medication must be taken on a regular basis. This requires the patient to take six pills each day.

Patients undoubtedly will react in different ways to this information. Our patient chose not to accept this therapy.

## Rationale for a book on evidence-based gastroenterology and hepatology

Gastroenterologists, hepatologists and general surgeons are fortunate to have many excellent textbooks that provide a wealth of information regarding digestive diseases. Such traditional textbooks concentrate on the pathophysiology of disease and are comprehensive in their scope. *Evidence-based Gastroenterology and Hepatology* is not intended to replace these texts, since its focus is on clinical evidence.

Excellent electronic databases are available, and many traditional publications contain relevant research evidence and important summaries and reviews to support evidence-based practice. However, Cumbers and Donald have found that physicians in clinical practice find the acquisition of data from these sources time consuming [39]. Their study revealed that even locating relevant articles required on average three days for practitioners with an on-site library and a week for those without such a facility. This book has been written for the purpose of saving valuable time for busy practitioners of gastroenterology and hepatology, and for general internists and general surgeons who deal with substantial numbers of patients with disorders ranging from gastroesophageal reflux disease to liver transplantation.

It has been extensively revised since the second edition was published in 2004, in order to provide more recent evidence that serves as the basis for recommendations. For example, we present data from Cochrane reviews that summarize the strong evidence that anti-TNF agents are effective for both induction and maintenance of remission of Crohn's disease, along with a careful consideration of the adverse effect profile of these agents.

The book cannot claim to be comprehensive. However, the third edition has been expanded significantly, with new chapters on eosinophilic esophagitis, travelers' diarrhea, antibiotic-associated diarrhea, non-invasive markers for the diagnosis of fibrosis, drug-induced liver injury, liver biopsy, and hepatic outflow syndromes and splanchnic thrombosis. In addition, all chapters have been extensively revised and updated to reflect current evidence. A limitation of any textbook is the timeliness of the information that it is possible to provide in print form. New evidence accumulates rapidly in clinical medicine and it is impossible to include the most up-to-date information in a textbook because of the time required for production. To meet the needs of our readers for the most timely information the editors have endeavored to include, where possible, new evidence that became available during the editorial process. It is also planned to produce electronic updates of chapters at regular intervals. These updates will appear on the Evidence-Based Medicine Series website: <http://www.evidencebasedseries.com/Summary of updated evidence in the Third Edition>.

These summaries highlight the most significant changes to *Evidence-based Gastroenterology and Hepatology* since the second edition, particularly regarding treatment recommendations in specific conditions. The full discussion of the evidence can be found in the relevant chapters.

## Part I: Gastrointestinal disorders

### Gastroesophageal reflux disease (Chapter 2)

Data support the use of empiric antisecretory therapy for patients presenting with symptoms thought to be caused by GERD, without performing confirmatory diagnostic testing. PPI are significantly better than H<sub>2</sub>-RA for healing esophagitis and relieving symptoms. There are insufficient data to support routinely using PPI doses higher than standard doses for healing esophagitis, treating symptomatic GERD or atypical symptoms of GERD, although higher doses may be effective for preventing relapse that occurs at standard doses. The most cost-effective strategies are PPI-based "step-down" or PPI "on-demand" approaches. Laparoscopic fundoplication is an effective alternative to medical therapy, particularly for patients whose symptoms responded to medication.

### Barrett's esophagus (Chapter 3)

Aggressive anti-reflux therapy with either high-dose PPI or surgery has not been shown to revert Barrett's esophagus to normal squamous mucosa or reduce the risk of developing cancer. Although endoscopic ablative therapy is a reasonable option in the Barrett's patient with high grade dysplasia or superficial adenocarcinoma, these therapies are not recommended for the Barrett's patient without neoplasia, since continued surveillance will still be required,

complications are frequent and the risk/benefit ratio is not established. Estimates of the cost effectiveness of surveillance of Barrett's esophagus vary widely, and it is not possible currently to make a recommendation for population screening for Barrett's either in the general population or in those with chronic GERD.

#### **Esophageal motility disorders (Chapter 4)**

The costs and cost effectiveness of Botulinum toxin injections and pneumatic dilation for achalasia are lower than the cost of Heller myotomy. In the longer term, pneumatic dilatation appears to be more cost-effective than Botulinum toxin injection therapy.

#### **Eosinophilic esophagitis (Chapter 5)**

Conventional oral corticosteroids and swallowed inhaled fluticasone both appear to be effective for this condition. However, the adverse effects of oral steroids are more frequent and severe, and inhaled (swallowed) steroids should be used as initial treatment for uncomplicated EE.

#### **Ulcer disease and *Helicobacter pylori* infection (Chapter 6)**

Half of ulcer bleeding may be attributable to NSAIDs, and patients who are also positive for *H. pylori* have a synergistically high risk of re-bleeding. *H. pylori* eradication significantly reduces ulcer re-bleeding rates. Clarithromycin resistance accounts for most treatment failures. When a clarithromycin-based eradication regimen has failed, it is not worthwhile to administer it again. More effective options include PPI/amoxicillin/metronidazole or PPI with amoxicillin and levofloxacin for ten days, as well as more conventional bismuth-based quadruple regimens.

#### **NSAID induced gastroduodenal toxicity (Chapter 7)**

*H. pylori* contributes to an excess ulcer-risk in NSAID naive patients, whereas ulcers occurring in long-term NSAID users are probably largely caused by the NSAIDs, irrespective of *H. pylori* status. It is appropriate to eradicate *H. pylori* in NSAID naive patients prior to starting chronic ASA or NSAID therapy. However, *H. pylori* eradication alone appears to be insufficient for ulcer prophylaxis in chronic non-ASA NSAID users. Misoprostol prophylaxis and substitution of COX-2 inhibitors appear to reduce the risk of developing endoscopically diagnosed gastric ulcers by 80% and the risk of complicated ulcers by 50%.

#### **Functional dyspepsia (Chapter 9)**

Patients undergoing endoscopy for dyspeptic symptoms tend to be more satisfied and have improved quality of life and subsequently create significantly lower health care costs than patients initially treated empirically. The practical bottom line for use of PPIs in functional dyspepsia is that it is reasonable to give patients a trial of 4–8 weeks of

therapy, with the understanding that heartburn is a predictor of response and that the majority of patients will not respond (NNT = 15). *H. pylori* infection is present in 30–70% of patients, and eradication may lead to long-term symptom improvement in a small proportion of these patients. There is no convincing evidence for the use of prokinetic or antidepressant medications.

#### **Celiac disease (Chapter 10)**

Although the human recombinant anti-tissue transglutaminase antibody test (tTG) has a sensitivity of 96% and a specificity of 99% for diagnosis of celiac disease in some studies, the sensitivity in other studies is considerably lower. The tTG will likely remain as an adjunct to endoscopy for the diagnosis of celiac disease, rather than a replacement. A substantial amount of evidence demonstrates a lack of toxicity of oats in newly diagnosed patients with celiac disease, and in celiac disease patients in remission.

#### **Crohn's disease (Chapter 11)**

Infliximab, adalimumab and certolizumab have all been shown to be effective for induction and maintenance of remission. There is emerging evidence that early combined immunosuppression with infliximab combined with azathioprine and, if necessary, steroids is superior to conventional management with corticosteroids, followed in sequence by azathioprine and infliximab in terms of steroid-free remission and avoidance of surgery at 26 and 52 weeks. Serious adverse events are not significantly more frequent in the early combined immunosuppression group. The combination of infliximab and methotrexate, although safe, has not been shown to be more effective than infliximab alone in Crohn's disease patients who are also receiving treatment with prednisone.

Although an earlier small randomized placebo-controlled trial suggested that omega-3 fatty acids are effective for maintenance of remission in patients at a relatively high risk of relapse of Crohn's disease, two large randomized trials that included 762 patients have now shown that this approach is not effective.

Natalizumab (300 mg or 3 to 4 mg/kg) is effective for induction of clinical response and remission in patients with moderately to severely active Crohn's disease. One patient with Crohn's disease treated with natalizumab in combination with azathioprine developed progressive multifocal leukoencephalopathy (PML). A retrospective investigation suggests that the incidence of PML is approximately 1 case per 1000 patients.

#### **Ulcerative colitis (Chapter 12)**

Probiotic preparations of a specific lyophilized *E. coli* strain, or mixtures of several bacteria, when added to conventional therapy, may increase rates of induction and enhance maintenance of remission in mild ulcerative colitis. An

apheretic technique that removes granulocytes from the blood of patients is ineffective. Infliximab is effective for induction of remission in severe refractory disease.

**Pouchitis (Chapter 13)**

Small controlled trials have demonstrated the efficacy of ciprofloxacin and metronidazole for acute pouchitis, of budesonide enemas for active chronic pouchitis, and of probiotic bacteria for maintaining remission of chronic pouchitis and for prophylaxis.

**Microscopic colitis (Chapter 14)**

Budesonide is effective for short-term treatment, but the optimal strategy for long-term management needs further study. The long-term prognosis is good, and the risk of complications including colonic cancer is low.

**Drug-induced diarrhea: (Chapter 15)**

Faced with an aging patient population and an ever increasing population of diabetic patients physicians should be aware that cholinesterase inhibitors, increasingly used in Alzheimer's disease, produce diarrhea in 14% of patients and metformin produces malabsorptive diarrhea in up to 50% of patients.

**Metabolic bone disease in gastrointestinal disorders (Chapter 16)**

Bisphosphonate therapy reduces the risk of vertebral fractures in IBD patients by 6.3%. The improvement in BMD in IBD patients taking infliximab + a bisphosphonate may be greater than that observed with a bisphosphonate alone.

Chronic PPI users may not have an increase in the risk of hip fracture with PPI use if they have no other identifiable risk factor. If there is a true association (as opposed to an association with confounding variables) between PPI use and decreased bone density, the fracture risk in chronic PPI users is low. The increased risk may be clinically relevant in patients with multiple other risk factors for osteoporosis, especially in patients with long-term, high-dose therapy.

**Colorectal cancer in ulcerative colitis: surveillance (Chapter 17)**

Chromoendoscopy with targeted biopsies may increase the yield of surveillance colonoscopy. Estimates of sensitivity and specificity are made from an increased number of large surveillance programs.

**Colon cancer screening (Chapter 18)**

The sensitivity of fecal occult blood testing, when three stools are tested using a sensitive immunochemical technique, approaches 90%. The miss rate for significant lesions at colonoscopy may be as high as 5%. There is consistent evidence that colonoscopy is less effective for reduction in right-sided CRC than it is for left-sided CRC. Colonoscopy

may be more cost effective than CT colonography, depending on relative procedural costs.

**Prevention and treatment of traveler's diarrhea (Chapter 19)**

This new chapter summarizes the evidence for a number of interventions for chemoprophylaxis (with Rifaximin being the recommended agent). Early evidence for the efficacy of immunoprophylaxis is also presented.

***Clostridium difficile* disease (Chapter 20)**

Preventive strategies, including enhanced infection control programs and antibiotic stewardship, are effective in reducing the incidence of CDAD. Complicated cases of CDAD have increased in frequency in some outbreaks, and it is postulated that the emergent hypervirulent BI/NAP10/27 strain is responsible. Evidence still favors metronidazole for treatment of initial episodes, but vancomycin appears to be the more effective treatment for severe disease. Observational studies suggest that tapered and pulsed vancomycin regimens may be effective for recurrent disease.

**Irritable bowel syndrome (Chapter 21)**

Colonic investigation has a very low yield in patients presenting with symptoms that are highly suggestive of IBS in the absence of alarm features. Screening to exclude celiac disease and thyroid dysfunction appears to be of value, but a panel of blood tests, including ESR and CRP, often performed when patients with suspected IBS are first seen in the outpatient clinic, has a low yield in detecting organic disease. Data to support the role of lactose hydrogen breath testing to exclude lactose intolerance are conflicting. Soluble fibre, antispasmodics (particularly hyoscine) and peppermint oil may be of some benefit in treatment of IBS patients, although the evidence is less than convincing. Both TCADs and SSRIs are effective (NNT = 4). Probiotics may also be used as second-line interventions in individuals with particularly troublesome abdominal pain and bloating. Psychological interventions should be reserved for individuals who are unresponsive to, or intolerant of, more conventional therapies, since they are time-consuming and expensive.

**Ogilvie's syndrome (Chapter 22)**

Evidence is presented that polyethylene glycol may reduce the frequency of recurrent cecal dilatation in patients who had initial resolution with neostigmine or decompression. Polyethylene glycol may also prevent the development of acute pseudoobstruction in patients with multiple organ failure admitted to an ICU.

**Gallstone disease (Chapter 23)**

The natural history of asymptomatic cholelithiasis in diabetic patients appears to be similar to that in the general population, and preventative surgery should not be recom-

mended routinely. Laparoscopic cholecystectomy appears to be as safe as open cholecystectomy and may provide short-term improvement in quality of life. Acute cholecystitis should be treated with early laparoscopic cholecystectomy. In patients with gallstone pancreatitis preoperative ERCP may increase overall morbidity compared with the approach of cholecystectomy with intraoperative cholangiography. Patients with acute severe gallstone pancreatitis should undergo cholecystectomy following resolution of the acute episode, but during the initial hospital stay. Patients with mild to moderate pancreatitis can be considered for early laparoscopic cholecystectomy. Three approaches to the management of common duct stones (open common bile duct exploration, ERCP and sphincterotomy, and laparoscopic common bile duct exploration) have been compared, and conflicting data may relate to variation in operator expertise. The approach to CBD stones should be individualized and based on the type of expertise available at each institution.

### **Acute pancreatitis (Chapter 24)**

Several recent, well-planned RCTs provided no evidence for benefit from the early use of prophylactic antibiotics in severe pancreatitis, and it is no longer recommended.

### **Obesity (Chapter 25)**

The risk for co-morbidities, including cardiovascular disease, type 2 diabetes, obstructive sleep apnea and certain cancers, is reduced up to 40% by bariatric surgery.

## **Part II: Liver disease**

### **Hepatitis C (Chapter 26)**

There are concise guidelines for treatment of naive patients, based on genotype and viral load. Re-treatment is reviewed in detail as much more evidence is available from randomized studies. In the main, relapsers are worth re-treating, but genotype 1 non-responders may not yield cost-effective benefit.

### **Hepatitis B (Chapter 27)**

New therapies and new evaluation of interferon have revolutionized the management of these patients. The importance of monitoring for viral resistance, and using the correct combination, or sequential use, of agents is outlined.

### **Alcoholic related liver disease (Chapter 28)**

In alcoholic hepatitis there has been a consolidation of the evidence for the use of steroids and evidence for “stopping rules”, and validation of indices of non-response. Trials of agents to help abstinence are reviewed.

### **Non-alcoholic fatty liver disease (Chapter 29)**

This disease spectrum is far better characterized, including the association with the other factors which make up the

metabolic syndrome. Whilst diagnostic methodology has improved, specific therapeutic agents are not available. What has been tried so far is summarized, with an outline of future prospects.

### **Hemochromatosis (Chapter 30)**

Genetic hemochromatosis is underdiagnosed in the general population, and overdiagnosed in patients with secondary iron overload. A mild elevation in ferritin is very common, and may be related to obesity with NAFLD, regular alcohol consumption, or inflammation.

The hepatic iron index reported on histological examination has limited use with the advent of genetic testing. The C282Y homozygote is the classic genetic pattern in >90% of typical cases. With other genetic variants severe iron overload is usually seen in the setting of a concomitant risk factor (alcoholism, viral hepatitis, NAFLD). Several studies have documented reversal of fibrosis following iron depletion therapy.

### **Wilson's disease (Chapter 31)**

Despite isolation of several genes, the diagnosis remains a clinical one in patients presenting with abnormal liver function. Trientine and zinc therapy have further documentation of their efficacy.

### **Primary biliary cirrhosis (Chapter 32)**

Updated information on the use of ursodeoxycholic acid (UDCA), particularly in early PBC, still leave this drug as the one most frequently used for this disease, but with gaps in robust evidence for its efficacy.

### **Autoimmune hepatitis (Chapter 33)**

Classical autoimmune hepatitis is well recognized, but “difficult to treat” cases not responding to standard immunosuppression, and the occurrence of overlap syndromes make some cases difficult to diagnose and to treat. Good outcomes have now been obtained with budenoside, tacrolimus and mycophenolate. New diagnostic algorithms have helped distinguish true overlap syndromes from disease variants.

### **Primary sclerosing cholangitis (Chapter 34)**

It is important to exclude IgG4 associated sclerosing cholangitis in the differential diagnosis. Use of UDCA is under scrutiny, and the use of high dose UDCA is reviewed.

### **Non-histological assessment of fibrosis (Chapter 35)**

This is a new chapter, which has evaluated both serum markers and transient elastography and the comparison with liver biopsy for the assessment of fibrosis.

### **Portal hypertensive bleeding (Chapter 36)**

Evolution of combined therapies using endoscopic and pharmacological ones, has replaced single mode approaches.

The use of primary prophylaxis with non-selective beta-blockers has been extended to grade Child C patients with cirrhosis even if varices are small. Antibiotics are now mandatory in the treatment of acute variceal bleeding as they improve control of bleeding, and mortality over and above specific endoscopic and pharmacological methods.

### **Hepatic outflow syndromes and splanchnic thrombosis (Chapter 37)**

This is a new chapter, updating current management of hepatic outflow obstruction with a defined algorithm and use of anticoagulation for portal venous thrombosis.

### **Ascites, hepatorenal syndrome and spontaneous bacterial peritonitis (Chapter 38)**

This is an updated review of therapy, particularly for hepatorenal syndrome, for which terlipressin and albumin improve renal function in about 30% of patients. Selection for antibiotic prophylaxis in a primary setting has expanded beyond patients with low concentrations of albumin in ascites.

### **Hepatic encephalopathy: treatment (Chapter 39)**

The diagnosis and management of minimal hepatic encephalopathy are integral to this chapter, as this is an evolving area, which does affect quality of life, ability to drive safely and so on.

### **Hepatocellular carcinoma (Chapter 40)**

Combined clinical and imaging characteristics have allowed a much better clinical staging system, which guides therapy. Indications and use of loco-regional therapy, liver resection and transplantation, as well as new agents such as sorafenib have evolved, and a rationale basis for therapy is presented.

### **Fulminant hepatic failure (Chapter 41)**

Supportive management has greatly improved over the past few years. Current best practice is reviewed by new authors, and referral and indications for liver transplantation are fully discussed. The current status of liver support devices is evaluated on the basis of the few controlled trials and observational studies.

### **Liver transplantation: prevention and treatment of rejection (Chapter 42)**

New data from randomized trials has been incorporated against a background of the method of diagnosis of rejection and long-term complications and outcomes, where these have been documented.

### **Liver transplantation: prevention and treatment of infection (Chapter 43)**

New authors have completely revised this chapter, dealing with the major cause of morbidity and mortality within one

year of transplantation. Hepatologists who may not be in transplant centers, but who follow up patients who have had liver transplant, need to be aware of infectious complications, their diagnosis and treatment.

### **Management of HCV infection and liver transplantation (Chapter 44)**

This is a major clinical problem, for which only recently there has been data from randomized studies and careful prospective observational studies to give some evidence-based guidance for therapy.

### **Management of HBV infection and liver transplantation (Chapter 45)**

The new therapies for HBV infection have revolutionized the outcome for HBV infected patients who come to liver transplantation. Treatment algorithms are now simplified and the importance for monitoring for viral resistance fully outlined.

### **Liver biopsy (Chapter 46)**

This is a new chapter reviewing the evidence base for diagnosis of liver disease, and staging/grading for chronic viral hepatitis. A full review of transjugular liver biopsy is given.

### **Drug induced liver injury (DILI) (Chapter 47)**

This is a new chapter, including etiopathogenetic mechanisms and practical algorithms to reach a diagnosis for this problem, which is being seen more frequently.

## Gastroesophageal reflux disease

Naoki Chiba<sup>1</sup> and M Brian Fennerty<sup>2</sup>

<sup>1</sup>Division of Gastroenterology, McMaster University Medical Centre, Hamilton and Guelph General Hospital, Guelph, Canada

<sup>2</sup>Oregon Health and Science University, Division of Gastroenterology and Hepatology, Oregon, USA

### Introduction

Heartburn and or regurgitation are very common symptoms encountered in patients seen in a clinical practice. Most patients with gastroesophageal reflux disease (GERD) will have these symptoms of heartburn and/or regurgitation, but many patients with these symptoms do not have GERD. Clinical studies prior to the mid-1990s focused on management of patients with predominant heartburn based on the endoscopic findings of esophagitis, as healing of the esophageal mucosa was an easily measured objective endpoint compared to subjectively assessing a patient's symptom response to a therapy. More recently it has become known that GERD symptom severity does not predict the presence or absence of endoscopic mucosal damage (e.g. esophagitis), and patients with GERD including those with and without esophagitis, experience decrements in quality of life (QoL) associated with their symptoms. In treating GERD patients with esophagitis and those with non-erosive reflux disease (NERD), as well as those patients with symptomatic heartburn that have not undergone endoscopy, proton pump inhibitors (PPIs) offer better healing and symptom relief than less potent acid inhibitors (e.g. histamine-2 receptor antagonists or H<sub>2</sub>-blockers) or acid neutralizing agents (e.g. antacids). The available PPIs are, for the most part, equally effective as treatment for GERD symptoms and healing esophagitis, although esomeprazole more effectively heals the small minority of GERD patients with more severe grades of esophagitis (Los Angeles Grades C and D). For patients with documented erosive esophagitis and in those with NERD and/or uninvestigated heartburn that relapses quickly upon discontinuing treatment, maintenance

therapy with a PPI may be appropriate. For patients with documented NERD, lower doses of PPI therapy are often adequate, and treatment can also be given on demand or prn. The PPIs are very safe and offer excellent long-term control of symptoms, although recent evidence suggests that long-term use may be associated with some adverse outcomes. Anti-reflux surgery is also an effective option for treating GERD symptoms and healing esophagitis, especially since a laparoscopic alternative has now become well established and is widely available. The choice for surgery should be based on patient preference rather than issues of efficacy or cost, as there is ample evidence that neither therapeutic approach is substantially more cost-effective than the other.

### Definition of gastroesophageal reflux disease

Gastroesophageal reflux (GER) is a normal physiological process that most commonly occurs during and after meals in an upright position. However, due to acid neutralization by saliva and prompt esophageal clearance of physiologic refluxate, symptoms associated with physiologic GER occur in only a minority of people. Conversely, GERD occurs when reflux is frequent or caustic enough to cause the typical symptoms of heartburn, acid regurgitation and or dysphagia or result in esophageal mucosal injury. GERD also may result in extraesophageal manifestations such as non-cardiac chest pain, asthma, cough or posterior laryngitis and hoarseness [1]. Moreover, patients will often present not only with reflux symptoms but also with epigastric pain and/or discomfort, symptoms associated with "dyspepsia" rather than GERD [1–3]. It is difficult to determine at what point GER transforms a normal physiological state into a disease state, GERD. Many patients and providers regard some degree of heartburn as normal. Moreover only a small proportion of patients with GERD actually seek medical care, as noted in Castell's "GERD iceberg" [4].

Early literature often incorrectly used the terms hiatus hernia and gastroesophageal reflux synonymously, imply-

ing that the hernia was the cause of the symptoms of GERD or the root cause of GERD itself. Hiatus hernia is a common structural abnormality, whereas reflux is most often caused by functional or mechanical events. Once the hiatus hernia was dismissed as the root cause of GERD, reflux disease was considered to be present when abnormally prolonged esophageal acid exposure resulted in esophageal damage, either macroscopic (endoscopic esophagitis and/or Barrett's esophagus) or microscopic (histological esophagitis). However, more recently, it has been recognized that symptomatic gastroesophageal reflux without obvious macroscopic or microscopic esophageal injury, otherwise known as "endoscopy negative reflux disease" (ENRD) or "non-erosive reflux disease" (NERD), is an important and large part of the spectrum of reflux disease [5]. Another term, symptomatic GERD, has been used to refer to these patients previously classified as having NERD. However, this term is also imprecise and should be applied only to patients with uninvestigated reflux-like symptoms that adversely impact their normal quality of life (QoL).

It is now generally accepted that GERD is really a spectrum of diseases. Attention has been focused on the typical symptoms of heartburn and acid regurgitation that are often not accompanied by any easily identified pathological findings. Even without endoscopic esophagitis, these patients have reduced health-related QoL comparable with that experienced by patients with esophagitis [6–89]. Awareness of this fact has led some experts to erroneously equate a patient with the predominant symptom of heartburn with a confident diagnosis of GERD [10, 11]. Patients with heartburn alone have only a little better than chance probability of having GERD as defined by an abnormal ambulatory esophageal acid exposure [12]. Most patients with endoscopic esophagitis will complain of heartburn [13], and even if heartburn is not the predominant symptom, endoscopic esophagitis can be identified in up to 36% of patients with suspected GERD [14]. Thus, it is clear that the symptom of heartburn in and of itself is an insufficient criterion to diagnose GERD.

Many authors continue to mix symptoms and mucosal damage in the same definition of GERD. The American College of Gastroenterology definition of GERD is, "chronic symptoms or mucosal damage produced by the abnormal reflux of gastric contents into the esophagus" [15]. Experts from the Genval Workshop further expanded this definition to include the patient-centered perspective that gastroesophageal reflux is defined by the presence of "clinically significant impairment of health-related well-being (quality of life) due to reflux-related symptoms" [11]. These are similar to the 2004 Canadian GERD Consensus Conference definition: "GERD applies to individuals with reflux of gastric contents into the esophagus causing (a) symptoms sufficient to reduce quality of life and/or (b) esophageal injury" [9]. The subsequent 2006 Montreal definition:

"GERD is a condition which develops when the reflux of stomach contents causes troublesome symptoms and/or complications" was similar [1].

In summary, these data indicate that an encompassing, objective and validated definition of GERD is lacking and instead we are relying on imperfect measures to define this disease. Furthermore, the varied phenotypic expression of the disease(s) indicates that a single reproducible measure is unlikely to be an effective tool for the definition of GERD.

## Symptoms of gastroesophageal reflux disease

The typical symptoms of GERD include heartburn (usually defined as a rising retrosternal burning discomfort) and acid regurgitation [1, 9]. Many investigators suggest that the diagnosis of GERD should be based primarily on the presence of these typical symptoms, as the specificity of heartburn and acid regurgitation for GERD is approximately 89% and 95% respectively [27]. Indeed, up to 96% of patients with documented erosive esophagitis also have heartburn [13]. An early study reported that when heartburn or regurgitation occurred daily, there was a positive predictive value of 59% and 66% respectively, for the diagnosis of GERD [28]. When an abnormal pH-metry is used as the gold standard, these symptoms have demonstrated 72% sensitivity and 63% specificity for GERD [29]. Many patients also have other upper abdominal symptoms as noted previously, but according to recent concepts, these patients are probably more correctly classified as having dyspepsia rather than GERD [30].

In summary, the only validated symptom measure for GERD at this time is the word description for heartburn (e.g. a burning discomfort arising behind the breastbone towards the neck).

## Epidemiology of gastroesophageal reflux disease

Considering the lack of consistency of symptom based definitions and methods of diagnosis of GERD, it is difficult to determine the absolute prevalence of GERD in the general population. For instance, are we measuring the prevalence of the symptoms of heartburn or acid regurgitation, and to what degree, or are we measuring the prevalence of endoscopic esophagitis? The prevalence of GERD also varies between surveys of the general population and studies of symptomatic patients that present to the family practitioner. Heartburn is experienced by 4–7% of the general US population on a daily basis and by 34–44% of the population at least once a month (Table 2.1) [5, 20, 31–33]. Similarly high rates have been observed in New Zealand [34]. Recent data suggest that Asian patients have a lower prevalence of GERD symptoms than Western pop-

ulations [21, 35], as well as a much lower prevalence of esophagitis [36].

In contrast, the overall prevalence of reflux esophagitis in Western countries has been estimated to be about 2% [33]. However, this figure likely underestimates the true prevalence. In a group of 27% of adults self-treating with antacids more than twice a month, objective evidence of reflux esophagitis is revealed in 84% during investigation, suggesting that esophagitis is not uncommonly found in those with symptoms of heartburn [37]. Furthermore, some have estimated that the prevalence of GERD is as high as 20% of the adult population and that esophagitis is found in 35–50% of those with GERD. If these data are correct the prevalence of esophagitis in the adult population may be as high as 7–10%. A recent systematic review by El-Serag has shown an overall increase in the prevalence of GERD over the past two decades, particularly for North America and Europe, but not Asia [38].

The incidence of GERD is estimated to be 4.5 per 100,000 with a dramatic increase in persons over the age of 40 years [39]. A Canadian study found that heartburn occurred at least once a week in 19% of persons > 60 years old, compared with 4.8% of persons < 27 years old [17]. A large American retrospective cohort study in VA patients also identified older age along with being a white male as the group associated with the most severe forms of GERD [40].

Nebel *et al.* in 1976 [16] studied the point prevalence and precipitating factors associated with symptomatic gastroesophageal reflux using a questionnaire in 446 hospitalized and 558 outpatients (see Table 2.1). Age, sex or hospitalization did not significantly affect prevalence. In a Finnish study of 1700 adults, only 16% of symptomatic patients reported taking medications and only 5% had sought medical care [19].

In clinical practice, the relevant population is the group of patients that present with symptomatic heartburn. In this population, it has been estimated that about 50–70% of patients have normal endoscopies and the minority of patients (30–50%) have endoscopic esophagitis [41]. However, in a recently reported Canadian study of prompt endoscopy in patients with uninvestigated dyspepsia, the overall prevalence of endoscopic esophagitis was 43%, and in those with dominant heartburn, the prevalence of esophagitis was 55% [14]. Thus in this population, NERD was seen in less than half of the patients (45%).

In summary, the true population prevalence of GERD and esophagitis is unknown but appears to be approximately 10–15% and 3–7% based on current data.

### Pathophysiology of gastroesophageal reflux disease

GERD is primarily a motility and/or anatomical disorder of the esophagus, perturbations of which allow an abnormal amount or frequency of injurious gastric contents to reflux into the esophagus. Reflux occurs as a consequence of a defect of the normal anatomic and physiological anti-reflux barrier that is provided primarily by actions of the lower esophageal sphincter (LES) and crural diaphragm. The two key abnormalities are thought to be abnormal transient lower esophageal sphincter relaxations (TLESRs) [42, 43], precipitated by gastric distension in the postprandial period [44] and poor basal LES tone [42]. The result of these and other less common anatomic and physiological abnormalities is an increased intraesophageal exposure of gastric refluxate and increasing damage as the pH of refluxate falls below 4, which is optimal for pepsin activation [45,

46]. A hiatus hernia may act as a reservoir for acid refluxate that can then re-reflux up the esophagus [47, 48]. GERD patients with hiatus hernia have been found to have greater esophageal acid exposure and more reflux episodes vs GERD patients without a hernia [49].

### Pathophysiology in non-erosive reflux disease

Further support for the concept that acid alone can be the pathophysiological basis for reflux disease comes from the observation that in patients that have typical symptoms of reflux with a normal endoscopy, 6–15% with symptomatic reflux had normal 24-hour esophageal pH-metry [50–52]. Additionally, pathological reflux on pH studies has been identified in 21–61% of endoscopy negative patients [53–55]. A recent study identified abnormal acid reflux in 84% of patients with either erosive esophagitis or NERD, a much higher proportion than previously reported. The reason for these variable results is unknown. In contrast, 71–91% of patients with erosive esophagitis at endoscopy have pathological reflux on pH studies. Thus, abnormal intraesophageal acid exposure as measured by pH studies is more frequent but not an optimal gold standard for documenting reflux disease [53–55]. However, despite these limitations the data clearly demonstrate that the proportion of intraesophageal acid exposure increases over the spectrum from NERD to worsening grades of esophagitis and Barrett's esophagus [56].

Another conundrum in reflux disease is the patient with an apparent suprasensitive esophagus. Of 96 patients with normal 24-hour esophageal acid exposure, 12.5% were found to have a statistically significant association between their reflux symptoms and actual reflux episodes, despite having “normal” intraesophageal acid exposure [51]. In these patients, the duration of reflux episodes was shorter and the pH of reflux episodes was often lower than in patients with typical GERD, suggesting that esophageal hypersensitivity was the cause of their symptoms. These and other data have led to the concept of an acid-sensitive esophagus.

An esophageal balloon distension study provided further experimental evidence of esophageal hypersensitivity in patients with normal acid exposure times with a value for a symptom index (SI) > 50% [50]. In general, these patients had significantly lower thresholds for initial perception and discomfort from esophageal balloon distension, compared with both normal controls and patients with confirmed reflux. In contrast, Fass *et al.* studied patients with GERD and controls without GERD and determined that patients showed enhanced perception of acid perfusion but not of esophageal distension [57]. They concluded that chronic acid reflux by itself was not the cause of esophageal hypersensitivity to distension in patients with non-cardiac chest pain, although subsequent data from this group

suggest that the esophagus can be primed to be hypersensitive by repeated reflux events.

Carlsson *et al.* [58] have also demonstrated an impaired esophageal mucosal barrier in symptomatic GERD patients by measuring the transmucosal epithelial potential difference, suggesting a role for alteration in cell barrier function as a cause for reflux symptoms in some individuals.

Another study examined differences in spatiotemporal reflux characteristics between symptomatic and asymptomatic reflux episodes [59]. They used a pH sensor positioned 3, 6, 9, 12 and 15 cm above the LES and found that the duration of acid exposure was longer and the proximal extent was higher in symptomatic than in asymptomatic reflux episodes. A similar study also determined that patients with NERD compared with healthy controls, had a higher, intraesophageal proximal reflux of acid [60]. Even NERD patients with normal acid exposure time seemed to perceive proximal reflux very readily, implying that their proximal esophageal mucosa is more sensitive to short duration refluxes than that of patients with esophagitis.

More recently, there is a suggestion that up to two-thirds of patients with NERD have histological evidence of esophageal injury [61]. The commonest finding is dilation of intercellular spaces irrespective of esophageal acid exposure. Basal cell hyperplasia and papillary elongation were seen more frequently in NERD patients with abnormal acid exposure. However, these findings are not found consistently enough to reliably serve as the basis for the diagnosis of GERD.

### Hiatus hernia

The mere presence of a hiatus hernia (HH) bears no relationship to the diagnosis of esophagitis and is frequently seen in those without esophagitis. Moreover, up to half the healthy population has a hiatus hernia [62] and only half of the patients with symptoms of heartburn and regurgitation have a hiatus hernia [63]. However, some studies have suggested that patients with a hiatus hernia have greater esophageal acid exposure and more reflux episodes [49] and more severe reflux esophagitis than patients without, suggesting that a HH does have a role in some patients with reflux disease [64, 65]. A large HH may act as a reservoir for acid that re-refluxes more readily when a swallow is initiated and in this fashion contributes to GERD [47, 48].

Other supporting evidence for the role of HH in GERD comes from a study in patients with pathologic reflux (pH < 4 for more than 5% of a 24-hour intraesophageal pH-metry study) that identified hiatus hernia in 71% of patients with mild esophagitis, compared with 39% of those without esophagitis [66]. Patients with a hiatus hernia also had higher 24-hour intraesophageal acid exposure

compared with those without, particularly during the night. However, there were no differences in symptoms of heartburn or regurgitation, whether or not patients had a hiatus hernia or esophagitis.

Another study demonstrated that the presence of hiatus hernia correlated with more severe manifestations of GERD [67]. Hiatus hernia was seen in 29% of symptomatic patients, 71% with erosive esophagitis, and 96% with long segment Barrett's esophagus.

Although transient lower esophageal sphincter relaxations (TLESRs) are thought to be a key mechanism for pathological reflux, van Herwaarden *et al.* [49] did not find differences in LES pressure, and the incidence of TLESRs, and the proportion of TLESRs associated with acid reflux were comparable in those with and without hiatus hernia. They felt that the excess reflux in GERD patients with hiatus hernia was caused by malfunction of the gastroesophageal barrier during low LES pressure, swallow-associated normal LES relaxations, deep inspiration and straining.

In summary, the pathophysiology of GERD is varied, and the most common mechanism appears to be TLESRs but mechanical defects of the gastroesophageal junction and LES also play a role in many patients with this disorder.

### Natural history of gastroesophageal reflux disease

There are few data about this important topic, and existing studies are limited in that they usually include heterogeneous populations. In one such study using a Swedish population-based survey of over a thousand citizens conducted over seven years, the prevalence of GERD remained stable over time at about 17–19% [68]. In a more recent 10-year follow-up Swedish study of 197 respondents out of the original 337 subject cohort, 83% reported no change in their global symptom assessment, indicating relative stability of symptoms over time [69].

A small retrospective study published in 1991 identified patients with symptoms of GERD but with a normal endoscopy and 24-hour pH study [70]. All patients received antacids or prokinetic drugs or both for 3–6 months. Thus, this was not a study of untreated patients but a study that employed treatments now recognized to be relatively ineffective (vs true untreated controls). However, 19 of the 33 patients still had symptoms at the end of six months and of these, five (26%) developed erosive esophagitis. The remainder of the patients remained asymptomatic. There was no difference in baseline pH-metry between those that went on to develop esophagitis and those that did not.

Another study reported data on patients with objectively proven GERD conservatively managed without treatment

over a 17–22-year follow-up [71]. The authors reported on 60 patients from an initial cohort of 87 patients. Ten of these patients ultimately had an anti-reflux procedure, but of the remaining “untreated” 50 patients, 36 (72%) were less symptomatic at follow-up. Of this group, only six became symptom “free”. The majority no longer used anti-reflux medications. Only five patients remained unchanged and nine became worse. The prevalence of erosive esophagitis fell from 40% at referral to 27% at follow-up endoscopy, and six new cases of Barrett's metaplasia developed. At follow-up, 66% of the patients had objective evidence of GERD with esophagitis, a pathological pH study or newly recognized Barrett's metaplasia. Neither the presence of esophagitis or of hiatal hernia, nor the severity of symptoms at baseline predicted the course of the disease at follow-up. The authors concluded that the severity of reflux symptoms declined in the long term, but pathological reflux persisted in the majority of the conservatively managed patients.

For patients with mild esophagitis, the course of the disease may also be relatively benign from an oesophageal injury perspective, with only 23% progressing to more severe esophagitis, while 31% improved and 46% spontaneously healed with no further episodes. However, from an impact on quality of life GERD does not appear to be a benign disease. In one study, patients with endoscopic esophagitis diagnosed more than 10 years earlier were contacted by postal questionnaire and phone interview [71]. Of the respondents, over 70% continued to have significant symptoms of reflux, and 40–50% were still taking acid suppressive medications regularly and had reduced QoL (lower Short Form (SF)-36, physical and social function domain scores). Thus, GERD is a chronic disease with significant morbidity and it impacts negatively on QoL.

Despite frequent symptoms, even severe reflux disease has little effect on life expectancy, with almost no deaths directly due to GERD reported in long-term follow-up [39, 71, 72]. However, a recent population-based study identified GERD as a strong risk factor for esophageal adenocarcinoma, but not squamous cell carcinoma [73].

In summary, the above data indicate that GERD is a chronic but not static disease; progression and regression may occur, although this is not common. Despite impacting QoL adversely, GERD has little effect on life expectancy.

### Esophageal complications of gastroesophageal reflux disease

Complications of GERD include bleeding (< 2%), ulceration (approximately 5%) and strictures (1.2% to 20%) [71, 74, 75]. Patients with strictures are generally older and more frequently have a hiatus hernia [74]. Barrett's esophag-

gus has been identified in 10–20% of GERD patients [76]. Six of 50 patients (12%) developed Barrett's esophagus during approximately 20 years of follow-up, a crude incidence of 0.6% per year [72]. The association of Barrett's esophagus and esophageal adenocarcinoma are covered in Chapter 3.

### Effects of gastroesophageal reflux disease on quality of life (QoL)

Increased attention is being paid to patient QoL assessments, as opposed to histology of the esophagus as an outcome measure of importance in patients with GERD. Indeed, as there is no single physical marker for this disease, most experts now include decrements in QoL as part of the definition of GERD [9]. Several general health status and reflux-specific QoL instruments have been developed, validated and used. Examples include: Medical Outcomes Study SF-36 [77], Psychological General well-being (PGWB) index [78], the Gastrointestinal Symptom Rating Scale (GSRS) [79–81], the Gastroesophageal Reflux Disease – Health Related Quality of Life (GERD-HRQL) instrument [82], ReQuest [83–85], Reflux Disease Questionnaire [86], REFLUX-QUAL (RQS) [87], the Reflux questionnaire [88] and the Quality of Life in Reflux and Dyspepsia questionnaire (QOLRAD) [89]. Because of the development and availability of QoL instruments, more recent GERD clinical studies have used validated GERD-specific instruments focusing more on assessing patient satisfaction and QoL as primary endpoints [89–96]. Despite the development of more specific health-related QoL questionnaires, a 2008 systematic review identified that existing scales were still somewhat suboptimal [97]. Patients with gastrointestinal disorders have decreased functional status and well-being [98]. Those patients with chronic gastrointestinal disorders, including GERD, and congestive heart failure have the poorest health perceptions. These perceptions are worse than those that characterize some other chronic conditions such as hypertension and arthritis [79, 99, 100]. In patients with heartburn there was a substantial impairment of all aspects of health-related QoL when measured using the GSRS, QOLRAD, SF-36 and the Hospital Anxiety and Depression (HAD) scale [98].

Other studies have shown that successful treatment of GERD results in improvement in QoL. In general, patients with reflux esophagitis are considered to have equally impaired QoL to those with non-erosive disease, but those with very severe reflux esophagitis may have even more impairment [101]. NERD patients do not have objective markers such as endoscopic esophagitis that can be used to define treatment success. Symptom reduction to a level that does not cause significant impairment of health-related QoL is therefore an appropriate outcome by which to measure a therapy. Both the PGWB and GSRS scores show

good discriminative ability to reflect the severity of impairments in quality of life in NERD patients [102]. Improvements in health-related QoL with treatment of NERD and of erosive esophagitis have also been documented [7, 103, 104]. There are also now scales such as the Proton pump inhibitor Acid Suppression test (PASS) [105], the Gastroesophageal reflux disease impact scale [106] and the Reflux Disease Questionnaire (RDQ) [107] that have been developed as instruments to help guide patient care.

In summary, these data demonstrate that the impact GERD has on QoL is substantial and equivalent to many other diseases considered to be severe and important.

### Diagnostic tests for gastroesophageal reflux disease

The diagnosis of GERD depends on the definition of “pathological” in diagnostic tests. Problems in defining GERD have been recognized for more than two decades [62]. Methods of diagnosing GERD are outlined in Table 2.2. These tests evaluate different features of GERD, and none of them measures all aspects of the disease. Tests such as barium studies, scintigraphy and ambulatory oesophageal pH studies demonstrate whether reflux is occurring; endoscopy demonstrates mucosal injury and complications of GERD; ambulatory oesophageal pH studies quantify the amount of oesophageal acid exposure, the number and duration of reflux events and allow the correlation of reflux events with recorded symptoms; oesophageal sensitivity to acid is assessed by the Bernstein test. The correct interpretation of these diagnostic tests for GERD is critically important. For example, a patient with documented endoscopic esophagitis with a negative Bernstein test should not be regarded as having a “false negative” Bernstein test, but rather an acid insensitive esophagus as measured by this test. With variable patient populations, and with differences in definitions, techniques and gold standards, it is impossible to compare sensitivity and specificity values between the various diagnostic tests for GERD [108].

### Manometry and lower esophageal pressure measurement

LES pressures alone are not of diagnostic value, as there is considerable variation in the normal LES pressure as well as overlap of pressures in those with and without esophagitis. Furthermore, the most common finding of an LES pressure in patients with GERD is a normal one. In a review of six studies [109], LES pressure < 10 mmHg did correlate with abnormal oesophageal acid exposure but with a sensitivity of only 58% and specificity of 84%. However, there may still be some utility in low LES pressures as a predictor

**Table 2.2** Summary of diagnostic tests in gastroesophageal reflux disease.

GERD: gastroesophageal reflux disease; LES: lower esophageal sphincter; SI: symptom index; NCCP: non-cardiac chest pain; PPI: proton pump inhibitor.

for identifying patients with the most severe reflux or in identifying those at higher risk of complications associated with regurgitation [62]. Manometry prior to surgery has been advocated to document a mechanically defective lower esophageal sphincter [110], but there is no good evidence that this affects outcome. Some experts still advocate for preoperative manometry in GERD patients as it also measures distal esophageal amplitudes, a measure that may affect surgical decision making (type of wrap, whether to perform the surgery, etc.).

## Radiological diagnosis

A variety of outcome measures have been used in studies of the use of radiology procedures in GERD. Some of these tests have assessed gastroesophageal reflux (with and without reflux provoking maneuvers) and correlated this

with other measures of reflux such as esophageal pH studies. Other studies and tests examined the ability of radiological studies to identify esophagitis.

The radiological diagnosis of esophagitis is generally considered to be unreliable, especially in mild reflux esophagitis. The diagnostic accuracy of barium radiography compared with endoscopy has been demonstrated to be 0–53% for mild, 79–93% for moderate and 95–100% for severe esophagitis [28, 111]. Many of the early studies [112] compared radiological techniques to endoscopy as a gold standard. By 1980, it was recognized that about half the patients with symptomatic reflux did not have endoscopic esophagitis [54, 62]. Thus, many, if not most, patients with GERD would be expected to have normal barium studies. Additionally, from a technical perspective, the gastroesophageal junction (the site most involved by oesophageal inflammation, and fibrosis) is not well

visualized in up to a third of patients, due to inadequate distension [112, 113].

Documenting that reflux occurs during a radiological examination does not determine whether patients have GERD, nor does it correlate with patients' symptoms. With provocative tests, reflux is seen in 25–71% of symptomatic patients but also is noted in 20% of controls [114]. Low density contrast medium does not improve the diagnostic accuracy over that observed with the use of regular barium contrast [115]. When taken as a whole, radiological studies are frequently falsely negative in patients in whom endoscopy or esophageal pH-metry studies are abnormal and are not recommended as a diagnostic test for GERD.

Measurement of the internal diameter of the cardiac esophagus was shown to predict 89% of patients with mild endoscopic esophagitis [116]. However, this was not confirmed in a study that found that the gastroesophageal junction could not be adequately visualized in 29% of patients [112].

Free, severe reflux as seen on barium studies may be a highly specific predictor of reflux as defined by esophageal pH monitoring [109, 112, 117, 118]. However, esophagitis is often not diagnosed radiographically in patients with abnormal intraesophageal pH studies [119].

## Scintigraphy

Reflux can also be measured following the ingestion of a liquid containing a radiolabeled pharmaceutical such as sulfur colloid or  $^{99m}\text{Tc}$  in an acidified liquid suspension. This procedure is similar to the assessment of reflux during radiology, although scintigraphy may be superior in this regard [63]. Graded abdominal compression to induce and detect reflux is unreliable, with variable sensitivity of 14–90% [63, 111, 112, 114, 120]. The biggest problem with this method of testing for reflux appears to be the short duration of the imaging test, as reflux occurs intermittently and therefore can often go undetected in any study of short duration that depends on demonstrating abnormal frequency of reflux as part of the diagnostic criteria. With the availability of endoscopy and intraesophageal pH monitoring, this test also appears to have little value in the diagnosis of GERD.

## Upper gastrointestinal endoscopy

Endoscopy provides the most accurate means of assessing mucosal detail of the esophagus, but remains insensitive in diagnosing reflux. Definite endoscopic reflux esophagitis is unequivocal evidence that the patient suffers from GERD. However, patients with an "acid sensitive" esophagus who experience symptoms in the absence of esophagitis (the majority of patients with reflux) cannot be diagnosed by

endoscopy. Recent efforts attempting to increase the sensitivity of endoscopic detection of the mucosal changes of GERD using imaging enhancements such as narrow band imaging (NBI) have not been as promising as hoped. The intraesophageal pH study is abnormal in 50% or more of patients with reflux symptoms and normal endoscopy [54, 121]. Thus, using current endoscopic technology, a negative endoscopy does not exclude GERD. Histological diagnosis of reflux may be more sensitive than endoscopy alone in diagnosing reflux, but the sensitivity of this test is problematic due to inadequate size of the biopsy [122], patchy distribution of the histological findings [123] or minimal changes with variable interpretation [124].

Berstad and Hatlebakk [125] prospectively evaluated patients with GERD using their own unique endoscopic grading system. Those with "true" GERD all had endoscopic findings according to their classification, but the presence of whitish exudate in the lesions and the width of the lesions were the only two endoscopic features that correlated with the severity of esophageal acid exposure as measured by pH-metry [126]. Confirmatory data from other investigators using this endoscopic classification are lacking.

Previously, the most widely applied esophagitis grading system had been the Savary-Miller classification in the original and modified forms. A newer classification [127], which measures metaplasia, ulcer, stricture and erosions (known as the MUSE classification), records the degree of severity of each as absent, mild, moderate and severe. This is now adapted as the Los Angeles (LA) classification and is the one that is now most commonly used [118]. The key features are:

- Grade A: one (or more) mucosal break no longer than 5 mm that does not extend between the tops of two mucosal folds
- Grade B: one (or more) mucosal break more than 5 mm long that does not extend between the tops of two mucosal folds
- Grade C: one (or more) mucosal break that is continuous between the tops of two or more mucosal folds but which involves less than 75% of the circumference
- Grade D: one (or more) mucosal break which involves at least 75% of the esophageal circumference [128]

The LA classification has been tested in a study that evaluated the circumferential extent of esophagitis by the criterion of whether mucosal breaks extended between the tops of mucosal folds and gave acceptable agreement ( $\kappa$  0.4) among observers [128]. Severity of esophageal acid exposure was significantly ( $P < 0.001$ ) related to the LA severity grade of esophagitis. The pretreatment esophagitis grades A–C were related to heartburn severity ( $P < 0.01$ ), outcomes of omeprazole treatment ( $P < 0.01$ ), and the risk for symptom relapse off therapy ( $P < 0.05$ ).

### Bernstein test as a measure of esophageal acid sensitivity

This test was first described in 1958 and used to attempt to distinguish chest pain of esophageal from that of cardiac origin [129]. In an early 1978 prospective, comparative study of upper gastrointestinal endoscopy, upper gastrointestinal barium series, esophageal manometry and the Bernstein test in patients with suspected reflux esophagitis, the Bernstein test had the greatest sensitivity (85%) for diagnosing esophagitis. However, there were many false positives, as half the patients without esophagitis also had a positive Bernstein test. The lack of specificity for esophagitis is not very surprising, since most of these patients are now considered to have an acid sensitive esophagus, consistent with NERD. Another study found the sensitivity of the Bernstein test to be 70% in patients with typical reflux symptoms. However, 97% of patients with a negative test had either endoscopic, histologic or scintigraphy evidence of GERD [130]. In a review of seven studies [131], the overall sensitivity of this test was 77% and specificity 86%. Although the Bernstein test does not establish that there is mucosal damage (esophagitis), and patient acceptance is limited, a positive test result (defined as reproduction of symptoms during acid perfusion and not during saline perfusion) implies that the esophagus is likely to be the origin of the symptoms.

### Ambulatory esophageal pH monitoring

Catheter based esophageal pH recordings have been used for over 30 years. Previous versions of this chapter have critically reviewed and covered the standards and thresholds of esophageal acid exposure. Whether an abnormal intraesophageal pH study is the gold standard for diagnosing GERD remains controversial [54]. This test is useful in quantifying the amount and frequency of acid reflux that occurs. However, it can be difficult to separate physiological from low-level pathological reflux, and the threshold levels that separate “normal” from “abnormal” test results are not clear. A cutoff pH of 4 to define pathological reflux has been validated with catheter based systems [108, 132]. Furthermore, this pH threshold makes physiological sense, as proteolytic activity of pepsin is low at a pH above 4, and high below pH 3 [46]. Unfortunately, even this cutoff may mischaracterize up to 50% of reflux episodes [133]. The technique has many limitations, including lack of availability, invasiveness, cost, lack of patient acceptability, debatable reproducibility, and technical problems such as improper placement of the pH probe, probe failures and recording device failures [134].

The technique is now improved with a wireless pH monitoring method [135]. The main advantage is that a patient

does not have to walk around with a conspicuous and uncomfortable transnasal catheter. Since patients do not restrict their usual daily activities, the results are considered to be a more reflective and accurate identification of the true intraesophageal acid profile. The Bravo system is an example that transmits esophageal pH data every six seconds. With this new technique, thresholds were re-established and an acceptable discriminating threshold was determined to be 5.3% of 24 hours. The capsule is placed endoscopically and clipped into place 6 cm above the squamocolumnar junction. While a foreign body sensation is felt by the patient, the discomfort is minimal. As the capsule is clipped into place, prolonged pH measurements are possible and this factor may increase the sensitivity for the diagnosis of GERD [136, 137]. However, capsule detachment can occur and esophageal perforation has been reported [135].

These tests may be useful for investigating patients with atypical reflux symptoms or non-cardiac chest pain in whom GERD is suspected to be the cause of symptoms.

### Symptom index (SI)

A quantitative method for correlating symptoms and esophageal acid reflux events was developed in 1986 and called the “symptom index”. This index is calculated as the number of times the symptom occurred when the pH is < 4, divided by the total number of symptoms, multiplied by 100. Initial validation studies in 100 patients found the SI to be distributed in a bimodal fashion. Of patients with SI above 75%, 97.5% had an abnormal esophageal pH study [138]. If the SI was less than 25%, the proportion of patients with a normal esophageal pH study was 81%, and 90% of this group had a normal endoscopy [139]. Endoscopy was normal in nearly 30% of patients with a high SI. Thus, if endoscopy is found to be normal in the course of evaluating patients suspected of having GERD, an esophageal pH study combined with a measurement of SI may be a useful diagnostic test. There was very poor correlation between results of the Bernstein test and the SI. The negative predictive value of a low SI is useful. A limitation of the SI is that it does not take into account the reflux episodes that were symptom free. The SI was not found to be useful for diagnosing non-cardiac chest pain [140]. The next method to be developed was the symptom sensitivity index (SSI) that failed to take into account the total number of symptom episodes [141].

The symptom association probability (SAP) is another method that has been developed, with the intent to reduce the shortcomings of the SI [142]. This method correlates pH data during both symptomatic and asymptomatic reflux episodes and requires further validation, although some experts have suggested that this index is superior to the SI [135].

All three methods: SI, SSI and SAP were prospectively compared using symptom response to high dose omeprazole. SSI and SAP had better sensitivities of 74% and 65% compared to 35% with SI, but none predicted the response to PPI particularly well [143]. In summary, these data demonstrate that an objective gold-standard diagnostic test for GERD is lacking. Endoscopy has insufficient sensitivity but high PPV. Esophageal ambulatory pH monitoring has the highest diagnostic test sensitivity for GERD.

## Symptoms as a diagnostic test for GERD

An important study of patients with reflux-like symptoms was reported by Joelsson and Johnsson [144]. Erosive esophagitis (Savary-Miller grade I or worse) was identified in a third of patients with symptoms of GERD. Whether the patient had erosive disease or not, the frequency of heartburn and acid regurgitation correlated with median esophageal acid exposure time, measured by 24-hour pH monitoring. Although patients with an endoscopically normal esophagus had lower overall median acid exposure, there was a trend towards more acid exposure in those with more severe symptoms. Figure 2.1 shows the relationship between severity of symptoms and acid exposure time. The authors concluded that reflux-like dyspepsia is accompanied by increased esophageal acid exposure, a finding that is supported by others [55, 145]. Unfortunately, severity of symptoms is still a poor predictor of mucosal damage [54, 146, 147].

**Figure 2.1** Acid exposure of the distal part of the esophagus during eight three-hour periods expressed as median % time spent with pH < 4 in 190 patients with different degrees of heartburn and acid regurgitation and 50 asymptomatic endoscopically normal subjects. Reproduced with permission from Joelsson B *et al.* *Gut* 1989; **30**: 1523–1525 [144].

Johannessen *et al.* [148] determined that the symptom of heartburn showed the best discrimination for patients with esophagitis. Typical symptoms of GERD, such as heartburn, correlate with abnormal intraesophageal pH exposure in 56–73% of patients [29, 54].

In an effort to improve the diagnostic value of the symptoms of GERD based on the patient's history, investigators have applied structured questionnaires [149–154]. Using the questionnaire developed by Johnsson [149], a positive response to all four questions was required to achieve a high positive predictive value, thus limiting its usefulness. The description of symptoms as opposed to using the term heartburn, may be a factor that improves the predictive value of this questionnaire.

DeMeester reported a retrospective review of 100 consecutive patients with symptoms of GERD [54]. The combination of the presence of grade II or III symptoms on the standardized questionnaire and endoscopic esophagitis, predicted increased acid exposure on 24-hour intraesophageal pH monitoring, with a specificity of 97% and a positive predictive value of 98%.

The Carlsson-Dent questionnaire that is intended to identify responders to PPI therapy has been extensively validated for reflux esophagitis detected at endoscopy and abnormal 24-hour intraesophageal pH-metry [150]. The questionnaire has a maximum score of 18. In the endoscopic comparison, using a threshold score of 4, the questionnaire had 70% sensitivity but only 46% specificity for diagnosis of esophagitis. When used in dyspeptic patients, the questionnaire had a sensitivity of 92% but a specificity of only 19% for diagnosis of GERD when compared with abnormal 24-hour intraesophageal pH monitoring. The mean score of 11 for GERD patients was higher than that observed in the dyspepsia cohort (mean 4.6). Symptom relief during treatment with omeprazole was predicted by the presence of heartburn, described as “a burning feeling rising from the stomach or lower chest up towards the neck” (odds ratio 4) and by “relief from antacids” (odds ratio 2.2). Even in a non-ulcer dyspepsia study from which patients with predominant heartburn were excluded, 42% of the patients indicated that they had a “rising burning feeling”, a description that has been validated to define GERD-related heartburn in the Carlsson-Dent questionnaire. Even in this group of presumed non-GERD patients, those patients who answered positively to this key question had the best symptom relief with omeprazole. One prospective validation of this questionnaire in a primary care population did not find that the questionnaire was better than the physician's provisional diagnosis for discriminating omeprazole responders [155]. The utility of this questionnaire as a clinical practice tool appears to be limited, although it remains an important tool for research purposes because it allows for stratification of patients enrolled in GERD studies.

Similar in its goal to the Carlsson-Dent questionnaire, the 12-item “GERD Screener” demonstrated construct, convergent and predictive validity. This instrument was practical, short and easily administered and was intended to serve as a valuable case-finding instrument in primary care and managed care organizations [154].

Locke *et al.* [156] developed a GERD questionnaire in 1994 [152] and used it in a study in which patients underwent open access endoscopy. The study provided evidence that heartburn frequency was associated with esophagitis, that duration of acid regurgitation was associated with Barrett’s esophagus and that strictures were associated with dysphagia severity and duration. Unfortunately, despite these somewhat encouraging findings, the questionnaire overall was only able to modestly predict endoscopic findings. This questionnaire has also been adapted to the Spanish population with excellent reproducibility and concurrent validity [157].

Subsequent validated GERD questionnaires focused more on creating instruments for assessing QoL rather than for diagnosis of GERD [89–95]. However, a new, reliable and valid questionnaire to better diagnose GERD was developed [153] and the internal consistency, interobserver reliability, criteria validity using 24-hour esophageal pH monitoring, construct validity and extreme group validation were assessed using patients with pathologic GERD. This questionnaire had sensitivity, specificity and positive predictive values of over 90%, while the negative predictive value was 79% [153]. A new Chinese GERD questionnaire was found to discriminate between controls and GERD patients with a sensitivity of 82% and a specificity of 84% [158].

In summary, these data indicate that at the present, symptom based questionnaires have been demonstrated to be useful research tools but they are of insufficient validity or are too complicated to use to be useful in clinical practice.

### Therapeutic trial of acid suppression as a diagnostic test for GERD

All of the diagnostic tests described above are cumbersome or invasive and they detect different aspects of reflux. PPIs are the most effective intervention for all grades of esophagitis and for treatment of symptoms such as heartburn. The therapeutic response to a trial with a PPI was therefore thought possibly to be useful in diagnosing GERD in a variety of patient populations including patients with typical symptoms of GERD (heartburn), patients with GERD-related non-cardiac chest pain, and patients with positive and negative findings for GERD on endoscopy or pH monitoring. The variation of patient populations studied makes direct comparisons between studies impossible.

In a double-blind, placebo-controlled study of patients with reflux symptoms (92% had heartburn) and only minor or no esophagitis at endoscopy, patients were randomized to receive omeprazole 40 mg once daily or a placebo for 14 days [159]. A 75% reduction in heartburn was considered to be a positive diagnostic test. There was a significant ( $P = 0.04$ ) correlation between response to the PPI and the results of the pH-metry. A response to PPI occurred in 68% of patients with abnormal reflux and in only 37% of patients with a normal pH study. Only 13% of patients responded to placebo.

A randomized trial of omeprazole 20 mg twice daily or placebo for one week tested the efficacy of omeprazole to diagnose reflux disease among dyspeptic patients [160]. A diagnosis of GERD was made on the basis of either grade II–III esophagitis or esophageal reflux with  $\text{pH} < 4$  for more than 4% of the esophageal pH monitoring time. Using this definition, 135 of 160 (84%) patients were found to have GERD. Of those patients with presumed NERD, 63% had an abnormal pH study. Twenty percent (18/92) of patients with esophagitis had normal pH studies. Using symptom improvement of at least one grade for the definition of a positive test, the “omeprazole test” had a sensitivity of 71–81% for diagnosing GERD, compared with the sensitivity of placebo of 36–47%. With a more stringent definition for a positive test of total symptom relief, the sensitivity of omeprazole to diagnose reflux was lower at 48–59%, compared with 6–19% for placebo. However, the specificity of the test was also low, and actually was higher with placebo than with omeprazole. Thus, the test in this study was more useful for ruling out the diagnosis than for ruling it in. Even patients who did not have GERD by definition had better symptom relief with omeprazole than with placebo. These may be patients with an acid sensitive esophagus who respond well to acid suppression despite their esophageal pH being within normal limits.

A recent UK study of 90 patients with dyspeptic symptoms suggestive of GERD evaluated the cost-effectiveness of an open course of treatment with omeprazole 40 mg daily for 14 days as a diagnostic test [161]. The cost per correct diagnosis was £47 for omeprazole (95% CI: £40 to £59) compared with £480 for endoscopy (95% CI: £396 to £608). The authors concluded that an empirical trial of omeprazole was cost-effective both for symptom relief and for diagnosing GERD in patients with typical symptoms.

In a small, four-week, randomized placebo-controlled crossover study [162] in patients with normal endoscopy and esophageal pH-metry, but with an SI of  $> 50$ , 10 of 12 (83%) of patients with a positive SI showed improvement on omeprazole 20 mg twice daily for decreased symptom frequency, severity and consumption of antacids ( $P < 0.01$ ). The SF-36, QoL parameters for bodily pain and vitality also significantly improved. In the group with a negative SI only one patient clearly improved.

Thirty-three consecutive patients with symptoms of reflux, abnormal pH studies, but normal endoscopies were sequentially allocated to receive ranitidine 150mg twice daily, omeprazole 40mg once daily, or omeprazole 40mg twice daily for 7–10 days [163]. On the last day of treatment an esophageal pH study was repeated, and the results were correlated with symptoms. Using a 75% reduction in symptoms as a positive test, and the pH test as the gold standard, the sensitivity of the omeprazole test using a dose of 40mg twice daily was 83.3%, while the sensitivity with omeprazole 40mg once daily was only 27.2%. The authors concluded that the diagnosis of GERD could be ruled out if a patient failed to respond to a short course of high dose PPI.

Fass *et al.* [164] also used an omeprazole 60mg daily test versus placebo in GERD positive (35/42, 83%) and GERD negative patients (17%). Twenty-eight GERD-positive and three GERD-negative patients responded to the omeprazole test, providing sensitivity of 80.0% and specificity of 57.1%. Economic analysis revealed that the omeprazole test saved US\$348 per average patient evaluated, with 64% reduction in the number of upper endoscopies and a 53% reduction in the use of pH testing.

Most studies have used omeprazole in the “PPI test”. However, a study using 60mg of lansoprazole once daily versus placebo for five days found that 85% tested positive during active treatment compared with 9% with placebo [165]. The PPI test sensitivity was 85% and specificity was 73%.

Esomeprazole is more potent than omeprazole and it also has been evaluated as a diagnostic tool [166]. Patients ( $n = 440$ ) were randomized to receive esomeprazole 40mg once daily, esomeprazole 20mg twice daily or a placebo for 14 days. Endoscopy and 24-hour esophageal pH-monitoring were carried out to determine the presence of gastroesophageal reflux disease (GERD). The esomeprazole treatment test had sensitivity in confirming the diagnosis of GERD of between 79% and 86% (for the two doses of PPI) after five days, while the corresponding value for placebo was 36%.

In a small, eight-week, placebo-controlled study of 36 patients with non-cardiac chest pain and abnormal esophageal 24-hour pH-metry, overall pain improvement was reported by 81% of omeprazole and 6% of placebo-treated patients [167]. Similar results were reported in another small study of 39 patients [168]. The omeprazole test correctly classified 78% of patients considered to be GERD patients by 24-hour esophageal monitoring and/or endoscopy and was positive in only 14% of patients considered not to have GERD by these criteria. Thus, a therapeutic trial may be useful in conditions other than typical GERD such as non-cardiac chest pain, an observation that is further supported by more recent studies [169, 170].

A meta-analysis of studies that used a trial of acid suppression for diagnosing GERD systematically and quantifiably evaluated all published studies prior to 2004 and concluded that “successful short-term treatment with a PPI in patients suspected of having GERD does not confidently establish the diagnosis, when GERD is defined by currently accepted reference standards” [171]. In summary, these data indicate that a therapeutic trial of a PPI for 1–2 weeks may be a reasonably useful clinical tool but it is by no means a gold-standard test for the diagnosis of GERD. The advantages of this approach include simplicity, non-invasiveness, ease of prescription and consumption, tolerability, and savings in terms of direct costs and time lost by the patient, but it does not demonstrate optimal sensitivity or specificity. A positive therapeutic trial may also predict longer term therapeutic response, but data confirming this notion are limited. These studies also support the notion that a symptom-based treatment is reasonable for most patients with reflux disease without a specific diagnosis. Perhaps the greatest value of this test lies in determining that GERD is not likely to be the cause of a given patient’s symptoms (high negative predictive value) when no response to high-dose PPI is achieved.

---

## Treatment of gastroesophageal reflux disease

Symptoms of gastroesophageal reflux are common and have a significant adverse impact on QOL. The costs of disease include both drug acquisition costs and indirect costs such as testing, physician visits and time off work. Because of the difficulty in making a definitive diagnosis of GERD through diagnostic investigations, the physician must make a presumptive diagnosis and initiate a management plan. The goals of therapy are to provide adequate symptom relief, heal esophagitis and prevent complications. Since initial studies in GERD have focused on mucosal healing; healing of erosive esophagitis will be discussed first, followed by discussions on NERD, and finally on symptomatic treatments in the uninvestigated patient.

## Acid suppression therapy for gastroesophageal reflux disease

While transient relaxations of the LES and defective basal LES tone are thought to be the primary pathophysiological determinants of reflux, symptoms and damage arising from the esophagus are the result of acidic reflux as a consequence of these and other physiological perturbations [43]. Thus, the focus of treatment has been on acid suppression.

Acid secretion and/or gastric pH can be affected by various drugs. Antimuscarinic agents are weak inhibitors

of the parietal cell  $M_3$  cholinergic receptors, and their clinical use is limited by their anticholinergic side effects.  $H_2$ -receptor antagonists ( $H_2$ -RAs) inhibit parietal cell histamine receptors; thus acid inhibition can be largely overcome by stimulation of gastrin and cholinergic receptors, as occurs when food is eaten [172]. Tolerance or tachyphylaxis to  $H_2$ -RAs develops rapidly and reduces their efficacy with continued use over time [173]. PPIs provide the most potent acid inhibition through covalent binding to the  $H^+$ ,  $K^+$ -ATPase (acid or proton pump) located in the secretory canaliculus of the parietal cell. Inhibiting the proton pump, which is the final common pathway of acid secretion, diminishes acid secretion to all known stimuli. Despite short serum half-lives, the PPIs have a longer duration of pharmacological action owing to the dependence of acid secretion recovery on the rate of synthesis of new proton pumps by the parietal cell.

Studies of intragastric acidity have been used to assess the degree and duration of acid inhibition with anti-secretory drugs [174, 175]. These studies have confirmed that PPIs are far superior to  $H_2$ -RAs in their ability to suppress food stimulated, daytime and total 24-hour acid secretion. Bell *et al.* [174] have shown, by meta-analysis, that the healing rate of erosive esophagitis correlated directly with the duration of gastric acid suppression over a 24-hour period. The primary determinants of healing were the duration of antisecretory treatment, the degree of acid suppression and the duration of acid suppression over the 24-hour period. There was also a highly significant correlation between the time that the pH in the esophagus was above 4 and the ability to heal erosive esophagitis. The authors concluded that if intragastric acidity could be maintained above a mean pH of 4 for 20–22 hours of the day, 90% of patients with erosive esophagitis would be healed by eight weeks. Thus, the superiority of PPIs over  $H_2$ -RAs was predicted prior to the performance of clinical trials based on their pharmacologic ability to achieve more effective suppression of acid secretion.

## Lifestyle modifications

Although lifestyle modifications as a treatment for GERD are frequently recommended, there is little evidence that these are of benefit (Box 2.1). Changing dietary habits and lifestyle modifications are generally considered useful by physicians [176, 177]. However, when patients were asked about advice they had received from physicians, lifestyle changes were only modestly recommended [178]. If a patient is under the age of 50, and has no serious “alarm symptoms” such as unexplained weight loss, dysphagia or hematemesis, it is reasonable to start empirical therapy [9, 163] as the most cost-effective approach [179].

One study assessed patients with 24-hour esophageal pH testing and found no difference in lifestyle alteration and

### BOX 2.1 Recommended lifestyle modifications in gastroesophageal reflux disease

- Avoid precipitating foods and drinks: fat [200, 201] (two studies found no effect of fat [202, 203], another found no effect of caloric density [204]), chocolate [205, 206], peppermint [207], spices [208], raw onions [209], carbonated beverages [198, 210], caffeine [4, 185, 211–213], coffee [185], orange juice and tomato drink [210, 214]
- Avoid alcohol [4, 210, 215–217]
- Avoid cigarette smoking [4, 186, 216–218]
- Avoid large meals and gastric distension [44, 219]
- Avoid lying down within 3–4 hours of a meal [220]
- Aggravating factors to be avoided: posture [220], physical exertion especially running [188, 189], weightlifting and cycling [189, 193]
- Raising the head of the bed may have some efficacy [220–223]
- Sleeping on the left lateral position reduces reflux [195–197]
- Avoid tight clothes [4]
- Obesity may be a risk factor [4, 22, 216–224], weight reduction helps symptoms [225], weight reduction does not help [226, 227], Roux-en-Y gastric bypass may benefit [224]
- Avoid certain drugs if possible:  $\beta$ -blockers, anticholinergics including certain antidepressants, theophylline, calcium antagonists, nitrates

anxiety between those with positive and negative pH profiles [180]. However, the data that white wine (vs red wine) induces reflux is reasonably robust [181, 182]. There are several mechanisms identified, including reduced LES pressure [182], disturbed esophageal clearance due to increased simultaneous contractions and failed peristalsis [183, 184]. The most recently identified mechanism is the occurrence of repeated reflux events into the esophagus when pH is still acidic from a previous reflux episode, the so-called “re-reflux” phenomenon [185]. Although caffeine itself is thought to be associated with reflux, one study has proposed that it is something in coffee other than caffeine that is responsible [186]. Smoking is also often implicated (Box 2.1) but results concerning its role are controversial. One 24-hour pH study has shown an association with smoking [186] while another has not [187]. Vigorous exercise has also been implicated as exacerbating reflux, with emphasis on running [188–193], but with evidence also for weightlifting and cycling [189, 193]. Thus, there is some rationale for “mother’s advice” not to exercise right after eating. In one study ranitidine 300mg, given one hour before running, reduced esophageal acid exposure [192]. While there is some evidence that elevating the head of the bed is beneficial, not all investigators agree as the effective-

ness has been studied using esophageal acid exposure (which is improved but not normalized) and not symptoms as an outcome [194]. Lastly, the effect of posture is interesting, as more acid reflux seems to occur in the right lateral position. Thus the left lateral position is recommended for sleeping [195–197]. Meining and Classen reviewed the efficacy of lifestyle modifications as a treatment for GERD in detail and determined that for many of the recommendations, the data are conflicting, weak and, at best, equivocally supportive [198]. A recent systematic review investigating the effect of lifestyle modifications on GERD found that most were not evidence based and had little to recommend their routine use [199].

In summary, these data do not allow one to recommend lifestyle modifications as a therapy for GERD, although some of the modifications are known to positively affect health in other ways (smoking cessation, weight loss, etc.) and can be recommended on that basis alone.

### Placebo response rates

Because healing of moderate to severe esophagitis with placebo therapy occurs in about 28% of patients [13, 228], the use of placebo controls has been important, especially for the less effective drugs, such as H<sub>2</sub>-RAs and prokinetics. Additionally, the symptomatic placebo response rate ranges from 37–64%, further underscoring the need for placebo controls in less effective therapies for GERD [229]. For PPIs, the therapeutic gain is so large that placebo-controlled trials are less necessary, although they remain useful [13].

### Antacids and alginate

A small randomized placebo-controlled trial of Maalox TC at a full dose of 15 ml seven times daily for four weeks in 32 GERD patients showed no significant symptom relief [230]. Other trials have reported marginal if any benefit of antacids and alginates over placebo, and antacids do not heal esophagitis [231–233]. **A1d** However, a recent meta-analysis concluded that compared with the placebo response the relative benefit increase was up to 60% with alginate/antacid combinations, and 11% with antacids [229].

In an uncontrolled study of patients with grade I to III esophagitis healed with either an H<sub>2</sub>-RA or omeprazole, patients were given alginate for symptomatic maintenance treatment [234]. At six months, 76% were in remission. Those with more severe baseline esophagitis relapsed more frequently. In a randomized controlled trial, sodium alginate 10 ml four times daily was slightly more effective than cisapride 5 mg four times daily for reducing both symptoms measured on a visual analog scale (0–100) (alginate

29 ± 22, cisapride 35 ± 25,  $p = 0.01$ ) and the number of reflux episodes in a four-week period (alginate 2 ± 2, cisapride 3 ± 4,  $p = 0.001$ ) [235]. Conservative symptomatic therapy with alginate may be useful in some patients. **A1d**

Collings *et al.* [236] recently demonstrated that a calcium carbonate gum decreased heartburn and intraesophageal acidity more than chewable antacids, with effects that lasted for a couple of hours. This observation suggests that such a gum may be useful for intermittent therapy, possibly because of an effect on salivation.

In summary, there are sufficient data supporting a recommendation for antacids as a short-term treatment for symptomatic heartburn; alginate/antacid combinations appear to be superior to antacid use alone.

### Prokinetic drugs

In a randomized, placebo-controlled trial, metoclopramide and domperidone did not improve esophageal motility, duration of acid exposure or esophageal clearance, although both agents significantly increased LES pressure [237]. Cisapride is the only prokinetic drug that increases both esophageal clearance and enhances LES tone [238, 239]. However, one study provided evidence that cisapride increased acid reflux in comparison with omeprazole and famotidine [240].

Placebo-controlled trials show marginal benefit for cisapride in healing esophagitis and improving symptoms [239, 241–243]. **A1d** For mild grades of esophagitis, cisapride has been demonstrated to be as effective as H<sub>2</sub>-RA for healing and symptom relief with comparable tolerability [243–248]. However, this drug requires prolonged use for up to 12 weeks before clinical benefit is seen [242, 243, 245, 247, 249–251].

In one randomized trial in patients with milder GERD, omeprazole 10 or 20 mg daily was significantly more effective than cisapride 10 mg four times daily for relief of heartburn, regurgitation and epigastric pain [104]. This and other studies suggest that for symptomatic GERD, the degree of acid suppression is a more important determinant of symptom relief than prokinetic activity. **A1d**

In healing grades I and II esophagitis, adding cisapride to omeprazole did not significantly increase efficacy over omeprazole alone [252]. In another study of healing grades II and III esophagitis, cisapride 20 mg twice daily added to pantoprazole 40 mg once daily did not improve healing over pantoprazole alone [253]. Thus, these two studies provide strong evidence that the addition of cisapride does not add any clinical benefit to treating with PPIs alone. **A1d**

Cisapride has demonstrated only modest benefit for maintenance therapy for mild esophagitis [251, 252, 254, 255]. However, in patients with more severe erosive esophagitis initially healed with antisecretory therapy, cis-

apride was not effective for maintenance treatment [243, 245, 256, 257] and was not more effective than placebo [258]. **A1d**

The recent Cochrane meta-analysis concluded that there was a paucity of evidence on prokinetic therapy, with no substantive evidence that it is superior to placebo [259]. Cisapride has also been associated with the development of serious cardiac arrhythmias including torsades de pointes, when used with other drugs that inhibit cytochrome P450 3A4. These include fluconazole, itraconazole, ketoconazole, erythromycin, clarithromycin, ritonavir, indinavir, nefazodone, tricyclic antidepressants and certain tetracyclic antidepressants, certain antipsychotics, astemizole, terfenadine, and class IA and III anti-arrhythmics [260]. Thus, cisapride is not recommended for the treatment of GERD because its potential for producing significant adverse events is greater than that for other more effective agents, and in many countries the drug has now been withdrawn.

In summary, there are insufficient data to recommend the use of cisapride in the treatment of GERD.

### Sucralfate in gastroesophageal reflux disease

For grade I–III GERD, there have been four small, randomized trials of sucralfate 1 g four times daily compared with standard dose H<sub>2</sub>-RA, none of which demonstrated any significant differences with respect to symptom resolution and healing [261–264]. However, none of these studies showed very large benefits from either intervention, with low rates of heartburn relief (34–62%) and healing (31–64%). Combining sucralfate and cimetidine was not better than monotherapy with either drug [265, 266]. The meta-analysis of randomized trials for grade II–IV esophagitis performed by Chiba *et al.* yielded a pooled value for healing of 39.2% for sucralfate compared with 28% for placebo [13]. However, the 95% CI was wide (3.6 to 74.8%). **A1c**

In a six-month study of grade I–II GERD, sucralfate was more effective than placebo for preventing relapse (sucralfate 31%, placebo 65%; ARR 34%, NNT 3,  $p < 0.001$ ) [267].

#### **A1d**

It is interesting that sucralfate, which does not lower acid output, reduce esophageal acid exposure or improve esophageal transit time [268] has any efficacy given our understanding of the pathophysiology of this condition. The adverse effect of constipation, the need for four times daily dosing and the modest observed benefit make sucralfate a less than optimal GERD treatment choice for most patients.

In summary, there are insufficient data to support a recommendation for the use of sucralfate in the treatment of GERD.

### H<sub>2</sub>-receptor antagonists

H<sub>2</sub>-RAs are not optimally effective in the treatment of GERD but still maintain a role in symptomatic therapy and are discussed here somewhat briefly.

#### Intermittent/on-demand therapy for heartburn relief

Acid suppressive therapy with H<sub>2</sub>-RAs has been the mainstay of treatment for acid-related disorders and in many countries these agents are available for over-the-counter (OTC) use [269]. This availability permits intermittent, on demand use by the patient. A blinded crossover trial of famotidine 5, 10 and 20 mg versus placebo showed that all famotidine doses were more effective than placebo for the prevention of meal-induced heartburn and other dyspeptic symptoms [270]. This study established that heartburn severity peaked 1–2 hours after a meal. Thus, a small dose of H<sub>2</sub>-RA taken before eating is useful to reduce GERD symptoms induced by meals.

A unique formulation of a readily dissolving famotidine wafer (20 mg) was compared with standard dose (150 mg) ranitidine [271]. With both treatments, about half the patients had some symptom relief within three hours. A similar randomized trial found trivial but statistically significant differences between ranitidine and famotidine for time to adequate symptom relief (ranitidine 15 minutes, famotidine 18.5 minutes,  $p = 0.005$ ) and for the proportion of patients with symptom relief at one hour (ranitidine 92%, famotidine 84%;  $p = 0.02$ ) [272].

A recent meta-analysis of OTC medications determined from ten trials, yielded a relative benefit increase of up to 41% with H<sub>2</sub>-RAs compared to placebo [229]. Thus, for mild reflux symptoms, use of H<sub>2</sub>-RA on an as needed basis remains a useful therapy for GERD.

#### High dose H<sub>2</sub>-receptor antagonists

While standard doses of H<sub>2</sub>-RAs heal more severe, grade II to IV esophagitis in about 52% of patients [13], higher doses of H<sub>2</sub>-RA (150–300 mg four times daily) are more effective, healing 74–80% of patients in 12 weeks, under conditions in which the healing rate with placebo is 40–58% [273, 274]. Silver *et al.* [275] compared regimens of ranitidine 300 mg twice daily and 150 mg four times daily for treatment of erosive esophagitis. At 12 weeks, the healing proportion observed for the four times daily regimen was 77% and for the twice daily regimen, 66% (absolute risk reduction (ARR) 11%, number needed to treat (NNT) 9). Ranitidine 150 mg four times daily was superior to standard dose (150 mg twice daily) ranitidine or cimetidine (800 mg twice daily) in patients with erosive esophagitis [276]. In another randomized trial in patients with erosive esophagitis [277], with ranitidine 150 mg twice daily the proportion of patients

healed was 54% at eight weeks compared with 75% with 300 mg four times daily (ARR 21%, NNT 5). **A1d** Famotidine is pharmacologically more potent than ranitidine and a large dose of 40 mg twice daily was superior to standard dose 20 mg twice daily or ranitidine 150 mg twice daily in patients with erosive or worse esophagitis [278]. **A1d** These data suggest that standard dose H<sub>2</sub>-RAs can be effective in GERD symptom relief, but higher doses are necessary for healing and maintenance of healing of esophagitis.

More complete data on oesophagitis healing with H<sub>2</sub>-RAs is found in the recently updated Cochrane Review [259], where there was a statistically significant benefit of H<sub>2</sub>-RAs compared to placebo.

In summary, these data indicate that H<sub>2</sub>-RAs have a limited but measurable effect in treating GERD, and symptoms respond better than healing to treatment.

## Erosive gastroesophageal reflux disease

### Meta-analysis of healing and symptom relief with proton-pump inhibitors and H<sub>2</sub>-receptor antagonists

An early meta-analysis of randomized trials of patients with more severe esophagitis (grade II in 61.8%, grade III in 31.7% and grade IV in 6.5%) established the clinical efficacy of PPIs [13]. Subsequent published studies support the conclusions derived from this meta-analysis [259, 279–295]. **A1d**

**Figure 2.2** Healing-time curve expressed as the mean total healing for each drug class per evaluation time in weeks. By week 4, PPIs (proton pump inhibitors) heal more patients than any other drug class, even after a much longer duration of treatment (12 weeks), implying a substantial therapeutic gain despite the fact that all drug classes achieve higher healing with longer durations of therapy. The number of studies is shown in parentheses. •: PPI; +: H<sub>2</sub>-RA; \*: placebo. Reproduced with permission from Chiba N *et al. Gastroenterology* 1997; **112**: 1798–1810 [13].

In the meta-analysis [13], the rate of healing, expressed as “percent healed per week”, was significantly superior with PPI therapy compared with H<sub>2</sub>-RA, particularly early in the course of treatment (weekly healing rate in first two weeks: PPI 32%, H<sub>2</sub>-RA 15%). The rate of healing slowed with increasing duration of treatment as fewer patients remained unhealed, but PPI remained superior to H<sub>2</sub>-RA. The overall healing proportions during 12 weeks, using pooled results irrespective of dose and duration were: PPI 84% (95% CI: 79 to 88), H<sub>2</sub>-RA 52% (95% CI: 47 to 57), sucralfate 39% (95% CI: 4 to 75) and placebo 28% (95% CI: 19 to 37). These data were used to plot rate of healing against time on a “healing time curve” (Figure 2.2). By the end of the second week, PPI had healed  $63.4 \pm 6.6\%$  of patients, while H<sub>2</sub>-RA required 12 weeks to achieve healing in a similar proportion of patients ( $60.2 \pm 5.9\%$ ). Linear regression analysis of individual study results showed that PPI heal at an overall rate of 11.7% per week (95% CI: 10.7 to 12.6), twice as rapidly as H<sub>2</sub>-RA (5.9% per week, 95% CI: 5.5 to 6.3) and four times more rapidly than placebo (2.9, 95% CI: 2.4 to 3.4).

Heartburn was present in all but 3.8% (95% CI: 2.1 to 5.5) of patients at baseline. Overall, heartburn relief was seen in  $77.4 \pm 10.4\%$  of patients treated with PPI and in  $47.6 \pm 15.5\%$  treated with H<sub>2</sub>-RA. Data for heartburn relief were plotted against time to create a “symptom relief time curve” (Figure 2.3). Linear regression analysis of the data yielded an overall heartburn relief rate of 11.5% per week

**Figure 2.3** Symptom relief-time curve expressed as the mean total heartburn relief for each drug class corrected for patients free of heartburn at baseline at 1–2, 3–4, and 6–8 weeks. By week 2, more patients treated with PPIs (proton pump inhibitors) are asymptomatic compared with H<sub>2</sub>-RA (H<sub>2</sub>-receptor antagonists) even after a much longer duration of treatment (eight weeks), implying a substantial therapeutic gain despite the fact that both drug classes achieve greater symptom relief with longer durations of treatment. The number of studies is shown in parentheses. ■: PPI; x: H<sub>2</sub>-RA. Reproduced with permission from Chiba N *et al. Gastroenterology* 1997; **112**: 1798–1810 [13].

**Figure 2.4** Shift in heartburn relief with H<sub>2</sub>-RAs (H<sub>2</sub> receptor antagonists). From studies using a symptom scale of none, mild, moderate, or severe, the shift in symptom severity with duration of treatment can be observed. With H<sub>2</sub>-RAs, although there is an increase in the number of patients completely heartburn free, at the end of the study, more than half of the patients still have mild to moderate symptoms: none (■); mild (▨); moderate (▩); severe (■). Reproduced with permission from Chiba N *et al. Gastroenterology* 1997; **112**: 1798–1810 [13].

**Figure 2.5** Shift in heartburn relief with PPIs. PPIs (omeprazole)-treated patients have a dramatic shift in the number of patients completely symptom free, particularly early in-treatment, and at the end of the study, very few patients have any residual heartburn in contrast to patients treated with H<sub>2</sub>-RAs: none (■); mild (▨); moderate (▩); severe (■). Reproduced with permission from Chiba N *et al. Gastroenterology* 1997; **112**: 1798–1810 [13].

for PPI (95% CI: 9.9 to 13.0) and 6.4% per week for H<sub>2</sub>-RA (95% CI: 5.4 to 7.4).

Some studies measured heartburn in categories of none, mild, moderate or severe and reported the shift in heartburn relief with treatment (Figures 2.4 and 2.5). The proportion of patients with residual mild to moderate symptoms after eight weeks of therapy was 11.1% for PPI and 57.4% for H<sub>2</sub>-RAs.

This meta-analysis provided evidence that PPI are significantly better than H<sub>2</sub>-RA for both healing esophagitis and relieving symptoms in patients with moderately severe esophagitis. There was also evidence in one RCT that PPI therapy is effective for healing persistent grade II–IV esophagitis after treatment failure with 12 weeks standard dose H<sub>2</sub>-RA [296]. **A1d**

Other more recent Cochrane meta-analyses have demonstrated similar findings, with PPIs being superior to H<sub>2</sub>-RAs in healing and maintenance of healing of esophagitis [259, 297]. These data support a recommendation for the use of PPIs rather than H<sub>2</sub>-RAs for the healing and maintenance of healing of esophagitis, as well as for heartburn relief.

### Differences in efficacy between proton pump inhibitors

There are now five proton-pump inhibitors available in North America. These are omeprazole, lansoprazole, pantoprazole, rabeprazole and esomeprazole.

For symptom relief, esomeprazole has been shown to be more rapidly effective than omeprazole [32, 290], lansoprazole [284, 298] and pantoprazole [299]. In other studies, lansoprazole was more rapidly effective than omeprazole [33] and pantoprazole non-inferior to esomeprazole [300]. However, differences in symptom relief were no longer apparent at the end of these studies [279, 287, 301, 302]. In another study, omeprazole and pantoprazole were found to be equivalent with each other but not with lansoprazole regarding rapidity of symptom relief [303]. Similar results were found in a comparison of rabeprazole and omeprazole [294]. Low, half-doses of PPIs compared with standard doses were not found to be as effective for healing esophagitis or for symptom relief [146, 279]. However, for maintenance therapy some data suggest that low dose PPIs are as effective as standard doses [37, 304, 305]. While there were small differences between overall study results, the data from these studies were insufficient to establish the superiority of any one drug over all others [306].

Vakil and Fennerty recently carried out a careful systematic review of randomized controlled trials that directly compared PPIs to determine whether there is a difference in clinical outcomes between any of these agents [306]. They restricted this review to more recent (1998–2002), better quality trials. They found similar healing rates for the following comparisons:

- lansoprazole 30mg daily compared with omeprazole 20mg [301] or 40mg [280], or pantoprazole 40mg daily [291]
- pantoprazole 40mg [307] or rabeprazole 20mg [281, 289] compared with omeprazole 20mg daily **A1c**

They found that for esophagitis healing, esomeprazole was superior to omeprazole and lansoprazole [32, 284, 290]. Earlier randomized trials comparing two different

PPIs (lansoprazole, omeprazole, pantoprazole and rabeprazole) had also failed to show a difference in healing rates with drugs used at standard recommended doses [27, 31, 279, 280, 287, 301, 307, 308]. **A1d**

Two other meta-analyses also have shown that esomeprazole was superior to omeprazole and that other PPIs did not produce higher healing rates than omeprazole [309–311]. **A1c** Another review concluded that lansoprazole, pantoprazole and rabeprazole were comparable with omeprazole in terms of heartburn control, healing rates and relapse rates [312]. Systematic reviews of data from randomized trials performed up to 2005 that compared esomeprazole to other PPIs showed that esomeprazole was more effective than omeprazole, lansoprazole and pantoprazole for healing esophagitis at four and eight weeks, but there is still no direct comparative trial of esomeprazole against rabeprazole [311, 313]. Esomeprazole 40 mg daily was more effective for healing the more severe LA grades C and D esophagitis in randomized trials in which it was compared with omeprazole 20 mg daily [32, 290, 313], lansoprazole 30 mg [284, 298, 313] or pantoprazole [299, 313, 314]. **A1d** One randomized trial that included only 284 patients but was otherwise similar in design to the trial that included 5241 patients showed no difference between esomeprazole 40 mg and lansoprazole 30 mg for healing of erosive (or more severe) esophagitis in four or eight weeks; the smaller trial may have lacked statistical power [285]. **A1c** Subsequently, another study showed esomeprazole superior to pantoprazole [314].

Esomeprazole is the first PPI shown to be more effective than any other PPI; all other direct comparisons have shown that healing rates are essentially the same for all agents in this class [285]. However, in elderly patients over age 65 there may be some differences [315]. In a relatively small randomized trial, Pilotto and colleagues compared standard dose omeprazole, pantoprazole, rabeprazole and lansoprazole for healing of esophagitis using the outdated Savary-Miller classification [315]. They determined that at eight weeks, pantoprazole and rabeprazole were significantly more effective than omeprazole for healing esophagitis and were also more effective than omeprazole or lansoprazole for relieving symptoms. The authors were unable to provide an adequate explanation for apparent differences in response in the elderly population [315].

Esomeprazole, the (S)-isomer of omeprazole, produces potent acid suppression as a result of increased systemic exposure and less inter-individual variability in response to it. Hatlebakk [316] reviewed available data and concluded that esomeprazole 40 mg daily was significantly more effective at controlling gastric acidity than lansoprazole 30 mg daily, pantoprazole 40 mg daily and rabeprazole 20 mg daily in a mixed population of healthy volunteers and patients with GERD. Comparable results were also reported in patients with GERD symptoms [317]. Similar

results for greater potency of esomeprazole compared to pantoprazole have been reported [318–321]. Esomeprazole 20 mg daily was also significantly more effective than lansoprazole 15 mg daily. Another study reviewing half healing doses concluded that esomeprazole was significantly more effective than rabeprazole, lansoprazole or pantoprazole for control of intragastric acid [322]. Thus, the reports of greater clinical efficacy are consistent with the greater pharmacological potency of this drug.

A study of the Food and Drug Administration database reported very few drug interactions for omeprazole, lansoprazole and pantoprazole [323]. Of the rare interactions, vitamin K antagonist reactions were most common, but even these were seen in only 0.09–0.11 per million packages prescribed. This report concluded that the safety of the drugs was likely to be a class effect, with no significant differences among the PPIs.

In summary, these data indicate that there are statistically significant differences in potency and healing rates observed with the various proton pump inhibitors, with esomeprazole demonstrating the highest healing rates. However, these data do not indicate that the differences in healing or symptom response rates are sufficiently large to conclude that one agent should be used in preference to another.

### Is there a rationale for higher dose proton pump inhibitor therapy?

The standard doses of PPI are very effective for healing most cases of esophagitis, and it is clear that there is a correlation between the degree of acid suppression and healing [174]. In clinical practice, patients with persistent or recurrent symptoms are often told to double their dose of PPI, typically to take the doses on a twice daily regimen. This clinical recommendation was based on the 9–12 hour physiological effect these compounds have on gastric acid secretion; the pharmacological data demonstrated that a standard dose taken bid was more effective at prolonging acid control than a double dose taken once daily [324]. Patients with complicated or atypical GERD were randomly assigned to receive lansoprazole or pantoprazole once daily [325]. Esophageal acid exposure was normalized in all lansoprazole patients (in 35% of cases with double dose), whereas 25% of the pantoprazole treated patients did not have lowered or normalized esophageal acid exposure, even with the dose doubled ( $p = 0.008$ ). A study in patients with stage II or III esophagitis randomized to pantoprazole 40 mg or 80 mg daily healing was observed in 78% and 72% of subjects at four weeks [282]. These data suggest that increasing the dose of pantoprazole beyond the standard dose is not likely to be of any benefit.

Klinkenberg-Knol *et al.* have followed a cohort of GERD patients for many years and reported that doubling the

dose of omeprazole to 40mg daily was effective to treat relapses [326]. A longer term report followed 230 patients for up to 11 years on continuous therapy [327]. Of those followed, a third each had grade II, III and IV disease. It was estimated that there was only one relapse for every nine years of treatment and the median maintenance dose was 20mg daily. Dose titration (range 20mg every second day to 120mg once daily) allowed most patients to remain in remission. Another study showed that titrating the dose of omeprazole to 40–60mg daily was as effective for maintenance of remission as anti-reflux surgery [328]. **B4**

In a randomized trial in which patients with erosive esophagitis were randomized to receive rabeprazole 20mg daily or omeprazole 40mg daily in for 4–8 weeks, there were no significant differences in the rates of symptom relief or healing [294]. **A1d**

Further lack of support for using higher than normal doses of PPIs to treat GERD come from two recent meta-analyses of placebo controlled trials of standard and high doses of PPIs to treat laryngeal symptoms of GERD, providing no evidence for efficacy of these therapies for symptomatic improvement or resolution of laryngo-pharyngeal symptoms [329, 330]. There is also concern about having patients on multiple daily doses of PPIs, a practice that increases cost. Inadomi *et al.* [331] identified and recruited such patients through the use of pharmacy records of PPI prescriptions. Eligible subjects were stepped-down to single dose PPI (lansoprazole 30mg or omeprazole 20mg daily), and 80% did not report recurrent symptoms of heartburn or acid regurgitation. These authors concluded that “this intervention can decrease management costs without adversely affecting quality of life” [331]. **B4** Additionally, Lee *et al.* performed a systematic review that also confirmed the over utilisation of both increased and standard dose PPIs in clinical practice [332]. In summary, there are insufficient data to support a recommendation for routinely using PPI doses higher than standard doses for healing esophagitis, treating symptomatic GERD or atypical symptoms of GERD, although higher doses may be effective in preventing relapse that occurs at standard doses of PPIs. Higher doses are appropriate in only a minority of patients.

### Maintenance therapy for patients with documented healed esophagitis

For mild forms of esophagitis, as seen at a community level, 46% of patients will heal spontaneously [334]. For moderately severe GERD, healing and symptom relief are more readily obtained with PPI therapy. However, within 6–12 months, irrespective of the initial healing agent, relapses are reported in 36–82% of patients in the absence of maintenance therapy [335–338]. When maintenance therapy is either not commenced after an initial course of

**Figure 2.6** Actuarial life-table analysis. Estimated proportion of patients in endoscopic remission at the end of the 6-month follow up period with maintenance treatment. Reproduced with permission from Carlsson *et al.* *Aliment Pharmacol Ther* 1997; **11**: 473–482 [333].

therapy, or is stopped, symptoms often recur within a day, and erosive esophagitis can recur in many patients within 10 days [339] to one month [340]. Thus, maintenance therapy is required in most patients with esophagitis in order to maintain healing and symptom relief. However, a recent systematic review provided evidence that despite continuous therapy with PPI, 28% of patients suffer a relapse of esophagitis within six months [338].

A meta-analysis of the rate of relapse of erosive esophagitis reported in five omeprazole trials that included 1154 patients in whom erosive GERD was initially healed by omeprazole 20–40mg was carried out by Carlsson *et al.* [341]. Figure 2.6 shows the effects of various regimens. Omeprazole 20mg daily, which maintained 82.4% of patients in remission for six months, was significantly better than omeprazole 10mg daily ( $p = 0.04$ ). Both of these regimens were significantly better than ranitidine 150mg twice daily and omeprazole 20mg on weekends. PPI therapy taken on a regimen of three times in a week is less effective than daily dosing [342, 343]. Two trials have assessed maintenance over 12 months. Omeprazole 20mg daily was superior to ranitidine 150mg twice daily (omeprazole 80.2%, ranitidine 39.4%; ARR 40.8%, NNT 2). **Ala** The proportions of patients with asymptomatic endoscopic esophagitis relapse were: omeprazole 20mg 4.5%, omeprazole 10mg 12.5%, and ranitidine 14.6%. Regression analysis identified four risk factors for recurrence: pretreatment severity of esophagitis, younger age, non-smoking status and moderate to severe reflux pre-entry. A previous systematic review of continuous maintenance therapy [344] in patients with initial grades II–IV esophagitis was updated in the first and second editions of this book and readers are referred there for details [345, 346]. There are methodological issues in pooling these results. Not all studies provided precise numbers of patients in remission/relapse, and data were analysed on either an intention to treat basis or using data from all the evaluable patients in life-table analysis.

Most trials were of only six months' duration. The esomeprazole studies used the LA classification to grade esophagitis. LA grade A is not directly comparable to either the Hetzel-Dent or Savary-Miller grade I classifications. However, given these shortcomings, 12-month placebo relapse rates ranged from 71 to 91% [346], H<sub>2</sub>-blockers were not significantly more effective with relapse rates between 51 and 88% [346]. The data supported the concept that the greater degree of acid suppression resulted in better remission rates. PPIs resulted in the highest remission rate, particularly when the dose given was the full healing dose for omeprazole, lansoprazole, pantoprazole, rabeprazole and esomeprazole [346]. These data were also confirmed in a more recent Cochrane Review [297]. PPIs were rarely compared directly, but in one study, lansoprazole and omeprazole were comparable [347].

In trials comparing half doses, esomeprazole 20mg was more effective than lansoprazole 15mg once daily [348, 349]. With more severe LA grades of esophagitis, esomeprazole treatment provided a significantly longer time to relapse than was observed in the lansoprazole treated patients [348]. At six months, pantoprazole 20mg and esomeprazole 20mg were comparable [350]. Using half doses of these PPIs was less effective for maintenance therapy than full healing doses [346]. In the Cochrane Review of placebo-controlled trials, the observed relative risk of relapse was 0.46 for half doses of PPIs, compared to only 0.26 for full dose PPI therapy [297].

One trial [37] suggested that esomeprazole 20mg was as effective as 40mg daily. Another suggested that rabeprazole 10mg was as effective as 20mg daily [351], although this observation was not confirmed in two other similar trials [352, 353].

Studies looking specifically at patients aged 65 years and over have not found different esophagitis healing rates [354, 355]. There are no data indicating that the elderly respond any differently from younger patients with esophagitis.

There are limited data from maintenance studies of greater duration than one year. An observational maintenance study with pantoprazole 40mg once daily in 157 patients with healed stage II or III reflux esophagitis (Savary-Miller classification) showed endoscopic remission in 87% and 76% of patients after one and two years [356]. **B4** Another five-year follow-up study in patients with both peptic ulcer and reflux esophagitis found estimated rates of remission on maintenance treatment with pantoprazole (n = 115) of 82% at one year, 75% at two years, 72% at three years, 70% at four years and 68% at five years [357]. There have been two randomized trials of five years' duration. In the first, patients with initially healed erosive or worse esophagitis were randomized to receive rabeprazole 20mg once daily, rabeprazole 10mg once daily or omeprazole 20mg once daily [351]. Of the initial 243

patients, 123 completed the five-year study. Relapse rates were 11.5%, 9.8% and 13.3%, respectively. In the second study, patients were randomized to rabeprazole 20mg, 10mg or placebo with five-year relapse rates of 11%, 23% and 63% respectively [358]. All treatments were safe and well tolerated. These data provide evidence that remission can be effectively maintained over long time periods.

The problem of healing the more severe grades of esophagitis is well known. The proportion of patients who experience acute healing for grade II esophagitis ranges from 76–100%, for grade III from 63–95% and for grade IV from 56–75% [344]. Grade IV disease relapses more frequently than grade II and III disease [340, 359].

In summary, in clinical practice, it is suggested that the dose of PPI can be titrated upwards to maintain healing in most patients [326] or alternatively, the most potent PPI be used. **A1d C5** In some patients, lower doses of PPIs may be effective for maintenance therapy in patients with healed esophagitis. **B4**

### On-demand therapy as a strategy for maintenance of healing of mild/moderate esophagitis

Lansoprazole (15mg daily and 30mg on alternate days) was studied for maintenance of endoscopic healing and symptom relief over a six-month period after healing of Savary-Miller grades I–III reflux esophagitis [360]. After six months, recurrence of esophagitis was observed in 12% of the 15mg once daily group and in 19% of the 30mg alternate day group. This difference was not statistically significant. However, 12.1% of patients who received 15mg daily and 28.6% of those who received alternate day higher dose therapy (p = 0.007) had heartburn. **A1d**

In another study, patients with esophagitis were initially treated until symptoms had resolved. Thereafter, they took "on-demand" lansoprazole (30mg) or omeprazole (20mg) for six months, only when reflux symptoms relapsed [361]. There were no differences observed in the frequency of reflux symptoms or in the number of doses taken by subjects in the lansoprazole (0.73 doses/day) and omeprazole (0.71 doses/day) groups. **A1d**

In a study population of mild LA grades A and B esophagitis, esomeprazole 40mg was more effective than omeprazole 20mg once daily, on-demand for symptom relief and fewer tablets were consumed [362]. Another study examined patients with more severe LA grades A–D initially healed with esomeprazole 40mg daily [363]. On continuous esomeprazole 20mg once daily, 81% remained in remission at six months compared to 58% with on-demand treatment (ARR 23%, NNT = 4, p < 0.0001). Heartburn was significantly more common in the on-demand group, and continuous therapy more effectively maintained healing of erosive esophagitis [363].

There are relatively few studies that have examined this strategy in patients with more severe initial erosive esophagitis compared to patients with mild esophagitis, uninvestigated heartburn or NERD. An important factor reducing efficacy of an on-demand strategy is obesity [364]. In a recent systematic review on the use of on-demand therapy, Pace and colleagues demonstrated that “on-demand therapy”, while effective for the treatment of GERD symptoms, was less effective than continuous PPI maintenance therapy for maintenance of healing of esophagitis [365].

In summary, these data do not support a recommendation for “on-demand” therapy for patients with documented erosive esophagitis, since relapse is more common with this strategy, patients must experience recurrent symptoms before treatment is taken, and these patients are left with unhealed lesions. **C5**

### Cost-effectiveness of maintenance therapy

PPIs are the most effective treatments available to treat GERD. PPIs are in general more costly than H<sub>2</sub>-RAs, although the availability of multiple generic forms and OTC formulations of PPIs has markedly narrowed this disparity in cost. Therefore, cost-effectiveness analyses can be important in decision making regarding treatment options. Studies differ substantially with respect to methods, assumptions, interventions and outcomes being evaluated, the inclusiveness of cost items and the jurisdiction to which the analyses are applied. No perfect cost-effectiveness study exists, and new advances in therapy and changes in cost over time tend to render the conclusions out of date rather quickly. However, despite these limitations, these modelling studies are useful to put the role of existing interventions into perspective.

Many studies have indicated that PPIs are likely to be more cost-effective than H<sub>2</sub>-RAs in the treatment of patients with GERD, despite their higher initial acquisition costs [366–375]. Cost-effectiveness data from Canada [376], Sweden [377] and the USA [378, 379] arrived at similar conclusions. Maintenance PPI over a one-year period is consistently the most effective, but also the most costly intervention [376–379]. Intermittent omeprazole to treat symptomatic relapse was more cost-effective than continuous omeprazole therapy, although there was an increase in the number of symptomatic weeks per year [376]. Maintenance therapy with ranitidine or cisapride was less effective for controlling symptoms, but was of intermediate cost.

High dose H<sub>2</sub>-RA was both more costly and less effective than PPI, with more frequent relapses that ultimately led to PPI maintenance therapy [373]. Harris *et al.* [378] reported that treatment with continuous PPI becomes more cost-effective than H<sub>2</sub>-RA if patients with active symptoms of GERD experience a 9% decrement in QoL. When consider-

ing three different PPI maintenance strategies, starting continuous PPI after the second recurrence was least costly and least effective [379]. Continuous PPI started after the first recurrence added only a small increment of cost per recurrence prevented, compared with continuous PPI from the outset, which was ten times more costly [379]. However, for patients with a 22% decrement in QoL, continuous therapy became cost-effective when compared with maintenance after first relapse. All these strategies are modelled for only one year and may not be generalizable to lifelong treatment. Countering the potentially negative effect of acquisition costs is the fact that PPI unit costs have decreased substantially with the availability of multiple generic forms and OTC forms of this class of drugs.

More recent work has focused on comparisons between PPIs and various dosings. One paper using a Markov model compared low versus standard dose PPI therapy [380]. The standard dose PPI was found to be the more cost-effective strategy on the strength of the highest number of symptom-free patient-years and the quality adjusted life years gained. However, this study did not include estimates based on data from studies of esomeprazole 20mg or rabeprazole 10mg daily, two effective lower dosing regimens that may have altered the results. In another study, esomeprazole was found to be more cost-effective than lansoprazole in the maintenance of healing of erosive esophagitis [381]. In a UK study that compared all the PPIs, generic omeprazole and rabeprazole dominated the other PPIs, i.e. they cost less and resulted in more symptom free days [382].

In summary, these data support a recommendation for the use of PPIs as the most cost-effective for maintenance therapy for patients with GERD.

### Treatment of non-erosive reflux disease (NERD)

NERD or endoscopy-negative reflux disease (ENRD) is defined as GERD in the absence of macroscopic findings at endoscopy. Patients in this category are identified as having GERD, based on characteristic symptoms, occasionally an abnormal ambulatory esophageal pH test, a positive Bernstein test, or a positive symptom index and/or experience improvement with empirical acid suppressive therapy. These are patients with GERD symptoms often without objective abnormalities in other investigations undertaken.

One of the first studies in this group of patients was reported by Bate *et al.* in 1996 [383]. Patients with NERD were randomized in a double blind trial to receive omeprazole 20mg once daily (n = 98) or placebo (n = 111). At four weeks, omeprazole was more effective than placebo (p < 0.0001) with respect to the proportion of subjects with

freedom from heartburn (omeprazole 57%, placebo 19%), or regurgitation (omeprazole 75%, placebo 47%) and complete relief of symptoms (omeprazole 43%, placebo 14%).

**A1c** Patients in the omeprazole arm used less antacids and time to first heartburn-free day was more rapid with omeprazole.

Another randomized trial in 495 patients with NERD compared low dose omeprazole 10mg or a placebo for six months [163]. Placebo-treated patients were nearly twice as likely to discontinue treatment before the end of six months. Life-table estimates for cumulative remission at six months, were 73% for omeprazole and 48% for placebo (ARR 25%, NNT 4,  $p = 0.0001$ ). QoL assessments showed a more significant deterioration in the GSRS reflux domain for placebo patients ( $p < 0.05$ ), but no significant differences were noted in PGWB. Thus, a continuous dose of omeprazole 10mg daily is effective maintenance therapy for the majority of patients with heartburn but no esophagitis (NERD). However, a larger dose of omeprazole may be required for up to a quarter of patients.

A Cochrane Review evaluating short-term treatment in NERD was updated in 2006 [384], and determined that PPIs are more effective than  $H_2$ -RA therapy, but the magnitude of benefit was smaller than was observed in patients treated empirically.

A randomized trial compared omeprazole in doses of 20mg or 10mg daily and placebo in 509 patients with NERD in whom heartburn was the predominant complaint [80]. Symptomatic remission of heartburn (no more than one day of mild symptoms in the week prior to the final visit) was significantly more frequent after 2–4 weeks of therapy with omeprazole in either dose, and the standard dose of omeprazole was more effective than the lower dose. Symptom relief occurred in most patients by the end of the second week. With four weeks of treatment the proportion of patients indicating sufficient control of heartburn was 66% and 57% for the standard and low doses of omeprazole and only 31% for the placebo group. **A1c** The more abnormal the initial pH study, the better the response to a greater degree of acid suppression. There was a significant correlation of response to therapy with acid reflux, age and the presence of a hiatus hernia. No correlation was identified between body mass index and degree of acid exposure, despite the widely held view that being overweight worsens reflux. A randomized trial of four weeks' duration in NERD patients in the USA [385] found omeprazole 20mg once daily to be better than omeprazole 10mg once daily or placebo for increasing the proportion of patients with no heartburn at both day 7 (omeprazole 20mg 62%, 10mg 41%, placebo 14%) or day 27 (omeprazole 20mg 74%, 10mg 49%, placebo 23%). Omeprazole was also significantly ( $p = 0.003$ ) more effective than placebo for relief of acid regurgitation, dysphagia, epigastric pain and nausea. **A1c**

Katz *et al.* [386] reported the results of two randomized, double-blind trials with identical methodology that compared esomeprazole 40mg once daily or 20mg once daily with placebo for four weeks in 717 NERD patients. Complete resolution of heartburn was achieved in 65% of patients treated with either esomeprazole dose compared with 40% of placebo patients (ARR = 25%, NNT = 4,  $p < 0.001$ ). **A1a**

Two studies of lansoprazole in NERD patients have been reported by Richter [387, 388]. The first study [387] compared lansoprazole 15mg, lansoprazole 30mg or placebo for eight weeks. Lansoprazole patients reported less daytime and night-time heartburn and antacid usage, compared with placebo patients. The second study [388] found lansoprazole to be more effective than ranitidine 150mg twice daily or placebo. In this study, lansoprazole 15mg and 30mg daily were equally effective. **A1c**

A randomized trial compared pantoprazole 20mg once daily versus omeprazole 20mg once daily in patients with very mild grade I reflux esophagitis [389]. While these patients are not strictly a NERD population, grade I is considered by some investigators to be almost normal. The rates of symptom relief and healing were comparable at four and eight weeks. Another trial of pantoprazole 20mg once daily versus ranitidine 150mg twice daily in a similar patient group with grades 0–I GERD found pantoprazole to be superior to ranitidine [390]. **A1c** In a trial with a similar population of grade 0 and I esophagitis, pantoprazole 20mg was more effective than placebo with lower numbers of patients showing “unwillingness to continue” or numbers of additional antacids taken [391]. In a similar trial, pantoprazole 20mg and 40mg were not significantly different and both were more effective than placebo [392].

A randomized trial comparing rabeprazole (10mg or 20mg once daily) with placebo in NERD patients with moderately severe symptoms found that rabeprazole, like other PPIs, rapidly and effectively relieved heartburn [393]. Other symptoms such as regurgitation, belching, bloating, early satiety and nausea were also improved. There was no difference in efficacy between the two rabeprazole doses. A six-month on-demand trial with rabeprazole 20mg once daily was effective for symptom control in 85% of patients, limited PPI consumption to a mean of 0.3 tablets per day and improved HRQoL [394]. **A1c**

Bytzer [395] has performed a comprehensive review of the studies dealing with symptomatic GERD [80, 146, 383, 385, 387, 388, 393, 396–401]. The studies included patients with mild erosive esophagitis as well as patients with NERD. Bytzer noted that the endpoint in many of these studies was that of complete heartburn relief, a result that most patients probably do not aim for in the long term. For example, in the “on-demand” studies, patients took their PPIs once every 2–3 days, suggesting that patients accept relapse of their symptoms before they took on-demand

medication. Also, the lowest response rates were observed in the studies that evaluated complete symptom relief, compared with those studies in which the endpoint was less rigorous and which permitted continued therapy despite lack of complete symptom relief.

In summary, these data support the recommendation for the use of PPIs as being more effective than H<sub>2</sub>-RAs for the treatment of NERD, but the magnitude of the treatment effect is not as great as that seen in patients with esophagitis [402, 403]. This apparent difference in efficacy may be explained in part by the difficulty of ensuring that patients enrolled in these studies actually have GERD rather than functional heartburn or dyspepsia.

### Long-term treatment of non-erosive reflux disease

Another approach in endoscopy negative heartburn patients is the use of patient-controlled, on-demand therapy. The first methodologically sound on-demand randomized trial in 424 NERD patients compared omeprazole 20 mg or 10 mg, with placebo [400] for the outcome of time to discontinuation of treatment (due to unwillingness to continue) over a six-month period. With life-table analysis, the remission rates were: omeprazole 20 mg 83% (95% CI: 77% to 89%) omeprazole 10 mg 69% (61% to 77%) and placebo 56% (46% to 64%) ( $p < 0.01$  for all intergroup differences). **A1c** The mean number of study medications used daily was 0.43–0.47. Treatment failure was associated with more than a doubling of antacid use and deterioration in patient QoL.

The results of several “on-demand” trials with esomeprazole have been published. The first of these compared esomeprazole 20 mg once daily with placebo in 342 NERD patients for six months after initial symptom relief with PPI [401]. The proportion of patients who discontinued treatment due to lack of heartburn relief were esomeprazole 14% and placebo 51% (ARR = 37%, NNT = 3,  $p < 0.0001$ ). **A1c** Most patients took the study medication for periods of 1–3 consecutive days (esomeprazole) or 4–13 consecutive days (placebo). Use of antacids was more than two-fold higher among placebo recipients. In the second study, patients who had achieved complete heartburn resolution after short-term esomeprazole or omeprazole treatment ( $n = 721$ ) were randomized to esomeprazole 20 mg ( $n = 282$ ), 40 mg,  $n = 293$  or placebo ( $n = 146$ ) on-demand (maximum one dose/day) for six months [404]. Treatment was discontinued (due to unwillingness to continue) less often by esomeprazole treated patients (esomeprazole 20 mg 8%, 40 mg 11%, placebo 42% ARR = 34%, 0.31, NNT = 3). **A1c** Patients took an average of one esomeprazole tablet every three days.

In another trial, patients were randomized to either esomeprazole 20 mg on-demand or to lansoprazole 15 mg

daily continuously for six months [405]. Those in the esomeprazole 20 mg on-demand arm took a pill only 38% of the time as opposed to 100% of the time with lansoprazole, yet still reported greater willingness to continue taking on-demand therapy, and greater satisfaction [405]. This strategy greatly lowers the cost of treatment and the evidence from this trial indicates that not all PPI are the same with respect to maintenance.

In an open study in patients with moderate to severe heartburn but normal endoscopy, rabeprazole at the low dose of 10 mg daily was highly effective, with an 83% complete response rate at four weeks [406]. Responders entered a six-month on-demand phase of rabeprazole 10 mg vs placebo and patients in the PPI arm had significantly lower rates of strategy discontinuation and antacid use [406]. **A1d**

Cost-effectiveness analysis using a Markov model was designed to compare the following three strategies for six months: on-demand esomeprazole 20 mg daily, intermittent four-week acute treatment courses of omeprazole 20 mg daily, and continuous omeprazole 20 mg daily treatment following acute treatment. The expected number of relapses per patient was estimated to be 0.10 for the on-demand esomeprazole strategy, 0.47–0.75 for continuous omeprazole treatment and 0.57–1.12 for the intermittent omeprazole strategy. The on-demand treatment with esomeprazole 20 mg was found to be cost-effective compared with the other strategies [407]. Another study evaluated costs and effectiveness of on-demand maintenance therapy with all available PPIs: omeprazole, esomeprazole, lansoprazole, pantoprazole and rabeprazole. There were no significant differences in outcomes but differences in cost were significant [408].

A meta-analysis has also confirmed the utility of intermittent or “on-demand” therapy for milder forms of GERD. In this study adequate symptom relief and maintenance of QoL was demonstrated for on-demand therapy [365].

In summary, there is evidence that on-demand therapy for maintenance treatment of NERD is clinically effective and cost-effective.

### Adverse effects of long-term antisecretory drug use

While the short-term and long-term use of PPIs and H<sub>2</sub>-RAs has been proven to be remarkably safe and effective, the profound alteration on gastric secretory physiology that occurs with PPI use has been postulated potentially to result in deleterious effects. Even if such effects are rare, the widespread and ubiquitous use of these agents over the last 20 years and the expected continued widespread use increases the probability that even rare adverse effects may become commonly encountered clinical issues. The preponderance of data suggests that potent inhibition of parietal cell secretion can adversely impact cobalamin serum levels, although no discrete adverse clinical outcomes have been reported related to B12 deficiency [409]. There is also

concern about the possibility that PPIs raise the risk of community acquired pneumonia [410]. The Canadian Association of Gastroenterology has presented a position statement with the conclusion that an association appears to be present, but this translates into an attributable risk of one case of community acquired pneumonia per 100 years of acid suppressive use [411].

An observed association between prolonged acid suppression with PPIs and an increase in hip fracture [412–414] may not be seen until seven years or more of exposure [415]. A recent matched nested case-control study in patients without major risk factors found no increased risk of hip fracture with PPIs [416]. This result suggests that confounding factors may account for the association found in earlier studies. Additionally, Moayyedi and Cranney critically reviewed the data and found no evidence to support either causation or biological plausibility [417].

Enteric infections, particularly those caused by *Clostridium difficile*, also appear to be more common in patients taking PPIs, even away from the usual hospital based setting for these infections. The adjusted odds ratio for this infection was nearly three for those taking PPIs in a large population based controlled study [418]. A systematic review of acid suppressive drugs and the risk of enteric infections has confirmed this association, but the authors also warned that this result does not prove causation [419]. In summary, these data suggest that the safety record for antisecretory treatment is substantial and enviable, but there are potential concerns with long-term use. Population based studies indicate an association between PPI use and complications such as community acquired pneumonia, hip fracture and *C. difficile* infection but causation has not been proven. Despite the apparent rarity of these events, the recommendation to use the lowest, effective dose of antisecretory medicine needed to control symptoms is justified, given the possibility of cause and effect.

### Symptomatic gastroesophageal reflux disease: empirical therapy for uninvestigated patients

At the primary care level, patients often present with predominant reflux symptoms of heartburn or acid regurgitation with no prior diagnostic studies or trials of therapy. If these patients do not have alarm symptoms, especially if they are under the age of 50 years, there is a considerable degree of agreement that they can be treated empirically with antisecretory therapy without prior endoscopy. With this approach in mind there has been an increase in the number of studies in patients with GERD-like symptoms without any initial investigations, i.e. studies in which therapy is studied in uninvestigated patients with the predominant symptom of heartburn. These studies obviously

include a mixed group of patients, many of whom do not have esophagitis and some in whom GERD is not the cause of their symptoms.

A randomized trial that included 424 patients with a history of proved esophagitis enrolled from general practices in the UK [420] showed that omeprazole 20mg once daily was more effective for relief of heartburn and regurgitation than ranitidine 150mg twice daily for four weeks (omeprazole 59%, ranitidine 27%, ARR = 22%, NNT = 5).

**Ala** The prior history of esophagitis limits generalizability of this study to all patients in primary care practices, but the good relief of symptoms regardless of initial symptom severity is noteworthy.

In a trial in primary care settings in the USA, 590 patients with moderately severe symptomatic GERD were randomized without endoscopy to receive ranitidine 150mg twice daily or a placebo [421]. Ranitidine rapidly and significantly improved heartburn severity scores, physician global assessment of the response to treatment, and the SF-36 score for physical functioning, bodily pain and vitality dimensions. **Ala** Using a heartburn specific questionnaire a significant improvement in all dimensions: physical, heartburn pain, sleep, diet, social functioning and mental health was observed for ranitidine-treated patients.

In another trial conducted in the USA, uninvestigated heartburn patients were randomized to receive either ranitidine, lansoprazole or stepped up therapy from ranitidine to lansoprazole or stepped down therapy from lansoprazole to ranitidine [422]. The continuous lansoprazole treatment was more effective than the other strategies in terms of reducing heartburn severity and increasing the number of heartburn-free days, and there appeared to be little rationale to stepping down to ranitidine.

A randomized trial [423] of 307 patients with GERD symptoms in Australian primary care settings showed that even a low dose of pantoprazole (20mg daily) was significantly more effective than ranitidine 300mg daily for complete control of symptoms at four weeks (40% vs 19%;  $p < 0.001$ ), eight weeks (55% vs 33%;  $p < 0.001$ ), six months (71% vs 56%;  $p = 0.007$ ) and twelve months (77% vs 59%;  $p = 0.001$ ).

In the CADET-HR randomized, double blind trial in Canadian primary care settings, 390 patients with reflux predominant symptoms were randomized to receive ranitidine 150mg twice daily or omeprazole 20mg daily [424]. Heartburn relief at four weeks was reported by 55% of omeprazole and 27% of ranitidine-treated patients (ARR = 22%, NNT = 5). **Ala** Greater improvements in GSRS for indigestion, abdominal pain, and reflux ( $p < 0.05$ ) and in the GASTROQoL health-related QoL scales ( $p < 0.003$ ) were also observed in omeprazole patients. After four weeks, patients with inadequate symptom relief were stepped up every 4–8 weeks from ranitidine to omeprazole 20mg once daily or from omeprazole 20mg once to twice

daily [424]. “Step up” occurred in 100 patients with ranitidine and 57 with omeprazole. With step-up therapy, by 16 weeks, heartburn relief resulted in 88% of patients who started with omeprazole and in 87% of those who started with ranitidine. **Ala** In the first eight weeks, omeprazole provided complete heartburn relief in 53% while it took 16 weeks to achieve a similar degree of relief in the group who were treated initially with ranitidine. Thus, starting with omeprazole therapy produced significantly faster symptom relief. Patient responders then had the medications stopped and 50% of patients experienced symptomatic relapse within nine days [424]. Only 10% of patients had no further relapse over a six-month period of follow-up.

In a Cochrane Review evaluating short-term treatment in symptomatic, non-endoscoped patients updated in 2006 [384], van Pinxteren *et al.* identified 15 empiric treatment trials. The relative risk for heartburn remission in placebo-controlled trials was 0.37 for PPI, 0.77 for H<sub>2</sub>-RAs and 0.86 for prokinetics. In direct comparative trials PPIs were significantly more effective than H<sub>2</sub>-RAs (seven trials, RR 0.66, 95% CI: 0.60 to 0.73) and prokinetics. Thus, PPIs were superior to H<sub>2</sub>-RAs in empirical treatment of typical GERD symptoms. **Ala**

In a large, methodologically sound, double-blind, randomized trial in 3034 patients in 360 sites in the USA, patients with symptomatic, uninvestigated GERD symptoms received lansoprazole 30mg once daily or esomeprazole 40mg once daily [425] and heartburn assessments were carried out at days 1, 3, 7 and 14. The study setting was unclear and was unlikely to include only primary care practice. No statistically significant difference in heartburn relief was observed [425]. **Ala** Patients indicated that they were very pleased with their treatment, experienced substantial benefit and would recommend the medication to others. However, nearly 40% of patients still had some degree of day or night heartburn at the end of two weeks.

More studies are now available that compare various PPIs. Furthermore, longer term maintenance studies to assess the effectiveness of PPIs are now available [426–430]. In a Norwegian study, patients were initially treated with esomeprazole 40mg for four weeks. They were then randomized to esomeprazole 20mg daily continuously or on-demand, or to ranitidine 150mg twice daily for six months [428]. Either esomeprazole strategy gave better symptom relief and better patient satisfaction than was observed with ranitidine, indicating that on-demand therapy is a viable option.

In a rabeprazole study 331 uninvestigated heartburn-predominant patients, were treated with rabeprazole 20mg daily for four weeks [427]. Responders were then randomized to receive either rabeprazole 20mg continuously daily (COT) or on demand (ODT) for six months. Not surprisingly, the continuous therapy arm experienced a greater mean percentage of heartburn-free days (COT

90.3%  $\pm$  14.8%, ODT 64.8%  $\pm$  22.3%,  $p < 0.0001$ ). Ninety-two percent of COT patients and 79% of ODT patients were either “satisfied” or “very satisfied” with treatment. While COT provides better symptom improvement, both strategies were acceptable [427].

An interesting study evaluated a patient’s willingness to pay for complete symptom relief in GERD [431]. The authors found that patients were willing to pay up to US\$182 to obtain more complete and faster symptom relief without side effects. Older patients were less willing to pay than younger patients to obtain symptom relief.

In summary, these data support a recommendation for the use of empirical antisecretory therapy for patients presenting with symptoms thought to be caused by GERD, without performing confirmatory diagnostic testing.

### Economic evaluation in uninvestigated symptomatic heartburn

The costs and effectiveness of each drug and of each management strategy need to be evaluated. However, there are many subtle variations between studies that render direct comparisons difficult. Furthermore, decision analyses suffer from the inherent weakness of having to rely on estimates of treatment outcomes. Ofman recently reviewed the cost-effectiveness studies in symptomatic GERD [432]. He concluded that the most cost-effective strategies are PPI based step-down or PPI on-demand strategies [432]. He noted that most decision analyses had been constructed around uninvestigated GERD symptoms.

One recent study comparing esomeprazole 20mg daily or on-demand provided estimates of similar efficacy with either strategy but reduced cost of the on-demand strategy over six months [426]. Similarly, it has been shown that esomeprazole 20mg daily on-demand is more cost-effective than esomeprazole 20mg continuously or than ranitidine [429]. In a large trial of 1357 uninvestigated heartburn patients, the esomeprazole 20mg on-demand strategy was less costly, with comparable efficacy and satisfaction to esomeprazole 40mg prescribed intermittently by the physician for either two or four weeks [430].

In summary, on-demand therapy requires that a patient becomes symptomatic before self-treating. However, patient satisfaction with this approach is high, and this management strategy is cost-effective and is recommended.

### Does symptom improvement predict healing of esophagitis?

There is evidence that relief of symptoms by H<sub>2</sub>-RAs does not reliably predict healing of mucosal damage. Patients with heartburn initially treated in a four-week study with omeprazole or cimetidine [433] were randomized to receive

maintenance therapy with either omeprazole 10 mg once daily or cimetidine 800 mg qhs for 24 weeks [434]. Symptomatic remission, defined as no more than mild heartburn on one out of the seven previous days, was significantly more frequent with omeprazole (omeprazole 60%, cimetidine 24%; ARR 36%, NNT 3). Erosive esophagitis was seen in only 10% of patients in symptomatic remission on omeprazole compared with 33% on cimetidine.

One-third of patients with relapse of erosive esophagitis by endoscopy during maintenance therapy with famotidine 40 mg twice daily were completely asymptomatic [435].

A meta-analysis [333] suggested that if heartburn resolved, only 4.5% of patients treated with omeprazole 20 mg once daily, but 14.6% with ranitidine 150 mg twice daily, experienced asymptomatic relapse of erosive esophagitis at endoscopy. **A1c**

The more recent trials show that significantly fewer esomeprazole-treated patients had persistent esophagitis, despite symptom relief, than is the case for omeprazole-treated patients [32, 290]. In patients with heartburn resolution at four weeks, esophagitis remained unhealed in 14.8% [290] to 16.8% [32] of patients receiving esomeprazole 40 mg daily compared with 23.2% [290] to 26.9% [32] of those receiving omeprazole 20 mg daily. **A1a** A similar result was seen in a comparison of esomeprazole 40 mg daily and lansoprazole 30 mg daily, with unhealed esophagitis in spite of heartburn resolution in 17.3% and 20.5% of these patients [284]. In the most severe forms of esophagitis, the healing was 11% more frequent for grade C and 17% for grade D disease in esomeprazole-treated patients. It is unclear why, despite effective symptom resolution, many patients still have esophagitis. The most likely explanation in these studies is that when patients were healed at four weeks, they came out of the studies, and the healing and symptom resolution could not be assessed at eight weeks. In all these studies, esophagitis healing was much more frequent at eight weeks than at four weeks. Therefore, if patients been endoscoped at that interval, the proportion of healed patients among those with heartburn resolution would have probably been higher.

In summary, these data demonstrate that esophagitis relapse is unusual in patients who remain asymptomatic while being treated with PPIs, but relapse is more common in those without symptoms who are being treated with an H<sub>2</sub>-RA. Thus, continuous PPI therapy is recommended as maintenance therapy in patients with esophagitis, particularly with more severe esophagitis.

## Treatment of esophageal peptic stricture

Esophageal peptic stricture, the most severe GERD complication, can be difficult to manage. H<sub>2</sub>-RA are at best mar-

ginally more effective than a placebo for reducing the need for repeat dilatations [436, 437]. One study found no benefit from ranitidine 300 mg daily compared with placebo [438]. There are three randomized trials comparing standard dose omeprazole 20 mg daily with H<sub>2</sub>-RA [439–441] and one comparing lansoprazole with high dose ranitidine [442].

In one small study [440], 34 patients with strictures were randomized to receive omeprazole 20 mg once daily, or ranitidine 150 mg or famotidine 20 mg twice daily. After three months, if esophagitis remained unhealed, the dose of medication was doubled and the patient was re-endoscoped at six months. At three months, there was no significant difference between PPI and H<sub>2</sub>-RA for esophagitis healing or relief of dysphagia, although there was a trend in favor of the PPI. By six months, omeprazole treatment resulted in significantly better healing of esophagitis (omeprazole 100%, H<sub>2</sub>-RA 53%; ARR 47%, NNT 2;  $p < 0.01$ ) and relief of dysphagia (omeprazole 94%, H<sub>2</sub>-RA 40%; ARR 54%, NNT = 2;  $p < 0.01$ ). **A1d** *Post hoc* analysis also showed a trend toward reduction in the proportions of patients requiring dilatations in omeprazole-treated patients (omeprazole 41%, H<sub>2</sub>-RA 73%; ARR = 32%, NNT = 3,  $p = 0.07$ ). The number of dilatations required was significantly less for the omeprazole treated patients (11 vs 31 dilatations, mean of 0.6 vs 2.1 sessions per patient,  $p < 0.01$ ). Cost-effectiveness analysis for healing and relief of dysphagia, that included costs of drugs, endoscopy and dilatations, and management of perforations, showed that omeprazole was 40–50% more cost-effective than H<sub>2</sub>-RA.

A second adequately powered trial compared constant doses of omeprazole 20 mg once daily and ranitidine 150 mg twice daily for one year [439]. Endoscopy was done as required and at the end of the study. Repeat dilatation was required less frequently in omeprazole-treated patients (omeprazole 30%, ranitidine 46%; ARR = 16%, NNT = 6). **A1c** Fewer dilatation sessions were required in omeprazole-treated patients (omeprazole 0.48, ranitidine 1.08;  $p < 0.01$ ). Omeprazole was also superior with respect to the number of patients without stricture at the end of the study, esophagitis healing and improved heartburn and dysphagia.

In a study of 158 patients over six months, lansoprazole 30 mg daily was more effective than ranitidine 300 mg twice daily for relieving dysphagia. There was a trend toward a reduction in the need for repeat dilatations (lansoprazole 30.8%, ranitidine 43.8%;  $p = 0.09$ ) over 12 months [442]. **A1d**

Omeprazole 20 mg once daily was found to be more effective but more expensive than ranitidine in a cost-utility study [443].

In an observational study 30 of 36 patients with reflux esophagitis and stricture treated with dilatation and omeprazole 20 mg twice daily for 6–8 weeks experienced

healing of esophagitis and relief of dysphagia [444]. These 30 patients were then randomized to receive omeprazole 20mg twice daily, lansoprazole 30mg twice daily or pantoprazole 40mg twice daily ( $n = 10$  each arm). After four weeks of treatment, significantly more omeprazole-treated patients remained healed, but no difference was seen with respect to the need to repeat dilatation of strictures. This small study may lack power to demonstrate differences between effects of these strategies. **A1d**

In summary, these data lead to the recommendation for the use of PPI vs an  $H_2$ -RA in those with peptic strictures as a means of reducing recurrence of the stricture or symptomatic dysphagia following dilatation.

---

## Endoscopic treatments

Several endoscopic techniques for treating GERD have now been investigated and all demonstrated some early promise [445–452]. However, all of these techniques (injection, radiofrequency ablation, endoscopic stapling and or suturing), were either less effective than hoped, produced more adverse effects than anticipated or were too expensive or complex to be incorporated into clinical practice. All have either been withdrawn from the marketplace or remain as investigational tools. A recently published systematic review details the devices, and preclinical and clinical studies published up to the end of 2006, before this field collapsed from a clinical standpoint [453]. However, there continue to be developments in endoscopic anti-reflux therapies, and one or more of these devices may be introduced for clinical use in the foreseeable future.

---

## Anti-reflux surgery

### Medical therapy versus surgical anti-reflux therapy

Early randomized trials comparing open anti-reflux surgery (ARS) with medical therapy ( $H_2$ -receptor antagonists and or prokinetic agents) demonstrated that surgery was more effective than medical therapy in treating patients with esophagitis [454, 455]. However, these studies are no longer relevant, since they did not compare present day medical therapy with PPIs with surgical therapy using laparoscopic techniques. Spechler *et al.* have provided an update of a cohort of patients from the original study [456]. They were able to account for 97% (239/247) of the original cohort, 79 of whom had died. After a mean of 9–10 years follow-up, of the surviving and measurable patients 92% of the medical treated patients and 62% of the surgically treated patients ( $p < 0.001$ ) were regularly taking anti-reflux medications. Patients with Barrett's esophagus at

baseline developed esophageal adenocarcinomas at an annual rate of 0.4%, whereas these cancers developed at a lower 0.07% annual rate in patients without Barrett's. This study indicates that anti-reflux surgery should not be recommended, with the expectation that patients with GERD will no longer need to take antisecretory medications or that the procedure prevents esophageal cancer among those with GERD and Barrett metaplasia. **A1c**

There are few direct comparisons of a PPI versus anti-reflux surgery. The first was a study by Lundell *et al.* with five-year follow-up [328]. Three hundred and ten patients were randomized to receive open surgical fundoplication or continuous omeprazole therapy and followed for up to five years. Only 11 of 155 patients randomized to surgery refused the treatment. Omeprazole-treated patients were allowed dose increases to 40–60mg daily to control symptoms. No significant differences in efficacy were demonstrated and QoL assessments (PGWB and GSRS) improved in both groups. Thus, surgical therapy was demonstrated to be as effective as continuous omeprazole therapy in this trial. **A1a** However, laparoscopic fundoplication, the technique that is now widely used, was not performed. The seven-year follow up suggested that surgery was more effective than omeprazole but there were specific post-fundoplication complaints that remained problematic [457]. A more recent, short-term observational study compared the efficacy of laparoscopic fundoplication and lansoprazole in normalizing abnormal reflux in patients with GERD [458]. After anti-reflux surgery, all 55 patients were heartburn free, and esophageal pH-monitoring 3–6 months after surgery was normal in 85% of patients. Patients treated with lansoprazole were titrated upwards to 90mg daily and esophageal acid exposure was normalized in 96% of cases. Patients who became heartburn free did not necessarily normalize their esophageal acid exposure. The results suggest that either approach may be reasonable for any given patient. **B4**

A more recent study has compared outcomes of modern laparoscopic ARS and potent antisecretory therapy using esomeprazole. In this three-year interim analysis of 554 patients with GERD randomized as part of an open-label prospective randomized trial comparing laparoscopic ARS to esomeprazole, the proportion of patients in remission in the two groups was similar (surgically treated 90%, and medically treated 93%) in an intention to treat analysis [459].

These data do not support the contention that either anti-reflux surgery or use of PPIs is a more effective GERD therapy, as both are safe and similarly effective therapies [460]. Surgical proponents often argue that medical therapies do not correct the underlying anatomical abnormalities. However, there are no long-term data to support the view that surgery achieves this result permanently either. One small follow-up observational study of patients after

20 years demonstrated that about 30% of the fundoplications were defective, and abnormal reflux on esophageal pH studies was also seen in about 30% of patients assessed [461]. **B4** Another study of 441 patients after a mean follow-up of 18 years following the Hill procedure for GERD, reported good and excellent subjective results in 80% of patients [462]. **B4** A ten-year follow-up study after laparoscopic anti-reflux surgery suggested that while 89% would select surgery again, 28% were taking acid suppressive drugs [463]. Thus, the long-term results of fundoplication are good but not completely durable. Even after one year, 6% of patients will require PPI therapy [464]. A retrospective questionnaire of 844 patients at a mean of six years after ARS identified that 26% of patients still had abnormal pH despite being on medication and in total, 37% were taking acid suppressive therapy [465]. There is also no credible evidence that surgery prevents progression to Barrett's metaplasia or protects against esophageal cancer, an often claimed benefit of surgery [464].

One randomized trial of open versus laparoscopic fundoplication [466] found no difference between the two approaches and more than 85% of patients were satisfied with their results. The major advantage for laparoscopic fundoplication is a significant reduction in hospital stay from 8–9 days for an open procedure to 2–5 days [467–469], and less time off work for the patient (laparoscopic 21.3 days, open surgery 38.2 days,  $p = 0.02$ ) [468]. Thus, the procedure of choice is laparoscopic fundoplication; **A1d** however, data on long-term outcomes are lacking.

Surgical results continue to depend on surgical expertise, and the issue of a learning curve remains [468, 470]. An intra-operative complication rate of 8% has been reported [470]. The most frequent adverse effects are dysphagia, inability to belch or vomit, postprandial fullness, bloating, pain and flatus [471]. Also, laparoscopic fundoplication is not without serious complications such as esophageal perforation, paraesophageal herniations, pneumothorax and splenic damage requiring splenectomy [472].

For some patients, there may be incomplete symptom relief with PPI therapy. In one randomized trial of anti-reflux surgery and omeprazole, those patients who were not improved on omeprazole 40mg daily were offered anti-reflux surgery and fared well [464]. **B4** Thus, some patients with a partial response to PPIs may improve with anti-reflux surgery. However, it is of concern that 6/178 (3%) of these patients experienced postoperative complications that necessitated reoperation.

The best results with ARS are obtained in the patient with typical reflux symptoms, an abnormal esophageal pH study and good symptomatic response to PPIs [473]. Thus, the best indication for surgery is a patient who responds well to PPI but does not wish to take continuous medications to control their reflux [474, 475]. **B4 C5** With the relative ease and safety of laparoscopic surgery, it has become

a reasonable alternative for selected patients. As with all surgery, patient selection has improved through objective testing with pre-operative esophageal pH-metry and manometry. Even if cost-effectiveness modelling studies favor surgery, a decision to have surgery should not be imposed upon a patient. Ultimately, the final decision should rest on the preferences of an informed patient.

In summary, these data lead to a recommendation that surgery can be offered as an effective alternative to medical therapy in patients with reflux. The patients most likely to benefit from this treatment are patients who have been effectively treated for their symptoms with medication. Neither medical therapy nor surgery has proven more effective than the other in managing GERD symptoms or avoiding the complications of this disorder, and treatment choices should be based on patient preference for treatment.

### Introduction

Barrett's esophagus was first described by Norman Barrett in 1957 [1]. It is a condition in which the normally squamous mucosa of the esophagus is replaced by metaplastic columnar epithelium due to injury from gastroesophageal reflux. Barrett's esophagus is thus one of the complications of gastroesophageal reflux disease (GERD). Its importance is derived entirely from its association with esophageal adenocarcinoma, the latter of which develops in approximately 0.5% of patients with Barrett's esophagus per year [2].

### Definition

The definition of Barrett's esophagus has changed over the last several years. From its original description as a columnar-lined lower esophagus [1, 3], to one requiring at least 3 cm of circumferential columnar lining or intestinal metaplasia [4], it has evolved most recently to the presence of any length of columnar epithelium in the tubular esophagus that is characterized histologically as intestinal metaplasia [5, 6]. In keeping with this evolution in diagnostic criteria the Practice Parameters Committee of the American College of Gastroenterology has most recently defined this entity as "a change in the distal esophageal epithelium of any length that can be recognized as columnar-type mucosa at endoscopy and is confirmed to have intestinal metaplasia by biopsy of the tubular esophagus" [7].

There are three important components to this definition that are worth highlighting. First, intestinal metaplasia must be present. It has been argued, however, that, even if

not present initially, intestinal metaplasia could be subsequently identified in endoscopically characteristic columnar mucosa. This has led to proposals from the British Society of Gastroenterology to exclude the requirement of intestinal metaplasia from the definition of Barrett's esophagus [8]. However, the clinical significance of changing the definition is unclear, since it is the intestinal specialized epithelium that is associated with adenocarcinoma [6, 9, 10].

Second, this definition encompasses not only the classical Barrett's esophagus ( $\geq 3$  cm of columnar-lined mucosa of the distal esophagus with intestinal metaplasia) but also short segment Barrett's esophagus (SSBE) defined as specialized columnar epithelium lining less than 3 cm of the distal esophagus [11]. Although the risk for developing dysplasia and esophageal cancer with SSBE is lower than with classical longer-segment Barrett's esophagus (LSBE) (OR 0.55), it is not statistically significantly less. Moreover, as SSBE is much more common than LSBE, most adenocarcinomas arising from Barrett's likely arise in SSBE not LSBE even if the incidence in LSBE is higher [12–18].

Finally, intestinal metaplasia must be present in the tubular esophagus (not just the gastric cardia) for a diagnosis of Barrett's esophagus, as the latter does not have the same implications as intestinal metaplasia of the tubular esophagus and may actually be a variant of a normal histological finding of the cardia.

### Epidemiology

#### Incidence and prevalence

The estimates of prevalence of Barrett's vary according to the population studied and the definition used. Approximately 6–12% of patients undergoing endoscopy for symptoms of GERD have documented the presence of Barrett's esophagus, with the majority having SSBE ( $\approx 6$ –10% versus 5% LSBE) [12, 19–21]. In patients with mod-

erate to severe erosive esophagitis, rates of underlying Barrett's esophagus may be as high as 27% [22]. For patients with dyspeptic symptoms as opposed to only GERD symptoms, the prevalence was 2.4% [23]. Another study of dyspeptic patients obtained a rate of only 0.3%, but this estimate excluded patients with alarm symptoms and those over 45 years [24]. Others have also obtained an estimate of  $\leq 1\%$  in unselected patient populations undergoing endoscopy [12, 25, 26]. Autopsy studies, on the other hand, suggest that the prevalence of Barrett's esophagus is about 21 times higher than that detected endoscopically, and these data suggest that the vast majority of patients with Barrett's esophagus remain unrecognized [27].

The incidence of Barrett's esophagus has continued to increase since the 1970s, and has now reached approximately 10 new cases per 100,000/year [28–30]. The median age of development of the condition has been estimated at 40 years and the mean age at diagnosis at 63 years of age [25]. Although this increase in incidence parallels the increasing use of endoscopy, this is probably not the only explanation, and the true incidence has probably increased as well.

### Risk factors

Barrett's esophagus appears to occur predominately in male Caucasians [6, 19]. Although the prevalence of Barrett's esophagus in black, Asian and Hispanic populations has been occasionally found to be higher than expected [31–33], most observational data suggest that the prevalence of Barrett's esophagus is significantly lower (OR 0.35) for these groups compared to white populations [34, 35]. One might expect that as lifestyle and dietary habits change in developing regions, the prevalence will approximate that of the Western World. The decreasing prevalence of *Helicobacter pylori* infection has also been suggested to play a role in the increased incidence, but this association, although plausible, is controversial [36–38].

In addition to age, gender and race, longer duration of GERD is also a risk factor for Barrett's esophagus [19, 38, 39]. Compared to patients with reflux symptoms of less than one year, Barrett's esophagus was three times more common if reflux symptoms were present for one to five years, five times more common for symptoms present for five to ten years, or more than six times more common if reflux symptoms were present longer than ten years [39]. Increased severity of nocturnal reflux symptoms [38–40] and increased complications of GERD such as esophagitis, ulceration, and bleeding are also associated with an increased prevalence [38] but the evidence regarding association with peptic strictures is conflicting [38, 41, 42]. There is also an association of hiatal hernia with Barrett's esophagus [43, 44]. Although these findings are associated with a higher prevalence of Barrett's esophagus, many

patients with this condition have reflux symptoms no different than those experienced by other GERD patients [27, 45].

Within the last ten years, some controversy in the literature has emerged concerning the suggestion that obesity is a risk factor for reflux and, by extension, Barrett's esophagus and esophageal adenocarcinoma. Recently, it has been shown that visceral fat deposition that is associated with an increased abdominal circumference (greater than 80 cm) appears to confer perhaps the greatest risk association, potentially explaining the male predominance of Barrett's esophagus [46]. The reasons for this are not entirely clear, but it has been hypothesized that the metabolic activity of visceral fat interferes with the production of cytokines that protect against carcinogenesis [47].

Recently, some data have emerged implicating diet in the relationship between GERD, Barrett's and cancer. In a case-control study, the odds ratio of Barrett's was significantly less in the highest quartile of fruit/vegetable consumers (OR 0.25–0.56) compared with the lowest quartile. Supplemental antioxidants (Vitamin C, E and beta carotene) did not appear to affect the odds ratios [48]. Another recent study examining the effect of "Western" diet (fast-food and meat-based) versus "health-conscious" diet (fruits, vegetables, and non-fried fish) demonstrated a clear advantage for the latter in the association with Barrett's (OR 0.35) [49]. Although no randomized trials have been conducted as of yet, such findings suggest a possible benefit to a diet rich in fruits and vegetables with minimal meat or fast-food consumption in decreasing the incidence of Barrett's and its associated complication of esophageal adenocarcinoma.

### Natural history

The survival of a patient with Barrett's esophagus is very similar to that of patients with benign esophageal disorders such as achalasia or Schatzki's ring [50]. The overwhelming majority of patients with Barrett's esophagus will never develop esophageal adenocarcinoma. Yet, if it were not for this association, Barrett's esophagus would not have much clinical importance.

Early studies estimated the incidence of esophageal adenocarcinoma in Barrett's esophagus at 1–2% per annum. More recent analyses of epidemiologic studies have suggested an incidence ranging from 0.5 to 0.6% per annum, in part due to publication bias of the more positive results with initial studies [50]. This incidence is also probably an overestimate as it likely reflects a higher risk population, with men progressing twice as quickly as women [51–56].

Nevertheless, Barrett's esophagus is definitely associated with the occurrence of esophageal adenocarcinoma (EAC), and this cancer is on a dramatic rise in Western societies.

Since the mid-1970s, the incidence of EAC in Caucasian men from the USA rose from 0.7/100,000 person-years to an estimated 5.69/100,000 person-years by 2004 [12, 30]. This rise is not thought to be due to the previous misclassification of gastroesophageal junction esophageal carcinomas as gastric cancer, since there has not been a concomitant decrease of gastric cardia cancers [12]. The proportion of esophageal cancer due to adenocarcinoma has also increased substantially in the same period, but the absolute number of all esophageal cancers is still quite low in comparison to colorectal cancer, for example, which is ten times more common [12, 57]. Indeed, EAC remains a relatively uncommon cancer, ranked fourteenth for males and eighteenth for females in estimated new cancer cases in Canada in 2008 [58].

The length (extent) of Barrett's esophagus is a risk factor for esophageal adenocarcinoma. A landmark study published in 2000 showed that a 5 cm difference in segment length was associated with a 1.7-fold (95% CI: 0.8–3.8) increase in cancer risk [17]. Although this difference is not statistically significant, a similar association has been repeatedly demonstrated. A meta-analysis published in 2007 demonstrated a statistically significant increase in adenocarcinoma with longer segments of Barrett's esophagus [18]. Other reported risk factors for esophageal adenocarcinoma include severity, frequency and duration of reflux symptoms [59–61], size of hiatal hernia [62], obesity [63], smoking [64] and a diet low in raw fruit content [65]. The use of medications that reduce the lower esophageal sphincter pressure has also been found to be associated with esophageal cancer, in some but not in all studies [66, 67]. Also controversial is the possibility that *H. pylori* protects against GERD and esophageal cancer. A meta-analysis of twenty studies demonstrated a lower prevalence of *H. pylori* in patients with GERD (OR 0.6) [68]. A beneficial effect of *H. pylori* on reducing the risk of development of esophageal adenocarcinoma (OR 0.37 in patients under 50 years of age) has also been suggested by a case-control study [69]. It appears that infection with *cagA* + *H. pylori* is particularly protective [70, 71]. One study found the prevalence of *H. pylori* infection with *cagA* + strains to be inversely associated with GERD complications (non-erosive GERD 41% *cagA* +, erosive GERD 31%, Barrett's esophagus 13% and Barrett's with dysplasia or adenocarcinoma 0%) [70]. These apparent associations, however, still remain controversial and are not necessarily causal (or protective).

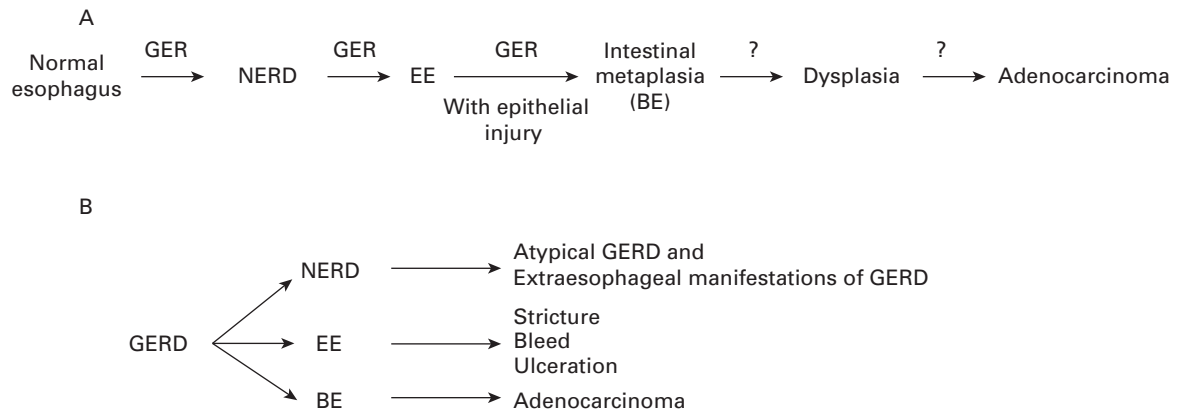

The presence and degree of dysplasia associated with Barrett's esophagus is also a risk factor for the subsequent development of esophageal adenocarcinoma. Dysplasia is a histological diagnosis primarily considered as absent, indefinite, low grade, or high grade. There is significant interobserver variability (less than 50% agreement) in the interpretation of low grade dysplasia and there are few prospective studies related to risk [72, 73]. Estimates of

progression from normal, indefinite or low-grade dysplasia to high-grade dysplasia or adenocarcinoma are highly variable but there appears to be a low risk [73]. Patients with high-grade dysplasia, however, have been shown to have a substantially increased risk of cancer. Reid *et al.* [74] found that cancer developed in 33 of 76 patients (43%) with high grade dysplasia, compared to 9 of 251 (4%) with negative, indefinite or low-grade dysplasia by five years. The results from different studies, however, vary substantially with five to seven-year cumulative cancer incidence estimates of 16% to 59%. This variation largely appears to be related to prevalent cancers (those found within a year of diagnosis of cancer) suggesting that the lower rate is the more accurate [72, 75, 76]. Other studies have suggested that flow cytometry can also be used to predict outcome [74].

## Pathogenesis

Barrett's esophagus is felt to result from a perturbation in the repair of mucosal injury of the esophagus in an abnormal milieu of gastroesophageal reflux (abnormally acidic and/or acid- and bile-exposed esophageal environment) in a genetically predisposed individual. This hypothesis is based, in part, on animal studies, that demonstrated that excision of the esophageal mucosa results in re-epithelialization of the esophagus with columnar epithelium only if performed in an environment of acid reflux or acid and bile reflux [77, 78]. Although there is no direct human experimental evidence that reflux causes Barrett's esophagus, this theory is supported by human ambulatory esophageal pH monitoring studies, which demonstrate a greater esophageal acid exposure in patients with Barrett's esophagus compared to GERD patients without Barrett's esophagus [79, 80]. In addition, the duration of esophageal acid exposure correlates with the length of Barrett's esophagus [81]. The increase in esophageal acid exposure does not appear to be due to increased acid production, as no difference is present in gastric acid outputs [82].

The most widely accepted conceptual approach to GERD is that it represents a spectrum of disease that ranges from non-endoscopic reflux disease (NERD) to esophagitis, Barrett's esophagus, dysplasia and esophageal adenocarcinoma (Figure 3.1a). Acid reflux is felt to contribute to esophagitis and Barrett's, but the cause of development of dysplasia in Barrett's patients is unknown. Patients with NERD, however, uncommonly develop erosive esophagitis [83] and Barrett's esophagus is almost always diagnosed on first endoscopy [84]. It is for this reason that Fass *et al.* [85] have suggested a new conceptual model that divides GERD into three distinct groups of patients: NERD, erosive esophagitis and Barrett's esophagus (Figure 3.1b). They suggested that patients do not usually move into a differ-

**Figure 3.1** (a) Conventional concept for GERD.

(b) New concept of GERD as three distinct entities and complications associated with each, Fass *et al.* [85].

ent group, but each group has its own potential complications (noted in Figure 3.1b).

## Diagnosis

As noted previously, the diagnosis of Barrett's esophagus requires the demonstration of intestinal metaplasia on targeted biopsy sampling of endoscopically abnormal appearing esophageal mucosa [7]. The definition and diagnosis of Barrett's is difficult for several reasons. First, there are no symptoms specific for this condition. For the most part, the symptoms are essentially identical to those of GERD and most patients are asymptomatic [27]. In addition, accurate identification of the location of the gastroesophageal junction is required in order to determine if the squamo-columnar junction is displaced proximal to this location, since this displacement is what alerts the endoscopist to the possibility of the diagnosis of Barrett's and thus leads to biopsy of the mucosa. The former junction can at times be very difficult to determine endoscopically because of the presence of a hiatal hernia, esophagitis, and the constant movement of the area. This is highlighted by a multicenter study in which only 72% of the endoscopists correctly recorded endoscopic landmarks in the diagnosis of Barrett's esophagus [86]. SSBE can thus be particularly difficult to identify and distinguish from an irregular Z line (a normal anatomical finding). This is very important because intestinal metaplasia in the gastric cardia does not seem to have the same implications as intestinal metaplasia of the esophagus and, indeed, may be a normal histological finding in this location. Erythema or erosive esophagitis can also impair the visual recognition of Barrett's esophagus, and repeat endoscopy after treatment with acid suppression may be necessary to make the diagnosis of Barrett's in this situation [87].

Currently, intestinal metaplasia is a prerequisite in order to make the diagnosis of Barrett's esophagus. This fact, however, seems not to be fully understood as some pathologists continue to classify patients without intestinal metaplasia as Barrett's esophagus. In one study, correct identification of intestinal metaplasia without dysplasia occurred in only 35% of 20 community-based pathologists [88]. The hematoxylin and eosin stain combined with alcian blue at pH 2.5 can be used to facilitate the recognition of the acid mucin-containing goblet cells characteristic of intestinal metaplasia [5].

A further difficulty with diagnosis is sampling error. When obtaining biopsies for Barrett's esophagus, samples may miss the area with metaplasia and hence fail to lead to the diagnosis. This addresses the important issue of the number of biopsies required; intuitively, the more endoscopic biopsies taken, the more accurate the diagnosis of Barrett's. It has also been suggested that endoscopic adjuncts such as chromoendoscopy and/or narrow band imaging (NBI) may help in targeting biopsies and thus increase the diagnostic yield. Methylene blue, toluidine blue, indigo carmine, and Lugol's iodine have all been used as chromoendoscopic agents to identify specialized intestinal metaplasia as well as the characteristic surface patterns suggestive of neoplasia [89–92]. These contrast agents are sprayed over the esophageal mucosa at the time of endoscopy, with areas of intestinal metaplasia and dysplasia demonstrating a variety of characteristic staining patterns. However, interpretation of the staining process may be tedious, and the results are not necessarily reproducible [93]. More recently, the pairing of magnification endoscopy [94] with narrow-band imaging (NBI) has emerged as a new modality that may obviate the need for staining altogether.

Dysplasia is only detectable histologically. Dysplasia, the next step in the neoplastic process, represents a change in

architecture of the metaplastic glands and is associated with individual cellular nuclear abnormalities. Dysplasia is felt to progress along a continuum from no dysplasia to low-grade dysplasia, high-grade dysplasia and finally adenocarcinoma, although the time course of this progression is highly variable and not inevitable. Furthermore, it is likely reversible in the stages leading up to adenocarcinoma. Dysplasia is often focal and not easily detectable endoscopically without the aid of stains, magnification and narrow-band imaging, rendering the targeting of biopsy sampling difficult. It has been established that random biopsies taken every 2 cm detect 50% fewer cancers than four-quadrant biopsies taken every 1 cm [95]. The latter approach has yet to be recommended in formal guidelines because of the effort involved in following such an intensive biopsy protocol. In addition, there is significant inter-observer variation in the diagnosis and grading of dysplasia by both academic and non-academic pathologists [12]. Reactive change due to esophagitis is difficult to distinguish from dysplasia and further compounds the problem. However, recent data from a randomized controlled trial demonstrated that roughly half the biopsies are required to detect dysplasia with methylene blue-targeting compared with four-quadrant biopsies every 2 cm within Barrett's metaplasia [96]. Furthermore, the combination of NBI and high-magnification endoscopy reportedly identifies microstructural changes suggestive of dysplasia with a sensitivity and specificity of 90% and 100% respectively [97]. Although not formally recommended yet, such advances in endoscopic imaging are likely to be incorporated into endoscopic practice if confirmed and reproducible.

Although the diagnosis of Barrett's esophagus can be difficult, if the endoscopist suspects that the level of the squamo-columnar junction is above the esophagogastric junction (the proximal margin of the gastric folds), biopsies are required. If intestinal metaplasia is present, then the diagnosis of Barrett's esophagus has been established.

## Treatment

The goals of treatment for Barrett's esophagus are the same as for GERD; the control of symptoms and maintenance of healed mucosa [6].

### Acid suppression

Lifestyle modifications (including dietary adjustment) may help control GERD symptoms somewhat, but these measures are unlikely to have an effect on the regression of Barrett's metaplasia. In fact, some individuals with Barrett's esophagus are asymptomatic, possibly due to the replacement of the normal squamous epithelium with the acid

insensitive Barrett's epithelium. Nevertheless, these patients may still benefit from acid suppression given the potential regression of Barrett's metaplasia as discussed below [6].

Histamine H<sub>2</sub>-receptor antagonists (H<sub>2</sub>-RA) often improve GERD symptoms but they do not effect regression of Barrett's metaplasia [98, 99]. Proton pump inhibitors (PPI) are the most potent antisecretory agents, superior to H<sub>2</sub>-RA in the treatment of symptoms and the healing of esophagitis [100]. In Barrett's esophagus, these same endpoints are effectively achieved with PPIs [101–103]. Some studies have also suggested a modest endoscopic regression of Barrett's esophagus with use of PPIs, although these usually utilized a high dose PPI [99, 101, 104–106]. In a randomized controlled trial, Peters *et al.* [99] demonstrated that omeprazole 40 mg bid resulted in an 8% reduction of surface area of Barrett's esophagus and a 6% decrease in length, superior to the comparator, ranitidine 150 mg bid (Table 3.1). There is also evidence that normalization of intra-esophageal acid exposure decreases cellular proliferation rates and use of PPIs has been associated with a decreased incidence of dysplasia [107, 108]. It is noteworthy that, despite adequate symptom control, even high dose PPI therapy often does not normalize esophageal acid exposure in patients with Barrett's metaplasia [109–112]. However, there is no evidence that normalization of pH leads to a decreased incidence of adenocarcinoma and, therefore, it is not rational to routinely perform pH-metry to determine the level of acid suppression. What is often seen with acid suppression is an increase in islands of squamous epithelium within the Barrett's segment. Biopsies of such islands have often shown underlying intestinal metaplasia, indicating that complete regression of Barrett's does not occur with pharmacological acid inhibition [113]. At this point, no study has shown a reduction of esophageal adenocarcinoma or mortality, although a large randomized control trial examining PPIs and/or aspirin as a chemopreventive agent is underway [114]. Nevertheless, PPIs remain the best pharmacological treatment for Barrett's presently available. **B2**

Given that even high dose PPI may fail to normalize esophageal pH [109–112, 115–117], some have considered anti-reflux surgery as an alternative to decreasing cancer risk with the consideration that continued reflux is the promoting agent. Surgery does provide excellent control of symptoms, and the development of squamous islands after surgery suggests possible regression. One randomized trial comparing medical therapy with anti-reflux surgery with follow up for one to eleven years (Table 3.1) demonstrated a 25% rate of some regression in the surgically treated group (9% progression, 3/32) compared to 7% regression (41% progression, 11/27) in the medical group [118]. However, complete regression of Barrett's metaplasia with surgery is very uncommon and may, in fact, reflect "pseu-

<sup>b</sup>This includes all GERD patients, not just those with Barrett's esophagus.

Abbreviations: PDT: Photodynamic therapy.

doregression" due to surgical repositioning of the esophagus [12]. Some studies have also reported a reduced risk of progression of low grade dysplasia [119]. However, both dysplasia and cancer continue to occur after surgery [120–124]. Csendes *et al.* [123] found that dysplasia developed in 17 (10.5%) and adenocarcinoma in 4 (2.5%) of 161 patients who had undergone surgery at late (7–21 years) follow-up. In a small randomized controlled trial comparing medical to surgical anti-reflux therapy, there was no significant difference between groups in incidence of esophageal cancer (Table 3.1) [124], although this study probably lacked power to demonstrate a true difference should one exist. A more recent retrospective observational study of Barrett's patients who underwent Rosetti-Nissen fundoplication for medically-refractory reflux demonstrated regression of LGD to nondysplastic Barrett's esophagus in six of eight patients, and complete regression of metaplasia to normal mucosa in eight of fifty-seven patients (14%). However, six of fifty-seven (11%) demonstrated an increase in length of involvement with Barrett's postoperatively, and two patients went on to develop adenocarcinoma after surgery [125]. Hence, surgery does not reliably prevent dysplasia or cancer and, therefore, does not obviate the need for surveillance and should not be promoted as a cancer prevention therapy.

### Chemoprevention of esophageal adenocarcinoma with anti-inflammatory agents

The use of aspirin (ASA) or nonsteroidal anti-inflammatory drugs (NSAID) has been demonstrated to be associated with a significantly reduced risk of developing esophageal adenocarcinoma [126, 127]. Cyclooxygenase-2 (COX-2) expression is increased in Barrett's epithelium [128] and COX-2 inhibition has been shown to reduce cell growth in esophageal adenocarcinoma cell lines, as well as inhibit cancer formation in animal models of Barrett's [129, 130]. Modeling the use of aspirin in patients with HGD suggests that this may be a very cost-effective intervention [131]. As such, it has been suggested that using NSAIDs and ASA as chemoprevention agents in Barrett's esophagus may be a viable management option. In a randomized controlled trial reported in 2007 in which 100 patients with low or high-grade dysplasia were randomized to receive celecoxib 200 mg twice daily or placebo, no significant differences were demonstrated in progression of either extent of Barrett's, dysplasia, or cancer at 48 weeks [132]. The possibility of a type II error exists in this study. Despite significant biological plausibility and epidemiological evidence of an ASA/NSAID chemoprevention effect in Barrett's, at this time no recommendation for the use of

NSAIDs as chemopreventive agents in patients with Barrett's can be made. Studies involving larger populations and follow-up periods are in progress and may provide a definitive answer in the future [12, 133, 134].

## Ablative therapies

Given the theory that Barrett's esophagus develops in the predisposed individual as a consequence of a perturbation in healing of the injured esophageal epithelium in an abnormal esophageal acidic environment, it was further hypothesized that reversal of Barrett's would require re-injuring of the metaplastic epithelium with ablative therapy in an acid normalized esophageal environment, resulting in re-epithelialization with a native normal squamous epithelium. This effect could eliminate or decrease the risk for dysplasia and esophageal adenocarcinoma. Endoscopic injury or ablation of Barrett's has been demonstrated with a variety of endoscopic techniques, including thermal techniques (radiofrequency energy, electrocoagulation, heater probe, argon plasma coagulation, or laser), cryotherapy, chemical induced injury with photodynamic therapy, or resection via endoscopic mucosal resection.

Reports using a wide variety of different thermal techniques have suggested both complete and incomplete histological regression in Barrett's esophagus, but complications are not uncommon [12]. Multipolar electrocoagulation (MPEC) has resulted in a fibrotic and friable esophagus with adhesions to the pleura in one patient [135]. Argon plasma coagulation (APC) has had significant complications including chest pain and odynophagia (58%), fever and pleural effusion (15%), strictures (9%), pneumomediastinum (3%) and perforation [136, 137]. In addition, one study using heater probe reported buried islands of intestinal metaplasia in 23% of patients [138].

Photodynamic therapy (PDT) is a process in which a light-sensitive agent, which concentrates in neoplastic tissue, is administered and subsequently activated by light of an appropriate wavelength. This results in selective damage of the neoplastic tissue. The sensitizing agents used include porfimer sodium, a hematoporphyrin derivative, or 5-aminolaevulinic acid (5-ALA). Reports describe elimination and regression of dysplasia and early cancers, but complete regression of Barrett's was not achieved in the majority of patients [139]. A randomized trial compared PDT using sodium porfimer to medical therapy with omeprazole in 208 patients (Table 3.1) with high grade dysplasia [140]. At 12-month follow-up, 9% of the PDT group developed cancer compared to 19% of the omeprazole group (NS), but strictures developed in 38% of the patients who underwent PDT. The same authors reported five-year follow-up data on an incomplete subset of these patients in 2007. They demonstrated twice the rate of HGD elimination (77% versus 39%) and nearly half the progres-

sion to cancer (15% versus 29%) for the PDT group. The reported strictures were limited to the first phase of the trial in the PDT group, and all had resolved at five-year follow-up [141]. Another randomized study compared PDT with 5-ALA to placebo in low-grade dysplasia patients and achieved regression of dysplasia in 89% (16/18) versus 11% (2/18) of patients in the placebo group (Table 3.1), but only 30% of the surface area was eliminated in the 5-ALA group [142]. Hence, some risk of progression for residual neoplastic and non-neoplastic tissue still remains with this intervention. In fact, a case of adenocarcinoma developing underneath new squamous epithelium after treatment for high grade dysplasia with PDT using sodium porfimer has been reported [12]. **A1d**

Radiofrequency ablation (RFA) is a relatively new technique that involves the application of high-frequency energy through an endoscopic balloon probe or contact device. The device, comprised of a radiofrequency energy generator and ablation catheter, is usually mounted on a balloon to ensure circumferential ablation. Early uncontrolled trials demonstrate considerable success with this technique. Sharma *et al.* demonstrated elimination of Barrett's with RFA of 70% at one year of follow-up, in addition to a complete absence of buried IM (or squamous overgrowth) [143]. Recent studies have also examined the use of RFA for the treatment of low-grade and high-grade dysplasia, demonstrating elimination rates for both non-dysplastic IM and dysplasia in excess of 90% after one to two years of follow-up [144, 145]. Furthermore, stricturing and buried islands of IM rarely (if ever) occurred in these studies, suggesting potential for this Barrett's ablation modality as a safer (versus PDT) and/or more efficacious (versus MPE or APC) therapy. **B4**

Endoscopic mucosal resection (EMR) has also been performed in patients with and without visible lesions within Barrett's esophagus. In one study, EMR resulted in complete local remission of 97% (34/35) of patients with low-risk lesions characterized by diameter of less than 20mm, well or moderately differentiated histology, lesions limited to mucosa, or non-ulcerated lesions, compared to 59% (13/22) of patients with high-risk lesions characterized by diameter of greater than 20mm, poorly differentiated histology, lesions extending into sub-mucosa, or ulcerated lesions [146]. However, metachronous lesions or recurrent high-grade dysplasia or cancer were detected in the subsequent year in 17% of the low risk and 14% of the high risk group. Larger studies with longer follow-up are required, but EMR also appears to be relatively safe and promising as an effective non-surgical alternative for management of neoplastic Barrett's metaplasia. **B4**

With all endoscopic Barrett's ablative therapies, even if all of the Barrett's epithelium is thought to be eliminated, some residual intestinal metaplasia may be present under-

neath the neosquamous epithelium, along with the continued risk of cancer development. Thus, these patients have a continued need for surveillance which may be more difficult given that the endoscopic landmarks may be less easily identifiable after ablative therapy [12]. In addition, most of these techniques are associated with a small but significant risk of stricture and perforation. They are (for the most part) costly, the methods have not yet been standardized, and the results are likely very operator dependent. At this time, endoscopic ablative therapy is a reasonable option in the Barrett's patient with high grade dysplasia or superficial adenocarcinoma. **A1d** There are no data allowing one to recommend these therapies in the Barrett's patient without neoplasia, since continued surveillance will still be required, and the risk/benefit ratio is not firmly established.

## Screening and surveillance

Screening for the detection of Barrett's esophagus is currently recommended in patients with chronic GERD symptoms, especially in those over age 50 [7, 147]. This recommendation is based in part on the observation that patients with a longer duration of symptoms have a higher prevalence of Barrett's esophagus [39, 60]. GERD patients who are white, male or have more severe acid reflux also have a higher prevalence of Barrett's esophagus [6, 79, 80]; hence the emphasis on screening this population. Most authors have recommended that a "once in a lifetime" endoscopy should be performed in all GERD patients (based on the premise that Barrett's occurs early on in a GERD patient and thus repeat screening endoscopy is not required), although the optimal timing and utility of such a recommendation is unknown [148]. This approach seems to be favored by Canadian gastroenterologists, of whom 76% agreed that all patients with chronic GERD should have a "once in a lifetime" endoscopy [149]. Although the asymptomatic Barrett's esophagus patient would not be picked up with this screening method, a generalized screening endoscopy in the general population is not recommended.

The aim of the "once in a lifetime" gastroscopy in GERD patients is to detect Barrett's esophagus, as this entity increases the risk of developing esophageal adenocarcinoma. Some have argued that cancer surveillance once non-neoplastic Barrett's is discovered is too costly and/or may be ineffective in improving outcomes. In Barrett's patients with dysplasia there is little controversy that either heightened surveillance or an intervention should be recommended, as it is the only method currently available to identify the high risk patients with dysplasia who may benefit from treatment, including new ablative therapies.

## Arguments in support of a screening and surveillance strategy

The rationale for screening for and carrying out surveillance of patients with Barrett's esophagus is based on the fact that GERD is a risk factor for esophageal adenocarcinoma (EAC) [60], that Barrett's esophagus represents an intermediate step between esophagitis and adenocarcinoma (and is also the only known precursor of esophageal adenocarcinoma) [6], that the rate of esophageal adenocarcinoma is steadily increasing in Western societies [150] and the prognosis for esophageal adenocarcinoma is very poor unless detected early [151]. Over 50% of all esophageal tumors on the National Cancer database for 1988 were stage III or IV at the time of detection with five-year disease specific survivals of 15% and 3% respectively [152]. It is argued that surveillance programs will detect dysplasia or cancers at an earlier stage when the prognosis is much better. In stage I or II EAC cases the five-year disease specific survival rates were 42% and 29% respectively [152]. In addition, small retrospective observational studies suggest that Barrett's surveillance improves survival. A comparison was made between patients who initially presented with esophageal adenocarcinoma ( $n = 54$ ) versus those in whom the cancer had been detected during surveillance ( $n = 16$ ) of Barrett's esophagus [153]. Surveyed patients had significantly earlier stages than non-surveyed patients (75% had stage 0 or I, 25% stage II, and 0% stage III compared to 26%, 25% and 56% respectively, for non-surveyed patients). Survival was also significantly better in the surveyed group, with a two-year survival of 86% versus 43%. Similar results were also demonstrated in an earlier retrospective study comparing 17 adenocarcinoma patients found from surveillance programs versus 35 patients who had not been in a program [154]. Again, the cancers were at an earlier stage and survival was significantly greater in the surveyed group than in the non-surveyed group prior to diagnosis. A third study obtained similar results, with a five-year survival of 62% in those who underwent surveillance, compared to 20% in those that did not [155]. In addition, a prospective study from the UK reported on the results of a surveillance program involving 126 patients and spanning more than nine years; although there was no non-surveillance comparator group, 4% of all patients with Barrett's developed adenocarcinoma, half of which were cured by esophagectomy [156]. These data lead to the recommendation by many experts to advocate for a Barrett's screening and surveillance program in higher risk GERD patients. **B3**

## Arguments against a surveillance strategy

Although the incidence of esophageal adenocarcinoma is on the rise, the absolute prevalence of this condition

remains relatively low in comparison to other malignancies such as colon cancer. In addition, the benefits of screening and surveying patients with Barrett's esophagus are not as clear as they are with colonic polyps and colon cancer. Decision makers may believe that it is more appropriate to spend health care resources on proven cancer preventive strategies. Furthermore, 93–98% of esophageal adenocarcinomas occur in patients without prior diagnosis of Barrett's esophagus [28, 157–159]. Most patients with Barrett's esophagus do not die from esophageal cancer [160–162]. GERD is very common and approximately 90% of these patients do not have Barrett's esophagus [21]. Surveillance is expensive, time consuming (prevents endoscopists from carrying out other tasks) and not error free; sampling error is a problem, as is interobserver variation in endoscopic and histological diagnosis. In addition, many patients with Barrett's esophagus are asymptomatic. The prevalence of Barrett's esophagus at autopsy was 20 times higher than the estimate from endoscopic diagnosis [27]. Thus, for each case of Barrett's, up to another 20 cases go unrecognized. Considering that the true prevalence of Barrett's esophagus in the community is much higher than previously thought, the observed incidence of adenocarcinoma of the esophagus is very small in relation to the community prevalence of Barrett's epithelium [163].

A group of 166 patients with Barrett's esophagus who chose not to undergo surveillance were re-examined a mean of 9.3 years later [162]. They determined that the incidence of esophageal cancer was one in 180 patient years; a 40-fold increased risk compared to an age and gender-matched group from the general population. All eight patients with cancer were symptomatic and the cancer was detected at diagnostic endoscopy. Only two of these patients died because of their esophageal cancer; one of postoperative complications and the other four years postoperatively with liver metastases. Three had successful surgery, and three died of unrelated illness (pancreatitis, myocardial infarction and asthma). During the follow-up period, there were 77 other unrelated deaths at a mean age of 75 years. The authors concluded that an endoscopic surveillance program in this population of patients with Barrett's would have had marginal benefit, as so few actually died of esophageal cancer. A Danish study found that only 1.3% of patients had a diagnosis of Barrett's esophagus more than one year before cancer was identified [157]. Thus, most cancers were detected in patients who would not have entered into a surveillance program, suggesting that such a strategy would be unlikely to reduce the death rate from esophageal cancer in the general population.

### Cost-effectiveness

Unfortunately, there are no randomized controlled trials of surveillance strategies. A cost-effectiveness study examin-

ing screening assumed that GERD patients underwent a one-time gastroscopy at age 60 [164]. The calculated screening cost of \$24,700 per life-year saved, is considered to be reasonable for a cancer screening program. However, the results were based on a relatively high prevalence of Barrett's esophagus, high-grade dysplasia, and adenocarcinoma, a high sensitivity and specificity of endoscopy, and a minor reduction in quality of life after esophagectomy. Any variation in these parameters altered the cost effectiveness of the strategy.

Another report estimated the cost of detecting one esophageal cancer at \$23,000 for male and \$65,000 for female patients with Barrett's esophagus [165]. Another found that the cost was lower than the cost of surveillance mammography [166]. Sonnenberg *et al.* [167] found that the incremental cost-effectiveness of surveillance every other year was approximately \$16,700 per year of life saved. Provenzale *et al.* [51] evaluated surveillance strategies with a Markov model, and concluded that surveillance every five years was the preferred strategy, with a cost of \$98,000 per quality-adjusted life-year gained.

### Conclusions regarding screening and surveillance of Barrett's metaplasia

Applying the World Health Organization's 10 principles of early disease detection helps determine whether screening for Barrett's esophagus is beneficial [168, 169]. Although some of these criteria are met, many are not (Table 3.2), and thus one cannot make a recommendation for screening for Barrett's either in the general population or in those with chronic GERD. Furthermore, at this time a recommendation as to whether surveillance should be undertaken once non-neoplastic Barrett's is discovered cannot be made. In the absence of a definitive study, there are arguments to support both sides of the controversy. However, recognizing that Barrett's mucosa is a risk factor for esophageal adenocarcinoma, it may be difficult to disregard present recommendations for surveillance endoscopy until evidence to the contrary is available.

### How to perform surveillance

Screening is currently recommended for patients with chronic GERD symptoms [6]. Some are certainly more at risk of Barrett's, and perhaps screening should be focused on those at higher risk (such as white males over age 50 with greater than 10 years of GERD symptoms). Once Barrett's is established, the patient should have the pros and cons of a surveillance program discussed with them. Patients who have co-morbid illness which would not allow them to be candidates for esophagectomy or ablative therapy are unlikely to receive much benefit from surveillance.

**Table 3.2** World Health Organization principles for early disease detection.

Principles	Are principles met in Barrett's esophagus?
1 The target health problem is important	Yes (esophageal cancer)
2 There should be an accepted treatment for the target problem	Yes (endoscopic ablation, surgery, or intensive endoscopic surveillance)
3 Facilities for diagnosis and treatment should be available	Yes
4 There should be a recognized latent or early symptomatic stage	Yes (dysplasia)
5 There should exist a suitable screening test or examination	Yes
6 The test should be acceptable to the population to be screened	Yes
7 The natural history and development of the condition should be adequately understood	Possibly
8 There should be an agreed policy on who to treat	No
9 The process of case finding should be cost effective	No
10 Case finding should be a continuing process	Possibly

Updated and modified from references 168 and 169.

During surveillance gastroscopy, four-quadrant biopsy specimens should be obtained at least every 1–2 cm along the entire length of Barrett's epithelium. The endoscopy should be performed in patients receiving acid suppressive therapy so that esophagitis and reactive changes do not confound the diagnosis. In addition, any mucosal abnormalities detected at endoscopy should be targeted for biopsy [12]. It has been suggested that 1 cm intervals with jumbo biopsy forceps is more accurate [95, 170], but this is more labor intensive and also requires endoscopy with a therapeutic gastroscope. Hence, this form of intensive surveillance may not be practical in community practice, despite appearing to be the optimal endoscopic surveillance method.

### Summary of practice guidelines

Guidelines for the diagnosis, surveillance and treatment of Barrett's esophagus have been established and updated [7,

171–173]. Table 3.3 summarizes the most recent recommendations. Essentially, the guidelines provided by several groups are very similar. The American Society of Gastrointestinal Endoscopy (ASGE) guidelines (which were generated together with the Society for Surgery of the Alimentary Tract and the American Gastroenterological Association) are similar to those of the American College of Gastroenterology (ACG) and the Canadian Association of Gastroenterology (CAG). For patients without dysplasia, surveillance endoscopy should be repeated within one year, and can then be performed every two to five years, depending upon the guideline followed (Table 3.3). For patients with low-grade dysplasia, confirmation should be sought by a second expert pathologist and a repeat surveillance endoscopy should be performed at six to twelve months. Endoscopies should continue annually until there is no low-grade dysplasia on two successive occasions, at which point a normal surveillance protocol may resume. Finally, for patients with high-grade dysplasia, management should be individualized. The ACG guidelines stipulate that high-grade dysplasia requires expert pathologist confirmation, followed by a repeat endoscopy at three months to rule out esophageal adenocarcinoma. At this point, surgery or endoscopic ablative therapy should be offered to candidates. Those who are unfit for such procedures (or refuse) should be followed with surveillance endoscopy every three months. The recommendations of the French Society of Digestive Endoscopy (FSED) differ slightly from the other guidelines as is demonstrated in Table 3.3. [172].

### Conclusion

Barrett's esophagus is likely a complication of chronic gastroesophageal reflux and a risk factor for esophageal adenocarcinoma. It should, however, be realized that esophageal cancer is uncommon and most patients with esophageal cancer do not have clinically recognized Barrett's esophagus before cancer is diagnosed. Also, no randomized controlled trials or large cohort studies have convincingly demonstrated that an endoscopic screening or surveillance strategy prolongs survival or improves quality of life for these patients. However, for some patients, surveillance of Barrett's esophagus may permit detection of cancer at an earlier stage, and therefore improve survival. Therefore, endoscopic screening for Barrett's esophagus can be considered for patients with chronic symptoms of gastroesophageal reflux disease and, particularly, in certain high risk patients such as Caucasian males over the age of 50.

At this time, there is insufficient scientific evidence that aggressive anti-reflux therapy with either high-dose PPI or surgery will revert Barrett's esophagus to normal squa-

**Table 3.3** Current practice guidelines for surveillance of Barrett's esophagus.

Source	Date published	No Dysplasia	Surveillance Intervals <sup>a</sup>		
			Low-grade dysplasia	High-grade dysplasia <sup>b</sup>	Biopsy sampling <sup>c</sup>
ACG [7]	2008	3 years after 2 normal EGD (1 year apart) with biopsy	Confirmatory endoscopy in 6 months, then every year until no dysplasia	Continued 3-month surveillance or individualized intervention (ablative therapy, EMR, or surgery)	4 quadrants every 2 cm and mucosal abnormalities
SFED [172]	2007	SSBE – 5 years CBE 3–6 cm – 3 years, >6 cm – 2 years	6 months – 1 year, then annually	Surgery or alternative therapy if still present at 1 month after high dose PPI	4 quadrant CBE – every 2 cm SSBE – every 1 cm
ASGE [173]	2000	Periodic (interval not specified)	More frequent than if no dysplasia	Consider surgery	4 quadrants every 1–2 cm
CAG [171]	2005	2–5 years	Confirmatory endoscopy in 12 months, then annually	Confirmatory in 3 months, then surgery or esophageal mucosal ablation for poor risk patients	4 quadrants every 2 cm

<sup>a</sup>Interval at which surveillance endoscopy should be performed;<sup>b</sup>requires confirmation;<sup>c</sup>protocol to be followed for biopsy sampling.

Abbreviations:

ACG: American College of Gastroenterology

ASGE: American Society for Gastrointestinal Endoscopy

EGD: Esophagogastroduodenoscopy

CBE: Classical Barrett's esophagus (length &gt; 3 cm)

SFED: French Society of Digestive Endoscopy

CAG: Canadian Association of Gastroenterology

EMR: Endoscopic mucosal resection

SSBE: Short segment Barrett's esophagus (length &lt; 3 cm)

mous mucosa or reduce the risk of developing cancer. Likewise, there are insufficient data to support the routine use of the various ablative therapies in patients with non-neoplastic Barrett's esophagus. These modalities remain experimental until proven to be effective in randomized trials.

At present, patients with clinically recognized Barrett's esophagus can be offered participation in a surveillance program, with surveillance every 2–3 years for patients without dysplasia (after two normal examinations) and every 6–12 months for patients with low-grade dysplasia. For patients with high-grade dysplasia, surgical intervention or endoscopic therapy should be considered once this change is confirmed by an expert gastrointestinal pathologist, preferably in a center performing a high volume of these procedures.

## Esophageal motility disorders: Achalasia and spastic motor disorders

Jason R Roberts<sup>1</sup>, Marcelo F Vela<sup>2</sup> and Joel E Richter<sup>3</sup>

<sup>1</sup>Division of Gastroenterology and Hepatology, Medical University of South Carolina, South Carolina, USA

<sup>2</sup>Gastroenterology Section, Baylor College of Medicine, Houston, Texas, USA

<sup>3</sup>Department of Medicine, Temple University School of Medicine, Philadelphia, USA

Esophageal motility disorders present with dysphagia and chest pain as the main symptoms, accompanied by abnormalities on manometric studies. The best characterized esophageal motility disorders are achalasia and diffuse esophageal spasm. The treatment options for these disorders, which range from non-invasive medical therapy to surgery, are presented in this chapter.

### Achalasia

Achalasia is a primary esophageal motor disorder characterized by abnormal relaxation of the lower esophageal sphincter (LES) and absent esophageal peristalsis. With an estimated incidence of approximately 1/100 000 and a prevalence of close to 10/100 000 [1], this uncommon disease stands out among the esophageal motility disorders as the most clearly defined (clinically, manometrically and radiographically) and the most successfully treated.

The exact etiology of achalasia remains unknown, but autoimmune, infectious, degenerative and hereditary processes, whether alone or in combination, lead to a chronic inflammatory response in the myenteric plexus that results in selective loss of inhibitory neurons [2]. Manometrically this is manifested by high LES pressure, abnormal LES relaxation and aperistalsis [3]. The combination of an atonic esophageal body with a functional obstruction at the gastroesophageal junction produce esophageal dilatation that can, over a prolonged period of time, lead to the development of a megaesophagus.

The most common symptoms of achalasia are dysphagia for solids and liquids in over 90% of patients, and regurgitation of undigested food and saliva in approximately 75%. Chest pain is present in 40–50% of patients, weight loss in nearly 60%, and heartburn in approximately 40% of sub-

jects [4, 5]. The presence of the disease is strongly supported by a barium esophagram showing a dilated esophagus that tapers into a “bird-beak” at the gastroesophageal junction with fluoroscopy revealing lack of normal peristalsis, usually with to-and-fro disordered bolus movement. The manometric features described above, the most important of which is abnormal LES relaxation, confirm the diagnosis.

### Treatment of achalasia

#### Overview

Currently, there is no available treatment that can correct the underlying neuropathology of achalasia; LES function and peristalsis cannot be restored. Therefore, therapy is based on reduction of the resting LES pressure to allow esophageal emptying by gravity. The goals of treatment are three-fold: relieve symptoms, improve esophageal emptying and prevent the development of megaesophagus. In assessing response to a therapeutic intervention, useful endpoints are symptom relief and physiologic evaluation, the latter through manometric determination of LES pressure and measurement of esophageal emptying by barium examination or nuclear scintigraphy.

Reduction of the LES pressure can be achieved through different therapeutic modalities, including pharmacologic therapy, endoscopic injection of botulinum toxin, pneumatic dilatation and surgical myotomy [6]; the last two being the most effective treatments [4, 7]. “Endstage” cases presenting with a markedly dilated and sometimes sigmoid esophagus may require esophagectomy [8]. The choice of therapy depends on patient characteristics (age, co-morbid illnesses and disease stage), patient’s preference, degree of expertise and available modalities in the medical center, and a careful balance between risks and benefits.

#### Pharmacologic treatment

Pharmacological reduction of the LES basal pressure through smooth muscle relaxants has been attempted with

**Table 4.1** Nitrates and calcium channel blockers in the treatment of achalasia.

Modified from Vaezi M, Richter JE. *J Clin Gastroenterol* 1998; **27**: 21–35.

several medications. The most studied classes include nitrates, calcium channel blockers and, more recently, sildenafil (Table 4.1).

Nitrates activate guanylate cyclase, leading to production of a protein kinase that inhibits smooth muscle contraction through dephosphorylation of the myosin light chain. Additionally, nitrates liberate nitric oxide (NO), an inhibitory neurotransmitter mediated by cyclic guanosine monophosphate (cGMP). Significant reduction of LES pressure has been demonstrated 10 minutes after sublingual administration of a 5 mg dose of isosorbide dinitrate [9]. Very few randomized controlled trials have evaluated the effect of nitrates on achalasia. Wong *et al.* [10] found a significant decrease in LES pressure and significant improvement in esophageal emptying 30 minutes after a single dose (0.4 mg) of sublingual nitroglycerin in a randomized crossover study. In several other small studies [11–14], nitrates have decreased LES pressure by 30–65%, with symptom improvement in 58–87% of patients (Table 4.1), but these were uncontrolled studies that traditionally tend to overemphasize the benefits of interventions. Calcium channel blockers produce smooth muscle relaxation by decreasing entry of calcium, necessary for contraction, into smooth muscle cells. In a double-blind randomized controlled trial in 10 achalasia patients [15], sublingual nifedipine (10–30 mg dose, titrated according to patient tolerance) given before meals achieved a significant reduction in LES pressures 30 minutes after administration. However, despite this reduction, LES pressures were still substantial after treatment (mean LES pressure of 30 mmHg). These investigators also reported a modest improvement of dysphagia with nifedipine, with a reduction in the average number of meals per day with dysphagia from 1.9 to 0.9.

**Ald** Other uncontrolled studies suggest that calcium

channel blockers decrease LES pressure by 13–49% and improve symptoms in 53–77% of patients [11, 12, 15–17].

#### B4

In a small randomized controlled trial comparing calcium channel blockers and nitrates in 15 patients, 12 found sublingual isosorbide dinitrate (5 mg) to be superior to sublingual nifedipine (20 mg) for the treatment of achalasia. **Ald** In comparison to nifedipine, isosorbide dinitrate achieved a more pronounced reduction in basal LES pressure (47% vs 64%). Additionally, more patients receiving isosorbide dinitrate experienced complete radionuclide meal clearance at 10 minutes (53% vs 15%) and relief of dysphagia (87% vs 53%).

Sildenafil (Viagra) inhibits smooth muscle contraction by promoting accumulation of NO stimulated cGMP (NO-cGMP) through inhibition of NO phosphodiesterase type 5, an enzyme that degrades NO-cGMP. Recently, in a placebo-controlled randomized trial of sildenafil (50 mg) in 14 achalasia patients, Bortolotti *et al.* [18] showed that sildenafil by direct intragastric infusion significantly reduced basal LES pressure, post-deglutitive LES residual pressure and esophageal body contraction amplitude. Peak effect was reached 15–20 minutes after infusion and lasted less than one hour. Eherer *et al.* [19] administered sildenafil orally (50 mg) to 11 patients with esophageal motor disorders, three of whom had a diagnosis of achalasia. LES pressure decreased in two of these patients, but none had relief of symptoms.

Overall, nitrates and calcium channel blockers can reduce LES pressure. The effect on symptoms is variable, short-lived, and usually suboptimal. **Ald** Additionally, adverse effects such as headache, hypotension, and pedal edema that are frequent may limit their use [11]. Therefore, these agents should be reserved for the short-term relief of achalasia symptoms, either as a temporizing measure while awaiting more definitive therapy, or in patients who are too sick or unwilling to undergo other treatments. Sildenafil merits further study in randomized controlled trials.

#### Botulinum toxin

Endoscopic injection of botulinum toxin into the LES is a relatively recent addition to the treatment options for achalasia. It produces reduction in LES pressure by inhibiting acetylcholine release from nerve endings, thereby counterbalancing the effect of the selective loss of inhibitory neurotransmitters (nitrous oxide and vasoactive intestinal peptide) in achalasia. It is safe, easy to administer and provides symptom relief initially in approximately 85% of patients; however, the effect of a single injection is usually limited to six months or less in over 50% of patients [3]. **B4**

In a six-month randomized controlled trial of 21 patients, the administration of botulinum toxin (100 units) resulted in significant symptom score improvement (from  $7.1 \pm 1.2$  to  $1.6 \pm 2.2$ ), compared to placebo (from  $5.9 \pm 1.6$  to  $5.4 \pm 2.0$ )

**Table 4.2** Botulinum toxin injection for the treatment of achalasia: symptomatic improvement after one injection.

( $p = 0.001$ ) at one week. By six months the proportion of patients in remission had declined from 82% to 66% [20].

**Ald** A subsequent study by the same group [21] evaluated the efficacy of botulinum toxin over a 2–3-year period and found that 65% (20/31) of patients had good symptom improvement at six months. However, 19 of these 20 responders eventually relapsed, requiring repeat injections, and two-thirds of the patients eventually chose a more definitive form of therapy. In the analysis of subgroups in this small study the response rate appeared to be higher for patients over the age of 50 years and those with the “vigorous” form of achalasia. Subsequent studies [20–34] have confirmed that botulinum toxin is initially effective, but the benefit of a single injection lasts less than one year in the majority of patients, with all patients requiring repeat injections or other forms of therapy for their achalasia (Table 4.2). **Ald, B4** Botulinum toxin is extremely safe, with 25% of patients presenting with transient, mild, post-procedural chest pain, and 5% developing symptomatic gastroesophageal reflux disease (GERD) [6].

Botulinum toxin is an effective and safe option for the short-term treatment of achalasia. Symptoms are relieved on average for six months with repeat treatments being required to keep patients in long-term remission. Botulinum toxin is inferior to pneumatic dilatation or surgery (see comparative studies below), but it can be particularly useful in the elderly, who may have a higher response rate than younger patients (under age 50 years) and who may have a life expectancy of  $\leq 2$  years. Clouse *et al.* showed the survival analysis curve did not differ significantly for repeated botulinum toxin injections compared to pneumatic dilatation at year 1 and year 2 ( $p = 0.5$  and  $p = 0.4$  respectively) [35].

### Pneumatic dilatation

Disruption of the muscle fibers of the LES through forceful dilatation has been used as treatment of achalasia for many years. The first description of dilatation dates from 1674 when a patient with achalasia was treated by passing a piece of carved whalebone with a sponge affixed to the distal end down the esophagus into the stomach [7]. The first pneumatic (i.e. air filled) dilators were introduced in the late 1930s, and both the equipment and technique have evolved over the years. Not only are the dilators and techniques varied, but the definitions of success differ across studies. However, there is sufficient experience with the currently used balloon dilators to comment on their efficacy and safety.

Kadakia and Wong calculated the pooled effect of the older dilators (Brown-McHardy Mosher and Hurst-Tucker balloons) among a total of 235 patients studied in five prospective studies. Symptomatic response was excellent or good in 61–100% of patients who were followed for a mean of 2.7 years [36]. **B4** Currently, the most widely used dilator in the USA is the Rigidflex polyethylene balloon (Boston Scientific, Boston), which is available in three different diameters (30, 35 and 40 mm) [11]. The current technique consists of endoscopy to determine landmarks, followed by placement of a balloon across the LES, usually under fluoroscopic guidance. The balloon is then inflated to sufficient pressure (usually 7–12 psi; 48.3–82.7 kPa) for up to 60 seconds to disrupt the muscle fibers of the LES.

There are no clinical trials that compare pneumatic dilatation to placebo (i.e. sham dilatation). In recent randomized controlled trials comparing pneumatic dilatation to Botulinum toxin injection, symptom improvement rates for dilatation at 12 months ranged between 53% and 70% [28,

**Table 4.3** Rigiflex balloon dilatation for the treatment of achalasia.

29, 32]. **Ald** Table 4.3 summarizes the results of 26 uncontrolled studies of Rigiflex pneumatic dilatation for the treatment of achalasia with <5 years follow-up [5, 37–61], the degree of heterogeneity of these studies is not known. The pooled results of 1256 patients followed for a mean of 20 months yield an excellent to good response in 77% of patients. **B4** However, it should be emphasized that uncontrolled studies tend to exaggerate the benefits of interventions, and the criteria used to determine the response to treatment varies among studies. Furthermore, while a graded approach to pneumatic dilation using repeat treatment with a larger balloon size is considered standard, in some studies a repeat procedure within a graded dilation protocol is considered a failure. Zerbib *et al.* [62] used an iterative approach with pneumatic dilation based on recurrence of patient symptoms. In their protocol, graded dilations were performed every 2–3 weeks until remission

occurred. Patients were considered treatment failures with persistent symptoms after four or five procedures and only 11 of 150 failed with this approach. **B4**

Another important issue is the relative paucity of long-term outcome studies of pneumatic dilatation. There have been few randomized controlled trials evaluating pneumatic dilation performed with the currently available balloons. In the most recent trial by Kostic *et al.* that included 26 patients treated with pneumatic dilation and followed for 12 months, 77% of patients improved with treatment [56]. In an older randomized controlled trial with follow-up extending beyond 12 months, 50% of patients treated with pneumatic dilatation had relapse of dysphagia at 30 months [28]. **Ald** West *et al.* [63] reported on the success of pneumatic dilatation in patients followed for more than five years. Although this study was characterized by serious methodological limitations, including the use of

different types of balloons and the use of a symptom questionnaire to define therapeutic success, it was the first study with extended follow-up. The overall therapeutic success rate was 50% in 81 patients followed for more than five years, and the mean number of dilatations per patient was four. Success rate decreased in patients with longer follow-up: 60% in patients followed between 5 and 9 years, 50% for those followed between 10 and 14 years, and 40% in the group followed for more than 15 years. **B4** There have been three subsequent studies with extended follow-up beyond five years. The success rate in 254 pooled patients reached 55% after a mean follow-up period of ten years (Table 4.4) [58, 64, 65].

The overall perforation rate associated with pneumatic dilatation is approximately 2% (this varies across different studies, from as low as 0%, to as high as 8%) [11]. Mortality from the procedure is estimated to be 0.2% [6]. Gastroesophageal reflux after pneumatic dilatation occurs in 15–33% of patients [5, 35]. **Ald B4** Overall, pneumatic dilatation results in good to excellent symptom relief in approximately 80% of patients based upon follow-up of one or two years. However, the limited long-term follow-up data suggest that the remission rates decline with time and the few studies with extended follow-up periods beyond five years indicate a 57% success rate [58, 64, 65]. That said, pneumatic dilatation is the most effective non-surgical treatment available for achalasia and has a success rate comparable with that of surgery (see comparative studies below). It should be considered an acceptable alternative to surgery for treatment of achalasia.

### Heller myotomy

Surgical myotomy was originally described by Ernest Heller in 1914 and involved cutting the anterior and posterior aspects of the LES through a thoracotomy [66]. The surgical technique has evolved first with a laparotomy approach and again with the advent of minimally invasive surgery in the 1990s. While a thoracoscopic approach has been used, laparoscopic myotomy has become the preferred method, as it is associated with less morbidity and

quicker recovery times [67]. Whether an anti-reflux procedure should be performed (to prevent reflux) or not (to avoid postoperative dysphagia) has been a matter of controversy [3, 7]. Recent studies by Rice *et al.* and Richards *et al.* determined that the addition of anterior fundoplication (Dor) does reduce the amount of acid reflux following Heller myotomy [68, 69]. In the study conducted by Rice *et al.*, the esophageal acid exposure time in the upright position varied from 0.4% with anterior fundoplication to 2.9% without ( $p = 0.005$ ). The same study compared the incidence of reflux, resting LESP, and esophageal emptying. The addition of a Dor fundoplication resulted in significantly less reflux (0.4% vs 2.9%  $p = 0.005$ ), a higher LESP (18 mmHg vs 13 mmHg  $p = 0.002$ ), and no difference in the esophageal emptying ( $p = 0.6$ ) [68]. Similar results were demonstrated by Richards *et al.*, who observed that the addition of anterior fundoplication decreased the amount of reflux ( $p = 0.005$ ), without increasing dysphagia scores [69]. These limited data indicate that anti-reflux procedures may decrease post-esophagomyotomy reflux without impairing emptying, but the long-term effect on this balance is still unknown.

Minimally invasive surgery and especially laparoscopy, has become the standard approach to perform myotomy. Uncontrolled studies of the thoracoscopic [11, 70–75] and laparoscopic [11, 56, 57, 75–100] techniques are summarized in Tables 4.5 and 4.6 respectively. Pooled results of 103 patients in five studies of thoracoscopy yield good to excellent symptom response in 82% of patients with a mean follow-up of 16 months, although GERD developed in 42% of patients. The pooled symptom response rate was 84% in 1420 patients undergoing laparoscopic or open Heller myotomy in 30 uncontrolled trials; 37% of these patients developed GERD [11, 56, 57, 75–100]. **B4**

As with pneumatic dilation, the efficacy of Heller myotomy decreases with longer follow-up periods. In a series of 73 patients treated with Heller myotomy, excellent/good responses were reported in 89% and 57% of patients at six months and six years' follow-up [57]. Csendes *et al.* observed 80% of patients with good/excellent results

at 7–10 years, 74% at 10–20 years and 65% at >20 years [100].

As stated earlier, the degree of benefit may be overestimated in uncontrolled studies. Heller myotomy, preferably through the laparoscopic approach, should be considered as effective as pneumatic dilatation and should be offered to patients who present an acceptable surgical risk. It can also be offered to those who have failed pneumatic dilatation.

### Comparisons of different treatment modalities

**Pneumatic dilatation versus botulinum toxin** These two therapeutic approaches have been compared in three randomized controlled trials (Table 4.7). **Ald** Vaezi *et al.* [29] randomized 42 patients to receive botulinum toxin injection or graded pneumatic dilatation with 30 and 35 mm Rigiflex balloons and reported success at 12 months (defined as improvement in symptom score greater than 50%) to be 70% for dilatation and 32% for botulinum toxin. Using a similar design and criteria for symptom response, Mikaeli *et al.* [32] reported response rates at 12 months of 53% with single pneumatic dilatation and 15% with a single botulinum toxin injection. Success after repeat dilatation or repeat injection was observed, respectively, in 100% and 60% of patients at 12 months. Muehldorfer *et al.* [28] randomized 24 patients to botulinum toxin or dilatation with a 40 mm latex balloon; symptomatic response was superior with pneumatic dilatation compared with botulinum toxin at 12 months (67% vs 25%) and at 30 months (50% vs 0%). Identification of predictors of response was not possible in any of these three small randomized trials. Although randomization codes were concealed, patients and investigators were not blinded as to the treatments received.

Two studies have compared the costs of Heller myotomy, pneumatic dilation and botox injection. The costs per symptomatic cure over a ten-year horizon were \$10,792 for Heller myotomy, \$3723 for BoTox injection, and \$3111 for pneumatic dilation [101]. A cost-effectiveness study that accounted for quality of life over a five-year horizon determined the costs of BoTox injection, pneumatic dilation and

Heller myotomy to be \$7011, \$7069, and \$21,407 respectively. While the cost of BoTox was slightly lower, PD was more cost-effective, with an incremental cost-effectiveness of \$1348 per QALY (quality adjusted life year) [102].

**Heller myotomy versus botulinum toxin** There is only one prospective randomized controlled trial comparing the effectiveness of laparoscopic myotomy and botulinum toxin injection. A total of 80 patients were randomized to either treatment group. The lower esophageal resting and relaxation pressures, esophageal body dilation, and dysphagia/regurgitation scores were all measured before and after treatment. After six months there was a greater symptom reduction (82% vs 66%) in the myotomy group compared to the BoTox group. The two-year probability of remaining symptom free was 87% after myotomy and 34% after BoTox. Median LESP was significantly lower in the surgery group (27 mmHg vs 36 mmHg  $p < 0.05$ ). The esophageal body diameter was not significantly different 4.1 cm vs 3.5 cm [99]. Two cost minimization studies compared Heller myotomy, pneumatic dilation and botox injection. Heller myotomy was associated with greater costs compared to BoTox injection in both studies (US\$10,792 vs \$3723 and US\$21,407 vs \$7011) [103].

**Pneumatic dilatation versus Heller myotomy** The first randomized controlled trial that compared pneumatic dilatation to myotomy [70, 100] found that myotomy via laparotomy had a success rate of 95% compared with 65% for pneumatic dilatation with the Mosher bag. **Ald** Neither of these techniques are widely used today, and the results may not be generalizable to other techniques. Spiess and Kahrilas [7] pooled all uncontrolled series of ten or more patients undergoing pneumatic dilatation or surgery with follow-up greater than a year performed between 1966 and 1997. They reported response rates as weighted means and found good to excellent symptom response in  $80 \pm 42\%$  of participants with pneumatic dilatation. Response rates for surgery were  $84 \pm 20\%$  with thoracotomy,  $85 \pm 42\%$  with laparotomy, and  $92 \pm 18\%$  with laparoscopy. However, criteria for including or excluding reports were not stated, and these uncontrolled studies may tend to overestimate

**Table 4.7** Randomized trials comparing symptomatic response 12 months after pneumatic dilatation or botulinum toxin injection for treatment of achalasia. No. (%) of patients with symptomatic remission.

Authors	No. of patients	Pneumatic dilatation	Botulinum toxin injection	P value

Muehldorfer <i>et al.</i> [28]	24	8/12(67)	3/12(25)	<0.05

the benefits of treatment. **B4** Kostic *et al.* [56] were the first to conduct a randomized controlled trial comparing patients treated with current techniques, laparoscopic Heller myotomy and pneumatic dilation with the Rigidflex balloon. The results of this trial showed 96% success in the myotomy group versus 87% in the dilation group during a 12-month follow-up period compared to the data reported by Csendes (95% vs 65%). The duration of treatment response for either intervention is not clear, as most studies include follow-up periods <5 years. Vela *et al.* [57] demonstrated the effectiveness of myotomy and dilation declines over time. In 106 patients undergoing pneumatic dilation and 73 treated with Heller myotomy, there were similar results at six months (90% vs 89%), but after six years only 44% and 57% of patients continued to have a good/excellent response. The only variables associated with patient outcomes in the dilation group were sex and age. Women more frequently required a single dilation, and younger patients, especially men, were more likely to have early failure requiring more than one dilation within the first six months. The frequency of post-treatment GER varies among studies for both PD and HM. In a retrospective study comparing PD to HM, the use of PPIs for heartburn was more common in the myotomy patients (56% vs 26%,  $p < 0.01$ ). Gastroesophageal reflux was a cause for symptom recurrence in only 4% of patients that were dilated, compared to 36% of those who received myotomies. An antireflux procedure was performed in 33% of the patients treated with myotomy. However, reflux still occurred in 39% of them compared to 65% of those who did not receive an anti-reflux procedure [57].

From these data and the uncontrolled studies summarized in Tables 4.5 and 4.6 we conclude that Heller myotomy and pneumatic dilatation have similar success rates. **B4** The success rates for both of these treatments decline over time, and repeat intervention may be required. Pharmacologic acid suppression may be needed in either

case, but it should be strongly considered, and perhaps mandatory, for patients who are treated with Heller myotomy since GER is a cause of late treatment failure [57].

Only one study has compared the costs of pneumatic dilation and Heller myotomy. At a seven-year follow-up period, pneumatic dilation cost US\$8474 compared to US\$20,064 for myotomy. A limitation of these data is that the myotomy was done through an open approach, and Ancona *et al.* found that a Heller myotomy done through a laparoscopic approach costs less than an open approach (US\$2699 vs US\$3082) [103].

### Esophagectomy

A small number of patients develop “endstage” achalasia, characterized by progressive dilatation and tortuosity of the esophagus [8]. This complication may be seen in cases that are refractory to treatment and in patients with long-standing untreated disease. If these patients do not respond to Heller myotomy, esophageal resection is frequently required. Esophagectomy is associated with a greater morbidity/mortality than laparoscopic Heller myotomy, and should be a “last resort” for patients who have failed pneumatic dilation and/or Heller myotomy. Patti *et al.* [104] demonstrated the technical feasibility of a laparoscopic Heller myotomy in patients with a dilated (>6cm) sigmoid esophagus. There was not an increased complication rate in this group, and success rates (91%) were similar to those observed in patients with less dilated and tortuous organs.

There are few studies that assess the effectiveness of the two approaches to resection of the esophagus, i.e. the use of colonic interposition or a gastric pull-up. No randomized controlled trials have been carried out in this area. The available uncontrolled data show symptom improvement in over 80% of endstage cases of achalasia with mortality rates between 0% and 5.4%, and development of GERD in 8–36% of patients (Table 4.8) [8, 105–112]. The studies per-

formed do not provide sufficient evidence to determine whether there are advantages of colonic interposition compared with gastric pull-through. **B4**

## Summary

Several options are available for the treatment of achalasia, ranging from medications to esophagectomy. Unfortunately, there have been very few controlled trials with long-term follow-up to guide our approach to these patients. Techniques and outcome measures vary over time and between studies. The outcomes of symptom resolution and objective improvement in esophageal emptying are not always correlated. This problem was demonstrated in a study by Vaezi *et al.* [113] who performed timed studies of barium emptying (measuring the column of barium in the esophagus one and five minutes after a bolus) in patients treated with pneumatic dilatation. They found that 31% of patients who reported near complete symptom resolution had less than 50% improvement in barium emptying after treatment. Studies with at least five years of follow-up indicate the response to treatment decreases over time for myotomy and pneumatic dilation [57, 70]. With these limitations in mind, the available evidence is sufficient to make the following recommendations.

- Pharmacologic therapy has variable and limited response and is hindered by adverse effects.
- Calcium channel blockers and nitrates should be used in patients who cannot tolerate or are unwilling to receive other treatments.

- The use of sildenafil should be restricted to research protocols.

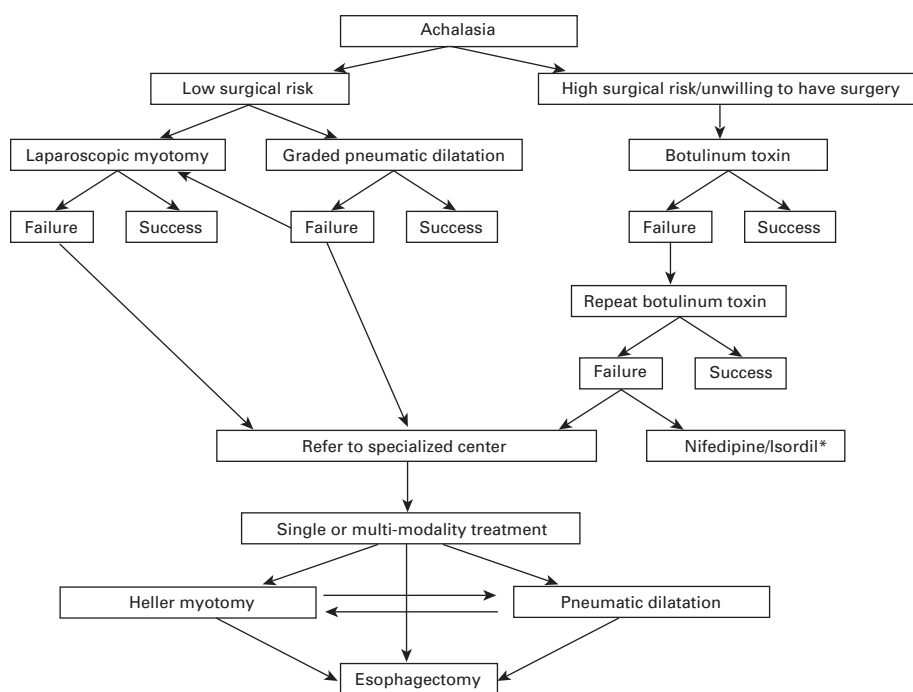

- Botulinum toxin is safe and effective but benefit generally lasts less than six months to one year. It should be used in elderly or frail individuals in whom more aggressive treatments pose a high risk.

- Pneumatic dilatation and laparoscopic Heller myotomy have similar efficacy and should be offered as first-line treatments to all patients who can tolerate these procedures. Pneumatic dilatation appears to be the more cost-effective therapeutic approach over a five-year horizon, but whether this holds true with longer follow-up is not known [114, 115]. Although some patient characteristics such as age and sex and patients' preferences should be taken into consideration, we currently have no way of predicting which patient will respond better to pneumatic dilatation or surgery. The risks and benefits of the intervention need to be carefully weighed in each case.

- Esophagectomy may be necessary in patients with end-stage achalasia.

The algorithm in Figure 4.1 depicts a general approach to the treatment of achalasia supported by a guideline paper by the American College of Gastroenterology [4]. A randomized controlled trial of pneumatic dilatation versus laparoscopic Heller myotomy to compare efficacy, cost and safety over an extended follow-up period, and to identify predictors of response is greatly needed. One such study is currently being conducted in Europe.

Complicated patients, including those who are refractory to initial treatment, may benefit from evaluation and

**Figure 4.1** Algorithm for the treatment of achalasia. Isosorbide dinitrate (modified from reference 4).

treatment at a tertiary center that can offer expertise in all the treatments available for this disorder. A multi-modality approach is often necessary in this group.

## Spastic motility disorders

Spastic motor abnormalities of the esophagus include diffuse esophageal spasm (DES), the nutcracker esophagus (NE), and hypertensive lower esophageal sphincter. These abnormal manometric patterns have been described in association with chest pain and dysphagia. However, whether these abnormal motility patterns represent true diseases, as opposed to manometric findings present in but not responsible for dysphagia and chest pain, remains controversial. Therefore, in contrast to achalasia, the clinical importance of these abnormalities is less clear.

Diffuse esophageal spasm is characterized by normal peristalsis with intermittent simultaneous contractions that can lead to chest pain and dysphagia. The manometric description requires 20% or more simultaneous contractions during water swallows. Adhering to these criteria DES is rare, with an estimated incidence of 0.2/100 000 [116]. This motility disorder is seen in 3–5% of patients who undergo manometry for non-cardiac chest pain or dysphagia [117]. NE, which may be considered a variant of DES, is a manometric abnormality characterized by an average distal esophageal contraction amplitude of 180 mmHg or greater during swallows. Symptoms, i.e. dysphagia and chest pain, are similar for DES and NE. Furthermore, manometric findings may show fluctuation across these disorders, with periods of return to normal peristalsis and, rarely, progression to achalasia.

The etiology of DES and its spastic variants remains unknown. Proposed theories include a dysfunction in endogenous NO synthesis and degradation [118] and defects in cholinergic mechanisms [116]. Other studies suggest that DES can be caused by gastroesophageal reflux [119] and stressful events [120].

The most common presenting symptoms are chest pain, which can occur in association with swallowing or spontaneously, and dysphagia. The chest pain may be clinically indistinguishable from angina of cardiac origin. Dysphagia occurs with both solids and liquids and is transitory and non-progressive.

The diagnosis of a spastic motility disorder is based on the presence of dysphagia or chest pain, accompanied by an abnormal manometry. Chest pain may be stimulated during provocative testing with edrophonium [3]. The diagnosis should only be made after cardiac causes have been thoroughly ruled out. It is important to determine whether gastroesophageal reflux is present by 24-hour pH monitoring, because acid reflux can be a cause of chest

pain. If GERD is found, it should be aggressively treated with acid suppression.

## Treatment of spastic motility disorders

### Overview

Therapeutic trials for spastic motility disorders are scarce, and most of them are uncontrolled studies with small numbers of patients. The unknown etiology and pathophysiology, the controversies surrounding the clinical importance of DES and NE, which make development of therapies challenging, and the rarity of these disorders, have interfered with design and performance of large randomized trials. Furthermore, a high association with psychiatric diseases (depression, anxiety, panic disorder) and issues of heightened visceral sensation pose additional problems [120, 121]. The main goal of therapy is symptomatic relief. An important component in the treatment of DES and NE consists of educating and reassuring the patient about the non-progressive and benign nature of the disease. Many of the treatments used for achalasia have also been used in spastic motility disorders; these include medications such as calcium channel blockers and nitrates, endoscopic botulinum toxin injection, pneumatic dilatation and surgical myotomy.

Additionally, psychotropic agents have been shown to be useful in patients with chest pain of esophageal origin. Observational studies of a number of interventions for these disorders have been carried out [19, 122–132] and the results of a small number of randomized trials are summarized in Table 4.9.

### Medications

Treatment aimed at reducing muscle contractility has been attempted with nitrates or calcium channel blockers. Intravenous nitroglycerin (100–200 mg/kg) was shown to decrease the duration of contractions and relieve symptoms in five patients with DES [118]. **B4** There are no randomized controlled trials evaluating the efficacy of nitrates in the treatment of esophageal spasm. In a randomized controlled trial of diltiazem 60 mg three times daily for two weeks, chest pain and dysphagia were not improved [122]. **Ald** In another randomized controlled trial of 14 patients with chest pain, nine of them with manometric diagnosis of NE, diltiazem 60 mg PO four times daily for eight weeks resulted in a significant decrease in mean chest pain scores [123]. **Ald** However, the symptomatic improvement occurred regardless of whether manometry showed NE. In uncontrolled studies, nifedipine resulted in relief of dysphagia in five of six patients with DES [124] and improved chest pain in four of six patients with DES or NE [125]. However, in a 14-week, double-blind crossover study of patients with non-cardiac chest pain and NE, nifedipine 10–30 mg PO three times daily for 14 weeks decreased the

**Table 4.9** Randomized controlled trials of treatment for spastic disorders of esophageal motility.

Authors	No. of patients	Treatment	Design	Duration	% symptom improvement
Drenth <i>et al.</i> [122]	8	Diltiazem 60 mg three times daily	Crossover	4 weeks	0
Richter <i>et al.</i> [126]	20	Nifedipine 10–30 mg three times daily	Crossover	6 weeks	10
Clouse <i>et al.</i> [127]	29	Trazadone 100–150 mg/day	Double-blind Parallel	6 weeks	Trazadone 50 Placebo 10 ( $p = 0.02$ )
Cannon <i>et al.</i> [121]	49	Imipramine 50 mg at bed time	Double-blind Parallel	3 weeks	Imipramine $52 \pm 25$ Placebo $1 \pm 86$ ( $p = 0.03$ )

distal esophageal contraction amplitude but did not reduce the frequency or severity of chest pain compared to placebo [126]. **Ald** Although other small studies or anecdotal reports described manometric improvement with nitrates or calcium channel blockers, these were not always accompanied by a good clinical response, and adverse effects such as headache, hypotension or lower extremity edema were frequent. More recently, a small uncontrolled study of sildenafil (50 mg PO every day) for the treatment of four patients with NE and one patient with DES, found a symptom relief rate of 60% [19]. **C5**

The use of psychotropic drugs for DES is aimed at altering visceral sensation and targeting stress as a potential cause of spasm. In a randomized controlled trial of 29 patients with chest pain treated with the serotonin reuptake inhibitor trazodone (100–150 mg/day for six weeks), distress over esophageal symptoms was significantly reduced, with no effect on the manometric abnormalities [127]. In a second randomized controlled trial, the tricyclic antidepressant imipramine (50 mg at bedtime) in patients with chest pain and normal cardiac evaluation achieved a  $52 \pm 25\%$  reduction in episodes of chest pain compared with only  $1 \pm 86\%$  reduction in placebo-treated patients ( $p = 0.03$ ) [121]. **Ald** Abnormal manometry was present in only half of the patients and did not predict the response to treatment.

In summary, there are no good data showing improvement of chest pain or dysphagia with nitrates or calcium channel blockers. However, given the lack of established treatments, and since symptoms may be alleviated in some subjects, a therapeutic trial with these agents is reasonable. Therapeutic trials with trazodone or imipramine are recommended for treating chest pain of esophageal origin, although their effect on dysphagia has not been studied. As in the treatment of achalasia, controlled trials with sildenafil are needed.

### Botulinum toxin

Inhibition of esophageal contraction after botulinum toxin injection has been recently introduced as a treatment of

spastic motility disorders. Miller *et al.* [128] used botulinum toxin to treat chest pain in patients with a diagnosis of non-reflux, non-cardiac, non-achalasia spastic esophageal motility disorder (including DES, hypertensive LES or NE). This uncontrolled study of 29 patients receiving botulinum toxin injection at the esophagogastric junction into the LES muscle (the esophageal body was not injected), found 50% or greater reduction in chest pain in 70% of patients and complete relief in 48%. Mean duration of symptom relief was seven months. B4 Storrs *et al.* [129] injected botulinum toxin in 1.5 cm intervals into the esophageal body of nine patients with DES, finding 50% or greater improvement in dysphagia and chest pain in 89% of patients at six months. There are no randomized controlled trials evaluating the use of botulinum toxin for the treatment of DES or NE. Uncontrolled studies tend to overestimate the benefits of treatment. However, this agent has a remarkable safety profile and can be tried in patients who fail medical therapy. **B4**

### Pneumatic dilatation and Heller myotomy

In an uncontrolled study, Ebert *et al.* [130] found that pneumatic dilatation improved symptoms in eight of nine (89%) patients with DES and manometry showing high LES pressure in addition to spasm. The procedure, however, did not result in correction of the abnormal esophageal body contractions. Irving *et al.* [131] used dilatation with Rigidflex balloon to treat 20 DES patients with severe symptoms that were refractory to conservative management; symptom response was reported to be good in 70% of patients. **B4**

Patti *et al.* [132], using thoracoscopic myotomy in ten patients with DES and NE, found that this minimally invasive approach improved symptoms in 80% of patients. Ellis *et al.* [133] reported an overall symptomatic improvement rate of 70% in 42 patients with esophageal motor disorders (32 had a diagnosis of esophageal spasm) treated with long esophagomyotomy performed through a thoracotomy. In contrast, a more recent study by Patti *et al.* [134] compared the symptom scores in patients with primary motility disorders pre and post-intervention with either thoracoscopic or laparoscopic Heller myotomy. In patients with DES,

myotomy relieved dysphagia and chest pain in more than 80%; however, patients with nutcracker esophagus had a less predictable response, and surgery most often failed to relieve the symptoms.

There are no randomized controlled trials evaluating pneumatic dilatation or esophageal myotomy as treatment of DES. The uncontrolled studies may overestimate the benefit of these treatments. Given the morbidity associated with these invasive procedures, they should be reserved for patients with severe symptoms who are refractory to other forms of treatment. These procedures should only be carried out after careful discussion of risks and benefits with the patient. **B4**

## Summary

Diffuse esophageal spasm and its spastic variants are rare disorders. It is critical that a cardiac etiology is ruled out before making the diagnosis of a spastic motility disorder as a cause of chest pain. Gastroesophageal reflux should be investigated and treated when present. Randomized controlled trials in large populations evaluating treatment for these disorders are lacking. The available data suggest that therapeutic trials of muscle relaxants, such as nitrates and calcium channel blockers, may be warranted in some patients. Psychotropic medications, like trazodone or imipramine, are recommended as symptomatic treatment for chest pain associated with a motility disorder but have no proven role in the treatment of dysphagia. Botulinum toxin has resulted in symptom improvement in uncontrolled trials; this agent warrants further study in randomized controlled trials and is attractive because of its excellent adverse effect profile. Finally, pneumatic dilatation and myotomy should be reserved for patients with severe, refractory symptoms after careful consideration of the risks associated with these procedures.

### Introduction

Eosinophilic esophagitis (EE) is a relatively “new” disorder, first described in the late 1970s in adult patients who presented with symptoms of esophagitis, often suffered from atopic disease and were noted to have high numbers of eosinophils on esophageal (and sometimes duodenal and gastric) biopsy. Although their symptoms resembled those of gastroesophageal reflux disease (GERD), these patients frequently had no evidence of acid reflux and almost invariably failed to respond to therapy with acid blockers. The putative causes of the disease resulted in the terms idiopathic EE, allergic EE and primary EE being used synonymously with the term EE, which will be used throughout this chapter.

Increasingly, EE is recognised worldwide as an emerging and significant cause of upper gastrointestinal disease in all age groups. Clinicians should be aware of its clinical and pathological features and will need to keep abreast of the literature regarding its management in order to provide optimal patient care.

The 2007 American Gastroenterology Association (AGA) guideline on EE in children and adults, which is based on a systematic review of the literature, highlights our lack of understanding about the pathophysiology of EE and the ways in which eosinophils contribute to tissue damage, and the lack of universally accepted criteria for diagnosis [1]. Above all, they identify the paucity of high level evidence available from randomised controlled trials (RCTs) to inform clinical management, and our current reliance on

evidence from uncontrolled studies, expert opinion and anecdote.

---

### Searching for the evidence

To inform this chapter, the medical literature contained in electronic databases (Cochrane Library, Medline, Embase, Clinical Evidence) was searched (to October 2008) for articles relevant to the etiology, epidemiology, diagnosis, prognosis and management of EE in adults and children. Emphasis was placed on identifying and reporting in this chapter, summary information from well-conducted systematic reviews of the literature on the diagnosis, management and prognosis of EE. With regard to treatment, the aim was to identify high-level evidence (from meta-analyses of RCTs, RCTs and quasi-RCTs) that compared pharmacological, dietary or surgical interventions for the management of established EE with a placebo or an alternative intervention. Interventions of interest included oral and inhaled corticosteroids, sodium cromoglycate, leukotriene-receptor antagonists (e.g. montelukast), immune modulators (e.g. anti-IL-5 and anti-IgE), dietary interventions (e.g. elemental formulae and food exclusion diets) and surgical interventions (e.g. esophageal dilation). The primary outcomes of interest were improvement in clinical symptoms and histological abnormalities. Harms of interest included adverse effects of medications and dietary or surgical interventions and relapse of symptoms and/or histological abnormalities on cessation of treatment. Several systematic reviews (including the AGA guideline [1], a Cochrane Review on the non-surgical management of EE [2], and reviews on the diagnosis [3] and management [4, 5] of EE) were identified, none of which contained a meta-analysis. Recent non-systematic reviews were also useful information sources [6–8]. Three RCTs [9–11] of therapies for EE were identified. The grading of evidence used in this

chapter to support treatment is based on the levels proposed in Box 1.1 in Chapter 1.

## Definition

Eosinophilic esophagitis (EE) is an inflammatory disorder of the oesophagus characterised clinically by upper gastrointestinal symptoms, histologically by esophageal infiltration with intraepithelial eosinophils (IEE), and endoscopically by a range of abnormalities which vary according to disease severity and chronicity. EE is part of a spectrum of disorders that, while clinically distinct, are characterised by eosinophilic infiltration of different parts of the gastrointestinal tract and include eosinophilic esophagitis, eosinophilic gastroenteritis and eosinophilic proctocolitis.

## Etiology

Our understanding of the pathophysiology of EE is incomplete and the exact role of eosinophils in damaging the oesophagus is not known, limiting our ability to develop rational, safe and effective therapies. The most often proposed etiology for EE is intolerance to ingested (food) or inhaled allergens, mediated through IgE (a type I hypersensitivity response) and/or type 2 T-helper cells (Th2) – a type IV immune response. Mast cell numbers are increased in EE and correlate with eosinophil numbers [6] and the presence of activated mucosal mast cells may help distinguish EE from GERD [12]. In support of an allergic etiology, many patients with EE have a family or personal history of allergic disease, including eczema, allergic rhinitis, asthma and food allergy, the latter being common in young children [13]. It is estimated that up to 75% of patients with EE are atopic and many have measurable food allergen-specific IgE [6]. Some patients respond clinically and histologically to an elemental or a restricted diet, with recurrence of disease after resumption of a normal diet. Furthermore, there is evidence at the cellular level that the pattern of inflammation seen in EE (including activation of eosinophils, mast cells, and type 2 T-helper cells (Th2) and production of Th2-like cytokines (IL-4, IL-5 and IL-13) and eotaxin chemokines) is consistent with the pattern seen in other allergic diseases [6]. It is proposed that inflammation in the esophagus is driven by Th-2 cytokines, e.g. IL-5, which promote Th2 differentiation, regulate IgE expression and promote the production of eosinophils, their release from the bone marrow, and their movement to and survival in other sites. In further support of an allergic basis for EE, most patients respond positively to treatment with corticosteroids. Of interest, cytokine and microarray profiles are similar in both “allergic” and “non-

allergic” patients with EE, suggesting a common etiological pathway to esophageal inflammation [6]. The importance of eotaxins has been demonstrated in one cohort study, in which children with EE expressed the gene for eotaxin-3 (a substance that attracts circulating eosinophils to disease sites) at levels of more than 100 times the levels found in disease-free controls [14]. The study authors went on to demonstrate that this was due to single nucleotide polymorphisms in the eotaxin-3 gene of affected individuals. Furthermore, they showed that mice lacking eotaxin receptors were protected against developing EE.

It is acknowledged that GERD and EE may coexist: some patients with features typical of EE have abnormal pH studies and respond to PPIs [15]. Indeed, an alternate etiological theory for EE is that acid damage in patients with GERD results in increased esophageal permeability and that the resultant antigen entry results in eosinophilic infiltration and a subsequent inflammatory response that induces fibrotic change in the esophagus. Also, products released by eosinophils may lower esophageal sphincter pressure and alter esophageal motility, predisposing to acid reflux [8]. It is likely that the etiology of EE will prove to be multi-factorial. Nevertheless, future studies of disease pathogenesis and genetics will be crucial to guide rational development and use of new therapies.

## Epidemiology

The AGA’s guideline, which provides pooled data from epidemiological studies including over 1000 patients, suggest that EE occurs worldwide in most ethnic backgrounds; that adult men are more commonly affected than women; and that the mean age of onset is 38 (range 14–89) years in adults and 8.6 (range 0.5–21.1) years in children and young adults [1]. Familial disease clusters have been reported but it is not clear whether these reflect genetic predisposition or exposure to common environmental triggers. Variations in reported incidence and prevalence rates may simply reflect study selection bias and use of different diagnostic criteria. In the only published population-based study of a random sample of 1000 adults in Sweden, four individuals (0.4%; 95% CI: 0.2–1.2%) had eosinophilic esophagitis on biopsy, using a cutoff of  $\geq 20$  per HPF and the diagnosis was associated with dysphagia (2/66 vs 2/926;  $p = 0.025$ ). According to the study definition, an additional seven individuals (0.7%) had “probable” EE (15–19 eosinophils per HPF), which was associated with esophageal narrowing (2/15 vs 5/978;  $p = 0.005$ ) [16]. Using the AGA definition [1], this study suggests a prevalence of EE of ~1%. Increased clinician awareness of EE may account for the reported increase in disease prevalence in some settings, although the increase may be real [1].

## Diagnosis

Criteria for the definitive diagnosis of EE are not internationally agreed upon or uniformly accepted. The diagnosis may be suspected in patients of any age who present with symptoms of oesophageal disease, including symptoms of GERD (e.g. regurgitation, vomiting, heartburn, or epigastric, chest or abdominal pain), which occur in both children and adults. In young children, symptoms may be accompanied by food intolerance or refusal and failure to thrive. Dysphagia with solid food or recurrent food impaction occurs more often in adults, commonly males, with long-standing symptoms. Many patients have a strong family or personal history of atopic diseases. Common clinical, endoscopic and histologic features and positive investigations at diagnosis are shown in Table 5.1, although their frequency varies considerably between studies.

The “gold standard” for the diagnosis of EE is a histological abnormality. However, varying cutoffs are used in the literature for the number of eosinophils required per high power field (HPF) to make the diagnosis of EE and distinguish it from conditions such as GERD [1, 8]. This is demonstrated in a systematic review of the literature [3]. In 318 publications identified, 35% of authors did not state the diagnostic criteria they used: 10 different histological definitions were used, and the criterion for the diagnosis of EE ranged from 5 to 30 eosinophils per HPF. There was also variation in the area of the HPF used in these studies [3]. Another difficulty in making the diagnosis is the patchy nature of EE (hence the patchy distribution of IEE), which influences the number of biopsies necessary and the esophageal sites (distal and proximal) that should be biopsied.

Diagnostic test sensitivity increases with the number of biopsies obtained: in one study sensitivity increased from 55% with one biopsy to 100% with five biopsies [17]. However, the choice of the biopsy site can also be difficult. In one study the appearance of the esophagus was normal at endoscopy in 30% of children with EE [18], suggesting that multiple biopsies should be taken from the length of the esophagus when the diagnosis is suspected, regardless of the endoscopic appearance. In the systematic review, only 39% of authors reported using specific biopsy protocols [3]. In addition, different investigators have used different histological grading systems, including a score that included both eosinophil numbers and thickness of the basal cell layer [9]. The lack of consistency in diagnostic methods makes comparison between epidemiological and intervention studies impossible. Acceptance of a universal, standardised histological definition for EE, such as that proposed in the AGA guideline ( $\geq 15$  IEE per HPF in one or more biopsy specimens) [1] and of a standardised biopsy protocol and fixing technique (e.g. using formalin or paraformaldehyde), is imperative. Many clinicians biopsy the stomach and duodenum to exclude eosinophilic gastritis and duodenitis and some studies exclude patients in whom eosinophils are identified outside the esophagus and an accepted universal standard must also be reached in this regard.

To complicate matters, it has been suggested that eosinophilic infiltration may be a non-specific response to any injury of the esophageal epithelium [19]. Eosinophilic infiltration of the esophagus has been documented in other conditions including Crohn’s disease, drug reactions, parasitic infection and hypereosinophilic syndrome, which should be excluded when considering a diagnosis of EE [1]. Although the AGA guideline suggest that, in order to make

**Table 5.1** Clinical, endoscopic and histological features of eosinophilic esophagitis.

Common clinical features	Endoscopic features	Histological features	Laboratory investigations
GERD symptoms: regurgitation vomiting, heartburn, epigastric, chest or abdominal pain	Normal appearing esophagus Erythema Edema	$\geq 15$ eosinophils per high power field in one or more esophageal biopsy specimens	Skin prick tests for food and environmental allergens Patch tests to food allergens Peripheral eosinophil count
Dysphagia, choking, food impaction (increase with age, usually occur in adults)	Exudates or micro-abscesses appearing as raised white dots, plaques or nodules (representing eosinophilic microabscesses)	Squamous epithelial hyperplasia	(~2 fold elevation seen, more commonly in children)
Food refusal or intolerance, poor weight gain/failure to thrive, fussy eater (in infants and young children)	Longitudinal furrowing	Eosinophilic microabscesses	Distal esophageal pH studies
Early satiety	Esophageal rings or corrugation	Degranulation of eosinophils	if diagnosis of GERD considered
Hematemesis	Stricture	Basal zone hyperplasia	
Unresponsive to PPI	Small-calibre esophagus	Papillary lengthening	
Personal or family history of atopic disease (food allergy, positive skin prick tests, asthma, eczema)	Longitudinal shearing or friability (crepe paper mucosa) at endoscopy <sup>a</sup>	Normal duodenal, gastric histology	

<sup>a</sup>Characteristic of EE.

the diagnosis of EE, GERD should have been excluded by a normal lower oesophageal pH study and partial or complete lack of response to high dose proton pump inhibitor (PPI) therapy [1], this diagnostic criterion is not universally accepted, particularly in children in whom pH studies may be difficult to perform [10]. As discussed above, there is overlap between the clinical and histological features of EE and GERD and the two conditions may coexist with a complex inter-relationship [15]. Nevertheless, a pH study may be helpful to exclude GERD as a cause for esophagitis when the endoscopy and biopsy findings are equivocal.

Endoscopy findings in EE are extremely variable (Table 5.1) and may reflect disease severity and chronicity; at one end of the spectrum the esophagus may appear normal and at the other end luminal narrowing and strictures (usually in adults with long-standing symptoms) may be evident [20]. Furuta suggests that apart from the findings of longitudinal shearing and “crepe paper” mucosa, endoscopic features described in EE are not unique to this condition [1]. Nevertheless, identification of more than one of the typical features (including exudates or micro-abscesses appearing as raised white dots or nodules, esophageal narrowing, ringed (or feline) esophagus, longitudinal furrows or longitudinal shearing and friability) in the context of consistent clinical symptoms should raise the index of suspicion for EE [1]. Barium studies are not routinely recommended but may be useful to define the site and extent of esophageal narrowing found at endoscopy and to exclude other diagnoses.

In accordance with the current AGA guideline [1] diagnostic criteria include:

- Clinical symptoms of esophageal disease *and*
- Histological abnormality: ( $\geq 15$  IEE in one or more HPF on a biopsy specimen) *and*
- Exclusion of differential diagnoses including GERD (by normal pH study or lack of response to high dose PPI) *and*
- Consistent endoscopic findings

## Prognosis

Due to the relative rarity and recent recognition of this disorder, there are few prospective longitudinal cohort studies that provide good evidence about the long-term prognosis of EE. Three follow-up studies in adults were identified in the AGA guideline [1]. In summary, most patients had significant prior symptoms of refractory GERD, dysphagia, or impaction at study entry and up to 86% went on to develop oesophageal narrowing, strictures, or corrugation. Strictures were proximal in over half of the patients and dilation commonly caused longitudinal tears. The diagnosis of EE had frequently been missed and treatment delayed. Symptoms were chronic and in one study, symptoms worsened during the follow-up period (up to 11.5 years) in about one-quarter of patients and remained

stable in about one-third but were not life-threatening [21]. In some patients there was histological evidence of increasing subepithelial fibrosis or thickening of the esophagus over time in the absence of macroscopic change at endoscopy. There is no evidence in these cohorts with relatively short-term follow-up that EE is associated with development of esophageal neoplasia.

Outcomes in children are also poorly studied. Liacouras reported on nearly 400 children with EE who had presented with refractory GERD at less than 10 years of age and were followed for up to 10 years [18]. About 6% developed esophageal narrowing but only one child required dilation. Clinical and histological response to oral steroids was almost universal and response to inhaled fluticasone was about 50%, but most children relapsed when either treatment was ceased. The majority of children subjected to dietary manipulation (with a restriction diet or elemental diet) went into disease remission, which included improvement in esophageal calibre. A recent retrospective review of 89 children with EE supports the observation that EE is both chronic and relapsing; 79% of the 66% who initially responded to treatment had relapsed within the eight-year follow-up period [22].

## Management

A range of pharmacological therapies has been used to treat EE, including oral and inhaled (swallowed) corticosteroids, sodium chromoglycate, PPIs, montelukast (a leukotriene inhibitor) and mepolizumab (an IL-5 monoclonal antibody). Dietary interventions include restricted or elemental diets and surgical interventions include esophageal dilation. However, there is a dearth of high-level evidence to support use of any of these interventions. Only three RCTs (two placebo-controlled trials and one comparing two current therapies) have been performed in EE [9–11]. All had methodological limitations, including small sample size, inconclusive results, and potential confounding from simultaneous use of co-therapy. Two of the RCTs were conducted in children and evaluated the role of steroids [9, 10] but used different criteria for the diagnosis of EE, for inclusion of trial participants and for determining histological response. Neither evaluated long-term maintenance therapy (Table 5.2). There is only one small RCT ( $n = 11$ ) evaluating a novel therapy in adults with EE [11].

## Pharmacological therapies

### Corticosteroids

Steroids have been widely used in the treatment of EE and several uncontrolled studies, previously summarised [1, 8]

**Table 5.2** Randomised controlled trials in patients with eosinophilic esophagitis.

Author date setting	Participants	Intervention	Comparison	Outcome measures	Evidence level; study quality	Results and comments
Schaefer, 2006. Children's Hospital, Indiana, USA	Included: 80 children (age range 1–16 years) with EE ( $\geq 15$ eosinophils per HPF and negative pH probe study). 58% of children tested positive for food allergies at entry and were asked to eliminate relevant food. Excluded: other esophageal condition, <i>H. pylori</i> infection, CIBD, current treatment with corticosteroids.	Oral prednisone (1 mg/kg/dose twice daily (maximum of 30 mg bd) for 4 weeks then weaned for 8 weeks (n = 32).	Topical (swallowed) fluticasone via metered dose inhaler (110 µg per puff (age 1–10 years) and 22 µg per puff ( $\geq 11$ years of age) (n = 36).	Histological improvement (to $< 15$ eosinophils per HPF) at 4 weeks; symptom remission; adverse drug effects; symptom relapse.	Grade A evidence. Randomisation: yes, random number assignment. Allocation concealment: yes. Blinding: no, open-label. Baseline characteristics: similar. ITT analysis: no. Adequate sample, power. Follow-up: 6 months.	Benefits: histological improvement in majority at 4 weeks (no difference between groups). Majority symptom free at 4 weeks (no difference between groups). Harms: prednisone group: 40% adverse effects and 3 withdrew $< 4$ weeks with severe adverse effects (hyperphagia, weight gain, cushingoid features). Fluticasone group: 15% esophageal candidiasis. Symptom relapse 45% at week 24.
Konikoff, 2006. Children's Hospitals, Cincinnati, San Diego, USA	Included: 36 children (age range 3–18 years with EE ( $\geq 24$ eosinophils per HPF in $\geq 1$ biopsy from distal/proximal esophagus and epithelial hyperplasia); not failed PPI. Excluded: patients with food allergy on SPT who responded to exclusion diet; recent steroid use; pregnant.	Fluticasone propionate (400 µg bd for 3 months) via metered dose inhaler and swallowed (n = 20). Normal diet and PPI (if taken) continued in both groups.	Placebo (bd) for 3 months via metered dose inhaler (n = 11).	Histological remission ( $< 1$ eosinophil per hpf); adverse effects	Grade A evidence. Randomisation: yes, computer generated. Allocation concealment: yes. Blinding: yes (participants, clinicians, histologists). Baseline characteristics: similar (participants, clinicians, histologists). Small sample, adequate power. Follow-up at 3 months: 100%. Analysis: ITT. Compliance monitored: yes.	Benefits: fluticasone vs placebo: Histological remission 50% vs 9%; RR 5.5 (95% CI: p = 0.05). Disappearance of distal esophageal furrowing, decreased epithelial hyperplasia. Response better in non-allergic, young children. Vomiting decrease in responders. Harms: candidiasis in 1 patient receiving fluticasone

HPF: high power field (400x); PPI: proton pump inhibitor.

suggest that both oral and topical steroids may improve histological abnormalities and clinical symptoms. Historically, oral steroids were reserved for patients with EE with severe dysphagia, strictures and weight loss because of concerns of adverse effects. The more recent use of topical steroids (fluticasone propionate or beclomethasone), administered by a metered-dose inhaler and swallowed, has been documented in uncontrolled studies with variable effectiveness for the initial treatment for EE [1, 8] and few adverse effects. There is limited evidence about the long-term use of either topical or oral steroids, although available studies suggest that discontinuation of steroid therapy frequently results in relapse.

Since publication of the AGA guideline [1] two RCTs have been published (summarised in Table 5.2), which provide the only reliable evidence for steroid therapy for EE. The first was a well-designed and adequately powered, open-label RCT that recruited 80 children (16 years or under) with EE (defined as  $\geq 15$  IEE per HPF and negative pH studies) [9]. Children were randomised to receive four weeks' initial treatment with either oral prednisone or topical fluticasone and were weaned off treatment over the next eight weeks. A histological grading score incorporating both eosinophil count and thickness of the basal cell zone was used to assess therapeutic response. Although most of the 68 children who completed the study had symptomatic improvement and showed histological improvement within one month, there was no significant advantage for one medication over the other. Importantly, 40% of the prednisone group experienced adverse effects of treatment and three children withdrew from the trial within four weeks of commencing therapy because of severe adverse effects. Of the fluticasone group, the majority (34/36) showed histologic improvement, 35/36 improved clinically and 15% experienced esophageal candidiasis, which was sometimes asymptomatic and responded to anti-fungal treatment.

Symptom relapse usually occurred within six weeks of stopping therapy and had occurred in 45% of all trial participants at six-month follow-up (although endoscopy and biopsy were not performed at this time) with no difference between treatment groups in the rate or timing of relapse. A potential confounder in this study is that 58% of all children tested positive for food allergies prior to commencing steroids and were asked to eliminate the relevant food. Although the proportion receiving a special diet was similar in each group it is possible that benefits of the diet resulted in an overestimation of the beneficial effect of both medications. In view of the similar effectiveness of the two steroid preparations and the potential adverse effects of oral steroids documented in this RCT, inhaled (swallowed) steroids should be used in preference to oral steroids as initial treatment for uncomplicated EE. **A1c** Patients should

be advised to use the medication without a spacer and, after spraying the medication into their pharynx, to swallow rather than inhale. Patients should be asked not to eat or drink or wash out their mouths for half an hour after medicating. **B4** In view of the high relapse rate of EE after treatment is stopped, the long-term use of fluticasone requires evaluation both for efficacy and for adverse effects. Systemic effects from long-term fluticasone use have not been evaluated in EE. It has been suggested that oral therapy should be reserved for short-term use in patients with acute or severe dysphagia or stricture requiring dilation [1], although RCT evidence in this group is lacking.

The second RCT (placebo-controlled and blinded) included 36 patients aged 18 years or under with EE (defined as  $\geq 24$  IEE/HPF in  $\geq 1$  biopsy specimen from either the proximal or distal esophagus and epithelial hyperplasia) [10]. Patients were randomised to receive either fluticasone propionate or placebo for three months. The primary outcome was histological remission, complete remission being defined as an eosinophil count of  $\leq 1$  per HPF. In contrast to Schaefer's study [9], failure to respond to PPI was not a criterion for inclusion in Konikoff's study and children who were receiving PPI continued to take them during the trial, a potential confounder. In contrast to Schaefer's trial, children with food allergy who had responded to an exclusion diet were excluded from Konikoff's trial; children who refused or failed to respond to dietary manipulation were included. Half of the children who received fluticasone responded histologically. Histological remission (the primary outcome of interest) was higher in the treatment group compared with the placebo group (50% vs 9%;  $p = 0.047$ ) with a RR of 5.5 (95% CI: 0.81–37.49;  $p = 0.05$ ), which may reflect the small sample size.

The study thus identifies both a considerable proportion of non-responders to fluticasone and the potential for spontaneous remission of EE and highlights the need for placebo-controlled trials. In this trial, distal esophageal furrowing was less frequently seen following treatment with fluticasone than placebo (50% vs 90%) and reduction in epithelial hyperplasia was greater with fluticasone. With fluticasone there was an improvement in vomiting (in 67% compared with 27% in the placebo group) but not in dysphagia, suggesting that caution should be employed in generalizing these findings to adults with EE, who more often have dysphagia. Young children who were found to be non-allergic using skin-prick testing were more likely to respond to fluticasone therapy. Side effects (namely candidiasis) from fluticasone were uncommon. This study supports the use of fluticasone for EE in children: **A1d** the dose recommended in the AGA guideline based on the literature and consensus is 440 to 880 micrograms per day for chil-

dren in a divided (bd) dose and 880 to 1760 micrograms per day for adolescents or adults [1] although there are not RCTs in adults.

### Mast cell stabilizers

In one small, uncontrolled cohort there was no clinical or histological benefit from oral sodium cromoglycate given to children with EE at dose of 100 mg four times daily for one month [18]. **B** There is no RCT evidence to support use of this medication which is not currently recommended for EE.

### Anti IL-5 medications

The finding, in a mouse model, that IL-5 can induce EE and that blocking IL-5 can ameliorate disease [23] led to the successful treatment of a young adult with EE and chronic symptoms with mepolizumab (an anti-IL-5 medication) and supported trial of this intravenous preparation in four adults with chronic EE and dysphagia who had failed to respond to a range of other therapies [24]. In this small, uncontrolled trial in a heterogeneous group, the clinical and histological response was positive but variable (adverse events were not reported). **B4** Similarly, responses to treatment with reslizumab in four patients with EE were variable [25]. **B4** One recent placebo-controlled RCT evaluated use of up to four doses of mepolizumab in 11 adults with EE and confirmed a greater reduction in esophageal eosinophils in the treatment compared with the placebo group (67% vs 25%), but no difference in symptom response. [11] Mepolizumab was given at a dose of 750 mg at 0 and 7 days and if the response was incomplete two doses of 1500 mg were given at four-weekly intervals up to a maximum of four doses. **A1d** Larger RCTs are required to assess the benefits and harms of these treatments.

### Leukotriene-receptor antagonists

In a small, uncontrolled study (n = 8) in adults with EE, high dose montelukast (Singulair) resulted in symptom resolution in the majority but caused minor adverse effects (nausea and myalgia) and did not result in histological improvement [26]. Recurrence occurred with cessation of or decrease in the dose of the medication. Currently, there is insufficient evidence to recommend use of this medication. **B4**

### Proton pump inhibitors

A number of small uncontrolled studies, summarised in recent reviews [1, 8], report variable clinical and

histological improvement in patients with EE when PPIs were used alone or in conjunction with dilation in patients with strictures. **B4** RCT evaluation of PPIs for use in EE is required before their routine use can be recommended.

---

### Dietary interventions

Clinical studies suggest that food allergies may be present in up to 50% of cases of EE in children, and the most common foods implicated are peanuts, milk products, eggs, soy, wheat and seafood [13]. Food allergies are more prevalent in children than in adults and in a subset of patients they play an important role in initiating and maintaining esophageal inflammation. The predictive value of food-specific IgE radioallergen sorbent testing (RAST) for diagnosing IgE-mediated food allergy in EE is unknown and skin prick tests are recommended [1]. Type IV Th2 delayed hypersensitivity reactions can be diagnosed by skin patch testing. Although elemental diets (consisting of free amino acids, medium-chain triglycerides and corn syrup solids) and diets restricting specific foods (based on food allergy testing) or excluding the six most common food allergens have been used to treat EE [1, 8], there is little high level evidence to support their use.

Bohm [8] identified eight uncontrolled studies which showed a good clinical and histological response to dietary intervention in between 74% and 100% of children. In the largest study, 172 children were treated with an elemental diet (administered by nasogastric tube because children could not tolerate its taste), with a clinical and histological response in 100% [18]. A similar response was observed in 76% of 146 children treated with a restrictive diet based on skin prick and patch testing [27]. Thirty nine of the 40 children who failed to respond initially subsequently went into remission with an elemental diet. Limitations of these studies include the lack of controls, failure to monitor adherence to diet and, in Spergel's study, concomitant use of steroids in more than half the children and lack of standardisation of diagnostic allergy tests. Long-term use of elemental diets may be regarded as impractical: they are poorly tolerated orally, administration by nasogastric tube is invasive, and they are expensive and do not help identify the offending food. Thus, although there is some evidence to support the use of dietary interventions in EE, **B4** and the AGA guideline recommends they be "considered as an effective therapy in all children diagnosed with EE" [1], there remains the need for placebo-controlled and comparative RCTs to adequately assess the effectiveness, tolerability and cost-effectiveness of elemental and restrictive diets in both children and adults.

## Endoscopic dilation

Although dilation of esophageal strictures is often used in adult (and occasionally paediatric) patients with EE and has been reported in several uncontrolled studies [1, 8], the procedure has not been adequately evaluated and has been questioned following reports of perforation, esophageal tearing and other complications. In a recent, small, retrospective case series, in 10 patients treated at two tertiary referral centres in Germany, the use of gentle (3 mm) dilation was reviewed in patients with esophageal strictures (of varying number, length and location) and dysphagia (mean 11 years duration) that were secondary to EE and resistant to at least eight weeks of topical treatment with corticosteroids [28]. Patients had had between one and five dilations; mucosal tears and pain on swallowing for a few days following the procedure were common but there were no perforations. All patients had an immediate improvement in dysphagia score, and their response to treatment (almost complete disappearance of dysphagia) was sustained for an average of 6 (range 2–11) months following the procedure. These findings are consistent with previous, heterogeneous, uncontrolled case series in adults [20, 21, 29, 30] and children [31] in which the majority of patients show clinical improvement. **B4** However, lack of consistency in diagnostic criteria, prior treatment and outcome measures makes comparison between studies difficult. Although it is important to relieve symptoms dilation is not curative, it is associated with significant adverse effects and recurrence occurs in up to 50% cases [1]. It is not clear whether this treatment should be reserved only for patients resistant to medical (steroid) treatment (the current recommendation), or whether prior use of steroids increases the risk of adverse outcomes or improves dilation outcomes. There is an urgent need for larger scale, prospective studies examining the safety and long-term efficacy of dilation in well characterized groups of patients.

## Future therapies

Based on our increasing understanding of the pathogenesis of EE, a number of novel therapies have been proposed for potential use, but not yet adequately trialled in EE, and these are summarised by Stone [6]. Known immune modulators, Azathiaprine and 6-mercaptopurine, have been used only in a limited number of cases of EE to induce and maintain remission [32]. Omalizumab, the only clinically available monoclonal antibody against IgE, which prevents activation of mast cells, has been used effectively in a small number of patients with eosinophilic gastroenteritis but may increase esophageal eosinophil numbers and its role in EE is unclear [33]. It has been proposed that calcineurin

inhibitors (e.g. tacrolimus), which decrease expression of Th2 and mast cell cytokines, may have a role in treating EE. However, the potential for this medication to induce eosinophilic gastrointestinal disease has been noted in some patients after liver transplantation [34]. Other potential therapies include anti-IL-5 receptor monoclonal antibodies (as an alternative to neutralizing IL-5) and monoclonal antibodies to CD25 and TNF- $\alpha$  [6]. Because epithelial TNF- $\alpha$  levels are increased in EE, infliximab, an anti-TNF therapy, has been used in small numbers of adults with severe, refractory EE with equivocal clinical and negligible histological effect [35]. Antagonists to IL-4 and IL-13, which increase eotaxin expression, and to the eotaxin receptor, to eotaxin and to  $\alpha 4\beta 7$  (which are involved in recruiting eosinophils to the gastrointestinal tract) may also have a role in therapy [6].

It will be important that putative therapies are carefully selected, based on our knowledge of pathogenesis and rigorously tested by RCT to confirm their safety and efficacy. Although there are now three published RCTs evaluating treatments for EE, it is discouraging that the study authors used different diagnostic and inclusion criteria for patients with EE and different outcome measures, and that the studies had methodological limitations including small sample size. In view of the variable clinical characteristics of EE and the possibly different etiologies of paediatric and adult EE, it will be important that participants recruited to trials are well characterised and that trials are either restricted to subgroups of EE or adequately powered to enable subgroup analysis. Diagnostic criteria and outcome measures must also be standardised. Although symptom relief is the aim in established disease, it will also be important to evaluate long-term therapy to prevent disease complications and to consider possible therapies to prevent development of EE.

## Ulcer disease and *Helicobacter pylori* infection: Etiology and treatment

Naoki Chiba

Division of Gastroenterology, McMaster University Medical Centre, Hamilton, and Guelph General Hospital, Guelph, Canada

---

### Introduction

Peptic ulcer disease, particularly duodenal ulcer disease, was thought to result from gastric acid hypersecretion and pepsin damage. Indeed Schwarz's dictum [1], "no acid, no ulcer" is still relevant, as acid is a prerequisite for most ulcer formation. Peptic ulcers were also thought to be caused by a variety of other cofactors such as smoking, stress and non-steroidal anti-inflammatory drugs (NSAIDs) including aspirin. Therapy was directed primarily against lowering acid production in the stomach to permit healing of ulceration. However, the discovery and characterization of gastric infection with *Helicobacter pylori* has revolutionized our concepts of ulcer pathogenesis and therapy. As duodenal ulcer has long been thought to result from an imbalance between protective and aggressive factors in the mucosa, *H. pylori* can be considered an "aggressive" factor which may tip the balance toward mucosal damage and result in ulceration. Thus, the assignment of an etiologic role to *H. pylori* does not contradict the traditional concepts of ulcer pathogenesis, but rather extends them.

Warren and Marshall's seminal paper in 1983 first identified the spiral bacterium that is now known as *Helicobacter pylori*, associated with active chronic gastritis [2]. Their subsequent paper [3] determined an association between the gastric infection and peptic ulcer, particularly duodenal ulcer, where *H. pylori* was present in all antral biopsies. For their discovery, Doctors Barry Marshall and Robin Warren were awarded the 2005 Nobel Prize in Physiology and Medicine.

Indisputable evidence has dispelled initial skepticism of the role of this infection as an important gastroduodenal pathogen. This chapter reviews and presents the evidence

for the etiological role of *H. pylori* in peptic ulcer disease. Causes of ulcers other than *H. pylori* will also be discussed. Last, treatment of ulcer disease with an emphasis on *H. pylori* eradication will be reviewed.

---

### What is the evidence for the role of *H. pylori* in peptic ulcer disease?

One approach would be to determine whether "Koch's postulates" which link an infectious agent with disease(s) are fulfilled. The postulates state that the "agent (1) must be found in patients with the disease only, (2) must be grown outside of the body, (3) when inoculated into a susceptible animal, must cause the same disease, and (4) must be grown from the lesions observed" [4]. Many of the organisms currently accepted as disease causing pathogens do not necessarily fit all of Koch's postulates. Furthermore, there is limited applicability to chronic disease such as that caused by *H. pylori* infection [5]. A more applicable approach is [5] to use the criteria for assessing epidemiological evidence, as outlined by Hill [6].

There is sufficient evidence to establish *H. pylori* as a cause of duodenal ulcer and this evidence is summarized in Box 6.1.

---

### Association of *H. pylori* with ulcer disease (strength, consistency and specificity)

In this section, the prevalence of *H. pylori* in both duodenal and gastric ulcer patients is considered.

#### Duodenal ulcer

The prevalence of *H. pylori* in ulcer disease had been well reviewed by Kuipers *et al.* [9], who identified relevant studies published since the discovery of *H. pylori* in 1983.

**BOX 6.1** Evidence for role of *H. pylori* in peptic ulcer disease (PUD) according to Hill's criteria

Association (strength, consistency, specificity) of *H. pylori* with PUD

Prevalence of *H. pylori* in DU ~ 90%, GU ~ 80%:

- strength and consistency of association is high
- specificity is low as *H. pylori* seen in many without ulcers
- overall, data is supportive

Temporal relationship: does *H. pylori* infection precede PUD?

- self-administration of *H. pylori* shown to cause active chronic gastritis – fulfils one of Koch's postulates
- but, no direct evidence that PUD is caused
- case control study (Nomura [7]) shows preceding *H. pylori* infection increases risk of DU, GU and gastric cancer
- cohort study (Sipponen [8]), >10% *H. pylori* positives developed DU over 10 years but <1% if *H. pylori* negative
- thus, data is supportive

Biological gradient: no consistent data to support higher levels of bacterial load correlate with PUD

Biological plausibility: numerous plausible pathophysiological alterations (see text) that include:

- vacA causing epithelial cell damage – not consistent
- cagA associations with disease states such as DU, gastric cancer and MALTomas – not consistent or universally seen
- elevated gastrin and acid secretion that revert to normal after *H. pylori* eradication
- numerous alterations in mucosal cytokines
- thus, data are supportive

Effects of interventions: outcomes following *H. pylori* eradication. Alterations in natural history of PUD with *H. pylori* eradication provides strongest evidence that *H. pylori* is a true pathogen. RCT data of *H. pylori* eradication shows:

- DU and GU relapse markedly decreased
- DU heal with eradication of *H. pylori* infection alone without ulcer healing drugs
- DU heal faster when *H. pylori* eradicated than with ulcer healing drugs alone
- DU refractory to ulcer healing drugs can heal if *H. pylori* eradicated
- Re-bleeding from ulcers can be prevented if *H. pylori* eradicated
- thus, data are strongly supportive

Coherence of *H. pylori* data with previous epidemiological data:

- consistent historical correlations between presumed *H. pylori* prevalence, ulcer disease prevalences, death rates and perforations from ulcer disease
- improvements in hygiene and sanitation in industrialized nations have resulted in declining prevalence of both *H. pylori* and ulcer disease
- prevalence of *H. pylori* infection and ulcer disease have become the same in males/females
- thus, data are supportive

In the decade to 1993 they found that infection with *H. pylori* was present in 94.9% (95% CI: 94–96%) of 1695 duodenal ulcer patients studied. Borody *et al.* found *H. pylori* in 94% of 302 duodenal ulcer patients in Australia [10]. Of the 14 patients who were negative for *H. pylori* at the time of endoscopy, four had taken antibiotics shortly before endoscopy and may have had false negative results, and eight had NSAID induced ulcers. Overall, only one of 302 patients had no cause for duodenal ulcer identified. Thus, almost all duodenal ulcers which were not caused by NSAIDs were associated with infection with *H. pylori*.

A strong association by itself, does not prove causality [4, 5]. While the association of *H. pylori* with duodenal ulcer is strong and consistent, it is not specific since *H. pylori* is also found in many patients without ulcer disease. The reasons why *H. pylori* infection cause disease in a minority of patients infected with the organism are not yet known. This question remains the subject of ongoing research.

The prevalence of *H. pylori* associated DU appears to be getting lower. In Italy, the prevalence of DU in 2001 was 6.5%, declining to 3.1% in 2004 [11]. Also, from another Italian study, over a 10-year period in two different regions,

there was a decline in DU to about 5% [12]. In South Korea, the prevalence of DU had decreased to 39% in 2004/5 compared to 45% a decade before, with an increase in *H. pylori* negative ulcers to 68% from 79% [13]. A Hong Kong study also showed a decline in duodenal ulcer disease between 1997 and 2003 [14].

In summary, there is a reduction in ulcer disease, mostly duodenal ulcer disease associated with the decline in *H. pylori* infection.

### Duodenal ulcers not related to *H. pylori* and NSAIDs

The new millennium has seen an increase in *H. pylori* negative duodenal ulcers, perhaps related to successful treatment of *H. pylori* [15]. Quan and Talley [15] concluded that it was difficult to determine the true prevalence of *H. pylori* negative ulcers accurately because of the cross-sectional nature of the studies. Patients could be misclassified as being *H. pylori* negative if there has been recent antibiotic or bismuth use and also if PPI use had not been stopped at least two weeks prior to testing, especially if testing was

done by the urea breath test. Also, as the presence of *H. pylori* in the gastric mucosa could be patchy, mucosal biopsy methods required adequate biopsy sampling and preferably, the use of multiple methods of *H. pylori* determination. Retrospective series suffer from the inability to accurately determine surreptitious NSAID use.

A meta-analysis of seven rigorously designed North American duodenal ulcer studies identified that 20% of patients in these studies had ulcer recurrence within six months, despite successful cure of infection and no reported use of NSAIDs [16]. In a review of similar studies, Ciociola *et al.* [17] estimated the prevalence of *H. pylori* and NSAID negative duodenal ulcers was 22%. One American study identified *H. pylori* infection in only 62% of DU and 44% of GU patients [18]. No reason for these lower *H. pylori* prevalence rates in ulcer patients was offered. A similarly high proportion of 29% *H. pylori* and NSAID negative ulcers was recently reported from Pakistan [19]. There may be ethnic differences in the proportion of ulcers related to *H. pylori*. For example, in Japan, the *H. pylori* negative peptic ulcer prevalence appears to be less than 5% [15]. Despite these reports of nearly 20% or more non-*H. pylori*, non-NSAID ulcers, a report from Italy suggested that of their patients, after careful review of *H. pylori* status, NSAID ingestion and recent antibiotic use, only 0.8% (6/774) could be truly considered idiopathic [20].

In an interesting, prospective population survey of 2416 Danish subjects that assessed risk factors for peptic ulcer disease, the *H. pylori* negative duodenal ulcer prevalence was 13% [21]. The causes of these ulcers could not be adequately ascertained as there were so few ulcers, but there were suggestions that smoking, minor tranquilizer use and tea consumption were possibly associated.

In Singapore, a carefully designed study that assessed thromboxane B2 levels as a surrogate for possible NSAID use, determined a corrected non-*H. pylori* and non-NSAID peptic ulcer proportion of about 8% [22].

In the Swedish Kalixandra study, the prevalence of peptic ulcer was 4.1% [23]. Of these 19% were *H. pylori* and NSAID negative duodenal ulcers.

A Spanish study of 754 peptic ulcer patients found only 1.6% of all duodenal ulcers were non-*H. pylori* and non-NSAID associated [24]. A similarly low prevalence of 2% was found in Finland [25] and 1.3–1.5% in Japan [26, 27]. Thus, these reports of varying prevalences of duodenal ulcers unrelated to *H. pylori* or NSAIDs suggests ethnic variability.

Most duodenal ulcer recurrences after eradication of *H. pylori* are related to NSAIDs [28] and the role of pentagastrin-stimulated peak acid output is unclear [29, 30]. Smoking has been implicated as an important additional risk factor to *H. pylori* and NSAIDs [23, 31]. Stress may be a factor [32, 33] as may other co-morbid illness and alcohol

abuse [33]. One study suggested that poor socioeconomic status was an important risk factor for PUD independent of *H. pylori* status [34]. A Japanese study suggested that persistent inflammation in the lamina propria may be an important factor for ulcer recurrence [35].

Overall, the proportion of duodenal ulcers that is both *H. pylori* and NSAID negative is between 1 and 20%. There are not a lot of recent data supporting a change in prevalence of these types of ulcer.

## Gastric ulcer

There are fewer studies on the role of *H. pylori* in gastric ulcer, and NSAIDs play an important role in their etiology. *H. pylori* infection is diagnosed in 60–100% of gastric ulcer patients (mean about 70%) [9, 36]. As Thijs *et al.* point out [21, 36], many of the earlier studies suffered methodological problems that probably led to an underestimate of the prevalence of *H. pylori* in gastric ulcer disease. Most gastric ulcers are associated with *H. pylori*-related active chronic gastritis whether or not NSAIDs are involved [36–38]. However, from 4 to 11% may have no identifiable cause [24, 37]. The study by Nomura *et al.* [7] also showed that prior infection with *H. pylori* increased the risk that the patient may develop gastric ulcer subsequently.

Other newer drugs such as bisphosphonates [39, 40] have been found to cause gastric ulcers and there may be a synergistic effect with naprosyn [41]. Potassium supplements and chemotherapeutic drugs such as floxuridine have also been identified as causative agents [15].

Thus, *H. pylori* remains an important cause of duodenal (DU) and gastric ulcers (GU) [42]. *H. pylori* negative ulcers are commonly caused by NSAIDs [36]. Furthermore, the proportion of *H. pylori* negative ulcers increases as the overall prevalence of *H. pylori* infection falls [18, 43].

---

## Temporal relationship

Whether *H. pylori* infection precedes the development of ulcer disease cannot be assessed by point prevalence studies, since it is impossible to assess retrospectively when these patients were infected [5].

Marshall [44] described three “self-administration” experiments in humans. In these cases active chronic gastritis ensued, fulfilling one of Koch’s postulates for at least the first step in the development of peptic ulceration, although actual ulcer disease did not develop.

The temporal relationship between infection with *H. pylori* and the development of duodenal ulcer has been best demonstrated in a cohort study reported by Sipponen *et al.* [8]. Of the 321 patients with *H. pylori* at study entry, 34 developed a duodenal ulcer over the next 10 years, while

only 1 of 133 *H. pylori* negative patients developed an ulcer.

An IgG serological nested case-control study of a group of 5443 Japanese-American men with stored sera obtained between 1967 to 1970 demonstrated that pre-existing *H. pylori* infection increased the subsequent risk of developing either duodenal or gastric ulcer disease over a surveillance period of greater than 20 years [7]. The odds ratio (OR) for development of ulcer was 4.0 (95% CI: 1.1–14.2) for duodenal ulcer and 3.2 (1.6 to 6.5) for gastric ulcer. The relationship was statistically significant even when the ulcer diagnosis was first made 10 or more years after the serum sample had been obtained. A further analysis of this Hawaiian cohort [45] identified that *H. pylori* infected men of higher birth order had an increased risk of gastric (OR 1.64) but not duodenal ulcer. These data are consistent with the hypothesis that early infection with *H. pylori* increases the risk of developing gastric ulcer.

### Biological gradient

If there were a higher bacterial load in the stomach of patients with ulcers vs those without an ulcer this would be additional evidence supporting a causative role [4]. In biopsy studies, there has been insufficient gastric mucosal sampling to assess whether there was a biologic gradient present [5]. It is problematic to rely on biopsy specimens due to sampling error. A test such as a urea breath test (UBT) may be more useful in this regard. Ingested urea is digested by bacterial urease activity with the labeled CO<sub>2</sub> breakdown product being excreted in the breath. Significant correlation has been observed between labeled CO<sub>2</sub> excretion in the breath and intragastric bacterial load [46, 47] and mucosal inflammation [46–48]. However, there has not been consistent correlation with endoscopic findings [46]. Most of the available literature did not find a correlation of endoscopic findings with higher urea breath test values, and authors did not report whether the finding of higher test results predicted the finding of a duodenal ulcer [49–51]. Thus, data supporting a relationship between a greater inoculum of *H. pylori* and ulcer development are limited.

### Biological plausibility

*H. pylori* is a unique bacterium that has evolved ecologically to survive and persist in the harsh acidic environment of the stomach. Bacterial urease, flagellar motility and surface adhesins appear necessary for colonization and persistence [52]. Despite the high prevalence of infection, not all infected persons develop ulcer disease, and most remain asymptomatic. Are there more virulent strains that

predispose to ulcer disease? The vacuolating cytotoxin (*vacA*) which causes surface epithelial cell damage and vacuolation of epithelial cells, has not been found consistently to correlate with ulcer disease [52]. The *cagA* protein is a marker of the *cag* pathogenicity island of *H. pylori* and several studies have determined that in developed countries, duodenal ulcers, intestinal metaplasia, gastric carcinoma and mucosa-associated lymphoid tissue (MALT) lymphoma are more commonly seen in patients infected with a *cagA* positive strains [52]. However, this relationship is not universally seen in all ethnic origins. The newest potential virulence marker has been the duodenal ulcer promoting gene (*dupA*). Although there has been a statistically significant association of *dupA* with DU, it was identified in only 37% of North Indian patients [53]. In another study *dupA* was not associated with DU disease [54].

If *H. pylori* is primarily an *intra*gastric infection, how does it cause ulcers in the duodenal bulb? Observations prior to and after the discovery of *H. pylori* identified that patients with duodenal ulcers had gastric metaplasia and associated *H. pylori* colonization in the duodenal bulb [55–60]. This change is thought to arise as a result of hypersecretion of acid as observed in duodenal ulcer patients. The gastric metaplasia may [61–63] or may not [64] improve after *H. pylori* eradication. Patients infected with *H. pylori* have increased basal and stimulated gastrin release irrespective of whether they have duodenal ulcer disease or not [65–67]. The elevated gastric acid secretion also results in increased postprandial duodenal acid load [68]. Furthermore, *H. pylori* eradication [69, 70] or suppression [71] results in normalization of these gastrin levels in most subjects, with lowering of acid secretion [65, 69]. However, a subset of patients with recurrent duodenal ulcer have persistently high acid secretion despite *H. pylori* eradication [72]. *H. pylori* can colonize islands of gastric metaplasia in the duodenum. Numerous toxigenic factors have been identified by which *H. pylori* might cause mucosal damage, although there is no one pathophysiological factor accepted as being pathognomonic. Adhesion of *H. pylori* to epithelial cells results in elevated levels of mucosal cytokines such as interleukin (IL)-8 which is increased in the mucosa of *H. pylori* infected patients [73]. *CagA* positive strains have higher levels of tumor necrosis factor (TNF)- $\alpha$ , IL-1 $\beta$ , IL-6, IL-8 and are associated with more severe inflammation (active chronic gastritis) in the gastric mucosa [74]. This T-helper subtype 1 (Th1) proinflammatory cytokine response may predominate in ulcer disease whereas a mixed Th1/Th2 pattern predominates in those with chronic gastritis but no ulcer [75]. There may be a link between increased IL-8 and gastrin release that is potentiated by *H. pylori* sonicates [76]. Thus, there are plausible multifactorial mechanisms by which *H. pylori* may cause pathogenic effects resulting in peptic ulcer.

## Effects of interventions: outcomes following *H. pylori* eradication

In the days before recognition of *H. pylori*, ulcers could be healed but inevitably relapsed over the next year [77–82]. The most clinically relevant evidence for the role of *H. pylori* comes from intervention trials in which *H. pylori* was eradicated and recurrence of ulcer disease markedly reduced [83].

The first reported randomized trial in 1987 [84] showed that the risk of recurrent duodenal ulcer could be reduced to virtually zero when *H. pylori* eradication therapy was given. In 1988, Marshall *et al.* [85] reported a randomized double-blind trial in duodenal ulcer patients in which more ulcers healed and fewer ulcers recurred over 12 months with *H. pylori* eradication therapy. Other important early contributions supported these observations [86–90]. **A1c**

Reviews of studies from 1987 to 1994 demonstrated that the recurrence rate for duodenal ulcer at one year ranges from 0 to 9% when *H. pylori* infection is successfully eradicated [36, 91, 92]. There are fewer data on ulcer recurrence after periods longer than one year after *H. pylori* eradication, but reported recurrence rates range from 0 to 18% [92]. Labenz reported that at one year, infection with *H. pylori* and duodenal ulcer recurred in 2.4% and 0.8% of patients, respectively [93]. Longer follow-up showed no further *H. pylori* or ulcer recurrence at three and four years [93]. Another study reported that 92% of patients remained free of *H. pylori* after seven years of follow-up, while those who were *H. pylori* positive remained persistently positive [94]. **B4** In 15 randomized trials in which *H. pylori* eradication was compared with no eradication, the ulcer recurrence rate was 7% in those in whom *H. pylori* was eradicated vs 67% in those who remained infected [92]. A systematic review [95] has shown that the median 12-month duodenal ulcer recurrence rate is 67% if *H. pylori* infection persists, but is reduced to 6% if *H. pylori* is eradicated. **A1a** Comparable results for gastric ulcer recurrence are 59% and 4%, respectively. A more recent meta-analysis examined studies that directly compared gastric and duodenal ulcers and identified that for DU the one-year ulcer recurrence rate was 2% and for GU 3% if *H. pylori* was eradicated, but if the infection persisted, the ulcer relapse rate was 42% for DU and 39% for GU [96]. **A1a** Thus, regardless of whether the patient suffers from DU or GU, successful eradication results in cure for most patients.

Other strongly supportive data include the observations that DU healed without ulcer healing drugs if *H. pylori* was eradicated and that the rate of healing was faster with *H. pylori* eradication. Eradication of *H. pylori* has been shown to prevent re-bleeding from ulcers as well. These important data will be further discussed in the sections below.

## Coherence of the data with earlier epidemiological information

The prevalence of *H. pylori* infection parallels data showing that there was a peak in the incidence of ulcer disease at the end of the nineteenth century [4]. This is consistent with epidemiological data that show that the death rate of duodenal ulcer patients was highest in those born around 1890 [97]. The highest risk for ulcer perforation was identified in a cohort of men born between 1900 and 1920 [98]. This is also the generation with the highest *H. pylori* prevalence in an *H. pylori* seropositivity study carried out in the UK [99]. This relationship is consistent with the hypothesis that *H. pylori* plays an important role in ulcer complications.

Improvements in hygiene and sanitation are associated with a declining risk of infection, as is the case today in industrialized nations compared with less developed countries, which still endure a poor socioeconomic status. The number of admissions for ulcer disease has steadily declined since the middle of this century which infers a declining severity and prevalence of duodenal ulcer [100]. This decline parallels a declining prevalence of *H. pylori* infection. However, more recent data suggest that the overall prevalence of peptic ulcer and its complications has not changed much in the USA, likely because of the ulcerogenic effects of increasing NSAID use [101].

While duodenal ulcer disease has long been thought to be a disease of men, data since 1979 have shown that the prevalence of duodenal ulcer and the death rate for men and women have become similar [102]. This is consistent with the effect of *H. pylori* infection of which the prevalence is the same in both sexes [103].

## Treatment of duodenal ulcer

### Healing of duodenal ulcer with acid suppressive therapy

A meta-analysis [104] has shown a close linear relationship between the degree of suppression of intragastric acidity and duodenal ulcer healing. A more complex meta-analysis of this relationship between the duration of acid suppression and healing led to the definition of three primary determinants of the benefits of antisecretory drugs: (1) the degree of suppression of acidity; (2) the duration of suppression of acidity over the 24-hour period; and (3) the duration of the treatment [105]. For duodenal ulcer, the duration of time the intragastric acidity can be maintained at or above pH 3.0 is the most important factor. This model identified that maintaining intragastric pH at or above the threshold pH of 3.0 for 18–20 hours of the day predicts a 100% healing of duodenal ulcer [105]. Lesser degrees of

acid suppression were found to prolong the duration of time needed to achieve optimal healing. Thus, these models of degree of acid suppression help explain the results of controlled trials of agents for healing ulcers.

Treatment of duodenal ulcer in the pre-*H. pylori* era was revolutionized by  $H_2$ -receptor antagonists ( $H_2$ -RAs), and subsequently PPIs, whose effects were proven in placebo-controlled trials. Numerous methodologically sound, double-blind, randomized controlled trials using comparative healing rates of endoscopically proven ulcers as the outcome measure, have established that PPIs heal ulcers faster than  $H_2$ -RAs and also provide more rapid symptom relief [78, 106–111]. In the chapter in the second edition of this textbook [112], the literature of 28 such randomized controlled trials was reviewed and summarized [18, 77–79, 106–111, 113–130]. **A1a** As the data were robust, this evidence was not updated in this present chapter.

There is no proven difference in ulcer healing rates and safety between different PPIs [127, 131, 132]. There are direct comparative trials of lansoprazole vs omeprazole [125, 126], pantoprazole vs omeprazole [127] and rabeprazole vs omeprazole [128] which showed equivalent duodenal ulcer healing. **A1c**

### Maintenance therapy for prevention of duodenal ulcer recurrence

Although ulcers were healed effectively by acid suppressive therapy, ulcer recurrence was almost inevitable, with about 80% recurrence at one year once treatment was stopped [77–82]. Thus, in an effort to prevent recurrent ulcer, patients were given maintenance therapy with  $H_2$ -RAs. In a large ( $n = 399$ ) two-year maintenance study of ranitidine 150mg daily vs placebo, ulcer symptoms remained controlled in only about half the patients but ulcer recurrence was prevented in 83% of patients [133]. This study also identified significantly ( $p < 0.002$ ) more complications such as bleeding in the placebo arm. **A1a** After a long-term follow up of 464 patients on maintenance ranitidine, 81% remained free of symptomatic DU recurrence over nine years [81]. A one-year relapse rate of between 20 to 30% has been identified consistently through meta-analyses [134, 135] and reviews [80]. Most of the maintenance studies used suboptimal half doses of the  $H_2$ -RAs, as full ulcer healing doses are more effective in preventing relapse [80, 136, 137]. **A1c** Ulcers treated with tripotassium dicitrate bismuthate appeared to have a more prolonged remission beyond that seen with  $H_2$ -RAs. It has since been suggested that this effect is, in part, due to the suppressive effects of bismuth on *H. pylori* infection and its ability as a single agent to eradicate *H. pylori* in around 20% of patients [138].

For duodenal ulcers resistant to healing with  $H_2$ RAs, lansoprazole was more effective than placebo in maintain-

ing healing over one year when used in doses of 15mg (70% remission) and 30mg (85% remission) [139]. **A1d** The sample size was inadequate to determine whether the larger dose was more effective.

### Influence of *H. pylori* eradication on healing of duodenal ulcer

The interval between *H. pylori* eradication therapy and reassessment may influence ulcer healing data. In a cohort study of patients given *H. pylori* eradication therapy it was observed that at one month, 22/212 (10.4%) had persistent DU. These patients were followed for another two months without additional ulcer healing treatment, and ultimately only three ulcers remained unhealed for a total healing success rate of 98.1% [140].

Furthermore, duodenal ulcers heal faster when *H. pylori* infection is eradicated than with acid suppressive therapy alone using either  $H_2$ -RAs [85, 88, 90] or omeprazole [141]. Ulcers refractory to healing with conventional acid suppressive therapy may heal with *H. pylori* eradication therapy [86, 142–145] **A1c** and remain healed over a four-year follow-up period [93]. **B4** In the pre-*H. pylori* era, it was shown that ulcers could be healed with antibiotics alone [146–148]. Similar results have been shown in subsequent studies that aimed to heal ulcers with anti-*H. pylori* antibiotic treatment alone, without the need for additional ulcer healing drugs [25, 149–153]. These findings further support the role of *H. pylori* as a bacterial pathogen for ulcer disease.

### Acid suppressive therapy need not be continued beyond the duration of eradication treatment

There is good evidence [25, 150, 154–157] that uncomplicated, active duodenal ulcers heal without the need to continue ulcer healing drugs beyond the duration of eradication therapy. **A1c**

There are several methodologically sound trials in which patients all received eradication therapy and were randomized to either placebo or an ulcer healing drug for a further 2–3 weeks to test the hypothesis that continued ulcer healing drugs were not required after the eradication period [154, 158–162]. In all these studies, the ulcer healing proportions at four weeks were the same, regardless of whether an antisecretory drug was continued or not. In one study, the trend towards ulcer healing at two weeks was higher in patients who continued antisecretory therapy (continued therapy 91%, placebo 76%;  $p = 0.14$ ), but at four weeks all ulcers had healed in both treatment groups [154]. In another study, by three weeks the healing rates were 89% in the continued omeprazole arm and 81% in the placebo arm and by eight weeks, the healing rates were the same [160].

## Duodenal ulcer complications and effects of *H. pylori*

Gastroduodenal ulcer disease causes serious complications, such as bleeding, in 15–20% of patients, perforation in about 5% and obstruction in up to 2% of affected patients [163].

### Bleeding

A natural history study of duodenal ulcer before the *H. pylori* era provided interesting data from 2119 patients [164]. Of these patients, 13.5% presented with hemorrhage as the first indication of ulcer disease. The overall mortality was 4.5% in those patients who bled and only 1% in those without bleeding. Most deaths not due to bleeding were due to perforation. The re-bleeding rate was 13% overall versus 2% for patients who continued on therapy. **B4** Even in a report to 2006, the mortality rate remained high at 5.4% after ulcer bleeding [165].

As the rate of recurrent bleeding in the past was high, strategies for prevention of re-bleeding were necessary. Two randomized, placebo controlled trials have evaluated the effect of a maintenance dose of ranitidine 150mg on ulcer bleeding. One trial did not show that ranitidine reduced re-bleeding. However, the study lacked statistical power [166]. The other trial [167] showed a significantly reduced risk of re-bleeding, (ranitidine 9%, placebo 36%, absolute risk reduction (ARR) 27%, number needed to treat (NNT) 4). **A1d** However, the maintenance H<sub>2</sub>-blocker arm still carried a re-bleeding risk of nearly 10% and half the episodes were not preceded by symptoms alerting one to the presence of a recurrent ulcer. The risk of re-bleeding did not diminish over time, as those patients on placebo were at continuous risk of re-bleeding over the three-year follow-up period. Surprisingly, long-term randomized controlled maintenance trials with more potent acid suppressive drugs (proton pump inhibitors) have not been reported [168]. There is one non-randomized report from 1996 where patients were allocated to either eradication therapy or to long-term antisecretory therapy with either omeprazole or ranitidine [169]. Overall, 12% of the patients (5 of 41) had a re-bleed in the 20-week follow-up, compared to only 2.3% in the antibiotic group [169]. One anecdotal report from Japan in a heterogeneous population of both gastric and duodenal ulcers showed that in those with persistent *H. pylori*, ulcer re-bleeding occurred in 12% of patients on H<sub>2</sub>-blockers and 10% of cases on PPIs [170]. The data are insufficient to allow any conclusion of the benefit of the PPIs.

Currently, it is accepted that eradication of *H. pylori* leads to a reduction in peptic ulcer recurrence, and hence prevents recurrent bleeding of both duodenal and gastric ulcers [170–173]. This has been well summarized by Gisbert *et al.* in a 2004 Cochrane Review and their subsequent

observational trial [171, 173]. In the Cochrane Review, the mean re-bleeding rate after *H. pylori* eradication therapy compared with continued antisecretory therapy was 1.6% and 5.6% (OR 0.25; 95% CI: 0.08 to 0.76) respectively [171]. In the studies comparing *H. pylori* eradication to no eradication and no continued antisecretory therapy, the re-bleeding rate was 2.9% and 20% respectively (OR 0.17; 95% CI: 0.10 to 0.32). Levels of evidence included observational studies and randomized controlled trials. Thus, *H. pylori* infection should be looked for in all patients with bleeding ulcers and eradication therapy should be standard of care for those who are infected. In some patients it may not be possible to eradicate *H. pylori*, and in these patients, PPI maintenance therapy is then recommended.

Despite the success of eradicating *H. pylori* and curing the traditional peptic ulcer, the problem of bleeding ulcers has not gone away. As half of ulcer bleeding may be attributable to NSAIDs, this is a substantial problem [174]. Those positive for both *H. pylori* and NSAIDs have a synergistically high risk of re-bleeding [175, 176].

In a Hong Kong study, there was an increasing proportion of bleeding idiopathic (non-*H. pylori* and non-NSAID related with no other cause) ulcers compared to *H. pylori* related ones [177]. Those with idiopathic ulcers seemed to have a worse prognosis with greater recurrent complications compared to *H. pylori*-associated ulcers that were treated with eradication therapy [177]. Another report found that those with idiopathic ulcers had a higher mortality rate and longer hospital stay than those with an *H. pylori* related ulcer [165]. There are no randomized management trials for preventing re-bleeding in these idiopathic ulcers which appear more serious than *H. pylori* related ulcers. It is recommended that these high-risk patients be treated with the most potent acid-suppressive therapy available, that is, with a PPI. As H<sub>2</sub>-blockers exhibit tachyphaxis and heal ulcers less effectively than PPI, there is little rationale to recommend them.

**Summary** The results of all studies are in agreement that *H. pylori* eradication significantly reduces ulcer re-bleeding rates and hence *H. pylori* should be looked for and eradicated if identified.

### Perforation

There are few data available concerning the role of *H. pylori* infection in other complications such as ulcer perforation. A controlled trial involving 60 patients undergoing simple closure of perforated duodenal ulcer demonstrated a significant ( $p < 0.05$ ) benefit for decreasing complications of peptic ulcer disease with postoperative cimetidine treatment [178]. **A1d** This study did not consider the role of *H. pylori* infection. NSAID use increases the risk of ulcer perforation by a factor of 5 to 8 [179] and in one series, 71% of the perforated DU patients had been using NSAIDs

[180]. Separate relative risks for duodenal and gastric ulcers are not known. In 80 patients presenting with acute perforated duodenal ulcer, the prevalence of *H. pylori* infection by serology was only about 50%, approximately equal to that in a control group, and NSAIDs were frequently the cause of the perforation [181]. More recent studies using biopsy based methods of *H. pylori* detection have shown *H. pylori* prevalence of 50% [180], 73% [182, 183] to 80% or more in perforated duodenal ulcer patients [184–186].

A case series of *H. pylori* positive patients with perforated peptic ulcer demonstrated that after *H. pylori* eradication, there was no need for re-operation and no mortality after a median 44-month follow-up [183]. **B4**

There are two randomized trials of *H. pylori* eradication in patients with perforated peptic ulcer [182, 187]. In a Hong Kong study, patients with perforated DU were initially treated with simple closure [187]. The *H. pylori* prevalence was 81% and these 99 patients were randomized to receive eradication therapy or four weeks of PPI alone. After one year, the rate of ulcer relapse was 38% in patients treated with omeprazole alone and 5% in those who received anti-*Helicobacter* therapy [187]. **A1d** Kate *et al.* followed 202 patients for two years after simple closure of a perforated duodenal ulcer and also retrospectively reviewed the records of an additional 60 patients [182]. In the prospective arm, patients were randomized to ranitidine alone or ranitidine quadruple eradication therapy. In patients in whom *H. pylori* was eradicated, the risk of recurrent ulcer was between 4 and 28% and the authors did not report any subsequent perforations. **B4** Thus, there is reasonably strong evidence to support a recommendation for *H. pylori* eradication in infected patients with a perforated ulcer.

### Obstruction

The prevalence of this complication may be as low as 0.5%, and the strength of evidence for this rare complication is restricted to case reports [188, 189] and observational studies [190, 191]. The prevalence of *H. pylori* with pyloric obstruction ranges from 45% to 90% [191], with a mean value of 69% reported in one review [192]. Gastric outlet obstruction seems to improve following *H. pylori* eradication in most reports [188, 189, 191, 193] **B4** and in combination with balloon dilatation of the pylorus in some reports [190, 193].

---

## Treatment of gastric ulcer

### Healing of gastric ulcer with acid suppressive therapy

Gastric ulcer healing rates with H<sub>2</sub>-RAs in the pre-*H. pylori* era were 3–43% at two weeks, 54–70% at four weeks, 82–

92% at eight weeks and 89–94% at 12 weeks [194]. Thus, gastric ulcers take four to eight weeks longer to heal than duodenal ulcers. There are no important differences in healing rate between various H<sub>2</sub>-RAs. However, PPIs have been shown to produce higher healing rates than H<sub>2</sub>-RAs in several randomized trials [194–197]. An early meta-analysis [194] demonstrated that the most important determinant of healing was duration of treatment. A later meta-analysis, comparing omeprazole and ranitidine in healing gastric ulcers demonstrated more rapid and complete healing with more potent acid suppression [195]. **A1c** Another meta-analysis in which the rates of gastric ulcer healing were expressed as ulcers healed per week, showed that PPI (represented by omeprazole) healed gastric ulcers 24% faster than other agents [198]. **A1c** A more recent update suggested that rabeprazole, pantoprazole, or lansoprazole showed better improvement in the clinical symptoms when compared with omeprazole [199]. **A1c** However, healing of gastric ulcer with pantoprazole [200] and rabeprazole [201] was comparable to that with omeprazole.

### Maintenance therapy for prevention of recurrence of gastric ulcer

Maintenance therapy with H<sub>2</sub>-RAs (cimetidine, ranitidine, famotidine, nizatidine) in half standard dose at night, has been shown to reduce the risk of symptomatic recurrence in one year to 6.7–36% compared with a rate of 49–76% without therapy [80]. A PPI (omeprazole, lansoprazole, pantoprazole) in standard dose once daily reduced the recurrence of gastric ulcers to only 4.5% over six months [202].

A randomized trial demonstrated that lansoprazole in doses of 15 mg and 30 mg prevented recurrence of healed gastric ulcer in 83% and 93% of patients over a 12-month period ( $p < 0.001$ ) [203]. **A1c**

### *H. pylori* eradication influence on healing and recurrence of gastric ulcer

Eradication of *H. pylori* speeds gastric ulcer healing in six weeks to 84.9% compared with a rate of 60% in patients with persistent *H. pylori* infection ( $p = 0.0148$ ) [204]. A larger study has shown that almost all GU can be healed if *H. pylori* is eradicated compared to 60–70% healing if the infection persists [205].

Curing *H. pylori* infection has been shown in randomized controlled trials to reduce the recurrence rate of gastric ulcers, although there are fewer data than is the case for duodenal ulcer [36, 89, 92, 206–210]. **A1c** Gastric ulcers can be healed by *H. pylori* eradication therapy alone, without the need for continued administration of an antisecretory drug for ulcer healing [208, 211–214]. A recent study compared *H. pylori* eradication alone, eradication therapy with

continued PPI and PPI without eradication therapy [214]. In this study, *H. pylori* eradication alone resulted in partial gastric ulcer healing, but healing was better if esomeprazole was continued. A corollary of this is that longer duration of treatment is needed to heal gastric ulcers. The accompanying editorial recommended that PPI be continued after eradication therapy to ensure ulcer healing [215].

*H. pylori* eradication almost eliminates gastric ulcer recurrence, while persistently infected patients have a relapse rate up to 50% [91, 92, 214, 216]. **A1c** Labenz and Börsch reported that at one year, *H. pylori* recurred in 3.4% of patients, while gastric ulcer recurrence was not observed [93]. Longer follow-up showed no *H. pylori* infection or ulcer recurrence at three and four years [93]. **B4** In studies with higher relapse rates, NSAIDs are an important cause of the recurrent ulcers [217].

## ***H. pylori* eradication therapy**

### **Antibiotic regimens**

The evolution of *H. pylori* eradication treatment has been rapid. It was determined early on that this infection was easy to suppress but difficult to cure. Thus, if the patient were tested too early following completion of a course of an eradication treatment, the organism would be “cleared” but be falsely identified as having been eradicated. A time interval of at least four weeks after the end of eradication treatment was identified as the minimum necessary to define eradication [138, 218].

The first meta-analysis of *H. pylori* eradication regimens [138] established that single antimicrobial agents were insufficient to eradicate *H. pylori*. A later review identified clarithromycin as a drug that can eradicate *H. pylori* infection in up to 54% of patients when given alone. However, as resistance rapidly develops, its use as a single agent is not recommended [219]. Combinations of two antimicrobials were found to result in improved eradication rates, but the best regimens were “bismuth triple therapies” [138]. The best regimen in 1992 was triple therapy with bismuth, metronidazole and tetracycline (BMT) which was superior to triple therapy with bismuth, metronidazole and amoxicillin [92, 138, 220]. However, this combination was felt to be too cumbersome and hence, more “user friendly” PPI based therapies emerged.

Because the literature is extensive, background materials and reviews will be summarized and only recent data about effects of new therapies and treatment of eradication failures will be discussed. Ranitidine bismuth citrate is an effective drug in combination therapy for *H. pylori* eradication. However, since it is no longer available in most parts of the world, it will not be discussed. The previous chapter on *H. pylori* in the second edition of this

book contains details of these previously discussed therapies [221].

### **PPI based combination therapies**

The PPIs are potent acid suppressing agents that effectively heal duodenal and gastric ulcers and provide prompt symptom relief. They may have a synergistic effect with antimicrobials by providing an optimal intragastric pH milieu [222, 223]. They also have some direct suppressive effects on *H. pylori* [224]. In an interesting Japanese study patients were treated with lansoprazole, amoxicillin and clarithromycin and 24-hour intragastric pH was measured on day 6 of treatment [225]. Patients with successful eradication had a higher median intragastric pH of 6.4 compared to those who were eradication failures, where the median pH was 5.2 [225]. **B2** Thus, there is good rationale to use these agents as part of an *H. pylori* eradication regimen.

### **PPI dual therapy**

*PPI plus amoxicillin* Dual therapy with PPI and amoxicillin (PPI-A) enjoyed a brief period of popularity. Overall efficacy in several reviews and meta-analyses was in the order of 60%, and results were not consistent. Therefore this regimen is not recommended for standard therapy [92, 219, 220, 226–230]. However, one potential advantage with an amoxicillin regimen is that *H. pylori* rarely ever becomes resistant to amoxicillin. Thus, this dual regimen could be given more than once. More potent acid inhibition with higher PPI doses [231, 232] are not more effective.

*PPI plus clarithromycin* With the identification of clarithromycin as the most effective single therapy [233], it came to be used as dual therapy with omeprazole. This combination gave more consistent and reliable results than PPI-A dual therapy, with eradication rates as high as 70% [220, 226, 229, 234]. Two weeks of therapy with relatively high doses of clarithromycin 500 mg bid to tid and hence higher cost [220] were required. More importantly, the high development of clarithromycin resistance in treatment failures would then preclude its use again as part of an *H. pylori* eradication regimen [235]. Thus, any regimen that uses clarithromycin should be one that has the best possible eradication success to prevent development of secondary clarithromycin resistance [235].

*Other PPI dual therapies* One study used rabeprazole with levofloxacin for either 5, 7 or 10 days and found low eradication rates of 50–70% while a triple therapy with rabeprazole, amoxicillin and levofloxacin was 90% effective [236]. These data suggest that dual therapy with a PPI and one antibiotic are unlikely to be of clinical utility.

### PPI, clarithromycin and amoxicillin or nitroimidazole triple therapies

Better eradication rates were achieved with regimens that combined a PPI with two antimicrobials. The first regimen, known as the Bazzoli regimen [237], used omeprazole 20mg od, clarithromycin 250mg bid and tinidazole 500mg bid for one week and achieved 100% efficacy. A meta-analysis of such treatments suggested that this was the most effective therapy overall [220]. Many subsequent trials using omeprazole, lansoprazole or pantoprazole have demonstrated that the PPI-based triple therapies are consistently superior to dual therapies [220].

The first large randomized placebo controlled eradication trial was the MACH 1 study [238]. While this study was criticized for having only one test of *H. pylori* eradication after treatment, the regimens identified as being the most effective have stood the test of time and remain recommended by most consensus conferences as first-line therapy [239–243].

The most effective one week, twice daily regimens in the MACH 1 study were: (1) omeprazole 20mg, clarithromycin 500mg and amoxicillin 1g or (2) omeprazole 20mg, clarithromycin 250mg and metronidazole 400mg [238]. Studies with similar efficacy for analogous regimens have subsequently been reported using lansoprazole [244–252], pantoprazole [220, 253–255], rabeprazole [256–258] and esomeprazole [234, 259–261] based triple therapies. Meta-analyses have shown the same results [262, 263].

#### A1a

Some studies have shown some slight benefit of one PPI over another, but the significance of such observations is unclear. For example, a direct comparative study of rabeprazole or lansoprazole with clarithromycin and amoxicillin found that the rabeprazole triple therapy was significantly more effective (88% ITT) than the lansoprazole triple (78% ITT), and eradication success with clarithromycin resistant strains was poor for both therapies [264]. Whether there are genetic differences to account for this is unclear. A Taiwanese study compared esomeprazole to pantoprazole with clarithromycin and amoxicillin for one week with ITT eradication rates of 94% and 82% ( $p = 0.009$ ) respectively [265]. The authors speculated that the greater acid inhibition and anti-*H. pylori* effects of esomeprazole may explain this result.

Most experts recommend that the PPI, clarithromycin and amoxicillin be considered first-line over PPI, clarithromycin and a nitroimidazole triple therapy because of the higher prevalence of resistance of *H. pylori* to imidazole compared to clarithromycin. However, in comprehensive meta-analyses, no difference in efficacy between these two regimens was found [266, 267]. **A1a** Also, one study found that the PPI-CA regimen gave slightly lower eradication with more frequent adverse effects (38%) compared to PPI-CM (20%,  $p < 0.05$ ) [268].

These twice daily, one-week regimens are well tolerated, with few drop-outs due to drug intolerance. A meta-analysis did not show any difference in efficacy between a lower dose of clarithromycin (250mg bid) vs the conventional 500mg bid dose in combination with a PPI and metronidazole [269]. Patients treated with the lower dose had only half the incidence of adverse effects [270]. While the smaller dose of clarithromycin may be adequate for many patients, consensus groups have advocated the 500mg bid dose for consistency and to avoid possible confusion and prescribing errors. For PPI-CA combinations, the larger clarithromycin dose of 500mg bid was found to be superior to the 250mg bid dose [269].

Another triple therapy with PPI, amoxicillin and metronidazole is generally less effective than the PPI, clarithromycin and amoxicillin (PPI-CA) and PPI, clarithromycin and metronidazole (PPI-CM) triple therapies in head-to-head trials [205, 238, 252]. However, as empiric second-line therapy, there may be some advantage, as this is not a clarithromycin containing regimen, and efficacy may be reasonable in some populations [271–273]. It seems particularly effective in Japan [274], even after eradication failure with standard triple therapy [275].

### Some declining efficacy

Recent data suggest that these PPI based triple therapies may not be quite as effective as was observed some years ago. For example, a randomized Canadian study published in 2003 compared esomeprazole vs omeprazole with metronidazole and clarithromycin for seven days and found that ITT eradication rates were now less than 80% at 76% and 72% [276], whereas in the 1996 MACH-1 study, the eradication rate for the same regimen was 90% [277]. Unfortunately, this study did not assess *H. pylori* antibiotic resistance.

However, other studies published more recently [278–281] demonstrate continued high eradication success, with ITT eradication rates remaining above 80%. Results are indeed variable in various publications, and the true efficacy is unclear. In areas of high clarithromycin and metronidazole resistance, gold standard triple therapy may be less effective.

### Optimum duration of PPI triple therapy

Original recommendations were for a one-week treatment course. Laine reviewed triple therapy with esomeprazole, clarithromycin and amoxicillin and demonstrated that a seven-day regimen gave 86–90% ITT eradication rates in DU patients from Europe and Canada but in the USA, even 10 days seemed slightly less successful, with 77–78% success [260]. Thus, this suggested that in America, longer 10–14 day therapy was necessary. However, a recent US study [282] and a Spanish study [283] using rabeprazole, amoxicillin and clarithromycin found comparable eradica-

tion rates with 7 and 10-day treatment. More recently, with the apparent decline in treatment success, even the Maastricht II consensus guidelines nebulously state that treatment should be given for a minimum of seven days [284] and the Maastricht III consensus indicates that 14 days is more effective than seven days [243]. One study that used lansoprazole, clarithromycin and amoxicillin to eradicate *H. pylori* found that one week of treatment eradicated 75% and two weeks eradicated 86%, a difference that was not statistically significant [285].

Calvet *et al.* [286] performed a meta-analysis of 13 randomized studies to 1999 that directly compared different durations of treatment to determine the optimal treatment duration for triple therapy. They found that pooled data suggested that 10–14 day regimens were better than seven-day regimens and in direct head-to-head comparisons, 14-day regimens were more effective than seven-day regimens, with a therapeutic gain of 7–9%. **A1a** These authors performed a cost-effectiveness analysis of the different durations of treatment in relation to two basic strategies; UBT post treatment for all patients or UBT only if symptoms relapsed [287]. They studied the economic costs in Spain (low cost model) and USA (high cost). For either follow-up strategy, the shortest, seven-day duration produced the lowest costs. In sensitivity analyses, the 10-day regimen would have to be 10–12% more effective than seven-day therapy and the 14-day therapy 25–35% more effective than seven days for the longer duration therapies to become cost effective in Spain. For the USA, the corresponding figures were 3–5% and 8–11% respectively. Thus, even though the longer duration regimens are more effective, in terms of economic evaluation, the shorter duration approaches may be cost effective overall. Indeed, a more recent meta-analysis suggests that extending the duration of PPI triple therapy beyond seven days may not be a clinically useful strategy [288].

### Influence of antibiotic resistance on PPI triple therapies

*Resistance to nitroimidazole (i.e. metronidazole, tinidazole)* A meta-analysis of studies performed prior to 1997 evaluated *H. pylori* eradication rates with a variety of regimens in nitroimidazole resistant and sensitive strains [289]. Pooled data from studies using PPI with nitroimidazole and amoxicillin or clarithromycin, showed that eradication was achieved in 93% of sensitive strains and only 69% in resistant strains. PPI, nitroimidazole and amoxicillin was a less effective regimen (64%) than the corresponding regimen that included clarithromycin (76%) for nitroimidazole resistant strains. For sensitive strains, both regimens were very effective, with pooled eradication rates of 92–93%, and the duration of therapy (7, 10 or 14 days) did not influence eradication success.

The MACH-2 study published after this meta-analysis, carefully evaluated antibiotic resistance and determined that baseline metronidazole resistance reduced the efficacy of the OCM triple therapy from 95% to 76% [290, 291]. A similar reduction in efficacy of about 15% was reported in a lansoprazole study [252]. Importantly, the MACH-2 study also showed that the addition of omeprazole, with its potent acid suppression, helped partially to overcome metronidazole resistance. When baseline metronidazole resistance was present, clarithromycin and metronidazole alone was a successful combination in only 43% of cases, but with the addition of omeprazole the efficacy was improved to 76%. For metronidazole sensitive strains, the eradication rate with the antibiotics alone was 86% and the addition of omeprazole improved the eradication rate only slightly to 95% [290]. In the MACH studies, the dosage of metronidazole was 400mg bid, slightly lower than the 500mg bid available in Canada. However, a meta-analysis has shown these two doses to be similarly effective [292]. The higher metronidazole dose may be better on theoretical grounds, since higher doses may be more effective against resistant *H. pylori* strains [293].

Amoxicillin allergy is common and this is a contraindication to use of the PCA regimen. Since this regimen does not contain metronidazole, there is rationale for using it in patients with suspected or documented metronidazole resistant strains [294].

### Resistance to clarithromycin

There is no doubt that the primary determinant of treatment failure is resistance to clarithromycin (macrolides). Laine *et al.* summarized the data with esomeprazole, amoxicillin and clarithromycin and determined that in clarithromycin sensitive strains, the eradication rate was 89% but in those with clarithromycin resistant *H. pylori*, the eradication rate was much reduced to 45% [295]. After treatment with this triple therapy, clarithromycin resistance developed in 33% (2/6) compared to 85% (23/27) after treatment with esomeprazole and clarithromycin dual therapy. Even worse eradication success with clarithromycin resistance was reported by Murakami *et al.* [264]. In patients treated with rabeprazole or lansoprazole combined with amoxicillin and clarithromycin, the eradication success with clarithromycin sensitive strains was 98% and 89% but in clarithromycin resistant strains, the eradication rates were 8.1% and 0% [264]. Other studies have also shown that PPI triple therapies containing clarithromycin are ineffective in the presence of clarithromycin resistance [296].

For patients treated with PPI, clarithromycin and amoxicillin triple therapy, the primary determinant of treatment failure has been found to be clarithromycin resistance with

minor if any influence of CPY-2C19 genetic polymorphisms [297, 298]. For clarithromycin sensitive strains, the eradication rate was 97% vs 6% (1/16) for resistant strains [297] in one study, and in another, corresponding rates were 86% vs 24% [298].

The rate of acquired clarithromycin resistance was found to be 88.9% (8/9) in patients treated with PPI-C dual therapy, while with PPI, clarithromycin and amoxicillin or PPI, clarithromycin and metronidazole triple therapies these rates were 38.7% (12/31) and 90.0% (9/10) respectively ( $p < 0.01$ ) [299]. Murakami *et al.* suggested that amoxicillin containing regimens may help prevent acquired clarithromycin resistance [299].

### Other factors affecting eradication success

Wermeille *et al.* [300] treated 78 patients with one week LCA and overall ITT eradication success was only 65.4% (95% CI: 54.8–76.0%). The eradication rate in “good compliers” was 69.6% (95% CI: 58.7–80.5%). **B4** These authors found that presence of an ulcer, age, gender and smoking habit did not differ significantly between the eradicated and non-eradicated groups. They concluded that while poor compliance and bacterial resistance were important in determining treatment success, these factors only explained 40% of failures.

Broutet and colleagues reported a retrospective analysis using individual patient data from triple therapy eradication studies performed prior to 1999 in France in order to identify risk factors for *H. pylori* eradication failure [301]. The key finding was that eradication failure occurred more frequently if the patient diagnosis was functional dyspepsia compared to duodenal ulcer (34% vs 22% failure,  $p < 0.000001$ ). This result is consistent with another literature review [302]. However, in another review, the use of PPI, clarithromycin and amoxicillin triple therapy, resulted in the same eradication rates in patients with peptic ulcer or functional dyspepsia [303]. With the decline in prevalence of ulcer disease, deciding on treatment choice based on diagnosis is not a practical alternative. Broutet found that for DU patients, eradication failure occurred more often in smokers, while 10-day therapy was better than seven days [301]. For all patients, age over 60 gave better eradication rates. Smoking was also found to impair eradication success in Japan, particularly in functional dyspepsia patients [304].

A very comprehensive meta-analysis by Fischbach identified that there were differences in eradication success according to differences in ethnic origin [305]. She found the highest eradication rates in north-eastern Asia. Populations characterized by a high prevalence of childhood *H. pylori* infection and high levels of drug resistance exhibited lower treatment success.

### PPI is an essential component of PPI-triple eradication regimens

There is good evidence to support the view that the PPI is a necessary component of PPI triple therapies, as eradication rates are higher when a PPI is used with the antibiotics than when the antibiotics are given alone [291, 306–308]. In one such study, all patients were given one week clarithromycin 250mg and tinidazole 500mg bid and were randomized to receive either no omeprazole, omeprazole 20mg once daily or omeprazole 20mg bid. The eradication rates were higher in the omeprazole groups (omeprazole once daily 88%, twice daily 89%, placebo 64%, ARR for twice daily omeprazole vs antibiotics alone = 0.25, NNT = 4) [306]. **A1c** In the omeprazole groups, 22 patients who harboured metronidazole-resistant strains of *H. pylori* were cured by the omeprazole regimen, providing further evidence that the addition of the PPI may help overcome metronidazole resistance. Another study treated ulcer patients with once daily clarithromycin 500mg, tinidazole 1g and either placebo or lansoprazole 60mg and found that the antibiotics alone eradicated *H. pylori* in 39% of patients, but the addition of the PPI increased the eradication success to 72% [153]. Laine pooled results from three American studies treating duodenal ulcer patients with amoxicillin and clarithromycin and either placebo or omeprazole and determined that pooled eradication with antibiotics alone was 39%, but if omeprazole was added, the eradication rate was improved to 84% [152]. **A1c** In another study, the cure rate by ITT was significantly higher for omeprazole, clarithromycin and amoxicillin (82%) than for clarithromycin and amoxicillin alone (18%), while for omeprazole, clarithromycin and metronidazole the cure rate was 67%, only slightly better than the 59% cure observed with clarithromycin and metronidazole alone [309]. This study showed that the impact of the PPI was much more significant in improving the eradication efficiency of the PPI with clarithromycin and amoxicillin triple therapy. **A1a**

A meta-analysis has shown that pretreatment with a PPI prior to triple and quadruple therapies did not influence *H. pylori* eradication [310].

### Comparison of H<sub>2</sub>-RA vs PPI in triple therapies

Graham *et al.* conducted a meta-analysis of studies that directly compared an H<sub>2</sub>-RA with a PPI and two antibiotics [311]. They identified a total of 12 studies with 1415 patients. The overall pooled efficacy was similar in ITT analysis: 78% (549/701) with H<sub>2</sub>-RAs vs 81% (575/714) with PPIs (odds ratio, 0.86; 95% CI: 0.66–1.12). **A1c** Thus, they concluded that the PPI and H<sub>2</sub>-RA were similarly effective adjuvants for *H. pylori* triple eradication therapy [311]. However, another meta-analysis was published that concluded that PPI based

triple therapies were more effective than H<sub>2</sub>-RA based regimens [312]. This overview included more studies (20) and the population was 2374 patients. The pooled efficacy was 74% (95% CI: 71–76%) for the PPIs and 69% (95% CI: 66–71%) for the H<sub>2</sub>-RA triples (odds ratio, 1.31; 95% CI: 1.09–1.58). Based on these data, the PPI component remains an important part of combination eradication therapies. **A1a**

### Greater acid suppression: PPI twice daily dosing recommended

A meta-analysis found that the eradication rates with double doses of PPI were higher than single doses of PPI in ITT analysis (83.9% vs 77.7%; Peto odds ratio, 1.51; 95% CI: 1.23–1.85;  $p < 0.01$ ) [313]. **A1c** An earlier study that compared once daily omeprazole 80 mg, metronidazole and amoxicillin (35% success), omeprazole, metronidazole and azithromycin (65%) and omeprazole, metronidazole and clarithromycin found that 78% could be eradicated with the latter regimen [314]. A more recent study using lansoprazole, clarithromycin and tinidazole either as standard doses twice daily or double doses once daily, found that the once daily dosing was less effective [153]. Thus, there is little evidence to suggest that PPI triple therapy should be given less than twice daily.

There is additional evidence that increased levels of acid suppression lead to better eradication efficacy. In a comparison of PPI triple regimens in which rabeprazole 10 mg or 20 mg were used twice daily with amoxicillin and clarithromycin, the higher dose was more effective (eradication proportions: rabeprazole 10 mg, 85%, 20 mg 96%,  $p < 0.05$ ) [315]. **A1c** Another study used amoxicillin with clarithromycin with a variety of PPI doses designed to produce a range of acid suppression. In increasing order of acid suppression, patients were given one week of omeprazole 20 mg bid, esomeprazole 40 mg once daily and esomeprazole 40 mg bid, and the observed eradication rates were 71%, 81% and 96% respectively [316]. However, there may be a plateau effect, as one study used omeprazole either 20 mg or 40 mg bid with clarithromycin and tinidazole and found no difference in eradication rates. In patients with resistant strains, the eradication rate was lower and was no better with greater acid suppression [317]. With esomeprazole, which is considered to be one of the most potent acid inhibitors, there may be little difference whether a 40 mg dose is used once or twice daily [318, 319]. Overall, a recent meta-analysis showed that high dose PPI was more effective than standard doses for eradicating *H. pylori* with seven-day PPI triple therapy [320]. **A1a**

### Triple and quadruple bismuth based therapies

In the first meta-analysis published in 1992, the best regimen was triple therapy with bismuth, metronidazole

and tetracycline (BMT), which was superior to triple therapy with bismuth, metronidazole and amoxicillin [92, 138, 220]. However, the large number of pills required and relatively long two-week duration of treatment affected compliance adversely. Poor compliance (<60% of pills) led to only 69% eradication success compared to 96% in patients who take >60% of pills [321]. Later meta-analyses demonstrated that one week was as effective as two weeks of therapy [92, 220, 229]. The greater number of adverse effects suffered with bismuth triple therapies leads to more treatment discontinuation than is observed with PPI triple therapies [220] or PPI-BMT quadruple therapy [322]. In patients who harbour a metronidazole resistant *H. pylori* infection, eradication efficacy was reduced to 58–64% compared to 86–89% for metronidazole sensitive strains [220, 289]. **A1c**

Proton pump inhibitors (PPIs) have been used in combination with the traditional bismuth triple therapy. This quadruple regimen resulted in high eradication rates (80–90%) with one week of treatment [220, 229, 323, 324] and was superior to bismuth triple therapy without a PPI. **A1c** There have been studies using omeprazole [296, 325–328], lansoprazole [329, 330], pantoprazole [322, 331–333] and rabeprazole [334, 335] as the PPI in these quadruple therapies. Most of the regimens were given four times daily. Importantly, using a PPI with bismuth, nitroimidazole and tetracycline (BMT) helps to overcome metronidazole resistance, with higher eradication rates than if the BMT is used without a PPI [336].

### PPI-BMT vs PPI-CA

Published studies that have directly compared these regimens were summarized in the previous edition of this book [221]. A variety of different PPIs have been used, and the studies indicate that the PPI-BMT regimens were as effective or slightly more effective [337] than the PPI-CA triple therapies, with no significant differences between study treatments observed in any of the direct, head-to-head comparisons [296, 322, 327, 328, 330]. There appeared to be no real difference in rates of adverse effects with the PPI-BMT quadruple therapy compared to the gold-standard PPI-triple therapies. The proportion of patients who discontinued drugs due to side effects was very small and was comparable with all regimens. Thus, PPI-BMT should be considered an alternative first-line therapy.

### Attempts to improve compliance

#### New triple BMT capsule

The major drawback of this quadruple regimen is that it generally requires four times daily dosing with at least 18 pills. One recent study using a three times daily regimen appeared to be very effective [327]. Adverse events are generally mild, but frequent enough that they may impair

compliance. Most patients can complete the treatment if counselled about possible adverse effects, and treatment discontinuation is infrequent.

Recognizing the difficulty of taking large numbers of pills, a unique capsule has been developed that contains bismuth biskalcitrate 140 mg (as 40 mg  $\text{Bi}_2\text{O}_3$  equivalent), metronidazole 125 mg and tetracycline 125 mg (Helizide or Pylera™, Axcan Pharma, Mont Saint-Hilaire, Quebec, Canada). In an open study, three of these capsules qid with omeprazole 20 mg bid for 10 days eradicated 93% by ITT and 97% by per protocol analysis [338]. **B4** Eradication rates were 93% and 95% in metronidazole-resistant and metronidazole-sensitive strains, by ITT analysis. This capsule was also evaluated in a quadruple therapy regimen and compared to the gold standard PPI-CA triple therapy in a randomized controlled trial. This therapy was well tolerated with an adverse event rate comparable to PPI-CA, and eradication results were equal [296]. **A1c**

### Is twice daily dosing with PPI-BMT effective?

Another attempt to improve compliance and tolerability has been to use the PPI-BMT regimen twice daily. Earlier pilot studies reported modest ITT eradication rates of 71–78% using one week of OBMT bid [339, 340] and 70% with 10 days of LBMT [341]. The latter study showed that this LBMT regimen was more effective in metronidazole sensitive strains (90% eradication) than in resistant strains (41% eradication) [341]. These three studies all used bismuth subsalicylate as the bismuth compound.

More recently, two Italian studies reported by Dore revealed excellent rates of eradication [342, 343] with a regimen that included omeprazole 20 mg, tetracycline 500 mg, metronidazole 500 mg and colloidal bismuth subcitrate caplets 240 mg, all twice daily with noon and evening meals for 14 days. This regimen differs from those described above in terms of the bismuth compound used, the dosing at lunch and supper and the longer 14-day duration. In the first study, of 118 dyspeptic patients, of whom 76 were treatment naïve and 42 had experienced two or more previous treatment failures, the regimen was well tolerated, with 95% compliance and 3% drop-out rate due to medication-associated adverse effects. The overall eradication rate was 95% (ITT) or 98% (per-protocol analysis) [342]. There was no difference in eradication rates between naïve and “salvage” patients. **B4** The second study using the same drug regimen updated the data on the 42 patients from the first report and also included data on a total of 71 patients that had failed at least two prior attempts at eradication using a PPI triple regimen [343]. In this study, the observed eradication rate was 93% (ITT) or 97% (per-protocol analysis) [343]. **B4** The regimen was well tolerated, with only trivial adverse effects. In a second study by Dore, in treatment naïve elderly subjects using essentially the same regimen except for the substitution of

esomeprazole as the PPI, for a 10-day duration, the eradication rate was 91% (ITT) and compliance was excellent [344].

### **B4**

An American study used similar twice daily dosing at midday and the evening but used rabeprazole 20 mg, two Pepto-bismol tablets (bismuth subsalicylate – formulation of bismuth available in North America), metronidazole 500 mg and tetracycline 500 mg for 14 days [345]. In 37 patients treated, the eradication rate was 92.3%, 96% in metronidazole sensitive and 83% in metronidazole resistant *H. pylori* strains. **B4** Overall, one patient stopped medication because of adverse effects, but all the remaining patients exhibited 100% compliance, despite five patients having moderate to severe side effects. These data suggest that twice daily quadruple therapy may be very effective, and alternative forms of bismuth may be used.

A slightly different quadruple therapy was also evaluated in a twice daily regimen in 43 patients [346]. Treatment with omeprazole 20 mg, amoxicillin 1 g, tinidazole 500 mg and bismuth subcitrate 240 mg all bid (OATinB) for seven days was slightly less effective than the PPI-ACM regimen described below with eradication observed in 84% (ITT) or 86% (PP) of patients. **B4**

### Quadruple (PPI-BMT) therapy effective even with nitroimidazole resistance

PPI-BMT may be an effective regimen for treatment failures, and even metronidazole-resistant strains may be successfully eradicated [296, 322, 347]. In van der Wouden's meta-analysis, the only regimen that was not affected by metronidazole resistance was PPI, bismuth, nitromidazole and tetracycline for at least seven days [289]. Adding a PPI is responsible for this effectiveness in patients with metronidazole resistant strains. In the study by Katelaris *et al.* [322], patients were treated with pantoprazole with BMT (PBMT quadruple) for seven days, compared to BMT triple without a PPI for 14 days. In this study, PBMT eradicated 81% of metronidazole resistant strains while the BMT regimen was successful in only 55% ( $p < 0.02$ ). **A1c** Furthermore, the BMT regimen for 14 days resulted in 9% of patients discontinuing the drugs, compared to 3% observed with PBMT seven-day therapy.

As clarithromycin resistance significantly reduces the efficacy of clarithromycin containing triple therapies, it is noteworthy that OBMT eradication rates were not significantly different between clarithromycin sensitive and resistant strains [296].

### PPI-BMT in treatment failures

*Observational studies* Patients in whom triple therapy with PPI, clarithromycin and amoxicillin had failed were treated with pantoprazole 40 mg twice daily, CBS 120 mg qid, tetracycline 500 mg qid and metronidazole 500 mg tid for seven days [331]. *H. pylori* eradication rate was 82% (95%

CI: 75–88%); treatment was well tolerated and major adverse effects were not observed. No differences in eradication success were observed in relation to underlying disease, i.e. whether the patient had peptic ulcer or functional dyspepsia [331]. **B4**

Patients in whom RBC-based regimens had failed were treated with OCA for a week, and eradication was successful in 68% of patients [348]. Those who failed to respond to OCA were given quadruple therapy (omeprazole 20mg bid, bismuth subcitrate 120mg, tetracycline 500mg and metronidazole 400mg qid) with 71% (5/7) success. Of those treated previously with clarithromycin containing regimens, OCA was successful in 11 of 19 patients, while quadruple therapy was successful in five of six. **B4** The numbers are too small to permit definite conclusions, but it appears that quadruple therapy maintains some efficacy despite repeated failures of clarithromycin-based therapies.

*Direct comparative trials/systematic reviews* The study by Peitz [349] compared second-line therapy with OCA and OBMT. While neither regimen was particularly effective, OBMT was superior (68% eradication) to OCA (43%) as second-line therapy. Failures of the second-line treatment were treated with the alternative regimen, and OBMT produced eradication in 50% of these patients, compared to only 16% observed with OCA. Thus, while overall treatment success was not very good, OBMT had limited efficacy.

Two systematic reviews concluded that PPI-BMT was superior to an alternative PPI based triple therapy for second-line therapy and thus remained the treatment regimen of choice [350, 351]. **A1c**

Treatments for prior eradication failures

In patients who have failed initial therapy, successive therapies are usually less effective than when they are used as primary therapy. A number of regimens that have been studied are discussed below and summarized in Table 6.1. The most studied and consistently effective regimen is quadruple therapy with a PPI, bismuth compound, nitroimidazole and tetracycline for 7–14 days as discussed above. One drawback is that in some countries bismuth compounds are not available. Such is the case in Japan; however, rabeprazole, amoxicillin and metronidazole triple therapies may be an effective rescue regimen in that country [352, 353].

There are two basic approaches to treating an initial treatment failure, the first is to pick an empiric regimen based on the drugs used in the initial attempt, and the second is to perform *H. pylori* anti-microbial sensitivity testing and select antibiotic combinations based on the resistance pattern. The major drawback to this latter

Table 6.1 Promising “new” regimens for treatment failures.

Triple therapies
PPI, amoxicillin and metronidazole for seven days – observed to be effective in Japan
PPI, amoxicillin and rifabutin for 10–14 days
PPI, moxifloxacin, rifabutin for seven days
PPI, levofloxacin, rifabutin for seven days
PPI, amoxicillin, levofloxacin for 10 days
PPI, tinidazole, levofloxacin for 10 days
Quadruple therapies
PPI, bismuth, metronidazole, tetracycline bid at lunch and supper x 14 days
PPI, bismuth, tetracycline, furazolidone for seven days (limited availability of furazolidone)

approach is the general lack of availability of *H. pylori* culture and sensitivity testing.

One report of such a second-line approach described the treatment of patients with omeprazole, amoxicillin and clarithromycin (OAC) for 7 to 14 days or omeprazole, amoxicillin and metronidazole (OAM) for 14 days [271]. Re-treating empirically with clarithromycin-based regimens was largely ineffective, with eradication being achieved in 80% and 16% of clarithromycin sensitive and resistant strains respectively. Using the OAM regimen, metronidazole sensitive and resistant strains were eradicated in 81% and 59% of patients respectively. These data suggest that once clarithromycin has been used and the treatment fails, it is not worthwhile to administer it again. Also, while anti-microbial sensitivity testing may be helpful in some cases, this does not guarantee eradication success.

B4

*Rifabutin regimens* Rifabutin containing regimens have emerged as an option for treating eradication failures. The regimen was originally studied in Italy, and a randomized trial has shown that rifabutin is more effective in a dose of 300mg daily than 150mg daily, when used in combination with pantoprazole and amoxicillin for 10 days [332]. This triple regimen was more effective (87%) than pantoprazole-BMT quadruple therapy (67%), the most commonly recommended salvage therapy. **A1c** The 87% eradication rate observed in this study was better than the 71% eradication rate observed in 41 patients treated in the pilot study [354]. In another small pilot study assessing a regimen that included rifabutin 150mg, amoxicillin 1g, and lansoprazole 30mg all bid for one week the observed eradication rate was 72% (ITT) and 86% (per-protocol analysis) [355]. A regimen that included esomeprazole, amoxicillin and rifabutin produced similar results [356]. In a trial that compared omeprazole, amoxicillin and rifabutin 150mg bid for

seven days to OBMT the rates of eradication were respectively, only 44% and 70% [357]. These data suggest that one week of treatment may not be sufficient.

In a small group of patients who failed two courses of therapy, the first with PPI-CA and the second with either PPI or RBC-BMT, third-line therapy with omeprazole, amoxicillin and rifabutin 150mg bid for 14 days was successful in 11 of 14 patients [358]. **B4** In treating strains resistant to both metronidazole and clarithromycin, esomeprazole, rifabutin and amoxicillin triple therapy resulted in an eradication rate of 74% (ITT) in a German population [356]. Also in a German population with *H. pylori* strains resistant to both metronidazole and clarithromycin, triple therapy with esomeprazole 40mg, moxifloxacin 400mg and rifabutin 300mg daily for one week was effective in 78% of patients [359]. **B4** Some of these patients had failed four previous treatments. Considering that these dually resistant *H. pylori* strains are difficult to eradicate, these observational data are promising, particularly for amoxicillin allergic patients.

A drawback to rifabutin is that it is an expensive drug and is not readily available in some jurisdictions. In summary, the results of therapy in which a PPI is combined with amoxicillin and rifabutin, have been inconsistent.

A Chinese study compared the combination of rifabutin 300mg od, levofloxacin 500mg od and rabeprazole 20mg bid with rabeprazole-BMT quadruple therapy, each for seven days [335]. This triple therapy regimen is very simple, as both the levofloxacin and the rifabutin are given only once daily. In this study the eradication rate was very high (91%) with both regimens. Even in patients resistant to both metronidazole and clarithromycin, the eradication rates were 85% (17/20) in the triple therapy and 87% (13/15) in the quadruple therapy arm [335]. Thus, these are both promising regimens for treatment failure. **A1d**

*Levofloxacin regimens* Analogous to the first-line PPI triple therapies, regimens substituting clarithromycin with levofloxacin have been studied.

PPI (rabeprazole 20mg bid), amoxicillin 1g bid and levofloxacin 500mg od and PPI, tinidazole 500mg bid and levofloxacin 500mg od triple therapies were both very effective in treatment failures, with eradication rates of 90% or more with 10 days of treatment, when compared to the present gold standard for treatment failures, a PPI-quadruple therapy (rabeprazole-BMT) regimen for either 7 or 14 days [334]. **A1c** The quadruple therapies in this study produced disappointing eradication rates of 63–69% [334]. Not only were the triple therapies more effective, the adverse effects were significantly less frequent than were observed in the RBMT, 14-day group. In another study, even after patients had failed two or more previous standard regimens, the rabeprazole, amoxicillin and levo-

floxacin triple therapy for 10 days was effective in 83% of patients [360]. **B4** In a similar study in which pantoprazole was used instead of rabeprazole with amoxicillin and levofloxacin for one week the observed eradication rate was 63% [333]. **B4** In Perri's study, the PPI-BMT regimen appeared to be the more effective, with an 83% eradication rate. Another similar study with pantoprazole, amoxicillin and levofloxacin all twice daily for 10 days resulted in an eradication rate of 70% compared to a 37% observed with PPI-BMT [361]. **A1d**

As the results were not all consistent, a meta-analysis by Gisbert *et al.* has been reported where levofloxacin triple therapies were compared against bismuth quadruple therapy [362]. Overall, the levofloxacin triple therapy regimens appeared to be significantly more effective and better tolerated than the quadruple regimens, and highest eradication rates were observed when therapy was given for 10 days [362]. **A1c** The most commonly used regimen was a PPI with amoxicillin and levofloxacin. Another meta-analysis that restricted its scope to PPI, amoxicillin and levofloxacin also indicated that 10 days of this levofloxacin-based triple therapy was more effective and better tolerated than seven days' bismuth based quadruple therapy [363]. **A1c** One study observed that the eradication rate was the same whether levofloxacin was used 500mg once or twice daily [364]. In an Italian study, primary levofloxacin resistance was found in 30% of patients, and this was associated with a lower eradication rate of 33% compared to 75% in susceptible strains [365].

Levofloxacin has also been used as part of a quadruple therapy regimen in patients who had failed a course of PPI triple therapy [366]. When used with esomeprazole, bismuth and amoxicillin, the eradication rate was 73%, lower than the 88% rate observed with the usual gold standard quadruple therapy of esomeprazole, bismuth, metronidazole and tetracycline [366]. For patients who had failed more than one course of previous eradication therapy, the success of the levofloxacin quadruple regimen was even lower, with an observed eradication rate of 56% compared to 90%, observed with the EBMT regimen ( $p = 0.013$ ). **A1c**

*Moxifloxacin regimens* After a failure of PPI triple therapy, a Korean study compared one week of triple therapy with moxifloxacin, esomeprazole and amoxicillin against the gold standard esomeprazole, bismuth, metronidazole and tetracycline quadruple therapy [367]. The eradication rate with the moxifloxacin triple therapy was 76% and with the quadruple therapy, 55% ( $p = 0.042$ ). **A1c** In a different Korean population, a study of the same drugs administered for longer durations, 10 days of triple therapy and 14 days of EBMT quadruple therapy resulted in both regimens obtaining eradication rates of 72% [368]. **A1c** The

moxifloxacin triple regimen had significantly fewer adverse effects in both studies.

**Gatifloxacin regimens** In a small open-label study with one-week gatifloxacin 400 mg od, amoxicillin and rabeprazole in patients who had failed one or more clarithromycin containing regimens, the eradication rate was 84%, without significant adverse effects [369]. **B4** Of the seven treatment failures, secondary resistance to gatifloxacin did not develop. There are only limited data on acquired resistance to quinolones.

A Japanese study suggests that culturing *H. pylori* may be useful, in that strains resistant to clarithromycin and metronidazole could be eradicated with a gatifloxacin regimen if the strains were sensitive to gatifloxacin [370].

**Furazolidone regimens** A triple therapy regimen with omeprazole, amoxicillin and furazolidone was rather ineffective (52% eradication); however, if antibiotic sensitivity testing can be done, this regimen was shown to be 88% effective against strains that are still sensitive to metronidazole and clarithromycin [371]. In clinical practice, antibiotic sensitivity testing as a requirement after the first failure is impractical. Also, the chance that *H. pylori* would still be susceptible to both antibiotics after treatment failure is fairly small. However, another small study with furazolidone quadruple therapy did show some promise. Patients failing an initial regimen that included clarithromycin, metronidazole, and acid suppression with or without amoxicillin were treated with a quadruple therapy of lansoprazole, bismuth, metronidazole and tetracycline with only 39% success [372]. These treatment failures were subsequently treated with lansoprazole 30 mg bid, colloidal bismuth subcitrate 240 mg bid, tetracycline 1 g bid and furazolidone 200 mg bid for one week and eradication was seen in 9 of 10 patients.

A small RCT in patients with metronidazole resistant *H. pylori* by agar dilution [373] compared one-week bismuth, tetracycline and furazolidone 200 mg bid (BTF) with OBMT and the observed eradication rates were 86% and 74% ( $p = \text{NS}$ ). The BTF regimen resulted in fewer adverse effects than were observed with OBMT (31 vs 60%,  $p = 0.03$ ). Thus, furazolidone may be an excellent substitute for metronidazole.

**Faropenem** After initial *H. pylori* eradication failure with lansoprazole, amoxicillin and clarithromycin, 52% of patients had *H. pylori* that was resistant to clarithromycin [374]. These Japanese patients who failed therapy were then re-treated with rabeprazole, amoxicillin and faropenem 200 mg tid for seven days, and eradication was achieved in 91% (21/23) of patients, with no serious adverse events. However, another study in treatment naive patients found much lower eradication rates, with 46.5% with

seven-day therapy and 62.5% with 14-day therapy, despite the fact that all strains were highly sensitive *in vitro* [375].

In treatment failures resistant to metronidazole, rabeprazole, minocycline and faropenem triple therapy was only 10% effective [376]. Substituting minocycline for amoxicillin is thus ineffective. These data suggest that faropenem needs further study, and faropenem is not widely available outside of Japan.

**Minocycline** In a Japanese study, first-line therapy with rabeprazole, amoxicillin and minocycline was ineffective [376]. However, after initial therapy, if strains were metronidazole sensitive, rabeprazole, minocycline and metronidazole was 85% effective. Data for this regimen as first-line therapy are lacking; however, minocycline resistance is rare and this may be a useful regimen for penicillin allergic patients.

### Third-line and multiple failures

An uncontrolled study in patients with two consecutive eradication failures was reported by Gisbert *et al.* [377]. A wide variety of regimens were used in the first and second attempts that failed, and the investigators decided on one of four different regimens for the third eradication attempt, avoiding duplicating a previously used regimen in any given patient. Overall, in 48 patients, they gave empirical treatments without antibiotic sensitivity testing and achieved eradication success in 71%. This study has limitations because of the heterogeneity of regimens used but it does provide some clinical evidence that in community practice, where sensitivity testing is not available, even two previous eradication failures can be successfully eradicated with careful choosing of a third regimen.

Gisbert reported another study in patients who failed a first attempt with PPI, clarithromycin and amoxicillin, then a second attempt with bismuth based quadruple therapy [378]. These treatment failures were then treated with levofloxacin, amoxicillin and omeprazole for 10 days and the eradication rate was 60%. This modest rate of success is reasonable, considering that patients had failed two prior attempts. Gisbert also reported that this 10-day levofloxacin, amoxicillin and omeprazole triple therapy was more effective than rifabutin, amoxicillin and omeprazole, with eradication rates of 85% and 45% respectively [379]. Rifabutin appears to be not very effective and can cause leucopenia. Therefore it is not readily recommended.

### Newer drugs and regimens

Several newer regimens have been explored (see Table 6.1), and a partial summary appears in Table 6.2.

**Table 6.2** "Newer" *H. pylori* eradication regimens.

PPI triple therapies
Lansoprazole, furazolidone and tetracycline or clarithromycin for seven days
PPI, levofloxacin and amoxicillin or nitroimidazole or clarithromycin for seven days
PPI, moxifloxacin and amoxicillin or nitroimidazole or clarithromycin for seven days
PPI, gatifloxacin and amoxicillin for seven days
PPI quadruple therapies
PPI, amoxicillin, clarithromycin and nitroimidazole for five days
PPI, amoxicillin, bismuth and furazolidone or clarithromycin for 14 days
Sequential therapy
PPI + amoxicillin for five days then PPI, clarithromycin and nitroimidazole for five days

**Penicillin allergic patients** Penicillin allergy is fairly common, and in these patients, PPI-CM or PPI-BMT can be given first line. In a small study of 20 patients treated with esomeprazole 40mg, tetracycline 500mg and metronidazole 500mg all given four times daily, the eradication rate for the 17 patients undergoing first time treatment was 85% and the three patients who had failed prior eradication therapy were successfully eradicated [380]. The regimen was well tolerated, and confirmation in a second study of the efficacy of this promising regimen would be desirable.

**Furazolidone** Furazolidone is an older, inexpensive antibiotic that may be effective in areas of high metronidazole resistance, although it may not be available in all markets. A large scale Chinese trial has shown that when furazolidone 100mg bid was used in triple therapy with omeprazole and amoxicillin, an eradication rate of 86% was achieved [381]. In another Chinese study in DU patients, the observed eradication rate was 66% compared to a rate of 91% with the alternative regimen of omeprazole, furazolidone and clarithromycin (OFC). In this trial the eradication rates observed with standard triple therapy with omeprazole, amoxicillin and clarithromycin (OAC) and omeprazole, metronidazole and clarithromycin (OMC) were 90% and 71% respectively [382]. The furazolidone regimens were well tolerated with only minor side effects [382].

An interesting regimen using drugs with very low rates of *H. pylori* resistance was found to be very effective. In this Brazilian study, lansoprazole 30mg od, tetracycline 500mg qid and furazolidone 200mg tid for seven days achieved 88% success [383]. Adverse events were frequent but minor, with only 1 of 52 patients stopping therapy because of

nausea. This regimen deserves further study. For re-treatment the authors use the same regimen for 10 days (personal communication).

In Iran, where baseline metronidazole resistance is said to be high, two-week quadruple therapy with omeprazole, amoxicillin, bismuth subcitrate and either furazolidone or clarithromycin also resulted in high eradication rates of 84% and 85% [384]. A similar quadruple regimen with omeprazole, amoxicillin, bismuth and either furazolidone or metronidazole resulted in eradication rates of 87% and 75% respectively [385]. It appears that the furazolidone quadruple regimens are more effective than a metronidazole-based regimen in areas of high nitroimidazole resistance. Another Iranian study found lower eradication rates of approximately 70%, with no improvement with two weeks compared to one week of treatment [386]. In a study in which relatives of patients with gastric cancer were screened and offered treatment for *H. pylori* (if found) [387], patients were randomized to receive lansoprazole 30mg, clarithromycin 500mg and furazolidone either 200mg or 400mg for one week. The triple therapy with the 400mg dose resulted in an eradication rate of 87%. This regimen is interesting as the drugs are given once daily, are well tolerated and relatively inexpensive.

### Fluoroquinolones

**Levofloxacin** Levofloxacin combination regimens continue to look promising. Levofloxacin has been mostly used in place of clarithromycin. The first paper by Cammarota identified that levofloxacin, amoxicillin and rabeprazole and levofloxacin, tinidazole and rabeprazole triple therapies were both very effective with observed eradication rates greater than 90% [388]. A subsequent RCT confirmed that levofloxacin, amoxicillin and rabeprazole triple therapy for one week resulted in a 90% eradication rate [236]. The rabeprazole, levofloxacin and tinidazole regimen, also administered to an Italian population resulted in eradication rates of approximately 95% when used for four to seven days in treatment naive patients [389].

A slightly different regimen in which levofloxacin was used in place of amoxicillin (rather than clarithromycin), compared esomeprazole 20mg bid, levofloxacin 500mg od and clarithromycin 500mg bid for one week and resulted in an eradication rate of 87%, significantly higher than was observed with standard PPI triple therapies that were only 72–75% effective [390]. Cammarota *et al.* [391] also studied the effect of rabeprazole and levofloxacin once daily with clarithromycin in one of two doses, 250mg or 500mg twice daily for one week. The higher clarithromycin dose was more effective (94% vs 84%). Furthermore, all patients who failed eradication therapy developed clarithromycin resistance when the smaller dose of clarithromycin was used, compared to 33% who developed resistance with the larger dose of clarithromycin [391].

**Moxifloxacin** Another new fluoroquinolone, moxifloxacin appears promising. Used by itself or with lansoprazole, it was not effective, but used for one week in a regimen that included lansoprazole 30 mg od, clarithromycin 500 mg bid and moxifloxacin 400 mg od, the eradication rate in 40 Italian patients was 90% [392]. A larger four-arm study of 320 patients compared four different regimens in treatment naïve patients: two standard one-week PPI triple therapies (esomeprazole with clarithromycin and amoxicillin (ECA) or tinidazole (ECT)) and two moxifloxacin triple therapies (esomeprazole with moxifloxacin and amoxicillin (EMA) or tinidazole (EMT)) [393]. Observed eradication rates with standard triple therapies were 73% for ECA and 75% for ECT and the rates in the regimens with moxifloxacin in place of clarithromycin, were 88% with EMA and 90% with EMT. Adverse effects were also less frequent when moxifloxacin was used.

Another four-arm study of 277 patients also compared one week moxifloxacin with clarithromycin [394]. Patients were randomized to receive one of the following regimens: lansoprazole 30 mg bid, metronidazole 400 mg bid and moxifloxacin 400 mg od (LMM), lansoprazole, amoxicillin and moxifloxacin (LAM), or lansoprazole, metronidazole, clarithromycin (LMC), or lansoprazole, amoxicillin and clarithromycin (LAC). Eradication rates were 93.5%, 86.4%, 70.4% and 78.2% respectively [394]. **A1c** In this study, primary resistance to clarithromycin was seen in 10.8% and to moxifloxacin in 5.9% of strains. Moxifloxacin sensitive strains were significantly better eradicated with both LMM and LAM (98% and 91% respectively), while for resistant strains, the corresponding eradication rates were 75% and 67%. Thus, moxifloxacin based therapies were more effective than clarithromycin based regimens. **A1c**

**Gatifloxacin** Gatifloxacin 400 mg od and amoxicillin 1 g bid was used with rabeprazole 20 mg once daily or twice daily for seven days, in patients who were mainly treatment naïve [395]. The eradication rate in the rabeprazole twice daily arm was higher than in the once daily arm, 92% compared to 83%. All seven patients that had failed previous eradication treatment were cured in the twice daily rabeprazole arm. One caveat in this study is that in about half the patients, sensitivity testing was done, and all tested strains were sensitive to gatifloxacin. This may partially account for the high eradication success rate. This gatifloxacin triple regimen with PPI given twice daily was very effective and well tolerated and should be studied further.

#### **A1d**

A twice daily ofloxacin, rabeprazole and amoxicillin triple therapy was given for either seven days or 14 days with a observed eradication rates of 62% and 92% ( $p = 0.004$ ) [396]. **A1d** As this regimen does not contain clarithromycin or metronidazole, this approach may be useful for patients

who have failed treatment regimens with these drugs in the past.

**Nitazoxanide** This antibiotic has microbiological similarities to the nitroimidazoles without as much problem with resistance. It is ineffective as a single agent [397].

## Sequential therapy

An interesting study in 1049 dyspeptic Italian patients was reported by Zullo [398]. In this RCT, sequential therapy was given to an experimental group for a total of 10 days: during which patients were first treated for five days with rabeprazole 40 mg od and amoxicillin 1 g bid and then received rabeprazole 20 mg, clarithromycin 500 mg and tinidazole 500 mg twice daily for another five days. The control group received triple therapy with rabeprazole 20 mg, clarithromycin 500 mg and amoxicillin 1 g bid for one week. Sequential therapy was significantly more effective (sequential therapy 92%, standard therapy 74%,  $p < 0.0001$ ). **A1c** Zullo also examined this strategy in patients 65 years of age and over and observed comparable results, indicating that eradication efficacy is not necessarily affected by age [399]. A subsequent trial of this sequential therapy regimen compared two different doses of clarithromycin, 250 mg (low dose) vs 500 mg (high dose). Both doses were very effective, with eradication rates of 92–95% [400]. **A1c** Using pantoprazole as the PPI, Vaira reported that this 10-day sequential therapy was more effective than 10-day PPI triple therapy [401]. An additional observation in this study was that in clarithromycin resistant *H. pylori*, the sequential therapy was 89% effective, compared to only 29% observed with the triple therapy. Further data in resistant strains are awaited as an 89% eradication rate is unheard of in clarithromycin resistant strains. Further evidence showing sequential therapy to be more effective than standard triple therapy with esomeprazole, clarithromycin and amoxicillin for either 7 or 10 days has also been reported [402].

A systematic review also provides evidence that this 10-day sequential regimen has been consistently highly effective, with an eradication rate of approximately 90% and is more effective than the standard triple therapy [403]. Another meta-analysis reported data from 10 RCTs. The observed crude eradication rate with sequential therapy was 93.4% (95% CI: 91.3% to 95.5%) compared to 76.9% (95% CI: 71% to 82.8%) with standard triple therapy [404]. **A1a** The authors noted that the majority of data were from Italy, and data from other populations would be very desirable.

It has repeatedly been observed to be difficult to eradicate *H. pylori* in Turkey. Uygun *et al.* used an alternative

sequential therapy, starting with one week pantoprazole and amoxicillin followed by pantoprazole, tetracycline and metronidazole for a second week [405]. This regimen resulted in an eradication rate of 72.6%, compared to the rate of 58% observed with the gold standard pantoprazole, amoxicillin and clarithromycin triple therapy for two weeks ( $p = 0.01$ ). **A1d**

*PPI or RBC with amoxicillin, clarithromycin and metronidazole for five days* A short five-day therapy with rabeprazole 20mg, amoxicillin 750mg, clarithromycin 200mg and metronidazole 250mg (RACM) all twice daily achieved an eradication rate of 93% in 80 Japanese patients compared with rate of 81% with the standard RCA, one-week triple therapy [406]. Serious adverse events were not seen, and compliance was excellent. An earlier study by the same group used the same regimens but each for five days and found an eradication rate of 94% for RACM and 80% for RAC [407].

A similar regimen used for a short duration was also reported from Germany [408]. This was a three-arm study comparing quadruple therapy with lansoprazole 30mg bid, amoxicillin 1g bid, clarithromycin 250mg bid and metronidazole 400mg bid for five days (LACM5), with ranitidine 300mg bid with the same antibiotics (RanACM), and with lansoprazole for all five days combined with the antibiotics for three days, from the third to the fifth day (LACM3). The eradication rates were excellent at 89%, 89% and 81% respectively. The rates were not significantly different, but the three-day therapy may be slightly less effective. These results are similar to those reported in the original description of this regimen in 1998. In that study omeprazole with the same antibiotics (OACM) for five days was compared to OCM for seven days, and the observed eradication rate was 90% for each group [409].

Earlier trials of similar regimens have yielded remarkably consistent results. Neville used lansoprazole as the PPI (LACM) with an eradication rate of 88%, better than was observed with the first-line recommended LCM (81%) or LCA (59%) triple therapy regimens [410]. In this study, the baseline metronidazole resistance rate was 52%. Catalano *et al.* compared either omeprazole or RBC as the antisecretory drug for five days combined with ACM for only three days from days 3 to 5 with standard triple therapies of OCA and RBC-CA [411]. The eradication rates were 89% with OACM, 82% with OAC, 95% with RBC-ACM and 78% with RBC-CA. A similar regimen using omeprazole, amoxicillin, clarithromycin and tinidazole all bid for four days resulted in an eradication rate of 88% [412]. One study in 169 patients in which roxithromycin was used in place of clarithromycin for seven days yielded an eradication rate of 92% [413]. **B4**

What is remarkable is that this PPI-ACM regimen for five days has consistently shown eradication rates of 89–95%, compared to rates of 59–90% (mainly approximately 80%) observed with one-week triple therapies in these studies. Considering these results, further study of this approach, especially as a treatment failure regimen, is clearly warranted.

## Less promising regimens

### Azithromycin

Azithromycin does not appear to be a very useful drug for *H. pylori* eradication. When used in place of clarithromycin as part of a quadruple therapy, a lower eradication rate was observed [414]. Azithromycin is usually administered for five days even when the other drugs are given for seven days. A potentially attractive regimen is that of a PPI with levofloxacin and azithromycin as each drug can be given once daily. In one study using this regimen for one week, the eradication rate was comparable to that observed with standard PPI, clarithromycin and amoxicillin but the success was only 65% [415]. In a study conducted in France the combination of omeprazole, amoxicillin and azithromycin yielded an eradication rate of only 38%, substantially less than the rates of 72% and 61% observed with OCA or OCM [416]. In other studies where azithromycin was used for only three days, eradication success was suboptimal [383, 417–419]. Used in place of clarithromycin in a once daily, six-day regimen with tinidazole and lansoprazole provided eradication in only 67% of patients [420].

Rifaximin is a poorly absorbed antibiotic and when used as triple therapy with rifaximin, esomeprazole and clarithromycin or levofloxacin it was ineffective [421].

### Mucosal protective agents

Cetraxate is an anti-ulcer drug with mucosal protective effects and it can inhibit the growth of *H. pylori* [422]. In triple therapy with clarithromycin and amoxicillin, an eradication rate of 70% was observed compared to a rate of 94% observed with standard pantoprazole, clarithromycin and amoxicillin triple therapy, suggesting that cetraxate is less effective than PPI for this purpose [422].

Sofalcone and polaprezinc are mucoprotective agents with anti-*Helicobacter* activity. In a Japanese trial, patients were randomized to receive one of three regimens: rabeprazole, amoxicillin and clarithromycin triple therapy, sofalcone plus triple therapy, or polaprezinc plus triple therapy and the observed eradication rates were 78%, 87% and 80% respectively [423]. The difference between the sofalcone and rabeprazole regimens was statistically significant.

**Table 6.3** *H. pylori* eradication treatment recommendations 2009.

**Recommended first-line therapies**

PPI triples

- PPI bid + clarithromycin 500mg bid + amoxicillin 1g bid for seven days
- PPI bid + clarithromycin 500mg bid + metronidazole 500mg bid for seven days

PPI-BMT

- PPI bid + colloidal bismuth citrate 240mg or bismuth subsalicylate two tabs qid, metronidazole 250–500mg qid, tetracycline 500mg qid for seven days

PPI-BMT bid

- PPI bid + colloidal bismuth subcitrate 240mg or bismuth subsalicylate two tabs bid, metronidazole 500mg bid and tetracycline 500mg bid, at noon and supper with the meal for 14 days

**Promising first-line therapies**

Levofloxacin triple therapy

- PPI od or bid, levofloxacin 500mg od, amoxicillin 1g bid for seven days
- PPI od or bid, levofloxacin 500mg od, nitroimidazole 500mg bid for seven days
- PPI od or bid, levofloxacin 500mg od, clarithromycin 500mg bid for seven days

Moxifloxacin triple therapy

- PPI od or bid, moxifloxacin 400mg od, amoxicillin 1g bid for seven days
- PPI od or bid, moxifloxacin 400mg od, nitroimidazole 500mg bid for seven days
- PPI od or bid, moxifloxacin 400mg od, clarithromycin 500mg bid for seven days

Sequential therapy

- PPI bid and amoxicillin 1g bid for first five days, then PPI, clarithromycin 500mg and nitroimidazole 500mg twice daily for five more days (total 10 days)

PPI-ACM for five days

- PPI bid, amoxicillin 750mg to 1g bid, clarithromycin 250mg bid and metronidazole 500mg bid

Furazolidone regimens

- PPI od, furazolidone 200mg tid, tetracycline 500mg qid for seven days
- PPI od, furazolidone 400mg od, clarithromycin 500mg od for seven days
- PPI, amoxicillin 1g, CBS 240mg, furazolidone 200mg all bid for 14 days

**Recommended for treatment failures**

PPI-BMT

- PPI bid + colloidal bismuth citrate 240mg or bismuth subsalicylate two tabs qid, metronidazole 250–500mg qid, tetracycline 500mg qid for 14 days

Promising quadruple therapies

- PPI-BMT bid: PPI bid + colloidal bismuth subcitrate 240mg or bismuth subsalicylate two tabs bid, metronidazole 500mg bid and tetracycline 500mg bid, at noon and supper with the meal for 14 days PPI bid, CBS 240mg bid. tetracycline 1000mg bid, furazolidone 200mg bid for seven days

PPI triple therapy

- PPI, amoxicillin 750–1000mg, metronidazole 250mg bid for seven days (best in Japan)

Rifabutin regimens

- PPI bid, amoxicillin 1g bid, rifabutin 150mg bid for 10–14 days
- PPI od, moxifloxacin 400mg od, rifabutin 300mg od for seven days
- PPI od, levofloxacin 500mg od, rifabutin 300mg od for seven days

Levofloxacin regimens

- PPI bid, levofloxacin 500mg od, amoxicillin 1g bid for 10 days
- PPI bid, levofloxacin 500mg od, nitroimidazole 500mg bid for 10 days

PPI = omeprazole 20mg, lansoprazole 30mg, pantoprazole 40mg, esomeprazole 40mg or rabeprazole 20mg.

CBS = colloidal bismuth subcitrate.

Nitroimidazole = metronidazole or tinidazole.

Ecabet sodium when added to standard triple therapy did not improve ITT eradication rates in a Korean study [424].

### Probiotics in *H. pylori* eradication

An increasing number of studies have evaluated the effects of probiotics such as *Lactobacillus* GG [425, 426], *Lactobacillus reuteri* ATCC 55730 [427], *Saccharomyces boulardii* [426, 428, 429], a combination of *Lactobacillus* and *Bifidobacteria* [426, 430], a combination of *Bacillus subtilis* and *Streptococcus faecium* [431] or *Bacillus clausii* [432] as adjuvant therapies for *H. pylori* treatment. One study used a combination of *Lactobacillus rhamnosus* GG and C705, *Bifidobacterium breve* Bb99 and *Propionibacterium freundenreichii* ssp. *shermanii* JS [433]. Most studies [425, 426, 429, 432] showed no improvement in *H. pylori* eradication rates with the probiotic, but adverse effects of eradication therapy such as diarrhea and taste disturbances were reduced, and this approach may help some patients complete their treatment course [428, 433, 434].

Some probiotic studies have actually shown an improvement in eradication rates [430, 431, 434–436]. In one study, four weeks' pre-treatment with *Lactobacillus* and *Bifidobacterium*-containing yogurt (AB-yogurt) significantly improved eradication of one-week quadruple therapy with omeprazole, bismuth, amoxicillin and metronidazole [437].

Tong *et al.* [438] conducted a meta-analysis of 14 randomized trials of the effects of probiotic supplementation on *H. pylori* eradication. They concluded that probiotics increased eradication rates and reduced adverse effects, particularly diarrhea. **A1c**

### Alternative agents

Fish oil (eicosapen) contains  $\omega$ -3-fatty acids which have been shown to have anti-*H. pylori* bacteriostatic effects. However, replacing metronidazole with eicosapen is ineffective [439]. **C5**

Pronase, a mucolytic agent with no antibacterial effect on *H. pylori*, added to lansoprazole, amoxicillin and metronidazole significantly improved eradication success to 94% compared with 77% ( $p = 0.004$ ) observed with the LAM triple therapy alone [440]. **A1d** Regimens adding pronase deserve further study.

Lactoferrin is a multifunctional protein found in milk and when added to standard esomeprazole, clarithromycin and amoxicillin triple therapy it did not improve the eradication rate [441]. In an Italian study, lactoferrin significantly reduced the rate of adverse effects from 29.41% 17.64% ( $p < 0.05$ ) [442]. When used with rabeprazole, clarithromycin and tinidazole, the addition of lactoferin resulted in an eradication rate of 72%, not significantly different from the rate of 68% observed with the alternative triple

therapy regimen containing rabeprazole, levofloxacin and amoxicillin [443]. **A1d**

### Summary

*H. pylori* remains an important cause of ulcer disease, with acceptance as a definite pathogen that fulfills almost all of Hill's criteria for causation. In the new millennium, ulcers not caused by *H. pylori* or non-steroidal anti-inflammatory drugs appear to be on the increase. The older data from the pre-*H. pylori* era has become important again as in these patients there may be little else to offer for ulcer healing and prevention of recurrence other than continuous acid-suppressive therapy. For those with *H. pylori* infection, eradication remains important to facilitate ulcer healing, reduce ulcer relapse and prevent complications such as recurrent hemorrhage. Eradication of *H. pylori* heals ulcers without the need to continue ulcer healing drugs, heals refractory ulcers and also results in faster ulcer healing than occurs with traditional acid-suppressive therapy.

The present recommended first-line therapies include triple therapy with either PPI or RBC with clarithromycin and amoxicillin or metronidazole or a quadruple therapy with a PPI, bismuth compound, metronidazole and tetracycline (Table 6.3). First-line therapy should be administered for 7–10 days and for treatment failures, 10–14 days of treatment is recommended.

With emerging antimicrobial resistance, first-line therapies may not be quite as effective as in the recent past. There is evidence to support the use of a number of regimens for these eradication failures (see Table 6.3).

## Introduction

This chapter was first written in 1999. At the time, evidence from non-clinical and early clinical trials suggested that the gastrointestinal (GI) safety of the newer cyclo-oxygenase-2 (COX-2) selective NSAIDs was such that a fundamental change in clinicians' choice from the use of standard NSAIDs with a gastroprotective agent to monotherapy with a COX-2 selective NSAID (COX-2 inhibitors) was on the horizon. However, much has changed since then in the field of non-steroidal anti-inflammatory drugs (NSAIDs). The release of the cyclo-oxygenase-2 selective inhibitors (COX-2s) brought about significant changes in the NSAID marketplace. Traditional non-selective NSAIDs (tNSAIDs) prescription numbers fell rapidly, to be replaced by COX-2 prescriptions. Additionally, overall NSAID prescriptions rose in number suggesting that clinicians were starting COX-2s on patients who were not considered candidates for tNSAIDs. The rise of COX-2s continued until 2004 when greater data regarding their cardiovascular and other toxicities became available, leading to the withdrawal of most of these agents from the market over the following years. Non-naproxen tNSAIDs were also suggested to have important cardiovascular toxicity leading to considerable uncertainty amongst clinicians treating patients with arthritis and other pain disorders as to the choice of agent to use.

## Background

Non-steroidal anti-inflammatory drugs (NSAIDs), including aspirin, are important agents in the management of patients with a variety of arthritic and inflammatory conditions [1]. Additionally, aspirin is important in the treatment and prevention of both myocardial infarction and stroke [2–5]. The efficacy of these agents is well described, making NSAIDs among the most frequently used medications, with an estimated world market in excess of \$6 billion annually [6]. One cohort study found that short-term NSAIDs were prescribed for about 25% of Canadians, including about 4% for whom these agents were prescribed long term (defined in this study as  $\geq 6$  months) [7]; this equates to approximately 6.2 million short-term users, and 1.0 million long-term users of NSAID therapy. However, this substantially underestimates the true magnitude of NSAID uses since it does not include use of over the counter NSAIDs. A US cohort study, reported the point prevalence of NSAID use as 8.7% [8]. Low-dose ASA is extensively used for cardiovascular risk reduction. In addition, some evidence supports the use of these agents for the prevention of colorectal adenomas in at-risk individuals [9, 10].

NSAIDs including aspirin (ASA) cause a variety of gastrointestinal toxicities, which are associated with excess utilization of health care resources at a substantial cost [11]. Minor adverse effects such as nausea and dyspepsia are relatively common, but these clinical symptoms correlate poorly with serious adverse gastrointestinal events [12, 13]. Although, endoscopic ulcers, occurring with or without symptoms, can be documented in as many as 40% of chronic NSAID users [14], serious NSAID induced gas-

gastrointestinal toxicities are much less common [13]. Due to the vast numbers of individuals using these drugs, however, they have been linked directly to over 70,000 hospitalizations and over 7000 deaths annually in the USA alone [15]. NSAID use can also add significantly to the morbidity and mortality of chronic arthritic conditions. Among rheumatoid arthritis patients who are chronically using NSAIDs, the chance of hospitalization or death due to a gastrointestinal event is about 1.3 to 1.6% per year [15], accounting for about 2600 deaths and 20,000 hospitalizations each year [1]. These figures have led some to the suggestion that NSAID toxicity is among the “deadliest” of rheumatic disorders [15].

The serious gastrointestinal complications such as hemorrhage, perforation or death occur collectively with an incidence of about 2% per year in an average patient population on NSAIDs [13]. The relative risk of upper gastrointestinal hemorrhage or perforation with NSAID use varies in the literature from 4.7 in hospital based case control studies to 2.0 in cohort studies [16–18]. Gabriel *et al.* in a meta-analysis of 16 studies found that non-ASA NSAIDs were associated with a 2.7-fold increased risk of serious gastrointestinal events resulting in hospitalization [19]. Similarly, Langman *et al.* found that ASA and non-ASA NSAID use increased the risk of bleeding peptic ulcer 3.1-fold and 3.5-fold respectively [20]. In a recent large, prospective cohort study of 126,000 patients conducted over three years, MacDonald *et al.* found that NSAIDs increased the risk of any adverse gastrointestinal event 3.9-fold. However, NSAIDs appeared to raise the risk 8.0-fold, when only hemorrhage or perforation were considered [21], a level that is sufficiently high to imply causation. Armstrong *et al.* found that 60% of 235 consecutive patients presenting with a significant peptic ulcer complication were taking tNSAIDs, and nearly 80% of all ulcer related deaths occurred in NSAIDs users [22].

NSAIDs have also been linked to a variety of other gastrointestinal toxicities, including pyloric stenosis, small bowel ulcerations, strictures, lower gastrointestinal bleeds, and the exacerbation of colitis [6, 23–25]. Some experts suggest that the most effective means to prevent NSAID induced gastrointestinal toxicity is to discontinue the use of the NSAID, or to substitute an alternative non-NSAID analgesic [26]. However, this approach is clearly not always feasible, since a large proportion of NSAID users rely heavily on these medications, and a delicate balance exists between the therapeutic benefits and the risks of these drugs [27].

NSAIDs inhibit the enzyme cyclo-oxygenase (COX). This enzyme exists in two isoforms: COX-1 and COX-2. It is felt that NSAIDs exert their therapeutic anti-inflammatory and analgesic effects through the inhibition of inducible cyclo-oxygenase-2 (COX-2), whereas their gastric and renal toxicities arise from the inhibition of the constitutive COX-1

isoform [28, 29]. The anti-platelet effect of NSAIDs including ASA is mediated through inhibition of the COX-1 isoform. It has been recognized for some time that different NSAIDs have differing propensities toward gastroduodenal toxicity [21], and recently it has been proposed that those NSAIDs with the greatest affinity for COX-1 are associated with the highest risk of gastrointestinal toxicity. As a result of these observations, there has been a rapid development of new NSAIDs with increasing COX-2 selectivity, with claims of retained anti-inflammatory and analgesic activity, but with little gastrointestinal toxicity. However, increasing COX-2 selectivity may lead to increased prothrombotic effects and an increased risk of cardiovascular events. Extensive data now associate COX-2 inhibitors and non-naproxen tNSAIDs with an increased risk of cardiovascular events [30, 31], which has led regulatory authorities to introduce warning statements and advisories. Additionally, the COX-2 inhibitors, rofecoxib, valdecoxib and lumiracoxib have been withdrawn from the market because of cardiovascular, cutaneous, and hepatic adverse events respectively [7, 8, 32–34]. Health Canada and the Food and Drug Administration (FDA) require the product information for NSAIDs (tNSAIDs and COX-2 inhibitors) to include a warning of the increased incidence of cardiovascular (e.g. heart attack, stroke) and gastrointestinal (e.g. ulcer, bleeding) adverse events, as well as recommendations to limit use of the drug to the lowest effective dose for the shortest possible duration of treatment [8, 34].

A great deal of variability exists in the literature regarding the criteria by which an NSAID is classified as COX-2 selective and for the techniques used to make this determination. The most accepted technique involves determination of the COX-2 IC<sub>50</sub> to COX-1 IC<sub>50</sub> ratio (a ratio of the concentrations of the drug that results in 50% blockage of the COX-2 and COX-1 iso-enzymes) through a whole blood assay. A value below one indicates greater affinity for COX-2 inhibition than COX-1 inhibition. The lower the value, the greater the COX-2 selectivity. However, a ratio below 1 does not guarantee COX-2 selectivity in clinical practice, since other factors are at play, such as the COX-2 selectivity at target tissue such as the gastric mucosa, and the effect of clinically used dosages of the drug on its COX-2 selectivity (i.e. an agent may be COX-2 selective only at sub-therapeutic doses). Also, the reported COX-2 to COX-1 IC<sub>50</sub> ratios for the available COX-2 selective NSAIDs differ from one report to another.

This chapter includes updates to two Cochrane collaboration systematic reviews on: the effects of pharmacologic interventions used to prevent the GI harms associated with the chronic use of non-selective tNSAIDs (diclofenac, ibuprofen, naproxen); the GI safety of COX-2s when used alone, as well as the influence of aspirin co-administration on GI harms, and the GI safety of a combined COX-2 proton pump inhibitor strategy.

### Risk factors for NSAID related gastrointestinal toxicity

Several studies, meta-analyses and reviews have addressed the issue of risk factors for NSAID induced gastrointestinal toxicity. Increasing age (>65), previous peptic ulcer disease with or without previous hemorrhage and co-morbid medical illnesses, particularly heart disease, have been consistently shown to increase the risk of an adverse gastrointestinal event among patients on long-term NSAID therapy [13, 15, 17, 19, 35–39]. Using multiple logistic regression to adjust for risk factors simultaneously, Silverstein *et al.* found that among patients on chronic NSAIDs with none of these risk factors, only 0.4% developed a serious adverse gastrointestinal event at six months, whereas 9% of patients with all three risk factors experienced such an event [13]. Other risk factors have also been identified (Table 7.1). High doses of NSAIDs and the use of multiple NSAIDs increase the risk of adverse outcomes, as do the combined use of NSAIDs with corticosteroids, ASA, or warfarin [38, 40]. Specific NSAIDs (Table 7.2), and in some studies female gender is also associated with an increased risk of gastrointestinal toxicity [36–38, 41–44].

The duration of NSAID use has been reported as a risk factor for gastrointestinal toxicity, with most studies suggesting that the risk is highest within the first month of use [16, 20, 42, 45, 46]. However there is increasing evidence to suggest that the risk of significant NSAID toxicity does not diminish with prolonged use beyond one month. Silverstein *et al.*, in their prospective study of misoprostol for the prevention of serious NSAID related gastrointestinal events, did not find a decreased risk with continued NSAID use [13]. Furthermore, in a large prospective cohort study of NSAID related gastrointestinal toxicity, MacDonald *et al.* found that there was a four-fold relative risk increase associated with the use of NSAIDs and that this risk was nearly constant over the three-year follow-up period [21]. Additionally these investigators found that a two-fold rela-

tive risk of gastrointestinal toxicity persisted for at least one year after the last exposure to NSAIDs.

Compliance with NSAID use also appears to be a risk factor for gastrointestinal toxicity. Wynn *et al.* in a study of patient awareness of adverse effects and symptoms associated with NSAIDs, found that patients suffering an adverse gastrointestinal event had a higher rate of compliance (96%) with their NSAID use than those not suffering an event (70%) [47]. Similarly, Griffin *et al.* found that patients suffering a terminal NSAID related gastrointestinal event were more likely to have filled a prescription for an NSAID in the preceding month [16]. Symptoms, however, correlate quite poorly with the occurrence of endoscopic ulceration and adverse gastrointestinal events, and thus cannot be considered predictors of adverse gastrointestinal events [12, 13, 22, 40, 48].

The role of *Helicobacter pylori* infection as a risk factor for NSAID related gastrointestinal toxicity is controversial and will be discussed in the following section.

### Do endoscopic ulcers predict clinical events?

Gastrointestinal ulcers are established as the pathophysiologic correlate of clinical gastrointestinal events resulting from the chronic use of NSAIDs. For this reason endoscopically confirmed ulcers have been used as surrogate outcomes for clinical gastrointestinal events resulting from NSAID use. Endoscopic definitions of gastroduodenal ulcers are controversial [49], and do not equate with the pathological definition, which defines an ulcer as a loss of

**Table 7.1** Risk factors for NSAID gastrointestinal toxicity.

Age >60
Previous peptic ulcer disease
Underlying medical conditions
Concomitant corticosteroid use
Concomitant anticoagulant therapy or ASA
High dose of NSAID or multiple NSAIDs
Type of NSAID
Duration of NSAID use/compliance

Ibuprofen	1.00
Dose: (Ibuprofen)	
Low	1.6
High	4.2

mucosal surface of sufficient depth to penetrate the muscularis mucosa [50]. In most clinical trials of NSAID prophylaxis, an endoscopic ulcer is defined as a break in the mucosal surface, usually greater than 3 mm in diameter with some appreciable depth. The strictness of these criteria has varied from study to study, with some authors requiring the use of an endoscopic measuring tool, or estimation based on the size of an open biopsy forceps to measure the ulcer diameter. Formal estimates of inter-observer variability among the endoscopists are often not presented, particularly in the larger multicentre trials. Some authors define an ulcer as the loss of mucosal surface of 5 mm or greater in diameter to better differentiate them from erosions and to achieve closer agreement with clinical events [49]. Varying definitions of endoscopic ulcers and the occasional use of composite endpoints all complicate comparison of results across studies.

Unfortunately, endoscopic ulcers are not ideal surrogate outcomes for clinical gastrointestinal events such as bleeding or perforation of an ulcer. In fact, the proportion of endoscopic ulcers that never become clinically symptomatic, is estimated to be as high as 85% [13, 51].

With the publication of several large randomized controlled trials (RCTs) that used actual clinical endpoints to measure the safety of COX-2 inhibitors and of misoprostol prophylaxis [13, 52, 53], it became possible to compare the reduction in clinical events with that of the reduction in endoscopic ulcers from the endoscopic studies [54–56]. Although these are indirect comparisons that have to be interpreted with caution, we have found in our systematic reviews that the standard NSAID arms of both the NSAID prophylaxis trials and the COX-2 trials were quite similar clinically, and demonstrated nearly identical NSAID ulcer and complication rates.

The relative risk reduction in endoscopic gastric ulcers with misoprostol prophylaxis and with COX-2 inhibitors is about 80%. In the clinical endpoint studies, the relative risk reductions in NSAID ulcer related perforations, obstructions and bleeding is about 50% with both these strategies. The consistency suggests that there is a relationship between the endoscopic and clinical endpoints. The relationship does not have to be 1:1. In fact based on our results, prophylactic agents and COX-2 inhibitors are 1.5–2.0 times more effective at reducing the risk of endoscopic ulcers than they are at reducing the risk of clinical endpoints. Unfortunately the studies using clinical gastrointestinal events as the primary outcome measure were not designed to look at the relationship of clinical events to endoscopic ulcers, and we used indirect comparisons to arrive at this result [13]. However, with the cautions described above, the reader can estimate what the expected reduction in clinical events would be based on the results of an endoscopic endpoint study, assuming the control groups are average risk arthritic patients requiring long-term NSAID use.

## The role of *Helicobacter pylori* in NSAID associated ulcers

The causal role of *Helicobacter pylori* in the development of gastroduodenal ulcers has added a new perspective to the management of patients with gastrointestinal complaints [57–59]. NSAIDs are now thought to cause approximately 25% of gastroduodenal ulcers [60], and do so in the absence of *H. pylori* [61–64]. The study of the potential interaction between *H. pylori* and NSAIDs has been complicated by the following facts: (1) NSAID use is most frequent among elderly patients, the same group with the highest *H. pylori* prevalence in western populations [65, 66], (2) in the presence of both factors, it has been difficult to determine whether an ulcer is caused by NSAIDs with incidental *H. pylori*, or caused by *H. pylori* with incidental or exacerbating NSAIDs [67, 68], and (3) whereas one would expect, based on conventional thinking, an increased incidence of ulcers in the presence of these two well-established risk factors, some clinical and observational studies found that infection with *H. pylori* decreased the likelihood of ulcers or gastroduodenal injury in NSAID users [69–72]. Still other studies have found no effect of *H. pylori* infection on NSAID induced gastroduodenal injury [70, 73].

A systematic review published in 2002 has shed some light on our understanding of the clinical impact of the co-existence of *H. pylori* infection and NSAID use [74]. In this systematic review of observational studies of PUD in adult patients taking NSAIDs and of *H. pylori* infection and NSAID use in PUD bleeding, strict diagnostic criteria for the documentation of *H. pylori* infection and endoscopic ulcers were used. Twenty-five studies were included out of 61 potentially relevant publications. Sixteen studies with a total of 1625 patients assessed the effect of *H. pylori* infection on the risk of uncomplicated PUD in adult NSAID users. In these patients, *H. pylori* infection increased the risk of uncomplicated PUD 2.12-fold (95% CI: 1.68–2.67).

The interaction between *H. pylori* infection and NSAID exposure was derived from five age-matched controlled studies of chronic (>4 weeks) NSAID exposure. In the presence of *H. pylori* infection, the use of NSAIDs increased the risk of uncomplicated PUD 3.55-fold (95% CI: 1.26–9.96); while in the presence of NSAIDs, *H. pylori* infection increased the risk of PUD 3.53-fold (95% CI: 2.16–5.75). Compared to control patients without either NSAID or *H. pylori* exposure, the combined exposure to both factors increased the risk of uncomplicated PUD 6.36-fold (95% CI: 2.21–18.31) after correction for a zero event rate in *H. pylori* negative controls.

Nine case-control studies with 893 patients and 1002 controls assessed the effects of *H. pylori* infection and NSAID exposure on the risk of ulcer bleeding. *H. pylori* infection conferred a marginally increased risk, with an OR 1.67

(95% CI: 1.02–2.72), which was more pronounced when the analysis was limited to studies using serology for diagnosis of *H. pylori* infection (OR 2.16 (95% CI: 1.54–3.04)). Studies using patients with non-bleeding ulcers as controls (as opposed to either healthy or hospitalized non-ulcer controls) tended to be negative, but the results of a sensitivity analysis based on the type of controls were not presented. NSAID exposure, which was principally short term in these studies (<1 week and <1 month in six and two out of nine studies respectively), conferred an increased risk of ulcer bleeding (OR 4.79; 95% CI: 3.78–6.06), whereas the combined exposure to NSAIDs and *H. pylori* led to an increased risk of PUD bleed of 6.13 (95% CI: 3.93–9.56). These findings are in keeping with the hypothesis that short-term NSAID exposure renders “silent” *H. pylori*-related ulcers clinically manifest, a notion that has been suggested by others [75–77].

The authors of this systematic review support the conventional thinking that in peptic ulcer disease two sources of injuries are worse than one. However, the outcome of combined exposure to NSAIDs and *H. pylori* infection differs depending on the patient population (prior history of PUD or not), the type of NSAID exposure (first time or not, short term or long-term; ASA or non-ASA NSAID), the study outcome (ulcer healing, ulcer bleeding, ulcer prevention) and the co-administration of ulcer prophylaxis. Several recent randomized trials have addressed some of these issues.

### Ulcer healing

Ulcer healing with omeprazole or ranitidine occurs more readily in the presence of *H. pylori* infection [78, 79]. As well, the presence of *H. pylori* enhances the ability of omeprazole to raise gastric pH among patients with duodenal ulcer [80]. However, Bianchi Porro *et al.* found that the presence of *H. pylori* did not statistically affect the healing rates at either four or eight weeks in a study of 100 chronic NSAID users with peptic ulcers [81].

In a group of 81 *H. pylori* positive ulcer patients with ongoing requirement for NSAIDs, Hawkey *et al.* observed that the addition of *H. pylori* eradication to a one-month course of omeprazole led to a significantly lower healing rate for gastric ulcers (50 vs 88% healing at four weeks and 72 vs 100% healing at eight weeks, for the *H. pylori* treated and omeprazole alone groups, respectively ( $p = 0.006$ )), while the rates of duodenal ulcer healing were similar in both groups [82].

### Ulcer prevention in NSAID naive patients

Chan *et al.* randomized 100 *H. pylori* positive, NSAID naive, patients with no prior history of peptic ulcer, to receive either naproxen alone or *H. pylori* eradication (bismuth,

tetracycline and metronidazole) followed by naproxen for eight weeks [83]. At eight weeks, the rate of ulcer recurrence was statistically lower in the triple therapy group (7% vs 26% in the naproxen alone group in the intention-to-treat analysis,  $p = 0.01$ ), for a 74% relative risk reduction with *H. pylori* eradication. The importance of coexistent risk factors was highlighted by the fact that 73% of ulcer patients were older than 60 and that 73% of them also had co-morbidity.

In a more recent study, the same group enrolled 100 *H. pylori* positive, NSAID naive, patients with either a prior history of peptic ulcer (16% of the patients) or dyspepsia, to receive *H. pylori* eradication or omeprazole plus placebo for one week, followed by diclofenac 100mg daily for six months [84]. Once again, in these NSAID naive patients, *H. pylori* eradication conferred a protective effect, leading to a significantly reduced incidence of both endoscopic ulcers (12.1% (95% CI: 3.1–21.1) vs 34.4% (21.1–47.7) in the eradication vs omeprazole alone groups respectively), and of clinical ulcers (4.2% (1.3–9.7) vs 27.1% (14.7–39.5) in the eradication vs omeprazole alone groups respectively) at six months. Of note, 17% of these patients had received low-dose ASA prior to enrolment.

### Secondary ulcer prevention in patients on continuous NSAID

The role of *H. pylori* eradication for the prevention of recurrent upper gastrointestinal bleeding was studied by Chan *et al.* [85]. Four hundred *H. pylori* positive, chronic users of ASA or other NSAID, presenting with a bleeding peptic ulcer, were randomized to receive either *H. pylori* eradication or ulcer prophylaxis with omeprazole and followed up for six months for the recurrence of clinical events. In the group of patients on low-dose (80mg daily) ASA, the probability of ulcer recurrence was similar among *H. pylori* treated patients and those on PPI prophylaxis. However, in patients on a non-ASA NSAID (naproxen 500mg twice daily), *H. pylori* eradication did not confer the same magnitude of ulcer protection as omeprazole, so that the trial was terminated after the second interim analysis (probability of recurrence 18.8% vs 4.4% for the *H. pylori* eradication and omeprazole groups respectively ( $p = 0.005$ ) at that point).

Hawkey *et al.* studied the role of *H. pylori* eradication in a group of 285 *H. pylori* positive patients with a history of ulcer or dyspepsia and ongoing requirement for NSAIDs [82], who were randomized to a one-week course of either *H. pylori* eradication or omeprazole plus placebo. All patients then received a three-week course of omeprazole for ulcer healing. During the follow-up period patients received continuous NSAIDs without ulcer prophylaxis. The probability of ulcer recurrence at six months was similar in both groups, and the study concluded that in chronic NSAID (non-ASA) users, *H. pylori* eradication did not confer a protective effect on ulcer recurrence.

In summary, we can conclude based on these recent RCTs, that *H. pylori* contributes to an excess ulcer risk in NSAID naive patients, whereas ulcers occurring in long-term NSAID users are probably largely caused by NSAIDs themselves, irrespective of *H. pylori* status. Therefore, the impact of *H. pylori* is likely to be manifest early in the course of NSAID exposure, either because these patients are prone to early ulcer complications with NSAIDs, or because the administration of NSAIDs has precipitated complications in pre-existing *H. pylori* ulcers. We can also conclude that the impact of *H. pylori* eradication is related to the amount of co-existing ulcerogenic factors; while its benefits are more obvious in conjunction with low-dose ASA administration, they are not significant in comparison to the ulcerogenic effects of “regular” NSAIDs and are less marked in the elderly or in the presence of co-morbidity.

Based on this evidence, it would seem appropriate to eradicate *H. pylori* in NSAID naive patients prior to starting chronic ASA or NSAID therapy. However, *H. pylori* eradication alone appears to be insufficient for ulcer prophylaxis in chronic non-ASA NSAID users.

## Definition of terms

In the discussion that follows, we use the relative risk (RR) to indicate the likelihood of an outcome in subjects on treatment compared to those on placebo [86, 87]. For example a RR of 0.25, means that the treatment is associated with only 25% or 1/4 the probability of the outcome as compared to placebo. Expressed in another way, an RR of 0.25 means that the treatment reduces the “risk” of an event by 75% compared to placebo ( $1 - 0.25 = 0.75$  or 75%). This relative risk reduction differs from the absolute risk reduction (ARR), the arithmetic difference in the proportion of patients with the outcome between the placebo and treatment groups. If the stated 95% confidence interval overlaps with 1, then the observed risk is not statistically significant. Several clinical endpoints are used in the chapter. The composite endpoint of perforation, obstruction or bleeding is referred to as POB; while a PUB refers to a POB or a symptomatic ulcer. Endoscopic ulcers refer to endoscopically detected ulcers as part of studies with predetermined endoscopy schedules. Non-selective traditional NSAIDs are referred to as tNSAIDs; and cyclo-oxygenase-2 inhibitors as COX-2s. The term NSAID is used when referring to the overall group including (tNSAIDs and COX-2s).

## Misoprostol

Misoprostol is a synthetic prostaglandin E<sub>1</sub> analogue [88–91]. It reduces basal and stimulated gastric acid secretion

through a direct effect on parietal cells [91], and reduces gastric damage caused by a variety of aggressive factors including bile salts and NSAIDs [92]. Misoprostol’s protective effects are felt to be related to its ability to stimulate gastric bicarbonate and mucus secretion, and to maintain mucosal blood flow and the mucosal permeability barrier. Misoprostol also promotes epithelial proliferation in response to injury [88]. It appears that at doses of misoprostol sufficient to protect gastric mucosa, suppression of acid secretion also occurs [90]. However, since standard doses of H<sub>2</sub>-receptor antagonists inhibit gastric acid secretion at least as effectively as misoprostol, and yet have not been shown to protect the gastric mucosa against NSAID induced ulceration (see next section), it is likely that mechanisms other than acid suppression are important for the prevention of gastric ulcers. Additionally, it has recently been suggested that misoprostol may be superior to PPIs for the prevention of NSAID induced gastric ulcers and gastroduodenal erosions [93, 94].

Misoprostol appears to be effective in preventing acute gastroduodenal injury induced by short courses of ASA and NSAIDs as measured by mucosal, or fecal blood loss, and by endoscopic injury scores [95–99]. However the clinical relevance of this effect is unclear, given the adaptation of gastroduodenal mucosa to acute injury with continued NSAID use [73, 100, 101].

## Long-term efficacy of misoprostol

In our meta-analysis, we found 23 studies that assessed the long-term effect of misoprostol on the prevention of tNSAID ulcers [13, 33, 94, 102–121]. The dosage of misoprostol varied from 200ug to 800ug daily, and follow up ranged between 4 to 48 weeks.

## Endoscopic ulcers

Eleven studies with 3641 patients compared the incidence of endoscopic ulcers, after at least three months, in misoprostol and placebo treated patients [94, 102, 103, 106, 110–113, 116, 118, 121]. The cumulative incidence of endoscopic gastric and duodenal ulcers with placebo was 15% and 6%, respectively. Misoprostol significantly reduced the relative risk of gastric ulcer and duodenal ulcers by 74% (RR = 0.26; 95% CI: 0.17–0.39 random effects), and 58% (RR = 0.42; 95% CI: 0.22–0.81 random effects). These relative risks correspond to 12.0% and 3% absolute risk reductions for gastric and duodenal ulcers, respectively. The observed heterogeneity in these estimates was due to inclusion of all misoprostol doses in the analyses. Analysis of the misoprostol studies stratified by dose eliminated this heterogeneity.

### Analysis by dose

All the studied doses of misoprostol significantly reduced the risk of endoscopic ulcers and a dose response relationship was demonstrated for endoscopic gastric ulcers (Figure 7.1). Six studies with 2461 patients used misoprostol 400 ug [103, 106, 111, 113, 116, 121], one study with 928 patients used 600ug daily [116], and seven with 2423 patients used 800ug daily [94, 102, 110–112, 116, 118]. Misoprostol 800ug daily was associated with the lowest risk (RR = 0.17; 95% CI: 0.11–0.24) of endoscopic gastric ulcers when compared to placebo, whereas misoprostol 400ug daily was associated with a relative risk of 0.42 (95% CI: 0.28–0.67 random effects model for heterogeneity). The

observed heterogeneity in the 400ug dose group was the result of the addition of the Chan study (Chan 2001). This study compared the relatively more toxic naproxen with low dose misoprostol to nabumatone alone. In this study the risk of ulcers was inexplicably greater in the misoprostol group, but this result is probably based on the differences between the safety of the comparator tNSAIDs rather than on an effect of the prophylactic agent. In a sensitivity analysis, removal of the Chan study eliminates the observed heterogeneity without significantly altering the results, giving low dose misoprostol prophylaxis a RR of 0.39 (95% CI: 0.3–0.51). This difference between high and low-dose misoprostol was statistically significant ( $p = 0.0055$ ). The observed risk for the intermediate misoprostol dose (600 ug

**Figure 7.1** Misoprostol vs placebo for the prevention of gastric ulcers – efficacy by dose: Misoprostol 800ug/day is superior to 400 or 600ug/day for the prevention of endoscopically detected gastric ulcer.

daily) was not statistically significantly different from that observed for either the low or high dose. The pooled relative risk reduction of 78% (4.7% absolute risk difference, RR = 0.21; 95% CI: 0.09–0.49) for duodenal ulcers with misoprostol 800ug daily was not statistically different from those observed with lower daily misoprostol dosages.

### Studies including data with less than three months' tNSAID exposure

Eight studies, with 2206 patients, assessed the rates of endoscopic ulcers with misoprostol compared to placebo at 1–1.5 months [33, 104, 105, 107, 109, 110, 114, 119]. The pooling of these studies revealed an 81% relative risk reduction for gastric ulcers with misoprostol (RR = 0.17; 95% CI: 0.09–0.31) and a 72% relative risk reduction for duodenal ulcers (RR = 0.28; 95% CI: 0.14–0.56).

One study compared misoprostol to a newer cytoprotective agent, Dosemofate, for tNSAID prophylaxis and found no statistically significant difference in ulcer rates between the two agents [108].

## Clinical ulcers

Only one RCT, the MUCOSA trial, evaluated the efficacy of misoprostol prophylaxis against clinically important tNSAID induced ulcer complications as the primary endpoint. In this study, of 8843 patients studied over six months, the overall GI event incidence was about 1.5% per year [13]. Misoprostol 800ug/day was associated with a statistically significant 40% risk reduction (OR = 0.598; 95% CI: 0.364–0.982) in combined GI events ( $p = 0.049$ ), representing a risk difference of 0.38% (from 0.95% to 0.57%).

## Adverse effects

Misoprostol was associated with a small but statistically significant 1.6-fold excess risk of drop-out due to drug induced adverse effects, and an excess risk of drop-outs due to nausea (RR = 1.30; 95% CI: 1.08–1.55), diarrhea (RR = 2.36; 95% CI: 2.01–2.77), and abdominal pain (RR = 1.36; 95% CI: 1.20–1.55). In the MUCOSA trial, 732 out of 4404 patients on misoprostol experienced diarrhea or abdominal pain, compared to 399 out of 4439 on placebo for a relative risk of 1.82 associated with misoprostol ( $p < 0.001$ ). Overall, 27% of patients on misoprostol experienced one or more adverse effects [13].

When analyzed by dose, only misoprostol 800ug daily showed a statistically significant excess risk of drop-outs due to diarrhea (RR = 2.45; 95% CI: 2.09–2.88) and abdominal pain (RR = 1.38; 95% CI: 1.17–1.63). Both misoprostol doses were associated with a statistically significant risk of diarrhea. However, the risk of diarrhea with 800ug/day

(RR = 3.25; 95% CI: 2.60–4.06) was significantly higher than that seen with 400ug/day (RR = 1.81 95% CI: 1.52–2.16) ( $p = 0.0012$ ).

In conclusion, misoprostol prophylaxis significantly reduces the risk of ulcers as well as serious gastrointestinal events in patients on long-term NSAID therapy. **A1a** Misoprostol is more effective at reducing the risk of gastric than duodenal ulcers, and may be more effective than PPIs at reducing the risk of gastric ulcers. The use of misoprostol, particularly at higher doses, is associated with more frequent gastrointestinal adverse effects, often resulting in the patient discontinuing the medication, which is an important consideration, given the symptoms associated with NSAID use alone. The effectiveness outside of clinical trials of misoprostol for prevention of ulcer may be lower than figures which have been presented above. However, since misoprostol is the only prophylactic agent that has been directly shown to reduce serious NSAID related gastrointestinal complications, it should be considered as the first-line agent in the primary prophylaxis of NSAID complications, particularly in high risk groups. **A1a**

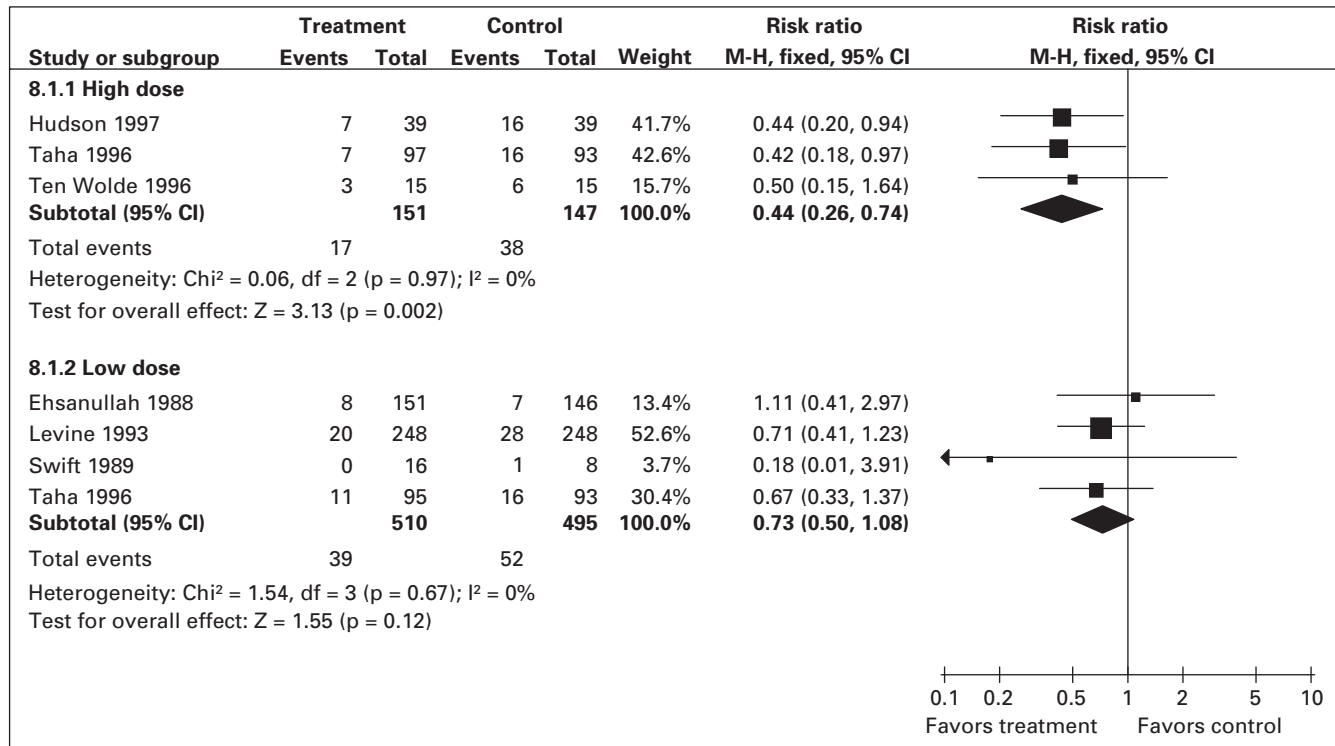

## H<sub>2</sub>-receptor antagonists

### Treatment of NSAID induced ulcer

The efficacy of H<sub>2</sub>-receptor antagonists in the treatment and prevention of NSAID related upper gastrointestinal toxicity has been exclusively evaluated in studies in which ulcers were defined endoscopically. In several early open label studies of cimetidine for healing of ulcers associated with the use of NSAIDs, it was shown that greater than 75% of gastric and duodenal ulcers could be healed with 12 weeks of therapy despite continued use of NSAIDs [122–126]. There was a trend toward improved efficacy with higher doses. However, in a randomized trial in which patients with NSAID – induced ulcers were randomized to receive standard dose ranitidine, or the more potent acid suppressor omeprazole, omeprazole was nearly twice as effective [127], although ranitidine was still somewhat effective [127, 128]. **A1a** O'Laughlin *et al.* found that ulcer size correlated inversely with healing rates. At eight weeks, ulcers with a diameter <5 mm were healed in greater than 90% of patients compared to 35% healing for ulcers >5 mm [129]. Hudson *et al.* reported similar observations [130]. The potency of acid suppression and initial ulcer size are important determinants of the rapidity of ulcer healing, and the continued use of NSAIDs in the presence of gastric acid may slow ulcer healing.

### Prevention of NSAID- induced ulcers

Standard doses of H<sub>2</sub>-receptor antagonists have been consistently shown to be effective for prevention of endoscopy-

**Figure 7.2** H<sub>2</sub>-receptor antagonists compared to placebo for the prevention of gastric ulcers: While all doses of H<sub>2</sub>-RAs are effective for reducing the incidence of endoscopically detected duodenal ulcers (figure not shown), only high doses of H<sub>2</sub>-RAs (equivalent to ranitidine 300mg bid) are effective for reducing the incidence of gastric ulcers.

cally defined duodenal ulcers, but not of gastric ulcers (Figure 7.2) [117, 131–140]. Koch *et al.* [141] in a meta-analysis of randomized trials that employed standard doses of H<sub>2</sub>-receptor antagonists [131–133, 135, 137, 138] and Stalnikowicz *et al.* [14] were also unable to show a benefit for the prevention of gastric ulcers. Similarly, our meta-analysis of the standard dose H<sub>2</sub>-receptor antagonist trials confirms that there is no statistically significant reduction in the relative risk of endoscopically defined gastric ulcers [54, 55].

Six trials that included 942 patients assessed the effect of standard dose H<sub>2</sub>-RAs on the prevention of endoscopic tNSAID ulcers at one month [131–134, 138, 142], and five trials with 1005 patients assessed these outcomes at three months or longer [131, 134, 135, 140, 143]. Standard dose H<sub>2</sub>-RAs are effective at reducing the risk of duodenal ulcers (RR = 0.24; 95% CI: 0.10–0.57, and RR = 0.36; 95% CI: 0.18–0.74 at one and three or more months respectively), but not of gastric ulcers (NS). One study did not have a placebo comparator and was not included in the pooled estimate [140].

Although achlorhydria has been reported not to prevent early NSAID induced gastric lesions [144], there is accumulating evidence that profound acid suppression can reduce acute NSAID and ASA induced gastric mucosal injury

[145–147]. Based on these observations, several investigators have tested the hypothesis that higher doses of H<sub>2</sub>-receptor antagonists may achieve more consistent acid suppression and may therefore be effective for prevention of gastric ulcer among chronic NSAID users. We identified three RCTs that included 298 patients that assessed the efficacy of double dose H<sub>2</sub>-RA for the prevention of tNSAID induced upper GI toxicity [130, 134, 148]. Double dose H<sub>2</sub>-RAs when compared to placebo were associated with a statistically significant reduction in the risk of both duodenal (RR = 0.26; 95% CI: 0.11–0.65) and gastric ulcers (RR = 0.44; 95% CI: 0.26–0.74). This 56% relative risk reduction in gastric ulcer corresponds to a 12% absolute risk difference (from 23.1% to 11.3%). **A1c**

Analysis of the secondary prophylaxis studies alone yielded similar results.

**Symptoms** H<sub>2</sub>-RAs, in standard or double doses, were not associated with an excess risk of total drop-outs, drop-outs due to adverse effects, or symptoms when compared to placebo. However, high dose H<sub>2</sub>-RAs significantly reduced symptoms of abdominal pain when compared to placebo (RR = 0.57, 95% CI: 0.33–0.98).

H<sub>2</sub>-RAs were generally quite well tolerated in the presented studies. Standard doses of these agents appear to be

effective in preventing NSAID induced duodenal but not gastric ulcers. However, double dose H<sub>2</sub>-receptor antagonists appear to be effective for healing and prevention of both gastric and duodenal ulcers in patients taking NSAIDs chronically. The clinical use of this class of drugs for the prevention of gastroduodenal ulceration may be questioned for several reasons. In terms of the trial results, the ulcer rates in the placebo groups of the famotidine studies are higher than are generally reported. Furthermore, since H<sub>2</sub>-receptor antagonists are associated with tolerance to their acid suppressive effects [149–151], the long-term efficacy of these drugs must be questioned. Finally, even if effective for ulcer prevention, there is no economic or therapeutic advantage to using double doses of these drugs rather than standard doses of proton pump inhibitors that produce more potent and reliable acid suppression. **C5**

Proton pump inhibitors

Proton pump inhibitors (PPIs) block the final step of gastric acid secretion by inhibiting parietal cell H<sup>+</sup>-K<sup>+</sup>-ATPase. Direct evidence for the efficacy of PPIs in the primary or secondary prevention of clinically important NSAID induced upper gastrointestinal toxicity is lacking. Several factors have prompted interest in the use of PPIs for prophylaxis against NSAID induced ulcers: (1) dissatisfaction with the adverse effects of misoprostol; (2) the apparent efficacy of PPIs in healing NSAID ulcers; (3) the proven efficacy of PPIs in other acid-peptic disorders; (4) the attractive tolerability profile of PPIs.

PPIs appear to be effective for the prevention of early NSAID induced upper gastrointestinal injury assessed either endoscopically or through the detection of mucosal blood loss, in healthy volunteers given aspirin or naproxen

[145–147, 152]. However, as discussed previously the clinical relevance of these early lesions is in question.

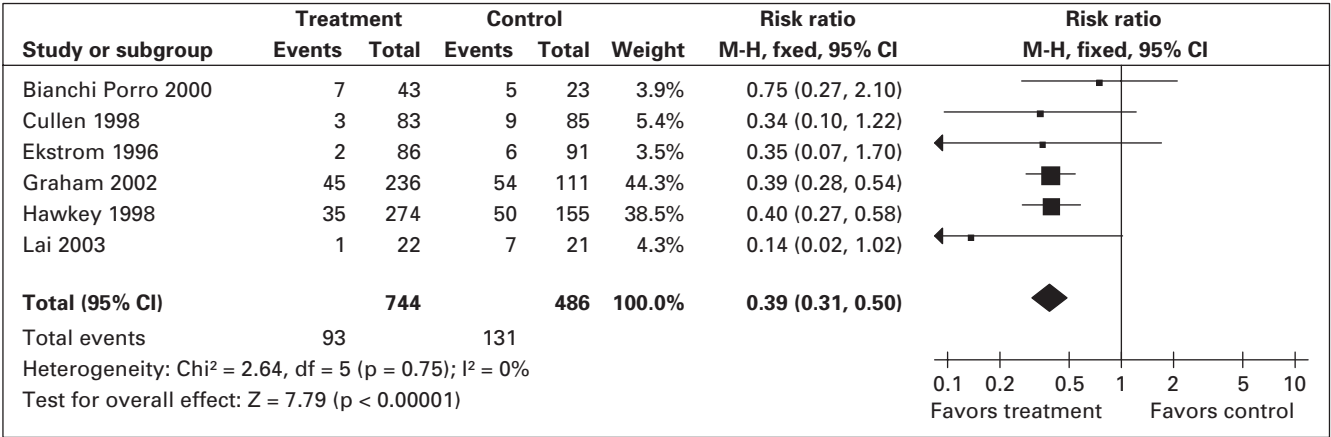

Healing of ulcers with continued NSAID use

Omeprazole has been shown to heal both gastric and duodenal ulcers irrespective of continued NSAID use [79, 93, 127, 153–155]. Walan *et al.* in a double-blind trial, assessed the healing rates of benign gastric and prepyloric ulcers in 602 patients randomized to receive either omeprazole (40mg or 20mg) or ranitidine 150mg bid [127]. In a subset of 58 patients with endoscopically documented ulcers who continued to take NSAIDs, the proportions of patients whose ulcers healed at eight weeks were: omeprazole 40mg, 95% (similar to results for patients with non-NSAID ulcers), omeprazole 20mg, 82% and ranitidine, 53%, (*p* < 0.05). These data suggest that selected patients with endoscopically documented NSAID ulcers can experience ulcer healing with omeprazole despite continued NSAID use. However, caution should be exercised in extrapolating these results to patients presenting with NSAID induced upper gastrointestinal hemorrhage. In these patients the decision to continue the NSAID must be individualized, since the safety and efficacy of omeprazole in this setting has not been assessed.

NSAID ulcer prevention

Six RCTs with 1259 patients assessed the effect of PPIs on the prevention of tNSAID induced upper GI toxicity [94, 113, 156–159].

PPIs significantly reduced the risk of both endoscopic duodenal (RR = 0.20; 95% CI: 0.10–0.39) and gastric ulcers (RR = 0.39; 95% CI: 0.31–0.50) compared to placebo (Figure 7.3) [94, 113, 156–159]. The results were similar for both primary and secondary prophylaxis trials. **A1a**

**Figure 7.3** PPIs compared to placebo for the prevention of gastric ulcer in studies of eight weeks or longer duration. PPIs are effective for reducing the incidence of both gastric and duodenal ulcers. Data for gastric ulcers is shown.

## Symptoms

Four omeprazole trials used the same composite endpoints to define treatment success [79, 113, 157, 158]. In these trials omeprazole significantly reduced “dyspeptic symptoms” as defined by the authors. In the combined analysis, drop-outs overall and drop-outs due to adverse effects were not different from placebo.

## Head-to-head comparisons

### Misoprostol vs H<sub>2</sub>-RAs

Two trials with 600 patients compared misoprostol to ranitidine 150mg twice daily [116, 120]. Misoprostol appears to be superior to standard dose ranitidine for the prevention of tNSAID induced gastric ulcers (RR = 0.12; 95% CI: 0.03–0.51) but not duodenal ulcers (RR = 1.00; 95% CI: 0.14–7.14). **A1a**

### PPI vs H<sub>2</sub>-RA

Yeomans *et al.* in a study of 425 patients, compared omeprazole 20mg daily to ranitidine 150mg twice daily for tNSAID prophylaxis [79]. In this study, omeprazole was superior to standard dose ranitidine for the prevention of both gastric (RR = 0.32; 95% CI: 0.17–0.62) and duodenal ulcers (RR = 0.11; 95% CI: 0.01–0.89). **A1a**

### PPI vs misoprostol

Four trials with a total of 1478 patients [32, 94, 113, 115] compared a PPI to misoprostol. Two studies compared low dose misoprostol (400ug) daily to a standard dose PPI [32, 113] or high dose misoprostol (800ug) to lansoprazole 15 or 30mg daily. PPIs are significantly more effective than misoprostol for the prevention of duodenal (RR = 0.25; 95% CI: 0.11–0.56), but not gastric (RR = 1.61; 95% CI: 0.88–3.06 random effects) or total gastroduodenal ulcers (RR = 0.90; 95% CI: 0.47–1.72 random effects). **A1a** The trial conducted by Hawkey *et al.* showed a non-significant trend towards greater benefit with misoprostol over omeprazole for the prevention of gastric ulcers, while the study reported by Graham *et al.* actually showed that misoprostol was superior to lansoprazole for the prevention of gastric ulcers. The pooled results mirrored these findings but did not demonstrate a statistically significant benefit of misoprostol over PPIs (RR = 0.62; 95% CI: 0.33–1.18 random effects).

## Symptoms

In the two head-to-head comparison of omeprazole and misoprostol [94, 113], PPIs were associated with signifi-

cantly fewer drop-outs overall (RR = 0.71; 95% CI: 0.52–0.97), as well as significantly fewer drop-outs due to adverse effects (RR = 0.48; 95% CI: 0.29–0.78). **A1a** When compared to H<sub>2</sub>-RA used for less than two months, misoprostol caused significantly more drop-outs due to abdominal pain (RR = 3.00, 95% CI: 1.11, 8.14) and more symptoms of diarrhea (RR 2.03, 95% CI: 1.38, 2.99). **A1a** There were no significant differences in drop-outs due to adverse effects (RR 1.90, 95% CI: 0.77–4.67) or symptoms of abdominal pain or diarrhea between low dose H<sub>2</sub>-RAs and PPIs. Misoprostol also appears to be associated with a lower quality of life amongst chronic tNSAID users compared to PPIs [79].

## Summary

Collectively these studies demonstrate that PPIs are effective for healing both gastric and duodenal NSAID induced ulcers irrespective of continued NSAID use or *H. pylori* status. These agents also appear to be effective for the prevention of endoscopically diagnosed NSAID induced ulcers. In high risk GI patients (secondary prophylaxis), a study from Hong Kong suggested that strategies employing a COX-2 or an NSAID + PPI show similar efficacy at reducing re-bleeding events, though both strategies were associated with important re-bleeding rates [160, 161]. A second study performed in Hong Kong showed that for very high risk GI patients, a strategy of a COX-2+ a PPI was associated with very low re-bleeding rates [162].

### A1c

The appropriate choice of therapy for secondary prophylaxis against NSAID ulcer recurrence among chronic NSAID users is unclear. Currently misoprostol is the only prophylactic agent of proven benefit for the prevention of NSAID induced clinical events. However, in reality most clinicians will prescribe a PPI to heal NSAID-induced ulcers, and will continue the same agent for secondary prophylaxis. Given the results of the OMNIUM and ASTRONAUT studies, this approach may be appropriate, but a degree of caution is indicated given the limitations of these studies, and the absence of direct evidence for effectiveness of PPIs for prevention of clinical gastrointestinal events. The cost-effectiveness of PPIs for the primary or secondary prophylaxis against NSAID induced upper gastrointestinal toxicity has not been established.

## Cyclo-oxygenase-2 inhibitors

Since the publication of the last edition of this book, several endoscopic studies demonstrating the safety of COX-2 inhibitors, and several important clinical outcome studies similar to the misoprostol MUCOSA study have been published. In this section we will present the latest evidence

for the GI safety of COX-2 inhibitors. We will concentrate on the following COX-2s: celecoxib, rofecoxib, etoricoxib, valdecoxib, and lumiracoxib.

NSAIDs are believed to exert their therapeutic anti-inflammatory and analgesic effects through the inhibition of inducible cyclo-oxygenase-2 (COX-2), whereas their gastric and renal toxicities, and antiplatelet effects appear to arise from the inhibition of the constitutive COX-1 isoform [28, 29]. This COX-2 hypothesis, along with the unfavorable safety profile of standard NSAIDs, has prompted the development of newer NSAIDs with selectivity for the COX-2 isoform.

## Endoscopic ulcer trials

### Cyclo-oxygenase-2s vs nonselective non-steroidal anti-inflammatory drugs

Seventeen studies with over 10,000 patients assessed the proportion of patients who developed endoscopic ulcers while taking a COX-2 compared to those taking a non-selective tNSAID [163–179]. There were seven studies that assessed celecoxib [163–165, 169, 175, 176, 178], three that assessed rofecoxib [166–168], two that assessed etoricoxib [173, 174], five that assessed valdecoxib [170–172, 177, 179], and two that assessed lumiracoxib [169, 175]. Some studies assessed more than one intervention [169, 175].

### Endoscopically detected gastro-duodenal ulcers

Thirteen studies with a total of 7839 patients showed a 74% RRR (relative risk reduction) in combined gastro-duodenal ulcers with COX-2s versus tNSAIDs (RR = 0.26; 95% CI: 0.23–0.30) (Figure 7.4) [163–174, 180]. This represented a 16% absolute risk reduction (ARR) and NNT = 6. Addition of the FDA studies did not significantly alter the results (RR = 0.28; 95% CI: 0.24–0.32). **A1a**

Eleven studies with a total of 6726 patients compared the safety of a COX-2 to a comparator tNSAID for endoscopic gastric ulcers [163–172, 180]. The use of a COX-2 in this setting was associated with a 79% RRR in gastric ulcers (RR = 0.21; 95% CI: 0.18–0.25). This represented a 14% ARR in gastric ulcers with the use of COX-2s compared with tNSAIDs. (NNT = 7). Addition of the FDA studies did not significantly alter the results (RR = 0.26; 95% CI: 0.22–0.30).

#### A1a

The same eleven studies also compared the proportions of duodenal ulcers that occurred while using a COX-2 versus a tNSAID [163–172, 180]. Compared to using a tNSAID, the use of a COX-2 was associated with a 66%

RRR in duodenal ulcers (RR = 0.34; 95% CI: 0.25–0.45) (Figure 7.4). This represented a 3% ARR (NNT = 33). **A1a** Addition of the FDA studies did not significantly alter the results (RR = 0.29; 95% CI: 0.23–0.38). Keeping in mind that tNSAID related gastric ulcers were more commonly observed than duodenal ulcers, a trend was observed for greater RRR and ARR for gastric ulcers than for duodenal ulcers with COX-2s, compared to tNSAIDs (RR = 0.21 vs 0.34, ARR of 14% vs 3%). This trend was consistent when celecoxib, rofecoxib and valdecoxib were analyzed separately.

### Analysis by duration

The data presented above are for any dose and duration up to six months. Subgroup analysis of these studies on the basis of duration (1–3 months and 3–6 months) did not significantly alter the results.

### Analysis by cyclo-oxygenase-2

#### Celecoxib

Five studies with a total of 2439 patients compared celecoxib to tNSAIDs, showing a 79% RRR in total gastro-duodenal ulcers (RR = 0.21; 95% CI: 0.16–0.28) with celecoxib [163–165, 169, 180]. Similar RRR were observed for gastric ulcers (RR = 0.20; 95% CI: 0.14–0.28) and duodenal ulcers alone (RR = 0.29; 95% CI: 0.18–0.47), as well as when the FDA studies were included (RR = 0.26; 95% CI: 0.21–0.32).

#### A1a

#### Rofecoxib

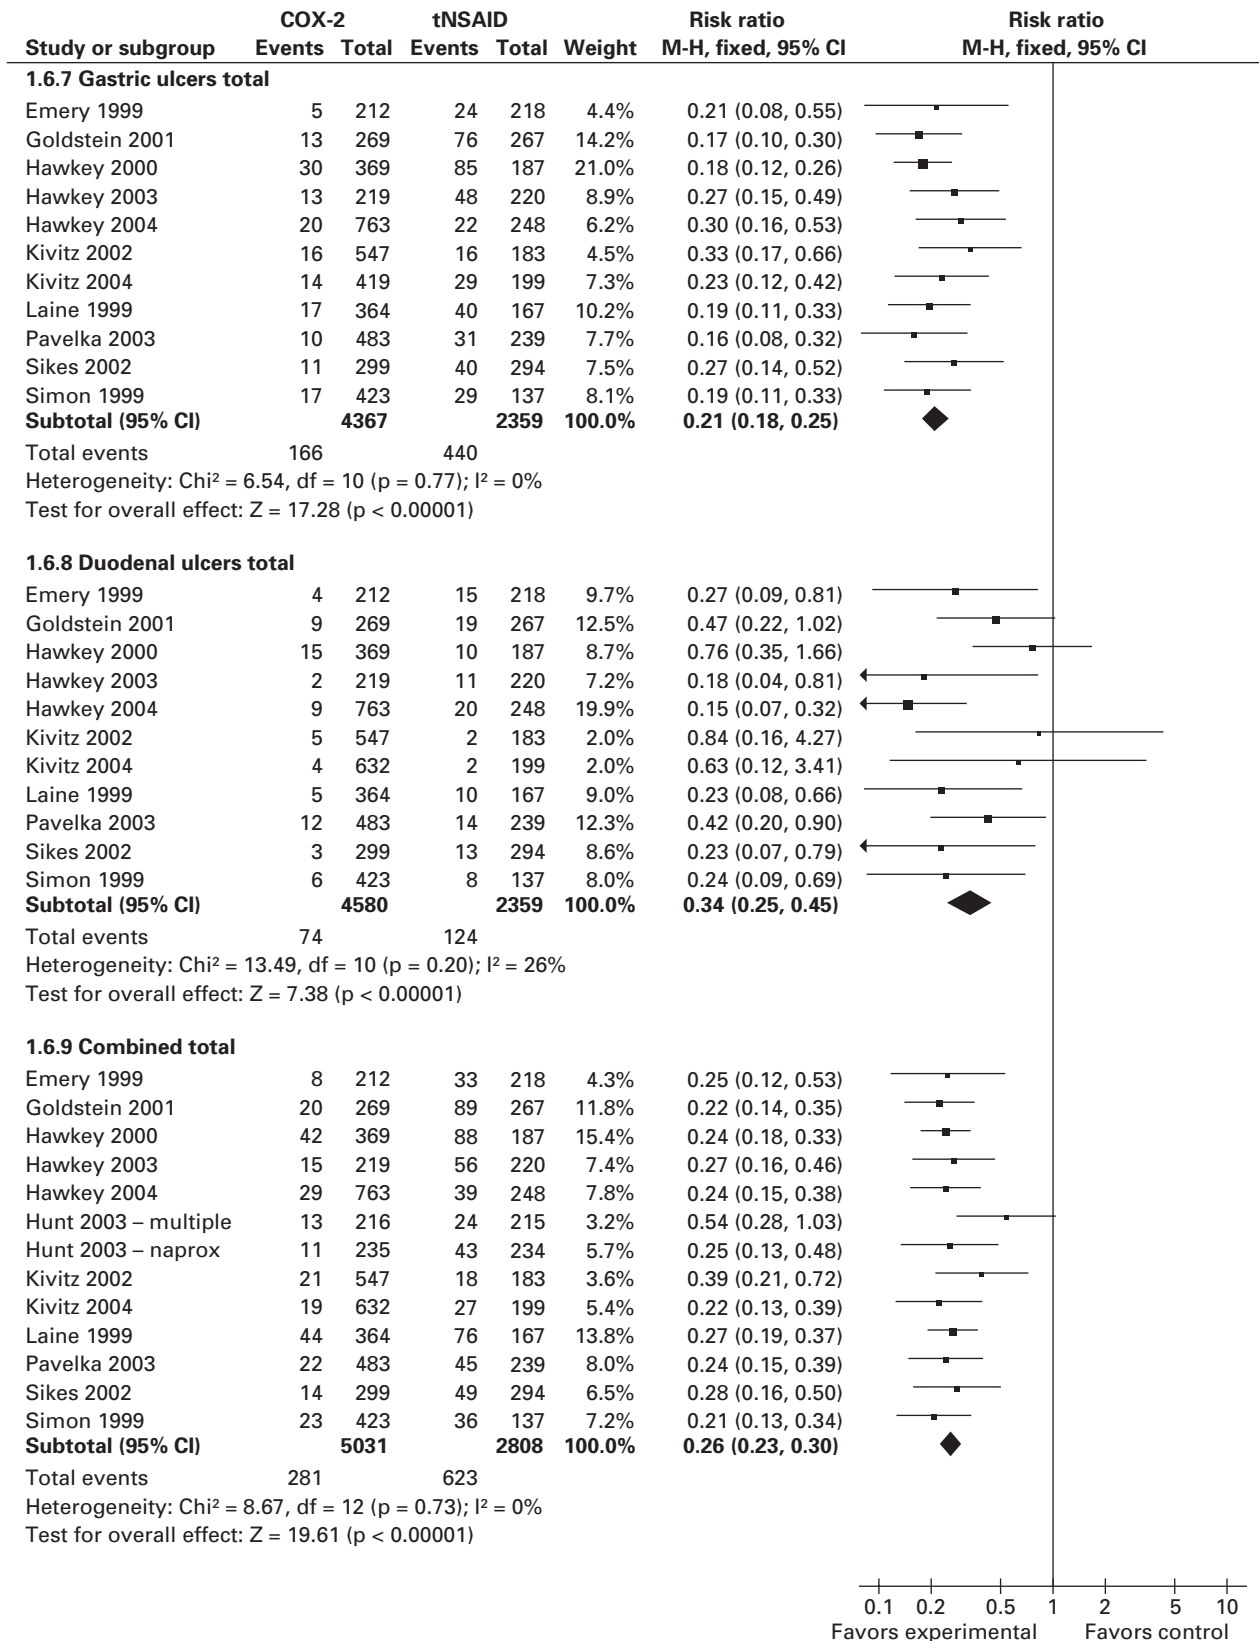

Three studies with a total of 1526 patients compared rofecoxib to tNSAIDs [166–168]. In this case, a 74% RRR was seen with rofecoxib (RR = 0.26; 95% CI: 0.21–0.32). The results were similar when FDA studies were added to the analysis as well as when the analysis was done only for gastric ulcers (RR = 0.20; 95% CI: 0.15–0.26) or duodenal ulcers (RR = 0.36; 95% CI: 0.14–0.93 random effects). **A1a**

#### Etoricoxib

Two studies, with a total of 900 patients compared etoricoxib to tNSAIDs using the endpoint of endoscopic gastro-duodenal ulcers [173, 174]. These trials demonstrated a 64% RRR (RR = 0.37; 95% CI: 0.18–0.77 random effects) with etoricoxib. **A1a**

#### Valdecoxib

Three studies compared valdecoxib to tNSAIDs in 2045 patients and demonstrated a 70% RRR in gastro-duodenal ulcers (RR = 0.29; 95% CI: 0.21–0.39) with valdecoxib [170–172]. Similar RRR were observed when the analysis was done for gastric ulcers (RR = 0.24; 95% CI: 0.18–0.37) and duodenal ulcers alone (RR = 0.39; 95% CI: 0.21–0.70), and

**Figure 7.4** COX-2 inhibitors compared to tNSAIDs. Both low and high doses of COX-2s are associated with a significantly lower incidence of endoscopically detected gastric and duodenal ulcers compared to tNSAIDs. Data for “any” doses shown.

when the FDA studies were included in the gastro-duodenal ulcers analysis (RR = 0.30; 95% CI: 0.24–0.39). **A1a**

### Lumiracoxib

Two studies with a total of 1376 patients compared lumiracoxib to tNSAIDs [180, 181]. Lumiracoxib was associated with a 74% RRR in gastro-duodenal ulcers (RR = 0.26; 95% CI: 0.18–0.39). Similar results were observed for gastric ulcers (RR = 0.25; 95% CI: 0.16–0.40) and duodenal ulcers (RR = 0.20; 95% CI: 0.09–0.43) when they were considered alone. **A1a**

## Analysis by comparator non-steroidal anti-inflammatory drugs

### Naproxen

Five studies compared either celecoxib or valdecoxib to naproxen in 2734 patients. These showed a 75% RRR in endoscopic gastro-duodenal ulcers in favour of the COX-2s (RR = 0.25; 95% CI: 0.20–0.32). Results were similar when the FDA studies were included in the analysis (RR = 0.27; 95% CI: 0.22–0.32) [163, 165, 168, 170, 174]. **A1a**

### Ibuprofen

Six studies that included over 3800 patients (two rofecoxib [166, 167]; one etoricoxib [173]; two lumiracoxib [180, 181] and one valdecoxib [171]) showed a 73% RRR in gastro-duodenal ulcers with COX-2s compared with ibuprofen (RR = 0.27; 95% CI: 0.23–0.32). Results were similar when the FDA studies were included in the analysis (RR = 0.28; 95% CI: 0.23–0.32). **A1a**

### Diclofenac

Three studies that included a total of 1596 patients demonstrated a 75% RRR in gastro-duodenal ulcers with COX-2s compared to diclofenac (RR = 0.25; 95% CI: 0.18–0.35). This effect was somewhat reduced when the FDA studies were included in the analysis (RR = 0.36; 95% CI: 0.27–0.47) [164, 171, 172]. **A1a**

Similar results were obtained when individual COX-2s were compared with the individual tNSAIDs.

## Cyclo-oxygenase-2s vs placebo

Eight studies with a total of 4081 patients compared low and high-dose COX-2s to placebo [165–168, 170, 171, 173, 174]. Low dose COX-2s appeared to demonstrate no greater risk of gastric or gastro-duodenal ulcers than placebo. **A1a** However, there was a non-significant trend toward high dose COX-2s increasing the relative risk of gastric (RR = 1.22; 95% CI: 0.83–1.80) duodenal (RR = 1.29; 95% CI: 0.63–2.66), and combined gastro-duodenal ulcers (RR = 1.57; 95% CI: 0.96–2.56 random effects).

## Clinical gastrointestinal events

### Cyclo-oxygenase-2s vs non-selective non-steroidal anti-inflammatory drugs

Nine studies with a total of 94,294 patients assessed the safety of COX-2s by using the clinically important endpoint of ulcer complication, POB [52, 53, 182–188]. Three of these trials studied celecoxib [53, 182, 187], two studied rofecoxib [52, 183], two trials evaluated etoracoxib [186, 188], and one each evaluated valdecoxib [184] and lumiracoxib [185] separately. Overall, the use of these COX-2s was associated with a 57% RRR in POBs (RR, 0.43; 95% CI: 0.28–0.67 random effects), compared with using tNSAIDs (Figure 7.5). Removal of the combined analyses studies had no influence on the result (RR = 0.39; 0.29–0.53) and the inclusion of the FDA 12-month CLASS study data [53] did not alter the results (RR = 0.42; 95% CI: 0.33–0.54). The 60% RRR in these analyses represent an ARR of 0.4% (NNT = 250). **A1a**

Fourteen studies compared COX-2s with tNSAIDs by using PUB as the study endpoint [52, 53, 173, 182–192]. In this analysis, the use of a COX-2 was associated with a 57% RRR in PUBs (RR, 0.43; 95% CI, 0.34–0.55 random effects). Removal of the combined analyses studies eliminated the observed heterogeneity but had little effect on the point estimate (RR, 0.49; 95% CI: 0.41–0.58). Similarly, the use of the FDA CLASS data did not significantly alter the estimate (RR, 0.42; 95% CI: 0.33–0.53 random effects). **A1a**

## Analyses stratified by cyclo-oxygenase-2s

### Celecoxib

Four studies with 31,106 patients assessed the effect celecoxib versus tNSAIDs on clinical GI events (POBs or PUBs) [53, 182, 189]. Celecoxib use was associated with a 77% RRR in POBs (RR = 0.23; 95% CI: 0.07–0.76 random effects) and a 61% RRR in PUBs (RR = 0.39; 95% CI: 0.21–0.73 random effects). Removal of the combined analyses study [182] eliminated the heterogeneity observed in both the POB (RR = 0.42; 95% CI: 0.22–0.80) and PUBs (RR = 0.34; 95% CI: 0.22–0.80) analyses. The use of the FDA 12-month CLASS data did not alter the RR estimates for POBs or PUBs significantly. **A1a**

### Rofecoxib

Four studies with 19,288 patients assessed the effect of rofecoxib versus tNSAIDs on clinical GI events (POBs or PUBs) [52, 183, 190, 192]. Rofecoxib use reduced the relative risk of POBs by 58% (RR = 0.42; 95% CI: 0.24–0.73) and the relative risk of PUBs by 56% (RR = 0.44; 95% CI: 0.34–0.58).

**Figure 7.5** COX-2 compared to tNSAIDs for clinically important ulcer complications. COX-2s are associated with significantly reduced incidence of POBs (perforation, obstructions or bleeding) than tNSAIDs. Removal of the MEDAL study eliminated the observed heterogeneity, likely stemming from the “real practice” design that allowed co-interventions such as PPIs. Data for PUBs (not shown) are similar.

Removal of the combined analysis study did not alter the point estimates. **A1a**

### Valdecoxib

One combined analysis study with 6461 patients evaluated the effect of valdecoxib on POBs and PUBs [184]. Valdecoxib reduced the relative risk of POBs by 65% (RR = 0.35; 95% CI: 0.14–0.87) and the relative risk of PUBs by 77% (RR = 0.23; 95% CI: 0.15–0.36). **A1a**

### Etoricoxib

Four studies with 10,856 evaluated the effect of etoricoxib on POBs [186, 188] and PUBs [173, 191]. Etoricoxib demonstrated a non-significant trend in reducing the risk of POBs (RR = 0.82; 95% CI: 0.44–1.51 random effects), but it significantly reduced the RR of PUBs by 46% (RR = 0.64; 95% CI: 0.42–0.96). **A1a**

### Lumiracoxib

One study with 18,244 patients demonstrated a significant 64% RRR in POBs (RR = 0.36; 95% CI: 0.24–0.55) and a 44% RRR in PUBs (RR = 0.56; 0.41–0.78) with the use of lumiracoxib, compared with using tNSAIDs [185]. **A1a**

## Analysis by comparator non-steroidal anti-inflammatory drugs

In general, COX-2s appeared to maintain their safety advantage regardless of the comparator tNSAID. COX-2s were statistically superior to naproxen (RR = 0.34; 95% CI: 0.24–0.48), and ibuprofen (RR = 0.46; 95% CI: 0.30–0.71) for the POB endpoint. The data comparing COX-2s to diclofenac are predominately derived from two studies and heavily influenced by the CLASS trial data which

showed no significant difference between celecoxib vs diclofenac [53, 182]. In the current analysis, celecoxib demonstrated a non-significant trend towards fewer POBs than diclofenac (RR = 0.31; 95% CI: 0.06–1.61) while a statistically significant 59% RRR in PUBs was observed (RR = 0.41; 95% 0.30–0.55). **A1a**

### Cyclo-oxygenase-2s vs placebo

There are limited data, mostly derived from the combined analyses studies, comparing COX-2s with placebo for the clinical outcomes of POBs [182, 184] and PUBs [182–184, 189, 191]. In these analyses, the use of COX-2s was associated with non-significant trends toward an increased RR of POBs (RR = 2.66; 95% CI: 0.34–20.95) and PUBs (RR = 2.26; 95% CI: 0.96–5.33). These findings are supported by the APPROVe polyp prevention study, which demonstrated that over a three-year period, rofecoxib was associated with a statistically significant 4.9-fold increased risk of clinical ulcer complications compared to placebo [193].

## Influence of acetylsalicylic acid co-administration on clinically important ulcer complications

Five trials allowed assessment of the effects of the co-administration of acetylsalicylic acid (ASA) with a COX-2 [53, 184, 185, 188, 194]. In a pooled subgroup analysis of over 18,000 patients taking ASA, there was no statistically significant difference in the RR of ulcer complications (POBs) between those in the COX-2 arms and those in the non-selective arms of these trials (RR = 0.93; 95% CI: 0.68–1.27 for POBs). **A1a** A small advantage of COX-2s over tNSAIDs cannot be ruled out by these results because this subgroup analysis may lack adequate power. The PUB

analysis showed a statistically significant benefit for COX-2+ASA vs tNSAID+ASA (RR = 0.72; 95% CI: 0.62–0.95), but data from one study could not be used in this analysis. In more than 40,000 patients in the COX-2 arms, patients taking ASA had a 3.46 (95% CI: 2.44–4.91) greater RR of POBs than COX-2 users not taking ASA. **A1a** Among 34,000 patients in the tNSAID arms of these studies, those taking ASA had a 1.65 greater RR of POBs than those not taking ASA, although this result was not statistically significant (95% CI: 0.76–3.57). These are *post hoc* subgroup analyses that may be subject to bias. Furthermore, the subgroup analysis within a tNSAID treatment group (e.g. COX-2 vs COX-2 + ASA) represents a non-randomized comparison in which differences could be influenced by factors other than ASA use.

### Addition of a proton pump inhibitor to cyclo-oxygenase-2s

The comparative safety of a COX-2s compared to a tNSAID with a PPI has been addressed in high-risk patients with recent ulcer bleeding who were enrolled after ulcer healing and *H. pylori* eradication. Chan *et al.* [161] found recurrent ulcer bleeding at six months to occur in 4.9% of patients treated with celecoxib 200mg twice daily and in 6.4% of those treated with diclofenac 75mg twice daily plus omeprazole 20mg daily. Lai *et al.* [195] found recurrent ulcer complications (bleeding and one case of severe pain) in 3.7% with celecoxib 200mg daily and 6.3% with naproxen 750mg daily plus lansoprazole 30mg daily at a median follow-up of 24 weeks. These results suggest high risk patients have high rates of recurrent bleeding even with the protective strategy of a coxib or a tNSAID + PPI. **A1d**

The combination of a coxib and PPI was assessed in the same high-risk population in a subsequent one-year study by Chan *et al.* [162]. Recurrent ulcer bleeding occurred in 9% of patients who received celecoxib alone vs 0% in patients treated with celecoxib plus twice daily esomeprazole. The MEDAL Program also demonstrated that a coxib plus PPI resulted in significantly fewer upper GI clinical events (again, driven by a decrease in uncomplicated events) compared to a tNSAID plus PPI (RR = 0.62; 0.45–0.83) [188]. **A1d**

## Symptoms and treatment withdrawals

### Treatment withdrawals as a result of gastrointestinal side effects: cyclo-oxygenase-2s vs non-selective non-steroidal anti-inflammatory drugs

Twenty-one studies that included approximately 47,000 patients assessed the effect of COX-2s on patient withdraw-

als due to GI symptoms [52, 53, 163–165, 174, 179, 187, 189, 190–192, 196–204]. Overall, compared to tNSAIDs, COX-2s were associated with a significantly lower relative risk of withdrawals due to GI “side effects” (RR = 0.65; 95% CI: 0.57–0.73 random effects), withdrawals due to dyspepsia (RR = 0.37; 95% CI: 0.18–0.74), and due to abdominal pain (RR = 0.25; 95% CI: 0.13–0.49). **A1a** Compared to placebo, low dose COX-2s showed no statistically significant difference for these same endpoints, while high dose COX-2s were associated with a small but significantly increased relative risk of drop-outs due to GI “side effects” (RR = 1.74; 95% CI: 1.13–2.68) **A1a**

### Adverse gastrointestinal symptoms with cyclo-oxygenase-2s compared with non-selective non-steroidal anti-inflammatory drugs

Twenty-eight studies that included approximately 60,000 patients assessed the effect of low or high dose COX-2s compared to tNSAIDs for treatment-related overall GI adverse effects, dyspepsia, nausea and abdominal pain [53, 163, 164, 169, 171, 172, 180, 185, 189–191, 197–199, 201, 203, 205–210]. Low dose COX-2s were associated with a lower relative risk of “GI symptoms” (RR = 0.78; 95% CI: 0.74–0.82); dyspepsia (RR = 0.83; 95% CI: 0.75–0.90); nausea (RR = 0.72; 95% CI: 0.64–0.82); and abdominal pain (RR = 0.64; 95% CI: 0.58–0.70). The results for high dose COX-2s were similar. **A1a**

### Adverse gastrointestinal symptoms with cyclo-oxygenase-2s compared with placebo

Twenty studies with over 10,000 patients compared the occurrence of adverse GI symptoms between COX-2s and placebo. Low dose COX-2s were associated with a slight but statistically significant increased relative risk of overall “GI symptoms” (RR = 1.26; 95% CI: 1.13–1.42); dyspepsia (RR = 1.28; 95% CI: 1.08–1.51); nausea (RR = 1.24; 95% CI: 1.01–1.53); and abdominal pain (RR = 1.24; 95% CI: 1.02–1.52) [170, 171, 189–191, 201, 203–216]. The results for high dose COX-2s were similar. **A1a**

## Summary

The results of these systematic reviews demonstrate that there are several therapeutic strategies available to reduce the incidence of tNSAID related upper GI harms. Large, well powered, studies have shown that strategies using either a tNSAID with misoprostol, or the use of a COX-2 inhibitor instead of a tNSAID reduce the incidence of endoscopically detected upper GI ulcerations, and clinically important UGI events such as bleeding. **A1a** Misoprostol in doses that prevent UGI ulcer complications is associated with important adverse effects that may limit its long-term

use. Standard doses of H<sub>2</sub>-RAs reduce the incidence of duodenal ulcers but not gastric ulcers. Double doses of H<sub>2</sub>-RAs and standard dose PPIs reduce the incidence of duodenal as well as gastric ulcers, but because tachyphylaxis can occur with chronic H<sub>2</sub>-RA use, a standard dose PPI strategy is preferred. **A1a C5** H<sub>2</sub>-RAs and PPIs have not been directly assessed in large primary prevention clinical outcome studies powered to detect ulcer complications. However, in secondary prevention studies of high risk GI patients, tNSAIDs with a PPI, appear as effective as a COX-2s strategy at preventing clinical ulcer complications. In these high risk patients, these strategies were still associated with important ulcer relapse rates, suggesting that both strategies may provide incomplete protection for the secondary prevention of NSAID related ulcers. However, a recent study has shown that a strategy of combining a PPI with a COX-2s was superior to a COX-2s alone for the secondary prevention of ulcer complications, suggesting that a COX-2s+ PPI strategy is the preferred strategy in high risk GI patients. **A1d** Furthermore, the current meta-analysis, supported by the APPROVe polyp prevention study [193] has shown that while COX-2s offer greater GI safety than tNSAIDs as a group, COX-2s are associated with a statistically greater risk of clinical upper GI complications than is observed with placebo.

#### **A1a**

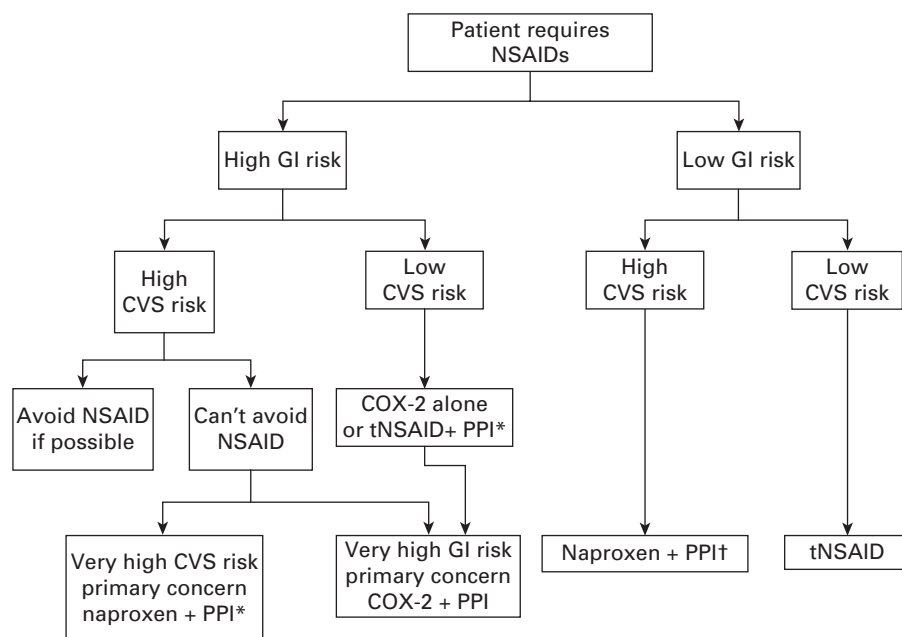

The discovery that COX-2s are associated with important CVS harms has complicated the clinical use of NSAIDs significantly. Furthermore, in Canada all COX-2s except celecoxib, have been withdrawn from the market due to cardiovascular and other harms and it is unlikely that a new COX-2s will be released to market unless it is truly “cardiovascularly neutral” or it is combined with a “GI safe” antithrombotic agent. During this time of uncertainty, when physicians were actively switching patients back to tNSAIDs + a gastroprotective agent such as a PPI, it became increasingly clear that non-naproxen tNSAIDs were also associated with important CVS harms. A meta-analysis by Kearney *et al.* using an extensive set of RCT data derived from published and unpublished studies has suggested that, as a group, COX-2s are associated with an increased risk of CV outcomes when compared with placebo or naproxen, but not when compared with non-naproxen-non-ASA tNSAIDs [30], suggesting that non-naproxen-tNSAIDs share the cardiovascular harms of COX-2s. **A1a**

In light of the cardiovascular harm data relating to COX-2s, it is tempting to suggest combining these agents with ASA. However, the available data from this meta-analysis suggest that this strategy would likely undermine the GI safety advantage of COX-2s. In patients taking ASA, we found no statistically significant difference in POBs or PUBs in patients randomized to a COX-2 or a tNSAID. However, the analyses did not stratify the randomization for ASA use. Thus, it is possible that other patient-related

factors played a role in this result. Furthermore, although the analysis included about 7000 patients, it is still possible that a protective effect of COX-2s over tNSAIDs in this setting is present but not detected because of insufficient statistical power. We also found that the addition of ASA to a COX-2 significantly increased the risk of a POB 4.12 times over that observed with a COX-2 alone, and that the addition of ASA to a tNSAID demonstrated a non-significant 1.27 increased risk of POBs over the use of a tNSAID alone. These analyses represent non-randomized comparisons, and the group sizes were somewhat uneven (more patients in the COX-2 or tNSAID alone groups than in the groups with ASA). Nonetheless, the results are not entirely unexpected, because it has been known for some time that concomitant use of multiple tNSAIDs increases the risk of GI complications over a single tNSAID alone. These results are also in keeping with an RCT by Laine *et al.* [217], revealing that the incidence of endoscopically detected ulcers with rofecoxib and low-dose ASA was not lower than that seen with ibuprofen alone. However, it is clear that further study in this area is required to verify these findings, such as performance of a dedicated RCT or from analysis of individual patient data in systematic reviews. Further, adding ASA to a COX-2 implies that the COX-2s will not interfere with the effect of ASA. However, this hypothesis also requires further study, because there are suggestions that the use of a tNSAID might interfere with the action of ASA in this setting, although there appears to be less interference from selective COX-2s [218–222].

When COX-2s were released, they promised an era of improved GI safety, as well as an era of greater clinical simplicity, with the option of prescribing a single low risk agent when chronic NSAID use was required. However, with the greater understanding of the GI, cardiovascular, and other end organ safety profile of tNSAIDs and COX-2s, clinicians must now stratify their patients on the basis of GI, CVS, and other organ system risk factors and choose an NSAID strategy that minimizes a patient’s overall risk. This has become especially difficult for patients who are known to be at high risk of GI and CVS harms.

Figure 7.6 presents an evidence-based algorithm for the use of long-term NSAID therapy according to individual gastrointestinal and cardiovascular risk. Since low-dose ASA is recommended for patients at increased cardiovascular risk [223, 224], the algorithm assumes the use of low-dose ASA in such patients. For patients with both low gastrointestinal and cardiovascular risk, a tNSAID alone may be acceptable. For patients with low gastrointestinal risk and high cardiovascular risk, naproxen may be preferred because of the potentially lower cardiovascular risk with this drug than with other tNSAIDs or COX-2 inhibitors. However, since these patients are assumed to be on low-dose ASA therapy, the combination of naproxen plus ASA would increase the gastrointestinal risk, and there-

**Figure 7.6** Algorithm for management of patients requiring long-term NSAID therapy (Canadian Association of Gastroenterology Consensus Conference).

\*In high risk patients a COX-2 inhibitor and a tNSAID + PPI show similar reductions of rebleeding rates, but these reductions may be incomplete.

†In general, most patients on ASA + naproxen would need the addition of a PPI. However, for some patients at very low GI risk naproxen alone may be appropriate.

fore, the addition of a gastroprotective agent such as a PPI should be considered.

Long-term NSAID therapy is more complex in patients with high gastrointestinal risk. Testing for and eradicating *H. pylori* in patients at high risk of NSAID-related gastrointestinal bleeding should be considered, but this strategy will be insufficient without ongoing gastroprotection [159, 225–228]. In these patients, if cardiovascular risk is low, the use of a COX-2 inhibitor alone or a tNSAID with a PPI appear to offer similar protection from recurrent gastrointestinal bleeding, but this protection is incomplete. Therefore, for patients at very high risk of upper gastrointestinal events, the combination of a COX-2 inhibitor plus a PPI may offer the best gastrointestinal safety profile. When both gastrointestinal and cardiovascular risks are high, the optimal strategy is to avoid NSAID therapy if at all possible. If NSAID therapy is deemed to be necessary, then the clinician must prioritize the cardiovascular and gastrointestinal risks, recognizing that these patients are likely taking ASA for their cardiovascular risk. If gastrointestinal risk is the primary concern (i.e. a very high risk gastrointestinal patient), a COX-2 inhibitor plus a PPI is recommended. If the primary concern is cardiovascular risk, naproxen plus a PPI in patients on ASA would be preferred. However, gastrointestinal risk should be closely monitored as this strategy carries a higher gastrointestinal

risk than a COX-2 inhibitor plus a PPI in patients on ASA (Figure 7.6) [229].

## Acute non-variceal gastrointestinal hemorrhage: Treatment

Nicholas Church<sup>1</sup> and Kelvin Palmer<sup>2</sup>

<sup>1</sup>Centre for Liver and Digestive Disorders, Royal Infirmary of Edinburgh, Edinburgh, UK

<sup>2</sup>Gastrointestinal Unit, Western General Hospital, Edinburgh, UK

### Introduction

Peptic ulcer is the commonest cause of acute non-variceal bleeding, accounting for approximately one-third of cases [1]. Other major causes such as gastroduodenal erosions, gastritis, esophagitis, Mallory–Weiss tears, and vascular malformations are not usually life-threatening and respond to conservative therapy.

Approximately 80% of cases pursue a benign course without re-bleeding in hospital and specific intervention is not required. The remaining 20% have severe bleeding due to erosion of a major artery. Most deaths from bleeding arise from this subgroup. Despite significant advances in resuscitation, diagnosis and therapy, the crude death rate from gastrointestinal bleeding has only marginally improved over five decades. Avery Jones in 1947 reported a hospital mortality rate of 16% [2], whilst a large audit of acute gastrointestinal bleeding performed in England in 1995 reported a very similar mortality rate of 14% [3]. The recent UK National audit of gastrointestinal bleeding included 6750 cases and reported an overall mortality of 10%, with a rate of 7% in those admitted to hospital because of bleeding, rising to 26% for inpatients [1]. This observation is disappointing but must, however, be tempered by the fact that the case mix of patients now admitted is very different to that of previous decades. For example, less than 2% of patients admitted with acute bleeding in 1947 were aged over 80 years, whilst approximately a quarter of patients currently admitted are octogenarians. There is a close relationship between increasing age and hospital mortality: increasing age is inevitably associated with a high prevalence of chronic disease, rendering patients susceptible to complications following major hemorrhage.

This chapter will review the evidence to support risk assessment and resuscitation, medical and endoscopic therapies for bleeding peptic ulcer, management when endoscopic therapy fails and treatment in the early post-endoscopy period.

### Risk assessment and resuscitation

The risk of death following admission to hospital for gastrointestinal bleeding has been quantified by Rockall *et al.* [4]. Independent factors associated with a poor prognosis were identified from data derived from a large population of patients whose clinical course was observed following hospital admission and a scoring system was developed. This comprises three clinical variables, from which an initial clinical Rockall score is derived, and two endoscopic variables, for the complete score (Table 8.1). The Rockall score correlated well with observed mortality, but not re-bleeding, in a Dutch validation study [5].

As shown in Table 8.2, Rockall *et al.* showed a good correlation between the risk score, re-bleeding and hospital mortality. Deaths following admission to hospital because of acute gastrointestinal bleeding are rarely due to exsanguination. They are usually a consequence of postoperative complications when an urgent operation is undertaken, or of deterioration of co-morbid conditions.

In Rockall's study [4] 0.2% of 595 patients with a clinical score of zero died. This very low mortality has been observed in other studies in which the clinical Rockall score has been calculated both retrospectively [6], and prospectively [7]. This has led to the suggestion that patients with a clinical score of zero may be safely managed with early discharge and outpatient endoscopy. The safety or otherwise of this approach has not been tested in clinical trials.

In order to evaluate the use of the Rockall scoring system in patients at highest risk, Church *et al.* calculated scores for a series of 247 patients who had been entered into a randomized trial of endoscopic therapy for major peptic

**Table 8.1** The Rockall scoring system for risk of re-bleeding and death after admission to hospital for acute gastrointestinal bleeding.

Variable	Score			
	0	1	2	3
Age	<60 yr	60–79 yr	≥80 yr	
Shock	No shock Systolic BP > 100 Pulse <100	Tachycardia Systolic BP > 100 Pulse >100	Hypotension Systolic BP < 100	
Co-morbidity	Nil major		Cardiac failure, ischemic heart disease, any major co-morbidity	Renal failure, liver failure, disseminated malignancy
Diagnosis	Mallory–Weiss tear, no lesion and no SRH	All other diagnoses	Malignancy of upper GI tract	
Major SRH	None, or dark spot		Blood in upper GI tract, adherent clot, visible or spurting vessel	

SRH: Stigmata of recent hemorrhage.

8+	190	101 (42)	78 (41)

ulcer bleeding in Scotland [8]. Following endoscopic therapy, the Rockall system did not adequately predict re-bleeding but accurately identified patients at high risk of death. The findings suggested that patients scoring 6 or above should be managed in a high dependency unit after endoscopic therapy.

A number of other risk scoring systems have been developed of which the best known is that developed by Blatchford *et al.* [9]. The Blatchford system differs from the other scores in two ways. First, the system was designed to predict a need for intervention to treat bleeding, rather than to quantify the risk of re-bleeding or death. Second, the score does not include endoscopic findings as a component and is therefore potentially useful in patient triage at the time of admission. Data were obtained from 1748 patients admitted following upper gastrointestinal bleed-

ing in the west of Scotland. After logistic regression analysis a risk score was developed based on the admission hemoglobin, blood urea, pulse, systolic blood pressure, presentation with syncope, presentation with melena, evidence of hepatic disease and evidence of cardiac failure. Intervention was defined as the requirement for a blood transfusion, endoscopic therapy or surgery to control bleeding. Increasing scores correlated with the need for intervention. A receiver operator curve was plotted for a subsequent internal validation sample of 197 patients, and the score discriminated well with an area under the curve of 0.92 (95% CI: 0.88–0.95). The number of patients requiring each intervention was not reported and this limits an assessment of its utility and clinical relevance. External validation of this scoring system is required before it can be recommended for clinical use.

Optimum management of patients with major upper GI hemorrhage relies very much on a team approach, with appropriate use of drug therapy, endoscopic intervention, radiological intervention and surgery. Despite much evidence from randomized trials, the management of an individual patient still depends on clinical judgment. Endoscopy should only be undertaken once appropriate resuscitation has been achieved in order to minimize cardiorespiratory complications of the procedure [10]. For the majority of patients with peptic ulcer bleeding an endoscopy within 24 hours of presentation is appropriate, and there is no evidence to support emergency endoscopy for all comers. However, in the small proportion of cases with severe, life-threatening bleeding resulting in a failure to respond to resuscitation efforts, an immediate endoscopy may be required.

Management may be best undertaken in a specialized “bleeding unit” in which the patient is treated using agreed protocols and guidelines and with management decisions based upon endoscopic and surgical opinions. Relatively weak evidence derived from comparison of results in case series with historical controls suggests that this approach may achieve lower hospital mortality and more efficient use of resources than management by generalists working in conventional medical or surgical units [11, 12]. More recently a study by Sanders *et al.* described the outcomes of 900 patients with significant bleeding who were managed over a three-year period in a dedicated bleeding unit [13]. Rockall scores were calculated for all patients and outcomes were analyzed prospectively. Patients were stratified into groups at low, medium and high risk of death according to their Rockall score and outcomes were compared with those of the patients in Rockall’s national audit [3] by calculation of standardized mortality ratios (SMR). Although there were more high-risk patients in the Sanders cohort, their overall mortality was significantly lower than that of the Rockall patients (SMR 0.63 (95% CI: 0.48–0.78)). The difference was most marked for patients at medium risk (Rockall score 4–6; SMR 0.56 (CI: 0.34–0.78)). However, it is worthy of note that if the SMRs had been calculated using the findings of the UK National Bleeding audit [1] the findings of this study may well have been negative. A trial in which patients with major bleeding have been randomized to management in either a specialized bleeding unit or a general medical or surgical ward has not been performed.

### Specific therapy

For the 80% of patients who have relatively minor bleeding and who do not have major endoscopic stigmata of bleeding, supportive therapy including use of intravenous fluid and the management of co-morbidity (particularly cardiorespiratory disease) is sufficient.

Patients who present with clinical shock and who at endoscopy have an actively bleeding peptic ulcer have an 80% risk of continuing to bleed or re-bleed in hospital [14]. Those who have a non-bleeding visible vessel have a 50% risk of further hemorrhage [15]. The “visible vessel” represents a pseudoaneurysm of the involved artery, or adherent blood clot, plugging the arterial defect [16]. Patients who are found to have a tightly adherent blood clot over the ulcer usually have an underlying high-risk lesion and should also be regarded as being at considerable risk of further hemorrhage in hospital. Patients who at endoscopy have a clean ulcer base or who have black or red spots are at very little risk of re-bleeding.

It follows from these observations that patients with major endoscopic stigmata should be considered for spe-

cific hemostatic treatment and only such patients should be included in clinical trials of therapy for gastrointestinal bleeding. This review will only consider those studies that exclusively include patients having a non-bleeding visible vessel, active hemorrhage, or tightly adherent blood clot as entry criteria.

The specific non-surgical approaches to hemostasis are drug therapy, endoscopic therapy and transcatheter arterial embolization.

### Drug therapy

There are three principles underlying the use of drugs as agents which might stop active hemorrhage and prevent re-bleeding. The first of these is that the stability of a blood clot is poor in an acid environment [17]. Thus, agents that suppress acid secretion, including H<sub>2</sub>-receptor antagonists (H<sub>2</sub>-RA) and proton pump inhibitor (PPI) drugs might reduce re-bleeding. The second is that a blood clot may be stabilized by decreasing fibrinolytic mechanisms using agents such as tranexamic acid. The third approach is that, since major gastrointestinal bleeding is due to arterial erosion, reduction of arterial blood flow by agents such as somatostatin and octreotide could achieve hemostasis and prevent re-bleeding.

### Acid suppressing drugs

The efficacy of H<sub>2</sub>-RA in the management of acute upper gastrointestinal bleeding has been assessed in randomized trials [18, 19]. Unfortunately, no trial has shown benefit in terms of reduction of re-bleeding incidence or mortality.

#### A1c

Experience involving the use of PPIs is inconsistent, but the evidence now supports their use in patients who have required endoscopic hemostasis. The largest trial involved 1147 patients who were randomized to receive omeprazole, (initially intravenously, then orally) or placebo [20]. No significant differences in hospital mortality, operation rate or re-bleeding were demonstrated. The study was not restricted to the high-risk patients who had endoscopic stigmata of recent hemorrhage. Accordingly, event rates were rather low in the placebo group, and this may have limited the power of the study to show a difference. **A1a**

Khuroo *et al.* randomized 220 bleeding ulcer patients who had major endoscopic stigmata to receive high dose oral omeprazole or placebo [21]. Although all patients had major stigmata of hemorrhage, an adherent clot in the ulcer base was reported in 57% of patients. Re-bleeding, the need for urgent surgery, blood transfusion, and mortality were all reduced in the actively treated group of patients (Table 8.3). The number of patients needed to treat with omeprazole to prevent one death was 25, and to prevent one opera-

**Table 8.3** Omeprazole vs placebo for bleeding peptic ulcer.

Outcome	Omeprazole (n = 110)	Placebo (n = 110)	p value

tion was seven. **A1c** This trial has been criticized because it included relatively young patients with relatively little co-morbidity and because endoscopic therapy was not administered to any patient. The observation that omeprazole reduced re-bleeding and surgery rates when no endoscopic therapy was performed suggested a beneficial effect of the PPI. This effect might, however, have been exaggerated by the fact that the majority of patients in the trial were bleeding from ulcers in which an adherent clot was found at endoscopy.

Two trials published back to back in the *Scandinavian Journal of Gastroenterology* [22, 23] examined the use of high dose intravenous omeprazole after endoscopic hemostasis. All patients had major peptic ulcer bleeding, but as in the trial by Khuroo *et al.* half the patients had adherent clot as the reported stigma of hemorrhage. The conclusions were that intravenous omeprazole infusion for three days following endoscopic therapy improved outcome. **A1d** Both trials used composite endpoints which were complex and ill-defined and both were discontinued early due to an unexplained imbalance in mortality in one of the trials [23], factors that weaken the impact of these results. Villanueva *et al.* randomized 86 patients following successful endoscopic hemostasis for peptic ulcer bleeding to either intravenous omeprazole or ranitidine. There were no differences between the groups for the endpoints of re-bleeding, surgery or death [24]. **A1d** In contrast, a similar small trial by Lin and colleagues [25] concluded that intravenous omeprazole was superior to cimetidine in terms of reduction of re-bleeding rates, but not those of surgery or death.

The most important recent trial was performed by Lau *et al.* [26]. Two hundred and forty patients in whom endoscopic therapy for major ulcer bleeding had been successful were randomized. All patients had high-risk ulcers with active bleeding or non-bleeding visible vessels, and were treated by adrenaline injection followed by heater probe thermocoagulation. Adherent clots were removed to allow therapy to the underlying vessel. The patients then received either an 80mg bolus dose of intravenous omeprazole followed by an infusion of 8mg per hour for 72 hours or

**Table 8.4** Omeprazole vs placebo for bleeding peptic ulcer treated with endoscopic therapy.

Outcome	Omeprazole (n = 120)	Placebo (n = 120)	p value
Re-bleed (%)	8 (7)	27 (23)	<0.001
Surgery (%)	3 (3)	9 (8)	0.14
Transfusion (mean units +/- SD)	2.7 +/- 2.5	3.5 +/- 3.8	0.04
Length of stay <5 days (number of patients (%))	56 (47)	38 (32)	0.02
Death	5 (4)	12 (10)	0.13

Source: Lau *et al.* [26].

placebo. Re-bleeding rates, blood transfusion requirements and length of hospital stay were significantly reduced in the omeprazole group compared to placebo. **A1a** There was a trend toward fewer operations and deaths in the omeprazole group, but these differences were not statistically significant (Table 8.4). These results have been closely replicated in a similar sized trial by Zargar *et al.* in which an almost identical design to that of Lau *et al.* was used, except that pantoprazole was substituted for omeprazole [27]. This supports the likelihood that the observed outcomes of therapy with PPIs following endoscopic hemostasis are the result of a class effect of PPIs, rather than a specific response to omeprazole.

A subsequent trial by the Hong Kong group included 156 patients with peptic ulcers containing non-bleeding visible vessels or adherent clot in the ulcer base [28]. Patients were randomized to endoscopic therapy using adrenaline injection and heater probe thermocoagulation plus the previously published high dose intravenous PPI regimen, or to the PPI regimen alone. The probability of re-bleeding within 30 days of the index episode was significantly reduced in the combination therapy group, suggesting that PPI infusion in combination with endoscopic therapy is superior to PPI infusion alone. **A1c** Seventeen percent of patients with non-bleeding visible vessels rebled in the PPI only group, and although a control group receiving no treatment was not included for ethical reasons, this represents a substantial improvement over the expected re-bleeding rate of 30–50% based on previous studies.

Following the publication of the trial by Lau *et al.* [26] the use of high dose intravenous PPI after successful endoscopic therapy for bleeding ulcer has become standard management in many centers in the UK and Europe. The 80mg bolus and 8mg per hour infusion regimen consistently raises intragastric pH above six for the majority of a 24-hour period [29]. It is not known, however, whether this

optimum regimen is actually necessary following endoscopic therapy, and whether bolus intravenous or even oral PPI would suffice. A recent study has suggested that frequent oral PPI therapy with lansoprazole could raise intragastric pH to similar levels to those achieved by lansoprazole infusion. However, the confidence intervals were wide and the conclusion can be questioned [30]. Two small clinical studies have attempted to answer these questions.

Udd *et al.* [31] randomized 142 patients with ulcer bleeding to the high dose three-day intravenous omeprazole regimen or to a single daily bolus dose of 20 mg for three days. Rates of re-bleeding (8% for high dose vs 12% for standard dose), surgery (4% vs 7%) and death (6% vs 3%) were comparable between the groups. Only 102 patients had required endoscopic therapy, and approximately 30% of patients had an ulcer with a black base only. Thus, the number of high-risk ulcers in the trial was small, the event rates were low and the study may have lacked power to demonstrate a difference between the effects of the two treatments.

The effect of oral omeprazole following endoscopic therapy for bleeding peptic ulcer was studied by Javid *et al.* [32]. One hundred and sixty six patients with ulcers which were actively bleeding, and had non-bleeding visible vessels or adherent clots were treated with a combination of 1:10,000 adrenaline plus 1% polidocanol injection. They were then randomized to receive oral omeprazole 40 mg bd or placebo. Six (7%) of the 82 patients in the omeprazole group re-bled compared with 18 (21%) of the 84 patients in the placebo group ( $p = 0.02$ ). **A1c** Surgery was required in two patients in the omeprazole group and seven patients in the placebo group ( $p = 0.17$ ). One death occurred in the omeprazole group compared to two in the placebo group. The results are comparable to those achieved by Lau *et al.* with the high dose intravenous regimen [26]. It should be noted, however, that 40% of patients in this trial had ulcers with adherent clot, and the number of patients with high-risk lesions was therefore correspondingly lower than that in the Hong Kong study. A further high quality trial comparing the use of intravenous and oral omeprazole in high-risk ulcer bleeding patients is required.

The trials involving PPI therapy in ulcer bleeding are heterogeneous but have been subjected to several meta-analyses. The most comprehensive is the recently updated report from the Cochrane group [33]. This systematic review of 24 trials included 4373 patients with peptic ulcer bleeding who had been treated with PPIs compared with  $H_2$ -receptor antagonists or placebo. Seven trials included high-risk patients following endoscopic therapy, and four of these used high dose PPI infusion in the active therapy arm. Overall results demonstrated a reduction in re-bleeding (OR 0.49; 95% CI: 0.37–0.65, NNT 13), surgery (OR 0.61; 95% CI: 0.48–0.78, NNT 34) and requirement for further endoscopic hemostatic therapy (OR 0.32; 95% CI: 0.20–0.51,

NNT 10). Mortality was not reduced (OR 1.01; 95% CI: 0.74–1.40). However, in a subgroup analysis, mortality in PPI groups was significantly reduced in Asian patients (OR 0.35; 95% CI: 0.16–0.74, NNT 34) and in the high-risk patients entered into the endoscopic therapy trials (OR 0.53; 95% CI: 0.31–0.91, NNT 50).

The more pronounced PPI treatment effect observed in Asian patients is likely to be the result of a combination of lower mean age, reduced parietal cell mass and a greater proportion of slow metabolisers of PPIs. There is a need to further evaluate the use of PPI therapy in non-Asian populations, but in our view the available evidence supports the routine use high dose intravenous PPI therapy for 72 hours following endoscopy in those patients who have required hemostatic therapy. **A1a**

As PPI therapy has become more widely used in acute peptic ulcer bleeding it has become common practice to institute intravenous PPI therapy before endoscopy is undertaken. This approach is not evidence based and to try to determine whether PPI prior to endoscopy was beneficial, Lau *et al.* randomized 638 patients with overt clinical signs of upper GI bleeding to high dose IV PPI or to placebo infusion before endoscopy was performed [34]. Patients who were taking aspirin were excluded as they were randomized into a concurrent study. One hundred and eighty seven patients in the omeprazole arm and 190 patients in the placebo arm were found to be bleeding from peptic ulcers. Fewer patients pre-treated with omeprazole were actively bleeding at endoscopy, resulting in a reduced need for endoscopic therapy (22.5% vs 36.8%, RR 0.61; 95% CI: 0.44–0.84) and a shorter hospital stay (median 3 days (range 1–43) vs 3 days (1–54),  $p = 0.003$ ). Despite these findings, the important outcomes of re-bleeding, surgery and mortality were unchanged. The conclusion was that PPI therapy prior to endoscopy reduced the proportion of patients found to have stigmata of hemorrhage, with consequent resource savings. These results are encouraging, but do not show a benefit in terms of clinical outcomes and may not be applicable generally. The principal criticism of this trial is the exclusion of patients requiring long-term aspirin therapy. In addition, 60% of patients presenting with upper GI bleeding in Hong Kong are found to have peptic ulcer compared to 50% or lower in Western populations, in whom the effect of general prescription of PPIs before endoscopy is likely to be significantly less apparent. Further studies in non-Asian populations are required.

### Tranexamic acid

Two meta-analyses have been published examining the role of tranexamic acid for gastrointestinal bleeding [35, 36]. The most recent by Gluud *et al.* [36] included 1754 patients from seven placebo controlled trials. Pooled analysis demonstrated a reduction in all cause mortality for

patients treated with tranexamic acid (5% vs 8%, RR 0.61; 95% CI: 0.42–0.89). Rates of further bleeding, surgery and blood transfusion were unaffected.

The largest study included in the meta-analysis was undertaken by the Nottingham group [37]. Seven hundred and seventy-five patients presenting to hospital because of acute gastrointestinal bleeding were randomized to receive oral cimetidine, tranexamic acid or placebo. No significant difference in bleeding or operation rates was demonstrated, but there was a rather surprising large difference in mortality. Mortality was 7.7% in cimetidine treated patients, 6.3% in tranexamic acid treated patients and 13.5% in those treated with placebo. The mortality rate of 13.5% in the placebo treated group is greater than that expected for conservatively treated patients based on the results of other studies. Furthermore, other studies do not demonstrate benefit from the use of cimetidine. It is possible that more high-risk patients were inadvertently randomized to the placebo group in this study.

The meta-analyses included trials in which many patients did not have major endoscopic stigmata of bleeding. In addition, there were significant differences in methodology, doses and routes of administration of tranexamic acid and adjunctive therapy, and few patients received endoscopic therapy and PPI administration. Therefore, it is unlikely that the patients studied can be seen as representative of the current population, and further randomized trials in high-risk patients are required before tranexamic acid can be recommended as a standard therapy for peptic ulcer bleeding.

### Somatostatin and octreotide

Somatostatin and its analogs have two actions which are theoretically valuable in the management of ulcer bleeding, namely inhibition of acid secretion and reduction of splanchnic blood flow. Mesenteric blood flow falls dramatically during infusions of somatostatin but it is not clear whether this is principally due to vasoconstriction of major blood vessels or peripheral arterioles.

There have been 14 controlled trials of somatostatin versus other therapy in the management of patients presenting with acute gastrointestinal bleeding [38–51]. Two meta-analyses suggest that somatostatin but not octreotide has a primary hemostatic role and reduces the need for surgical intervention [52, 53]. However, scrutiny of the relevant trials reveals many problems. Many of the studies were small and inclusion criteria varied widely from gastritis to major active bleeding. In common with the studies of tranexamic acid, the somatostatin trials were conducted before the widespread use of endoscopic therapy and PPI administration.

Currently, the evidence for routine use of somatostatin is weak and further studies are needed before this agent

can be advocated as therapy for acute non-variceal gastrointestinal bleeding.

## Endoscopic therapy

Many therapeutic endoscopic treatments have been used to try to stop active ulcer bleeding and prevent re-bleeding. These can be classified into three basic endoscopic approaches (Table 8.5).

Thermal approaches involving laser, the heater probe and electrocoagulation by monopolar or bipolar probes attempt to induce thermocoagulation with thrombosis of the bleeding point. In experimental bleeding ulcers these approaches are more effective than injection treatments [54]. However, there is currently no good model of acute peptic ulcer bleeding. Experiments in animals were historically based upon observation or intervention following superficial mucosal injury, which is different from erosion of arteries by chronic or acute peptic ulceration. A novel pig model has recently been developed, which appears to resemble the real life situation of an actively bleeding peptic ulcer more closely, although the element of chronic inflammation cannot be reproduced [55]. This model could facilitate the development of new endoscopic therapeutic methods. Injection therapy may produce tamponade by the injection of a relatively large volume of fluid into a rigid compartment, compressing the bleeding artery. Vasoconstriction induced by dilute adrenaline, endarteritis induced by sclerosants, dehydration following absolute alcohol injection or a direct effect upon blood clot formation following injection of thrombin or fibrin glue are other putative mechanisms. Mechanical clips, staples and sewing

**Table 8.5** Endoscopic therapy.

attempt to produce hemostasis by clamping the bleeding arterial lesion. Many clinical trials of endoscopic therapy for non-variceal bleeding have been published. The quality of these trials varies greatly. In general, the number of patients randomized in any one study is small and clinicians managing the patients have not been blinded to the type of endoscopic therapy. Only one trial has included a placebo control intervention for endoscopic therapy [56].

## Thermal methods

### Laser photocoagulation

Lasers were the first endoscopic therapeutic modality shown to be effective in managing acute non-variceal gastrointestinal bleeding. Initial experience involved the use of argon lasers but it subsequently became clear that the tissue characteristics of thermal injury achieved by Nd-YAG were more appropriate. There have been a number of trials involving lasers for peptic ulcer bleeding [57–68]. Most of these studies show that laser treatment significantly reduced the rates of re-bleeding, transfusion requirement and operation rate. One trial showed significant improvement in hospital mortality [60].

Endoscopic laser therapy was found to be relatively safe with few complications; in particular, gastrointestinal perforation was rare. However, since the technique is difficult, relatively expensive and because other approaches are at least as effective, laser therapy for peptic ulcer bleeding is no longer used.

### Heater probe

The heater probe transmits preset amounts of energy to the bleeding point via a Teflon tipped catheter. A powerful water jet is used to clean the ulcer base, help visualize the bleeding point and also to prevent the probe sticking to the bleeding point. Hemostasis is achieved by coaptive coagulation, using both tamponade and the application of heat. Best results are achieved using large sized probes. There have been two trials in which the heater probe has been compared to conservative therapy [69, 70]. Both showed benefit in terms of further bleeding, and surgery, and one published only in abstract form [71] demonstrated a trend towards reduction in mortality (Table 8.6). **A1d**

The heater probe is “user friendly”. Its capacity to apply thermal energy by tangential application and its powerful water jet are particular advantages. Perforations have occurred following treatment, although these are unusual, and are of the order of 1% [71]. In general, medium power settings (20–30 joules) are used, but it is not possible to be prescriptive concerning the total amount of energy that should be applied. Most authorities consider that treatment should be continued until active hemorrhage is stopped and until the treated area is blackened and cavitated.

**Table 8.6** Heater probe for gastrointestinal bleeding.

Study	Group	Re-bleed	Surgery	Mortality
Fullarton 1989 [69]	HP (n = 20)	0	0	0
	Sham (n = 23)	22 <sup>a</sup>	13 <sup>b</sup>	0
Jensen 1988 [70]	BICAP	44	33	3
	HP	22 <sup>c</sup>	3 <sup>c</sup>	3
	Nil	72	41	9
	n (total) = 94			

<sup>a</sup>p = 0.05.

<sup>b</sup>p = 0.23.

<sup>c</sup>p < 0.05.

HP: heater probe; BICAP: bipolar electrocoagulation.

### Electrocoagulation

Monopolar electrocoagulation uses a metal ball-tipped probe. An electrical circuit is completed by a plate attached to the patient. Application of energy is rather haphazard and perforations and a death were reported in early series. Consequently this device is no longer used. Multipolar electrocoagulation is based upon transmission of electrical energy between adjacent electrodes. The BICAP has eight separate electrodes over its surface. Early studies from the UK involving small numbers of patients showed no benefit for active treatment compared to conservative therapy. Subsequently, however, trials from the UK and the USA showed improved outcomes including primary hemostasis, re-bleeding, the need for surgery and transfusion requirements with bipolar electrocoagulation compared to conventionally treated patients (Table 8.7) [72–75]. The efficacy of the heater probe and BICAP appear to be comparable with similar low complication rates [71, 76].

### A1d

### Argon plasma coagulation

This procedure is based upon coagulation through a jet of argon gas. Relatively superficial thermal damage is achieved. The method is particularly applicable to mucosal and superficial bleeding lesions and its final role may be in dealing with vascular malformations such as gastric antral vascular ectasia. One small trial has shown that argon plasma coagulation is comparable in efficacy to heater probe therapy for ulcer hemostasis [77]. A second trial compared the argon plasma coagulator with combination injection of adrenaline and polidocanol [78]. Again the two approaches were equally effective. Nevertheless the tissue damage characteristics of argon plasma coagulation are less than ideal for managing arterial bleeding, and it will probably prove to be less appropriate for managing peptic ulcer bleeding than contact methods.

## Conclusions

Thermal methods of hemostasis were shown to be superior to conservative management in two meta-analyses. In the study of Cook *et al.* [79] the odds ratio for prevention of re-bleeding was 0.48 (95% CI: 0.32–0.76); and for avoidance of surgery was 0.47 (95% CI: 0.27–0.80). Similarly, in the study of Henry and White [80], the odds ratio for prevention of bleeding was 0.32 (95% CI: 0.22–0.41) and for the avoidance of surgery was 0.31 (95% CI: 0.19–0.43). **A1d** Thermal contact methods (heater probe and bipolar coagulation) are technically easier to undertake than laser techniques. There are insufficient data to determine whether the heater probe is better than the BICAP.

The safety profile of thermal modalities is generally very good. Perforations are unusual and treatment induced exacerbation of bleeding is not usually clinically important.

## Injection therapy

Injection treatment is simple to perform and is the cheapest available hemostatic modality. A large range of injection materials have been studied and it is difficult to prove that any one of these is superior to the others.

### Dilute adrenaline

In 1988 Chung *et al.* reported a controlled trial in which patients with active ulcer bleeding were randomized to

**Table 8.8** Adrenaline for gastrointestinal bleeding.

Outcome	Adrenaline n = 34	Conservative n = 34

receive endoscopic injection with 1:10,000 adrenaline or were treated conservatively [81]. Primary hemostasis was achieved in all injected patients and the need for subsequent urgent surgery was significantly reduced (Table 8.8). **A1d** Re-bleeding occurred in 24% of injected patients, suggesting that although dilute adrenaline did stop active bleeding, its effects were temporary.

It seemed logical to combine an injection of adrenaline with that of an agent which might cause permanent sealing of the bleeding arterial defect. For this reason a series of trials were undertaken in which adrenaline injection was combined with a range of sclerosants.

The results of trials in which a combination of adrenaline plus sclerosants were compared to conservative therapy are summarized in Table 8.9 [82–85]. All showed that active bleeding stopped more rapidly in treated patients, that re-

bleeding rates were less, and that the need for surgery was reduced. No single trial, however, was powerful enough to determine whether mortality was affected. A subsequent meta-analysis, involving thermal contact devices, laser and injection therapy performed by Cook *et al.* [79] did show a modest reduction in mortality, although this was statistically significant only for laser therapy. **A1a**

## Sclerosants

The sclerosants that have been studied are polidocanol, 5% ethanolamine oleate and 3% sodium tetradecyl sulphate. There are no controlled trials in which outcome has been assessed in patients randomized to sclerosants versus conservative (no injection) therapy. Several trials compared the efficacy of sclerosants with other endoscopic therapies. Benedetti *et al.* [86] showed similar efficacy for polidocanol and thrombin injection in patients presenting with a range of bleeding lesions. Strohm *et al.* [87] randomized patients to one of four treatment arms (fibrin glue, 1% polidocanol, dilute adrenaline or adrenaline plus polidocanol) and showed no advantage for any one approach. Rutgeerts *et al.* showed no difference in outcome for patients treated by polidocanol or Nd-YAG laser therapy [88]. In general these studies suffer from the problem of small sample size and they probably lacked statistical power.

A series of case reports documented complications of injection by sclerosant [89, 90], particularly perforation and necrosis of the upper gastrointestinal tract. These complications did not occur following adrenaline injection and indeed the latter seems remarkably safe. Fears concerning the possible systemic effects of circulating adrenaline have not translated into cardiovascular mishaps [91]. Since complications are mainly due to sclerosant injection, it was

important to confirm the importance of combining the sclerosant with the adrenaline injection. Whilst the logic of attempting to induce endarteritis using sclerosants was reasonable, experiments in animals did not demonstrate that this could be achieved by injection using ethanolamine or absolute alcohol [92]. **C** Three trials have compared the efficacy of injection by adrenaline alone versus a combination of adrenaline plus a sclerosant [93–95], and a further two have compared adrenaline to adrenaline plus alcohol [96, 97]. As shown in Table 8.10, these five studies did not show that combination treatment was superior to injection by adrenaline alone. **A1c** No study has directly compared outcome in patients randomized to dilute adrenaline or to a sclerosant.

Since the addition of sclerosants to an injection of adrenaline offers no proven advantage over injecting adrenaline alone, and because sclerosants have the potential to cause significant local complications following injection, they should no longer be employed as part of the injection treatment regimen.

## Alcohol

The efficacy of injecting absolute alcohol into bleeding ulcers has been examined in several clinical trials. Two of these (Table 8.11) [98, 99] randomized patients to alcohol injection or to conservative therapy and showed benefit in terms of reduction in re-bleeding rates and need for surgical intervention. **A1d**

In a randomized controlled trial, Lin *et al.* [100] reported that alcohol injection stopped active bleeding and prevented re-bleeding in 86% of patients whose ulcers were injected, and this result was similar to the proportion of bleeding ulcers responding to injection with 3% sodium

chloride, 50% dextrose, or normal saline. Only one small study [101] has attempted to compare the efficacy of alcohol with dilute adrenaline injection, but this study lacked statistical power to demonstrate differences in the effects of these interventions, should any exist.

The evidence that alcohol stops active bleeding and prevents re-bleeding is stronger than that for the sclerosants. Unfortunately, the potential for adverse effects is higher for alcohol than for adrenaline. Deep ulcers commonly follow alcohol injection and perforations have occurred [102]. Two trials have examined the need to combine alcohol injection with adrenaline and found no beneficial effect over the injection of adrenaline alone (Table 8.10) [96, 97].

Whilst alcohol injection is an effective hemostatic therapy, current evidence suggests that the magnitude of its effect is probably similar to that achieved by injection with adrenaline alone. Because of its propensity for causing adverse effects, alcohol injection is not recommended as treatment for ulcer bleeding.

## Thrombin and fibrin glue

The most attractive endoscopic approach is to directly cause blood clot formation by injecting thrombogenic substances. In the 1980s small trials examined the efficacy of bovine thrombin and showed little benefit compared to other modalities.

In 1996 Kubba *et al.* [103] reported a comparison of endoscopic injection therapy using a combination of adrenaline plus human thrombin with dilute adrenaline injection alone (Table 8.12). A proportion of randomized patients had active bleeding at the time of randomization, while the remainder had non-bleeding visible vessels. Re-bleeding and mortality were significantly reduced in the group receiving combination therapy compared to patients receiving adrenaline alone. The number of patients needed to be treated with combination therapy rather than adrenaline alone to prevent one death is approximately 14. Paradoxically, no statistically significant differences in the

need for surgical operation and the overall rate of hemostasis were demonstrated. Indeed, deaths in this study all occurred, as is usually the case, in patients who had significant co-morbidity. Complications in this study were minimal. Although this was not a direct comparison of adrenaline versus thrombin, it did strongly suggest that human thrombin is an effective modality.

Balanzo *et al.* [104] randomized 64 ulcer bleeding patients to adrenaline injection or adrenaline plus thrombin in a similar, but smaller trial. There were no differences in the rates of primary hemostasis, re-bleeding, surgery or death (Table 8.13).

To further investigate the use of thrombin as a potential adjunct to standard endoscopic therapy Church *et al.* randomized 247 patients to treatment with heater probe plus thrombin injection or to heater probe plus placebo injection [56]. This trial included only patients with bleeding peptic ulcers who were at high-risk for re-bleeding and death, and was the first trial to include placebo endoscopic therapy. Initial hemostasis was achieved in 97% of patients in both groups, and the rates of re-bleeding, surgery and mortality were similar (Table 8.14). The results of this trial do not suggest that thrombin is any more effective than placebo

when combined with the heater probe for endoscopic hemostasis. **A1a**

Fibrin glue is a mixture of fibrinogen and thrombin which is injected through a double-channeled endoscopy needle. Its effect was studied by Song *et al.* in a trial of 127 patients with bleeding ulcers and major stigmata of hemorrhage [105]. Patients were randomized to injection of fibrin glue or hypertonic saline-adrenaline. There were no significant differences between rates of re-bleeding, surgery and death (Table 8.15). **A1c** This trial is the only one which has compared the efficacy of fibrin glue directly with that of another endoscopic therapeutic modality.

In a large multicenter European study (Table 8.16) [106] 850 patients were randomized to endoscopic injection with dilute adrenaline plus a single injection of fibrin glue, to adrenaline and repeated injection of fibrin glue given at daily intervals according to the discretion of the endoscopists, or to adrenaline plus 1% polidocanol. Re-bleeding rates were lowest in patients treated by repeated injection. The rate of serious re-bleeding requiring major blood transfusion or surgical operation was significantly reduced in patients receiving repeated injections of glue compared to the polidocanol treated group. **A1a** A total of seven perforations occurred in this study and these were distributed equally amongst the treatment modalities.

The most recent trial involving fibrin glue randomized 135 patients to injection of adrenaline plus fibrin glue or to

adrenaline alone [107]. Endoscopy was repeated daily with retreatment of stigmata until the ulcer base contained flat pigmented spots or was clean. The rate of re-bleeding in the combination group was not significantly different from that in the single agent group (24% vs 22%). Rates for surgery were also similar (10% vs 6%), and mortality was 3% in both groups. **A1c**

The evidence regarding the use of thrombogenic substances is conflicting. There is evidence of benefit in some studies, but not in others, and currently there is not enough evidence to recommend thrombin or fibrin glue over other injection agents. Thrombin is derived from pooled plasma, and although viral (or other infective agent) transmission has not been reported, this is a possibility. Acute complications are infrequent and no adverse effects have been apparent in terms of systemic coagulation.

Human thrombin is not currently commercially available. It is relatively inexpensive, although more costly than adrenaline.

### Mechanism of action and volume of injection

The mechanism of injection therapy is not completely understood. It is thought to work at least in part by exerting a tamponade effect resulting from the injection of a volume of fluid into the rigid ulcer base. This possibility is supported by the study reported by *Lin et al.* [100] who compared injection of normal saline, 3% NaCl solution, 50% glucose/water solution and pure alcohol in 200 patients with actively bleeding ulcers or non-bleeding visible vessels. There were no statistical differences between rates of initial hemostasis, re-bleeding, and surgery for any group. Larger injected volumes were required to achieve initial hemostasis in the saline and glucose/water groups, suggesting that tamponade was an important factor. These

results are challenged by those of Laine and Estrada [108]. In this study patients with high-risk ulcers were randomized to injection of normal saline (n = 48), or to bipolar electrocoagulation (n = 52). Twenty nine percent of patients in the saline group had recurrent bleeding compared with 12% of those treated with the BICAP. The saline-treated patients required significantly more blood, but there were no differences in length of hospital stay or mortality. It is likely that tamponade does not completely explain the mechanism of injection therapy, and active agents should continue to be used.

The optimum volume of injection is not known. Small volumes of alcohol and sclerosants are required in order to reduce the risk of perforation. Much larger volumes of saline and adrenaline can be used without major complications. In the trial by *Lin et al.* [100] discussed above, the mean injection volume in the saline group was 15 ml. Laine and Estrada injected a mean volume of 30 ml [108]. A further trial by *Lin et al.* compared large with relatively small volume injection [109]. One hundred and fifty six ulcer bleeding patients were randomized to injection of 5–10 ml of adrenaline (the small volume group) or injection of 13–20 ml (the large volume group). Re-bleeding occurred in 31% of the small volume patients compared with 15% in the large volume group. The other usual endpoints were similar. The conclusion of this trial is that larger volume injection of adrenaline is safe and more likely to prevent re-bleeding than injection of a smaller volume. These results are supported by those of two other groups. *Park et al.* [110] randomized 72 patients with high-risk stigmata of bleeding to either 15–25 ml adrenaline injection (mean volume 19.4 ml) or to 35–45 ml injection (mean volume 41.1 ml). The overall rates of re-bleeding were significantly lower in the large volume group (0% vs 17.1%, p < 0.05), this effect being entirely due to a reduction in re-bleeding from ulcers in the gastric body. There was one perforation in the large volume group, but no other complications. The largest trial was performed by *Liou et al.* [111]. Two hundred and twenty eight patients with actively bleeding ulcers were randomized to receive either a 20 ml, 30 ml or 40 ml total volume adrenaline injection. Initial hemostasis was achieved in almost all patients. Recurrent bleeding occurred in a significantly greater proportion of patients in the 20 ml injection group. Those patients treated with the 40 ml injection had increased rates of perforation and injection related abdominal pain (Table 8.17). The conclusion was that 30 ml was the optimal volume of adrenaline injection for treatment of actively bleeding ulcers.

### Conclusion

Injection therapy is effective and safe. The optimum injection regimen should include 1:10,000 adrenaline, which

**Table 8.17** Optimal volume of adrenaline for peptic ulcer bleeding.

stops active hemorrhage. Studies suggest that a volume of at least 13 ml should be injected. Re-bleeding rates are not convincingly reduced by the addition of agents such as thrombin or a thrombin–fibrinogen mixture. Sclerosants and alcohol should not be used, since there is no evidence that they are beneficial and they increase the risk of serious complications.

### Comparison of injection and thermal treatments

A number of small trials have compared injection with thermal therapies. In general, the two modalities appear to have similar efficacy.

Six trials have compared heater probe with injection (Table 8.18) [112–117]. The two trials reported by Lin *et al.* [112, 113] showed that heater probe treatment was more effective in achieving primary hemostasis. These authors noted the heater probe to be better when ulcers were difficult to approach, since it can be applied tangentially. They also found the water jet to be useful in the presence of spurting bleeding. It may be argued that alcohol is a less appropriate injection therapy than adrenaline, which may account for the apparent superiority of the heater probe in these studies. This view was supported by the findings of Chung *et al.* [114]. They concluded that heater probe and adrenaline were equally effective, but that initial hemostasis was more easily achieved with adrenaline. Choudari *et al.* [115] compared the heater probe with adrenaline plus ethanolamine and found no differences between the modalities. The remaining two trials by Saeed *et al.* [116] and Llach *et al.* [117] support this conclusion. Laine [118] showed that electrocoagulation and injection with ethanol

were equivalent, although the size of this trial was suboptimal. **A1c**

Two trials involved the Nd-YAG laser. Carter *et al.* [119] compared laser with adrenaline and Pulanic *et al.* [120], in a much larger trial, compared laser with polidocanol. Neither showed a difference in outcome.

Current evidence does not allow a conclusion to be drawn on whether injection or thermal treatment is superior as a single modality. We advocate the heater probe as the thermal method of choice. Some situations, particularly those involving awkwardly placed posterior duodenal ulcers, lend themselves better to use of the heater probe than to injection therapy.

### Mechanical clips

The hemoclip was first used for non-variceal bleeding by Japanese investigators in the early 1970s [121]. Early clips were difficult to apply, but since modifications were introduced in the late 1980s the device has gained favor as the endoscopic method most analogous to under-running an ulcer at operative surgery. Various types of clips have been evaluated but of the most frequently used devices only the Olympus Hemoclip and the Cook TriClip have been investigated in human studies [122].

### Hemoclip

The Olympus Hemoclip is the most widely used clipping device, and has the largest evidence base. Three large case series [123–125] support hemoclips as a safe and effective method for the treatment of bleeding peptic ulcer, and

there are eight randomized trials of reasonable size comparing clips to other hemostatic therapies (Table 8.19) [126–133]. Other trials combining hemoclips with injection therapy are discussed in a later section.

The first randomized trial was published by Chung *et al.* in 1999 [126]. Primary hemostasis was achieved in over 95% of patients. Re-bleeding and surgery rates were lower in the hemoclip groups but these were not statistically significant. Three patients had complications, all in the adrenaline only group. In one patient severe bleeding requiring surgical operation was precipitated; two patients developed submucosal hematoma. Cipoletta *et al.* [127] randomized 113 patients with endoscopic stigmata of hemorrhage to heater probe thermocoagulation or to application of hemoclips. A mean of three clips per patient were used with up to six being required in some cases. Re-bleeding was dramatically reduced in the hemoclip group. Surgery and mortality rates were similar in the two groups and there were no complications.

The two previous trials suggested clips to be effective, with re-bleed rates below 3% in the clip only groups. However, subsequent studies have been less encouraging. Lin *et al.* [128] achieved primary hemostasis in only 85% of patients in a group of patients treated with clips versus 100% of those treated with the heater probe (p = 0.01). The following year the same group compared ulcer bleeding patients treated by hemoclip placement with patients in

whom heater probe thermocoagulation and adrenaline injection were used. The rate of primary hemostasis was lower in the hemoclip group (95.1% vs 100%) but this difference was not statistically significant [129]. Gevers *et al.* [130] performed a similar trial to Chung *et al.* [126] in which patients were randomized to injection with adrenaline and polidocanol, hemoclip application or a combination of the two. Patients treated with clips had lower primary haemostasis rates but this did not reach statistical significance. A composite endpoint defined as the overall failure rate was significantly higher in the hemoclip alone group than in the injection and combination groups (34%, 6% and 25% respectively, p = 0.01). Patients in the other three trials [131–133] fared better, although clips were only demonstrated to be superior to injection in terms of a reduction in rebleeding in the trial by Chou *et al.* [131]. There were no other differences in any category.

Hemoclips have been the subject of two recently published meta-analyses [134, 135]. The first of these [134] was restricted to trials comparing the hemoclip alone with other hemostatic techniques. Twelve randomized trials were identified, including all those mentioned above, in addition to four other small trials which studied patients who were not bleeding from high-risk peptic ulcers. In a pooled analysis considering only those patients with bleeding peptic ulcer, 351 patients were treated with hemoclips and 348 patients received another form of therapy. Initial hemosta-

sis was lower in the clips group when compared to controls, but this was not significant (92% vs 96%, OR 0.58; 95% CI: 0.19–1.75). There was a non-significant trend towards a reduction in rebleeding in the clip group (8.5% vs 15.5%, OR 0.56; 95% CI 0.30–1.05), and no other differences were identified. **A1a**

Sung *et al.* [135] reported a more wide ranging study in which the main difference to the Yuan study was the inclusion of a number of trials comparing hemoclips in combination with injection to injection therapy alone. There was total of 1156 patients in 15 trials and several subgroup analyses were performed. Comparing hemoclips alone to injection therapy alone, re-bleeding rates were lower in patients treated with clips (9.5% vs 19.6%, RR 0.49; 95% CI: 0.30–0.79). There was also a significant reduction in the need for emergency surgery (2.3% vs 7.4%, RR 0.37; 95% CI: 0.15–0.90). A similar effect was not surprisingly demonstrated when clips combined with injection were compared to injection therapy alone (8.3% vs 18.0%, RR 0.47; 95% CI: 0.28–0.76 for re-bleeding; 1.3% vs 6.3%, RR 0.23; 95% CI: 0.08–0.70 for surgery). Despite these results, an

effect on mortality was not demonstrated. In another analysis, clips were found to have equivalent efficacy to thermal therapies for all the usual endpoints (definitive hemostasis 81.5% vs 81.2%, RR 1.00; 95% CI: 0.77–1.31). The conclusion that can be drawn from both meta-analyses is that hemoclips are probably equivalent to other forms of endoscopic therapy, and may be superior to injection therapy alone when the clips are optimally applied. **A1a**

The major difficulty with hemoclip placement occurs when ulcers are difficult to reach and tangential application is required. In the Sung meta-analysis, the ulcer locations most associated with failure of clip application were the posterior duodenal bulb, the posterior wall of the stomach and the high lesser curve of the stomach – precisely the areas where the highest risk lesions are found. Initial clip applicators resulted in problems with clip alignment, but a rotating applicator is now in general use. Further problems arise when clips are applied to the fibrous base of a chronic ulcer, as in this situation it may not be possible to adequately compress the bleeding vessel. In the trial by Lin *et al.* [128] a surveillance endoscopy was

performed 72 hours after therapy. Hemoclips had been successfully placed in 31 patients, but at 72 hours the clip was still attached to the ulcer base in only 10 patients. This could have accounted for the disappointing performance of the clip group, and perhaps clips with a more powerful clamping mechanism would improve the efficacy of the device. Further trials with improved clips are required.

### Triclip

The Cook triclip was developed to try to overcome the difficulties encountered with tangential application reported with the hemoclip. As its name suggests the clip comprises three prongs instead of two. The triclip can be rotated in a similar way to the hemoclip. Trials involving the triclip are few in number.

Following experimental studies suggesting the device to be effective [136], a pilot study in human subjects was carried out by Chan *et al.* in 2004 [137]. Twenty seven high-risk ulcer bleeding patients were treated with triclips. Initial hemostasis was achieved in 22 (81.5%) but at repeat endoscopy 24 hours later four (14.8%) were oozing from the treated site, giving an overall definitive hemostasis rate of only 66.7%. At the second endoscopy clips were found to be dislodged in 11 patients (40.7%). It was noted that if more than one clip was required, the three prong design could make the application of a second clip difficult. Further disappointing results were reported following a randomized trial by Lin *et al.* comparing the triclip with the hemoclip in 100 ulcer patients with active bleeding or non-bleeding visible vessels [138]. Primary hemostasis rates were significantly lower in the triclip group (76% vs 94%,  $p = 0.011$ ). This difference was principally due to failure of triclip application in ulcers which were difficult to reach on the lesser curve and posterior wall of the stomach and in the posterior duodenum. Outcomes for the other endpoints were similar. The conclusion was that the hemoclip is superior to the triclip for high-risk ulcers in difficult to reach sites. **A1c**

### Conclusion

Mechanical clips appear to be similar in efficacy to other endoscopic hemostatic modalities and there are few reports of adverse events following their use. Several devices are in clinical use, but the evidence in human subjects to date supports the use of the hemoclip. The major limitation of clipping devices relates to suboptimal deployment of clips in the posterior duodenum and high lesser curve of the stomach. With future development and modifications to clip applicators these difficulties may be overcome.

### Combination of injection, thermal and mechanical treatments

The mechanisms leading to hemostasis associated with thermal treatment and injection therapy may differ, providing a rationale for combining a thermal modality with injection treatment. **C** Currently, only two small studies have shown a benefit from use of such a combination. The first trial by Lin *et al.* [139] used the gold probe, a bipolar coagulation probe containing an injection needle in the center. Using this device heat and injection therapy may be applied without removing the probe from the ulcer. Ninety six patients were randomized to receive injection alone, coagulation alone or combination therapy. Re-bleeding rates were lower in the combination group compared to the injection alone and coagulation alone groups (7% vs 36%,  $p = 0.01$  and 7% vs 30%,  $p = 0.04$  respectively). **A1c** The volume of blood transfused in the combination group was also significantly lower. Although this small trial demonstrated a beneficial outcome following combination endoscopic therapy, the results were not confirmed by the subsequent trial of Bianco *et al.* reported in 2004 [140]. This group randomized 114 patients with high-risk bleeding to initial injection of adrenaline followed by coagulation, again using the gold probe, or to gold probe therapy alone. In the event of failure of primary hemostasis in either group, repeat therapy using both injection and coagulation was applied. There were trends towards a reduction in re-bleeding, surgery and mortality in the combination group. The study probably lacked power to demonstrate statistically significant differences between the groups, should they exist, but the numbers were too small for these to reach statistical significance. There were 19 patients with active bleeding in each arm. Initial hemostasis was possible in only 68.4% of these patients treated with gold probe alone, compared to 100% in the combination group ( $p = 0.02$ ), suggesting that combination therapy was advantageous when active bleeding was present.

A similar trend relates to a finding within a study reported by Chung *et al.* [141]. This study involved randomization of appropriate ulcer bleeding patients to injection therapy using 1:10,000 adrenaline or to a combination of adrenaline plus the heater probe (Table 8.20). Although there was no overall difference in outcome between patients randomized to either arm, a post hoc subgroup analysis did reveal positive findings. Sixty patients had active spurting hemorrhage from large ulcers, and within this group the primary hemostatic effect of both treatments was similar. However, the need for operation was significantly reduced in the group treated by heater probe and injection. The number of surgical endpoints was very small, and this observation from subgroup analysis requires confirmation in further trials.

Five trials have examined the combination of mechanical clips with injection compared to injection therapy alone [126, 130, 132, 142, 143]. The combined results of these trials are included in the meta-analysis by Sung *et al.* [135] and the results of the first three trials are shown in Table 8.19. Park *et al.* [142] randomized 90 patients to either a combination of adrenaline injection plus one of hemoclip or band ligation or to adrenaline injection as monotherapy. Re-bleeding rates were significantly lower in the combination group (4.5% vs 20.5%,  $p = 0.024$ ). **A1c** A separate analysis of the individual effects of clips or bands was not included in the published data. The most recent trial was of the same design, but restricted the mechanical component of the combination therapy group to the hemoclip [143]. One hundred and eight patients were randomized and both the

re-bleeding and surgery rates were significantly reduced in the combination therapy group (3.8% vs 21%,  $p = 0.008$  for re-bleeding; 0% vs 9%,  $p = 0.02$  for surgery). **A1c** The authors reported technical difficulty in the application of clips to ulcers in the posterior duodenum and high lesser curve of the stomach. However, with good technique it was possible to place clips in all patients.

Two meta-analyses have been performed to try to confirm the suspicion that combination therapy was superior to single modality treatment [144, 145]. The results are shown in Table 8.21. Calvet *et al.* [144] showed that rates of re-bleeding, surgery and mortality were significantly reduced when an additional therapy (either injection, thermal or mechanical) was added to adrenaline injection. Of the 16 trials included (1673 patients), 11 studied additional injection therapy, a sclerosant being used in eight of these. Perforations were seen in six of 558 patients in the combination group, but these were not all related to sclerosant injection. Patients with active bleeding were most likely to benefit from combination therapy. The more extensive study by Marmo *et al.* [145] included 2472 patients in 20 trials. Again, rebleeding and surgery rates were significantly lower in patients treated with combination endoscopic therapy. There was a trend towards mortality reduction but this did not achieve statistical significance. This study attempted to explore the differences between the outcomes of combination therapy and injection, thermal and mechanical monotherapy by dividing the trials into subgroups. The resulting analysis suggested that combination therapy was superior to injection monotherapy, but not to either thermal or mechanical monotherapy. However, the numbers of patients in the thermal and mechanical subgroups were small, and the study is not sufficiently powered to make this conclusion definitive.

The current evidence suggests that adrenaline injection for peptic ulcer bleeding should be combined with a second therapeutic modality. **A1d** Further trials are needed before it is possible to recommend any particular additional therapy over the others.

## Endoscopic therapy for ulcers with adherent blood clot

There is debate concerning the appropriate intervention when blood clot is tightly adherent to an ulcer base. To remove a clot seems counterintuitive in the situation of acute bleeding, but to leave it *in situ* prevents accurate categorisation of stigmata of hemorrhage, and may prevent correct application of endoscopic therapy.

Lin *et al.* [146] showed that when clot is tightly adherent after washing for 10 seconds with Water Pik irrigation, the re-bleed rate is 25%. Factors independently associated with re-bleeding in this situation are the presence of shock, comorbid disease and hemoglobin at presentation of <10 g/dl. In the trial by Sung *et al.* [28] clot was defined as adherent only after five minutes irrigation with the 3.2 mm heater probe. Patients received high dose PPI infusion plus or minus endoscopic therapy. Of 39 patients with adherent clot only one (in the combination group) re-bled, suggesting that when clot is truly adherent to an ulcer base a PPI infusion may be all that is required. Bleau *et al.* published a small trial in which patients with adherent clot were randomized to pre-injection with adrenaline followed by clot removal and thermocoagulation of a visible vessel, or to medical therapy with PPI [147]. The patients in the endoscopic therapy group had a significantly lower re-bleeding rate, although the numbers were small (56 patients). A similar but very small trial (32 patients) has been reported by Jensen *et al.* [148]. The results again indicate that clot removal and therapy to the underlying stigmata is a safe and effective strategy. However, it should be noted that both the Bleau and the Jensen trials were terminated prematurely. The Jensen trial was also a subgroup analysis of a larger trial which was, therefore, not designed primarily to study outcomes in relation to adherent clot. Despite these limitations, Jensen's group included both trials in a meta-analysis of six studies including 240 patients which was published in 2005 [149]. Of the other four trials included, only two had been published in peer-reviewed journals. There was significant heterogeneity with regard to methodology and in particular the type, dose and delivery of medical therapy. The conclusion was that there was a significant reduction in re-bleeding rate for the endoscopic therapy group compared to those treated with medical therapy alone (5 of 61 (8.2%) vs 21 of 85 (24.7%); RR 0.35; 95% CI: 0.14–0.83). **A1c** Other outcomes were unaffected. Further trials specifically designed to address the question of whether or not to remove adherent clot are required before this approach can be advocated.

## Elective repeat endoscopic therapy

It is not yet clear whether electively repeating endoscopy and hemostatic therapy in the absence of clinical or endo-

scopic signs of re-bleeding is a useful strategy. There are six trials which include patients receiving repeated endoscopic therapy [106, 107, 150–153] and four of these have specifically addressed the question of the efficacy of endoscopic retreatment [150–153]. The trial by Pescatore *et al.* [107] reported no clear benefit from the use of an elective repeat endoscopy approach. A similar conclusion was reached by Messmann *et al.* in a study of 105 patients who had required endoscopic therapy for bleeding ulcers. Patients were randomized to daily repeat endoscopy with re-treatment of persistent stigmata, or to close observation. There was no difference between the groups for any of the usual endpoints [150]. In contrast to these results, Rutgeerts *et al.* reported a clear positive trend towards reduction in re-bleeding in patients treated with programmed repeat endoscopic therapy [106]. Villanueva *et al.* randomized 104 patients in whom endoscopic hemostasis had been achieved following injection of adrenaline, to repeat endoscopy or to observation [151]. There were trends towards a better outcome in the repeat endoscopy group, but statistically significant reductions in re-bleeding, surgery and mortality were not demonstrated.

Two trials suggested that repeat endoscopic therapy significantly reduces re-bleeding rates. The very small trial by Saeed *et al.* included only 40 patients [152], but Chiu *et al.* randomized 194 patients following endoscopic hemostasis using adrenaline injection and heater probe thermocoagulation [153]. One hundred patients underwent a scheduled repeat endoscopy and 35 of these required further endoscopic therapy. The remaining 94 patients were observed closely. All patients received intravenous omeprazole 40 mg twice daily for 72 hours following endoscopy. The mean total volume of adrenaline injected in the repeat endoscopy group was 11.1 ml compared with 9.1 ml in the control group ( $p = 0.008$ ). The mean total joules of heater probe therapy in the two groups were 95.3 and 110.2 respectively. Re-bleeding rates were significantly lower in the repeat endoscopy group compared to the control group (5% vs 14%,  $p = 0.034$ ). There was also a trend towards reduction in the requirement for surgery (1% vs 6%,  $p = 0.05$ ). Mortality rates were similar in the two groups.

Two meta-analyses examining the above trials have been published [154, 155]. Both suggest that elective repeat endoscopy significantly reduces re-bleeding (12% vs 18.2%; OR 0.64; 95% CI: 0.44–0.95) [155], but has no beneficial effect on the rates of surgery or mortality. **A1c**

Complications of repeat endoscopic therapy including sedation related cardiorespiratory adverse events, and heater probe related perforation have not been reported. However, in the trials by the Hong Kong group, perforation of the duodenum following repeat thermal therapy with the heater probe occurred in 3% [114] and 4.5% [156] of cases. This is considerably higher than the overall heater probe related perforation rate and suggests that aggressive

repeat thermal therapy in the duodenum should be avoided. In many cases repeat endoscopic therapy is not required at the time of second look endoscopy, and a cost-benefit analysis of a policy of elective repeat endoscopic therapy is required. Currently, the total number of patients studied is small, but the available evidence indicates that elective repeat endoscopic therapy may be beneficial in patients at high-risk of re-bleeding or surgery. Repeat endoscopy should also be considered in cases where the endoscopist is not convinced that adequate hemostasis has been achieved at the time of the initial endoscopy.

### Failure of endoscopic therapy

It may be argued that endoscopists can adversely affect outcome in patients who fail endoscopic therapy. Repeated unsuccessful therapeutic endoscopy, large blood transfusion and delayed surgical operation in those who ultimately fail attempted endoscopic hemostasis may all increase the risk of death. A number of studies have reported factors associated with failure of endoscopic therapy. These have been summarized in a paper by Elmunzer *et al.* [157]. Independent pre-endoscopic predictors of failure were hemodynamic instability and the presence of co-morbid disease. Endoscopic factors associated with a poor outcome were active bleeding, large ulcer size, posterior duodenal ulcer and high lesser curve gastric ulcer. Although none of these predictors is particularly surprising, it is interesting to note that patient age appears to have no independent effect on outcome. It should be noted that none of the patients in the studies reviewed were treated with high dose PPI infusions, and combination endoscopic therapy was not universal. Thus, the results may not be generalisable to current practice, but could be used to aid decisions regarding elective repeat endoscopy and to focus future trials to ensure that only high-risk patients are included.

Unfortunately, we cannot reliably predict who will fail and who will respond to endoscopic therapy, and even in the highest risk group of patients, who present with active spurting hemorrhage from large posterior duodenal ulcers, endoscopic hemostasis can be achieved in approximately 70% of patients [158]. Currently, it is not possible to accurately define a subgroup of patients in whom endoscopic therapy should not be attempted. What is clear, however, is that patients who have actively bleeding, large posterior duodenal ulcers should be considered to be at very high-risk of requiring urgent operation.

The management of re-bleeding after failed endoscopic therapy has been examined by Lau *et al.* [156]. Of 3473 patients admitted with bleeding peptic ulcers, 1169 underwent endoscopic therapy in an attempt to achieve hemostasis. Primary hemostasis was achieved in a remarkable 98.5% of patients. One hundred of these re-bleed after endo-

**Table 8.22** Repeat endoscopic therapy vs surgery for patients who re-bleed.

Outcome	Endoscopic therapy	Surgery
n	48	44

Mortality (30-day) (%)	5 (10)	8 (18)

<sup>a</sup>p = 0.03.

Source: Lau *et al.* [156].

scopic therapy and 92 were randomized to receive endoscopic retreatment or to emergency surgery. The characteristics of the two groups of patients were similar, including the median transfusion requirements before randomization. Endoscopic retreatment consisted of a combination of adrenaline injection plus the heater probe. Overall, more complications occurred in the group randomized to surgery and there was no significant difference in 30-day mortality between the two groups (Table 8.22). This paper suggests that endoscopic retreatment rather than immediate, urgent surgery may be undertaken in patients who re-bleed after endoscopic hemostatic therapy. **A1c**

In cases when endoscopic therapy fails, transcatheter arterial embolization (TAE) may offer an alternative to immediate surgery in selected patients. Two retrospective case series in patients who had failed endoscopic therapy or were re-bleeding after surgery for peptic ulcer disease have reported high levels of technical success, definitive haemostasis rates of 65–72% and no significant complications [159, 160]. **B** Occasionally it is not possible to advance a microcatheter to the bleeding site. In this situation embolization with N-butyl-2-cyanoacrylate has been shown to be effective and safe [161, 162]. There are no randomized, controlled trials comparing embolization to emergency surgery, but two retrospective analyses have been published. Ripoll *et al.* [163] reviewed 70 patients with refractory ulcer bleeding, 31 of whom were managed by embolization. The patients in this group were elderly (75.2 vs 63.3 years), had a high incidence of heart disease (67.7% vs 20.5%) and many were coagulopathic (25.8 vs 5.1%). These considerations probably accounted for the decision to perform TAE rather than operative surgery. The rates of both re-bleeding and mortality following salvage therapy were similar (29.0% vs 23.1% for re-bleeding and 25.8% vs 20.5% for death), suggesting that TAE could be an acceptable alternative to urgent surgery. There were no complications relating to TAE. The second review analyzed 91 patients who had failed endoscopic therapy [164]. Forty patients were treated with TAE and the remainder underwent surgery. Again the patients in the TAE group were

older with more co-morbid conditions. Mortality at 30 days was 3% in the TAE group compared with 14% in the surgery arm. **B** This difference did not reach statistical significance but was seen as an encouraging trend. These results are promising and a randomized trial of TAE versus surgery following failed endoscopic hemostasis for bleeding peptic ulcer is warranted.

## Endoscopic therapy: summary

Endoscopic therapy for non-variceal hemorrhage is safe and effective, and should be used in the 20% of patients who have major endoscopic stigmata of recent hemorrhage. Thermal hemostasis is effective using either the heat probe or multipolar electrocoagulation. No injection agent has been convincingly shown to be superior to dilute adrenaline solution. Injection of larger volumes may improve outcome. The hemoclip is an effective and safe mechanical device which would benefit from technical development. The addition of a second therapeutic modality to adrenaline injection improves outcome, and it is likely that combination therapy is the best approach for patients with active, spurting hemorrhage. Re-bleeding should be treated first by further endoscopic intervention, although clinical judgment should dictate when urgent surgery is required for specific high-risk cases. Transcatheter arterial embolization may be considered as an alternative to urgent surgery but this requires further study.

Intravenous infusion of proton pump inhibitor drugs is recommended following successful endoscopic hemostasis. There is little evidence currently that other drug therapies are effective.

## Functional dyspepsia

*Sander Veldhuyzen van Zanten*

Division of Gastroenterology, Department of Medicine, University of Alberta, Edmonton, Canada

---

### Introduction

In this chapter the diagnosis of functional dyspepsia and efficacy of therapeutic interventions will be evaluated. Functional dyspepsia, often referred to as non-ulcer dyspepsia, is an important health problem with a very high prevalence in the general population. Data from Sweden and Canada show that 5–7% of all consultations in primary care are for the symptom of dyspepsia [1, 2]. In Sweden, up to 98% of patients receive a prescription if they consult a physician for dyspepsia [1]. Consequently, for the health care system the cost of medications, which are often prescribed for long periods of time, adds significantly to the already substantial expenditures for consultations and diagnostic investigations. The following topics will be reviewed: definition of functional dyspepsia, evaluation and diagnostic tests, methodology of trials, and pharmacological treatments including antacids, H<sub>2</sub>-receptor antagonists, proton pump inhibitors (PPIs), prokinetic agents, anti-*Helicobacter* therapy and antidepressant therapy.

---

### Definition of functional dyspepsia

There is agreement that the cardinal feature of functional dyspepsia is unexplained pain or discomfort centered in the upper part of the abdomen. Epigastric pain or discomfort may be accompanied by other symptoms such as excessive burping or belching, nausea, bloating, postprandial fullness, early satiety, or burning sensations. Increasingly, investigators have accepted the definition of the Rome Working Party which has now been revised three times [3, 4, 5].

The general definitions of dyspepsia and functional dyspepsia have remained unchanged, but in Rome III major changes have been introduced. For a diagnosis of functional dyspepsia to be made, it is required that investigations, usually upper gastrointestinal endoscopy, have not revealed abnormalities such as ulcers that could explain the symptoms of the dyspepsia. The Rome criteria continue to exclude the symptoms of heartburn and acid regurgitation as these are considered to be diagnostic of gastro-esophageal reflux disease (GERD). Although there is consensus that “dominant” symptoms of heartburn and acid regurgitation make a diagnosis of GERD likely, it is less clear how heartburn should be handled if it is of severity equal to or less than epigastric pain. Furthermore, heartburn and acid regurgitation are often present as associated symptoms in patients who otherwise fit the dyspepsia diagnostic criteria. In the context of functional dyspepsia the recent publication on the definition of gastro-esophageal reflux Disease (the “Montreal definition”) is very relevant [6].

The criteria proposed by the Rome III working group included very significant changes [5]. It was proposed that for research studies the term functional dyspepsia should be replaced by more distinctively defined disorders, for which there was felt to be increasing evidence in the literature. The two new proposed diagnostic categories are: (1) meal-induced dyspeptic symptoms (PDS, postprandial dyspepsia symptoms); and (2) epigastric pain (EPS, epigastric pain syndrome). This new subclassification is supported by some studies in which factor analysis supported a division into four symptom subgroups: epigastric pain, epigastric burning, postprandial fullness and early satiation [7]. Furthermore, some studies from a tertiary referral center also reported significant weight loss (10%) as a feature of functional dyspepsia, especially in patients complaining of early satiety [7, 8], but at this time these findings are not considered to be generalizable. Given that the overall empiric evidence surrounding the definitions of most functional GI disorders including functional dyspep-

sia is weak, it remains to be seen whether any new classification will indeed help research in this area to move forward. To date the utilization of the Rome III functional dyspepsia definitions appears to be low.

There is evidence, especially in primary care, that excluding heartburn from the dyspepsia syndrome does not fit with the conceptual framework for dyspepsia used by primary care physicians [9]. This is especially true for uninvestigated dyspepsia patients who are commonly seen in primary care. The Canadian Dyspepsia Working Group has developed a definition for dyspepsia that includes heartburn and acid regurgitation [9]. There is some empiric support for the latter definition, as a few studies in *Helicobacter pylori* infected patients have demonstrated that cure of the infection not only led to a decrease in epigastric pain but also in symptoms of heartburn in a small but definite proportion of patients [10, 11, 12]. Other studies in primary care have included similar broad definitions of dyspepsia [13].

## Diagnosis of functional dyspepsia

There is consensus that there is so much overlap in symptoms among patients with duodenal and gastric ulcers, GERD and functional dyspepsia that it is impossible to make a definitive diagnosis based on symptoms alone. This is supported by the results from the Canadian Prompt Endoscopy (CADET-PE) Study [14]. In this study, 1014 patients underwent endoscopy within ten days without having received acid suppressive therapy. There was a marked overlap in symptoms and it was impossible to distinguish between individuals with ulcers, esophagitis, or functional dyspepsia based on symptoms. In both the Enter and STARS studies reflux esophagitis was the most frequent reason for exclusion, despite the fact that the study entry criteria for heartburn were strict [15, 16]. In essence, functional dyspepsia is a diagnosis of exclusion, and in the setting of clinical trials generally requires an upper gastrointestinal endoscopy to exclude other diseases. In practice, physicians often decide on a trial of empiric therapy for patients presenting with dyspepsia, without worrying about a definitive diagnosis of a particular disease. This strategy is often attractive, given that the treatments for duodenal and gastric ulcers, GERD and functional dyspepsia are similar. The current standard of practice is a trial of acid suppressive therapy. Therefore, subclassification into separate diseases is not always necessary and in primary care may not be feasible. The decision whether or not to refer a patient for further investigation, usually either an upper gastrointestinal endoscopy or a barium study, is based on the severity of the presenting symptoms, age of the patient and on the presence or absence of "alarm symptoms" such as

weight loss, evidence of bleeding or anemia, dysphagia and vomiting.

## Subgroups of dyspepsia and overlap with GERD

The description of subgroups of dyspepsia has become popular despite evidence of the existence of considerable overlap among them. The Rome II classification recognized four subgroups: ulcer-like dyspepsia, reflux-like dyspepsia, dysmotility-like dyspepsia, and unclassified dyspepsia [17, 18]. An attractive, although not empirically proven feature of the Rome II classification was that the terms non-ulcer, reflux-like and dysmotility like dyspepsia conform with clinical beliefs about the pathophysiology of functional dyspepsia [4]. However, a study by Talley *et al.* demonstrated considerable overlap among the different subgroups [18], as did the CADET-PE Study [14]. Over the last few years functional dyspepsia trials have become increasingly strict in excluding patients with heartburn symptoms, and there is evidence that the treatment response rate using a proton pump inhibitor is lower when heartburn exclusion criteria become stricter [15, 16]. For example, in the STARS I study patients were excluded if they had >2 days with any heartburn symptom [16]. However, in contrast in the itopride Phase II trial it was unclear how heartburn symptoms were handled [19]. This is especially relevant since there was a suggestion that patients with heartburn showed a better response.

Increasingly, endoscopy negative GERD is now recognized as a distinct entity. This is a difficult issue for the methodology of trials of functional dyspepsia. In practice the preferred operational definition excludes patients with heartburn and/or regurgitation, based on severity and frequency criteria for these symptoms. An example of how this approach can be operationalized is the inclusion of patients who have heartburn no more than one day a week that is, at most, mild in severity.

What constitutes a normal endoscopy has been poorly defined in the literature. It is especially important to determine whether or not patients are, or were recently taking, acid suppressive therapy, as the use of these agents can mask the presence of esophagitis or ulcers. It would be ideal for trials of functional dyspepsia treatment to require that patients are not allowed to have consumed acid suppressive therapy for at least four weeks before the endoscopy. After withdrawal from acid suppressive therapy, it may take longer than four weeks for endoscopic abnormalities to become visible; however, a four-week period of avoidance of acid suppressive therapy seems a reasonable compromise as was recommended in the Montreal GERD definition publication [6].

## Diagnostic investigation: endoscopy or radiographs?

Referral for endoscopy is indicated for older patients presenting with new-onset dyspepsia. Formerly, the recommendation was to use age >45 years as an indication for investigations, but it seems likely that this can be increased to 50 years or perhaps even higher [20, 21, 22]. This cutoff age is largely driven by the incidence of gastric cancer in the population where one practices. Interestingly, the Scottish guidelines have removed all age criteria, as there are insufficient data to support them [23]. In primary care, upper gastrointestinal barium studies are still commonly used to rule out peptic ulcer disease and esophageal or gastric cancer in patients with dyspepsia. The technical review of the American Gastroenterology Association (AGA) on dyspepsia summarizes the consistent evidence of the superiority of upper gastrointestinal endoscopy for detection of structural abnormalities [20]. Radiographs are still frequently used because of their lower cost, wider availability in the community and the speed with which the procedure can be arranged. Often there is a significant waiting time before patients can be seen after they are referred to a gastroenterologist. "Open access endoscopy" is one method by which delay in diagnostic endoscopy can be reduced. The AGA technical review assessed whether patients with new onset of symptoms should be investigated or treated empirically and came to the conclusion that the evidence is equivocal [20]. For example, in the study by Bytzer *et al.*, empiric treatment was compared with direct endoscopy in patients presenting with dyspepsia [24]. Patients in the endoscopy arm were more satisfied, and subsequent health care costs were significantly lower in this group. There is further evidence that a patient's quality of life is improved following a normal endoscopy [24]. This is largely due to alleviation of fear of a serious underlying disease when the dyspepsia symptoms persisted. However, a recommendation that endoscopy should be done in all or most patients presenting with dyspepsia would probably be too costly for most health care systems. A more rational approach therefore seems to be to stratify patients according to their risk of having serious underlying disease. Factors that can be considered are age of the patient, background prevalence of serious disease, especially of esophageal and gastric cancer, and the presence or absence of alarm symptoms. The recent significant increase in the incidence of esophageal adenocarcinoma in the West will likely drive the demand for gastroscopy, which although resource intensive is relatively easy to perform [25].

## Methodological problems in trials of functional dyspepsia

In order to determine whether a treatment does more good than harm, valid and reliable outcome measures must be used in clinical trials. In the case of functional dyspepsia the lack of definite structural or pathophysiological abnormalities which explain the origin of the symptoms of functional dyspepsia has hampered the development of such measures. Clinical trials must use outcome measures that rely on the recording of symptoms and their severity, as is the case in other functional gastrointestinal disorders. A systematic review of drug treatment of functional dyspepsia evaluated the quality of clinical trials in this field [26]. Few studies used validated outcome measures, and methodological weaknesses were apparent in several trials. Problems included a lack of definition of functional dyspepsia, unclear inclusion and exclusion criteria, suboptimal study design and short duration of treatment. The most important problem in randomized controlled trials of interventions for functional dyspepsia is the lack of consensus on outcome measures. Only a small number of outcome measures have been validated. In the systematic review of studies on functional dyspepsia, only 5 of 52 studies used a validated outcome measure [26]. In a recent systematic review on outcome measures in functional dyspepsia and GERD 26 ways of measuring outcomes were identified [27]. Of these 12 only assessed symptoms (unidimensional) and 14 assessed both symptoms and quality of life (multidimensional). Eleven questionnaires assessed both frequency and severity of dyspepsia, and ten were felt to be sufficiently validated [27].

Subjective endpoints, such as recording of symptoms and their severity, used to measure a clinical outcome in a trial should fulfill four requirements [28]: (1) the range of symptoms included should be important to, and representative of, the disease process; (2) the measurements should be reproducible (producing consistent results when repeated in subjects who have not changed); (3) the measurements should be responsive (able to detect change); (4) changes in the measurement should reflect a real change in general health status.

Ideally, a separate study is required to demonstrate that an instrument meets these requirements, prior to its use in a randomized controlled trial. However, when dealing with symptoms, their severity and frequency, the face validity of their use is generally high. What is less clear is how one determines what amount of improvement is clinically important. The latter point is important because it drives the definition of what constitutes a patient responder. Both the Rome II and III working parties on design of clinical trials recommended the use of a primary outcome

measure that integrates the global overall severity of symptoms, although it did not specify how this should be done [4, 5]. A common method to measure overall severity of symptoms is by using four, five or seven-point Likert scales. The Rome II report on study design provides a detailed discussion of the different scales that can be used [4, 29]. The Rome III working party went further in supporting the use of adequate or satisfactory relief as a suitable primary outcome measure [5]. These outcome measures have been used in large clinical trials evaluating the use of alosetron and tegaserod in irritable bowel syndrome [5]. These outcome measures have methodological shortcomings. They do not allow a comparison of post-treatment scores to baseline severity, making it impossible to determine the true effect size [30]. Furthermore, patients who reported severe or mild symptoms at baseline are considered the same if they report adequate or satisfactory relief during the study [30].

Another important weakness of many trials has been the relatively short duration of treatment. The duration of treatment was four weeks or less in 44 trials evaluated in the

systematic review of 52 studies [26]. It was eight weeks or longer in only four studies. Only seven studies had a follow-up period (varying from 3 to 52 weeks) after treatment was discontinued.

The short duration of treatment is surprising given the known chronicity of the symptoms of functional dyspepsia. The placebo response rate is high in clinical trials in patients with functional dyspepsia and other functional gastrointestinal disorders, such as irritable bowel syndrome. In the systematic review of trials of functional dyspepsia it varied from 13–73% [26]. Studies should also report the proportion of patients who become asymptomatic, since the placebo response is lowest for this outcome [30]. This approach permits a good estimate of true effect size. An explanation for the high placebo response rate may be the reassurance effect of a “normal” endoscopy. Fear of cancer is a frequent reason for concern among patients with functional dyspepsia undergoing gastroscopy [20, 22]. Wiklund *et al.* measured quality of life and gastrointestinal symptoms just prior to endoscopy and seven days later [31]. In patients in whom no significant endoscopic abnormalities were found overall quality of life improved, although there was little change in the severity of individual gastrointestinal symptoms. This observation supports the concept that endoscopy has a powerful placebo effect through reassurance of patients. However, a Dutch study did not confirm these findings [32]. The higher satisfaction with care in the study by Bytzer *et al.* may also be explained by a reassurance effect [24].

---

## Functional versus uninvestigated dyspepsia

It is important to distinguish between uninvestigated dyspepsia and functional dyspepsia. The diagnosis of functional dyspepsia is generally considered to require an endoscopy. Most studies to date have dealt with investigated dyspepsia. Studies of uninvestigated dyspepsia will include a proportion of patients with duodenal or gastric ulcer, esophagitis and, rarely, gastric cancer. The frequency with which structural abnormalities are found has changed over the past decade [20]. With the declining prevalence of duodenal and gastric ulcers, reflux esophagitis is now by far the most common abnormality. Its prevalence ranges from 20% to 40% among patients and is far more common than duodenal and gastric ulcers which were present in 3% and 4% of patients in the CADET-PE Study [14]. However, these rates clearly depend on the prevalence of these disorders in the population being studied. Gastric cancer is rare below the age of 50 years [20, 33]. In most endoscopic dyspepsia studies the rate of functional dyspepsia is high and varies between 30% and 60% [20]. In this chapter we will focus on patients with investigated dyspepsia, that is functional dyspepsia. Given the problems in study design, especially the large variation in the way outcome measures have been used, it is difficult to do quantitative meta-analysis. Over the past few years, several meta-analyses have been reported including Cochrane reviews. Although several of these systematic reviews have statistically combined results of individual trials, it is important to stress that this is usually done by transforming the various outcome measures. For example, in one of the Cochrane meta-analyses, all outcomes of included studies were dichotomized into improved versus not improved [34]. No evidence has been provided that such an approach is valid, although some kind of transformation is required if one wants to combine studies which have used substantially different outcome measures. This author also believes that it is important that studies report the proportion of patients who become asymptomatic in the active and placebo treated patient groups [30]. This is the hardest outcome measure for which the placebo response is also the lowest. This does help to allow estimation of true effect size.

---

## Drug treatment

### Antacids

Over-the-counter medications, especially antacids, are commonly prescribed as first-line treatment. Many patients will probably have tried these medications before

consulting a physician. As several reviews have been written on the use of antacids, the details of individual studies will not be discussed here. Clinical trials have generally not shown significant benefit from antacids [20, 35, 36]. The frequently cited and methodologically strong randomized controlled trial reported by Nyren *et al.* did not show benefit of antacids over placebo over a three-week treatment period [36].

## H2-receptor antagonists

Over the past few years, four systematic reviews have evaluated the use of H2-blockers in functional dyspepsia [3, 37–39]. The number of studies that met the inclusion criteria varied in these reviews. All four came to the same conclusion: that there is some evidence that these agents provide benefit in functional dyspepsia patients (see Box 9.1). However, it is important to point out several methodological issues. The reason why the results for H2-blockers have varied is that several of the included studies which showed benefit probably included GERD patients. This factor may explain why the meta-analysis by Dobrilla *et al.* showed a therapeutic gain of 18% of active treatment over placebo [37]. Two methodologically strong studies did not show a benefit of either cimetidine or nizatidine over placebo [36, 40]. It is also worth pointing out that most studies have used low doses of H2-receptor antagonists (H2-RA), for example ranitidine 150mg twice a day. It is possible that higher doses of H2-RA might yield larger and more consistent treatment effects, but this needs to be assessed in future studies. Finally there is also evidence that the reported benefit of H2-blockers is larger in methodologically weaker studies [41]. One of the likely explanations for this is contamination with patients who have GERD. Many of the included studies were vague concerning this particular inclusion criterion [41].

### BOX 9.1 Results of meta-analyses of clinical trials of treatment of functional dyspepsia with H2-blockers

- (1) Dobrilla *et al.*: Therapeutic gain H2-blockers compared with placebo 18% [34].
- (2) Bytzer: Therapeutic gain H2-blockers compared with placebo 22% [36].
- (3) Soo *et al.*: Relative risk reduction of ongoing dyspepsia of H2-blockers compared with placebo 22% [30].
- (4) Redstone *et al.*: Odds ratio studies of H2-blockers compared with placebo reporting complete relief from epigastric pain 1.8 (95% CI: 1.2–2.8) [35]. Odds ratio studies of H2-blockers compared with placebo reporting global improvement dyspepsia symptoms 1.48 (95% CI: 0.9–2.3)

## Proton pump inhibitors

PPIs have largely overtaken the use of H2-RAs in the treatment of acid related-disorders. The first large studies were the BOND-OPERA studies which evaluated the role of PPI therapy in functional dyspepsia [42]. Over a four-week period, 1262 functional dyspepsia patients received either omeprazole (20mg or 10mg) or placebo. Complete relief of symptoms was achieved in 38% of patients on omeprazole 20mg, 36% on omeprazole 10mg, and 28% on placebo ( $p < 0.001$ ). The absolute risk reduction (ARR) of 10% and 8% correspond to an NNT (the number of patients needed to treat with omeprazole to yield one additional patient with a complete response) of 10 for 20mg omeprazole and 12 for 10mg omeprazole. Subgroup analysis suggested that patients with ulcer-like and reflux-like dyspepsia benefited from omeprazole therapy, while patients fulfilling the criteria for dysmotility-like dyspepsia did not. Although it is generally not felt useful to make a diagnosis of specific dyspepsia subgroups, the results of this study suggest that use of the two subgroups – ulcer-like and reflux-like dyspepsia – may help predict a response to PPI therapy. Interestingly, although overt reflux patients were supposed to have been excluded, a proportion of patients reported heartburn as their most bothersome symptom. This is one of the reasons why in recent years the study entry criteria have become much more stringent for reflux symptoms. Moayyedi *et al.* conducted a systematic review on the effectiveness of PPIs in treatment of functional dyspepsia [43]. Eight trials were identified that compared PPI therapy with placebo in a total of 3293 patients. Response is expressed as the Relative Risk (RR) of having ongoing symptoms, which clinically is not the most user friendly way of expressing efficacy, although it is sound methodologically. For clinicians it is easier to understand that patients treated with a specific intervention are more likely to have improved or become asymptomatic relative to those who received a placebo, rather than considering a decreased risk of ongoing symptoms. The relative risk of remaining dyspeptic with PPI therapy versus placebo was 0.86 (95% CI: 0.78–0.95;  $p = .003$ , random-effects model) with a number needed to treat of 9 (95% CI: 5–25). The response rate in PPI treated patients was 33% compared to 23% for placebo. The placebo response rate was lowest in studies that used absence of symptoms as the primary outcome measure. There was statistically significant heterogeneity between trials. As expected, the presence of heartburn was a predictor of response. No benefit was seen in the subgroup that met the dysmotility criteria.

In another recent meta-analysis performed by Wong *et al.* seven studies with a total of 3725 patients met inclusion criteria [44]. Use of PPIs was more effective than placebo for reducing symptoms in patients, expressed as a relative risk reduction RRR of 10.3%; (95% CI: 2.7–17.3%). The

number needed to treat is 15 (95% CI: 9–57). In subgroup analysis a significant difference in the benefit was observed for patients with ulcer-like (RRR, 13%; 95% CI: 7–18%) and reflux-like dyspepsia (RRR, 20%; 95% CI: 2–34%), but not in those with dysmotility-like dyspepsia (RRR, 5%; 95% CI: –11–19%) and unspecified dyspepsia (RRR, –8.0%; 95% CI: –24–6%).

The practical bottom line for use of PPIs in functional dyspepsia is that it is reasonable to give patients a trial of 4–8 weeks of therapy, with the understanding that heartburn is a predictor of response and that the majority of patients will not respond.

## Use of prokinetic agents

The following prokinetic agents will be discussed: domperidone, cisapride, itopride and tegaserod.

### Domperidone

Prokinetics have been evaluated in functional dyspepsia because of the hypothesis that disturbed gastrointestinal motility may in part be responsible for the symptoms of dyspepsia. Domperidone is a dopamine receptor antagonist, which has shown a benefit in several randomized placebo controlled trials in patients with functional dyspepsia. However, as a systematic review pointed out, many of these trials enrolled only small numbers of patients and had other important methodological weaknesses [45]. These data can certainly not be considered as being conclusive.

### Cisapride

This a prokinetic agent with 5-HT<sub>4</sub>-agonist activity specifically targeted patients with dysmotility-like dyspepsia. The drug had also been proved to be effective in patients with mild GERD and in patients with delayed gastric emptying. Due to rare but serious cardiac side effects this drug has now been removed from most markets. The four systematic reviews that have looked at the efficacy of cisapride in functional dyspepsia all came to the same conclusion: that there was some evidence that the drug did improve dyspepsia symptoms [34, 39, 41, 45]. However, several of the cisapride studies suffered from serious methodological weaknesses, which made the conclusions about efficacy tentative. Furthermore, on funnel plots there was also evidence of a publication bias, almost certainly due to the fact that there was an overrepresentation of small studies with positive results [34].

### Itopride

Recently a comprehensive clinical trial program evaluated the use of itopride in the treatment of functional dyspepsia [9, 46]. Itopride, similarly to cisapride, is a benzamide

derivative. It exerts its activity by inhibition of the dopamine D<sub>2</sub> receptor and acetylcholinesterase.

The phase-II trial published in the *New England Journal of Medicine* received a lot of attention as it reported positive results in favor of itopride [19]. However, the results of two simultaneously conducted phase-III clinical trials involving 1170 patients unfortunately did not show a difference between itopride and placebo groups [46]. In the two phase-III studies the two primary outcome measures were global patient assessment measured on a five-point scale and two questions of the Leeds Dyspepsia Questionnaire (LDQ) [47]: the severity of pain in the upper abdomen and feeling of upper abdominal fullness. On the global scale, to be considered as a responder the patient had to become symptom free or to have reported a marked improvement. Either a one or two-point improvement on each of the two LDQ questions was used as a primary endpoint. Itopride was not more effective than placebo for any of these outcome measures. The only difference for the LDQ questions that did show a significant change was a two-point improvement in one of the two phase II studies (the International Study, 62% vs 53%,  $p = 0.04$ ), but this was not seen in the North American trial (47% vs 45%). No significant difference was found in the proportion of patients who reported complete absence of symptoms after eight weeks of itopride treatment (16.1% vs 13.7% in the international trial and 8.9% vs 6.6% in the North American trial). Further development of itopride for use in functional dyspepsia has been halted.

### Tegaserod

Tegaserod is a selective serotonin type 4 receptor agonist that has been comprehensively studied in irritable bowel syndrome, especially in the subgroup of patients with constipation dominant symptoms, where it has shown efficacy using the endpoint of satisfactory relief. Its use has also been studied in two trials of patients with dysmotility-like functional dyspepsia [48]. For this diagnosis patients needed to have postprandial fullness, early satiety and/or bloating. As in the tegaserod IBS trial program satisfactory relief (>50% of the time) was used as a primary outcome measure. In addition, a composite score of average daily severity (measured on a seven-point scale, which had to show >1 point improvement) of the three inclusion criteria symptoms was used. The program only included women and the combined studies included 2667 patients. In one study, improvement in tegaserod treated patients of borderline statistical significance was observed, but this improvement was not observed in the second study. When the results of the two studies were combined there was a 4.6% increase in days with satisfactory relief. This difference, in the author's opinion, is not clinically meaningful, especially in view of the fact that diarrhea as an adverse effect requiring study discontinuation was experienced

more commonly with tegaserod than with placebo (4.1% vs 0.3%) [48]. Unfortunately, tegaserod was withdrawn from the market in 2007 because of a small increase in cardiovascular events in post-marketing surveillance.

In summary currently there is no convincing evidence for use of prokinetic agents in treatment of functional dyspepsia.

### Anti-*Helicobacter* therapy

The prevalence of *H. pylori* in functional dyspepsia varies from 30% to 70%, but this is in large part dependent on known risk factors for *H. pylori* infection: age, socioeconomic status and race [49, 50]. Due to differences in study design and problems with selection bias, it is still unclear whether the prevalence of *H. pylori* infection is increased in patients with functional dyspepsia compared with normal controls, although a meta-analysis suggested that it is [51]. A hotly debated issue over the past 15 years has been the question of whether cure of *H. pylori* infection leads to a sustained improvement in symptoms of functional dyspepsia.

Related to this is the question of whether testing and treating for *H. pylori* infection is a worthwhile strategy in patients presenting with uninvestigated dyspepsia. Such testing can be done without the need for endoscopy by using a urea breath test or *Helicobacter* serology. A detailed discussion about this approach is beyond the scope of this chapter, which deals with functional dyspepsia, but there is evidence that it may lead to long term symptom improvement in a proportion of patients [10, 11, 12, 20].

Although there have been differences in the methodological quality of anti-*Helicobacter* therapy functional dyspepsia studies several high quality studies with large sample sizes have also been conducted [41]. A Cochrane meta-analysis on this topic was updated in 2006 [52]. Importantly, in this systematic review dyspepsia outcome measures were dichotomized into minimal remaining or resolved symptoms versus same or worse symptoms. Twenty-one trials met inclusion criteria, of which eighteen trials compared antisecretory dual or triple therapy with placebo antibiotics +/- antisecretory therapy. The study duration varied from 3 to 12 months. For the combined sample of 3566 patients there was a 10% relative risk reduction in the *H. pylori* eradication group (95% CI: 6–14%) compared to placebo. This translates to a number needed to treat to cure one case of dyspepsia of 14 (95% CI: 10–25). Based on these data it appears that there is a small but statistically significant benefit in curing *H. pylori* infection in infected non-ulcer dyspepsia patients. It is important to keep in mind that the overall contribution of *H. pylori* infection to functional dyspepsia is small and that despite cure of the infection many patients will have ongoing dyspepsia symptoms. It is possible that the benefit is mainly limited

to patients who have an underlying ulcer diathesis, but at the moment there is no reliable method to identify this subgroup of patients. Given that *H. pylori* is a true pathogen that leads to peptic ulcer disease in 5–15% of infected individuals and is associated with gastric cancer in up to 1% of patients, it seems reasonable that patients with chronic dyspepsia symptoms who come to endoscopy are tested for the infection and treated if positive.

### Use of antidepressants

Functional dyspepsia patients who do not respond to H<sub>2</sub>-RAs, PPIs, prokinetic agents and anti-*Helicobacter* therapy (if positive) are a difficult group to treat. As with IBS patients antidepressant therapy has been tested in this patient group. However, the overall evidence in favor of their use, when obvious psychopathology is absent, is weak. A Cochrane review identified only four trials, each of which used different psychological interventions so that no formal pooling of results was possible [53]. All trials reported that psychological interventions provided benefit in improving dyspepsia symptoms. An identified weakness in all trials was the use of statistical techniques that adjusted for baseline differences between groups. This was likely necessary to compensate for small sample sizes [53]. Unadjusted data was not statistically significant. The other problems in the included studies were low recruitment and high drop-out rates. The authors concluded that there were insufficient data to determine whether psychological interventions were effective in functional dyspepsia.

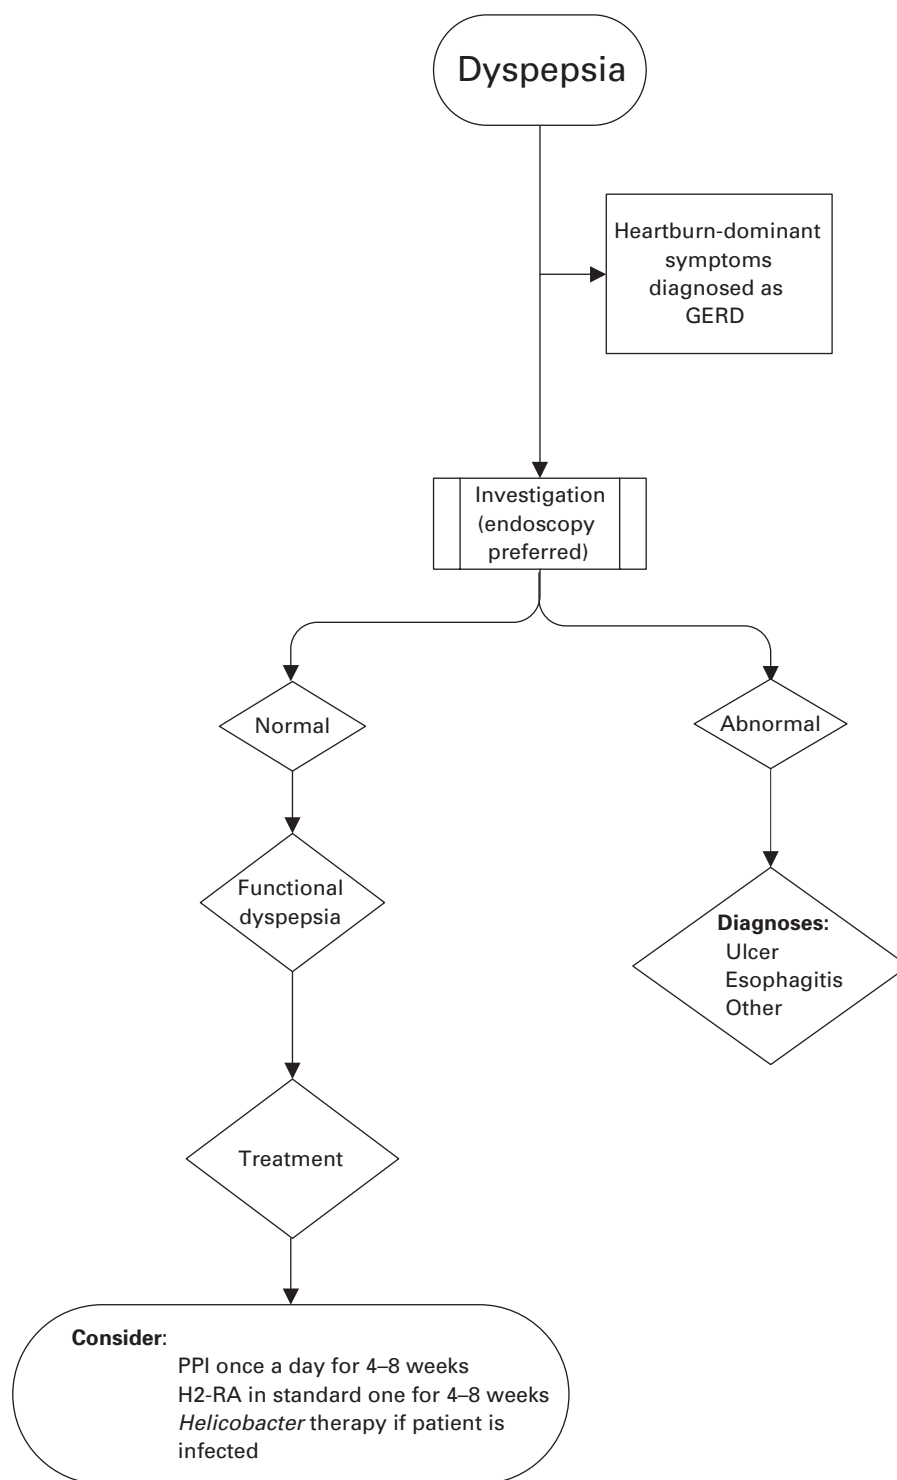

Recently, a study was reported in 166 functional dyspepsia patients who were randomized to treatment for eight weeks with either placebo or the serotonin and norepinephrine reuptake inhibitor venlafaxine (two weeks, 75mg once daily, four weeks, 150mg once daily, and two weeks, 75mg once daily) [54]. There was no difference in the proportion of venlafaxine treated patients who were symptom-free after eight weeks of treatment or at 20 weeks after inclusion, when compared to placebo (37% versus 39%).

Given the limited amount of available data the use of antidepressant therapy can not be recommended for functional dyspepsia patients.

---

## Conclusion

There are methodological shortcomings in many functional dyspepsia treatment trials, but their quality has improved over the last five years, in large part due to contributions of the pharmaceutical industry who have conducted many large-scale studies. There are no large sample size trials which compare the main treatment options for which there is supporting evidence: H<sub>2</sub>-receptor antagonists, PPIs and anti-*Helicobacter* therapy for patients who are *H. pylori* posi-

**Figure 9.1** Algorithm for dyspepsia.

tive. An algorithm that may serve as a useful guide is presented in Figure 9.1. It is reasonable to give functional dyspepsia patients a trial of acid suppression with either an H<sub>2</sub>-RA or a PPI. Evidence for effectiveness of PPIs is stronger. For all these treatments it is possible that patients with unrecognized GERD represent the main group who

respond to acid suppression, or that associated heartburn is a driver of response. There is evidence that cure of *H. pylori* infection will lead to a sustained improvement of functional dyspepsia symptoms in a small proportion of patients. Given that *H. pylori* is a true pathogen, capable of producing peptic ulcers and sometimes gastric cancer it is

advisable that patients coming for endoscopy are tested for *H. pylori* and treated if positive. There is no evidence that supports the use of currently available prokinetic agents and similarly the evidence for use of antidepressants is also weak.

# Celiac disease: Diagnosis, treatment and prognosis

*James Gregor and Michael Sai Lai Sey*

Department of Medicine, University of Western Ontario, London, Ontario, Canada

Since its first description in children by Gee [1] over a century ago, the term celiac disease has been used interchangeably with such designations as primary malabsorption, gluten-sensitive enteropathy, and non-tropical or celiac sprue. Due to the protean nature of its clinical manifestations and their consistent improvement with appropriate therapy, few medical conditions can rival celiac disease for both the frustration and gratification experienced by clinicians and patients.

The first clinical description of celiac disease in adults was provided by Thaysen [2] in 1932. In the early 1950s, Dicke first reported a putative link between the disease and the ingestion of certain grains [3]. Over the next decade the characteristic intestinal lesion was described in both surgical specimens [4] and those obtained using the newly developed peroral suction biopsy technique [5].

## Epidemiology

Celiac disease is most common in western Europeans and in immigrants from this area to North America and Australia; it is less common in non-Caucasoids, and although reported in Indians, Arabs, Hispanics, Israeli Jews, Sudanese and people of Cantonese extraction, it is very rare in those of Afro-Caribbean extraction. The true prevalence of celiac disease remains difficult to ascertain, and the prevalence varies with the intensity of screening [6].

Until the advent of new, accurate serologic tests, celiac disease was presumed to be a rare entity, with a prevalence of 1:1500 in Europe and 1:3000 in the USA [7]. The recognition of atypical presentations of disease has led to intensified serologic screening followed by intestinal biopsy, and

this protocol has revealed a true prevalence ranging from 1:300 in the UK [8] to 1:150 in Ireland [9, 10]. In the USA, screening of blood from 2000 blood donors has found a prevalence of raised anti-endomysial antibodies of 1:250 [11], while a retrospective cohort of 3654 school-aged subjects in Finland estimated a prevalence approaching 1 in 99 [12]. The suggestion has been made that celiac disease detected by screening is not silent, but rather undetected, given the range of pathology and symptomatology that correlate with this disease [13, 14].

## Clinical manifestations

The clinical manifestations of celiac disease are largely due to nutrient malabsorption, with iron-deficiency anemia being the most common presenting finding in an adult celiac patient [15]. Other symptoms, such as severe abdominal pain, nausea and vomiting are much less common. Although some patients may even complain of constipation, most describe increased stool volume. The diarrhea of celiac disease is classically described as high volume, pale, loose to semi-formed and foul-smelling. However, in many cases it is watery, probably due to the effects of malabsorbed fat and its bacterial degradation products on the secretory mechanisms of intestinal mucosal cells. A high fat content may produce an oily or frothy appearance and a high gas content can make the stools difficult to flush from the toilet bowl.

Constitutional symptoms of fatigue, weakness and weight loss, often despite a history of hyperphagia, are common. Many of these symptoms can be attributed to the presence of nutritional deficiencies. In some patients, insufficient calories and protein are absorbed to meet nutritional requirements and weight loss and muscle wasting ensue. Specific deficiencies resulting in anemia, bleeding diathesis, tetany, neuropathy and dermatitis can also occur.

Given the genetic and immunological factors felt to be important in the pathogenesis of the disease, it is not sur-

prising that investigators have sought and reported an association between celiac disease and over 100 medical conditions [16]. By far the most common of these is dermatitis herpetiformis. This pruritic rash is typically papulovesicular and characterized by IgA deposits at the dermal-epidermal junction. If adequate biopsies are performed, villous atrophy has been identified in up to 95% of these patients. In support of the validity of this association is the observation that the characteristic blistering skin lesions tend to improve in response to a gluten-free diet, although at a slower rate (up to two years) than the intestinal lesions [17].

Lymphocytic infiltration of the epithelium of the colon and even stomach has been widely reported in celiac disease. Recent data suggest, however, that the majority of patients with microscopic or collagenous colitis do not have serological evidence of disease [18].

Type I diabetes mellitus has been described in up to 5% of patients with celiac disease [16] and a similar proportion of insulin dependent diabetics has been reported to have occult villous atrophy [19, 20]. Autoimmune thyroid disease and selective IgA deficiency [21] also appear to be more prevalent in patients with celiac disease. Studies linking celiac disease to other autoimmune diseases such as ulcerative colitis [22], primary biliary cirrhosis [23] and sclerosing cholangitis [24] are primarily family studies or small case series.

Screening studies suggest an increased prevalence (up to 7%) of celiac disease in patients with Down's syndrome [25, 26]. In one study this generated an odds ratio as high as 100, compared to the general population [27]. However, due to the small number of celiac patients diagnosed in the groups with Down's syndrome, a statistically significantly increased prevalence has not been demonstrated uniformly.

## Pathology

Celiac disease primarily affects the mucosal layer of the small intestine, often involving only duodenum and jejunum, with damage decreasing in severity more distally. In severe disease, the entire length of the small bowel may be involved, and there have even been occasional reports of abnormalities of the gastric and rectal mucosa [14]. The characteristic lesion includes lymphocytic infiltration of the lamina propria and, in particular, the surface epithelium, resulting in villous atrophy and crypt hyperplasia. The degree of villous damage ranges from mere blunting to total atrophy. The degree and extent of disease involvement grossly correlates with the severity of gastrointestinal symptoms [28]. In some studies the prevalence of asymptomatic celiac disease is four-fold greater than the prevalence of symptomatic disease [29].

Historically, the gold standard for the diagnosis of celiac disease has required not only the identification of the typical histological lesion, but also clinical and histological improvement with appropriate dietary therapy. It has been clearly demonstrated in human subjects that the instillation into the small bowel of wheat, rye, or barley flour or their alcohol-soluble protein components, "prolamins", produces both clinical symptoms and histological lesions [30].

Wheat gluten must be processed into alcohol soluble prolamins in order to develop antigenicity. Although the exact epitope(s) within gluten remain unknown, the generation of this epitope from the antigenic wheat protein is accomplished by a brush border enzyme known as tissue transglutaminase (tTG). Once the epitope has been generated by the tTG enzyme, the enzyme itself becomes one of the targets of the autoimmune response [14].

Although the environmental trigger of wheat gluten is implicated in the development of this disease, it is apparent that genetic factors also play a prominent role. Concordance between identical twins approaches 100%, and first-degree relatives of celiac disease have a 10% prevalence of CD, which is higher than that cited in the general population [15]. Current theories of disease pathogenesis therefore focus on the interaction between the antigen (wheat gluten) and the HLA predisposition of affected individuals. Over 95% of patients with CD express the HLA DQ (a1\*501,  $\beta$ 1\*02) heterodimer (HLA-DQ2). This class II MHC molecule exists on antigen-presenting cells, including the gluten-sensitive T helper cells, which preferentially present gluten-derived gliadin peptide epitopes to intestinal mucosal T cells. A Th1/Th0 type inflammatory response is mounted, thus producing the observed mucosal damage. One of the targets of this autoimmune response is the tTG brush border enzyme which generates the gluten-derived epitope. An anti-tTG assay may therefore be used to screen populations for celiac disease [14, 15].

Much of the fundamental research relating to celiac disease in recent years has focused on the immunologic and genetic factors associated with sensitivity to gliadin and the other prolamins. In clinical practice the diagnosis and treatment of the disease are well-defined. Thus most of the recently published clinical research has addressed a few specific questions, namely:

- (1) **Diagnosis:** the role of the anti-endomysial antibody and the anti-tissue transglutaminase antibody for screening populations at risk, diagnosing symptomatic individuals and following the response to a gluten-free diet.
- (2) **Treatment:** whether oats (or specifically the oat prolamins avenin) can safely be consumed by patients with celiac disease or dermatitis herpetiformis.
- (3) **Prognosis:** whether patients are at an increased risk of malignancy and other autoimmune diseases, and whether adherence to a gluten-free diet reduces that risk.

## Serological testing

In patients with typical signs, symptoms and laboratory parameters the diagnosis of celiac disease is usually made by performing a mucosal biopsy of the small bowel. Though the differential diagnosis of villous injury is long (including tropical sprue, lymphoma, cows' milk induced enteritis, Zollinger–Ellison syndrome, Whipple's disease, eosinophilic gastroenteritis, bacterial overgrowth, and even viral gastroenteritis), in most patients the diagnosis is not in doubt. From the 1950s until the introduction of flexible endoscopic equipment, specimens were usually obtained using peroral suction instruments, a cumbersome procedure which was uncomfortable for the patient. With the recognition of the immunological nature of the disease it was predictable that serological testing would be developed and evaluated to simplify diagnosis and to facilitate the institution of screening programs in areas of high prevalence.

A number of serological tests have been developed employing antireticulin antibodies (ARA), antigliadin antibodies (AGA), anti-smooth muscle endomysium antibodies (EMA) and, more recently, anti-tissue transglutaminase antibodies (tTG). Given that the pathogenesis of celiac disease appears to involve the interaction between cereal grain gluten, or more specifically the alcohol-soluble gliadins, it is not surprising that many of the early reports have focused on AGA as the primary serological test. As is often the case following the introduction of a new diagnostic test, the initial promise has to some degree yielded to acknowledgement of the test's limitations. Most studies have examined both the IgG and IgA subsets of AGA [31, 32]. The data demonstrate reasonable sensitivity (69–91%) but poor specificity (2–79%) for the IgG antibody, suggesting that it may be a general marker for increased gut permeability of any cause rather than an important factor in disease pathogenesis. The IgA AGA has improved specificity (90–94%) at the expense of sensitivity (66–87%).

The development of the anti-endomysial antibody test has produced a renewed interest in serological diagnosis. Initial reports suggested almost perfect test accuracy in subjects not restricted to a gluten-free diet. Because it employs an IgA antibody, it is acknowledged that the test may be falsely negative in a celiac patient with associated IgA deficiency. The test is generally performed on serum diluted at 1:10 and 1:20 concentrations, using an immunofluorescence technique. The substrate used is derived from monkey esophagus, which has the disadvantages of being expensive (US\$20–40) and morally controversial. Recently, studies have shown that using human umbilical cord as a substrate (UCA) produces similar test results [33–36].

One of the largest studies evaluating the EMA assay involved 22 pediatric gastroenterology centers throughout Italy [37]. Almost 4000 children underwent testing with both AGA (IgA and IgG) and IgA EMA. "Gold standard" biopsies had been obtained from all patients with a diagnosis of celiac disease who had not yet been placed on dietary therapy ( $n = 688$ ) and from those with compatible gastrointestinal symptoms who subsequently were given a different diagnosis ( $n = 797$ ). Limiting the analysis to these two groups, the EMA assay was more sensitive than the IgG AGA assay (94% vs 90%) and more specific than the IgA AGA assay (97 vs 90%), both differences being statistically significant. Healthy first-degree relatives ( $n = 599$ ) were also studied. Of the 46 positive EMA results (7.6%), 32 underwent biopsy. Ninety percent of these patients were found to have pathological changes consistent with a diagnosis of celiac disease. In patients on a strict gluten-free diet ( $n = 96$ ) it was found that 81% were negative for EMA, suggesting that the test may have a role in monitoring intestinal response after diagnosis.

One useful way of summarizing the utility of a test is to consider both its positive and negative likelihood ratios (LR). In Bayesian analysis the appropriate LR (depending on the positivity or negativity of the test) is multiplied by the estimated pretest odds to determine the likelihood that a particular condition is present or absent. Positive LRs greater than 10 and negative LRs less than 0.1 are generally agreed to be quite useful. Consider an example of a patient with non-specific symptoms and a family history of celiac disease in whom the pretest likelihood of celiac disease was estimated to be 8% (odds of 2:23). Using the LRs from the large Italian study [37] of 31 and 0.06 respectively, the post-test likelihood of celiac disease after a positive test would be 65% and after a negative test 0.5%. In a patient with more specific symptoms and therefore a higher pretest probability estimated at 50%, a positive test would produce a post-test likelihood of 97% while a negative test would reduce this likelihood to 6%. Similarly, if one screened the general population (with a prevalence of 0.25%) the post-test probabilities would be much different at 8% and 0.02% respectively, significantly lower than a high risk or symptomatic population.

There have been many studies from several countries [29, 33–49] that have evaluated the diagnostic accuracy of EMA. Though varied in sample size, ranging from 35 to 1485 children and adults, the majority have consistently found a positive LR greater than 10 and negative LR less than 0.1.

The discovery of tissue transglutaminase (tTG) as the antigen recognized by EMA has led to the development of assays to directly detect the tTG antibody. Since tTG assays utilize ELISA, they offer several advantages over conventional immunofluorescence based EMA, which is more

labour intensive, subjective in nature and require a limited substrate (monkey esophagus or umbilical cord).

In a 2005 systematic review of the diagnostic performance of serologic tests for celiac disease, the sensitivity and specificity of tTG was found to be comparable to EMA [50]. Rigorous studies utilizing duodenal biopsies as the gold standard were included in the review and weighted sensitivities and specificities were calculated separately for EMA (EMA-monkey esophagus, EMA-umbilical cord) and tTG (tTG-human recombinant (tTG-HR), tTG-guinea pig (rTG-GP)) in children and adults. The sensitivity and specificity for EMA was found to be approximately 96% and 100% respectively, with the exception of EMA-umbilical cord which had a sensitivity of only 90% in adults. In comparison, tTG-HR had a sensitivity and specificity of approximately 96% and 99% respectively. The performance of tTG-GP was inferior to tTG-HR, with a sensitivity and specificity of approximately 90% and 95% respectively.

Subsequent to this systematic review, numerous articles have been published regarding the test performance of tTG (Table 10.1) [51–60]. As in the systematic review, sensitivities and specificities in these studies generally exceed 90%. In the largest study, Hopper *et al.* prospectively biopsied 2000 adult patients referred for gastroscopy and determined the sensitivity and specificity of tTG to be 91% [53]. These results represent the lower end of the spectrum for tTG sensitivity and specificity, which is likely a function of

the study design. Unlike other studies, Hopper *et al.* selected a group of general gastroenterology patients who had a low risk for celiac disease, thus minimizing their ascertainment bias. In addition, the prospective nature of their study is consistent with the general observation that prospective studies often yield results of lesser magnitudes than retrospective ones. Lastly, unlike studies that biopsy only those in the control group who have positive serology, Hopper *et al.* biopsied all patients, resulting in the diagnosis of six cases of seronegative celiac disease. Studies that do not biopsy all patients fail to detect false negatives, resulting in a falsely elevated sensitivity.

Although non-invasive and relatively inexpensive, tTG is unlikely to replace endoscopy for the diagnosis of celiac disease. The primary limitation of this marker is its imperfect sensitivity. Several studies have documented a significant reduction in the sensitivity of tTG in patients with low grade lesions [50, 53]. In one report, the sensitivity of tTG decreased from 100% for patients with Marsh 3c lesions to 86% for patients with Marsh 3a [53]. In addition, since the most commonly utilized tTG assays detect the IgA immunoglobulin, patients with selective IgA deficiency may receive false negative results. Since selective IgA deficiency is associated with a 10–20-fold increased risk for celiac disease, this population represents a significant cohort of patients who are at risk [61]. Preliminary trials of IgG-tTG are limited in size and have reported mixed results, with

**Table 10.1** Sensitivity and specificity of tTG in recent studies utilizing small bowel biopsy as gold standard for celiac disease.

sensitivities and specificities ranging from 23 to 100 and 89 to 100, respectively [50, 58, 61]. Even in the absence of IgA deficiency, a small population of seronegative celiac patients exists, which would not be detectable with tTG assays. As a result of these limitations, tTG will likely remain as an adjunct to endoscopy for the diagnosis of celiac disease rather than a replacement.

## Therapy

The mainstay of therapy for celiac disease is a lifelong gluten-free diet. Because biopsy findings suggesting celiac disease may also be compatible with other conditions, some clinicians advocate a follow-up biopsy to confirm remission after implementation of a gluten-free diet. However, most are satisfied with a symptomatic response. In addition to a gluten-free diet, supplemental vitamins such as iron, folic acid, or vitamin K should be given where deficiencies are documented. Calcium and vitamin D may be deficient, and consideration may be given to measuring bone mineral density, particularly in women. Although it is suggested that the institution of a gluten-free diet protects against increasing bone loss, some patients may be candidates for hormone replacement or bisphosphonate therapy [62].

Poor dietary compliance is the most common reason for failure of a gluten-free diet. However, the complications of intestinal lymphoma and adenocarcinoma must be considered. Patients with persistent symptoms in whom other diagnoses are excluded are described as having refractory sprue [63]. There are considerable uncontrolled data to support the use of corticosteroids for this indication. Anecdotal evidence suggests that azathioprine [64] and cyclosporine [65] may also be effective in patients who do not respond to corticosteroids. In one known case of steroid-refractory celiac disease, infliximab followed by azathioprine was successfully used to induce and maintain remission [66]. In a subset of patients with refractory celiac disease, there is an increase in aberrant intraepithelial lymphocytes. Denoted refractory celiac disease type II, these patients have a significantly increased lifetime risk for enteropathy associated T cell lymphoma. Due to its resistance to conventional treatment regimens the prognosis is poor, with a five-year survival of less than 50% [67]. Emerging research into novel treatment strategies have been disappointing. In an open label phase II pilot study, Al-Toma *et al.* [68] evaluated the use of cladribine, a cytotoxic purine nucleoside, to treat type II refractory celiac disease. Of the 17 patients enrolled in the study, six demonstrated a clinical improvement (weight, diarrhea, hypoalbuminemia), 10 developed a histological improvement, and six had a decrease in aberrant T cells. Although one patient developed complete clinical and histological

recovery, seven patients still developed fatal enteropathy associated T cell lymphoma and one died secondary to complications of emaciation. The authors concluded that cladribine may induce clinical and histological improvement in a minority of patients but does not prevent T cell lymphoma and may in fact precipitate it.

Currently, the greatest controversy pertaining to therapy is the safety of including modest amounts of oats in the diet. Historically, wheat and rye were the first grains with demonstrated toxicity in celiac patients, followed subsequently by reports of toxicity with oats and barley. Similar injurious effects were not found with corn, rice and potatoes [69]. Biologic plausibility exists for the safety of oats, which stems from three primary difference between the gluten found in oat (avenin) and wheat (gliadin), barley (hordein) and rye (secalin) [70]. First, oat avenin is unique because it does not share substantial sequence homology with wheat gliadin, barley hordein, or rye secalin. Second, barley hordeins and rye secalins are antigenically related to wheat gliadin, whereas oat avenin is not. Third, oat avenin accounts for a smaller fraction of total protein as compared to wheat gliadin, barley hordein, or rye secalin. Thus, even if oat avenin were toxic in celiac disease, it would take a larger quantity to bring about the same effect as for wheat, barley, or rye. *In vitro* studies, however, have produced mixed results, with some studies demonstrating an immune response to avenin whereas others do not [71–73].

Despite this, clinical evidence is now accumulating to demonstrate a lack of toxicity of oats in newly diagnosed patients with celiac disease and in celiac disease patients in remission. In the largest study to date, Janathuinen *et al.* randomized 52 celiac patients on stable gluten free diets and 40 newly diagnosed celiac patients to a conventional gluten free diet (GFD) versus a GFD that included oats [74]. Patients in the established celiac disease group were followed for six months, while the newly diagnosed celiac group were followed for one year in terms of symptoms, BMI, laboratory parameters (hemoglobin, iron studies, albumin) and duodenal histology. Mean oat consumption was approximately 50g per day. Upon completion of the study, there was no significant difference in symptoms, BMI, laboratory parameters, or histology. All previously established celiac patients remained in remission and all newly diagnosed celiac patients were in remission at one year except for one in the control group. Six patients in the oats group withdrew from the study citing pruritis, abdominal complaints, or unspecified reason for withdrawing, although this was similar to the control group.

To provide long-term evidence for the safety of oats, a five-year follow-up study of the same patients was conducted [75]. Of the original 81 patients (39 oats, 42 controls) who had completed the initial study, 63 were recruited into the follow-up study (4 and 14 drop-outs in oat and control arm, respectively). Among the remaining 35 patients in the

oat group, 12 patients had stopped consuming oats, citing the following reasons: uncertainty regarding the long-term safety of oats (nine patients), flatulence (one patient) and rash (two patients). The remaining 23 patients in the oat group and 28 in the control group were subsequently enrolled in the study. During the five-year interval, mean oat consumption was 34g/day, with approximately two-thirds of patients consuming oats at least once a week. Similar to the original study, there was no significant difference in duodenal histology scores between those who consumed oats versus a conventional gluten-free diet. Although this study provides the first evidence of long-term safety of oats, it can be criticized for its high attrition rate. This is concerning as it may represent a substantial portion of symptomatic patients who were not accounted for.

To assess the safety of high doses of oats, Storsrud *et al.* challenged 20 celiac patients to a high dose oat diet [76]. During the two-year study period, patients were periodically assessed for symptoms, biochemical nutritional markers, EMA and duodenal histology. Fifteen patients completed the study, consuming on average 93g of oat/day. Similar to previous studies, there was no significant change in symptoms, biochemistry, EMA, or duodenal histology after exposure to oats. Three patients withdrew from the study for non-medical reasons and two withdrew due to abdominal distension and flatulence. Follow-up histology for both patients did not reveal any evidence of relapse and their symptoms were attributed to the increase in dietary fiber from the oats.

Despite the encouraging data supporting the safety of oats, significant concern remains due to the possibility of contamination with wheat, rye and barley. From the planting to the harvesting and manufacturing stage, multiple opportunities for contamination exist. In a 2008 study of 134 oat products from Canada, USA and Europe, 109 were found to be contaminated with wheat, barley, or rye [77]. The study utilized the new R5-ELISA assay, which replaced the conventional barley insensitive  $\omega$ -ELISA. Similarly, another study utilizing the R5-ELISA assay to examine four lots of oats from three brands found that only three lots were gluten free [78]. To address the issue of contamination, government and advisory bodies are beginning to implement purity standards for the production of pure oats. Recently, the Canadian Celiac Association, in conjunction with Health Canada and Agriculture Canada, established strict planting, harvesting, processing and testing criteria to facilitate the production of pure oats. Safety data for pure oats manufactured under these guidelines are lacking and future studies are needed to ensure the safety of these products.

For the time being, the ultimate decision regarding whether to incorporate oats into the gluten free diet will have to be made on a case by case basis. Although numerous studies support the safety of oats, the strength of the

evidence is generally limited by the small sample size. In addition, rare case reports have emerged describing cases of oat intolerance. In a 2003 case report, Lundin *et al.* [79] described a patient who developed diarrhea and villous atrophy during an oat challenge. During her oat challenge, her histology progressed from Marsh 1 to Marsh 3A. Elimination of oats from her diet resulted in resolution of her histology to Marsh 1. During a second oat challenge, her symptoms returned and she subsequently developed Marsh 3b lesions. Since the purity of the oats was confirmed by the barley insensitive w-ELISA assay in this case, it is plausible that her relapse was secondary to barley contamination although this cannot be confirmed. A minority of oat samples were further analyzed by western blot and mass spectrometry. Of six samples subject to additional testing, one was found to be contaminated. Thus, in deciding whether to include oats in the gluten-free diet, one must weigh the nutritional benefit of oats against the risk of contamination and the rare possibility of true oat intolerance.

---

## Prognosis

Celiac disease, if left unrecognized and untreated, has the potential to result in severe complications which are for the most part secondary to malnutrition. When appropriate dietary therapy is instituted, the prognosis for celiac disease is usually good; however, untreated, the morbidity and mortality, and the risk of certain malignancies has been postulated to be increased in a celiac population. Past studies have suggested an increase in age-adjusted mortality attributable to the disease itself [28]. However, these studies may have been biased because of the inclusion of substantial numbers of untreated patients. More recent studies have suggested that at least short-term survival is not different from that of the general population [16]. Despite this finding there is evidence, both from retrospective and cohort studies, which suggests an increased risk of certain malignancies [80]. A recent retrospective Italian study identified seven malignancies in a cohort of 549 celiac patients followed for a mean of seven years [81].

Immunological stimulation and increased permeability are among the characteristics of the gut in celiac disease which lend biological credence to the possibility that celiac patients are at increased risk for malignancies such as lymphoma and adenocarcinoma of the small bowel. Although the epidemiological studies are heterogeneous in their design and findings, most of the epidemiological evidence to date confirms a general increase in morbidity. The left-hand column of Table 10.2 summarizes some of the data from these studies.

Most of the reports are based on case-control studies. This design is particularly subject to problems with *bias* and *confounding*. A *selection bias* toward the inclusion of

**Table 10.2** A subjective assessment of current evidence attempting to establish a causal or non-causal relationship (see text).

particularly ill or refractory patients is one of the most frequently cited criticisms of the studies, which show a mortality rate that is increased as much as 3.4-fold over that of the general population [82–85] and complicating malignancy rates as high as 14% [83]. *Measurement bias* is another potential problem. Patients presenting with abdominal symptoms secondary to a malignancy may be more likely to undergo investigations like small bowel biopsy, which could lead to a diagnosis of celiac disease. Finally, some of the risk factors for celiac disease such as ethnic/geographic origin or immune markers (e.g. the class II HLA antigens HLA-DR3 and HLA-DQw2) could potentially be independent risk factors for certain diseases.

Despite these concerns, it is unlikely that the excess risk of small bowel lymphoma and adenocarcinoma seen in most studies can be explained by methodological flaws. In the early 1980s, a British registry collected data on approximately 400 cases of celiac disease and various cancers. The data were analyzed and compared to individual cancer rates in the local population [86]. Of the 259 histologically-confirmed tumors, slightly more than half of these were lymphomas, the majority of which had arisen in the small bowel. Two-thirds were discovered after the diagnosis of celiac disease was established at a mean interval of 7.3 years. A number of other studies have shown similarly high rates of lymphoma with death rates due to this complication varying from 2.6% to 8.9%, translating into relative risks of 25–122 with respect to the general population [87].

Of non-lymphomatous malignancies only those of the gastrointestinal tract were seen in excess, compared to the

general population. A statistically significant increased risk of adenocarcinomas of the pharynx, esophagus and small bowel was observed. The relative risk of pharyngeal or esophageal cancer was relatively small (five to six) and could possibly be explained by confounding risk factors. However, the relative risk of small bowel carcinoma, a rare malignancy in the general population, was markedly increased at 83 (95% confidence limits 46–117).

Another British series of 210 patients reported in 1976 [88] produced similar results. It was followed by a prospective cohort study published in 1989 [89] which also demonstrated increased cancer risk. The patients were a priori divided into three groups: patients following a strict gluten-free diet ( $n = 108$ ), patients intermittently adherent or adherent less than five years ( $n = 56$ ) and patients not adhering to any dietary restrictions ( $n = 46$ ). Increased risk was seen overall for cancers of the mouth, pharynx and esophagus (ratio of observed to expected (O/E) approached 10). The increase in risk was particularly strong for non-Hodgkin's lymphoma ( $n = 9$ ; O/E = 42.7). For these cancers there was a statistically significant reduced risk for the strict gluten-free diet group. In a follow-up article by the same author [90] on the same cohort of patients, *excess morbidity* for those not observing a gluten-free diet was confirmed.

Retrospective cohort and genetic studies on celiac patients who develop malignancy has yielded information on possible prognostic indicators of malignant disease. Refractory sprue, or celiac disease which does not respond to dietary treatment, is a negative prognostic indicator, possibly because of the ongoing immune stimulation which may predispose to malignant transformation. Non-response to therapy may be present from diagnosis or after a period of response to dietary therapy, but is always a negative prognostic indicator [90]. A confounding factor may exist in that other disease types that produce villous atrophy and inflammatory infiltrates may be present, such as ulcerative jejunitis or jejunoileitis or mesenteric lymph node cavitation syndrome, and thus the diagnosis of underlying celiac disease may be questionable. Genetic prognostic indicators are less well studied still. A small case study of six refractory sprue patients demonstrated the replacement of the normal IEL population with morphologically normal and phenotypically abnormal cells with intracytoplasmic CD3, no surface CD3, CD4, CD8 or TCR, and restricted TCR  $\gamma$  gene rearrangements. On this basis, the authors posited a spectrum of disease ranging from celiac disease to refractory sprue to enteropathy-associated T cell lymphoma (EATL), with refractory sprue being the transitional disease state between celiac disease and malignancy [91]. The same study showed a poorer prognosis for the three patients with the aberrant phenotype TCR  $\gamma$  gene rearrangement, intracytoplasmic CD3+, surface CD8–, and a better prognosis (in terms of treatment

response to diet and steroid therapy) for the three patients without this phenotype. This finding could be of practical importance, as non-response to treatment, coupled with the above phenotype implying a poor prognosis, would warrant closer follow-up for the implicated patient. Non-response to treatment in the absence of this phenotype would suggest non-compliance with dietary therapy.

The risk of malignancy in patients with dermatitis herpetiformis has also been studied. One study used a retrospective cohort design [92] to evaluate 109 patients who were followed for 13 years at one clinic, with almost complete follow-up. Seven patients (6.4%) developed a malignancy, three of which were lymphomas, one without small intestinal involvement. This translated into a relative risk of lymphoma of 100. The overall relative risk of malignancy was 2.38 (95% confidence intervals 1.22–3.56). However, in those patients adhering to a gluten-free diet, no increased risk was seen. A subsequent Finnish study [93] of 305 patients in whom 81% were compliant with a gluten-free diet also showed no excess risk of malignancy, with the exception of non-Hodgkin's lymphoma ( $n = 4$ ) (RR = 10, 95% confidence intervals 2.8–26.3). A cohort study of 487 patients with dermatitis herpetiformis reported a 2% incidence of lymphoma while on a normal diet or a gluten-free diet for less than five years [94].

In contrast to these results, another retrospective cohort study originating in Finland [16] compared 335 celiac patients to age and sex-matched controls with other gastrointestinal disease and normal villous architecture. A statistically significant increased incidence of endocrine disease (12%) and connective tissue disease (7%) was observed, but no increased incidence of malignancy was detected. Notably, no cases of small bowel adenocarcinoma or non-Hodgkin's lymphoma were identified. This negative finding may be accounted for by either the relatively short mean follow-up (3.1 years) or the high rate of dietary compliance with a strict gluten-free diet (83%).

Though debate persists on the magnitude and type of cancer for which untreated celiac patients are at risk, there is general acceptance among clinicians that the risk is significant enough to warrant lifelong strict dietary compliance even in asymptomatic patients. This concern is foremost among those advocating that oats should not be included in a gluten-free diet [95]. Table 10.2 suggests that the evidence supporting the view that the inclusion of modest amounts of oats in a celiac diet is safe may actually be stronger than the data demonstrating an increased cancer risk in celiac patients.

Strict dietary therapy is warranted in adolescent and pediatric populations alone on the sole basis of prevention of morbidity, even if the questions of malignancy and mortality are set aside. A large retrospective cohort analysis of 909 pediatric and adolescent celiac patients, 1268 control subjects and 163 patients with Crohn's disease was under-

taken to determine the effect of duration of gluten exposure on the development of autoimmune disease in patients with celiac disease [96]. The prevalence of autoimmune disorders was noted to be significantly increased in the celiac population (14%) with respect to the control population (2.8%) but not with respect to the Crohn's disease population (12.9%). When the celiac population was subdivided into groups according to age at diagnosis, a surrogate for duration of gluten exposure, it was noted that the first group (<2 years at diagnosis; 5.1% prevalence) did not have a significantly different prevalence of autoimmune disease compared to the control group, but that the second group (2–10 years; 17.0% prevalence) and the third group (>10 years; 23.8% prevalence) did have a significantly increased comparative prevalence of autoimmune disease. Furthermore, a logistic regression model predicted increased odds of developing autoimmunity of 1.1% per year of diagnosis delay, with the expected numbers derived from this model correlating well with the observed study numbers. A second analysis of a subset of the 374 celiac disease patients who were diagnosed before the age of two years was subdivided on the basis of exposure to a gluten challenge following diagnosis, and those exposed to gluten for an additional "challenge" period following diagnosis were susceptible to an increased prevalence of autoimmune disorders. The implications of this study support early clinical diagnosis with serologic and histologic confirmation, and avoidance of prolonged exposure to gluten, even in the form of a gluten challenge.

This study has been challenged by a subsequent, similar study in an adult population [95]. This retrospective cohort analysis analyzed 605 controls and 422 celiac disease patients. Although the prevalence of autoimmunity was three-fold higher in the celiac population than in controls, the duration of gluten exposure did not correlate with the development of autoimmunity in an adult population. The two studies may be reconciled by the pathogenesis of the disease; it is possible that immune modulation and gluten exposure play a role in the development of disease early in life, and that once exposure has occurred in youth, circulating autoantibodies to various organs arise and the risk of later development of autoimmune disorders is subsequently increased in the adult celiac population [97].

Other complications of celiac disease exist in addition to those listed above, but are more rarely seen than autoimmune disease and malignancy. These include refractory sprue, which often requires immunosuppressive therapy. Ulcerative jejunoileitis manifesting as chronic ulcers of the small and occasionally large bowel can rarely occur and can lead to the diagnosis of celiac disease [80]. This condition can be difficult to distinguish from intestinal lymphoma and may actually progress to this disease. Collagenous sprue, an even more rare complication of celiac disease, is histologically distinguished by a thick

subepithelial band of collagen. No effective therapy has been described and patients generally go on to parenteral alimentation [6, 98].

## Conclusion

The gold standard for the diagnosis of celiac disease remains the small bowel biopsy. Serological testing, particularly the anti-endomysial antibody and tissue transglutaminase, can be very useful in the appropriate clinical situation to diagnose the disease and to monitor the response to a gluten-free diet. The threshold for initial and follow-up biopsy, if necessary, should be low given the limitations of the test and the general ease of upper gastrointestinal endoscopy and biopsy. A gluten-free diet remains the cornerstone of management. The available evidence suggests that a substantial proportion of patients will tolerate a moderate amount of oats in their diet with the appropriate clinical follow-up. To prevent symptomatic recurrences, nutritional deficiencies (particularly bone disease), and malignant and autoimmune complications, a strict gluten-free diet should be encouraged in all patients.

## Crohn's disease

*Brian G Feagan and John WD McDonald*

Robarts Clinical Trials, Robarts Research Unit, University of Western Ontario, London, Ontario, Canada

### Introduction

The use of non-specific, anti-inflammatory drugs, such as the 5-aminosalicylates, glucocorticoids and antimetabolites was the foundation of the current management of Crohn's disease (CD). However, recent advances in molecular biology have yielded novel approaches which may be more relevant to the pathophysiology of the disease. This review offers an evidence-based approach to the management of active CD and of interventions that have been evaluated for maintenance therapy.

### Induction of remission

An ideal treatment for active CD should rapidly and reliably induce remission of symptoms. In clinical trials the most frequently used metric is a decrease in the Crohn's Disease Activity Index (CDAI) of from 50 to 100 points with a final score below 150 [1, 2]. A substantial placebo response (20–30%) is observed in short-term (8–16 week) studies. Four classes of drugs have been most frequently evaluated for treatment of active disease: 5-aminosalicylates (5-ASA), glucocorticoids, antibiotics and monoclonal antibodies.

### 5-aminosalicylates

The prototypic 5-ASA compound sulfasalazine has been used to treat CD for more than 40 years [3]. Although highly effective for ulcerative colitis, randomized trials showed that sulfasalazine was only marginally superior to a placebo for the induction of remission in active CD (see

Figure 11.1) [4, 5]. **Aic** Since the sulfa-related adverse effects of sulfasalazine often limit the maximum drug dose that can be administered, the development of 5-ASA formulations which lack a sulfa moiety and which target specific regions of the gastrointestinal tract raised the possibility that greater efficacy was possible. Multiple randomized controlled trials (RCTs) have compared the newer 5-ASA compounds with either a placebo (see Table 11.1) or an active treatment (sulfasalazine, glucocorticoids). Although many of these trials were at a high risk of a type II statistical error due to a small sample size, some definite conclusions can be derived.

Initial experience with 5-ASA doses of 1–5 g/day showed no clear benefit over a placebo [6, 7]. These negative studies led to the evaluation of higher dose regimens. Singleton and colleagues allocated over 300 patients with moderate disease activity to receive either 1 g, 2 g or 4 g of Pentasa daily or a placebo for a period of 16 weeks [8]. Although 5-ASA was well tolerated, only a modest benefit of treatment was observed; 43% of the patients who received 4 g/day of Pentasa entered remission as compared with 18% of those who were assigned to the placebo (absolute risk reduction (ARR) 25%, number needed to treat (NNT) 4;  $p = 0.017$ ). **Aic** No improvement over placebo was observed for those individuals who received the lower doses of 5-ASA. Subgroup analyses failed to identify any specific predictors of response. Pentasa was well tolerated; more patients who received the placebo were withdrawn from treatment due to adverse events than those who received the highest dose of the active drug.

Although this trial suggested a benefit of high dose 5-ASA therapy, a cautionary note was raised subsequently by the principal investigator, who described a second evaluation of Pentasa in 232 patients [15]. Data from this trial and a third unpublished study performed by Hanauer and associates have been combined in a meta-analysis, which suggested that patients assigned to 4 g/day Pentasa ( $n = 304$ ) improved on average only 18 points more on the CDAI score than those who received a placebo ( $n = 311$ )

No. significant

Prednisone (P)	85	74	57	52	58	57	54	55	52	50	45	44	43	41	40
Sulfasalazine (SPS)	74	65	62	50	58			56	55	51	48	25

Placebo	77		72		69	67	64	62	60	59	58	57			

**Figure 11.1** Cumulative percentage of patients in remission week by week: comparison of prednisone, sulfasalazine, azathioprine and placebo. Remission is defined as Crohn's Disease Activity Index (CDAI) less than 150 and continuing below 150 through week 17 (life-table using Kaplan-Meier method). Adapted with permission from Summers RW *et al.* *Gastroenterology* 1979; **77**: 847-694.

[16]. **Ala** No difference in remission rates was observed. Readers should be aware that a minimum clinically important difference in CDAI score is approximately 50 points.

No trials of adequate power have compared the efficacy of the newer 5-ASA drugs and sulfasalazine. However, several studies have compared 5-ASA to glucocorticoid therapy for induction of remission (see Table 11.1). Schölmerich randomized 62 patients to receive either 5-ASA at a dose of 2g/day or a standard tapering regimen of methyl prednisolone [9]. In this 24-week trial 73% of the 5-ASA-treated patients failed therapy compared with 34% of those who received methyl prednisolone (ARR 39%, NNT = 3;  $p = 0.0019$ ). **Aic** The authors concluded that treatment with 5-ASA, although well tolerated, was inferior to steroid therapy. Martin *et al.* compared a 3g/day dose of Salofalk to a standard oral prednisone regimen [10]. Although a similar proportion of individuals in the two treatment groups entered remission (47% 5-ASA vs 46% prednisone;  $p = 0.59$ ), an analysis of the change in mean CDAI and quality of life scores demonstrated a more rapid improvement in patients treated with prednisone. A study by Thomsen and colleagues provides important information on the relative efficacy of glucocorticoids and 5-ASA

[12]. In this methodologically rigorous trial 182 patients with active disease were assigned to receive either 9mg/day of a controlled ileal release preparation of budesonide (a locally active steroid) or 4g/day of Pentasa. Following 16 weeks of treatment, 62% of budesonide treated patients were in remission compared with only 36% of the patients who received 5-ASA (ARR 26%, NNT = 4,  $p < 0.01$ ). **Aid**

What conclusions can be drawn from these trials? The existing data show that the newer 5-ASA compounds are not more effective than sulfasalazine and are, at best, only marginally superior to a placebo for the induction of remission. A single clinical trial has demonstrated the superiority of budesonide over high dose 5-ASA, with no increased frequency of adverse events. Although many clinicians prescribe 5-ASA compounds as first-line therapy for mild disease activity and treat those patients who fail to achieve a remission with glucocorticoids, the wisdom of this approach is questionable. Although the reluctance of physicians to expose individuals to glucocorticoid therapy is understandable, the likelihood of a response to the newer 5-ASA formulations is so low that the strategy is inefficient. Most patients will ultimately require the more potent agents discussed below to induce remission. In any event,

**Table 11.1** Response rates of remission in studies comparing 5-ASA to placebo or glucocorticoid therapy.

Study	Drug dose	No. of patients	Duration (weeks)	Placebo	% remission 5-ASA	GL
NCCDS (1979) [4]	SPS 4–6 g/day	236	17	30	43	—

if a 5-ASA drug is used for induction of remission in patients with mild disease the best evidence supports the use of sulfasalazine. **A1c**

## Glucocorticoids

### Conventional steroids

The conventional glucocorticoid compounds, prednisone and 6-methyl prednisolone, are highly effective drugs for the treatment of active CD. The National Cooperative Crohn's Disease Study (NCCDS) and the European Cooperative Crohn's Disease Study (ECCDS) both showed that approximately 70% of patients who are treated with 40–60 mg/day of prednisone for 3–4 months enter remission, compared with 30% of patients treated with placebo (see Figure 11.1) [4, 5]. **A1a**

### Budesonide

Glucocorticoids have pluripotent actions on the immune system, including effects on the synthesis of inflammatory mediators, cellular immunity and neutrophil function [17]. Since the glucocorticoid receptor is widely expressed in tissues, the biological actions of these drugs are not restricted to the immune system. Unpleasant cosmetic effects (acne, moon faces and bruising) and more serious effects, such as metabolic disturbances (hypertension, metabolic bone disease and diabetes) are common and limit the usefulness of these agents [18]. An ideal glucocorticoid should retain the efficacy of conventional glucocorticoid drugs, while minimizing systemic effects. One possible means of achieving this objective is to specifically target the

bowel wall as the therapeutic compartment of interest [19]. The development of budesonide as a treatment for active CD is an example of this approach.

Budesonide is a novel glucocorticoid with a potency approximately five times that of prednisone. The systemic effects of budesonide are reduced in comparison to conventional steroid drugs as a result of extensive first pass metabolism to inactive compounds. Thus, a high local anti-inflammatory effect on mucosal surfaces is possible with low systemic activity [20]. Proof of this concept was first demonstrated in asthma therapy, where topical budesonide was shown to be highly effective, with few or no systemic adverse effects [21]. An oral controlled ileal release formulation of budesonide was developed for the treatment of active CD of the ileum and right colon. A Canadian multicenter dose finding study found that, first, 9 mg/day of budesonide was more effective than a placebo for the induction of remission in patients with moderately active CD (51% vs 20%,  $p < 0.001$  – and, second, the proportion of patients experiencing glucocorticoid-related adverse effects with this drug was not greater than with placebo treatment (26% 9 mg budesonide vs 26% placebo,  $p > 0.05$ ) [22]. **A1c** In a second study, Rutgeerts and colleagues compared 9 mg/day of budesonide with a standard prednisolone regimen [23]. Although a favorable trend in response rate was observed in favor of prednisolone therapy, the difference in efficacy between the treatment groups was not large (65% vs 52%,  $p = 0.12$ ). There were fewer glucocorticoid-related adverse events in patients who received budesonide (budesonide 29%, prednisolone 55%, ARR 26%, NNT = 4,  $p = 0.003$ ). **A1c** Finally, as described

earlier, Thomsen and colleagues have shown that 9 mg/day of budesonide is more effective than 4 g/day of 5-ASA and is equally well tolerated [12]. Data from the studies have been summarized in a Cochrane review by Seow and colleagues, who estimated that budesonide was approximately 15% less effective than conventional glucocorticoid therapy, but was much less likely to cause glucocorticoid-related adverse events [24]. **Ala** Thus, budesonide is an attractive alternative to 5-ASA or prednisone for induction of remission in patients whose disease is restricted to the appropriate anatomical sites.

## Antibiotics

A substantial body of experimental evidence supports the notion that bacteria play an important role in initiating and/or sustaining the pathological inflammatory reaction in the bowel wall [25, 26]. Antibiotics have been used empirically for the treatment of active CD for many years, and review articles and textbooks of medicine commonly advocate their use. However, few good data exist to support this endorsement. The Cooperative Crohn's Disease Study in Sweden compared 800 mg/day of metronidazole to 1.5 g/day of sulfasalazine in 78 patients with active disease [27]. A 25% response rate for both treatments was shown. Accordingly, it is debatable whether these results are more consistent with an equivalent benefit of metronidazole or the lack of any therapeutic effect for either treatment. The largest trial of metronidazole, carried out by Sutherland and colleagues, randomized patients to receive metronidazole (10 or 20 mg/kg per day) or a placebo for 16 weeks ( $n = 105$ ) [28]. Metronidazole therapy produced a dose-dependent decrease of disease activity (decrease in CDAI: metronidazole 20 mg/kg 97, 10 mg/kg 60, placebo 1;  $p = 0.001$ ). However, no difference in remission rate was observed (proportion in remission: placebo 25%, metronidazole 10 mg/kg 36%, 20 mg/kg 27%). Thus, the controlled data that support the efficacy of metronidazole are not impressive. **Ald**

More recently the quinolone antibiotic ciprofloxacin has been used in combination with metronidazole. Prantera and colleagues randomized 41 patients to receive combined antibiotics (ciprofloxacin 500 mg twice daily and 250 mg of metronidazole four times daily) or methyl prednisolone 0.7–1.0 mg/kg for 12 weeks [29]. A statistically significant difference in patients entering remission was not demonstrated (combined antibiotic therapy 10/22 (46%), steroid therapy 12/19 (63%),  $p > 0.05$ ). The small number of patients in this trial does not permit any definitive conclusion regarding the value of combined antibiotic therapy; however, the 17% difference in remission rates in favor of methyl prednisolone is most consistent with a clinically meaningful treatment advantage in favor of glucocorticoid therapy. **Ald**

Steinhart *et al.* conducted a double-blind study of oral ciprofloxacin and metronidazole (both 500 mg twice daily), or placebo for eight weeks in 134 patients with active CD of the ileum, right colon or both [30]. All patients received oral budesonide 9 mg once daily. At week 8, 21 patients (33%) assigned to antibiotics were in remission, compared with 25 patients (38%) in the placebo group ( $p = 0.55$ ; absolute difference –5%, 95% CI –21 to 11%). **Ala** An interaction ( $p = 0.025$ ) between treatment allocation and disease location on treatment response was identified. Among patients with disease of the colon, 9 of 17 (53%) were in remission after treatment with antibiotics, compared with 4 of 16 (25%) of those who received placebo ( $p = 0.10$ ). Discontinuation of therapy because of adverse events occurred in 13 of 66 (20%) patients treated with antibiotics, compared with 0 of 68 in the group who received placebo ( $p < 0.001$ ). In patients with active CD of the ileum, the addition of ciprofloxacin and metronidazole to budesonide was an ineffective intervention.

Although this antibiotic combination may improve outcome when there is involvement of the colon, the evidence supporting this possibility comes only from a *post hoc* analysis of a small number of patients and was not statistically significant. The section on antituberculous therapy for maintenance describes a trial conducted by Selby and colleagues that may also lend some credibility to the concept that alteration of bacterial flora may yet prove to be helpful for induction of remission [31].

In summary, of the traditional and most widely used interventions glucocorticoids are the most effective treatment for inducing clinical remission of active CD. For those patients whose disease is confined to the terminal ileum and/or right colon, budesonide is an attractive alternative to the conventional glucocorticoids because of the lower incidence of adverse events. Sulfasalazine is modestly effective in patients with mild disease activity. Although the newer 5-ASA compounds and antibiotics are used by many clinicians to treat patients with milder forms of the disease, current data do not provide good evidence for the efficacy of these drugs.

---

## Treatment of therapy-resistant or steroid-dependent patients

Munkholm and colleagues have documented the natural history of an acute exacerbation of CD in a cohort of patients from Copenhagen county [32]. One year after an initial course of treatment a high proportion (56%) of their patients were either therapy resistant (20%) or steroid dependent (36%). This observation has led many clinicians to conclude that earlier and more aggressive treatment with immunosuppressives may be warranted in selected patients.

## Conventional immunosuppressive drugs

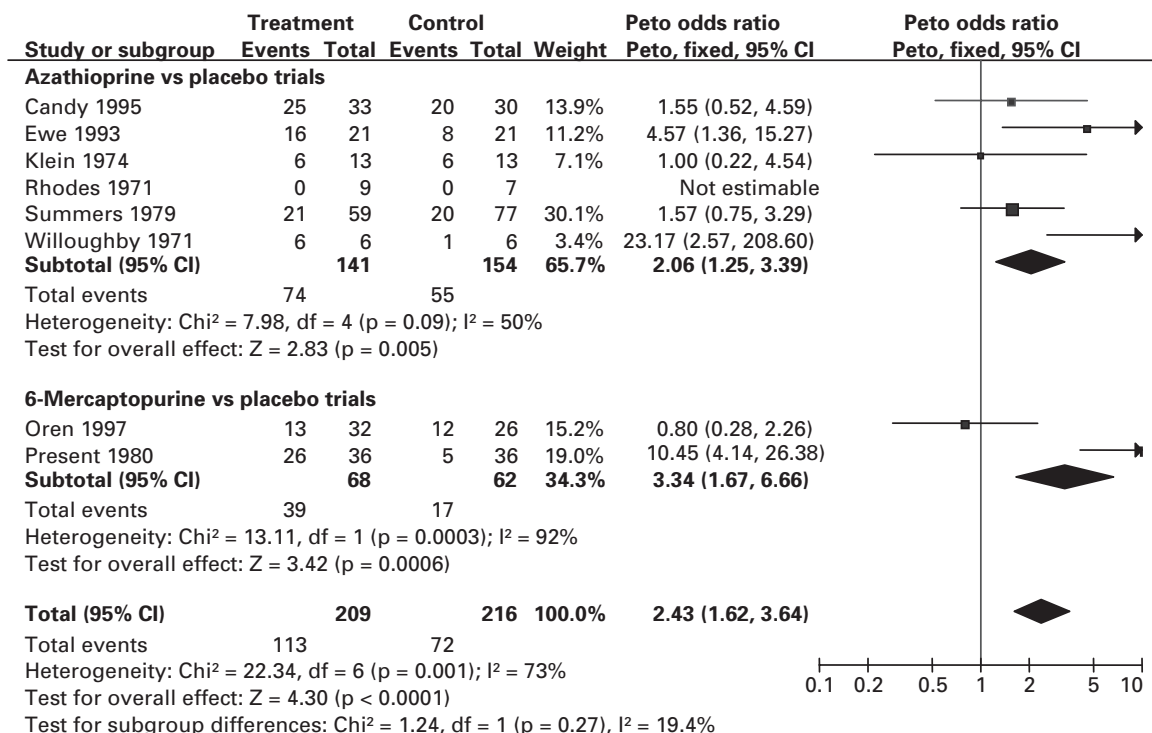

Three drugs or classes of drugs have been most frequently used: the purine antimetabolites (azathioprine (AZA)/6-mercaptopurine), cyclosporin and methotrexate.

### Purine antimetabolites

Until recently the use of the purine antimetabolites for the treatment of refractory patients was not widely accepted, perhaps because of the inconsistent results obtained from the early randomized trials of these drugs. However, more recent studies have for the most part confirmed their efficacy. One of the more important trials was conducted by Candy *et al.*, who randomized 63 patients with active CD to receive a standard tapering induction regimen of prednisone over three months and either AZA 2.5mg/kg daily or a placebo for 15 months [33]. Although no early (three months) benefit of AZA was identified with respect to remission rates (CDAI < 150 and no prednisone), the proportion of patients who remained in remission over the entire follow-up time was greater in the AZA group (42% vs 7%, ARR 35%, NNT = 3;  $p = 0.001$ ). **A1c** This result is consistent with observational data that suggest that the purine anti-metabolites require a minimum of three months to show a treatment effect. In an attempt to overcome this theoretical limitation Sandborn *et al.* did a small, uncon-

trolled study in which patients with active CD received an intravenous 1800mg loading dose of AZA [34]. This strategy rapidly achieved stable erythrocyte concentrations of the thiol metabolites, which are believed to be responsible for the immunosuppressive effects of AZA. Despite this promising finding, a subsequent RCT which evaluated 96 patients showed equally low (eight week) remission rates in patients who received either loading or conventional AZA regimens (25% vs 24%), in spite of achieving steady state nucleotide levels by week 2 [35]. **A1d** Furthermore, the proportion of patients entering remission did not increase after eight weeks of treatment. It should be noted that all patients in this study received oral AZA in a dose of 2mg/kg and that the proportion of these patients who entered remission and withdrew completely from steroids was only 24%, a figure roughly comparable with the expected response to a placebo in many induction of remission studies. The data are consistent with a slow onset of effect for the purine antimetabolites.

The data from the RCTs which have evaluated the purine antimetabolites for the treatment of active CD in adults have been summarized in a meta-analysis in which the pooled ARR for AZA treatment for induction of remission is approximately 20% (NNT = 5) (see Figure 11.2) [36]. **A1d** In the majority of these studies patients were receiving concomitant corticosteroid therapy. A steroid-sparing

**Figure 11.2** Azathioprine or 6-mercaptopurine for inducing remission in Crohn's disease. Source: *Cochrane Database Syst Rev* 2009; **4**: CD000545. Azathioprine or 6-mercaptopurine for induction of remission in Crohn's disease. Prefontaine E, Macdonald JK, Sutherland LR. Department of Community Health Sciences, University of Calgary, Health Sciences Centre, Calgary, Canada. Update of: *Cochrane Database Syst Rev* 2000; **2**: CD000545.

effect was also demonstrated in this analysis: the NNT for steroid sparing (the NNT for AZA to permit one additional patient to reduce steroids to < 10 mg/day) was estimated to be 3. These results should be interpreted with a degree of caution, since important clinical heterogeneity exists among the studies in their definitions of treatment response, duration and the use of cointerventions. No single, large, well-designed trial that resulted in a clinically and statistically significant benefit compared with placebo exists. Nevertheless, the meta-analysis suggests that some beneficial effect is present on disease activity, and the use of these drugs can be recommended for treatment of patients who fail to respond to steroid therapy or develop steroid dependence.

### Cyclosporine

The emergence of this drug as a standard therapy for organ transplantation led to large-scale evaluations for the treatment of chronically active CD. The results of four RCTs (see Figure 11.3 [37]) have shown that the therapeutic index for cyclosporin is low, if there is any efficacy [38–41]. **Alc** The study of Brynskov *et al.* [39], which demonstrated only a modest benefit, used a high cyclosporin dose (7.6 mg/kg per day), which cannot be recommended for chronic treatment, since the risk of nephrotoxicity is unacceptably high [42]. The three trials that assessed a dose of cyclosporin that is tolerable for long-term treatment (5 mg/kg per day) showed no benefit with this drug [38–40]. Thus, cyclosporin is not a practical therapy for long-term management. Although uncontrolled studies have suggested that short-duration, high-dose intravenous therapy may be beneficial in patients with refractory CD, data from controlled trials would be required to support a recommendation for widespread use [43, 44]. These trials are unlikely to be performed given the demonstrated efficacy and safety of other agents.

**Figure 11.3** Point estimates (•) and 95% confidence limits (I–I) of the therapeutic gain (% response cyclosporin–% response placebo) for four RCTs of cyclosporin for Crohn's disease. Reproduced with permission from Feagan B. *Inflamm Bowel Dis* 1995; **1**: 335–339.

### Methotrexate

The success of low dose (5–25 mg/weekly) methotrexate as a treatment for rheumatoid arthritis led to its evaluation in patients with chronically active CD. In 1989, Kozarek *et al.* reported the results of an open study in which two-thirds of patients with steroid refractory disease showed an improvement in symptoms and a concomitant reduction in prednisone requirements [45]. **B4** Some patients demonstrated an endoscopic remission. A controlled trial was subsequently conducted in which 141 patients who had failed previous attempts to discontinue prednisone were randomized to receive either methotrexate 25 mg/weekly intramuscularly or a placebo for 16 weeks [46]. All of the patients received 20 mg of prednisone per day at the initiation of the trial; a standardized prednisone withdrawal regimen was then used. Patients who responded to therapy discontinued prednisone entirely 12 weeks following randomization. A significant benefit of methotrexate therapy was observed for the primary outcome measure, the proportion of patients who were completely withdrawn from prednisone and in clinical remission as defined by a CDAI score of < 150 points (methotrexate 39%, placebo 19%, ARR 20%, NNT = 5;  $p = 0.025$ ) (see Figure 11.4). **Ala** Improvements in the median prednisone dose, Health Related Quality of Life and mean CDAI scores, and concentration of serum acute phase reactants were also associated with methotrexate therapy. In this short-term trial, no serious toxicity was observed, although withdrawals from treatment due to nausea were more common with methotrexate.

**Figure 11.4** Percentages of patients in remission at week 16 according to study group and stratum of daily prednisone dose before entry into the study. The high prednisone stratum was receiving a daily dose of more than 20 mg prednisone, and the low prednisone stratum a daily dose of 20 mg or less more than two weeks before randomization. The actual percentages are shown above the bars. P values were derived by the Mantel-Haenszel chi-square test, with adjustment for study center. ## Novel immunosuppressive drugs

New knowledge of the human immune system and the growth of the biotechnology industry have combined to yield an abundance of new treatments for chronic inflammatory diseases. The development of anti-TNF alpha (infliximab, adalimumab, certolizumab) and anti-integrin antibodies (natalizumab) as therapies for CD are examples of the development of this new technology.

### Anti TNF alpha antibodies

Tumor necrosis factor $\alpha$  (TNF) is a proinflammatory cytokine which plays an important part in the pathophysiology of CD [47]. Following the successful treatment of a young woman with a chimeric anti-TNF- $\alpha$  antibody by investigators in Amsterdam, a series of controlled studies were initiated with several different chimeric or humanized monoclonal antibodies [48].

*Infliximab* Targan and colleagues carried out a multicenter dose finding study that evaluated 108 patients whose disease was refractory to other forms of treatment [49]. Patients with moderately severe disease received one of three doses of infliximab (5, 10, 20 mg/kg) or a placebo administered as a single intravenous infusion. Patients continued to receive other treatments at a fixed dose. The primary endpoint of the study was the occurrence of a clinical response as defined by a decrement of 70 points in the CDAI score from the baseline value. No dose-response relationship was identified; 81.5% of infliximab-treated patients responded compared with 16.7% of those who received the placebo (ARR 65%, NNT = 2;  $p < 0.001$ ). **Ala** Minor allergic reactions to the antibody occurred infrequently, but clinically significant adverse effects were not encountered in this short-term study.

In a second pivotal trial Present and colleagues evaluated the efficacy of infliximab for the treatment of patients with fistulizing CD (no previous controlled trials had evaluated this population of patients) [50]. The patients studied had active, fistulizing disease for a minimum of three months prior to randomization. Concomitant treatment with steroids, 6-mercaptopurine or AZA, and antibiotics was permitted although the dose of these cointerventions was maintained at a stable level throughout the trial. The primary measure of response was a 50% reduction in the number of open fistulae. Ninety-four patients received three intravenous infusions of either a placebo or one of two dose regimens of antibody (5 or 10 mg/kg) during a total of 18 weeks of follow-up. Patients treated with infliximab were significantly more likely to respond (61.9% vs 25.8%, ARR 36.1%, NNT = 3;  $p = 0.002$ ).

**Ala** The response to treatment was rapid and in many cases dramatic. Again, no dose-response relationship was identifiable.

*Adalimumab* Adalimumab was developed as a human recombinant immunoglobulin G1 anti-TNF monoclonal antibody for subcutaneous administration. In the CLASSIC-1 trial 299 patients with moderate to severe CD naive to anti-TNF therapy were randomized to receive subcutaneous injections at weeks 0 and 2 of adalimumab 40 mg/20 mg, 80 mg/40 mg, or 160 mg/80 mg, or placebo [51]. The optimal induction dosing regimen for adalimumab in this study was 160 mg at week 0 followed by 80 mg at week 2, which produced clinical remission in 36% of patients compared to the rate of 12% observed in the placebo group. (NNT = 4,  $p = 0.001$ ). Adalimumab was well tolerated.

*Certolizumab* Certolizumab pegol is a pegylated humanized Fab' fragment that binds tumor necrosis factor alpha. In the PRECISE-1 study 662 adults with moderate to severe Crohn's disease were randomly assigned to receive either 400 mg of certolizumab pegol or placebo subcutaneously at weeks 0, 2 and 4 and then every four weeks [52]. Response rates at week 6 were 35% in the certolizumab group and 27% in the placebo group ( $p = 0.02$ ), although remission rates were not significantly different in the two groups.

**A1a** Serious adverse events were reported in 10% of patients in the certolizumab group and 7% of those in the placebo group. *Post hoc* analysis of the health-related, quality of life data (self-administered IBDQ questionnaire) from 290 patients showed improvement in emotional well-being and systematic symptoms in certolizumab treated patients at all intervals up to 12 weeks.

### Natalizumab

Natalizumab is a recombinant, humanized, monoclonal antibody against the alpha4 integrin. A systematic Cochrane review has summarized the results of pooled data from four randomized trials that investigated the ability of natalizumab, in a variety of dose regimens to induce remission in a total of 1641 patients with moderately to severely active disease [53–57]. Natalizumab (300 mg or 3 to 4 mg/kg) is effective for induction of clinical response and remission in patients with moderately to severely active disease. This benefit was statistically significant for one, two and three infusion treatments, although there was a trend toward increased benefit with additional infusions of natalizumab. The NNT for induction of remission or clinical response varied according to the infusion regimen and outcome and ranged from approximately 4 to 10. For example, pooled data from three studies that included 2456 patients showed that the number of patients required to be treated with a single infusion of natalizumab to produce clinical response at four weeks was eight. Subgroup analysis demonstrated significantly greater clinical response and remission rates for natalizumab compared with placebo in patients in whom active disease was characterized by elevated C-reactive protein levels and active disease despite

the use of immunosuppressants or prior anti-tumor necrosis factor therapy.

There were no statistically significant differences between natalizumab and placebo treated patients in the proportions of patients who withdrew due to adverse events or those who experienced serious adverse events. However, the included trials lacked adequate power to detect serious adverse effects that occur infrequently. When two patients with multiple sclerosis treated with natalizumab in combination with interferon beta-1a, and one patient with Crohn's disease treated with natalizumab in combination with azathioprine developed progressive multifocal leukoencephalopathy (PML) resulting in two patient deaths, a considerable degree of alarm arose about the safety of this preparation [58–60]. A retrospective investigation was conducted to assess the risk of PML in natalizumab treated patients and no new cases were identified. The incidence of PML has been estimated to be 1 case per 1000 patients (95% CI: 0.2–2.8 per 1000) in this population who received a mean of 17.9 monthly doses of natalizumab [61]. Subsequently, the FDA (US) has approved the use of this antibody for induction of remission in Crohn's disease.

### **Combination therapy with anti-TNF alpha antibodies and methotrexate or azathioprine for induction and maintenance of remission**

Two important randomized trials have been performed to compare the effectiveness of infliximab alone or in combination with immunomodulator therapy (azathioprine or methotrexate) for induction and maintenance of remission.

In the SONIC trial 508 patients who were immunosuppressant and anti-TNF naive, and whose mean disease duration was approximately two years, were randomized to receive infliximab plus a placebo (IFX + PI), azathioprine plus a placebo (AZA + PI), or infliximab plus azathioprine (IFX + AZA) [62]. The primary endpoint of steroid-free clinical remission at 26 weeks was achieved as follows: IFX + PI 44.4, AZA + PI 30.6, and IFX + AZA 56.8 ( $p < 0.05$  for all comparisons). The predefined secondary endpoint of complete mucosal healing was also observed significantly more frequently in infliximab than in azathioprine treated patients. The SONIC trial clearly showed benefit from combined anti-TNF alpha and antimetabolite therapy over monotherapies with these agents.

In the COMMIT study 126 patients with active disease (mean CDAI 208) requiring steroid therapy were randomized to receive standard infliximab induction and maintenance therapy (IFX 5mg/kg weeks 1, 3 and 7 and q 8 weeks) with either a placebo (IFX + PI) or methotrexate 25mg subcutaneously weekly (IFX + MTX) [63]. Prednisone therapy was tapered after the first week to be discontinued by week 14. The combination of IFX and MTX, although safe, was no more effective than IFX alone. Treatment

failure rates (percent) at 50 weeks were virtually identical: IFX + PI 29.8, IFX + MTX 30.6,  $p = 0.63$ ). This study showed that infliximab combined with initial prednisone therapy can result in very high steroid-free clinical remission rates at one year that are not improved with the addition of methotrexate therapy.

The results of these two trials should not be interpreted as showing that infliximab combined with azathioprine is an effective approach, while the combination with methotrexate is not. No "head-to-head" comparison has been made. The selection of patients and the use of concomitant therapy, particularly prednisone, were quite different in the SONIC and COMMIT trials. All patients in the COMMIT trial received corticosteroids as part of the induction regimen, and remission was achieved in a very high proportion of patients, compared to the rate observed in the SONIC study. It may not be possible to significantly increase the remission rate associated with anti-TNF alpha therapy in combination with steroids by the addition of methotrexate therapy under these circumstances. It is possible that combined therapy with infliximab and methotrexate is more effective than therapy with infliximab alone in other circumstances, for example in the absence of concomitant steroid therapy.

### **Conventional 'step-up' versus 'top-down' approach to use of immunosuppressive agents for induction and maintenance of remission**

It is clear that anti-TNF alpha antibodies are effective for induction of remission of CD in a patient population refractory to other treatments and that serious short-term toxicity is uncommon. However, potential safety concerns include the formation of autoantibodies, the risk of infusion reactions with re-treatment, and a possible increased risk of lymphoproliferative disease. Therefore, the conventional approach to induction of remission in patients with active Crohn's disease has been to employ initial therapy with corticosteroids, adding immunosuppressive medications when patients become resistant to or dependent on steroid therapy. D'Haens *et al.* compared this approach with the use of early combined immunosuppression in an open label, randomized trial in 133 patients who were randomized to receive three infusions of infliximab (5mg/kg at weeks 0, 2 and 6) combined with azathioprine (with additional treatments with infliximab and if necessary steroids) or conventional management with corticosteroids, followed in sequence by azathioprine and infliximab [64]. At 26 weeks 60% of patients who received early combined immunosuppression were in remission without corticosteroids and without surgical resection, compared to 35.9% for patients receiving conventional management (ARR = 24%, 95% CI: 7.3–40.8,  $p = 0.0062$ , NNT = 4). **Ala** These differences were maintained at 52 weeks. Furthermore, mucosal healing at two years was twice as

likely to occur in patients assigned to combined immunosuppressive therapy. Serious adverse events were not significantly more frequent in the early combined immunosuppression group. These results suggest that early combined immunosuppression may yield significantly better outcomes than the conventional approach of adding the more potent immunosuppressive agents in a stepwise approach when induction of remission is not achieved, or when patients become steroid dependent. However, many clinicians and patients are reluctant to adopt this type of aggressive strategy until more long-term efficacy and safety data are available. It may be that outcomes can be improved following an approach that recognizes in a timely fashion when particular therapies have not achieved specific, clinically relevant outcomes and advances to the next therapeutic "step" when this occurs. A cluster randomized trial has been organized to test this hypothesis [65]. Forty centers in Belgium and Canada will be randomized to utilize either a conventional or accelerated step-up approach to management of active Crohn's disease.

### Probiotics

A single small randomized trial that included only 11 patients failed to show any benefit of probiotics for induction of remission [66]. There are no methodologically randomized trials of adequate size to permit any conclusions about the efficacy of this approach.

## Maintenance of remission

The objectives of maintenance therapy are to prevent the recurrence of symptoms, to reduce the risk of complications, and to avoid the need for surgery and hospitalization. One year after a medically induced remission of CD approximately 30–40% of patients will experience a relapse of disease; and following surgery symptoms recur at a rate of approximately 15% per year [67]. The failure of the maintenance therapy components of the NCCD [4] and ECCDS [5] trials to demonstrate a long-term benefit of sulfasalazine or conventional, low dose glucocorticoid therapy led to the extensive evaluation of the newer 5-ASA and budesonide for this indication. **A1c**

### 5-aminosalicylates

The second edition of this textbook summarized data from over twenty randomized trials of 5-ASA compounds for maintenance of remission of medically or surgically induced remission of Crohn's disease. Although some randomized trials and early meta-analyses had suggested modest benefit, subsequent larger trials did not. Our overall review of the trials and meta-analysis led us to conclude

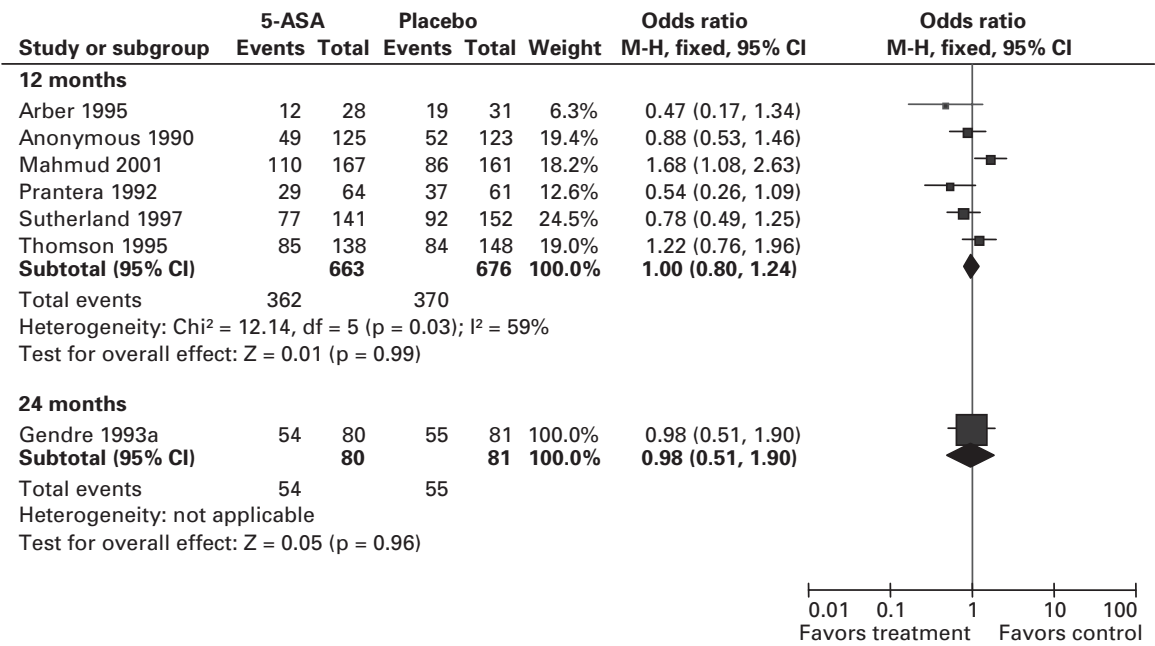

that it was increasingly difficult to recommend chronic use of 5-ASA therapy for Crohn's disease. More recently Akobeng and Gardener performed a Cochrane review on the use of 5-ASA for maintenance of medically induced remission [68]. The reviewers concluded on the basis of data from seven trials that included 1500 patients that there is no evidence to suggest that 5-ASA preparations are superior to placebo for the maintenance of medically-induced remission in patients with Crohn's disease, and that additional randomized trials of this agent are not justified (see Figure 11.5). **A1a** We concur with this conclusion, given that there are several other agents that are proven to be effective for this purpose.

On the other hand, Doherty *et al.* performed a Cochrane review of the use of 5-ASA for the prevention of relapse after surgically induced remission and concluded on the basis of five trials that included 652 patients that 5-ASA is modestly effective for this purpose with an RR of 0.76 (95% CI: 0.62–0.94) (see Figure 11.6) [69]. **A1a** The NNT to prevent a single clinical recurrence within 12 months was 12. However, it should be noted that the largest and methodologically rigorous trial performed by Lochs and colleagues did not demonstrate efficacy for this intervention [70].

### Budesonide

The efficacy of budesonide for induction of remission in CD suggested that chronic therapy might be an effective and safe maintenance strategy. Four randomized placebo controlled trials have evaluated the use of either 6 mg/day or 3 mg/day of budesonide for one year of treatment [71–73]. The first three studies were of similar design, following treatment of active CD with either budesonide, prednisolone or a placebo. Patients who responded to treatment were randomized to receive either one of the two doses of budesonide or a placebo. Patients who responded to treatment were randomized to receive either one of the two doses of budesonide or placebo. No other treatments for CD were permitted. The primary outcome measure of these studies was the proportion of symptomatic relapses of CD as defined by a 60 point increase in the CDAI and a minimum CDAI score of 200 at the time of the disease exacerbation.

Greenberg *et al.* (n = 105) found that the median time to relapse or withdrawal from treatment differed significantly between the three treatment groups: budesonide-treated patients remained in remission longer than those who received the placebo (178 days 6 mg vs 124 days 3 mg vs 39 days placebo; p = 0.027) [71]. However, the treatment effect was not durable. The greatest difference in remission rates was observed three months after randomization, whereas at one year no significant differences were present (39% 6 mg vs 30% 3 mg vs 33% placebo). **A1a** Budesonide therapy

Review: interventions for prevention of post-operative recurrence of Crohn's disease  
Outcome: clinical recurrence (at study completion)  
Comparison: 5-ASA versus placebo

**Figure 11.6** Interventions for prevention of post-operative recurrence of Crohn's disease. Source: Doherty G *et al.* Interventions for prevention of post-operative recurrence of Crohn's disease. *Cochrane Database of Systematic Reviews* 2009; Issue 4. Art. No.: CD006873. DOI: 10.1002/14651858.CD006873.pub2.

was well tolerated. No differences were observed among the treatment groups in the proportion of patients who experienced adverse events (78% 6 mg vs 70% 3 mg vs 89% placebo). Although glucocorticoid-related adverse events occurred more frequently in patients who were treated with budesonide, the proportion of patients who reported these events decreased throughout the follow-up period and the most common steroid-related adverse event identified was easy bruising. A dose-dependent depression of the plasma cortisol concentration was noted in the budesonide-treated groups.

Similar results were obtained by Lofberg and colleagues (n = 90) who observed that the median time to relapse or discontinuation of therapy was 258 days for the 6 mg/day group, 139 days for the 3 mg/day group, and 92 days for the patients who received a placebo (p = 0.021) [72]. Again, the time in remission was significantly prolonged for those patients who received budesonide, but the therapeutic effect was not sustained. At 12 months following randomization, 41%, 26% and 37% of the 6 mg/day, 3 mg/day, and placebo group respectively remained in remission (p = 0.44). **Ala** Thirty-eight percent of those patients

who had received 6mg/day reported glucocorticoid-related adverse events compared with 20% of those who received 3mg/day and 12% of those who received the placebo.

The third trial, by Ferguson *et al.*, which evaluated the smallest number of patients ( $n = 75$ ), failed to demonstrate any benefit of budesonide treatment [73]. The median time to relapse or discontinuation of therapy was 272 days in the 6mg/day group, 321 days in the 3mg/day group, and 290 days in the placebo group ( $p = 0.80$ ). **A1c** A similar proportion of patients in the three treatment groups experienced glucocorticoid-related adverse events (18% 6mg/day vs 36% 3mg/day and 15% placebo;  $p = 0.79$ ).

An analysis of the pooled data from these studies and additional studies in a Cochrane review showed that budesonide 6mg daily was no more effective than placebo for maintenance of remission at three months (RR 1.25; 95% CI: 1.00–1.58;  $p = 0.05$ ), six months (RR 1.15; 95% CI: 0.95–1.39;  $p = 0.14$ ), or 12 months (RR 1.13; 95% CI: 0.94–1.35;  $p = 0.19$ ) [74]. **A1a** Adverse events were more frequent in patients treated with 6mg of budesonide compared with placebo (RR 1.49; 95% CI: 1.01–2.19;  $p = 0.05$ ), but not in patients using lower doses of budesonide. These events were relatively minor and did not result in increased rates of study withdrawal. Abnormal adrenocorticoid stimulation tests were seen more frequently in patients receiving both 6mg daily (RR 2.88; 95% CI: 1.72–4.82;  $p < 0.0001$ ) and 3mg daily (RR 2.73; 95% CI: 1.34–5.57;  $p = 0.006$ ) compared with placebo.

Two additional randomized trials that used endoscopic relapse following surgery as endpoints have not demonstrated significant prolongation of remission with this therapy. Hellers *et al.* randomized 129 patients following ileal or ileocecal resection to receive budesonide 6mg daily or a placebo [5, 75]. Ileocolonoscopy, including biopsy, was carried out 3 and 12 months after surgery. The frequency of endoscopic recurrence did not differ between the groups. **A1a** The investigators reported a subgroup analysis which suggested that recurrence at 12 months was lower in patients who had undergone surgery for control of disease activity rather than for stricture (budesonide 32%, placebo 65%;  $p = 0.047$ ). However, this *post hoc* analysis should be viewed with caution.

Ewe *et al.* randomized 88 patients to receive budesonide 3mg (pH-modified release formulation) or a placebo for one year [76]. Endoscopic recurrence at 3 and 12 months was the primary measure of efficacy. The recurrence rate was not reduced by active treatment (budesonide 57%, placebo 70%;  $p = 0.2$ ). Survival analysis also failed to show prolongation of remission with active therapy. **A1c**

Given the lack of sustained benefit observed in any of these trials we do not recommend continued budesonide therapy for patients who have entered remission during treatment with this intervention.

## Antituberculous therapy

A systematic review of antituberculous therapy for maintenance of remission in CD demonstrated a possible small benefit in patients in whom remission was induced by steroid [77].

However, this observation was derived from a meta-analysis of subgroups from only two trials involving 90 patients, and the authors of the review do not recommend this form of therapy in the absence of further trials. More recently Selby reported the results from a trial in which 213 patients were randomized to receive, in addition to a 16-week tapering course of prednisolone, either a placebo or a combination of clarithromycin, rifabutin and clofazimine [31]. Relapse rates were not significantly different over the next two years. The remission rate at 16 weeks, however, was significantly higher in the antibiotic group than in the placebo group (antibiotic 0.66, placebo 0.5,  $p = 0.02$ ). This outcome was not the predetermined outcome for this study, but it does lend some continuing interest in the concept that altering bacterial flora may eventually prove to be beneficial in Crohn's disease.

## Nitroimidazole antibiotics

Rutgeerts and colleagues have performed three randomized trials that evaluated metronidazole for postoperative maintenance therapy [78]. In the first study, 66 patients were randomized to two weeks of therapy with 20mg/kg per day of metronidazole or placebo within one week of surgical resection of all visible disease. Following 12 weeks of therapy endoscopic recurrence occurred in 52% of patients assigned to metronidazole compared with 75% of those who received placebo ( $p = 0.09$ ). **A1c** Furthermore, a significant effect was shown for clinical recurrence at one year (4% for metronidazole vs 25% for placebo ( $p = 0.046$ )). However, peripheral neuropathy was common, making continuous therapy impracticable. A second trial of a potentially less neurotoxic nitroimidazole, ornidazole, also suggested a maintenance benefit of antibiotic therapy; unfortunately clinically relevant neuropathy was also observed [79]. More recently, a third trial evaluated the combination of azathioprine and metronidazole versus metronidazole monotherapy and observed a lower endoscopic recurrence rate at 12 months in the combined therapy group (combined therapy 43.7%, metronidazole monotherapy 69%,  $p = 0.048$ ) [80]. These trials indicate that manipulation of the endogenous bacterial flora with antibiotics may ultimately prove to be an effective strategy for the prevention of postoperative recurrence. Unfortunately, the problems of antibiotic resistance and neuropathy mitigate against the use of nitroimidazole antibiotics as long-term treatments.

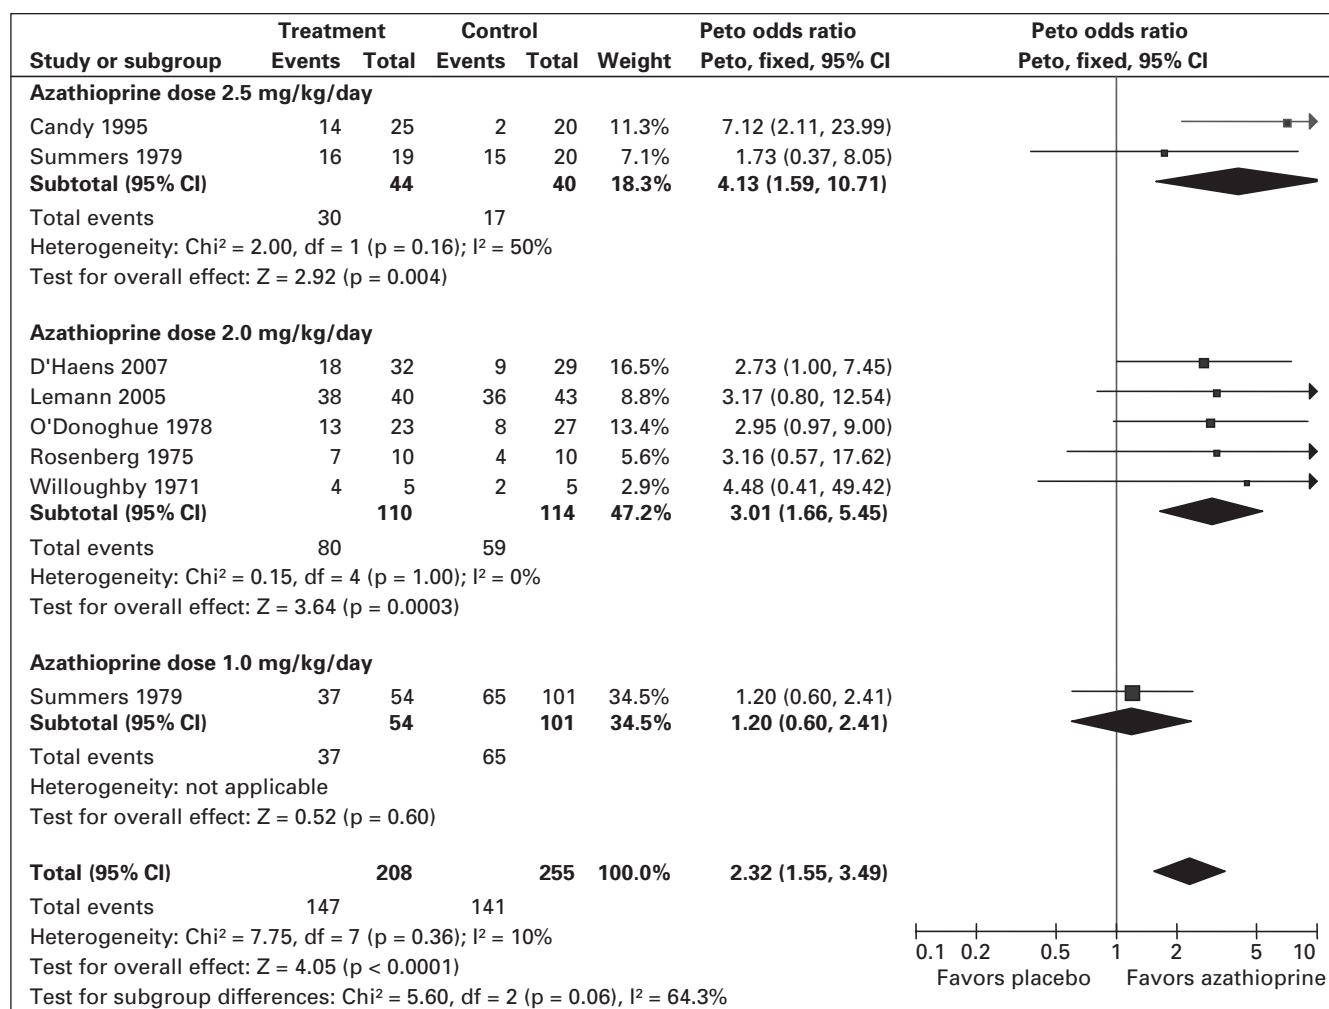

## Probiotics

A Cochrane review has concluded that there is no evidence to suggest that probiotics are beneficial for the maintenance of remission in CD [81]. However, the reported studies enrolled small numbers of patients and may have lacked statistical power to show differences should they exist. Larger trials are required to determine if probiotics are of benefit in Crohn's disease.

## Azathioprine

A systematic review published by Prefontaine *et al.* included seven trials of azathioprine therapy and one of 6-mercaptopurine therapy [82].

Seven trials of azathioprine therapy and one of 6-mercaptopurine were included in the review. Azathioprine and 6-mercaptopurine had a positive effect on maintaining remission (see Figure 11.7). The Peto odds ratio (OR) for maintenance of remission with azathioprine was 2.32 (95% CI: 1.55–3.49) with a NNT of 6. The Peto OR for maintenance of remission with 6-mercaptopurine was 3.32 (95% CI: 1.40–7.87) with NNT of 4. Higher doses of azathioprine improved response. A steroid sparing effect with azathioprine was noted, with a Peto OR of 5.22 (95% CI: 1.06–25.68) and NNT of 3 for quiescent disease. Withdrawals due to adverse events were more common in patients treated with azathioprine (Peto OR 3.74; 95% CI: 1.48–9.45, NNT = 20) than with placebo. Common events for withdrawal included pancreatitis, leukopenia, nausea, "allergy" and infection.

**Figure 11.7** Azathioprine or 6-mercaptopurine for maintenance of remission in Crohn's disease. Source: Prefontaine E *et al.* Azathioprine or 6-mercaptopurine for maintenance of remission in Crohn's disease. *Cochrane Database of Systematic Reviews* 2009; Issue 1. Art. No.: CD000067. DOI: 10.1002/14651858.CD000067.pub2.

Review: azathioprine or 6-mercaptopurine for maintenance of remission in Crohn's disease.

Comparison: 5-ASA versus placebo.

Outcome: maintenance of remission.

**Figure 11.8** Time (days) off of corticosteroid treatment after initial discontinuation, depicted as a Kaplan-Meier survival curve. ■ 6-mercaptopurine; ▲ controls;  $p < 0.0001$  Adapted from Markowitz *et al.* [83].

Markowitz *et al.* conducted a study that included 55 children (age 13  $\pm$  2 years) who were randomized within eight weeks of initial diagnosis to receive treatment with 6-mercaptopurine (1.5 mg/kg per day) or a placebo for 18 months in addition to prednisone (40 mg/day), with prednisone dosage withdrawal based on a defined schedule [83]. Although remission was induced in 89% of both groups, only 9% of the remitters in the 6-mercaptopurine group relapsed compared with 47% of controls ( $p = 0.007$ ) (see Figure 11.8). **Alt** In the 6-mercaptopurine group, the duration of steroid use was shorter ( $p < 0.001$ ) and the cumulative steroid dose was lower at 6, 12 and 18 months ( $p < 0.01$ ).

Growth was comparable in both groups. No clinically significant adverse events occurred, although mild leukopenia and increases in aminotransferase activity were noted in the 6-mercaptopurine group; 6-mercaptopurine decreased the need for corticosteroids and decreased the frequency of relapses.

Minor toxicity, such as nausea, fatigue, skin rash, fever and arthralgias, is relatively common with the purine antimetabolites. Asymptomatic elevation of liver and pancreatic enzymes also occur frequently. Clinically important pancreatitis occurs in 3% of patients. Although leukopenia, defined by a white blood cell count of  $< 3.8$ , develops in approximately 20% of patients per year, infection associated with severe neutropenia is uncommon [84]. Whether therapeutic drug monitoring can improve efficacy and/or reduce toxicity remains controversial and is being investigated by a National Institute for Health sponsored RCT [85, 86]. In the USA, the Food and Drug Administration has recommended genotype testing prior to the initiation of treatment so that patients with low thiopurine methyltransferase activity can be identified. These individuals develop profound leukopenia following treatment with

either agent. No studies have compared this strategy to the usual clinical practice of initiating treatment with a relatively low drug dose and following the white blood cell count each week.

Recent research has identified an association between purine antimetabolites and the occurrence of lymphoma. The meta-analysis performed by Kandiel *et al.* suggests a four-fold increased risk [87]. The prospective observational cohort study of the CESAME study group enrolled 29,486 patients with IBD (60% Crohn's disease) from the practices of 680 gastroenterologists. The multivariate-adjusted hazard ratio of lymphoproliferative disorder between patients receiving thiopurines and those who had never received the drug was 5.28 (2.01–13.9,  $p = 0.0007$ ) [88].

In summary, AZA or 6-mercaptopurine are moderately effective for maintenance of remission in adults and children and are relatively well tolerated. However, concerns about a significantly increased risk of lymphoma in patients receiving these agents appear to be increasing.

## Methotrexate

The efficacy of methotrexate in a dose of 15 mg per week for maintaining remission was evaluated in 76 patients with quiescent CD. Patients who entered remission and were totally withdrawn from steroids during the induction phase of the trial of methotrexate for induction of remission described above and additional patients who entered remission on a similar regimen outside the trial were randomized to receive methotrexate 15 mg weekly (40 patients) or a placebo (36 patients) for 40 weeks [89]. Methotrexate was effective for maintaining remission (proportion in remission at 40 weeks: methotrexate 65%, placebo 38.9%, ARR 0–26, NNT 4;  $p = 0.01$ ) [89]. **Alt** The survival data for maintenance of remission are shown in Figure 11.9. Methotrexate also reduced the requirement for prednisone use (methotrexate 27.5%, placebo 58.3%,  $p = 0.01$ ) and mean disease activity (CDAI) score at week 40 (methotrexate  $135 \pm 16$ , placebo  $196 \pm 18$ ;  $p = 0.005$ ). Only one methotrexate-treated patient withdrew because of nausea and no serious adverse events occurred. A low dose of methotrexate is safe and effective for maintaining remission in patients who have responded to methotrexate for inducing remission of active disease. The available data regarding the short-term efficacy of methotrexate have been summarized in a recently published systematic review [90].

The adverse event profile of low dose methotrexate is well established [91]. The most common minor adverse effect is nausea, which tends to develop for a period of 24–48 hours after the weekly injection. This problem, which occurs in at most 15% of patients, can usually be managed by coadministration of oral folate (1 mg every day), use of antiemetics around the time of dosing (metoclopramide, ondansetron), or, uncommonly, dose reduction. As with the

**Figure 11.9** Methotrexate for maintenance of remission Crohn's disease. With permission from Feagan BG *et al.* A comparison of methotrexate with placebo for the maintenance of remission in Crohn's disease. North American Crohn's Study Group Investigators. *N Engl J Med* 2000; **342**(22): 1627–1632.

purine antimetabolites, leukopenia and associated opportunistic infections occur uncommonly. Methotrexate is teratogenic and must not be given to women of childbearing potential who are not using effective contraceptive measures. This issue is the most important limitation to the use of the drug. Hepatotoxicity was first documented in psoriatic patients. Subsequent understanding of pharmacokinetics and the conversion to weekly, from daily, dosing has virtually eliminated this problem. Patients should be monitored according to the American Rheumatological Association guidelines, paraphrased as follows: (1) avoid treating patients with risk factors for hepatotoxicity (obesity, diabetes, excessive alcohol use); and (2) measure transaminases every 4–6 weeks [92]. If, over the course of one year, more than half of the transaminase values are abnormal, take a liver biopsy before continuing treatment. Finally, no good data indicate that methotrexate is associated with malignancy.

## Monoclonal antibodies

Behm and Bickston performed a Cochrane review of randomized trials of four different anti-TNF- $\alpha$  agents [94]: infliximab in three trials [95–97], CDP571 in three trials [98–100], adalimumab in two trials [101, 102], and certolizumab in one trial [103]. The authors decided not to statistically combine the data from trials involving different anti-TNF- $\alpha$  agents because of differences in drug administration, patient demographics, definitions of disease activity, and differences in clinical endpoints and study durations. These authors demonstrated that infliximab

maintains clinical remission (RR 2.50; 95% CI: 1.64–3.80), maintains clinical response (RR 1.66; 95% CI: 1.00–2.76), has corticosteroid-sparing effects (RR 3.13; 95% CI: 1.25–7.81) and maintains fistula healing (RR 1.87; 95% CI: 1.15–3.04) in patients with Crohn's disease with a response to infliximab induction therapy. There were no significant differences in remission rates between infliximab doses of 5 mg/kg or 10 mg/kg. Similarly, the results from a single randomized trial show that adalimumab maintains clinical remission (RR 3.28; 95% CI: 2.13–5.06), clinical response (RR 2.69; 95% CI: 1.88–3.86), and has corticosteroid-sparing effects (4.25; 95% CI: 1.57–11.47) in patients with Crohn's disease who have responded to or entered remission with adalimumab induction therapy. There were no significant differences in remission rates between adalimumab 40 mg weekly or every other week. Certolizumab pegol maintains clinical remission (RR 1.68; 95% CI: 1.30–2.16) and maintains clinical response (RR 1.74; 95% CI: 1.41–2.13) in patients who have responded to certolizumab induction therapy. The authors of the Cochrane review concluded that the evidence does not support the use of CDP571 for the maintenance of remission in Crohn's disease.

It can be calculated that the NNT, the number of patients needed to be treated with an anti-TNF  $\alpha$  agent rather than placebo for approximately one year to maintain remission and achieve steroid sparing is in the range of 4 to 5. For maintenance of healing of fistulae it appears to be approximately 10. It has also been demonstrated that this form of maintenance therapy maintains health-related quality of life and reduces the need for hospitalization and surgery [104, 105]. It appears that scheduled maintenance therapy with infliximab is more effective than episodic treatment for maintaining clinical response or remission, and reducing the need for hospitalization and surgery. It also reduces the proportion of patients who form antibodies against anti-TNF  $\alpha$  from 28% observed with episodic treatment to 6–9% observed with infliximab in 10 mg/kg and 5 mg/kg doses.

These benefits of maintenance therapy need to be considered in the light of knowledge about risk of infection and malignancy. The overall serious infection rates in the treatment groups summarized in the Cochrane review were in the range of 2.8–4% and did not differ significantly from the rates observed in placebo-treated patients. Recent data from the TREAT<sup>TM</sup> Registry revealed no increased risk of serious infections with infliximab after adjusting for disease severity and corticosteroid use (RR 0.99; 95% CI: 0.64–1.54) [106]. Tuberculosis and opportunistic infections have been associated with the use of these agents and are usually the result of disease reactivation [107, 108]. Since the introduction of appropriate screening methods (identification of high-risk patients, tuberculin testing, chest radiography) the incidence of tuberculosis has declined [109]. With respect to opportunistic infection, aspergillosis, liste-

riosis and *Pneumocystis carinii* infections have been reported [110–112]. The estimated rate of opportunistic infection is estimated at 0.43 cases per 1000 patient exposures. Data from the TREAT<sup>TM</sup> Registry have not shown a significant increase of malignancy in patients with inflammatory bowel disease treated with anti-TNF alpha therapy [113]. A link between anti-TNF- $\alpha$  therapy and malignancy in patients with Crohn's disease remains unproven, unlike the evidence described above that azathioprine or 6-mercaptopurine therapy increase the risk for development of lymphoma. The apparent relative safety of the TNF alpha agents with respect to serious infections is in contrast with observed data in the TREAT<sup>TM</sup> Registry for a significant association of serious infections with the use of steroids and narcotics.

### Combined immunosuppression therapy versus anti-TNF alpha alone for induction and maintenance

The evidence is presented above in the section on induction of remission that the combination of infliximab and azathioprine is more effective than infliximab alone for maintenance of steroid free clinical and endoscopic remission at one year [62]. There is no evidence that the combination of infliximab and methotrexate is more effective than infliximab alone in patients with active disease who are treated initially with conventional doses of corticosteroids in a tapering regimen [63].

### Omega-3 fatty acids

Omega-3 fatty acids are polyunsaturated long-chain fatty acids derived from fish. Diets high in marine fish oils increase the concentrations of the omega-3 fatty acids, eicosapentaenoic acid and docosahexaenoic acid, in cell membranes. As a consequence, the concentration of the pro-inflammatory eicosanoid precursor, arachidonic acid is reduced, which theoretically should attenuate inflammatory responses [114–115].

A preliminary randomized controlled trial by Belluzzi and colleagues evaluated the efficacy of an omega-3 fatty acid formulation in 78 patients with CD who were at a high risk for the development of a relapse [116]. Patients were randomly assigned to receive either 4–5 g/day of omega-3 fatty acids or placebo for one year. At the end of treatment, 59% of the patients assigned to active treatment remained in remission as compared with 26% of those who received placebo ( $p < 0.001$ ). **Alc** The only adverse event attributed to treatment was diarrhea, which occurred in 10% of patients. No serious adverse events were observed.

Please review

A second study published in the same year did not show benefit of omega-3 fatty acids [117]. Subsequently two

large-scale trials that included 761 patients have evaluated this approach [118]. In EPIC-1 383 patients who had been in remission for 3 to 12 months, and in EPIC-2, 379 patients who entered remission during a standardized 16-week tapering course of prednisone or budesonide, were randomized to receive 4 mg/d of the encapsulated fatty acids or a triglyceride oil placebo for one year. Although the treatment was well tolerated, the proportions of patients who experienced relapse did not differ between the treatment groups in either trial (EPIC-1: omega-3 fatty acids 31.6%, placebo 35.7%,  $p = 0.30$ ; EPIC-2: omega-3 fatty acids 47.8%, placebo 48.8%,  $p = 0.48$ ).

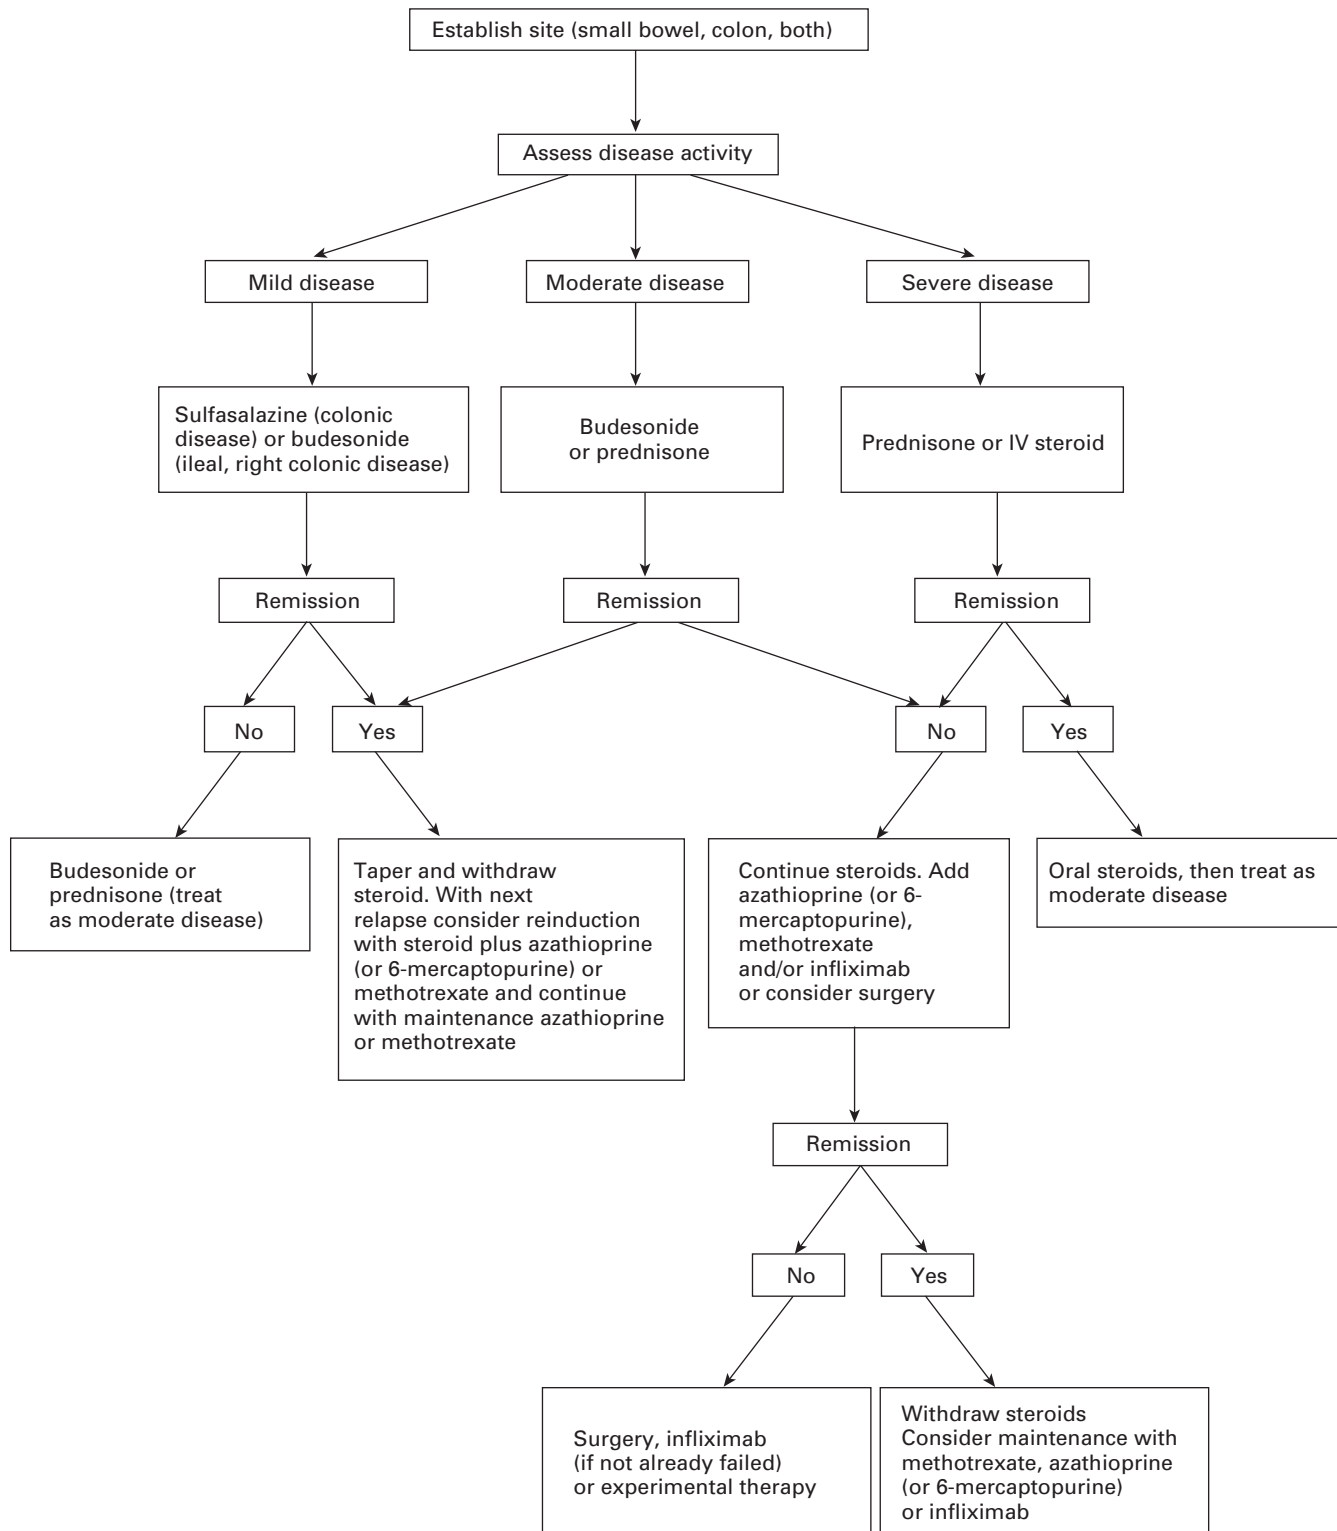

A Cochrane review of six studies has concluded that omega-3 fatty acids are safe but probably ineffective for maintenance of remission of CD [119]. Although the use of this approach is often attractive to patients, the evidence indicates that it is not effective for maintaining remission in Crohn's disease, and patients should be advised on the benefits of other proven interventions.

---

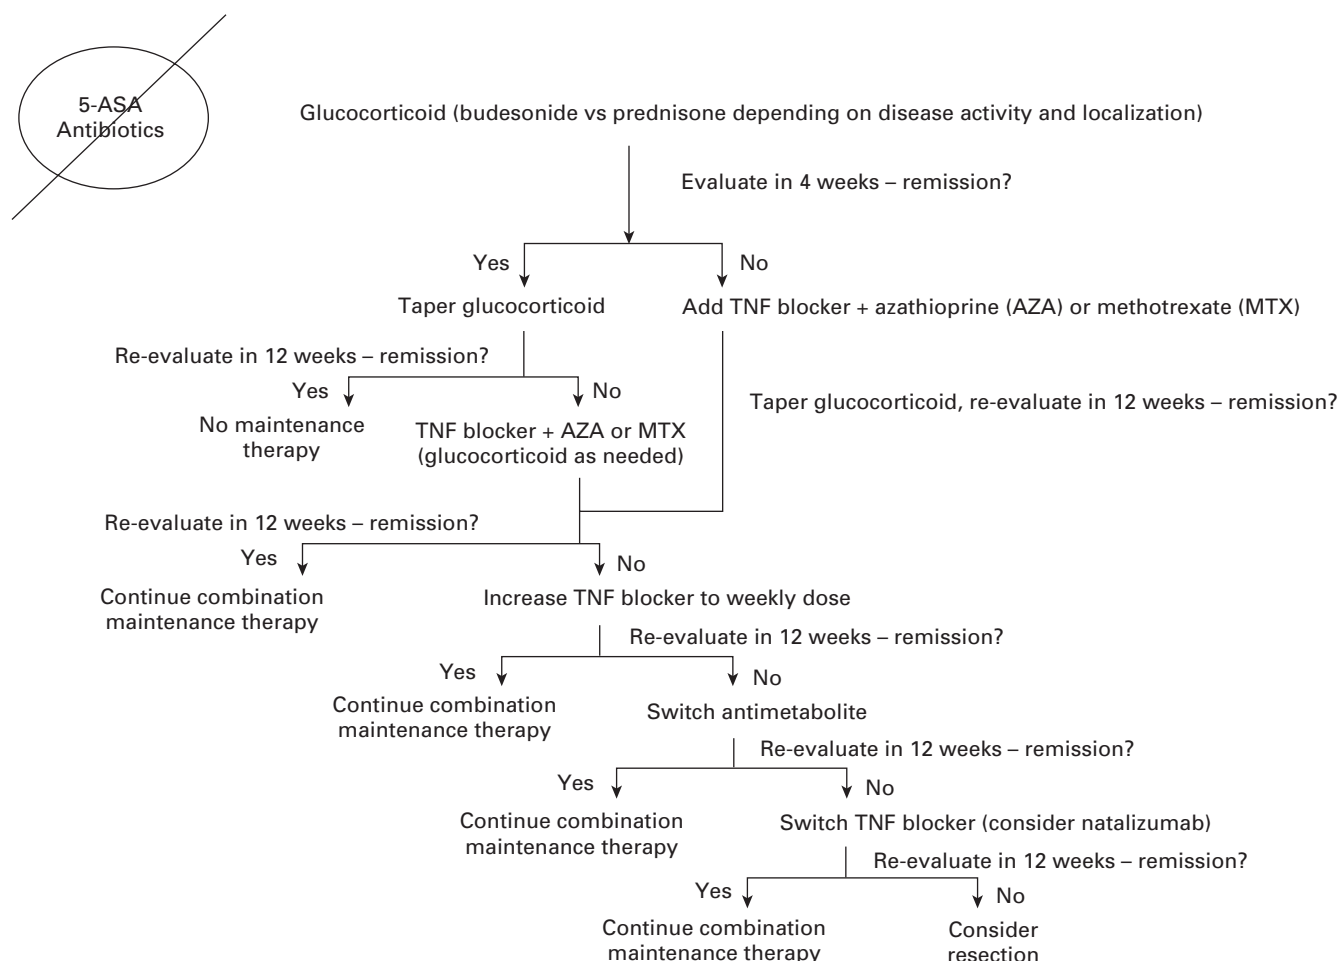

## Summary

An algorithm for the treatment of Crohn's disease is given in Figure 11.10 and Figure 11.11. Figure 11.10 summarizes the conventional stepwise approach, and Figure 11.11 provides detail on a more aggressive accelerated stepwise approach that is currently under evaluation with respect to the possibility that careful monitoring of response at specified intervals and the earlier addition of azathioprine or methotrexate and anti-TNF blockers results in better and earlier outcomes. The evidence is not yet available to support one approach as being superior to the other. We no longer recommend the use of 5-aminosalicylates for induction of remission. Patients with moderately severe disease and involvement of the terminal ileum and/or right colon may be treated with budesonide at a dose of 9 mg/day. Patients with more extensive colonic involvement, those who fail to respond to budesonide or those with severe disease activity should receive either prednisone or parenteral steroids. Failure to achieve control of disease activity with these drugs (therapy-resistant disease) is an indication for addition of azathioprine (or 6-mercaptopurine), methotrexate, infliximab or surgery. Individuals who respond to glucocorticoid therapy should be withdrawn from steroid therapy over a 12–16 week period. In those patients who fail to successfully discontinue prednisone without a reactivation of disease activity (steroid-dependent disease), the introduction of either azathioprine, (or 6-mercaptopurine) or methotrexate treatment is warranted. The use of an anti-TNF alpha agent is indicated for patients who do not respond to one of these drugs. Furthermore, individuals who experience early or frequent relapses of the disease are candidates for long-term therapy with one

**Figure 11.10** Therapeutic algorithm for 'accelerated step-wise' approach to treatment of active luminal Crohn's disease.

**Figure 11.11** Therapeutic algorithm for conventional approach to treatment of active luminal Crohn's disease.

of the purine antimetabolites, methotrexate or an anti-TFN agent. Natalizumab therapy may be considered for patients who fail to respond to these agents, in jurisdictions where it is approved. Surgery remains a highly effective therapy for patients with limited disease who are experiencing adverse effects of medical therapy.

Although our existing medical management is relatively effective for induction of remission of CD, and improves the quality of life of the majority of patients, current therapy for maintenance of remission is less effective. A substantial proportion of patients still experience morbidity from chronically active disease, complications, or adverse effects of drug therapy. Many patients require surgery and a majority undergo more than one resection. At the present time there is insufficient evidence to support the use of any available drug for maintenance of remission following surgery. 5-ASA products may have a small benefit but are probably not cost-effective for this purpose. Metronidazole may also have some benefit, but its use is limited by toxic-

ity. In the future it is highly likely that drugs will become available which are able to favorably modify the natural history of the disease.

## Introduction

Patients with ulcerative colitis have a variety of questions for those practitioners who treat their disease. This chapter focuses on the evidence on which decisions relating to patient advice (prognosis for the first attack, extension of disease, risk of cancer) and treatment options should be made. Our recommendations are based wherever possible on evidence from published population-based studies and randomized controlled clinical trials. Where several clinical trials have addressed the same question we have frequently used meta-analyses to summarize the results.

## Histological diagnosis

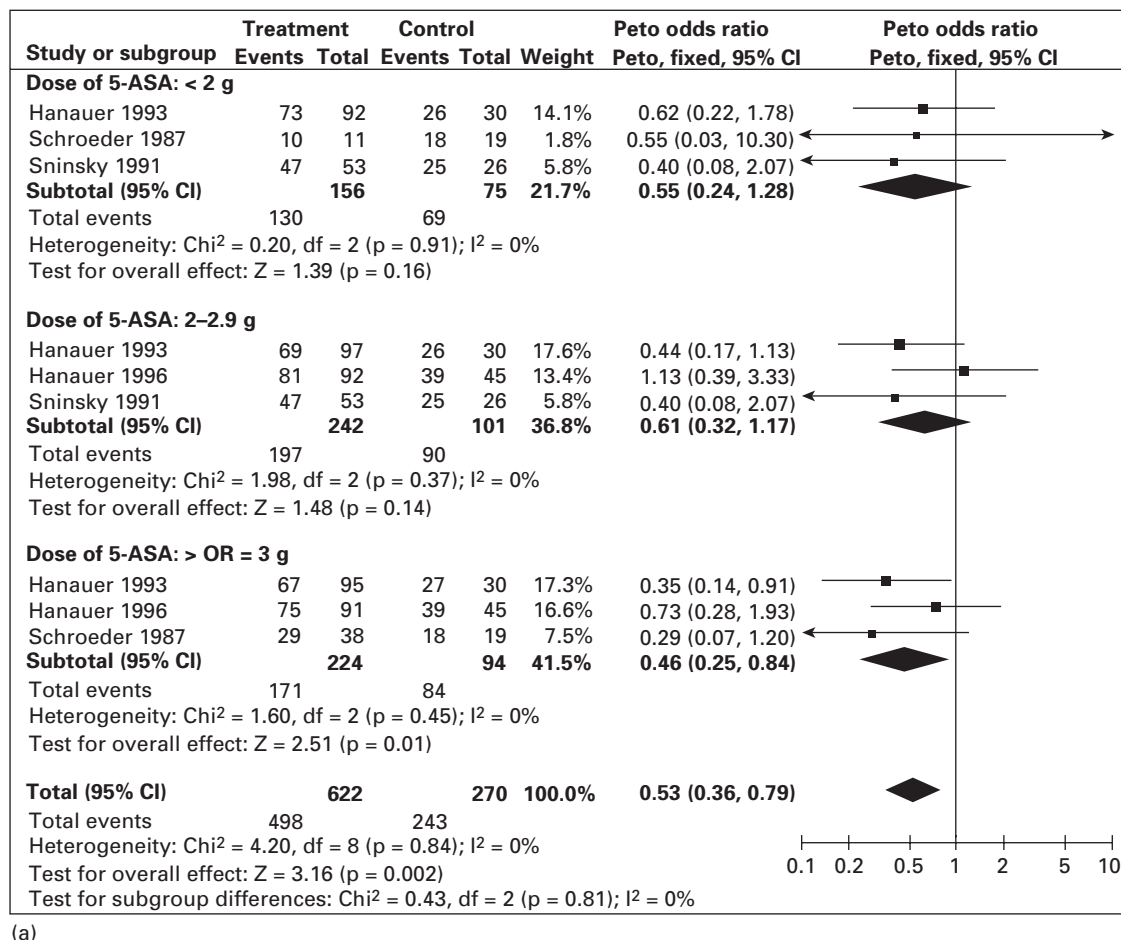

The diagnosis of ulcerative colitis and Crohn's disease, together with accurate differentiation between them and other inflammatory diseases of the colon relies on a combination of clinical, radiological, endoscopic and histological features. Accurate histological interpretation is crucial but is confounded by at least four major problems:

- Variability in assessing normal colorectal histology and assessing minimal degrees of inflammation.
- Considerable overlap in the histological changes of most colonic inflammatory conditions.
- Accuracy and reproducibility of many of the histological features commonly used for diagnosis have not been determined.
- Absence of standard nomenclature.

Recently, a working party of the British Society of Gastroenterology has published guidelines for the biopsy diagnosis of suspected chronic inflammatory bowel disease

[1]. Databases were searched for papers relating to reproducibility, sensitivity and specificity of histological features used for the differential diagnosis of inflammatory bowel disease (IBD). Only those achieving moderate reproducibility (a minimum  $\kappa$  statistic of 0.4 or a percentage agreement of 80% or more) were included. Precise definitions of mucosal architectural changes, lamina propria cellularity, neutrophil infiltration and epithelial cell abnormalities were derived from the systematic review of the literature. Then the quality of the evidence for these features with respect to differential diagnosis was rated according to the criteria recommended by the evidence-based working party. Features for which the literature review provided high quality evidence for their use in differential diagnosis are shown in Figure 12.1. These histopathological criteria formed the basis of guidelines for clinical practice, thereby helping to ensure uniformity and consistency of reporting. Subsequently, a workshop was set up to examine the value of these guidelines [2]. A group of histopathologists was asked to report on a series of colonoscopic biopsies from 60 patients. The group consisted of 13 pathologists with a special interest in IBD and 12 general pathologists. Following this, there was a discussion with regard to the evidence-based guidelines, and the biopsy specimens were then renumbered and re-reported. For ulcerative colitis, the accuracy of reporting was similar in both the first and second rounds, and there was little difference between the expert pathologists and the generalists. However, there was improved accuracy in reporting Crohn's disease following discussion of the guidelines: for the experts accuracy improved from 56% to 64% and for the general pathologists from 50% to 60%. The same workshop was also able to show that multiple, as opposed to single, biopsies led to better and more reproducible diagnoses, especially for Crohn's disease. Thus, the introduction of evidence-based guidelines and training in their use are helpful, predominantly for Crohn's disease, but result in a more accurate histopathological diagnosis only in one in ten colonoscopic series reported.

Review: Ulc. Colitis: induction of remission, 5-ASA  
 Comparison: 5-ASA vs placebo  
 Outcome: Failure to induce global/clinical remission

**Figure 12.1** Evidence-based features for histological diagnosis of colonic biopsy specimens. Note: all features have the highest quality of evidence except for: (a) evidence of diagnostic value from single studies only and (b) no published evidence of accuracy or reproducibility.  
 IBD: inflammatory bowel disease; UC: ulcerative colitis; CD: Crohn's disease.

## Prognosis

### Population-based studies

The importance of recognizing that the prognosis for referred patients differs from that of a regional population was recognized by Truelove and Pena over three decades ago [3]. They found that the survival of patients who were referred to Oxford (UK) from other regions was significantly reduced compared with that of patients who actually resided in the Oxford catchment area.

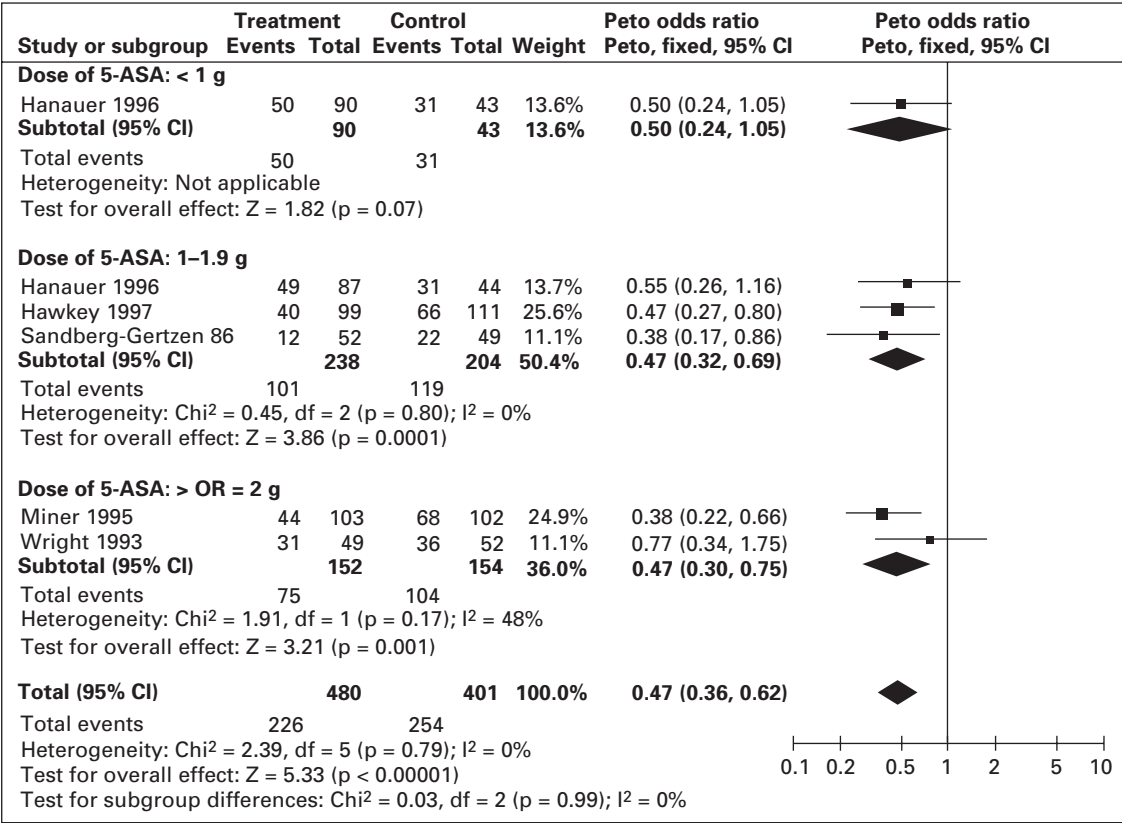

There are several population-based studies on the prognosis for patients with ulcerative colitis. Sinclair and associates described the prognosis of 537 patients with ulcerative colitis, seen between 1967 and 1976 in northeastern Scotland [4]. They found a high proportion of cases with distal

disease (70%). The overall mortality and surgical resection rates in the first attack were both 3%. During this period of time, the mortality for severe, first-time attacks was 23%. However, there were only modest differences in the observed and expected mortality for the ulcerative colitis population. The colectomy rate after five years was 8%.

The prognosis and mortality associated with ulcerative colitis in Stockholm county were reported by Persson *et al.* [5]. In their review of 1547 patients followed from 1955 to 1984, they found that the mortality in the patient population was higher than that expected in the general population. After 15 years of follow-up, the survival rate was 94% of that expected based on the age and sex of the study population. The relative survival rates differed more for patients with pancolitis than for patients with proctitis, but the confidence intervals overlapped. While ulcerative colitis was the most important influence on the increased

Review: Ulc. Colitis: maintenance of remission, 5-ASA  
Comparison: 5-ASA vs placebo  
Outcome: Failure to maintain clinical or endoscopic remission

(b)

Figure 12.1 Continued

mortality, deaths from colorectal cancer, asthma and non-alcoholic liver disease were also increased.

Danish investigators have also reported the results of their population-based assessment of the prognosis of ulcerative colitis. Their population included 1161 patients with ulcerative colitis followed for up to 25 years (median 11 years) [6]. Of the 1161 patients, 235 underwent colectomy. Interestingly, 60 of these patients presented with proctosigmoiditis initially. The cumulative colectomy rate was 9%, 24%, 30% and 32% at 1, 10, 15 and 25 years respectively, after diagnosis. At any one time, nearly half of the clinic population was in remission. Prognostic factors associated with frequent relapses included: the number of relapses in the first three years after diagnosis and the year of diagnosis (1960s vs 1970s vs 1980s). Surprisingly, signs and symptoms of weight loss or fever were associated with fewer relapses on follow-up. A recent report on the same inception cohort of patients, published nearly ten years after these initial observations, has shown that overall life expectancy is normal for patients with ulcerative colitis, but patients over 50 years of age with extensive colitis at diagnosis have an increased mortality within the first two

years, due to colitis-associated postoperative complications and co-morbidity [7].

Another report by the same investigators focused on the prognosis in children with ulcerative colitis [8]. Eighty of the 1161 patients in the cohort were children who presented with more extensive disease compared with adults. The cumulative colectomy rate did not differ from that of adults (29% at 20 years). At any interval from diagnosis, the majority of children were thought to be in remission.

Two prospective population studies are in progress in Europe (the European Collaborative Study on Inflammatory Bowel Diseases and the Inflammatory Bowel South Eastern Norway (IBSEN) cohort) but only one-year, follow-up data have so far been reported [9, 10].

Extension of disease

Ayres and associates reported their experience with extension of disease in 145 patients presenting with proctitis or proctosigmoiditis, followed prospectively for a median of 11 years. By life-table analysis, extension occurred in 16%

and 31% of patients at five and ten years' follow-up respectively. Extension was associated with a clinical exacerbation of disease in most cases, but no specific clinical factors were associated with disease extension [11].

Much higher rates of progression have been reported, largely in retrospective non-population-based series. However, in the IBSEN cohort, 22% of 130 patients with a new diagnosis of ulcerative colitis had progressed to more extensive disease during the first year of follow-up [12]. The most recent study from Italy included 273 patients with proctitis [13]. It is retrospective and not population-based (patients were identified in 13 hospitals) but it is the largest cohort yet reported. Overall, proximal extension occurred in 27.1% during clinical and endoscopic follow-up: 20% at five years and 54% at ten years. However, the disease only extended into the sigmoid in the majority and into the splenic flexure in only 10% of the patients. An interesting observation was that smoking protected against disease progression on univariate analysis.

While research for the most part has focused on extension of disease, Langholz and colleagues report a much more dynamic pattern. After 25 years of follow-up, 53% of patients with limited disease had extension of disease, but in 75% of patients with extensive disease, the disease boundary had regressed [14]. This dynamic process, if confirmed by others, could have implications in terms of cancer surveillance programs. One potential explanation for these findings is that in the early years of the study, disease extent was assessed by radiological techniques.

### Cancer surveillance (see also Chapter 17)

Although ulcerative colitis is a premalignant condition, the proportion of patients who develop cancer is small. In a population study using a retrospectively assembled cohort of patients the cumulative risk at 20 years of disease was about 7% and rose to 12% at 30 years [15]. This study is likely to have included all or nearly all patients with ulcerative colitis in two regions of England and one of Sweden and referral bias is probably minimal. Follow-up was both of long duration (17–38 years) and thorough (97%). On the other hand, in centers with an aggressive policy of colectomy, no increased cancer risk has been seen [16]. In all studies, length of history and extent of disease are important factors. Thus, left-sided colitis carries only a slightly increased risk while extensive colitis increases the risk about 20 times over that of an age and sex-matched population. Whether early age of onset of ulcerative colitis is an independent risk factor is controversial. Children tend to have extensive disease and have greater life expectancy than adults; they are, therefore, more likely to be at risk.

There is some controversy concerning the role of colonoscopic surveillance in detection of cancer. Most centers

carry out colonoscopy in patients with extensive disease 8–10 years after diagnosis. Even at that stage, a few patients with dysplasia or a frank carcinoma will be identified. However, the subsequent pick-up rate during the surveillance program is small (about 11%) and in one center only two cancers were detected in 200 patients over a 20-year period [17]. Furthermore, cancers can develop outside the screening program. Thus, the need for colonoscopic surveillance has been questioned and no controlled study has shown that surveillance reduces mortality. However, in the published studies, the five-year survival rates for cancers detected in asymptomatic patients have been considerably higher than was observed in those presenting with symptoms. **B4 C5**

A second controversial area is the management of patients with endoscopically visible lesions. Where such lesions are associated with dysplasia in the adjacent mucosa (dysplasia-associated lesions or masses (DALMs)) the incidence of cancer appears to be very high and prophylactic colectomy is recommended [18, 19]. However, polyps for which there is no associated dysplasia in adjacent mucosa do not appear to carry this high risk of cancer, and in such cases conservative management rather than colectomy is recommended [20, 21]. **B4 C5**

Reviewing the evidence for dysplasia surveillance, Riddell recommended obtaining three to four biopsies every 10 cm [22]. Annual colonoscopy is probably ideal, but two-yearly colonoscopy with intervening flexible sigmoidoscopy in alternate years is a compromise. Dysplasia detected at the initial screening colonoscopy should lead to colectomy, as there is a high chance of concomitant cancer. Indeed, most clinicians advocate colectomy whenever dysplasia is found, even when it is low grade. There is no doubt that such a policy abolishes the cancer risk but justification for it for patients with low grade dysplasia remains controversial [23, 24]. The development of molecular markers may help to resolve the issue.

### Treatment

The treatment of ulcerative colitis can be conveniently discussed for each category or class of medications, and in terms of either induction or maintenance of remission.

#### Aminosalicylates

With the discovery of sulfasalazine by Svartz [25], the first effective agent for the treatment of ulcerative colitis became available. The first trial that established the efficacy of sulfasalazine for the induction of remission was reported in 1962 [26]. **A1c** Misiewicz and colleagues were the first to study its efficacy as maintenance therapy [27]. An early

Review: Ulc. Colitis: induction of remission, 5-ASA  
Comparison: 5-ASA vs sulfasalazine  
Outcome: Failure to induce global/clinical remission

**Figure 12.2** Failure to induce clinical or endoscopic remission in ulcerative colitis. Randomized controlled clinical trials of mesalamine (5-ASA) and sulfasalazine (SASP): (a) mesalamine (Expt) versus placebo (Ctrl), (b) mesalamine (Expt) versus sulfasalazine (Ctrl). (Source: Sutherland LR et al. *Cochrane Database Syst Rev* 2006; 2: CD000543 [34]).

randomized trial in the UK established the importance of continuous therapy [28]. **Alc** Azad Khan and the Oxford group established that 2g/day of sulfasalazine provided the optimal trade-off between efficacy and adverse effects [29].

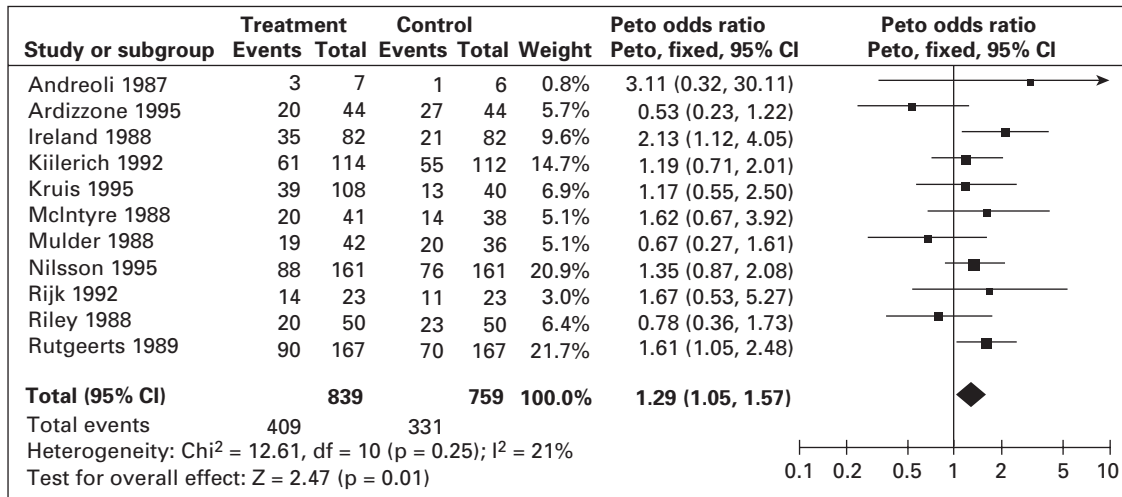

The finding that mesalamine (5-ASA) is the active moiety of sulfasalazine stimulated a decade of trials of induction and maintenance of remission [30, 31]. Numerous aminosalicylate delivery systems have been developed. These include drugs that release 5-ASA upon bacterial splitting of the azo bond (for example sulfasalazine, olsalazine and balsalazide), pH dependent release formulations (for example Asacol (pH 7) and Claversal/Mesasal/Salofalk (pH 6)), and a microsphere preparation (Pentasa) [32].

The efficacy of oral mesalamine has been evaluated by meta-analyses of randomized controlled trials [33–35]. As shown in Figure 12.2a, mesalamine is more effective than placebo for the induction of remission (pooled odds ratio 0.51; CI: 0.35–0.76) [34]. **Ala** The newer 5-ASA preparations

were not significantly more effective than sulfasalazine, however, for active disease (pooled odds ratio 0.75; CI: 0.50–1.13) (see Figure 12.2b). On the other hand, adverse events were less frequently noted with mesalamine than with sulfasalazine: the number of patients needed to treat (NNT) with mesalamine rather than sulfasalazine to avoid an adverse event in one patient is approximately 7. **Ala**

Figure 12.3a illustrates the results of a meta-analysis that demonstrates the superiority of aminosalicylates over placebo for maintenance of remission (pooled odds ratio 0.47; CI: 0.36–0.62) [35]. **Ala** Conflicting results were obtained in studies comparing sulfasalazine with mesalamine for maintenance therapy. The overall results are shown in Figure 12.3b; sulfasalazine appeared to be more effective than mesalamine (pooled odds ratio 1.29; CI: 1.05–1.57). **Ala** When only studies with a minimum of 12 months' follow-up were included in the analysis, however, there was no statistically significant advantage for sulfasalazine (pooled odds ratio 1.15; CI: 0.89–1.50). There are a number

Review: Ulc. Colitis: maintenance of remission, 5-ASA  
 Comparison: 5-ASA vs sulfasalazine  
 Outcome: Failure to maintain clinical or endoscopic remission

**Figure 12.3** Failure to maintain clinical or endoscopic remission in ulcerative colitis. Randomized controlled clinical trials of mesalamine (5-ASA) and sulfasalazine (SASP): (a) mesalamine (Expt) versus placebo (Ctrl), (b) mesalamine (Expt) versus sulfasalazine (Ctrl). (Source: Sutherland LR *et al.* *Cochrane Database Syst Rev* 2006; 4: CD000544 [35]).

of possible explanations for this discrepancy. First, the observation in the overall analysis may be correct: sulfasalazine may be a more effective delivery system than mesalamine. Second, the analysis that was restricted to studies with 12 months' follow-up might have lacked sufficient statistical power to detect a small difference in efficacy. Third, the high drop-out rate with olsalazine therapy might have biased the overall results against mesalamine. Finally, it is possible that the comparison studies suffered from selection bias. With the exception of one trial, the inclusion criteria included tolerance to sulfasalazine [36]. This factor would tend to minimize the occurrence of adverse events with sulfasalazine therapy.

Several oral 5-ASA preparations are available, but two warrant special mention. Olsalazine and balsalazide appear to be approximately as effective as sulfasalazine and mesalamine in the treatment of active ulcerative colitis and in the maintenance of remission. There have been concerns about the development of secretory diarrhea with olsalazine [37, 38], due to interference with  $\text{Na}^+/\text{K}^+$ -ATPase, but the frequency of this adverse effect can be minimized by taking the medication in divided doses with meals [39, 40]. Moreover, systemic absorption of 5-ASA and its metabolites is less with olsalazine than with mesalamine, which might translate into a smaller risk of nephropathy [41, 42]. Several randomized controlled trials have demonstrated a slight (and statistically insignificant) advantage of balsalazide (in a dosage of 6.75g/day) to sulfasalazine 3g/day or mesalamine 2.4g/day in the treatment of active ulcerative colitis. **Ald** The newer agent may provide relief of symptoms and sigmoidoscopic healing more quickly

than mesalamine [43–45], and may be better tolerated [46]. Balsalazide 3g/day appears to be as effective as mesalamine 1.2g/day at maintaining remission, and may provide better relief of nocturnal symptoms in the first three months of maintenance therapy [47]. It should be noted that these observations suggesting small advantages of balsalazide over mesalamine depend on *post hoc* subgroup analyses of relatively small groups of patients and should be interpreted with some caution.

Topical therapy is a logical option for patients with disease limited to the distal colon. In theory, it presents a high concentration of mesalamine to the affected area, while minimizing systemic absorption. Marshall and Irvine have published two meta-analyses of topical therapy [48, 49]. The first analysis established that topical mesalamine was effective for both induction and maintenance therapy in patients with distal disease [48]. **Aic** The second analysis found that mesalamine was more effective than topical corticosteroids for the induction of remission [49]. **Aic** Foam enemas can reliably deliver mesalamine to the rectum and sigmoid colon, and sometimes even to the descending colon, in healthy individuals and patients with ulcerative colitis [50–53]. Foam enemas are superior to placebo, and are at least as easily tolerated and effective as liquid enemas [54–56]. Gel enemas may be better tolerated than foam preparations [57]. Mesalamine suppositories have been shown to be effective for the maintenance of remission of ulcerative proctitis [58]. **Ald**

Some patients may benefit from a combination of oral and topical 5-ASA preparations. A small randomized trial performed by Safdi *et al.* suggested that combined topical

and oral 5-aminosalicylate therapy may be more effective than oral therapy alone [59]. This result was confirmed by Marteau *et al.* in a large randomized, double-blind, placebo-controlled trial in which 127 patients with mild to moderately active colitis were randomized to receive either a 5-aminosalicylate enema or a placebo enema for the first four weeks of treatment with oral 5-ASA 4g/day [60]. At eight weeks the observed remission rates were: 5-ASA enema 64%, placebo enema 43%,  $p = 0.03$ .

## Corticosteroids

Corticosteroids remain the standard therapy for moderate to severe ulcerative colitis. Truelove and Witts were the first to undertake a randomized, controlled trial of cortisone in patients with active colitis, and showed that 100mg/day, followed by tapering over six weeks, was an effective treatment [61]. **A1c** Lennard-Jones and associates reported similar efficacy for prednisone [62]. It appears that once daily dosage yields similar effectiveness as divided doses of the medication [63].

The assumption that there is no additional benefit from the use of more than 40mg/day of prednisone is based on a small randomized trial conducted by Baron and colleagues [64]. This trial compared the outcomes of 58 outpatients who were randomized to 20, 40, or 60mg of prednisone per day. Although either 40 or 60mg/day yielded better results than 20mg/day, no difference in results was observed in patients given 40 versus 60mg/day. The study included too few patients, however, to have sufficient statistical power to rule out a relative benefit from the 60mg dose. **A1d**

Budesonide is a potent second-generation corticosteroid with 90% first pass metabolism, resulting in decreased systemic toxicity [65]. A randomized, controlled trial demonstrated that a targeted colonic release formulation of budesonide appeared to be as effective as prednisolone

and exhibited a more favorable adverse event profile [66].

## A1d

Budesonide enemas have also been used for active distal disease. A meta-analysis published by Marshall and Irvine documented that they are as effective as conventional steroid enemas [67]. **A1c** The only published trial comparing budesonide enemas with 5-ASA enemas revealed no differences in endoscopic or histopathologic scores between the treatment groups, but the clinical remission rate was greater with 5-ASA (60% vs 38%,  $p = 0.03$ ) [67].

Most reported trials have demonstrated no benefit for corticosteroids in the maintenance of remission of ulcerative colitis [68–70].

## Azathioprine and 6-mercaptopurine

Most trials of anti-metabolite drugs in ulcerative colitis have been small. There is no evidence that azathioprine (2–5mg/kg/day) combined with prednisolone induces remission more effectively than steroids alone [71]. **A1c**

Nevertheless, azathioprine has been shown to have a steroid-sparing effect at doses between 1.5 and 2.5mg/kg/day, and the major indication for this drug in ulcerative colitis is for patients who require continuing steroid therapy [72, 73].

In the double-blind, randomized, controlled trial conducted by Jewell and Truelove, patients who had gone into remission during the acute stage were weaned off steroids and given either placebo or maintenance therapy with azathioprine for one year [71]. Overall, azathioprine offered no statistically significant advantage over placebo for reducing the relapse rate. There may have been some benefit to azathioprine, however, in the subgroup of patients who were treated for relapsing disease, as opposed to those who presented with their first episode of colitis, as illustrated in Table 12.1. Specifically, 9 of 24 azathioprine-treated patients in the former group had no relapse during

**Table 12.1** Clinical course during trial in two treatment groups of patients according to whether patients entered trial in first attack of ulcerative colitis or in relapse.

No. of relapses	Admitted in first attack		Admitted in relapses	
	Azathioprine group	Control group	Azathioprine group	Control group

<sup>a</sup>Fisher's exact test.

Reproduced from Jewell DP *et al.* *BMJ* 1974; iv: 627–630 [71].

follow-up, compared with 3 of 25 patients given placebo. More detailed *post hoc* analysis revealed that only seven patients in the azathioprine group experienced at least three relapses or failed therapy, compared with 15 patients in the placebo group ( $p = 0.055$ ). These analyses should be interpreted with caution because they represent *post hoc* subgroup analyses of small numbers of patients.

Hawthorne and colleagues conducted an azathioprine withdrawal trial that suggested a benefit for this drug in the maintenance of remission [74]. In this study, patients who were in long-term remission while taking azathioprine were randomized to continue with the medication or take placebo. During the subsequent year of follow-up, patients receiving placebo relapsed significantly more often than did those who remained on azathioprine. **Ald** It should be pointed out, however, that this type of trial design cannot be used to estimate the size of the treatment effect from an intervention. It is possible that only a small proportion of patients can be maintained in remission with azathioprine, and that most of these patients would relapse if the drug were withdrawn. More recently, Sood *et al.* randomized 35 patients with newly diagnosed ulcerative colitis, all of whom received corticosteroids to induce remission, to receive either sulfasalazine and azathioprine, or sulfasalazine and a placebo for one year [75]. Four patients (23.5%) who received azathioprine suffered relapse of disease, compared to 10 (55.6%) who received sulfasalazine alone ( $p < 0.05$ ). **Ald** This is somewhat stronger evidence that azathioprine is beneficial for maintenance of remission in ulcerative colitis, but the results should be confirmed with a larger study.

A single small randomized trial reported by Maté-Jimenez *et al.* using 6-mercaptopurine rather than azathioprine showed 6-mercaptopurine to be more effective than methotrexate or 5-ASA for induction and maintenance of remission in ulcerative colitis (see below) [76]. **Ald**

## Methotrexate

There have been anecdotal reports of the steroid-sparing effects of methotrexate in patients with chronic active ulcerative colitis. In a double-blind, randomized, controlled trial 67 patients with steroid-dependent disease were randomized to either oral methotrexate 12.5 mg per week (30 patients) or placebo (37 patients) for nine months [77]. No benefit was demonstrated for methotrexate in terms of disease activity, remission rate or steroid dosage. **Ald** The dosage of methotrexate employed in this study, however, was smaller than those used in case reports (up to 25 mg intramuscularly per week). A subsequent small study using oral methotrexate at a dose of 15 mg/week in steroid-dependent ulcerative colitis found that the dosage of corticosteroids could be reduced acutely but that the benefit was not maintained over the subsequent 76 weeks [76]. In

this study Maté-Jimenez *et al.* compared 6-mercaptopurine (1.5 mg/kg), methotrexate (15 mg orally weekly), and 5-ASA (3 g daily) for induction and maintenance of remission in 34 steroid-dependent patients with ulcerative colitis [76]. They reported that 6-mercaptopurine was more effective than either methotrexate or 5-ASA for both induction and maintenance of remission in these patients. **Ald** Larger studies using higher doses of methotrexate would be of interest.

## Cyclosporin

There have been no randomized controlled trials of oral cyclosporin in patients with ulcerative colitis, and case reports have not suggested impressive efficacy. Anecdotal reports of benefit from intravenous cyclosporin led to a randomized controlled trial by Lichtiger and associates, involving 20 patients with severe ulcerative colitis unresponsive to 7–10 days of intravenous hydrocortisone therapy [78]. Patients received either cyclosporin (4 mg/kg) or placebo by continuous intravenous infusion. Nine of the eleven cyclosporin-treated patients went into remission without surgery, compared with none of the patients in the placebo group. Moreover, five of the placebo-treated patients achieved remission after receiving intravenous cyclosporin. **Ald**

Since publication of Lichtiger's trial, intravenous cyclosporin has been extensively used for severe disease. Response rates between 60% and 85% have been reported outside of controlled trials, but many patients subsequently relapse and require colectomy [79, 80]. **B4** Nevertheless, intravenous cyclosporin may be useful especially for patients experiencing their first episode of severe colitis and for those who need time before deciding to undergo surgery. Although most clinical investigators have continued to use 4 mg/kg intravenously, 2 mg/kg was as effective as the higher dose in a randomized trial of 73 patients with severe colitis [81]. **Ald** Further trials are necessary to determine the optimal length of treatment and especially to decide what to do with the responders. Many clinicians discontinue cyclosporin and add azathioprine on the basis that this approach may provide sufficient time for azathioprine to become effective while the corticosteroids are being tapered. For patients who either refuse intravenous corticosteroids or who have previously had major adverse effects (for example psychoses), no difference in effectiveness was demonstrated in a small randomized trial between intravenous cyclosporin as monotherapy and intravenous hydrocortisone [82]. **Ald**

Several clinical trials have shown that oral cyclosporin is not an effective maintenance therapy in patients with steroid-resistant ulcerative colitis who achieved remission with either intravenous or oral cyclosporine [83–85]. Most patients either relapsed (and underwent colectomy) or

required corticosteroid therapy. Uncontrolled trials suggest that azathioprine may be effective in maintaining remission in patients whose disease remitted with intravenous cyclosporine [86–88]. **B4**

Topical cyclosporine has been used for patients with resistant proctitis or distal colitis. Enemas containing 250 mg of the drug have yielded minimal plasma concentrations and no systemic adverse effects. Small clinical series have been reported from Copenhagen, the Mayo Clinic and Oxford. These patients had failed to respond to oral or topical mesalamine, corticosteroids or antimetabolites. Approximately 70% of the patients seemed to improve with topical cyclosporin, although many relapsed when treatment was discontinued. **B4** No formal clinical trial has been conducted in patients with resistant proctitis, largely because of the negative results found by Sandborn and colleagues in a small randomized controlled trial [89]. **Ald** Because this study enrolled only 40 patients, it may not have had sufficient power to exclude a small therapeutic benefit. Furthermore, Sandborn's trial differed from the open series in that it involved patients with active distal colitis instead of resistant proctitis.

## Nicotine

Cigarette smoking seems to protect against the development of ulcerative colitis; ex-smokers and non-smokers are at increased risk [90]. Three randomized controlled trials have examined the efficacy of transdermal nicotine, given concurrently with mesalamine and/or corticosteroids, in the treatment of ulcerative colitis [91–93]. Pullan and associates found that the nicotine patch was more effective than placebo (49% vs 24%) for the induction of remission [91]. Sandborn and colleagues showed that nicotine was superior to placebo (39% vs 9%) at producing clinical improvement [92]. The NNT to induce remission or result in clinical improvement in these two trials was 4 and 3 respectively.

### A1c

A six-week trial failed to demonstrate any benefit of transdermal nicotine over prednisolone 15 mg/day [93]. A more recent randomized controlled trial involving patients with left-sided ulcerative colitis that relapsed despite taking mesalamine 1 g twice daily, compared nicotine patches with prednisone, each given for five weeks [94]. The study found that the rate of relapse after nicotine was less than with prednisone (20% vs 60%), and that patients in the latter group relapsed earlier. **Ald**

Two pilot studies found that nicotine enemas were effective for distal colitis, and randomized controlled trials are warranted [95, 96].

Thomas and associates reported the only randomized controlled trial of transdermal nicotine as maintenance therapy for ulcerative colitis [97]. The study demonstrated no benefit of nicotine 15 mg/day over placebo over a six-

month period, but this may be explained by poor compliance with the patch. **Ald**

## New agents

Many new approaches are being developed for the treatment of moderate to severe ulcerative colitis. Several have now been evaluated in randomized trials.

### Apheretic techniques

Apheretic techniques, in which leukocytes are removed by passing venous blood through absorption columns, have been widely reported to be effective, but virtually all the data are anecdotal, mainly from Japan. A single, small, randomized, controlled trial has been carried out in which 19 ulcerative colitis patients were randomized to receive apheresis or a sham procedure in addition to continuing their conventional therapy [98]. Apheresis appeared to be significantly more "effective" than the sham procedure (remission rates: apheresis 8/10, sham procedure 3/9,  $p < 0.05$ ) and was well tolerated.

However, in a randomized trial in which 168 patients were randomized in a 2:1 ratio to receive apheresis with the Adacolumn Apheresis System or sham apheresis for nine weeks of treatment, clinical remission rates (Mayo score 0–2, with scores of 0 on rectal bleeding and 0 or 1 on endoscopic examination) were: apheresis 17%, sham-treated 11%,  $p = 0.36$ . Clinical response was also observed to be similar in the two groups: apheresis 44%, sham-treated 39%,  $p = 0.62$  [99]. Similar results were obtained in a smaller trial conducted in Europe and Japan. This form of therapy is not effective for patients with moderate to severe ulcerative colitis. **A1c**

### Anti-integrin monoclonal antibodies

Monoclonal antibodies to adhesion molecules, ( $\alpha 4\beta 7$  integrin) have also been investigated in clinical trials, based on the hypothesis that inhibiting the recruitment of lymphocytes into the lamina propria might lead to a downregulation of the inflammation. Feagan *et al.* carried out a randomized placebo controlled trial of two doses (0.5 and 2.0 mg/kg) of the humanized  $\alpha 4\beta 7$  anti-body MLN02 in 181 patients with mildly to moderately active ulcerative colitis (median Ulcerative Colitis Clinical Score 7, median Modified Baron Score 3, minimum disease extent 25 cm) [100]. Remission rates two weeks after the two infusions were significantly greater in the MLN02-treated patients (MLN02 0.5 mg/kg 33%, 2.0 mg/kg 34%, placebo 15%;  $p = 0.03$ ). **A1a** A single patient experienced mild angioedema following MLN02 infusion. Further studies of this agent are required.

### Anti-interleukin-2 receptor antibodies

Based on the favorable experience with intravenous cyclosporine, it is plausible that inhibition of interleukin-2

by other, better tolerated, agents might be an effective therapeutic strategy. Preliminary studies that evaluated two different humanized monoclonal anti-bodies to the interleukin-2 receptor yielded promising results [101, 102]. However, this approach was not effective in a randomized, placebo-controlled dose ranging trial of daclizumab, a humanized antibody to the interleukin-2 receptor (CD25) in 159 patients with moderately severe colitis. The remission rates at week 8 were: daclizumab 1 mg/kg 2%, daclizumab 2 mg/kg 7% and placebo 10% ( $p = 0.11$ , 0.73 respectively, for comparisons of daclizumab doses with placebo). **Alc**

### Anti-tumor necrosis factor (TNF) monoclonal antibodies

The anti-tumor necrosis factor (TNF) strategies have primarily been directed towards Crohn's disease. Following many anecdotal reports of the use of infliximab for severe ulcerative colitis not responding to intravenous corticosteroids [103], and the reporting of two small randomized trials [104, 105], more definitive studies have been reported, and the results have been summarized in a Cochrane Review [106].

This systematic review included a meta-analysis of data from the two trials performed by Rutgeerts *et al.* that included 728 patients with moderate to severe ulcerative colitis refractory to conventional treatment using corticosteroids and/or immunosuppressive agents [107]. Infliximab (three intravenous infusions at 0, 2 and 6 weeks) was more effective than placebo in inducing clinical remission (Relative Risk (RR) 3.22; 95% CI: 2.18–4.76); inducing endoscopic remission (RR 1.88; 95% CI: 1.54–2.28); and in inducing clinical response (RR 1.99; 95% CI: 1.65–2.41) at eight weeks. A single infusion of infliximab was also more effective than placebo in reducing the need for colectomy within 90 days after infusion (RR 0.44; 95% CI: 0.22–0.87). **A1a** Severe adverse effects appear to be rare if patients are screened for latent tuberculosis.

### Alpha interferon

Pegylated interferon alpha in one of two doses (0.5 micrograms/kg or 1.0 micrograms/kg) infused weekly for 12 weeks was compared with placebo in a randomized trial in 60 patients who continued to receive conventional therapies (5-ASA, steroids, azathioprine) in stable doses [108]. A trend toward benefit with the lower dose of interferon was reported, but further studies are required. **Ald**

### Epidermal and fibroblast growth factors

Sinha *et al.* randomized 12 patients with active left-sided colitis or proctitis to receive daily enemas of the potent mitogenic epidermal growth factor (EGF), and 12 to receive placebo enemas for 14 days [109]. All patients received oral mesalamine. At two weeks 10 of the 12 patients given EGF

enemas were in clinical remission, as compared with 1 of 12 in the control group ( $p < 0.001$ ). **Ald** At the two-week assessment, disease-activity scores, sigmoidoscopic scores and histologic scores were all significantly better in the EGF group than in the placebo group ( $p < 0.01$  for all comparisons), and this benefit was maintained at 4 weeks and at 12 weeks. Sandborn *et al.* conducted a randomized, placebo-controlled trial of the fibroblast growth factor repifermin at doses of 1–50 micrograms/kg infused daily for five days in patients with active ulcerative colitis who were receiving 5-ASA, steroids or azathioprine [110]. They found this agent to be safe but not effective at these doses. **Ald**

### Probiotics

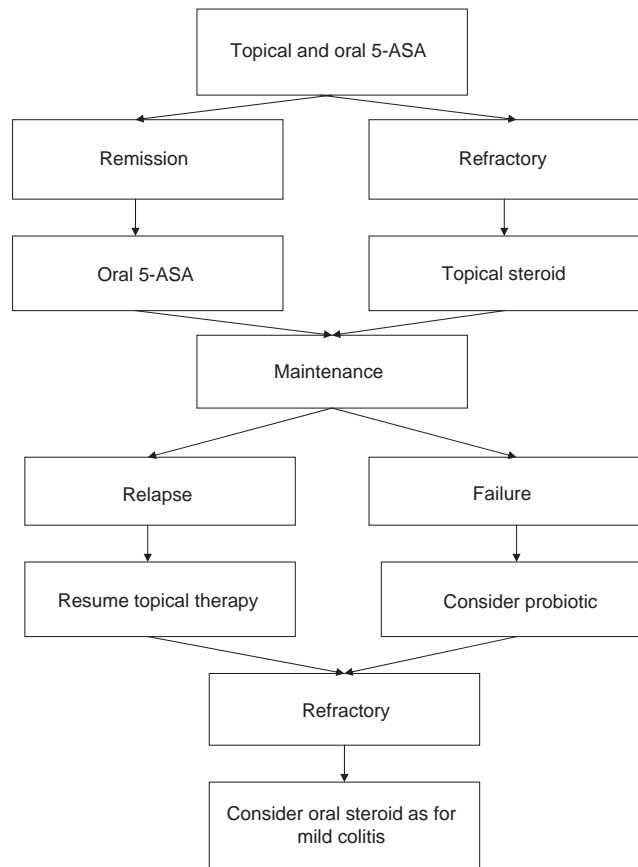

A popular theory regarding the pathogenesis of IBD contends that chronic inflammation is the result of an abnormal host response to the endogenous microflora. Thus, a sound rationale exists for attempts to modify host bacteria in the hope that this will down-regulate the pathological immune response [111]. Experiments in rodents have demonstrated the potential of this approach and preliminary studies in humans have been reported [112, 113]. Earlier studies evaluated single strains of non-pathogenic *E. coli* for maintenance of remission [114].

Kruis [109] randomly assigned 120 patients with ulcerative colitis in remission to receive either 1.5 g/day of 5-ASA or identically appearing tablets that contained *Escherichia coli* strain Nissle 1917 [115]. At the end of this one-year study 11.3% of patients who received 5-ASA relapsed as compared with 16.0% of those who received the probiotic ( $p > 0.05$ ). **Alc** No serious adverse events were associated with active treatment. This study can be criticized because of the very low relapse rate observed in the control group, despite the rather modest dose of 5-ASA that was used. Moreover, the trial was not designed as a formal non-superiority study and therefore lacked sufficient statistical power to assess whether the treatments were clinically equivalent.

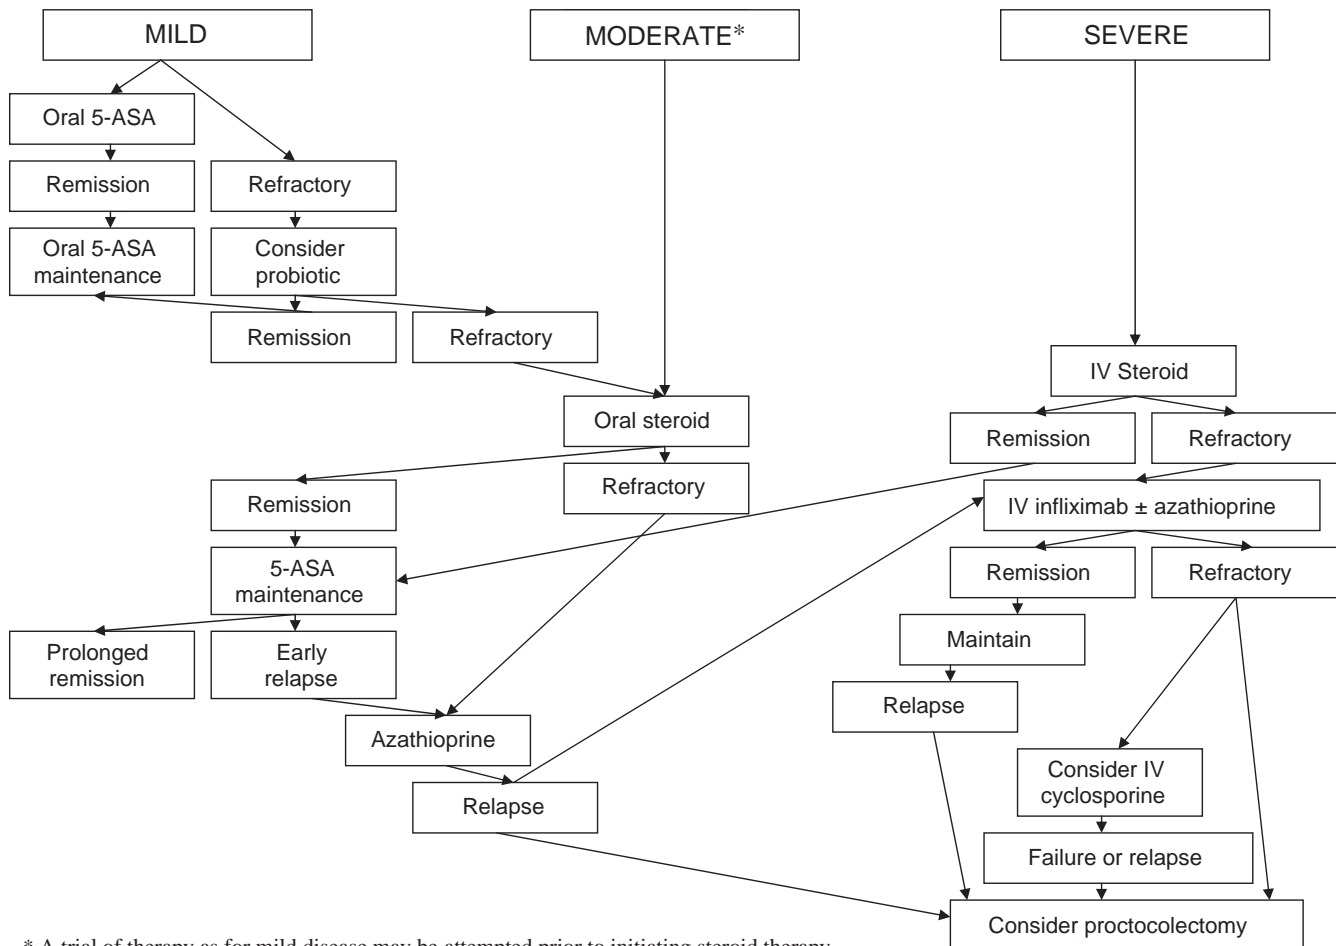

Rembacken *et al.* randomized 116 patients with active disease to receive 5-ASA or the *E. coli* strain [114]. Treatment was continued for one year. At the end of the trial 73% of the patients who had entered remission with conventional therapy relapsed as compared with 67% of those assigned to the probiotic ( $p > 0.05$ ). The authors concluded that the two strategies were of equivalent efficacy. **Alc** In a randomized trial that was designed as a formal non-superiority study, 109 randomized 327 patients with quiescent disease to 200 mg once daily of the probiotic or 500 mg three times daily of 5-ASA for 12 months of treatment. The rate of relapse was 45% in patients who received *E. coli* Nissle 1917 compared with 36% (absolute difference 9%) in favor of 5-ASA and met the investigators' prespecified criterion for therapeutic equivalence [116]. **Ala**

(a)

(b)

\* A trial of therapy as for mild disease may be attempted prior to initiating steroid therapy

**Figure 12.4** (a) Algorithm for management of distal ulcerative colitis. (b) Algorithm for management of more extensive ulcerative colitis.

In summary, these results from relatively large randomized trials provide evidence that probiotics are useful for maintenance of remission in ulcerative colitis. **A1c**

More recently the probiotic preparation VSL #3 that contains a high concentration of eight lyophilized bacterial strains was compared to a placebo containing lyophilized maize powder for induction of remission in 47 patients with mild or moderately active ulcerative colitis [117]. A majority of patients continued with mesalamine therapy alone (VSL #3 89.6%, placebo 67.1%), or in combination with immunosuppressants (VSL #3 6.4%, placebo 21.4%). Clinical remission was observed significantly more frequently in the VSL #3 treated groups (VSL #3 42.9%, placebo 15.7%,  $p < 0.001$ ). No major adverse events were encountered. This study provides evidence that probiotics may be useful as an adjunct to conventional therapy for induction of remission of mild to moderately active ulcerative colitis. **A1d**

## Surgery

Colectomy with construction of an ileal pouch-anal anastomosis has become the operation of choice for ulcerative colitis in major centers. Precise details of pouch construction may affect the eventual functional outcome, although a "J" pouch with 20cm limbs and a stapled anastomosis 1.0–1.5cm above the dentate line is the best for most patients [118–120]. Pouch dysfunction remains a frequent problem, and is often due to "pouchitis". The management of this disorder is addressed in Chapter 13.

## Algorithm for management of ulcerative colitis

When endoscopic evaluation leads to the diagnosis of distal ulcerative colitis, the evidence for efficacy of interventions to induce and maintain remission supports the management algorithm shown in Figure 12.4a.

Therapy should be initiated with topic and oral 5-ASA preparations. If the disease enters remission, maintenance therapy with an oral 5-ASA preparation should be continued. If the disease relapses, topical therapy may be resumed and may be continued for maintenance of remission. Distal disease that is refractory to a topical 5-ASA preparation may be treated with a topical steroid preparation. Although there is evidence that the 5-ASA preparations are more effective, and there is no good evidence that switching to topical steroids is effective, the latter approach is a logical one that may be successful in some patients. Failure to respond to oral and topical 5-ASA should also lead to consideration of adding a probiotic preparation (*E. coli* Nissile 1917 or VSL #3). Patients in whom distal disease is refractory to these interventions should be considered for interventions proven to be effective for mild but more extensive

disease, as outlined in Figure 12.4b.

The choice of interventions for treatment of more extensive colitis should be made after classifying the clinical disease severity as mild, moderate or severe. Mild disease should be treated with an oral 5-ASA. If the disease is refractory to this approach the addition of the probiotic preparation VSL #3 may be considered. If remission is achieved with these interventions the 5-ASA preparation, and possibly the probiotic, should be continued for maintenance therapy.

Moderately severe disease, and mild disease that is refractory to 5-ASA and probiotic therapy, should be treated with oral steroid. It is appropriate to treat some patients with moderately severe disease initially as outlined for mild disease, rather than initiating corticosteroid therapy, but the patients should be closely monitored for an increase in severity that would be a strong indication for steroid therapy. If remission is achieved maintenance therapy with oral 5-ASA is continued. Refractory colitis and early or frequently relapsing disease should lead to a consideration of introducing azathioprine therapy.

Severe colitis should be treated with IV steroids for a minimum of five days. Severe colitis that is refractory to IV steroids, and moderately severe disease that is refractory to or relapses on the regimen outline above, may be treated with IV Remicade as the next line of induction therapy. If remission is achieved maintenance therapy with Remicade and/or azathioprine should be considered.

Patients with severe or moderately severe disease that is either refractory to IV Remicade or relapses in spite of maintenance therapy, should be advised to consider proctocolectomy. This option, rather than immunosuppressive therapy with Remicade or azathioprine, may also be selected by some patients with less severe refractory or frequently relapsing disease. IV cyclosporine is another alternative therapy that may be considered for some patients with severe refractory disease who are reluctant to proceed to surgery, but the risk of severe adverse effects is relatively high, and a majority of such patients will eventually undergo proctocolectomy.

## Pouchitis after restorative proctocolectomy

*Darrell S Pardi and William J Sandborn*

Inflammatory Bowel Disease Clinic, Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, USA

### Introduction

Approximately 30% of patients with ulcerative colitis will require colectomy for fulminant or medically refractory disease, or because of dysplasia or another complication [1, 2]. The preferred operation for most patients is a restorative proctocolectomy, also known as a total proctocolectomy with ileal pouch anal anastomosis (IPAA). Although many studies have shown excellent quality of life in patients who have undergone IPAA, complications are common after this operation [3, 4]. Pouchitis, an idiopathic inflammatory condition in the pouch, is the most common, occurring in up to 60% of patients after IPAA for ulcerative colitis [1–7]. It has been estimated that the number of patients with pouchitis in the USA will reach 30,000–45,000 persons, or a prevalence of 12–18/100,000 [8]. Thus, pouchitis has emerged as an important third form of inflammatory bowel disease (IBD).

Despite these facts, criteria for diagnosis, classification and measurement of disease activity in pouchitis are still evolving. The previous lack of consensus on these issues hampered the design and conduct of randomized trials of proposed interventions, and medical therapy for pouchitis was largely empirical. This lack of consensus also makes it difficult to analyse the existing literature due to differing definitions or categories of disease and differing criteria for response or remission. In 1994, the Pouchitis Disease Activity Index (PDAI), an instrument to measure disease activity and efficacy of therapy, was developed [9]. This index facilitated clinical research in pouchitis, and there are now 13 controlled trials, and many more uncontrolled

studies, of various agents for induction and maintenance therapy in pouchitis. The medical therapies reported to be of benefit for pouchitis are shown in Table 13.1. This chapter will assist physicians and surgeons in becoming familiar with the diagnosis and classification of pouchitis, and will review the results from reports of empirical medical therapies and controlled trials, and the rationale for using various treatments.

### Diagnosis and classification

Pouchitis is suggested by variable clinical symptoms, including increased stool frequency, decreased stool consistency, abdominal cramping, fecal urgency, tenesmus, incontinence, and occasionally rectal bleeding, fever or extra-intestinal manifestations such as arthralgias. Since these symptoms are non-specific, a clinical suspicion of pouchitis should be confirmed by endoscopy and biopsy of the pouch [1]. Endoscopic examination shows inflammatory changes, which may include mucosal edema, granularity, contact bleeding, loss of vascular pattern, hemorrhage and ulceration [10]. Histologic examination shows acute inflammation with neutrophil infiltration and occasionally mucosal ulceration, superimposed on a background of chronic changes including villous atrophy, crypt hyperplasia and chronic inflammatory cell infiltration [11, 12]. Endoscopic examination of the neo-terminal ileum above the ileal pouch should be normal. Significant inflammation in this location is suggestive of Crohn's disease [10]. In addition, the anal transition zone, or rectal cuff, should also be inspected endoscopically [10]. Inflammation here is termed cuffitis, and can exist with or without pouchitis.

The PDAI is a quantitative 19-point index of pouchitis activity based on clinical symptoms and findings on endoscopy and histology (Table 13.2). Active pouchitis is defined as a PDAI score  $\geq 7$  points and remission is defined as a

**Table 13.1** Treatments reported to be beneficial for pouchitis.**Antibiotics**

- Single antibiotics  
Ciprofloxacin, metronidazole, amoxicillin/clavulanate, erythromycin, tetracycline, rifaximin
- Combination antibiotics

Pouchitis is defined as a total PDAI score > 7 points.

Adapted with permission from Sandborn WJ *et al. Mayo Clin Proc* 1994; **69**: 409–415.

PDAI score < 7 points, assuming other causes of pouch inflammation have been excluded.

Patients with pouchitis can be classified according to disease activity (mild, moderate, or severe), symptom duration, disease pattern or response to antibiotics [1]. Duration can be classified as acute (<4 weeks) or chronic (≥4 weeks). Disease pattern can be classified as infrequent (1–2 episodes per year), relapsing (≥3 episodes per year), or continuous. Relapsing pouchitis is also considered a form of chronic pouchitis, even if the symptoms during a single episode do not last for four weeks on therapy. Finally, pouchitis can be classified as antibiotic-responsive, dependent or refractory.

## Treatment with antibiotics

### Rationale

The fact that pouchitis typically does not occur until the diverting ileostomy is closed and luminal contents flow through the pouch suggests that bacterial antigens are important in driving the inflammatory process. However, it is not clear whether pouchitis occurs due to overgrowth of commensal bacteria or the presence of abnormal bacteria [13–17]. After IPAA, the primary function of the terminal ileum changes from absorption to storage, and bacterial

overgrowth occurs by design, with bacterial concentrations increasing to levels that are intermediate between those seen with an end ileostomy and in the colon [18, 19]. There is no correlation between fecal bacterial concentrations and histologic changes of acute inflammation [18, 19], suggesting that pouchitis and bacterial overgrowth are not directly related. However, anaerobic bacterial overgrowth of the pouch is associated with transformation of the ileal mucosa to a “colon-like” morphology (with villous atrophy, and chronic inflammatory cell infiltration) [18, 20]. Furthermore, the flora in pouch effluent has a higher ratio of anaerobes to aerobes and more *Bacteroides* and *Bifidobacteria* than effluent from subjects with an end ileostomy [19, 21]. However, in other studies, total aerobes and some pathogenic bacteria (*Clostridium perfringens* and hemolytic strains of *Escherichia coli*) may be increased, while total anaerobes are decreased [22]. Thus, pouch anaerobic bacterial overgrowth may indirectly set the stage for pouchitis to the extent that “colon-like” ileal mucosa may be more susceptible to a recurrence of UC. Strategies directed towards reducing fecal concentrations of anaerobic bacteria through the use of antibiotics may be useful in treating pouchitis.

## Clinical results

Antibiotics are the standard medical therapy for pouchitis, based on a small number of controlled trials as well as overwhelming clinical evidence that antibiotics are effective. Previously, the most commonly used antibiotic for pouchitis was metronidazole [19, 23–26], with most patients responding to doses of 750–1500 mg/day within 1–2 days. The first controlled trial of metronidazole was a small, placebo-controlled crossover trial [27]. Each patient had a seven-day washout period before crossing over to the second therapy. Metronidazole was better than placebo at improving the daily stool frequency, although the overall change was small, and there was no significant difference in endoscopic or histologic improvement. A second small controlled trial compared two weeks of treatment with metronidazole 20 mg/kg/day with ciprofloxacin 1000 mg/day in patients with acute pouchitis [28]. Both drugs significantly reduced the PDAI score, but ciprofloxacin had a greater reduction with fewer side effects. Based on this study, other reports of the effectiveness of ciprofloxacin [25], and the high risk of adverse effects seen during metronidazole treatment (33–55%, including nausea, vomiting, abdominal discomfort, headache and skin rash [27–29]), ciprofloxacin has become the antibiotic of choice for most patients with active pouchitis. **A1d** Amoxicillin/clavulanic acid, erythromycin, tetracycline and topical metronidazole have also been reported to be of benefit [1]. Rifaximin, a non-absorbed oral antibiotic, was not superior to placebo in a small randomized clinical trial [30]. **A1d**

In patients who do not respond to a single antibiotic, treatment with combination antibiotics, such as ciprofloxacin and rifaximin [31], ciprofloxacin and metronidazole [32], or ciprofloxacin and tinidazole [33] have been reported beneficial in open-label studies.

Patients with relapsing pouchitis may require chronic maintenance antibiotic therapy. Given the risk of adverse effects with prolonged metronidazole therapy, these patients are usually treated with ciprofloxacin at doses ranging from 250 mg every third day up to 1000 mg/day, although many can be controlled with 250 mg every 1–2 days.

---

## Treatment with probiotics

### Rationale

As mentioned above, there is extensive evidence implicating changes in the pouch bacterial milieu in the pathogenesis of pouchitis. Thus, strategies directed at altering the relative balance of bacteria using probiotic therapy may be useful in treating or preventing pouchitis.

## Clinical results

Three controlled trials have been performed [34–36]. The first two studies randomized patients with chronic pouchitis in remission after induction therapy with antibiotics to treatment with either an oral probiotic preparation (VSL-3, which contains strains of lactobacilli, bifidobacteria and streptococci) or placebo for 9–12 months [34, 35]. The relapse rates in the VSL-3 groups were 10–15% compared with 94–100% with placebo. In a third study, patients undergoing colectomy and IPAA were randomized to prophylactic therapy with VSL-3 or placebo for one year [36]. The rate of developing pouchitis during the first year was 10% in the VSL-3 group and 40% in the placebo group. **A1d** In this study, VSL-3 also reduced the stool frequency of patients without clinical pouchitis. Finally, an open-label study of VSL-3 suggested efficacy for the treatment of mildly active acute pouchitis [37], and a case report of two patients suggested that another probiotic, *E. coli* Nissle 1917, may be of benefit for the treatment of active pouchitis and for maintenance therapy [38].

In contrast, an open-label study of VSL-3 in clinical practice was less encouraging [39]. In this uncontrolled report of 31 patients with antibiotic-dependent chronic pouchitis treated at a referral center, <20% were able to maintain remission on VSL-3 during eight months of follow-up.

## Treatment with anti-inflammatory and immune modifier agents

### Rationale

Pouchitis may represent a recurrence of IBD in the ileal pouch. Data to support this view include: an increased frequency of pouchitis in patients with UC compared to those with familial polyposis; an increased frequency of pouchitis in patients who have extra-intestinal manifestations of UC, primary sclerosing cholangitis (PSC) or antineutrophil cytoplasmic antibodies (pANCA); and a decreased frequency of pouchitis in current smokers. Strategies directed towards empirical medical therapy with agents known to be efficacious in IBD may be useful in treating pouchitis. Unfortunately, few controlled trials have been reported to provide evidence for the efficacy of these approaches.

### Clinical results

Uncontrolled studies suggest that topical mesalamine (enemas or suppositories), sulfasalazine and oral mesalamine may be beneficial for active pouchitis [19, 26, 40–42]. Uncontrolled reports also have suggested that oral and topical corticosteroids may be of benefit in pouchitis [19, 26, 42, 43]. Budesonide suppositories resulted in clinical and endoscopic improvement, and decreased pouch concentrations of inflammatory mediators, in a small study in acute pouchitis [44]. A randomized controlled trial of budesonide enemas versus oral metronidazole showed equivalent efficacy, but fewer side effects from budesonide [29]. **A1d** Oral controlled release budesonide has also been reported to be effective for the treatment of pouchitis in uncontrolled reports. In one study, budesonide (9 mg/day for eight weeks) induced remission in 72% of patients not responding to one month of ciprofloxacin or metronidazole [45]. In another small open-label series [46], budesonide therapy induced a 60% response rate in patients refractory to antibiotics. **B4**

Cyclosporin enemas were reported to be beneficial in one patient with active chronic pouchitis [47]. Two studies involving 11 patients with IPAA who underwent liver transplantation for PSC have reported on the clinical course of pouchitis [48, 49]. Five of 11 patients had chronic pouchitis following transplantation, despite immunosuppression with cyclosporin or tacrolimus, prednisone, and azathioprine, suggesting that immunosuppression may not be efficacious for pouchitis, at least in this population. **B4** Two small reports have suggested a beneficial effect of azathioprine in patients with Crohn's disease and an IPAA [50, 51]. Recently, infliximab has been reported to be of benefit in patients with pouchitis [51, 52]

and patients with Crohn's disease of the ileoanal pouch [53, 54, 55].

## Treatment with nutritional agents

### Rationale

In a well-functioning ileal pouch, the bacterial flora produce short chain fatty acids (SCFA), including acetate, propionate and butyrate at concentrations similar to those in the colon of healthy controls, and increased compared with stomal SCFA concentrations in ileostomy patients [18, 56]. Some [57, 58], but not all [18], studies have reported that patients with pouchitis have significantly lower concentrations of SCFAs than healthy patients with IPAA, perhaps from dilution [57]. Strategies directed at administering SCFA enemas or suppositories, or dietary fiber that is fermented to SCFA, may theoretically be useful in treating pouchitis. Another nutritional approach to improving pouch function is through use of non-fermentable dietary fiber, with the goal of improving stool consistency.

### Clinical results

A case report using SCFA enemas containing sodium acetate, propionate and butyrate reported success in active chronic pouchitis [59]. However, SCFA enemas were of little or no benefit in two other reports of patients with active pouchitis [60, 61]. A fourth study, in patients with active chronic pouchitis, reported improvement in 3/9 patients treated with sodium butyrate suppositories compared with 6/10 patients treated with glutamine suppositories [58]. **B4** Inulin, a dietary fiber that is fermented to SCFAs, increases fecal butyrate concentrations and lowers fecal pH, concentrations of *Bacteroides fragilis*, and concentrations of some secondary bile acids in patients with IPAA compared to those treated with placebo [62]. However, the effectiveness of inulin for the treatment of active pouchitis is unclear. A crossover trial with pectin (a soluble fermentable fiber) and Citrucel (a methyl cellulose-based non-fermentable fiber) found that neither improved stool frequency, pouch function, bloating or stool consistency after IPAA [63]. Thus, these small studies suggest that neither SCFA enemas or suppositories, nor fiber, are highly effective therapies for active pouchitis.

## Treatment with allopurinol

### Rationale

During construction of the ileal pouch, the mesenteric vessels may be divided to avoid tension on the pouch-anal

anastomosis [64]. This ligation of the blood supply has the potential to cause ischemic injury to the pouch, and oxygen free radical formation is known to be one of the mechanisms by which ischemic injury occurs [26]. However, there are little or no objective data demonstrating that pouch ischemia occurs in many patients with pouch dysfunction. If ischemia did contribute to the pathogenesis of pouchitis, then medical therapy directed toward reducing oxygen free radical formation, such as the xanthine oxidase inhibitor allopurinol, might be a useful strategy for the treatment of pouchitis.

### Clinical results

An uncontrolled study reported that oral allopurinol induced clinical improvement in 4/8 patients with active acute pouchitis and maintained remission despite the withdrawal of suppressive antibiotic therapy in 7/14 patients with chronic pouchitis [65]. However, a randomized, double blind, placebo-controlled trial of allopurinol for the prophylaxis of pouchitis in 184 patients undergoing IPAA was negative [66]. **A1a** Additionally, there was no difference in overall pouch function between these two groups. These findings do not support the idea that ischemic damage and free radical injury contribute to the pathogenesis of pouchitis.

## Treatment with bismuth

### Rationale

Bismuth has both antimicrobial and antidiarrheal properties, and has been useful in the treatment of traveler's diarrhea. A controlled trial suggested that bismuth citrate may be comparable with mesalamine for the treatment of left-sided UC [67]. Given the benefit of bismuth for traveler's diarrhea, and its potential benefit in UC, therapeutic trials of bismuth in pouchitis seemed reasonable.

### Clinical results

An uncontrolled study of bismuth carbomer enemas suggested beneficial effects in chronic pouchitis [68]. However, a small randomized controlled trial in active chronic pouchitis showed no benefit compared with placebo [69]. **A1d** In this study, the placebo response rate was high, and thus it is possible that bismuth carbomer and the xanthan gum used for the placebo were both effective therapies. Furthermore the study may have lacked power to demonstrate a significant difference, should one exist. An uncontrolled maintenance study of bismuth carbomer foam enemas in patients with pouchitis demonstrated minimal systemic absorption of bismuth, no toxicity and possible

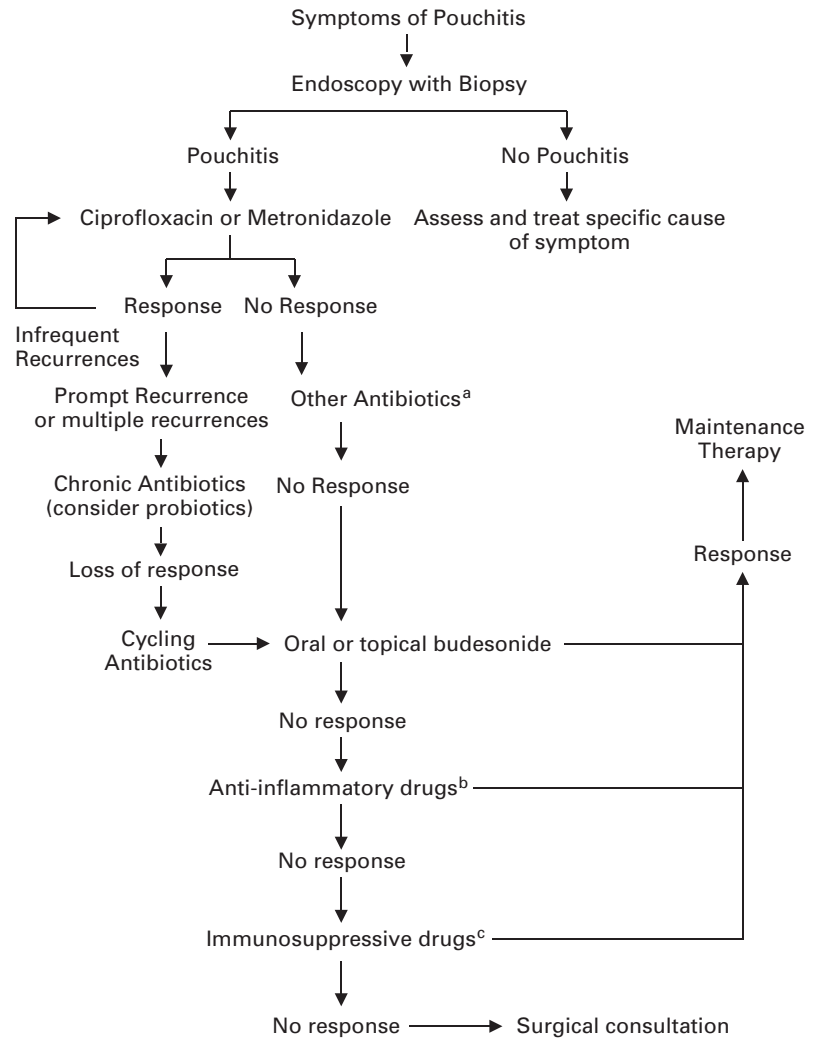

continued clinical benefit in patients with chronic pouchitis after treatment for 9–128 weeks [70]. Further support for a potential therapeutic effect of bismuth in pouchitis comes from an uncontrolled study of oral bismuth subsalicylate tablets, which suggested a beneficial effect in 11/13 patients with active chronic pouchitis [71]. **B4** Adequately powered controlled trials, using an inactive placebo, are needed to determine whether bismuth has a role in the treatment of pouchitis.

## Treatment algorithm for pouchitis

An algorithmic approach to treatment of pouchitis is shown in Figure 13.1. A presumptive diagnosis of pouchitis in patients with compatible symptoms should be confirmed by pouch endoscopy and biopsy. After the diagnosis is confirmed, treatment with ciprofloxacin or metronidazole is initiated. Responding patients who experience recurrent episodes and are able to tolerate the medication should be re-treated with the same regimen. Some patients with recurrent pouchitis (e.g.  $\geq 3$  episodes per year or recurrence within one or two months of stopping antibiotic therapy) will benefit from long-term suppressive or maintenance antibiotic therapy. If patients who require suppressive antibiotic therapy develop bacterial resistance after prolonged treatment, cycling of three or four antibiotics may be beneficial. Probiotic therapy can also be considered in patients with chronic pouchitis as an alternative to maintenance antibiotic therapy. Those patients who do not respond to a single antibiotic are usually tried on another antibiotic or combination antibiotics. If this strategy is ineffective, therapy with oral budesonide or aminosalicylate products, or topical pouch therapy with mesalamine or steroids, can be considered. In more refractory cases, azathioprine, 6-mercaptopurine or even infliximab may be useful. Some patients may require combination therapy with multiple agents, as for some patients with IBD, although there are no data to support this approach. There are few data and there is limited rationale to support empirical therapy with SCFA enemas, glutamine suppositories, inulin or allopurinol. A small number of patients will be refractory to all forms of medical therapy, and these patients should be referred to a surgeon for consideration of permanent ileostomy with pouch exclusion or excision.

## Response to treatment of pouchitis (natural history)

In patients with IPAA for UC, the cumulative risk of developing at least one episode of pouchitis is approximately 30–60% [1]. Of those patients who develop pouchitis, approximately 35% have one or two episodes per year

**Figure 13.1** Treatment algorithm for pouchitis. Rifaximin<sup>a</sup>; amoxicillin/clavulanate; erythromycin; tetracycline; and cycling of multiple antibiotics. Bismuth subsalicylate<sup>b</sup>, mesalamine enemas; sulfasalazine; and oral mesalamine. Budesonide<sup>c</sup>, steroid enemas; oral steroids; azathioprine. (Reproduced with permission from Mahadevan U and Sandborn WJ. *Gastroenterology* 2003; **124**: 1636–1650).

which respond to treatment with antibiotics, 50% relapse more frequently ( $\geq 3$  episodes per year) but still respond to antibiotics, and 15% require maintenance therapy and have been classified as having chronic pouchitis [8]. Of patients with chronic pouchitis, some require surgical exclusion or excision of the pouch. An algorithm showing the clinical course of pouchitis in IPAA patients is shown in Figure 13.2.

## Conclusion

Small controlled trials have demonstrated the efficacy of ciprofloxacin and metronidazole for acute pouchitis and budesonide enemas for active chronic pouchitis. Three trials suggested that probiotic bacteria may be useful in maintaining remission of chronic pouchitis and as prophylaxis against developing pouchitis. Controlled trials of rifaximin, bismuth carbomer and allopurinol did not demonstrate

**Figure 13.2** Clinical outcome with regard to pouchitis in 100 patients with ulcerative colitis (UC) undergoing proctocolectomy with ileal pouch-anal anastomosis (IPAA). (Reproduced with permission from Sandborn WJ. In: *Trends in Inflammatory Bowel Disease*. Kluwer Academic, Lancaster, UK, 1997).

efficacy. Uncontrolled studies suggest possible benefit from other antibiotics, sulfasalazine, mesalamine, corticosteroids and bismuth. There are few data suggesting that immune modifiers, SCFA enemas or inulin are of benefit.

Natural history studies suggest that most patients with pouchitis respond to a short course of antibiotic therapy. Some patients with chronic pouchitis require suppressive medical therapy with antibiotics or probiotics, and some will require permanent ileostomy with pouch exclusion or excision. Additional randomized, double blind placebo-controlled trials are needed to determine the efficacy of empirical medical therapies currently being used in patients with pouchitis.

## Microscopic colitis: Collagenous and lymphocytic colitis

Johan Bohr<sup>1</sup>, Robert Löfberg<sup>2</sup> and Curt Tysk<sup>1</sup>

<sup>1</sup>Department of Gastroenterology, Örebro University Hospital, Örebro, Sweden

<sup>2</sup>IBD Unit, HMQ Sophia Hospital, Karolinska Institute, Stockholm, Sweden

Microscopic colitis is characterised clinically by chronic, non-bloody diarrhea, a macroscopically normal or near-normal colonic mucosa and specific histopathologic features. Collagenous colitis and lymphocytic colitis constitute the two main forms of microscopic colitis. Collagenous colitis was first described by Lindström in 1976. The name emphasized the subepithelial collagenous band which characterises this disease [1]. The term lymphocytic colitis was introduced by Lazenby *et al.* in 1989, to reflect the fact that the major feature of lymphocytic colitis was an increased number of intraepithelial lymphocytes [2].

### Epidemiology

Collagenous colitis was initially regarded as being rare, until the first epidemiologic studies showed incidence rates of 1.8/100,000 and 2.3/100,000 inhabitants and a prevalence of 15.7/100,000 inhabitants [3, 4]. Recent epidemiologic studies, however, show that collagenous colitis is more common, and incidence figures of 4.6/100,000 to 6.2/100,000 inhabitants have been reported (Table 14.1) [5–9]. Patients with collagenous colitis are typically middle-aged women, the average age at diagnosis being around 65 years, and the female: male ratio is approximately 7:1 (Figure 14.1) [3–5]. However, 25% of 163 patients were diagnosed before the age of 45 years so the diagnosis must be considered even in younger patients with chronic watery diarrhoea [10]. A few children below the age of 12 have been reported [11].

Epidemiologic data for lymphocytic colitis have now been reported from five different regions in Europe and North America (Table 14.1) [5–9]. The data have been fairly

consistent in the more recent studies, in which an annual incidence of 4 to 5.5 per 100,000 inhabitants has been reported. The incidence of collagenous and lymphocytic colitis is close to the incidence of Crohn's disease and combined rates for collagenous colitis and lymphocytic colitis approach the incidence of ulcerative colitis. The data illustrate that these conditions are more common than was considered earlier. Microscopic colitis may be diagnosed in 10% of patients investigated for chronic non-bloody diarrhea, and in 20% of such patients older than 70 years [12]. The average age at onset of symptoms in lymphocytic colitis is approximately 60 to 65 years, but the female predominance is less pronounced than is reported for collagenous colitis (Figure 14.2).

### Histopathology

#### Collagenous colitis

The following histopathologic features are the hallmarks of collagenous colitis:

- Diffuse non-continuous thickening of a subepithelial collagen layer beneath the basement membrane (See colour plate 14.1) with the thickness of the subepithelial layer measuring at least 10 µm on a well-orientated section of the mucosa (in comparison to 0–3 µm in normal tissue)
- Chronic inflammation in the lamina propria dominated by lymphocytes and plasma cells
- Flattening and vacuolisation of the epithelial cells and detachment of the surface epithelium
- Intraepithelial lymphocyte infiltration may be present, although this feature is not as prominent as in lymphocytic colitis [2, 13].

Cryptitis does not exclude the diagnosis of collagenous colitis [14]. In the matrix containing the thickened collagen layer collagen type I, III and VI and fibronectin have been identified [15, 16]. The histopathologic findings are mainly

**Figure 14.2** Age and sex-specific incidence of lymphocytic colitis. Reprinted with permission from Olesen *et al. Gut* 2004; **53**: 346–350 [6].

Table 14.1 Annual incidence per 100,000 inhabitants of collagenous and lymphocytic colitis in population based epidemiological studies.		
Region and study period	Collagenous colitis	Lymphocytic colitis
Örebro, Sweden, 1984–88 [3]	0.8	
Örebro, Sweden, 1989–93 [3]	2.7	
Örebro, Sweden, 1993–95 [6]	3.7	3.1
Örebro, Sweden, 1996–98 [6]	6.1	5.7
Örebro, Sweden 1999–2004 [8]	5.2	5.5
Terrassa, Spain, 1993–97 [4]	2.3	3.7
Iceland, 1995–99 [5]	5.2	4.0
Olmsted, USA 1985–89 [7]	0.3	0.5
Olmsted, USA 1990–93 [7]	1.6	1.0
Olmsted, USA 1994–97 [7]	3.9	6.4
Olmsted, USA 1997–2001 [7]	6.2	12.9
Calgary, Canada 2002–2004 [9]	4.6	5.4

located in the colon and the rectum. The collagen layer is most prominent in the proximal colon, and may be absent in the rectal mucosa in between 18–73% of biopsy specimens [4, 5, 17, 18]. However, an increased subepithelial collagen layer in the stomach and duodenum as well as in the terminal ileum, so called collagenous gastritis and collagenous enterocolitis, has been reported occasionally [19–28].

Lymphocytic colitis

The histopathologic diagnostic criteria of lymphocytic colitis are:

- Epithelial lesions
- An increase in intraepithelial lymphocytes (>20 lymphocytes per 100 epithelial cells)
- Infiltration of the lamina propria with lymphocytes and plasma cells, in the absence of an increase of the collagen layer (See colour plate 14.2) [2, 29]

An increased number of intraepithelial T-lymphocytes may also be seen in the terminal ileum [28].

A recent blinded and independent study of the observer variability in diagnosing microscopic colitis histopathologically, showed that the interobserver agreement with final diagnostic categories was 91% [30], indicating that the histopathologic criteria are consistent and reproducible.

Etiology and pathophysiology

The etiology of microscopic colitis is largely unknown. At present, both collagenous and lymphocytic colitis are considered to be caused by an abnormal immunologic reaction to various mucosal insults in predisposed individuals.

Genetics

Data on genetics are sparse. A small number of familial cases with collagenous and lymphocytic colitis, and with mixed collagenous and lymphocytic colitis has been reported [31–35]. Twelve percent of patients with lym-

phocytic colitis reported a family history of other bowel disorders such as inflammatory bowel disease, celiac disease or collagenous colitis [12]. A recent study showed a significant association between both collagenous colitis and lymphocytic colitis and HLA-DR3-DQ2 [36]. Another study showed that HLA-DQ2 or DQ1,3 were seen more frequently in microscopic colitis than in controls, which indicate that there may be a partly genetic background for the diseases [37]. However, other studies have shown less strong associations [38], and there is no association found between NOD2/CARD15 gene polymorphisms and collagenous colitis [39].

### Reaction to a luminal agent

The increased number of T-lymphocytes in the epithelium has supported the theory that collagenous colitis may be caused by an abnormal immunologic reaction to a luminal agent [40–42]. The observation, that diversion of the fecal stream by an ileostomy normalises or reduces the characteristic histopathologic changes in collagenous colitis, further supports this theory [43]. Recurrence of symptoms and histopathologic changes were seen after closure of ileostomy. Furthermore, abnormalities of colonic histology resembling lymphocytic colitis have been reported in untreated celiac disease [44].

A recent cytokine study in both collagenous and lymphocytic colitis demonstrated a  $T_H1$ -cytokine profile, with increased IFN- $\gamma$  and TNF $\alpha$ , and normal levels of IL-2, IL-4 and IL-10 [45]. A down-regulation of E-cadherin and ZO-1 was observed, and another study demonstrated a decrease in occludin and claudin-4 expression [46]; both events might result in an impaired function of tight junctions. Taha *et al.* found a significant correlation between the increased concentrations of eosinophil cationic protein and albumin in rectal perfusate, indicating a disturbed mucosal permeability [47].

### Infectious agent

The sudden onset of the disease in some patients, and the effects of various antibiotics support a possible infectious cause [10]. An association with microscopic colitis and infections with *Campylobacter jejuni* [48] and *Clostridium difficile* [49–51] has been reported. In another study, *Yersinia enterocolitica* was detected in three of six patients prior to the collagenous colitis diagnosis, and a serologic study showed that antibodies to *Yersinia species* were more common in collagenous colitis patients than in healthy controls [52, 53]. “Brainerd diarrhea” is the term applied to an outbreak of chronic watery diarrhea characterised by acute onset and prolonged duration [54]. An infectious cause has been suspected but the responsible agent has not been identified. Colonic biopsies in these patients show epithe-

**Table 14.2** Drugs reported in association with microscopic colitis.

Lymphocytic colitis	Collagenous colitis
Ticlopidine [57–59]	Lanzoprazole [60, 61]
Cyclo 3 Fort [62–64]	NSAID [55]
Ranitidine [65]	Cimetidine [66]
Vinburnine [67]	
Tardyferon [68]	
Flutamide [59]	
Acarbose [69]	
Piroxicam [70]	
Levodopa-benserazide [71]	
Carbamazepine [12, 72, 73]	
Sertraline [12]	
Paroxetine [12]	
Oxetorone [74]	
Lanzoprazole [61, 75]	

lial lymphocytosis similar to lymphocytic colitis but the surface epithelial lesions are absent.

### Drugs

There are several reports of drug-induced microscopic colitis, especially lymphocytic colitis (Table 14.2). Most reports concern ticlopidine and Cyclo 3 Fort. In a case-control study the use of NSAIDs was significantly more common in collagenous colitis patients than in controls, and discontinuation of NSAIDs was followed by improvement of the diarrhea in some patients [55]. Others found that use of NSAIDs at presentation was associated with a greater need for 5-ASA and steroid therapy, possibly reflecting a more resistant form of disease, but withdrawal of NSAIDs did not improve clinical symptoms in that study [56]. The increased use of NSAIDs in collagenous colitis observed in collagenous colitis patients compared to controls is possibly due to the occurrence of concomitant arthritis. The number of reported cases of drug-induced microscopic colitis is small and chance associations are possible. It is, however, important to assess concomitant drug use in patients and consider withdrawal of drugs that may worsen the condition.

### Autoimmunity

Both collagenous and lymphocytic colitis are associated with autoimmune diseases. An autoimmune pathogenesis has therefore been proposed, possibly initiated by a foreign luminal agent that causes an immunologic cross-reaction with an endogenous antigen. A study of autoantibodies and immunoglobulins in collagenous colitis showed that

the mean level of IgM in collagenous colitis patients was significantly increased [76], similar to observations in primary biliary cirrhosis. A specific autoantibody in collagenous colitis has not been reported.

### **Bile acids**

Data on bile acid malabsorption in microscopic colitis are conflicting. In one study no association was found [77], whereas others found bile acid malabsorption in 27–44% of patients with collagenous colitis and in 9–60% of patients with lymphocytic colitis [78–80]. The coexistence of bile acid malabsorption seems to worsen the diarrhea in patients with collagenous colitis [78]. These observations are the rationale for recommendations of bile acid binding treatment, which was reported effective in a majority of patients with microscopic colitis and concomitant bile acid malabsorption [78, 80]. Even patients without bile acid malabsorption may respond to this treatment. This emphasises the possibility of a causative agent in the fecal stream, and the therapeutic effect may possibly be related to binding of luminal toxins [81].

### **Nitric oxide**

Colonic nitric oxide (NO) production is greatly increased in active microscopic colitis caused by an up-regulation of inducible nitric oxide synthase (iNOS) in the colonic epithelium [82–84]. The levels of NO correlated with clinical activity and histopathologic status of the colonic mucosa; i.e. patients in histopathologic remission had normal levels of colonic NO in contrast to increased levels in patients with histologic active disease [84, 85]. The role of NO in microscopic colitis is uncertain. NO is an inflammatory mediator but whether its role is proinflammatory or protective remains unclear. Nitric oxide may furthermore be involved in the diarrheal pathophysiology as infusion in the colon of  $N^G$ -monomethyl-L-arginine, an inhibitor of NOS, reduced colonic net secretion by 70% and the addition of L-arginine increased colonic net secretion by 50% [86].

### **Secretory or osmotic diarrhea**

Diarrheal pathophysiology in collagenous colitis has been regarded as secretory, caused by the epithelial lesions, the inflammatory infiltrate in the lamina propria and the collagenous band that may be a barrier for reabsorption of electrolytes and water [46, 87]. Furthermore, an impaired epithelial barrier function due to down-regulation of tight junction molecules was found to contribute to diarrheal pathophysiology [46]. Studies on the influence of fasting on diarrhea in collagenous colitis indicated, however, that osmotic diarrhea was predominant [88]. Many patients

report that fasting reduces their diarrhea in accordance with this observation.

---

## **Clinical features and diagnosis**

The main symptom in collagenous colitis is non-bloody diarrhea that may be accompanied by nocturnal diarrhea, fecal incontinence, crampy abdominal pain and distension [10]. Weight loss of up to 5 kg is common initially and occasionally is even more pronounced. Serious dehydration is rare, although 25% of patients report 10 or more daily stools, and stool volumes up to 5 litres have been reported. Mucus or blood in the stools is unusual. In some patients the onset of the disease may be as sudden as that of infectious diarrhea [10].

In most cases the clinical course is chronic, relapsing and benign [89, 90]. Serious complications are uncommon, although a number of patients with colonic perforation have been reported [91–94], and perforation seems to be related to “mucosal tears” that can be seen at colonoscopy [95–98]. The risk of developing colorectal cancer in collagenous colitis is not increased [89, 99]. In a follow-up study, 63% of patients had lasting remission after 3.5 years [100]. Another cohort study showed that all patients were improved 47 months after the diagnosis and only 29% of these required medications [101]. In a number of collagenous colitis patients, however, remission is difficult to achieve, and such patients have usually tried different medications unsuccessfully [10, 43].

Patients with collagenous colitis often have concomitant diseases. Up to 40% have one or more associated autoimmune diseases. The most common are rheumatoid arthritis, thyroid disorders, celiac disease, asthma/allergy and diabetes mellitus. Crohn’s disease or ulcerative colitis concomitant with collagenous colitis have occasionally been reported [10, 102]. Lymphocytic colitis is clinically indistinguishable from collagenous colitis and the predominant symptom is chronic watery diarrhea. In a recent report, however, it was found that symptoms in lymphocytic colitis were milder and more likely to disappear than in collagenous colitis [59]. Similar to collagenous colitis, lymphocytic colitis has also been reported in association with autoimmune diseases [59]. The prognosis of lymphocytic colitis is good [103]. There is no increased mortality and no increased risk of subsequent bowel malignancy reported. A benign course was reported in 27 cases with resolution of diarrhea and normalization of histology in over 80% of the patients within 38 months [104]. Others reported that the clinical course was a single attack in 63% of the patients with a median duration of six months from onset of symptoms to remission [12].

Only microscopic assessment of colonic mucosal biopsies can verify the diagnosis of collagenous or lymphocytic

colitis. Merely non-specific, minor laboratory abnormalities are found, and there are at present no blood tests available for screening purposes. Analyses of P-ANCA [76] or serum procollagen III propeptide are of no diagnostic value in collagenous colitis [105]. Stool examinations reveal no pathologic organisms though increased excretion of fecal leukocytes in more than half of the collagenous colitis patients has been reported [26]. Barium enema and endoscopy are usually normal, though subtle endoscopic changes such as mucosal edema, granularity or erythema may be seen in up to 30% of cases [10, 12]. Pancolonoscopy must be preferred to sigmoidoscopy as the thickened collagenous layer in collagenous colitis may be absent in a considerable percentage of rectal biopsy specimens [18]. The use of confocal laser endomicroscopy may aid in diagnosing collagenous colitis [106, 107].

---

### One or two diseases?

It has been questioned whether lymphocytic colitis and collagenous colitis are the same disease in different stages of development or two different but related conditions, as they have a similar clinical expression and similar histopathologic features, except for the subepithelial collagenous layer in collagenous colitis. Conversion of lymphocytic colitis to collagenous colitis or the opposite has been reported [7, 108], but the fact that conversion happens fairly seldom, and differences in sex ratio and HLA pattern [38] makes it more likely that collagenous colitis and lymphocytic colitis are two separate but related entities.

---

### Treatment of microscopic colitis

The enigmatic etiology of microscopic colitis has led to a wide range of anti-diarrheal and anti-inflammatory drugs being evaluated for medical treatment. A relatively small number of controlled trials has been conducted, and recommendations on therapy have mainly been based on retrospective reports and uncontrolled data [10, 109]. The benign course of microscopic colitis in general has led to suggestions of an algorithm with a “step-up” type of approach to medical treatment, depending on clinical response and outcome in the individual patient. Milder symptoms may be well controlled using drugs such as loperamide or cholestyramine [78, 110]. However, in patients with moderate to intense symptoms potent anti-inflammatory treatment is required. In a retrospective study, the degree of lamina propria inflammation in colonic biopsies was found to predict the response to therapy, and greater inflammation may indicate the need for corticosteroid therapy [56]. A finding of a substantial degree of

inflammation at the time of diagnosis may thus aid in clinical decision-making.

### Randomised controlled trials

Treatment of collagenous colitis and lymphocytic colitis has been evaluated in randomised, controlled trials (RCTs). Cochrane reviews performed in 2008 identified all published reports on the treatment of microscopic colitis between 1970 and 2007 [111, 112]. For collagenous colitis there are ten randomised trials, seven of which were placebo controlled, of which five studied budesonide [113–117], one prednisolone [118], and one bismuth subsalicylate [119]. One trial compared mesalazine to mesalazine + cholestyramine [120], and there was one trial of probiotics [121] and one of *Boswellia serrata* [122]. There are three completed randomised controlled studies in lymphocytic colitis: of budesonide [123], bismuth subsalicylate (includes also collagenous colitis) [119], and mesalazine compared to mesalazine + cholestyramine (includes also collagenous colitis) [120]. A number of these trials are described in some details below.

#### Budesonide

The use of oral preparations of budesonide has been well proven for induction of remission in active ileocolonic Crohn's disease. This glucocorticosteroid has a high potency and a rapid first pass metabolism, rendering it active topically with less systemic effects than are observed with conventional steroids. A total of 94 patients with collagenous colitis were enrolled in three placebo-controlled trials of budesonide 9 mg daily for six to eight weeks (Table 14.3). Fifty patients received active budesonide therapy. The pooled odds ratio for clinical response with budesonide was 12.32 (95% CI: 5.53–27.46), with a number needed to treat of two patients. Most responders experienced a decrease in the number of loose stools after two to four weeks of therapy. After cessation of active therapy most patients were reported to experience a flare-up of symptoms. Histological improvement was significant in all three trials. A decrease in the grade of infiltration of lamina propria mononuclear cells was observed in most patients, whereas a reduction in the thickness of the collagen layer was found less consistently. One of the trials demonstrated a significant decrease of the collagen band in the sigmoid colon, with almost a normalisation of the mean thickness to 10.2  $\mu\text{m}$  [115]. In a placebo-controlled trial of budesonide in lymphocytic colitis (9 mg daily for six weeks) [123] 21 of 41 enrolled patients received active treatment, which was more effective than placebo with respect to clinical ( $p = 0.004$ ; NNT = 3) and histopathological ( $p = 0.04$ ; NNT = 3) response [112].

In two trials studying maintenance treatment with budesonide in collagenous colitis, 80 patients who had

**Table 14.3** Data from four randomized, placebo-controlled trials of oral budesonide in collagenous colitis and lymphocytic colitis.

Author Year	Number	Dosage	Clinical response budesonide vs placebo	Histologic response budesonide vs placebo	Adverse effects
<b>Collagenous colitis</b>					
Baert <i>et al.</i> 2002 [113]	28	9 mg/day Budenofalk 8 weeks	Improvement: 8/14 vs 3/14 ( $p = 0.05$ )	Reduction of lamina propria inflammation in 9/13 vs 4/12 ( $p < 0.001$ )	Mild
Miehke <i>et al.</i> 2002 [114]	45	9 mg/day Entocort 6 weeks	Remission: 15/23 vs 0/22 ( $p < 0.0001$ )	Improvement in 17/23 vs 5/22 ( $p < 0.01$ ).	Mild
Bonderup <i>et al.</i> 2003 [115]	20	9 mg/day Entocort 8 weeks	Respones: 10/10 vs 2/10 ( $p < 0.001$ )	Reduction of overall inflammation ( $p < 0.01$ )	None
<b>Lymphocytic colitis</b>					
Miehke <i>et al.</i> 2007 [123]	41	9 mg/day Budenofalk 6 weeks	Remission: 18/21 vs 8/20 $p = 0.004$	Response in 11/15 vs 4/12 $p = 0.04$	Mild

responded to open-label treatment with budesonide, were randomised to active treatment or placebo. Clinical response was maintained in 83% of patients receiving active treatment, compared to 28% receiving placebo [111]. There was, however, no difference in the median time to relapse (39 days versus 38 days) in the two groups after stopping treatment [117].

### Bismuth subsalicylate

In a small pilot trial with oral bismuth subsalicylate 2.4 g daily vs placebo for eight weeks, patients with collagenous colitis given active treatment were more likely to improve clinically ( $p = 0.003$ ) as well as histologically ( $p = 0.003$ ). Patients with lymphocytic colitis given bismuth subsalicylate had no clinical or histological improvement, compared to placebo.

### Other anti-inflammatory compounds

Sulphasalazine and mesalazine have been extensively used in microscopic colitis, and in a recent trial, 64 patients with collagenous or lymphocytic colitis were randomised to mesalazine 2.4 g/day or mezalazine 2.4 g/day + cholestyramine 4 g/day for six months. A high remission rate was seen in both treatment arms, with 85% of patients with lymphocytic colitis and 91% of patients with collagenous colitis in remission at the end of the study. Combined therapy was superior in collagenous colitis and induced an earlier clinical response in both diseases [120]. Retrospective assessments of sulphasalazine and mesalazine have reported benefit in 34–50% of the patients [10, 109]. Antibiotics such as metronidazole and erythromycin have been used, but have not been studied in controlled trials.

Two studies showed no statistical evidence for the effectiveness of *Boswellia serrata* extract, or probiotics, although these small studies probably lacked power [121, 122].

Retrospective evaluations have shown that oral prednisolone may be effective with a reported response rate in open studies of 70 to 80%. The effect, however, is generally not sustained after withdrawal, and the dose required to maintain remission is often unacceptably high (>20 mg per day) [10]. A small RCT on prednisolone, showed no statistically significant effect but the duration of the trial (two weeks) was probably too short.

### Recommended therapy

Based on a meta-analysis and RCTs, short or medium time therapy with oral budesonide is the drug of choice for the treatment of collagenous and lymphocytic colitis in patients with significant symptoms that cannot be controlled with loperamide, cholestyramine or aminosalicylates. **A1c** Oral budesonide may even be more efficacious than conventional systemic corticosteroids (e.g. prednisolone) [124]. Local effects of budesonide on the terminal ileum may be of importance in explaining this apparent advantage. Budesonide has a benign safety profile, as proven in other IBD-conditions, but it would be prudent to taper the dose to the minimum necessary for controlling symptoms in patients with microscopic colitis if more than eight weeks of therapy is required. **C5** As mentioned above, there was no difference in the median time to relapse between budesonide and placebo after stopping treatment [117]. Most candidates for longer term budesonide treatment are females aged 50–70 years, a group with an increased risk for osteoporosis. In this respect, budesonide has been demonstrated to have less impact than prednisolone on bone mineral density in patients with Crohn's disease during treatment for up to two years [125]. Budesonide therapy given on demand may be an attractive option for long-term control of symptoms. **C5** Although we have positive expe-

rience from this approach in our own clinical practice, controlled data are lacking. Bismuth subsalicylate therapy may be an alternative to budesonide, but it is not available in all countries due to toxicity concerns. **A1d**

Severe attacks of microscopic colitis are rare, but a small number of patients may require hospitalisation, intravenous steroid therapy, bowel rest and total parenteral nutrition. For steroid-refractory or steroid dependent patients immunomodulators may be of value. In an uncontrolled trial azathioprine therapy resulted in partial or complete remission in eight of nine patients with microscopic colitis [126]. **B4** In another uncontrolled trial low dose methotrexate (median dose 7.5 mg/week) showed benefit in 16 of 19 patients with prednisolone-refractory collagenous colitis [127]. **B4**

## Surgical treatment

If medical therapy fails and alternative diagnoses are ruled out surgery may be considered in a patient with intractable microscopic colitis. Split ileostomy was conducted successfully in nine women with collagenous colitis [43] and successful outcomes both in collagenous colitis and lymphocytic colitis have been reported after total or subtotal colectomy [128–132]. **B4**

**Drug induced diarrhea**

More than 700 drugs have been implicated as causing diarrhea, accounting for approximately 7% of all drug adverse effects [1]. However, the mechanism of action by which certain drugs contribute to this adverse effect is not well known. Drug-induced diarrhea is frequently suspected in patients who develop it soon after starting a new medication. However, there is usually only circumstantial evidence to support the link. The medication is usually stopped, and when the diarrhea resolves, the side effect will be attributed to that medication. The basic mechanisms are rarely investigated in these cases. Therefore, our understanding of specific drug-induced diarrheas may vary from solid understanding, to reasonable hypothesis, to considerable conjecture.

Although it is clear that drug-induced diarrhea is common, employing an evidence-based approach to this topic quickly creates considerable conundrums. Evidence-based medicine focuses on both the accuracy of diagnosis and the efficacy of treatment. Both are problematic for drug-induced diarrhea.

For well-established (i.e. “old”) drugs, there rarely are controlled trials to quantify and characterize the association between a specific agent and diarrhea. The information for these drugs is derived from cohort or case-control studies. Although these studies may provide weaker evidence than controlled trials due to potential for biases in statistical analysis, they do provide better evidence than case-reports or case-series that lack control groups. For newer drugs that have gone through clinical trials, the assessment of adverse events permits a reasonable opportunity to characterize the frequency of drug-associated

diarrhea. However, even with clinical trials, there may be a considerable variability in the incidence of an adverse event such as diarrhea. This variability may depend on the underlying disease, the definition of the adverse event, and the type of clinical trial. For example, most randomized controlled trials (RCTs) are short in duration, thus magnifying or minimizing an adverse effect in reference to the time a patient is exposed to the drug, compared to long-term follow-up observational studies. Also, diarrhea as an adverse event is rarely defined clearly. Thus, a minimal change in consistency and a significant increase in stool volume would both be labeled “diarrhea”.

Evidence of the mechanisms underlying the diarrhea elicited by a specific drug may be elusive and serendipitous. For example, theophylline has been a standard for eliciting intestinal secretion in basic physiology. Thus, the effects of xanthine oxidase inhibitors are well understood. Similarly, as molecularly-designed agents move from the bench to the bedside, there may be considerable understanding of the underlying mechanism. However, for many drugs, the purported mechanisms are based on small fragmentary studies or simple speculation. Table 15.1 lists drugs that cause diarrhea, according to the frequency with which they produce this adverse effect.

In order to have a basic understanding on what mechanisms played a role in contributing to diarrhea, the patient's stool characteristics can provide some clues. Diarrhea can be broadly categorized based on the following stool characteristics: (1) watery, a category that includes changes in ion transport, shortened transit time, or increased motility (2) inflammatory, and (3) fatty. This review will examine the mechanism of drug-induced diarrhea within these broad classifications. However, as with other diarrheas, the process is frequently multifactorial. The gastrointestinal tract is regulated through the integration of paracrine, immune, neural, and endocrine systems that coordinate changes in mucosal and muscular function and adapt to changing conditions (see Figure 15.1) [2]. These systems involve mechanisms that regulate mucosal permeability,

<b>Table 15.1</b> Drugs that cause diarrhea.
<b>Drugs that cause diarrhea in ≥ 20 % of patients</b>
Alpha-glucosidase inhibitors
Biguanides
Aurorafin (gold salt)
Colchicine
Diacerein
Highly active antiretroviral therapy
Prostaglandins
Tyrosine kinase inhibitors
<b>Drugs that cause diarrhea in ≥ 10 % of patients</b>
Antibiotics
Chemotherapeutic agents
Cholinergic drugs
Cisapride (off the market)
Digoxin
Immunosuppressives agents
Metoclopramide
Orlistat (lipase inhibitor)
Osmotic laxatives
Poorly or non-absorbable carbohydrates
Selective serotonin reuptake inhibitors
Ticlopidine
<b>Drugs that occasionally cause diarrhea</b>
5-aminosalicylates (especially olsalazine)
Acetylcholinesterase inhibitors
Anticholinergics
Caffeine
Calcitonin
Carbamazepine
Chenodeoxycholic acid
Cholestyramine
Cholinesterase inhibitors
Cimetidine
Ferrous sulfate preparations (rare)
Flavanoid related veinotonic agents
HMG-CoA reductase inhibitors
Irinotecan
Isotretinoin
Levodopa-benserazide
Magnesium antacids
Methyldopa
Motilin agonists
Non-steroidal anti-inflammatory drugs
Octreotide
Penicillamine
Prebiotics
Proton pump inhibitors
Tacrine
Tegaserod (off the market)
Theophylline
Thyroid hormones

**Figure 15.1** “PINES” regulatory system in the intestine. The regulatory system of the intestine integrates *paracrine*, *immune*, *neural*, and *endocrine* systems and produces coordinated changes in mucosal and muscular function that permit adaptive responses to changing conditions. The regulatory system can widen or narrow the paracellular pathway that governs passive transmucosal permeation of electrolytes, accelerate or retard the transepithelial movement of nutrients and electrolytes by affecting membrane channels and pumps, relax or contract the various muscle layers in the intestine, and increase or decrease mucosal blood flow. Acting simultaneously, these mechanisms regulate mucosal permeability, intestinal transport, and the motility and metabolism of the gut. (From Sellin JH (1997) Small intestine: Functional anatomy, fluid and electrolyte absorption. In: Feldman M and Schiller LR (eds) *Gastroenterology and Hepatology. The Comprehensive Visual Reference*, vol. 7. Current Medicine, Philadelphia, 1997. p. 1.11.)

intestinal transport, and the motility and metabolism of the gut [2]. Medications may influence this regulatory system through these different pathways and contribute to diarrhea. This influence may be part of the pharmacologic effect of the drug. In other cases there may be an allergic reaction, or possibly a pharmacogenomic component. Diarrhea may be an appropriate physiologic response to the drug. On occasion, the drug may cause direct tissue injury.

Clinically, if drug-induced diarrhea is suspected, the simplest approach is to switch to an alternative medication or treat with an antidiarrheal agent. Novel approaches for certain drug-associated diarrheas have been shown to be effective in treatment. In some cases, diarrhea may resolve with continued use.

Thus, for most examples of drug-induced diarrhea, therapeutic trials are not relevant. Only where there are no satisfactory alternatives, as is the case for some anti-cancer therapies, is there sufficient impetus to understand the mechanisms of drug-induced diarrhea. Thus, there probably has been more significant and novel evidence in drug-induced diarrhea obtained in the field of oncology.

## Watery diarrhea

Watery diarrheas have been classified as either secretory or osmotic to explain underlying pathophysiology. However, the clinical utility of this classification has not been rigorously tested.

## Osmotic diarrhea

Osmotic diarrheas can occur from intentional use of a drug as part of its mechanism of action, or unintentionally. Poorly absorbed solute traps fluid in the lumen, and these unabsorbable solutes account for osmotic activity of stool water [2].

The most common medications associated with osmotic diarrhea are magnesium containing salts and laxatives such as sodium phosphates and long-chain polyethylene glycols, e.g. Miralax (Schering-Plough, Kenilworth, NJ) used for treatment of constipation, and for pre-colonoscopy colon purging [3, 4]. Their cathartic action results from poor absorption in the gastrointestinal tract, leading to osmotically mediated water retention, stimulating peristalsis [4]. The usual dose of magnesium salts produces 300 to 600 ml of stool within six hours [4]. Sodium phosphates cause osmotic diarrhea, but without producing an osmotic gap [5].

Used for constipation and for the treatment of hepatic encephalopathy, lactulose is a synthetic non-absorbable disaccharide that is known to cause diarrhea through this mechanism. Poorly-absorbed fructose, found in fruit juices and carbonated beverages, and non-absorbable sorbitol and mannitol, found in sugar-free candies and gums, may not cause diarrhea until 24 to 48 hours after ingestion. Acarbose and miglitol, used for the treatment of diabetes, prevent the breakdown of carbohydrates to monosaccharides by inhibition of intestinal  $\alpha$ -glucosidase, causing diarrhea. In a multicenter RCT of 286 patients comparing acarbose to placebo, tolbutamide and tolbutamide-plus-acarbose in NIDDM, 27% of patients taking acarbose and 35% taking acarbose + tolbutamide complained of diarrhea in comparison to 6% of patients taking placebo or tolbutamide ( $p < 0.05$ ) [6]. Diarrhea is minimized by starting therapy at low doses (50 mg three times daily), and tends to decrease with time [7]. In the large-scale, multinational study investigating different doses of acarbose (from 25 mg tid to 200 mg tid) good patient tolerability and compliance was observed, even at the highest dose [8]. The study also confirmed the marked tendency for adverse effects to decline after 4–6 weeks.

Interestingly, in a post-market surveillance study of almost 20,000 patients (both NIDDM and IDDM, only 3.2% of those taking acarbose complained of diarrhea [9]. What can explain this difference between the surveillance study

and the RCT? During RCT, there may be more attention directed toward minimal changes in signs and symptoms. Acarbose-associated diarrhea is most common in the early phase of treatment. Finally, surveillance generally separates out those subjects who had already discontinued acarbose because of diarrhea.

The prebiotics fructo-oligosaccharides and inulins, available in nutritional supplements and in functional foods, have been used for treatment of antibiotic-induced diarrhea at dose ranges of 4–10 g per day [10]. When given to healthy volunteers, doses higher than 30 g daily of these prebiotics caused significant gastrointestinal discomfort (flatulence, cramping, diarrhea) through fermentation in the colon and production of an osmotic effect in the intestinal lumen [11, 12]. If the dosage is split this usually alleviates the symptoms. Diagnosis can usually be made by checking fecal pH; a pH less than 6 is highly suggestive of carbohydrate malabsorption.

Some formulas for enteral nutrition are hypertonic and may induce osmotic diarrhea by a mechanism similar to dumping syndrome. Changing to an isotonic formula or slowing the infusion rate usually resolves the diarrhea [4].

Once recognized, the treatment of osmotic diarrhea is simple. Removal of the osmotic agent usually resolves this adverse effect. Loperamide or tincture of opium can be added, especially in the case of enteral nutrition. Dose reduction or dose splitting can also help. In some cases, such as acarbose, the diarrhea usually resolves over time with continued use.

## Secretory diarrhea

Secretory diarrhea, on the other hand, produces voluminous stools that persist despite fasting. Drug-induced secretory diarrhea results from a medication either increasing the active secretion of ions and thus pulling fluid into the lumen, or from decreasing the absorption of large amounts of water and electrolytes in the gut lumen. In secretory diarrhea, a minimal osmotic gap is found. Specifically, drugs induce a secretory diarrhea by two main mechanisms: the inhibition of  $\text{Na}^+$  absorption and the stimulation of  $\text{Cl}^-/\text{HCO}_3^-$  secretion. These changes may occur through either a direct effect on the transporter or changes in intracellular second messengers that alter the function of the transporter.

The  $\text{Na}^+$  pump ( $\text{Na}^+$ ,  $\text{K}^+$ -ATPase) is the final common pathway for  $\text{Na}^+$  absorption; inhibition of the  $\text{Na}^+$  pump blocks  $\text{Na}^+$  (and fluid) absorption and this may cause diarrhea. Digoxin's therapeutic target is the cardiac  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase. However, inhibition of intestinal or colonic  $\text{Na}^+$  pumps may cause diarrhea, most frequently at supertherapeutic drug levels, especially in elderly patients [3]. In fact, digoxin was the second commonest cause of diarrhea in a study of 100 elderly patients [13]. Similarly, auranofin,

used previously for rheumatoid arthritis, caused diarrhea in up to 74% of patients, requiring discontinuation in 14% of them [3]. By reducing  $K^+$  conductance and inhibiting calcium channels, the class I antiarrhythmic drugs quinidine and propafenone impede transepithelial  $Na^+$  and water absorption causing diarrhea in 8–30% of patients [14]. Lubiprostone was initially developed as a treatment for constipation, specifically because of its properties as a CIC2 channel opener; however, it is still unclear what specific role the CIC2 channel has in intestinal secretion.

Olsalazine, used in the treatment of ulcerative colitis, causes diarrhea in 12–25% of patients through the stimulation of bicarbonate and sodium chloride secretion in the ileum [1, 15]. Similar azo compounds sulfasalazine and mesalazine may also cause diarrhea, but less frequently. The mechanism is unclear, but may involve a direct effect on anion transporters, rather than an anti-inflammatory action [16].

Some drugs cause a secretory diarrhea by altering intracellular signaling cascades, increasing cyclic AMP, cyclic GMP or calcium. The phosphodiesterase inhibitor, theophylline, causes diarrhea by increasing cyclic AMP, opening chloride channels and increasing secretion [17]. In our hypercaffeinated society, coffee is used as a “drug” by many, causing “Starbucks® diarrhea” through this similar mechanism. Caffeine administration in amounts ordinarily contained in many beverages and medications (75 to 300 mg) resulted in striking net secretion in the jejunum and in the ileum [18]. Prostaglandin analogs can cause diarrhea through many pathways, including altered permeability, motility, electrolyte transport and by affecting peptides that stimulate secretion [17]. Misoprostol specifically stimulates epithelial  $Cl^-$  secretion through cyclic AMP, resulting in intraluminal fluid accumulation and diarrhea, which usually occurs within the first two weeks of treatment [3].

A secretory type of diarrhea limited the clinical use of chenodeoxycholic acid, a bile acid initially used to dissolve cholesterol gallstones. Early studies showed that the mechanism of secretory diarrhea in chenodeoxycholic acid therapy was due to a rise in intracellular cyclic AMP levels. However, recent *in vitro* studies using much lower doses of bile acids suggest a mechanism involving activation of luminal  $K^+$  channels and  $Cl^-$  secretion mediated through increased intracellular  $Ca^{++}$  levels [19, 20]. Another dihydroxy bile acid, ursodiol causes diarrhea much less frequently. Presumably this difference is due to the alternative configuration of the hydroxyl groups compared to chenodeoxycholic acid. However, there are some reports of ursodiol causing diarrhea. A meta-analysis of ursodiol and its adverse effects revealed that diarrhea was the single most frequent adverse drug event in patients treated for gallstone disease, with an incidence of 2–9% [21]. If and when ursodiol is associated with diarrhea, there are two possible

mechanisms: an increase in the secretion of all bile salts including chenodeoxycholic acid and/or luminal conversion of ursodiol to chenodeoxycholic acid by intestinal bacteria (Alan Hoffman, personal communication). In primary biliary cirrhosis patients, on the other hand, diarrhea was rarely reported, in five large-scale randomized trials. No report of ursodiol-induced diarrhea was found in the largest placebo-controlled randomized study of its use in primary sclerosing cholangitis [21].

These conflicting data highlight some of the challenges of evaluating adverse events of RCTs.

First of all, is this a real difference in that the incidence of diarrhea is truly higher in gallstone disease than in PBC/PSC. Perhaps bile salt metabolism is different in gallstone disease, where there is an increased conversion of ursodiol to chenodeoxycholic acid which is a potent secretagogue. The gallbladder in patients with gallstones is likely to be hypo-functional and may be altered in its contractility in response to a meal or in its concentrating capacity, thus allowing more bile acid to enter the duodenum per ursodiol dose. In addition, ursodiol may be stimulatory to the inflamed bowel, while neutral or inhibitory to the bowel of patients with gallstones (Roger Soloway, personal communication). Alternatively, the design of RCTs may account for the difference. The definition of diarrhea as an adverse event, the focus on a more serious disease, or an already increased baseline bowel movement frequency in patients with PSC are possible examples of this factor.

Used as an old home remedy, castor oil is hydrolyzed in the small bowel by the action of lipases into glycerol and the active agent, ricinoleic acid, which acts primarily in the colon to stimulate secretion of fluid and electrolytes by increasing cyclic AMP and speeding intestinal transit [22, 23].

Stimulant laxatives such as diphenylmethane derivatives and anthraquinones induce their effect by inducing a limited low-grade inflammation in the small and large bowel to promote accumulation of water and electrolytes and stimulate intestinal motility. This occurs through activation of prostaglandin-cyclic AMP and NO-cyclic GMP pathways, platelet-activating factor production and, perhaps, inhibition of  $Na^+, K^+$ -ATPase [4]. Anthraquinone laxatives are poorly absorbed in the small bowel, are activated in the colon, and produce giant migrating colonic contractions as well as water and electrolyte secretion. Other laxatives or stool softeners such as docusate (dioctyl sodium sulfosuccinate), can cause diarrhea when taken in large quantities, by stimulating fluid secretion by the small and large intestine [24]. Clinicians should thus be aware that surreptitious use of laxative may be the cause of diarrhea in patients who present with this complaint. Table 15.2 lists a number of commonly used laxatives.

Diarrhea associated with medullary carcinoma of the thyroid suggested that calcitonin may cause a secretory

**Table 15.2** Stimulant laxatives.

Anthraquinones
Diphenylmethane derivatives (bisacodyl)

Ricinoleic acid (castor oil)
Sodium picosulfate – available outside US
Sodium dioctyl sulfosuccinate (docusate)

type of diarrhea. Calcitonin in high doses can induce a secretory diarrhea in 1–3% of patients. Studies involving intravenous infusions showed prompt and marked increase in jejunal secretion of water, sodium, chloride and potassium, and reduced absorption of bicarbonate, which was reversed immediately with discontinuation of the infusion [25, 26]. However, in clinical practice, the use of salmon calcitonin for treatment of osteoporosis rarely causes diarrhea (Vassilopoulou-Sellin, R. personal communication) [27]. This paradox highlights the variable and sometimes unpredictable pattern of drug-induced diarrhea.

Colchicine, besides causing secretory diarrhea through the inhibition of  $\text{Na}^+, \text{K}^+$ -ATPase activity, is a microtubule inhibitor and may induce diarrhea by interfering with the migration of epithelial cells from the crypt to the villus and/or interfere with intracellular trafficking of specific transport proteins [17].

The biguanide metformin, used in the treatment of type II diabetes, has an effect on the brush border, reducing disaccharidase activity and leading to malabsorptive diarrhea in 10–53% of patients [28, 29].

Animal studies have found that metformin or the older biguanide phenformin inhibits intestinal glucose absorption in a dose-dependent manner through effects on mucosal and serosal glucose transfer mechanisms [30–33]. Based on a systematic review evaluating common adverse events of metformin monotherapy in type II diabetes mellitus, patients receiving metformin are 3.4 times more likely to develop diarrhea compared to those taking placebo ( $p = 0.002$ ) [34]. Most cases are transient and mild, but even in severe cases, lowering the dose usually resolves the diarrhea [35]. In clinical trials, only 5% of study participants discontinued metformin because of gastrointestinal side effects [34]. There have also been cases of metformin causing late-onset chronic diarrhea in whom discontinuation of the drug resolved the diarrhea [36]. Larger studies of 405 type II diabetics show that metformin was independently associated with chronic diarrhea with an odds ratio of 3.08 (CI: 1.29–7.36,  $p < 0.02$ ) [37]. In a diabetic clinic, metformin was found to be the most common cause of diarrhea based on a questionnaire based survey of 285

randomly selected diabetic patients [38]. Diarrhea in a diabetic patient may be related to the disease process itself. However, diabetic diarrhea usually occurs in type I diabetes for which metformin is not a treatment.

Some have speculated that anticholinergic drugs, which most often cause constipation by reducing intestinal motility, as well as the proton pump inhibitor omeprazole, can cause a secretory diarrhea. Although the proposed mechanism for diarrhea is thought to be bacterial overgrowth leading to bacterial deconjugation of primary bile salts to dihydroxy bile acids causing net fluid and electrolyte secretion in the colon, there is no substantial evidence to confirm this explanation [3]. In fact, a Cochrane systemic review showed no statistically significant difference in diarrhea occurrence in patients treated with PPI for reflux disease either at maintenance dose (PPI 1.1%, vs placebo 3.3%, RR 0.34; 95% CI: 0.04 to 3.18) or at healing dose for esophagitis (PPI 5.2% vs placebo 2%,  $p = 0.11$ ) [39]. A recent article suggesting a link between PPI use and small bowel bacterial overgrowth contributing to diarrhea predominant IBS shows that there is a common assumption among gastroenterologists that PPI can cause diarrhea, that is not necessarily supported by evidence [40].

Diarrhea is a common adverse effect with molecularly targeted agents. Epidermal growth factor receptor tyrosine kinase inhibitor, erlotinib, and other tyrosine kinase inhibitors such as sorafenib, imatinib and bortezomib cause diarrhea in up to 60% of patients [41]. Erbitux® (cetuximab), used for the treatment of EGFR-expressing, metastatic colorectal carcinoma and squamous cell carcinoma of the head and neck and Iressa® (gefitinib), used for non-small cell lung cancer, can cause diarrhea in 48–67% of patients, depending on dose [42, 43]. EGF can activate PI 3-kinase and the lipid products of this enzyme inhibit calcium-dependent  $\text{Cl}^-$ -transport in T84 human colonic epithelial cells [44, 45]. EGF-receptor inhibitors may cause diarrhea by blocking this inhibitory loop and causing secretion. Diarrhea can easily be managed by loperamide, dose reduction or treatment interruptions [41].

Flavopiridol, a cyclin-dependent kinase inhibitor, has undergone several clinical trials as an anti-tumor agent, with secretory diarrhea as a dose-limiting factor. Adding cholestyramine and loperamide as a prophylactic anti-diarrheal treatment allowed for use of higher doses [46]. Diarrhea may be related to flavopiridol binding to the gut mucosa acting as a modest secretagogue. Cholestyramine, by binding flavopiridol, eases the adverse effect [47]. Pharmacogenomics may play a role in drug-induced diarrhea. For example, those with extensive hepatic glucuronidation metabolism experienced less diarrhea than others [48]. The hepatic metabolism of the drug decreases the toxic metabolites that causes intestinal secretion. In this clinical study, mild cases of diarrhea were controlled by loperamide, whereas more severe diarrhea was controlled

by octreotide infusion and reduction of flavopiridol dosages in subsequent cycles [48].

### Disordered or deregulation motility

Although not as elegantly delineated as epithelial transport changes, disordered or deregulated motility can also cause diarrhea. Prokinetic agents reduce intestinal contact time between luminal fluid and the epithelium. The decreased amount of time chyme is exposed to intestinal epithelium can limit absorption, and ultimately lead to diarrhea [2]. Cisapride and tegaserod are 5-HT<sub>4</sub>-receptor agonists that stimulate motility and accelerate gastrointestinal transit. However, both of these drugs have been removed from the market due to potential cardiotoxicity.

Cholinergic drugs such as bethanecol, used for urinary retention and neurogenic bladder, have broad muscarinic effects via cholinergic receptors in the smooth muscle of the urinary bladder and the gastrointestinal tract [4, 49]. The effect of acetylcholine on smooth muscle of the gastrointestinal tract is mediated by two types of G protein-coupled muscarinic receptors, M<sub>2</sub> and M<sub>3</sub> in [4]. The activation of the M<sub>3</sub> receptor increases intracellular Ca<sup>2+</sup> mediated by the G<sub>q</sub>-PLC-IP<sub>3</sub> pathway [4, 28]. This results in increased gastrointestinal and pancreatic secretions, as well as increased peristalsis.

Acetylcholinesterase inhibitors, such as those used for Alzheimer's disease, allow acetylcholine to accumulate in the synaptic and neuromuscular junctions. These drugs enhance contractile effects producing diarrhea in up to 14% of patients [1, 3]. RCTs comparing donepezil to placebo for the treatment of Alzheimer's disease revealed diarrhea incidence of 15% with donepezil compared to 10% in placebo [50]. The Cochrane Review of the use of donepezil with over 1000 patients revealed that diarrhea occurred more frequently in donepezil treated patients (OR 2.78; 95% CI: 2.10, 3.69) [51]. In another Cochrane Review of the three anticholinesterases (donepezil, galantamine and rivastigmine) used for Alzheimer's dementia, the odds ratio for diarrhea with the use of anticholinesterases in comparison to placebo was 1.91 (95% CI: 1.59, 2.3) [52].

Neostigmine, used off-label for acute colonic pseudo-obstruction (Ogilvie's syndrome) and paralytic ileus, also can cause diarrhea [4]. Irinotecan, a chemotherapeutic agent, can cause severe diarrhea from cholinergic-like syndrome through the inhibition of acetylcholinesterase [3].

Motilin, a peptide hormone found in the gastrointestinal M cells, and in some enterochromaffin cells of the upper small bowel, is a potent contractile agent of the upper GI tract. The effects of motilin can be mimicked by macrolide antibiotics, especially erythromycin, and can cause diarrhea. In addition to its motilin agonistic effect, erythromycin at lower doses (40–80 mg) may also entail cholin-

ergic involvement, although the mechanisms are not well understood [4].

Just as in thyrotoxicosis, excess levothyroxine therapy can accelerate small and large intestinal transit, causing diarrhea [53–55]. Ticlopidine, an inhibitor of platelet aggregation, can cause diarrhea through many processes, including reported cases of lymphocytic colitis. However, increased motility is thought to be the principal mechanism based on manometric readings of jejunal motility revealing abnormal motility patterns [56].

The treatment of watery diarrhea includes discontinuation of the offending medication. Maintaining hydration is important to prevent dehydration from the amount of fluid loss. Loperamide, lomotil and bismuth subsalicylate can help relieve the symptom.

### Inflammatory diarrhea

Drug induced inflammatory diarrheas fall into several broad categories. Perhaps the most important is the disruption of colonic flora and precipitation of *Clostridium difficile* colitis. Other mechanisms include the direct damage to the integrity of the mucosa that occurs with NSAIDs and polyene antibiotics, stimulation of low grade inflammation causing microscopic colitis, disruption of the balance between proliferation and apoptosis with a resulting compromise of epithelial integrity seen with immunosuppressives and chemotherapeutic agents, and vascular compromise as occurs with ergotamine and cocaine.

Antibiotics account for 25% of drug-induced diarrhea [1]. The most well-known complication is pseudomembranous colitis due to *Clostridium difficile*, especially seen with the antibiotics clindamycin, amoxicillin, ampicillin, and cephalosporins [3]. *Clostridium difficile* causes diarrhea by secreting enterotoxin A, which adheres to the brush-border membrane of enterocytes inducing an inflammatory response, and cytotoxin B that induces direct mucosal damage [2, 57]. Diarrhea may occur a few days after antibiotic therapy is initiated and up to eight weeks after discontinuation. In the appropriate clinical setting, diagnosis is based on detection of toxin in the stool. Endoscopy reveals raised white to yellow plaques covering a normal or moderately erythematous colonic mucosa [57]. Recently, non-antibiotic associated community acquired *C. difficile* has become more frequent with the use of acid reducing agents and immunosuppressives. Lansoprazole, and in the elderly, histamine antagonist use, are reported to be significant risk factors for carriage of *C. difficile*, increasing the risk of developing pseudomembranous colitis [3, 58]. In fact, a meta-analysis to assess risk factors for recurrent *C. difficile* infection revealed that use of concomitant antacid medications increased the risk by two fold (OR: 2.15; 95% CI: 1.13–4.08; p = 0.019) [59].

There has been a rise in the incidence of *C. difficile* colitis in hospitalized patients with inflammatory bowel disease [60]. This may be attributable to the use of immunosuppressives and biologic agents [61]. Treatment is discussed in detail in Chapter 20 of this book.

Through multifactorial mechanisms, diarrhea occurs in 3 – 9% of patients treated with the non-steroidal anti-inflammatory drugs (NSAIDs), especially the older drugs mefenamic acid and flufenamic acid [1, 62–64]. Thirty nine percent (34 of 87) of patients in a six-week study given meclofenamate at doses of 200 to 400 mg per day experienced diarrhea [65].

Since NSAIDs stimulate *in vitro* absorption (increased  $\text{Na}^+$  absorption and decreased  $\text{Cl}^-$  secretion), other mechanisms must be involved in diarrhea [66]. NSAIDs most likely cause diarrhea through increased permeability and direct mucosal damage [67]. Histologic findings include prominent apoptosis and increased intraepithelial lymphocyte counts [68]. NSAIDs have been associated with both microscopic and pseudomembranous colitis. Ileal disease mimicking Crohn's disease has also been described.

Maiden and others have quantitatively analyzed by capsule endoscopy NSAID-induced pathology in 40 subjects taking diclofenac. Images revealed new pathology in 27 subjects (68%), with common lesions of mucosal breaks, bleeding, erythema and denuded mucosa, and the majority have concurrent lesions. These patients also had elevated fecal calprotectin (a marker for inflammation) levels from baseline. This study provides both biochemical and direct evidence of macroscopic injury to the small intestine from NSAID use [69]. In a case-control study of 105 cases of newly-diagnosed colitis based on endoscopic and histologic findings, 78 patients (74%) were taking NSAIDs or salicylates prior to or during the development of their disease [70]. These studies support NSAIDs as an important class of drugs in causing colitis.

Acute proctocolitis has been documented in four separate cases of NSAID etiology, with the use of flufenamic acid, mefenamic acid, naproxen and ibuprofen. Symptoms and signs resolved in all cases with removal of the drug, but a rapid relapse occurred in three of the five patients who were subsequently rechallenged with the NSAID [71].

NSAIDs have also been implicated in causing collagenous colitis. Based on a case-control study of 31 patients with collagenous colitis and 31 controls, the use of NSAIDs was significantly more common in the study group (19/31) vs (4/31) in the control group ( $p < 0.02$ ) [72].

Auranofin causes secretory diarrhea, but enterocolitis can also occur with relatively low dosages [62]. Over 30 cases have been reported of gold therapy causing severe enterocolitis. This adverse effect was unrelated to dosage, occurred within three months of beginning treatment and persisted despite withdrawal of the drug [3, 73].

**Figure 15.2** Gradients from crypt to villus. There is a significant spatial geometry of transport proteins along the crypt-villus (crypt-surface) axis. Some transport molecules are found at relatively constant concentrations along the axis, some exhibit a greater density in the base of the crypt, and others exhibit a greater density toward the villus or surface. (Adapted from Sellin JH (2002) Chapter 87: Intestinal electrolyte absorption and excretion. In: Feldman M, Friedman LS and Sleisenger MH (eds) *Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management*, 7th edn. Saunders, Philadelphia, 2002. Figure 87.3, p. 1695.)

Penicillamine has been shown in a few cases to cause acute proctosigmoiditis [62].

Inflammatory diarrhea can also be caused by immunosuppressive and chemotherapeutic agents. The balance between absorption and secretion may be disrupted by a change in the balance between mature villus and immature crypt cells (see Figure 15.2). This loss of intestinal epithelial homeostasis with some superficial necrosis causes an imbalance between absorptive, secretory, and motility functions of the gut contributing to diarrhea [17, 24, 57]. Epithelial apoptosis of more than five apoptotic bodies (per 100 crypts) is considered an increase above normal. NSAIDs and sodium phosphate bowel preparations cause 12 to 24 apoptotic bodies [58]. Chemotherapeutic agents, especially fluorouracil can cause greater than 100 apoptotic bodies [58]. These agents usually cause diarrhea in a dose-related fashion. It is most commonly seen with fluoropyrimidines (fluorouracil, irinotecan, methotrexate and cisplatin), the fluorouracil prodrug capecitabine and the combination treatment uracil-tegafur [1]. The patient's symptoms can range in severity from mild diarrhea to severe necrotizing enterocolitis [24].

Transplant immunosuppressives frequently cause diarrhea. This may be due to a similar apoptotic enteropathy. Mycophenolic acid may shift the balance between the pro and antiapoptotic factors Bcl-2 and Bax, leading to changes in mucosal homeostasis, and may also alter chloride secretion (Sellin, J unpublished observations).

Irinotecan can cause acute or delayed diarrhea in 50–88% of patients. Immediate-onset diarrhea is caused by

acute cholinergic effects and usually responds rapidly to atropine. The delayed onset diarrhea usually occurs 24 hours to several days after administration, can be unpredictable, occurs at all dose levels and is worse with combination regimens with intravenous fluorouracil and leucovorin [41]. Several hypotheses have been proposed to explain the underlying mechanism. Evidence of a direct toxic effect on intestinal epithelium was provided by animal studies. Mice treated with irinotecan had intestinal wall thinning with epithelial vacuolation, vascular dilatation, an inflammatory cell infiltrate and evidence of apoptosis in the ileum [74, 75]. These studies led to the discovery of bacterial  $\beta$ -glucuronidase which deconjugates the irinotecan metabolite SN38 glucuronide causing its direct effect on the intestinal epithelium [24, 76].

Multiple agents have been studied in an attempt to reverse irinotecan-induced diarrhea. In humans, the use of the oral antibiotic, neomycin, which decreases  $\beta$ -glucuronidase activity in the intestinal lumen, resulted in good control of irinotecan-induced diarrhea in seven colorectal cancer patients [77]. The Chinese herb Hange-Shashito (TJ-14), a natural inhibitor of the  $\beta$ -glucuronidase activity of bacterial microflora, has also been shown to prevent the delayed diarrhea from irinotecan [78]. Probenecid, a biliary inhibitor of irinotecan and SN-38 secretion, has been shown to reduce irinotecan intestinal toxicity in mice, but no evidence has confirmed this observation in humans [79]. Oral cyclosporin (to reduce SN38 and SN38G clearance into the small bowel lumen) used with irinotecan in a phase I clinical trial, prevented severe diarrhea. Only one patient out of 37 experienced grade 3 diarrhea, and grade 4 diarrhea did not occur [80]. At increased pH, equilibrium favors the less toxic carboxylate form of the irinotecan metabolite SN-38. Reduced cellular damage and diarrhea was noted with bicarbonate administration in hamsters given irinotecan [81]. Phase II clinical trials also suggested benefit from sodium bicarbonate supplementation for irinotecan-induced severe delayed diarrhea [82].

Oxaliplatin combined with fluorouracil and irinotecan makes diarrhea even more common than the incidence observed with either agent alone [41]. Diarrhea can also result from an increase in opportunistic infections: invasive bacterial infections such as tuberculosis and yersinosis; ulcerating viral infections such as cytomegalovirus and herpes simplex; and invasive parasitic infections such as amebiasis and strongyloides. Neutropenic enterocolitis may also complicate chemotherapy in neutropenic patients with leukemia. This is especially associated with cytosine arabinoside, cisplatin, vincristine, adriamycin, fluorouracil and mercaptopurine [58].

Isotretinoid used for acne has been associated with inflammatory diarrheas [1]. Histology from these patients often shows acute focal superficial inflammatory infiltrate of the mucosa. HMG-CoA reductase inhibitors such as sim-

vastatin, lovastatin and pravastatin cause an inflammatory diarrhea in less than 5% of patients [1].

Several drugs have also been linked to microscopic colitis. These include NSAIDs, carbamazepine, ticlopidine, flutamide, and the selective serotonin receptor inhibitors, especially paroxetine and sertraline [1, 58].

Management of inflammatory diarrhea includes treatment of intercurrent infections such as CMV, antibiotic associated colitis, dose reduction of the etiologic agent, or cautious use of empiric therapy. Loperamide, diphenoxylate, deodorized tincture of opium and octreotide are effective for diarrhea from fluoropyridimoles [3]. Acetorphan, an enkephalinase inhibitor that blocks epithelial cyclic AMP mediated secretion, has shown moderate activity in clinical trials in patients with irinotecan-induced diarrhea [83]. Budesonide and octreotide have been used to slow intestinal motility and decrease water and electrolyte movement through the bowel [84–86].

Fatty diarrhea

Fatty diarrhea occurs in the clinical setting of weight loss and steatorrhea. This is caused by either maldigestion or malabsorption. Table 15.3 lists several medications that can cause this adverse effect. Highly active antiretroviral therapy has been known to cause steatorrhea, although the mechanisms have not been elucidated [87].

Interestingly, in a study of 33 HIV patients who underwent evaluation for diarrhea, over 90% had steatorrhea, irrespective of HAART therapy (20/21 patients not on HAART vs 10/12 patients on HAART) [87]. Thus, the specificity of steatorrhea secondary to HAART may be called into question.

Of the nucleoside analog reverse transcriptase inhibitors, didanosine causes diarrhea in 17–28% of patients, espe-

<sup>b</sup> >10% incidence of diarrhea.

cially in the buffered formulations [57]. Enteric-coated tablets decrease this incidence. Abacavir can produce diarrhea, especially in association with a hypersensitivity reaction that occurs in 3–5% of treated individuals [88, 89]. Diarrhea, among other symptoms, appears one to four weeks after initiation of therapy, and usually resolves within one to two days after discontinuation. Re-challenge with the drug, even at a decreased dose, may cause the return of symptoms within hours with increased severity [88].

Virtually all protease inhibitors cause diarrhea. Ritonavir causes diarrhea in up to 52% of patients [90, 91]. Adverse effects appear to be more common in patients with more advanced HIV/AIDS, and in patients with higher plasma drug levels. Effects are greatest at the beginning of therapy, before ritonavir induces an increase in its own metabolism [88]. Combination therapy, especially lopinavir with ritonavir increases the risk of diarrhea [88]. *In vitro* studies showed that several protease inhibitors inhibited lipase significantly at or below physiological concentrations [92]. Thus, besides the use of antidiarrheal medications such as loperamide that have been shown to control diarrhea, the use of pancreatic lipase with protease inhibitors may in theory reduce or eliminate steatorrhea in these patients [88, 92].

Orlistat, used as a prescription gastrointestinal lipase inhibitor for weight loss, is now available over the counter as “alli” (2007, GlaxoSmithKline, Pennsylvania) which contains half the prescription dose. Those using this drug can have malabsorptive diarrhea if fat intake is high. Of those taking orlistat, 60–80% experience steatorrhea in a dose-related mechanism [93]. This resolves when fat intake is reduced to 45 g per day [93].

Olestra is a lipid that possesses properties of conventional fats and oils, but is neither digested nor absorbed. Olestra was approved by the FDA in January 1996 for use in snacks such as potato chips and crackers [94]. Although consumers complained of “diarrhea”, a randomized control trial using higher than consumption doses showed no effect on stool frequency, but a modest stool softening effect measured by stool viscosity in subjects consuming olestra compared to controls [94].

Long-term use of oral antibacterials such as neomycin, polymyxin and bacitracin can also cause malabsorptive diarrhea. These antibiotics damage the small intestinal mucosa, leading to a reduction of the enzyme activity of enterocytes [3, 49, 68]. They may also bind bile acids in the intestinal lumen and reduce the absorption of fat [1]. In *in vitro* transport studies, both neomycin and amphotericin act as membrane detergents, functionally “dissolving” the apical membrane of enterocytes or colonocytes. Administering 1 g of neomycin with a test meal to five healthy subjects caused a marked increase in fatty acid and bile acid in their aspirated intestinal contents [95]. However, a subsequent study of 2 g per day dose of neomycin given

to four patients revealed no evidence of steatorrhea, although daily stool weight increased in three or four patients [96].

Cholestyramine usually causes constipation, but in doses of 24–30 g per day may cause steatorrhea [1]. Animal studies show that increasing the dietary amount of cholestyramine markedly increased the excretion of both free and esterified fat in the stool [97].

Octreotide, used as an antidiarrheal, has a paradoxical effect at higher doses, causing steatorrhea in 5–13% of patients by a possible synergistic inhibition of biliary and pancreatic function through decreased bicarbonate and lipase secretion [1, 98]. L-dopa, allopurinol, tetracycline and NSAIDs, especially mefenamic acid, can cause steatorrhea through changes in jejunal mucosa [28, 66].

Several medications have been implicated for inducing steatorrhea in addition to other types of diarrhea. For example, in addition to its effects on intestinal transit, levothyroxine has been implicated in bile acid malabsorption because of abnormal selenohomocholytaurine (SeHCAT) testing. This test can be used to diagnose bile acid malabsorption as a cause of chronic diarrhea, but it best predicts the benefit of cholestyramine in these patients [99]. However, this adverse effect of levothyroxine may be a secondary effect of increased motility. Colchicine can cause secretory and inflammatory diarrhea, but can also cause malabsorption in large doses by causing villous atrophy [3]. Three out of twelve patients evaluated for gastrointestinal effects of the long-term use of colchicine prophylaxis for recurrent polyserositis developed mild steatorrhea [100].

Chemotherapeutic agents, besides causing inflammatory diarrhea, can damage immature epithelial cells in the crypts causing functionally compromised mature enterocytes. This effect leads to decreased nutrient absorptive capacity and potentially a malabsorptive diarrhea [3]. Rapamycin administration in rabbits showed significantly decreased jejunal and ileal villous surface areas and decreased fat and cholesterol uptake, possibly contributing to malabsorption [101].

Treatment of drug induced steatorrhea may require dose reduction or withdrawal of the drug. In some cases such as diarrhea due to metformin, continued symptoms may resolve with time even if the drug is continued, as the gastrointestinal system adjusts to the drug. Antidiarrheals such as loperamide and probiotics may help. In the case of antiretroviral drugs, soluble fiber and L-glutamine have been found to be helpful [102]. If prolonged, replacement of fat soluble vitamins maybe needed.

## Conclusion

Ideally, decisions about diagnosis or therapy should be evidence-based; however, as emphasized above, there is

frequently a dearth of high quality evidence to guide the clinician in the area of drug-induced diarrhea. Determining the etiology of drug induced diarrhea depends on a careful history to identify the offending agent. Any history of drug allergies or intolerances, and any new prescription medications taken within the six to eight weeks prior to symptom onset may reveal the etiology. One should always consider prescription as well as non-prescription drugs, nutritional supplements, excessive caffeine consumption and artificial sweeteners found in diet foods as potential causes. Most cases of drug-induced diarrhea resolve spontaneously within a few days after withdrawal of the drug, or with dose reduction. If diarrhea is severe or persistent, patient management should include replenishment of any fluid and electrolyte deficits with oral hydration or, if warranted, with intravenous fluids. Non-specific antidiarrheal agents can reduce stool frequency and stool weight as well as decrease abdominal cramps. Opiates (loperamide, diphenoxylate with atropine), intraluminal agents (bismuth subsalicylate) and adsorbents (kaolin) also can help reduce the fluidity of bowel movements [2, 58]. A low residue diet, specific treatment as described in above sections such as antibiotics for *C. difficile* colitis, and reduction of fat intake for patients taking orlistat, can also help. Probiotics as possible treatment or prevention have not been well studied, but future studies may prove to be useful.

### Introduction

Metabolic bone disease is seen in patients suffering from a variety of gastrointestinal disorders, including chronic liver disease, inflammatory bowel disease (IBD), and malabsorption syndromes such as celiac disease. In the setting of gastrointestinal disorders, bone disease can be broadly divided into osteoporosis and osteomalacia. Osteoporosis is a systemic skeletal disorder of reduced bone mass per unit volume (i.e. bone density) and disrupted micro-architecture, resulting in decreased bone strength and an increased risk of fragility fractures mainly of the hip, wrist and vertebrae [1]. Bone mass is a major determinant of bone strength. Osteomalacia, however, is characterized by defective mineralization of bone matrix, usually due to a disturbance of vitamin D and calcium homeostasis. It is clinically associated with pain, bone fractures, muscle weakness, difficulty walking and, radiologically, with pseudofractures (radiolucent bands perpendicular to surface of cortical bone) and loss of trabeculae.

There are two types of bone: cortical, which primarily makes up the long bones, and trabecular bone, which makes up most of the axial skeleton. Bone formation and resorption is a continuous process in which osteoblasts are responsible for the formation of new bone including the mineralization of bone, and osteoclasts are responsible for bone resorption. Metabolic bone disease results from abnormalities in the normal remodeling cycle. Osteoporosis is associated with disability, impaired quality of life and osteoporotic fractures can be associated with increased mortality [2].

This chapter will focus on metabolic bone disease associated with chronic liver disease, IBD, celiac disease and will review corticosteroid-induced osteoporosis and the potential link between proton pump inhibitors and osteoporotic fractures.

### Assessment of bone mass

Age-related bone loss begins during the fourth decade, and in women there is an accelerated bone loss at the time of menopause (5–15% in the initial five years after menopause), due to declines in estrogen. Perimenopausal bone loss is characterized by increased bone resorption and bone loss is greater at trabecular bone sites compared to cortical sites. Women experience greater rates of bone loss than men and their lifetime risk of an osteoporotic fracture is about 15% compared with 5% in men [3]. Osteoporosis can be detected by measurement of bone mineral density. Bone density is the most accurate predictor of fracture risk and it is a useful guide for monitoring therapy [4]. Prospective trials have established the ability of bone density to predict site-specific fractures [5]. For each reduction in bone density of the hip by 1 standard deviation (SD) from the mean for young normal individuals, the risk of hip fracture increases by a factor of 1.5–2.6 [6]. In men, low bone mineral density (BMD) has been demonstrated to be predictive of vertebral fractures [7]. In a prospective study which included 1690 men, it was estimated that a 1 SD decrease in femoral neck bone density was associated with a two-fold increase in risk of a traumatic fracture [8]. Increasing age and a history of a previous vertebral fracture are very important predictors of fracture.

Bone mass can be evaluated at a number of sites, such as the proximal femur, spine and distal radius. The most commonly used technique to evaluate BMD is dual energy X-ray absorptiometry (DXA). The reproducibility, accuracy

and precision of DXA are excellent, with a coefficient of variation of 2%. Another technique, quantitative computed tomography (QCT), provides a three-dimensional image which makes it possible to separate trabecular and cortical bone. The accuracy of QCT is not as good (5–15%) as DXA, and is associated with a higher radiation dose.

Bone mineral content (BMC) is the total amount of mineralized tissue (g) in the bone scan, usually normalized to the length of the scan path (grams per mineral per centimeter of bone or g/cm). BMD, on the other hand, is the amount of mineralized tissue in the scanned area (g/cm<sup>2</sup>). BMD can be expressed as a T-score (comparison of the patient's bone density with the peak bone mass in young normal individuals) or Z-score (comparison of patient's BMD to other age-matched controls). Individuals with a T-score or BMD less than 1 SD below the mean in young adults are considered to be osteopenic, while those with a BMD less than 2.5 SD below the young normal value are osteoporotic [1]. A study group on densitometry hosted by the World Health Organization (WHO) in 1993 defined these four diagnostic thresholds based on reference populations of healthy young women. Since these thresholds are based on young women, this definition does not account for biological variation and age-related bone loss and many have argued against the use of T-scores.

In addition to BMD, bone strength and fracture risk depend on other skeletal and non-skeletal factors such as trabecular micro-architecture and muscle strength. As a result, there has been a shift to the development of fracture risk prediction models which incorporate BMD, age and other clinical factors.

The increased use of DXA has resulted in more gastroenterology patients being diagnosed with osteoporosis. However, it is not clear what a diagnosis of osteopenia in gastrointestinal patients means in terms of increased fracture risk. On the basis of BMD, osteomalacia cannot be distinguished from osteoporosis.

## Hepatic osteodystrophy

Hepatic osteodystrophy, or chronic liver disease-associated metabolic bone disease, was previously thought to arise mainly in cholestatic liver diseases, as a result of calcium and vitamin D malabsorption. However, hepatic osteodystrophy has now been described in association with most types of chronic liver diseases, whether cholestatic or non-cholestatic [9]. Increased bone loss and/or increased incidence of fractures have been described in primary biliary cirrhosis (PBC) [10], primary sclerosing cholangitis (PSC) [11], alcoholic liver disease (ALD) [12, 13], autoimmune hepatitis (AIH) [14], hemochromatosis [15, 16], as well as viral cirrhosis [17–20]. Additionally, hepatic osteodystrophy has important clinical repercussions in the early period

after liver transplant, where immobilization, co-morbidity, corticosteroids and immunosuppressive drugs further reduce an already compromised bone mass [10], resulting in spontaneous vertebral fractures [21, 22].

## Prevalence

The prevalence of hepatic osteodystrophy varies from 13–56% [11, 17, 23, 24], while the incidence of fractures in ambulatory and non-alcoholic patients with chronic liver disease ranges from 6–18%. The prevalence of vertebral fractures ranges from 7–44% and is approximately twice that of age and sex-matched controls, with the highest rates in those individuals with AIH [17, 23–25]. The degree of bone loss correlates with the severity of the cirrhosis and increasing age, making patients with endstage liver disease the group most at risk of fractures [5, 23, 26]. The situation in PBC is becoming less clear as some studies show an association with osteoporosis and fractures [24, 25, 27], while some recent studies including a prospective cohort study showed an association with age, postmenopausal status and BMI, but not with cirrhosis or serum bilirubin [28]. While another showed no increased risk of fractures in PBC [29]. Similarly, a study in PSC showed that bone mineral density did not correlate with the severity of the disease [30].

The fracture risk in chronic liver disease was best studied by Diamond *et al.*, in a case-control study of 115 patients with chronic liver disease (72 men and 43 women), who were matched for age, sex and menopausal status with healthy controls [23]. The etiology of the chronic liver disease was ALD (n = 40), chronic active hepatitis (n = 27), hemochromatosis (n = 25), PBC (n = 10), and PSC (n = 13). Fifty-two percent of the patients were cirrhotic, while 30% had clinical and biochemical evidence of hypogonadism. It is important to note that, in men, hypogonadism correlates with the degree of liver dysfunction. All patients were ambulatory and none were on cholestyramine, vitamin D, estrogen, or calcium. From the data in this study, the relative risk (RR) of either spinal or peripheral fractures can be calculated, based on the absolute number of fractures (as opposed to the number of patients with fractures). In men this RR is 3.03 (95% CI: 1.35–11.09), while in women the RR is 2.13 (95% CI: 1.38–7.46). These authors did a stepwise regression analysis to define the main predictors of fracture and osteoporosis. Variables used were: age, sex, gonadal status, presence of cirrhosis, type of liver disease, liver function, 25(OH) D<sub>3</sub> level and parathyroid hormone (PTH) level. Lumbar spine bone density, liver dysfunction and hypogonadism were the main predictors of spinal fracture, while hypogonadism and the presence of cirrhosis were the main predictors of peripheral fractures. There was no association with serum PTH or 25-hydroxy-vitamin D<sub>3</sub>.

Because of the potential for impaired absorption of calcium and vitamin D [31, 32], as well as impaired hepatic

uptake and metabolism of vitamin D [33], osteomalacia was initially thought to be the major cause of hepatic osteodystrophy in cholestatic liver diseases [33, 34]. However, it then became evident that bone disease was still prevalent despite treatment with calcium and vitamin D, and that most patients with cholestatic liver disease and osteopenia did not have low 25-hydroxyvitamin D<sub>3</sub> levels [11] or histomorphometric characteristics of osteomalacia [26, 35, 36]. Osteoporosis appears to be the major metabolic bone disease found with chronic liver disease.

The mechanisms responsible for the osteoporosis in this setting are uncertain, and evidence exists for both decreased bone formation [26, 37–39] and increased bone resorption [11, 35, 40]. The presence of cirrhosis seems to play an important role through several mechanisms. Testosterone, 25-hydroxy-vitamin D, and insulin-like growth factor 1 (IGF-1) levels are all reduced in advanced liver disease and correlate inversely with the degree of osteopenia [17, 23]. As well, bone mass starts to increase within six months to a year after liver transplantation [10]. Other factors may also affect bone metabolism independently of cirrhosis: bone formation is directly suppressed by alcohol [13, 41], and possibly by iron in hemochromatosis. The majority of patients with advanced PBC are also postmenopausal females, which adds to the list of pathogenic factors of hepatic osteodystrophy [23]. Malnutrition, treatment with corticosteroids [14, 42] or immunosuppressive agents plays a role in some cases.

## Treatment

### Osteomalacia

Osteomalacia secondary to vitamin D deficiency is characterized by low serum 25-hydroxy-vitamin D (25(OH) D < 25 nmol/L), low or normal calcium, low phosphate and elevated alkaline phosphatase and usually increased serum parathyroid hormone levels. Based on measurement of 25(OH) D level and bone histomorphometry, osteomalacia can be successfully treated and prevented with combined calcium and vitamin D supplementation (oral or parenteral) [43, 44]. **B4** Vitamin D does not need to be given as its 25-hydroxy metabolite, since the capacity of the liver to hydroxylate vitamin D is maintained, even in advanced liver disease. However, since its absorption and/or hepatic uptake may be decreased, sufficient doses should be administered [32]. Successful treatment of osteomalacia has been achieved with calcium and either oral vitamin D<sub>2</sub> 2000–4000 IU daily, intramuscular vitamin D<sub>2</sub> 150,000 IU weekly [43], or oral 25-hydroxy-D<sub>3</sub> 1000–4000 IU daily [44], for a duration of 3–6 months. **B4**

### Osteoporosis

The evidence for interventions for the treatment of osteoporosis in chronic liver disease is summarized in Tables

16.1 and 16.2. There are a number of observational trials and randomized controlled trials (RCTs), most of which have relatively small numbers of patients.

*Vitamin D and calcium* Therapy with vitamin D has been studied in osteoporotic patients with either cholestatic [40, 51] or non-cholestatic liver disease [12] and low 25(OH) D levels. Uncontrolled studies in PBC (Table 16.1) suggest that normalization of 25(OH) D levels failed to arrest bone loss [40] or to prevent spontaneous fractures. **B4** In one of these two reports, improvements in bone mass occurred only in patients whose calcium absorption increased as a result of therapy [51]. However, in an RCT of 18 abstinent patients with alcoholic liver disease, Mobarhan *et al.* showed that normalization of 25(OH) D levels was associated with a significant increase in BMD after a mean duration of 10 months (Table 16.2) [12]. **Ald** Unfortunately, a bone biopsy to rule out osteomalacia was done in only 9 of 18 patients.

Shiomi *et al.* studied the efficacy of 1,25-dihydroxy-vitamin D<sub>3</sub> (0.5 micrograms) on lumbar spine BMD in 76 individuals with cirrhosis secondary to hepatitis B or C infection. The results suggested that calcitriol may be effective for increasing bone mass at the lumbar spine over a 12-month period [52]. **B4**

Calcium supplementation appeared to prevent or diminish bone loss compared with untreated controls [53].

*Antiresorptive and anabolic agents* A retrospective study of 107 females with PBC suggested that hormone replacement therapy (HRT) is associated with a significant reduction of annual bone loss (Table 16.1) [50]. **B4** A small RCT of HRT compared to vitamin D supplements showed statistically significant improvement in BMD of LS and FN with HRT [55], and a small prospective non-randomized study showed a significant 2.25% improvement in LS BMD with one year of HRT compared with vitamin D alone (0.87%) [46]. Another small prospective study showed a non-significant trend towards less FN bone loss and fewer fractures with HRT [54].

In another non-randomized study, four years of clodronate and calcium/vitamin D<sub>3</sub> supplements did not significantly improve osteoporosis or osteopenia in menopausal PBC patients but reduced “natural bone loss” [45].

Table 16.2 summarizes the results of randomized trials of a variety of other interventions. Guanabens *et al.*, in a two-year RCT of 32 women with PBC, compared cyclical etidronate at a dose of 400 mg for two weeks every 78 days, to sodium fluoride (NaF) 50 mg per day [59]. In the fluoride-treated group, the bone density of the lumbar spine decreased by 1.94% and the femoral neck decreased by 1.4%. By contrast, etidronate increased bone mass in the lumbar spine by 0.53% and femoral neck BMD was stable and was better tolerated. **Ald**

**Table 16.1** Case series of interventions for hepatic osteodystrophy.

Study	Disease (no. of patients)	Therapy (duration)	Measurement (site)	Comments
Floreani <i>et al.</i> (2007) [45]	PBC (100)	oral calcium carbonate (1000 mg/day) + vit D <sub>3</sub> (880 IU/day) + i.m. disodium clodronate 100 mg every 10 days (four years)	DXA LS (L2-L4)	Clodronate + calcium/vitamin D <sub>3</sub> supplements did not significantly improve osteoporosis or osteopenia, but reduced “natural bone loss”
Pereira <i>et al.</i> (2004) [46]	PBC (42)	Transdermal HRT vs oral vitamin D supplement (one year)	DXA LS	2.25% increase in BMD with HRT vs 0.87% with vitamin D
Floreani <i>et al.</i> (1997) [47]	PBC (34)	1,25(OH) <sub>2</sub> -D <sub>3</sub> 1 micrograms/day × 5d, calcitonin 40 U IM 3/week × four weeks every three months CaCO <sub>3</sub> 1–5 g/day × four weeks (three years)	DPA (LS)	Reduced bone loss in treated (uncontrolled)
Riemens <i>et al.</i> (1996) [48]	OLT (53)	1-OHD 1 microgram/day; Ca 1 g/day; etidronate 400 mg/day 2/15 week (one year)	DPA (LS)	No reduction in bone loss compared with historical controls
Neuhaus <i>et al.</i> (1995) [49]	OLT (150)	25-OH-D <sub>3</sub> 0.25–0.5 micrograms/day ± Ca 1 g/day ± NaF 25 mg/day (two years)	DXA (LS/FN)	Reduced bone loss in any of the treatment groups compared with untreated controls
Crippin <i>et al.</i> (1994) [50]	PBC (107)	Estrogen (low dose oral or patch) (one year)	DPA (LS)	Reduction in bone loss in estrogen group
Matloff <i>et al.</i> (1982) [51]	PBC (10)	25-OH-D <sub>3</sub> 40–120 micrograms/day (one year)	PBA (radius)	Normalization of 25-OH-D levels but ongoing bone loss and fractures
Herlong <i>et al.</i> (1982) [40]	PBC (15)	25-OH-D <sub>3</sub> 50–100 micrograms/day (one year)	PBA (radius)	Normalization of 25-OH-D levels but ongoing bone loss
Wagonfeld <i>et al.</i> (1976) [33]	PBC (8)	PO or SC D vs 25-OH-D <sub>3</sub> 100–200 micrograms/day (three months)	X-ray and PBA (hand)	Failure of oral or parenteral vitamin D to normalize 25-OH-D or to prevent accelerated bone loss

PBC: primary biliary cirrhosis; OLT: orthotopic liver transplantation; CAH: chronic active hepatitis; ALD: alcoholic liver disease; HA: hydroxyapatite; NaF: sodium fluoride; UDCA: ursodeoxycholic acid; DPA: dual photon absorptiometry; DXA: dual X-ray absorptiometry; PBA: photon beam absorptiometry; SPA: single photon absorptiometry; LS: lumbar spine; FN: femoral neck; 25-OH-D<sub>3</sub>: 25-hydroxy-vitamin D<sub>3</sub>; PO: per os; SC: subcutaneous; IM: intramuscular.

Wolfhagen *et al.* compared etidronate plus calcium with calcium alone in a randomized trial in 12 women with PBC on corticosteroids [61]. There was a statistically significant difference in the percentage change in mean lumbar BMD between the etidronate and calcium-treated groups (etidronate + 0.4%, calcium −3.0%,  $p = 0.01$ ) [61]. **Ald** In a randomized trial that was not blinded, Shiomi *et al.* evaluated etidronate in 45 women with cirrhosis due to underlying viral hepatitis and also found a statistically significant difference in the percentage change in lumbar spine BMD [57]. Guanabens *et al.* compared alendronate with etidronate in an RCT of 36 women with PBC [56]. After two years, both treatments increased bone density but the increase was significantly greater in women on alendronate. **Ald**

Camisasca *et al.* [60] evaluated the effect of a six-month course of calcitonin 40 IU every other day, given subcutaneously in a trial with a crossover design. The control group received 1 IU of porcine calcitonin (no metabolic effect).

Both groups received calcium and 100,000 IU of parenteral vitamin D<sub>2</sub> ( $n = 25$ ). Treatments were administered for six months with a three-month washout. There was no difference in bone density between the two treatment groups in either of the crossover periods. It is possible that this study was inadequately powered to detect a statistically significant difference. **Ald**

In another trial of 22 women with PBC followed for two years, Guanabens *et al.* [62] compared NaF to calcium in a two-year RCT. In the NaF group, the bone density of the lumbar spine increased by 2.9% compared with the control group in which it decreased by 6.6%. However, there was a high frequency of adverse effects, mainly gastrointestinal. Since NaF therapy was also less effective than etidronate in another study, this intervention is not recommended.

In summary, both cholestatic and non-cholestatic types of liver disease may be complicated by metabolic bone

**Table 16.2** Randomized trials of interventions for hepatic osteodystrophy.

Study	Disease (no. of patients)	Intervention (duration)	Measurement (site)	Comments
Boone <i>et al.</i> (2006) [54]	PBC (31)	Two years' estrogen/progestin	DXA, FN	High treatment drop-out rate Less bone loss with treatment, and no fractures vs two with placebo (NS)
Ormarsdottir <i>et al.</i> (2004) [55]	PBC (18)	Two years' transdermal oestradiol + medroxyprogesterone vs vitamin D	DXA, LS, FN	BMD increased with HRT at LS, and FN ( $p < 0.05$ )
Guanabens <i>et al.</i> (2003) [56]	PBC (36)	Two-year cyclical etidronate vs alendronate	DXA, LS, FN	Both treatments increased BMD, but increases with alendronate were significantly larger
Shiomi <i>et al.</i> (2002) [57]	Viral hepatitis (50)	Two years' cyclical etidronate	DXA LS	Significant reduction in bone loss in etidronate treated group
Lindor <i>et al.</i> (2000) [58]	PBC (67)	One year cyclical etidronate	DXA LS, FN	No significant difference from placebo
Shiomi <i>et al.</i> (1999) [52]	Cirrhosis, PBC and secondary to hepatitis B and C (76)	0.5 micrograms calcitriol twice daily 15 months	DXA (LS)	Significant reduction in bone loss in calcitriol group
Guanabens <i>et al.</i> (1997) [59]	PBC (32)	Etidronate 400 mg/day 2/15 week vs NaF 50 mg/day (two years)	DPA (LS)	Significant reduction in bone loss in etidronate group
Camisasca <i>et al.</i> (1994) [60]	PBC (25)	Carbicalcitonin 40U SC every day vs porcine calcitonin IU SC 2/week (15 months)	DPA (LS)	No difference between groups
Wolfhagen <i>et al.</i> (1997) [61]	PBC (12)	Etidronate 400 mg/day $\times$ two weeks + Ca 500 mg/day, 11/13 week vs Ca 500 mg/day (one year)	DXA (LS/FN)	Significant reduction in LS bone loss in etidronate group
Guanabens <i>et al.</i> (1992) [62]	PBC (22)	NaF 50 mg/day vs placebo (two years)	DPA (LS)	Significant reduction in bone loss in NaF group
Lindor <i>et al.</i> (1995) [63]	PBC (88)	UDCA 13–15 mg/kg/day (three years)	DPA (LS)	No difference between groups
Stellon <i>et al.</i> (1985) [64]	CAH (36)	HA 8 g/day (two years) X-ray/SPA	Reduced bone loss in HA group	
Mobarhan <i>et al.</i> (1984) [12]	ALD (18)	D2 50 000 U 2–3 $\times$ /wk v 25-OHD 20–50 micrograms/day vs control (one year)	DPA (LS)	Significant increase in BMD compared to baseline in all groups a crossover design

PBC: primary biliary cirrhosis; OLT: orthotopic liver transplantation; CAH: chronic active hepatitis; ALD: alcoholic liver disease; HA: hydroxyapatite; NaF: sodium fluoride; UDCA: ursodeoxycholic acid; DPA: dual photon absorptiometry; DXA: dual X-ray absorptiometry; PBA: photon beam absorptiometry; SPA: single photon absorptiometry; LS: lumbar spine; FN: femoral neck; 25-OH-D<sub>3</sub>: 25-hydroxy-vitamin D<sub>3</sub>; PO: per os; SC: subcutaneous; IM: intramuscular.

disease, predominately osteoporosis. The prevalence of bone disease increases with the degree of cirrhosis. Accelerated bone loss is most severe after liver transplantation. Patients with advanced liver disease, awaiting transplantation, on prolonged corticosteroid therapy or with a history of fragility fractures, should be investigated with BMD testing. **C5** Low 25-(OH) D<sub>3</sub> levels should be cor-

rected and calcium supplementation given. Bisphosphonates should be considered in patients with known osteoporosis or vertebral fractures, based on the evidence from a number of small randomized trials. **A1a** Testosterone therapy should be considered in males with hypogonadism. **C5**

There is a need for population-based studies of fracture risk in patients with chronic liver disease.

## Inflammatory bowel disease

### Prevalence

The importance of metabolic bone disease in patients with IBD has been recognized for some time. However, the point prevalence of bone disease in this population varies greatly from one study to another, with estimates as low as 5% to as high as 78%. This variation reflects a number of factors, including the definition of osteoporosis used, the site of bone density measurement and the heterogeneous nature of the IBD population. Furthermore, morphometric vertebral deformities also appear to be relatively common and are seen in 25% of both Crohn's disease, and ulcerative colitis patients [65]. A list of potential factors that need to be considered when evaluating studies in this area is provided in Table 16.3.

In a well-conducted study, Abitbol *et al.* [66] evaluated the BMD of 84 consecutive patients with IBD (34 Crohn's disease, 50 ulcerative colitis, excluding proctitis). Overall, 43% had osteopenia in the lumbar spine. Steroid users were at significantly greater risk of osteopenia (58% vs 28% in non-users,  $p = 0.03$ ). Six patients with a mean age of 50 had vertebral crush fractures (mean Z-score was  $-1.63$ ). Five patients were found to have low 25(OH) D<sub>3</sub> levels; however, the cause of this deficiency was felt to be extra-intestinal in all but one case. Multiple regression analysis of the lumbar spine Z-score revealed a significant correlation between osteopenia and age, cumulative corticosteroid dose, inflammatory status as assessed by the erythrocyte sedimentation rate (ESR), and low osteocalcin levels ( $r^2 = 0.76$ ,  $p < 0.05$ ).

The rate of bone loss in IBD has been studied in several longitudinal studies [67–73]. In the majority of the studies

the annual rate of bone loss appears to be greater in the spine than at the radius, and varies from 2% to 6%. Schulte *et al.* studied the rate of BMD change in 80 IBD patients and found that the annual rate of bone loss was small (0.8%/year for spine) [71]. Corticosteroid use [67] and low body mass index [68] were found, in some studies, to affect bone mass negatively. Overall, metabolic bone disease is an important problem among patients with IBD, with an estimated prevalence in the range of 45%.

Malabsorption of calcium and vitamin D because of small bowel disease appears to play a minor role in the pathogenesis of metabolic bone disease in IBD. Both low and normal 25(OH) D levels have been documented in patients with Crohn's disease and there is no clear correlation between vitamin D levels and bone mass [74, 75]. Osteomalacia appears to be much less common than osteoporosis in IBD. Hesso *et al.* did a bone biopsy and serum 25(OH) D determinations on 36 randomly selected Crohn's disease patients with previous surgical resections (mean length 105 cm). Only two patients were found to have below normal 25-hydroxy-vitamin D<sub>3</sub> levels and/or histomorphometric evidence of osteomalacia. However, the mean trabecular bone volume was reduced in this group compared with controls, suggestive of osteoporosis. This finding did not correlate with any of the measured clinical characteristics, including length of resection and serum 25(OH) D level [76]. Another bone histomorphometry study in IBD revealed decreased bone formation without evidence of osteomalacia [77].

Comparisons between Crohn's disease and ulcerative colitis patients suggest that osteoporosis may be more prevalent in the former [78–80]. However, careful review of these publications suggests that the analysis may not have been fully controlled for the effects of disease activity and/or steroid use. Jahnsen *et al.* in an age and sex-matched cross-sectional study of 60 Crohn's disease patients, 60 ulcerative colitis patients and 60 controls, found no differences in BMD between the patients with ulcerative colitis and the controls [79]. However, Crohn's disease patients had significantly lower BMD. Overall 16% of ulcerative colitis patients and controls had Z-scores  $< -1$  compared with 23% of Crohn's disease patients [79]. However, significantly more Crohn's disease than ulcerative colitis patients used corticosteroids (72% vs 47%), and smoked (57% vs 28%). Although disease activity was not specifically addressed in this study, 53% of the ulcerative colitis group had left-sided disease, with 40% having proctosigmoiditis or less. As well, the BMD of Crohn's disease patients who were not using steroids was not significantly different from that of the other two groups. Ghosh *et al.* [78] evaluated 30 IBD patients at the time of diagnosis and found that those with Crohn's disease had significantly lower bone density than those with ulcerative colitis. The mean lumbar spine Z-score for Crohn's disease patients

**Table 16.3** Factors influencing interpretation of studies of bone disease in gastrointestinal patients.

Definition of osteopenia	Z-scores of $\leq 1$ (? T-scores of $-1$ to $-2.5$ )
Diagnostic method	X-ray, SPA, DPA, QCT, DXA, US
Results expressed (outcome)	BMD, BMC, radiological or clinical fracture (vertebral or non-vertebral)
Bone site studied	Spine, forearm, femoral neck or total hip
High risk patients	Included or excluded
Control of confounders	Smoking, steroid use, BMI

SPA: single photon absorptiometry; QCT: quantitative computed tomography; DPA: dual photon absorptiometry; DXA: dual energy X-ray absorptiometry; BMD: bone mineral density; BMC: bone mineral content.

was  $-1.06$  versus  $-0.03$  for those with ulcerative colitis. However, 7 of 15 ulcerative colitis patients had proctitis alone, and one had a "distal colitis". As well, the mean duration of disease before diagnosis (18.6 vs 12 weeks), and of steroid use (1.2 vs 0.5 weeks) before BMD, measurements are slightly longer in the Crohn's group, again suggesting that disease severity rather than diagnosis may be the important factor. Bernstein *et al.* in a study of 26 Crohn's disease and 23 ulcerative colitis patients, also found a greater prevalence of osteopenia among the former [80]. However, using stepwise discriminant analysis, the authors found that steroid use rather than disease type was the most important predictive factor of osteopenia.

A cross-sectional study of 51 Crohn's disease, 40 ulcerative colitis patients and 30 age and sex-matched controls by Ardizzone *et al.* found no significant difference in mean T-score values between patients with Crohn's or ulcerative colitis but did find that 37% of Crohn's and 18% of ulcerative colitis patients were osteoporotic based on WHO criteria [81]. Stepwise regression showed that in Crohn's disease, the femoral neck T-score was inversely related to disease duration and lumbar spine T-score was inversely related to age. Refitt *et al.* also found that BMD improved with increasing duration of remission and found a benefit with azathioprine induced remission [82]. There were baseline differences in disease duration between the two groups. Schulte studied the rate of BMD change in 80 patients with IBD. The results indicated that the average annual rate of bone loss was small. There was a large range in BMD results in these patients, suggesting that certain subgroups may lose bone more quickly than others.

The study of metabolic bone disease in ulcerative colitis before and after restorative proctocolectomy also suggests that disease activity plays an important role, since BMD increases significantly with time after colectomy, with a mean annual increase of around 2% [83].

Fracture prevalence estimates in IBD from cross-sectional and prospective studies have been variable, with larger series reporting vertebral fractures in 7–22% [84] and non-vertebral fractures in 27% of patients, although these data may have been affected by referral bias. There have been three population-based studies of fracture risk in IBD. Bernstein *et al.* identified 6027 IBD patients through an administrative database in a Canadian population and matched them to 60,270 controls by age, sex and geographic residence [85]. The overall fracture rate was higher compared with controls with a 41% overall increased incidence of hip, spine, wrist and rib fractures among IBD patients (RR 1.41, 95% CI: 1.27–1.56). The incidence rate ratio was 1.59 (95% CI: 1.27–2.00) for hip fractures. There were no difference in fracture rates between males and females or between Crohn's and ulcerative colitis patients, except that males with ulcerative colitis had a higher fracture rate than females. Although the fracture risk of IBD patients was

higher than controls, the increase was one patient per 100 patient years. Another North American study in Olmsted County, Minnesota assessed fracture risk in 238 Crohn's disease patients through a review of radiology reports and found that compared with age and sex-matched controls the overall risk ratio for any fracture was 0.9 (95% CI: 0.6–1.4), which was not statistically significant. The risk ratio for vertebral fracture was 2.2 (95% CI: 0.9–5.5), and the relative risk for an osteoporotic fracture was 1.4 (95% CI: 0.7–2.7), all statistically non-significant [86]. Age was the only significant predictor of fracture risk in a multivariate analysis and fracture risk was not increased in comparison with the general population except in the elderly patients. The findings were similar for the ulcerative colitis patients. Vestergaard and Mosekilde in a population-based study from hospital discharge data did not find an increase in fracture risk except for a small increase risk of fracture that required hospitalization in Crohn's disease patients [87]. The difference from fracture rates seen in ulcerative colitis patients was not statistically significant. A potential weakness of this study was the use of administrative databases which could result in the underreporting of fractures that do not require hospitalization. In addition, the diagnosis of Crohn's disease and ulcerative colitis was only validated in a small sample of patients.

A recent nested case-control study of 231,778 fracture cases from the UK General Practice Research Database demonstrated an increased risk of vertebral (OR 1.72; 95% CI: 1.13–2.61) and hip fracture (OR 1–59; 95% CI: 1.14–2.23) in patients with IBD. There was a greater risk of hip fracture seen in Crohn's disease patients compared with ulcerative colitis patients. This study also noted that only 13% of IBD patients who had already sustained a fracture were on osteoporosis treatment [88]. Corticosteroid use was associated with an increased risk of fracture and this association persisted after adjustment for disease severity (OR 1.10; 95% CI: 1.00–1.20). Limitations of this study included the method used to ascertain fractures and the fact that only clinically diagnosed fractures were included.

The literature suggests that there is a discrepancy between BMD findings and fracture risk in the IBD population and that the greatest risk is in elderly patients with IBD.

## Treatment

Clements *et al.* in an uncontrolled two-year prospective study of HRT in 47 postmenopausal women with IBD (25 ulcerative colitis, 22 Crohn's disease), found that radial and spine BMD rose significantly over baseline with HRT [89].

**B4** The authors found no differences in the responses between patients with ulcerative colitis and Crohn's disease. Patients using corticosteroids also seemed to respond.

Vogelsang *et al.* randomized 75 Crohn's disease patients, without short bowel syndrome to either 1000IU vitamin D<sub>3</sub> + calcium or placebo. The BMD of the forearm decreased in 80% of the control group compared to 50% of the treatment group at one year. BMD decreased less in calcium/vitamin D-treated patients (median decrease in BMD: treated 0.2%, interquartile range 3.8–(+14)%; control 7%, range 12.6–(+14)%;  $p < 0.005$ ). **Ald** The correlation between the change in vitamin D and change in BMC was low ( $r = 0.19$ ) [90]. Bernstein *et al.* [91] in a pilot study of 17 IBD patients with a history of steroid use (14 men, 10 Crohn's disease), assessed the efficacy of calcium supplementation (1000 mg/day) and vitamin D 250 IU on BMD by DXA. The authors found that the dose of prednisone in the year prior to the study inversely correlated with bone density at the hip, but not at the lumbar spine. There was no effect on bone density demonstrated after one year. **Ald** However, there is a significant risk of a type 2 error in this small study.

Robinson *et al.* [92] assessed the effect of low impact exercise in a randomized controlled trial. Although no statistically significant increase in BMD was observed in the exercise group, secondary analysis revealed that the number of exercise sessions correlated significantly with increased BMD at the hip and spine. **Ald**

Haderslev *et al.* assessed the impact of alendronate in Crohn's disease patients with osteopenia in a 12-month RCT. Alendronate increased the BMD of the lumbar spine by 5.5% compared with control over a one-year period. Fractures were not evaluated [93]. Bartram *et al.* similarly evaluated IV pamidronate + calcium/vitamin D compared to calcium/vitamin D alone in an RCT and found that while both groups showed improvement in BMD of the LS and hip, the improvement with pamidronate was statistically significantly higher (2.6% vs 1.6% at the LS) [94]. Another bisphosphonate, risedronate also appears to be effective at improving BMD at the hip and LS [95]. However, in another study of 154 Crohn's disease patients, Siffledeen *et al.* found that the addition of etidronate to calcium/vitamin D did not further improve BMD over that seen with calcium and vitamin D alone [96]. **Ald**

von Tirpitz *et al.* studied the effectiveness of NaF (75 mg SR) on 33 subjects with Crohn's disease in a 12-month RCT. The results indicated that NaF is effective at increasing mean spine Z-score ( $p = 0.02$ ). In contrast, the control arm of calcium 1000 mg/day and vitamin D 1000 IU/day did not result in increases in spine BMD [97]. **Ald**

Biological therapies are now becoming commonplace for the treatment and maintenance of patients with IBD. The use of anti-TNF therapies appears to improve bone mineral density in IBD patients [98–101]. This effect may stem from several properties of these agents, such as: improvement in disease activity per se, reduction in inflammatory mediators, reduction in corticosteroid use, or a direct bone antire-

sorptive effect. To study the relative effect of these factors, Pazianas *et al.* conducted a retrospective cohort study and found a greater improvement in BMD in IBD patients taking infliximab with a bisphosphonate compared to a bisphosphonate alone. This effect was inhibited by corticosteroid use. The authors did not find an independent effect of infliximab alone, suggesting that a primary effect on bone is likely not the main mode of action of this agent [102].

In summary, osteopenia is an important problem among patients with IBD, even at initial diagnosis. The risk appears to be greatest among those with the greatest disease activity and duration, and those treated with corticosteroids. It is difficult to distinguish the impact on bone density of corticosteroid use from that of disease activity, since these factors are linked. The risk of osteoporosis and fracture in ulcerative colitis is similar to that seen in Crohn's disease and after proctocolectomy the bone density of ulcerative colitis patients increases. The risk for osteoporosis and fractures appears to be similar in males and females. Crohn's and ulcerative colitis patients seem to have comparable risks for fracture; although the overall rate for fracture is increased, the rate is affected by age.

There is evidence that IBD patients with low BMD benefit from a combination of vitamin D and calcium. HRT may be a less attractive option based on results from the Women's Health Initiative study and concerns about an unfavorable risk profile, including an increased risk of breast cancer. Existing studies have used surrogate outcome measures, such as BMD, and management has been frequently been based on results from postmenopausal osteoporosis treatment trials. Further studies are needed to assess the impact of bisphosphonates on the clinically important outcome of fracture in the IBD population. Current recommendations are that for individuals with T-scores  $< -2.5$  or vertebral compression fractures, therapy should include calcium and vitamin D, in addition to bisphosphonates. **Ald** For those with T-scores between  $-2.5$  and  $-1.0$ , therapy should include calcium, vitamin D and bisphosphonate therapy for patients on prolonged corticosteroid therapy. In patients with active Crohn's disease parenteral administration of a bisphosphonate such as pamidronate or zoledronic acid may be indicated. **C**

---

## Celiac disease

### Prevalence

#### Osteoporosis

Prevalence rates of osteoporosis in celiac disease vary depending on the population studied (adults vs children) and whether the disease has been treated. Lower BMD values have been noted in untreated populations, includ-

ing those individuals who are asymptomatic at presentation. A number of cross-sectional studies have evaluated the prevalence of osteoporosis in (1) newly diagnosed celiac patients and (2) individuals treated with a gluten-free diet [103–110]. In general, studies in untreated celiac disease demonstrate diminished bone density. When compared with age-matched controls (Z-score of  $<-2$  at the spine), the prevalence of osteopenia in untreated patients varied among studies from 15–40% [105, 108]. Serum PTH levels have been shown to correlate inversely with BMD [105, 109] and levels of 25(OH) D correlate positively with BMD in untreated celiac disease patients [109].

### Fractures

Vasquez *et al.* estimated the incidence of fractures from a case-control study (ascertained fractures by interview) and found that 25% of patients had a history of previous fractures, compared with 8% of age and sex-matched controls (odds ratio (OR) 3.5; 95% CI: 1.8–7.2), with the majority of fractures occurring prior to diagnosis or in those individuals who were non-compliant [110]. The most common fracture was a wrist fracture and there was a trend to increased vertebral fractures. Vasquez studied patients from a malabsorption clinic and therefore this rate may not be representative of the general celiac population. Neither BMD or body mass index correlated with the presence of fractures, suggesting that there are other factors beside BMD, such as disease duration, that account for increased fracture risk.

Vestergaard and Mosekilde (2002) in Denmark in a retrospective cohort study examined hospital discharge abstracts for patients previously hospitalized with a diagnosis of celiac disease and did not detect a significant difference in fracture rates compared with controls [87]. Age was the only significant risk factor for fracture. There are potential sources of bias in using hospital-based discharge data including the fact that outpatient fracture diagnoses are not included. Thomason *et al.* (2003) in a case-control study in which fractures were ascertained using a questionnaire did not find an increased fracture risk in celiac disease patients compared with controls [111], and other small longitudinal studies have yielded similar findings [106, 112].

A recent systematic review and meta-analysis identified 60 potential studies of which eight met the inclusion criteria for the meta-analysis (e.g. outcome of fractures and controlled studies). The pooled prevalence of fractures in celiac disease patients was 8.7% (1819/20,955) compared to 6.1% (5955/96,777) for controls for a pooled odds ratio = 1.43; 95% CI: 1.15–1.78) although significant heterogeneity was observed ( $I^2 = 85.1\%$ ), as evidenced by poor overlapping of confidence intervals for individual studies [113]. Six of the eight studies showed a significant association between fractures and celiac disease.

The largest included study in the meta-analysis was a retrospective population based cohort study by Ludvigsson

*et al.* (2007) that used the Swedish National Registers to estimate the risk of hip and any fracture. They found that individuals with celiac disease were at increased risk of hip fracture (HR 2.1; 95% CI: 1.8–2.4) and for any type of fracture (HR 1.4; 95% CI: 1.3–1.5) [114]. Limitations include the inability to control for all potential confounding variables such as body mass index, smoking and the use of bisphosphonates or hormone replacement therapy. West *et al.* (2003) in another large retrospective cohort study in the UK also found a significant increase in fractures in celiac disease patients [115].

Further clarification of the risk of fracture in celiac disease with a large prospective cohort study with rigorous ascertainment of fractures would be helpful.

### Pathogenesis

Reduced calcium absorption can result in hypersecretion of PTH, enhanced 1,25-dihydroxy vitamin D and decreased 25 hydroxy-vitamin D [116]. In addition, systemic inflammatory effects may result in bone loss via action of interleukin (IL)-1 and IL-6, the levels of which have been shown to correlate with BMD [117]. It is also thought that zinc deficiency may lead to reduced IGF-1 levels which in turn results in impaired bone metabolism and reduced bone mass [118]. It is not clear what proportion of individuals with celiac disease have osteomalacia, due to the lack of bone biopsy data, but many individuals are vitamin D deficient.

### Treatment

Longitudinal studies of patients with celiac disease have demonstrated increases in BMD after starting on a gluten-free diet and the majority of the change occurs within the first year, particularly at the lumbar spine [119]. **B4** The average increase in lumbar spine BMD is approximately 5% within the initial year. A number of observational studies have shown that children will often normalize their BMD after a gluten-free diet [119–122]. **B4** Adults, however, may continue to have BMDs below average (Z-score of  $-1$  at the spine) [106, 123]. Premenopausal females have shown a greater increase in BMD than postmenopausal females.

Valdimarsson *et al.* found that patients with secondary hyperparathyroidism at baseline did not increase their BMD to normal by three years in comparison to those who had a normal baseline PTH, and did achieve a normal BMD [105].

The goal of treatment should be to maintain normal serum 25(OH) D levels, with vitamin D supplements and higher doses may be required initially. Bone density scans should be recommended in newly diagnosed adult celiac patients after one year on a gluten-free diet. Initial evaluation should also include serum calcium, 25(OH)D and PTH

levels. Additional osteoporosis therapies may be considered depending on the severity of bone loss.

### Glucocorticoid-induced bone loss

Glucocorticoids are widely used in the treatment of inflammatory bowel disease, and are an important independent risk factor for bone loss. Observational studies have demonstrated an association between cumulative corticosteroid dose and increased bone loss, in multiple populations, but some prospective studies have failed to support this relationship, perhaps because of a beneficial effect of corticosteroids on disease activity [124].

Data from cross-sectional studies of patients on corticosteroids estimate that the incidence of fractures varies from 30% to 50% [84, 125]. In a study by Adinoff and Hollister, 11% of asthma patients on oral steroids for one year developed vertebral fractures [126]. In a case-control study, Cooper *et al.* (Van Staa *et al.* [127]) found that use of oral steroids resulted in an RR of 1.16 (CI: 1.47–1.76) for hip fracture and 2.6 (CI: 2.31–2.92) for vertebral fracture. A nested case-control study from the Study for Osteoporotic Fractures Cohort confirmed an increase incidence of hip fractures in patients on corticosteroids with an adjusted relative risk of hip fracture of 2.1 (95% CI: 1.0–4.4) [128]. A meta-analysis of seven prospective cohort studies, found that previous GC use was associated with an RR of 2.63 of sustaining an osteoporotic fracture and 4.42 for hip fracture after adjusting for BMD [129]. The risk of fracture is increased at higher doses of corticosteroids.

There is evidence that the relationship between bone density may underestimate the risk of fracture in patients on corticosteroids, highlighting the importance of bone quality [130, 131]. Glucocorticoid-induced bone loss is greatest in the initial 6–12 months of treatment [132–134], and involves areas of the skeleton which have the greatest turnover, in particular, the lumbar spine, cortical rim of the vertebral body, ribs and proximal femur. Hahn *et al.* demonstrated that trabecular bone loss is greater than cortical bone loss in rheumatoid arthritis patients on prednisone [135]. Fracture risk increases within the first 3–6 months of glucocorticoid treatment [131].

### Pathogenesis

The mechanism of corticosteroid-induced osteoporosis (CSOP) is multifactorial [139]. CSOP differs from postmenopausal osteoporosis in that bone formation is greatly decreased at a time of increased bone resorption. This imbalance between formation and resorption results in a reduction in the total amount of bone replaced in each remodeling cycle. Corticosteroids cause a reduction in bone formation by decreasing the production of osteoblasts and increasing the apoptosis of osteoblasts and osteocytes

[140]. Corticosteroids also prolong the lifespan of mature osteoclasts, resulting in bone resorption [133]. Glucocorticoids also suppress the hypothalamic-pituitary-gonadal axis that leads to a functional hypogonadism and increased bone loss [141]. Finally, steroids cause loss of muscle mass, decrease the intestinal absorption of calcium and increase renal excretion of calcium.

One explanation for the rapid bone loss seen with corticosteroids could be related to the increase bone resorption that occurs secondary to the down-regulation of osteoprotegerin (OPG), an osteoblast-derived soluble decoy receptor. OPG blocks the interaction between RANK and RANK-L (receptor activator of nuclear factor  $\kappa$ B ligand) that inhibits osteoclast formation and also increases expression of RANK-L by osteoblasts [142]. The result is a decrease in the OPG/RANK-L ratio leading to an increase in cancellous osteoclasts and rapid bone loss [143].

### Prevention and treatment

A baseline bone density measurement is recommended for patients who are to remain on steroids for a prolonged period and in patients who are at risk of other types of osteoporosis, such as postmenopausal osteoporosis. The first principle of prevention is to minimize the dose of steroids. **C5** Maintenance of muscle mass through exercise is also beneficial. Supplemental calcium 1000–1500 mg/day and vitamin D 800 IU/day should be recommended.

A number of medications have been used for the prevention and treatment of CSOP. Tables 16.4–16.6 summarize the results of those controlled trials of prevention and treatment of CSOP, which had vertebral fractures as an endpoint. These tables show results according to intention to treat analysis. Efficacy results are indicated. Unfortunately, patients with IBD have been underrepresented in these trials. WMD (weighted mean difference) is the weighted mean average of the trials and the weight given to each study is the inverse of the variance. To calculate the WMD, the mean percentage change from baseline in the treatment and control groups was multiplied by the inverse of the associated variance.

Recent guidelines have been developed by consensus groups for the primary and secondary prevention of glucocorticoid-induced osteoporosis, based on evidence from recent clinical trials [130]. This group recommends that patients be considered for therapeutic intervention if the BMD T-score is below  $-1.5$ . Follow-up bone densitometry is recommended after one year and then every 1–3 years depending on the result.

### Calcium and vitamin D

Calcium and vitamin D have been used to prevent losses that occur from decreased calcium absorption, increased renal excretion of calcium.

**Table 16.4** Randomized trials of calcium/vitamin D for prevention and treatment of steroid-induced osteoporosis and fractures<sup>a</sup>.

Study	Disease (no. of patients)	Placebo (M:F)	Treatment (M:F)	Intervention (duration)	Control	Lumbar BMD (% change)	Vertebral fractures RR (95% CI)
Sambrook <i>et al.</i> (1993) [136]	PMR/RA (63)	29 (7:22)	34 (7:27)	Calcitriol 0.5–1.0 micrograms (two years)	Calcium 1000 mg	–1.3	Efficacy: 0.43 (0.04 to 4.47)
Adachi <i>et al.</i> (1996) [137]	PMR/TA (62)	31	31	50,000 U vitamin D (three years)	Placebo	–0.7	ITT: 0.56 (0.24 to 1.32)

ITT: intention to treat analysis; PMR: polymyalgia rheumatica; RA: rheumatoid arthritis; TA: temporal arteritis; RR: relative risk.

Buckley conducted a two-year RCT with calcium (1000 mg/day) and vitamin D<sub>3</sub> (500 IU/day) in rheumatoid arthritis patients on steroids and found that the loss of BMD in the lumbar spine and trochanter was prevented [155]. **B4** Adachi *et al.* evaluated the efficacy of vitamin D (50,000 U per week) and 1000 mg calcium in patients on moderate to high dose corticosteroids and found that vitamin D and calcium prevented the early loss of bone but

did not seem to be beneficial in the long term [137]. A Cochrane meta-analysis found that calcium and vitamin D prevented bone loss at the lumbar spine with a pooled WMD of 2.6% (95% CI: 0.76–4.53) [156]. **A1a** Another meta-analysis by Amin *et al.* that examined all therapies concluded that vitamin D and calcium is more effective than placebo or calcium alone [157]. **A1a** Three trials using vitamin D and calcium have assessed vertebral frac-

tures as an outcome (Table 16.4). Neither the individual trials nor a meta-analysis of the three trials demonstrated a statistically significant reduction in vertebral fractures (pooled relative risk 0.56; 95% CI: 0.24 to 1.32). **A1c** However, the number of patients included in these trials was small.

### Antiresorptive agents

Since steroids increase bone resorption, antiresorptive agents such as bisphosphonates, calcitonin and hormone replacement have been used for the treatment and prevention of osteoporosis.

There have been six published RCTs of calcitonin (intranasal or subcutaneous) for prevention of osteoporosis in patients on corticosteroids with fracture data. These trials show a positive effect of calcitonin on lumbar spine bone

density at one year. However, no statistically significant reduction in fractures was demonstrated in the five trials in which this was analyzed (Table 16.5). Meta-analysis of these five trials did not demonstrate a significant reduction in fractures (pooled relative risk was 0.60; 95% CI: 0.24 to 1.46) [158]. **A1c**

HRT was compared to calcium supplementation in a two-year RCT in 200 patients with rheumatoid arthritis, of whom 41 were receiving corticosteroids [159]. BMD in the spine fell by 1.19% (95% CI: 2.29–0.09) in the control group, but increased in HRT-treated patients (2.22%; 95% CI: 0.72–3.72;  $p < 0.001$ ). **A1a** Subgroup analysis of the steroid treated group also showed benefit of HRT treatment on spine BMD (3.75%; 95% CI: 0.72–6.78). There are no published data on fracture reduction with HRT in CSOP. Similarly, there is little evidence to support the use of testosterone in men on

corticosteroids. A small RCT of 15 men with asthma on oral glucocorticoids demonstrated that monthly testosterone injections were effective in preventing bone loss [160]. **Ald**

Bisphosphonates have been used for the treatment and prevention of CSOP (Table 16.6). A Cochrane meta-analysis of 13 trials ( $n = 842$ ) published in 2000 found that the weighted mean difference of percent change in lumbar spine BMD between bisphosphonates and placebo groups was 4.3% (95% CI: 2.7–5.9) at one year, using a random effects model [161]. There was significant heterogeneity between trials. In the Cochrane Review, the pooled RR from four studies that reported outcomes on vertebral fractures was 0.76 (95% CI: 0.4–1.5), a result that was not statistically significant.

Since the Cochrane Review there have been additional randomized trials with vertebral fractures as an endpoint (see Table 16.6) [150, 153, 154, 162]. The baseline characteristics (BMD, prevalent fractures) were different among these trials. The relative risk reduction for vertebral fractures in these trials ranged from 40% to 70%, although the upper limit of the 95% CI overlaps 1.0. **Ala** The individual trials did not reveal a statistically significant effect of bisphosphonates on vertebral fractures. However, if all seven prevention and treatment trials with bisphosphonates are pooled, the RR of vertebral fractures is 0.50 (95% CI: 0.30–0.80), consistent with an absolute risk reduction of 6.3%. A one-year extension study of the original alendronate trial demonstrated a significant reduction in morphometric vertebral fractures (ARR of 6.1%) [162]. There was no significant difference in non-vertebral fractures between bisphosphonates and calcium and vitamin D, although these trials were not powered to detect a difference in fractures. Kanis *et al.* in a systematic review compared the efficacy of different therapies for CSOP. A pooled analysis of risedronate, etidronate and alendronate demonstrated a significant reduction in vertebral fractures, RR 0.46 (95% CI: 0.28–0.77). For non-vertebral fractures the pooled estimate was 0.77 (9% CI: 0.39–1.51) [163].

Amin *et al.* conducted a metaregression of all therapies for CSOP, using lumbar spine BMD as the outcome and found that bisphosphonates were more effective than calcitonin, vitamin D or fluoride [164] (with an effect size of 1.03, 95%, CI: 0.85–1.17). The authors also found that the efficacy of bisphosphonates was enhanced with the concomitant use of vitamin D.

Other new agents such as strontium ranelate have proved antifracture efficacy in postmenopausal osteoporosis and may be useful for the treatment of CSOP.

### Bone formation (anabolic) agents

Monosodium fluoride has been shown to increase BMD at the lumbar spine [165–167]. **Ald** However, efficacy of fluoride for vertebral fracture reduction has not been demonstrated for CSOP [165, 166]. Other anabolic agents include

injections of human PTH 1-34 (hPTH 1-34) fragment which stimulates osteoblastogenesis and inhibits osteoblast apoptosis. Lane *et al.* compared daily injections of synthetic hPTH 1-34 along with estrogens with estrogen therapy alone in 51 osteoporotic postmenopausal women receiving glucocorticoids for rheumatic diseases. These women had been taking HRT for more than one year and were randomized to receive either HRT and parathyroid hormone PTH 25 micrograms daily or HRT alone. All subjects received calcium and vitamin D. None of the patients had liver disease or IBD. The mean steroid dose was  $8.0 \pm 3.8$  mg for PTH with estrogen group and  $9.5 \pm 4.5$  for the estrogen alone group. At 12 months the mean difference in the lumbar spine was 9.8% favoring PTH and estrogen over estrogen alone. **Ald** There were no significant differences seen between treatment and control at the distal radius, femoral neck, trochanter and hip [168].

A second publication presented 24-month follow-up data after patients had discontinued medication at 12 months. The lumbar spine BMD was maintained at 24 months with a mean difference of 11.9%. The study was not powered to assess a difference in fractures [169].

The choice of corticosteroid may also influence the propensity for the development of CSOP. For example, in the subset of steroid naive patients with active ileocecal Crohn's disease, budesonide was associated with less bone loss than prednisolone. However, this effect was not seen in patients who had previously received steroids or those who were steroid dependent [170].

In a 36-month randomized trial Saag *et al.* compared daily human recombinant parathyroid hormone (1-34) or teriparatide 20  $\mu$ g s/c ( $n = 214$ ) to alendronate 10 mg daily ( $n = 214$ ) in patients (ages 22 to 89 years) who had received glucocorticoids at a dose of 5 mg or more for at least three months ( $n = 428$ ). Both groups received 1000 mg of calcium and 800 IU of vitamin D. The 18-month results were published in 2007. The majority of patients in this trial had a rheumatologic disorder with rheumatoid arthritis being the most common diagnosis. The median dose of glucocorticoids was 7.5 mg/day in the teriparatide group and 7.8 in the alendronate group. The majority of participants were taking glucocorticoids for more than one year. Mean lumbar spine BMD was  $-2.5$  and  $-2.6$  respectively. Loss to follow-up was a limitation of this trial, with over 40% of participants lost by 36 months. There was a significantly greater increase in lumbar spine BMD in the PTH 1-34 group compared to alendronate at 36 months (11 vs 5.3%,  $p < 0.001$ ). Using the last observation carried forward the difference was 8.9 vs. 4.2%,  $p < 0.001$ . At 18 months, significantly fewer radiographic vertebral fractures occurred in the teriparatide group (1/171) compared to alendronate treated group (10/165,  $p = 0.004$ ) although the incidence of non-vertebral fractures was not significantly different in both groups [171].

## Proton pump inhibitors and fracture risk

Proton pump inhibitors (PPIs) are widely used in a variety of gastrointestinal disorders including peptic ulcer disease, gastroesophageal reflux disease (GERD) and non-ulcer dyspepsia. Their main mechanism of action is an irreversible inhibition of active acid secreting pumps on the luminal side of gastric parietal cells. These medications are relatively well tolerated with few side effects.

There is an emerging body of literature suggesting a possible link between chronic PPI therapy and increased fracture risk [172, 173]. *In vitro*, achlorhydria limits the dissolution of ionized calcium from its insoluble forms, a step important for its absorption in the gastrointestinal tract [174]. *In vivo* calcium malabsorption has been associated with hypochlorhydria [175]. However, there are conflicting data about the biologic plausibility of this hypothesis as the majority of calcium is absorbed in the non-acidic environment of the small bowel [175–177]. Furthermore, *in vitro*, PPIs have been shown to inhibit osteoclastic  $H^+-K^+-ATPase$  which may in fact reduce bone resorption [178].

Studies using large administrative databases from Denmark [172], the UK [173] and Canada [179] consistently found a small increase in risk of hip fracture from chronic PPI use, with adjusted odds ratios (AOR) ranging from 1.45 (95% CI: 1.28–1.65) [172] to 1.62 (95% CI: 1.02–2.58) [179], (95% CI: 1.41–1.89) [173]. Yang *et al.*, using the UK's General Practice Research Database [173], which included nearly 200,000 PPI users, found that the risk of hip fracture was significantly increased after as little as one year of PPI exposure (AOR 1.22; 95% CI: 1.15–1.30), increasing with duration of therapy and daily PPI dosage. The association was stronger in men than women. In a restricted analysis for chronic GERD sufferers, the risk was greatest with high dose long-term PPI therapy (AOR 3.49; 95% CI: 1.24–9.84) [173]. Targownik *et al.*, in a retrospective cohort of almost 16,000 PPI exposed subjects from Manitoba, found that the risk of hip fracture was significantly increased after at least five years of continuous PPI exposure (AOR 1.62; 95% CI: 1.02–2.59), and that the risk of any osteoporosis-related fracture increased after at least seven years of continuous PPI exposure (AOR 1.92; 95% CI: 1.16–3.18) [179]. In elderly patients, a study of the risk of admission to hospital for hip fracture within five years of onset of therapy with either warfarin, thyroid supplements, corticosteroids or PPIs, showed that corticosteroid-exposed patients had a significantly increased risk compared to those on PPIs (ARR 1.44; 95% CI: 1.21–1.70) [180]; by comparison, the warfarin and the thyroid replacement patients had adjusted risk ratios similar to those on PPIs (ARR 0.94; 95% CI: 0.81–1.09 and 1.02; 95% CI: 0.89–1.18 respectively) [180]. This suggests that if PPIs do have an adverse effect on fracture risk, this effect is small.

The risk of lowered BMD and fracture was studied in three prospective cohorts, two from the USA [181] and one from Europe [182]. After a mean follow up of 6.1 years, postmenopausal women chronically using omeprazole had a significant increase in risk of vertebral fracture (RR 3.10; 95% CI: 1.14–8.44 in the multivariate analysis); by comparison, the RR was 3.62 (95% CI: 1.63–8.08) in those with history of prior vertebral fracture and 2.38 (95% CI: 1.03–5.49) in those with lumbar spine T-score  $<-2.5$  [182]. The Osteoporosis Fractures in Men Study (MrOS) and the Study of Osteoporotic Fractures (SOF) followed BMD and the incidence of non-vertebral fractures in 5755 men for an average of up to 5.6 years (MrOS) and 5339 women for an average of up to 7.6 years (SOF) [181]. When controlling for other risk factors for bone loss, chronic PPI use was not associated with any significant difference in change in total hip BMD, or of hip fracture risk. A small increase in the risk of non-vertebral fractures was seen in chronic female PPI users (relative hazard (RH) 1.34; 95% CI: 1.10–1.64) and among male PPI users who were not taking calcium supplements (RH 1.49; 95% CI: 1.04–2.14).

Multiple confounders can influence these observations, as chronic PPI users are more likely to harbour multiple risk factors for bone loss as well as increased fall risk. Such risk factors include: multiple co-morbidities; poor nutritional status; smoking and alcohol intake; and low BMI [183]. In addition, bone remodeling agents, corticosteroids and NSAIDs [181, 184] may cause dyspepsia, which in turn can lead to PPI use [185]. In the studies discussed above, controlling for confounding factors consistently lowered the magnitude of the risk associated with PPI use, sometimes by as much as 25% [179]. Moreover, a recent nested case-control study again using the UK's General Practice Research Database, but restricting the analysis to chronic PPI users with no other identifiable risk factor for fracture, did not find an increase risk of hip fracture with PPI use (RR 0.9; 95% CI: 0.7–1.1) [183].

In summary, current evidence suggests an association between chronic PPI use and osteoporosis-related fractures. There are multiple confounders of this association, which can falsely inflate the magnitude of the risk. If present, the absolute fracture risk in chronic PPI users is low, but may be clinically relevant in patients with multiple other risk factors for osteoporosis, especially if using high-dose, long-term PPIs.

## Conclusion

Metabolic bone disease is an important problem in patients with liver disease and inflammatory bowel disease and the pathogenesis is multifactorial. Osteomalacia does not appear to be common in IBD and osteoporosis appears to be the major metabolic bone disorder in IBD, Crohn's

disease and chronic liver disease. The use of corticosteroids in IBD and chronic liver disease is an important, but not a precisely defined contributing factor since it is difficult to distinguish corticosteroid use from disease activity. Few controlled trials have evaluated the efficacy of treatments in the absence of steroid therapy and the inflammatory cytokines that are involved in the immune response have been linked to increased bone resorption. In patients on corticosteroids, however, there is information from a number of RCTs about the efficacy of therapeutic agents in other patient populations.

Patients at particular risk for osteoporosis and fracture include: patients on glucocorticoids for IBD; those with endstage liver disease and liver transplant patients; postmenopausal women who may already be osteopenic; patients with Crohn's disease; and patients with low trauma fractures. In these individuals bone density measurement early in their treatment is recommended, although bone density does not exactly correlate with fracture risk in these populations. Minimization of steroid use and use of preventive agents such as calcium and vitamin D are indicated. In those individuals who are on corticosteroids (>3 months) (defined as daily dose ranges from 5–7.5 mg depending on guideline recommendation) or have a T-score below –2.0, although less stringent T-score cutoffs (e.g. –1.5) may be used on higher doses, or a fragility fracture, then bisphosphonates should be recommended.

While the evidence for prevention and treatment of steroid-induced osteoporosis is convincing, additional trials of interventions specifically for the bone disease associated with IBD and liver disease are needed. RCTs with fracture as the primary outcome may be difficult to conduct given the sample sizes required. Clarification of the risk of the fracture in patients with liver disease, IBD and celiac disease is required, with identification of high risk subgroups. Evidence-based guidelines of strategies to prevent osteoporosis in these populations are needed [186, 187] in addition to the development of better tools to predict the risk of fracture in individuals with IBD and celiac disease.

Additional research to clarify the association between PPI use and osteoporotic fractures is needed (e.g. prospective cohorts). Clinicians should assess the benefit-risk ratio for each patient and consider re-evaluating the need for long-term use in individuals at high risk of fracture or in patients who do not have a clear-cut indication for the use of PPIs.

## Colorectal cancer in ulcerative colitis: Surveillance

Paul Collins<sup>1</sup>, Bret A Lashner<sup>2</sup> and Alastair JM Watson<sup>1</sup>

<sup>1</sup>School of Clinical Sciences, University of Liverpool, Liverpool, UK

<sup>2</sup>Center for Inflammatory Bowel Disease, Cleveland Clinic, Cleveland, USA

### Epidemiological investigation

Many questions are posed by patients, clinicians and investigators regarding the recommended methods of cancer surveillance in ulcerative colitis. In the absence of scientific rigor conferred by randomized clinical trials, answers to these questions only can be inferred from observational studies. The evidence from cohort studies, case-control studies, and studies of diagnostic testing, coupled with surveillance theory and perceived patient preferences can be used to answer some of the more pressing questions and provide recommendations.

Cohort studies are epidemiological investigations that address specific natural history questions [1]. Groups of ulcerative colitis patients and controls are followed from the inception of disease until the development of specific outcomes, such as dysplasia or cancer, and incidence rates are compared between groups. Cohort studies, comparisons between patients with the designated outcome to those without the outcome, are particularly useful for quantifying cancer risk as well as for identifying risk factors for disease outcome [2–12]. For example, most recent cohort studies have found primary sclerosing cholangitis to be a risk factor for dysplasia or colorectal cancer in patients with ulcerative colitis (Table 17.1) [13–20]. However, incorrect conclusions related to prognosis can be made if cohort studies are carried out without careful attention to issues of bias and confounding variables. Standards have been published delineating the scientific requirements for the performance of valid cohort studies of cancer risk in ulcerative colitis. These include assembly of an inception cohort, blind assessment of objective outcomes, complete follow-up and a description of the referral pattern [1].

Case-control studies also can be used to examine etiological associations [21]. Patients with ulcerative colitis with cancer or dysplasia are compared with controls without neoplasia to test for differences in the odds of exposure to possible causative agents. Case-control studies are highly susceptible to bias and confounding variables. For a putative etiological factor to be considered valid it must be strong, consistent from study to study, occur before the effect, be biologically plausible and exhibit a dose–response relationship to the event of interest. As an example, case-control studies are best for identifying agents such as folic acid that may prevent the development of cancer or dysplasia [22–24].

Two case-control studies have shown that colonoscopic surveillance may be effective by identifying patients at high risk of developing cancer. Karlen and colleagues from Stockholm compared 40 ulcerative colitis patients who died from colorectal cancer with 102 ulcerative colitis controls [25]. Patients who had undergone a surveillance colonoscopy had a 71% decrease in risk of cancer mortality (odds ratio (OR) 0.29; 95% CI: 0.06–1.31). Having two or more examinations had an even greater beneficial effect (OR 0.22; 95% CI: 0.03–1.74). Similarly, Eaden *et al.* compared 102 patients with ulcerative colitis and colorectal cancer with an equal number of ulcerative colitis controls matched for age, sex and extent and duration of disease [26]. Surveillance colonoscopy was associated with a decreased risk of developing colorectal cancer (one to two examinations OR 0.22; 95% CI: 0.09–0.77; more than two examinations OR 0.42; 95% CI: 0.16–1.56).

Studies of diagnostic testing provide important insights into the optimization of parameters related to cancer surveillance [21, 27]. Studies comparing the sensitivity and specificity of different diagnostic tests can help choose the best test. Studies examining the sensitivity–specificity trade-off between different cut-points of the same test can help choose the optimal criterion for a positive test. Dysplasia in colonic biopsies is the best studied surveillance test for ulcerative colitis and has the best surveillance

**Table 17.1** Cohort studies of primary sclerosing cholangitis (PSC) as a risk factor for dysplasia or cancer in ulcerative colitis.

Study	Center	No. of patients	Dysplasia or cancer (%)	Relative risk (95% CI)
Broome <i>et al.</i> (1992) [13]	Huddinge	5 PSC 67 controls	4 (80) 8 (12)	6.7 (2.6 to 17.4)
Gurbuz <i>et al.</i> (1995) [14]	Baltimore	35 PSC	13 (37)	Increased
Broome <i>et al.</i> (1995) [15]	Huddinge	40 PSC 80 controls	16 (40) 10 (12)	3.2 (1.6 to 6.2)
Brentnall <i>et al.</i> (1996) [16]	Seattle	20 PSC 25 controls	9 (45) 406)	4.9 (1.4 to 17.7)
Loftus <i>et al.</i> (1996) [17]	Rochester	143 PSC	8 (6)	4.9 (0.1 to 27)
Marchesa <i>et al.</i> (1997) [18]	Cleveland	27 PSC 1185 controls	18 (67) 145 (12)	10.4 (4.1 to 26.1)
Shetty <i>et al.</i> (1999) [19]	Cleveland	132 PSC 196 controls	33 (25) 11 (16)	3.2 (1.4 to 7.3)
Lindberg <i>et al.</i> (2001) [20]	Huddinge	19 PSC 124 controls	12 (63) 31 (30)	3.1 (1.1 to 8.9)

program performance [28]. When evaluating biopsy specimens for dysplasia, the optimal criterion for a positive test is low grade dysplasia (a criterion with high sensitivity), rather than high grade dysplasia (a criterion with high specificity).

## Axioms

Many accepted practices related to cancer surveillance in ulcerative colitis have not been studied, but are assumed to be valid. Indeed, there are certain axiomatic statements that must be true for surveillance to be at all accepted by patients and physicians.

**(1)** *The cancer risk is elevated in ulcerative colitis patients and is too high to ignore.* There have been many epidemiological studies investigating the cancer risk in ulcerative colitis [2–12, 29–33], mostly from northern Europe or North America, where the incidence of ulcerative colitis is high and accurate and complete databases exist. From these studies, it is reasonable to assume that the lifetime incidence of colorectal cancer in a patient with pan-ulcerative colitis is approximately 6%, since a risk of this magnitude has been established for the background risk in the American population [34], and the risk of cancer-related mortality is approximately 3%. These figures are too high to ignore, assuming that there is either effective surveil-

lance available or acceptable prophylactic treatment. Furthermore, in some countries like the USA, either prophylactic colectomy or cancer surveillance colonoscopy have become the standard of care for ulcerative colitis patients, especially those diagnosed at a young age. In older patients, especially those with severe comorbidity or disability, the case for surveillance is much less clear, since they may be more likely to die from other diseases and not be fit for proctocolectomy.

Newer studies report a lower risk of cancer than previously described. In a recent meta-analysis, Jess and colleagues calculate a lower risk of cancer than previously reported (standardised incidence ratio, 1.9; 95% CI: 1.4–5.2) [35]. More recent cohort studies report a risk of cancer less than this [29–31, 33, 36]. This apparent reduction in cancer risk may be due to the protective effect of adherence to a colonoscopic surveillance program in which colectomy is offered to those in whom dysplasia is detected. It may also reflect the use of mesalamine for which there is evidence of a protective effect against colorectal cancer in ulcerative colitis [37].

**(2)** *Most patients would rather not have prophylactic colectomy.* Colectomy prior to the development of dysplasia or cancer is sure to dramatically reduce, if not eliminate, the mortality from colorectal cancer [38]. The existence of cancer surveillance programs, whether or not they are effective, has convinced some patients that the excess

cancer mortality risk with ulcerative colitis can be minimized, and that the minimized risk is preferred to the morbidity following proctocolectomy.

**(3)** *Patients would agree to proctocolectomy if the cancer risk is very high, as it is with a positive test from surveillance.* There is no point in performing surveillance colonoscopy if a patient will refuse to have a proctocolectomy for a positive test. Clinicians need to counsel patients carefully so they understand that surveillance is meant to identify the patients at very high cancer risk for proctocolectomy and allow the remaining patients to continue in the cancer surveillance program. From that approach, a majority of patients, those without dysplasia, will not have a colectomy recommended.

In an optimally performing program, all cancer deaths will be averted through colectomy on high risk patients, and no cancer deaths will occur among patients not having colectomy. There has been no perfectly performing surveillance program reported. Program performance is likely to improve following the development of a diagnostic test with better sensitivity and specificity than the presence or absence of dysplasia and/or with more frequent testing than is currently done.

## Questions

Existing evidence can only partially answer some of the questions related to cancer surveillance in ulcerative colitis. Understanding the limits of this evidence and identifying priorities for future investigation could improve technical aspects of surveillance and, ultimately, decrease cancer-related mortality. Questions regarding expected outcomes, the method of surveillance, testing intervals and the criterion for a positive test will be addressed.

**(1)** *How effective will a surveillance program be for reducing cancer-related mortality?* Although there is no direct evidence for a survival benefit in patients undergoing surveillance, there is evidence that cancers tend to be detected at an earlier stage, and these patients have a correspondingly better prognosis [39]. However lead-time bias may contribute substantially to this apparent benefit.

The number of patients needed to be enrolled in a surveillance program who comply with all of its parameters (i.e. repeated testing with colectomy for a positive test) in order to avert one cancer death can be calculated using expected risk reductions. The number-needed-to-treat (NNT) is the inverse of the absolute risk reduction [21]. Assuming the cancer-related mortality in high risk patients is 3%, the NNT in a perfectly performing program in which colectomy for dysplasia is highly effective for prevention of death from cancer and results in the complete elimination of cancer-related mortality is  $1/0.03$  or 33. For an absolute

risk reduction from surveillance of 1% (i.e. 3% to 2%), the NNT is 100, and for an absolute risk reduction of 2% (i.e. 3% to 1%), the NNT is 50. It is reasonable to assume that surveillance will have some benefit and the NNT most likely will fall between 33 and 100. Therefore, for every 100 patients with pan-ulcerative colitis who are entered into and faithfully comply with the parameters of a surveillance program, between one and three cancer deaths will be averted.

**(2)** *What is the best testing method for cancer surveillance?* Using colonoscopy with multiple biopsies of the colon to detect dysplasia is the best and most accepted strategy employed for cancer surveillance in ulcerative colitis. Since dysplasia can be present focally, and not necessarily diffusely, biopsies must be taken throughout the colon. Histological interpretation can be problematic in the presence of inflammation and surveillance endoscopy is best performed when the disease is in remission. It is necessary to take at least 33 biopsies from around the colon to have a 90% sensitivity for the detection of dysplasia [40], but even the most intensive sampling protocols sample less than 0.05% of the colon. While it has not been studied, it seems to be a reasonable trade-off between sensitivity and cost/morbidity to sample the colon with four biopsies taken from each 10cm colonic segment and of any raised or strictured lesions. **C5**

Intensive biopsy protocols, in which 33 or more biopsies are taken at each surveillance colonoscopy, have an impact on pathology services. Techniques to target biopsies to those sites likely to be harboring dysplasia would reduce this burden.

Dysplasia can be visualised at white light colonoscopy [41], which is able to detect prominent polypoid lesions. Careful mucosal inspection, even without chromoendoscopy will improve detection of dysplasia. The finding that there is a significant correlation between the mean duration of colonoscopy and detection rate of flat dysplasia seems intuitive [42].

Chromoendoscopy using indigo carmine or methylene blue highlights architectural abnormalities allowing flat or depressed dysplastic lesions to be seen with a related increase in diagnostic yield [43–47]. This was highlighted in the study by Rutter and colleagues in which one hundred patients with ulcerative colitis attending for surveillance colonoscopy underwent back-to-back colonoscopies with indigo carmine dye spraying at the second examination. No dysplasia was found in the 2904 random biopsies taken, whereas dye spraying and targeted biopsies revealed seven dysplastic lesions [48]. Combining chromoendoscopy with high magnification endoscopy allows the surface staining pattern to be analyzed. Kiesslich and colleagues have used this technique to differentiate between neoplastic and non-neoplastic tissue with a sensitivity and specificity of 93% [49].

Chromoendoscopy with targeted biopsies reduces the burden on the histopathologist while increasing the yield of surveillance colonoscopy. There is a trade-off in terms of increased procedural time, with examinations taking approximately 10 minutes longer in expert hands [49, 50]. Colonoscopists will require adequate training in this technique and guidelines exist to aid optimal performance [51].

The addition of endomicroscopy allows *in vivo* histology to analyse lesions identified by chromoendoscopy, which further increases the yield of intra-epithelial neoplasia as compared to chromoendoscopy alone [52]. The diagnostic yield for intraepithelial neoplasia was improved 4.75-fold using this technique [43].

Other emerging endoscopic technologies may aid in the visualisation of architectural abnormalities and distinguish neoplastic from non-neoplastic lesions (narrow band imaging, fluoroendoscopy, optical coherence tomography and confocal laser microscopy) [43, 53–56], but it remains to be seen to what extent these technologies will be utilized in daily practice.

A dysplasia-associated lesion or mass (DALM) correlates with a high risk for cancer and prophylactic colectomy can be advocated [57, 58]. On colonoscopic appearance, it can be difficult to distinguish a DALM from a sporadic adenomatous polyp. Although it has been suggested that such lesions may be safely removed provided surrounding flat mucosa shows no dysplasia, recurrent raised dysplastic lesions occur in half these patients [58–61]. If colectomy is deferred, intensive follow-up with 3–6 monthly colonoscopy is advised. **C5**

Problematic issues involve pseudopolyps and strictures. Pseudopolyps have been associated with double the risk of colorectal cancer [62, 63]. Multiple pseudopolyps cannot be adequately biopsied and could easily harbor dysplastic tissue. These patients need to be informed of the poor sensitivity of surveillance, and the benefits of prophylactic colectomy. **C5** Likewise, colonic strictures that do not allow passage of the colonoscope and adequate sampling could, and very often do, harbor dysplasia [64]. Once again, these patients should be considered for prophylactic colectomy since surveillance of these patients is insensitive. **C5**

Research is progressing in the area of alternatives to histological assessment of dysplasia as a surveillance strategy. Detection of acquired DNA changes in biopsy samples (aneuploidy, p53 and k-ras mutations) or glycosylation abnormalities (sialyl-Tn) may contribute to the sensitivity of surveillance [65]. DNA fingerprinting or fluorescent *in situ* hybridization has been used to demonstrate genomic instability in rectal biopsies as a marker of neoplasia in inflammatory bowel disease [66]. Analysis of DNA from stool samples allows analysis of DNA from more cells than pinch biopsies alone. Extraction of DNA from faecal samples and subsequent analysis for mutations associated

with sporadic colon cancer has been performed [67, 68], and it remains to be seen whether this non-invasive testing strategy will have a place in surveillance in ulcerative colitis.

Patients would be considered to have a positive test if either dysplasia or a genetic abnormality is present. Of course, improved sensitivity will be at the cost of specificity and result in increased numbers of false positives. The penalty for lowering specificity is high – a proctocolectomy in a patient who might not have developed cancer. These alternative tests would be acceptable for use in a surveillance program if the cost were relatively low, the availability high, the gain in sensitivity great and the loss of specificity minimal.

(3) *What is the best testing interval?* The more tests that are carried out in a lifetime, the higher the likelihood that dysplasia will be detected and treated prior to the development of cancer and that cancer-related mortality will be reduced. Of course, the more tests that are done, the higher will be the cost, morbidity and patient intolerance to colonoscopy. A balance between benefits and costs needs to be struck [69, 70].

While lesions could progress at different rates, the mean value for the time between the development of low grade dysplasia and cancer (lead time) is believed to be three years [71, 72]. Therefore, testing at intervals longer than three years should be discouraged, as the majority of patients who develop cancer would not have had an opportunity for dysplasia to be detected at surveillance examinations.

The risk of developing cancer or dysplasia increases with increasing duration of disease. The benefits of frequent testing (short interval) also increase with increasing duration of disease. It can be concluded that uniform testing intervals over a lifetime of disease is not an efficient way to allocate the performance of costly and invasive test procedures. A decision analysis suggests that efficient testing is characterized by decreasing the testing interval with increasing duration of disease [71]. One reasonable method, which certainly can be adjusted according to patient and physician preferences, specifies testing every 3 years for the first 20 years of disease, every 2 years for the next 10 years of disease, and yearly thereafter. **C5** Complications of colonoscopy are rare but can be serious or life-threatening. However, this approach would require at least 20 tests over a 40-year lifetime of disease, with most allocated in the later years when the risk is the highest and with the associated cumulative risk of multiple procedures. The risk of bleeding or perforation is less for diagnostic colonoscopy than for therapeutic colonoscopy (up to 0.35% and 2.3% respectively [73]).

(4) *What is the best criterion for a positive test?* The type of dysplastic lesion to be used as a criterion for a positive test is best determined by weighing the trade-off between

**Table 17.2** Contingency table for calculating sensitivity and specificity of dysplasia for the diagnosis of cancer.

	Cancer	No Cancer
Dysplasia	a	b
No Dysplasia	c	d

sensitivity and specificity. Sensitivity is defined as the proportion of patients with disease who are positive for the test in question. Likewise, specificity is defined as the proportion of patients without disease who are negative for the test in question. A standard  $2 \times 2$  contingency table for  $n$  patients ( $n = a + b + c + d$ ) is shown in Table 17.2.

In normally distributed populations, sensitivity ( $a / [a + c]$ ) and specificity ( $d / [b + d]$ ) are stable values that do not vary with prevalence of disease. Sensitivity and specificity will vary though, when the “cut-point” or the criterion for a positive test changes. For example, if the criterion for a positive test changes from high grade dysplasia to low grade dysplasia, the sensitivity will increase (more “a”s and less “c”s) and the specificity will decrease (more “b”s and less “d”s). As the criterion for a positive test changes, there is a trade-off between sensitivity and specificity – as one increases, the other decreases.

The sensitivity and specificity of screening for dysplasia to identify patients with asymptomatic cancer has been studied with remarkably consistent results. A blinded review from the University of Chicago of all regions in colectomy specimens in 22 ulcerative colitis patients with cancer identified dysplasia distant from the malignancy in 16 (73% sensitivity for any dysplasia) [74]. Eleven patients had high grade dysplasia (50% sensitivity for high grade dysplasia). In a comparable group of 22 ulcerative colitis patients without cancer, six had dysplasia (73% specificity for any dysplasia) and two had high grade dysplasia (91% specificity for high-grade dysplasia). Nearly identical results were found in a study from the Mayo Clinic, where one hundred colectomy specimens from patients with ulcerative colitis, 50 of whom had cancer, were studied [75]. The sensitivity for any dysplasia was 74% (37/50) and the sensitivity for high grade dysplasia was 32% (16/50). The specificity of any dysplasia was 74% (37/50) and the specificity of high grade dysplasia was 98% (49/50). Both studies acknowledged that only a small minority of patients were followed in cancer surveillance programs. In a study from St Mark’s Hospital, London, principally of ulcerative colitis patients participating in surveillance programs, 37 of 50 colectomy specimens with cancer had dysplasia distant from the malignancy (74% sensitivity for any dysplasia) [76]. Sixteen of those patients had high grade dys-

plasia (32% sensitivity for high grade dysplasia). A large review from Mount Sinai Hospital in New York of 590 colectomy specimens from ulcerative colitis patients, 38 (6%) of whom had colorectal cancer, found that multifocal dysplasia was highly associated with cancer (OR 6.0; 95% CI: 2.5–14.4) [77]. Another large review from Heidelberg, Germany, of 595 colectomy specimens in ulcerative colitis patients, found that high grade dysplasia, low grade dysplasia and backwash ileitis were highly associated with colorectal cancer [78]. Collectively from these studies, both the sensitivity and specificity of testing for any dysplasia are at least 74% (Table 17.3). If high grade dysplasia were to be used as a criterion for a positive test, the sensitivity would fall to about 50% and the specificity would rise to greater than 90%.

Thomas and colleagues have described the risk of colon cancer in patients in whom low grade dysplasia was found [79]. The positive predictive value of low grade dysplasia was calculated to be 18% for the progression to any advanced lesion and 8% specifically for cancer [79]. When low grade dysplasia was the reason for colectomy, colorectal cancer was present in 26% of patients.

Definitions for sensitivity and specificity for surveillance are somewhat different from these definitions for screening. The endpoint of interest in the former situation is death from colon cancer in distinction to its detection alone. Over the course of the disease, patients in a surveillance program will have several colonoscopic examinations with biopsies for dysplasia or cancer. The sensitivity of a surveillance

program may be regarded as the proportion of patients with cancer who are successfully treated with colectomy. Those who die from colorectal cancer are false negative patients (group “c” in Table 17.2) in whom surveillance has failed to prevent a cancer-related death. This definition of sensitivity represents a conservative value, since there are patients who had a colectomy for dysplasia in whom cancer would have developed if the colectomy had not been done. Since it is impossible to know which patients with dysplasia would have developed cancer, these patients are not included in the calculations of sensitivity. The specificity of a surveillance program is the proportion of patients who do not develop cancer and who do not have dysplasia detected. Since cancer is rare in a surveillance program, specificity is very well estimated by the proportion of patients in the surveillance program who do not develop dysplasia  $([c + d] / n)$ . For the purposes of this review, sensitivity of surveillance is defined as the proportion of patients with cancer who survive following colectomy, and specificity is defined as the proportion of patients without cancer who do not develop dysplasia. Using these definitions, estimates of sensitivity and specificity from 13 large surveillance programs are shown in Table 17.4 [80–92]. Specificity from surveillance is approximately 85%. The estimate of sensitivity is much less stable from study to study due to the low number of cancers in each program, but is for the most part over 50%.

If high grade dysplasia is used as the criterion for a positive test, specificity will increase. The trade-off between specificity and sensitivity is impossible to determine, since patients with low grade dysplasia often are not observed for the development of cancer; rather colectomy or more intensive surveillance is recommended. The increase in specificity with high grade dysplasia rather than low grade dysplasia as the criterion for a positive test is shown in Table 17.5. Specificity using high grade dysplasia as a criterion for a positive test is approximately 96%.

The optimal criterion for a positive test also depends on the consequences of false positive (group “b”, Table 17.2) and false negative (group “c”, Table 17.2) testing. Patients who have a false positive test have dysplasia but are not destined to develop malignancy. These are the patients who have proctocolectomy without truly needing one. Unfortunately, there is currently no way to predict which patients will fall into this false positive category. In the future, alternative markers of malignancy, such as the presence of p53 suppressor gene mutations, may help in determining which patient with dysplasia is a true positive patient (group “a”) and which is a false positive patient (group “b”). Likewise, patients with false negative examinations die of cancer without having proctocolectomy recommended from the detection of dysplasia. In these patients, either the testing interval was too long or the

imperfect specificity of testing (mostly due to the focality of dysplasia) led to a false negative test. A further complicating factor is the recognition that low grade dysplasia has high rates of inter-observer variation even among expert histopathologists [93, 94]. While both false positive and false negative errors are difficult to accept, false negative errors are the more grievous and the category that should be minimized with the most vigor. Therefore, the criterion for a positive test should be the detection of any dysplasia, low grade or high grade, on any biopsy of any examination. Also, since the mortality rate of proctocolectomy is very low, less than 1%, the risk/benefit ratio of opting for surgery in patients with dysplasia against no surgery favors surgical management [95].

**Table 17.5** Comparisons of specificity with low grade dysplasia or high grade dysplasia used as the criterion for a positive test in colorectal cancer surveillance from 13 large surveillance programs.

## Chemoprevention

A reduced risk of colorectal cancer with mesalamine use in ulcerative colitis has been reported in a recent meta-analysis (OR 0.51; 95% CI: 0.38–0.69) [37]. Mesalamine has low toxicity. **B4** The number needed to treat (NNT) to prevent one death from colorectal cancer may be seven patients with 30 years of disease [96]. Ursodeoxycholic acid, an agent with similarly low toxicity, has been associated with a significantly reduced risk of dysplasia and colorectal cancer in patients with ulcerative colitis and primary sclerosing cholangitis (RR 0.26;  $p = 0.034$ ) [97, 98]. It is interesting to note that use of statins was associ-

ated with a 94% risk reduction for the development of colorectal cancer in a subset analysis of patients in a case-control study of patients with colorectal cancer in Israel [99]. **B3**

## Improving cancer surveillance programs in ulcerative colitis

Evidence-based recommendations can be made to improve and optimize cancer surveillance strategies using currently available techniques. Factors related to the disease, the test and the treatment can be optimized based on the above discussion.

- Preferentially test high risk patients, such as patients with pan-ulcerative colitis of at least eight years' duration and patients with primary sclerosing cholangitis, with colonoscopy and extensive biopsy. **C5**
- Patients with lower cancer risk, such as ulcerative colitis patients with left-sided disease, could begin cancer surveillance after 15 years of disease. **C5**
- The risk of cancer in colonic Crohn's disease is similar to that in ulcerative colitis of similar extent and duration [100] and should undergo similar surveillance strategy.
- The testing interval should shorten with increasing duration of disease to maximize the efficiency of a surveillance program. **C5**
- Chromoendoscopy with targeted biopsy of highlighted areas should be undertaken by appropriately trained endoscopists. Alternatively, two to four biopsies should be taken every 10cm, with additional biopsies of any suspicious areas.

The natural history of the risk of cancer in IBD may well improve with the development of tools to enhance the detection of dysplasia at surveillance colonoscopy.

The criterion for a positive test should optimize sensitivity. A positive test is defined as the presence of any dysplasia on any biopsy on any examination. "Confirmatory" testing is unnecessary. A positive test places the patient at extremely high risk of dying from colorectal cancer and thus necessitates a strong recommendation for proctocolectomy.

### Rules of evidence and feasibility of evidence

The rules of evidence for evaluating studies of treatment interventions are well developed. The randomized controlled trial (RCT) is the scientific gold standard [1]. The prominence of RCT evidence is underscored in a comprehensive guideline that outlined five phases of biomarker development for the early detection of cancer, which described the final phase as “standard parallel-arm randomized clinical trial ... with one arm consisting of subjects undergoing the screening protocol and the other arm consisting of unscreened subjects” [2]. However, large-scale RCTs are expensive to conduct and their results may not be available for many years. This is certainly the case for RCTs of colorectal cancer (CRC) screening if CRC mortality is the primary outcome. A good example is the UK Flexible Sigmoidoscopy Trial which compared flexible sigmoidoscopy as an intervention for CRC screening versus usual care, with CRC mortality as the primary outcome. After several years of work, during which the trial was designed, the protocol was developed, funding was obtained, patients were enrolled during 1996–1999. The baseline findings were published in 2002 [3]. The results for the primary outcome, CRC mortality, are not yet available in early 2010. Since the original conception of this trial, CRC screening technology has evolved considerably.

---

### What to do when ideal evidence is lacking

The first US Multi-Society Task Force (USMSTF) guideline states that:

The authors believe that it might be appropriate in the future to substitute a newer test for currently recommended ones if there is convincing evidence that the new test has: (1) comparable performance (e.g., sensitivity and specificity) in detecting cancers or adenomatous polyps at comparable stages; (2) is equally acceptable to patients; and (3) has comparable or lower complication rates and costs. Provided this is the case, the authors feel that it would not be necessary to submit each new technology to the original standard of proof, i.e. a RCT with death from CRC as the outcome measure [4].

A recently published framework for evaluating diagnostic tests refines this approach by clarifying that the cases detected by the new technology should represent a similar spectrum of disease, so that the evidence of effectiveness applies to these new cases as well as the cases detected by the older technology [5]. It also goes one step further, indicating a role for decision analytic modeling when the new test has both favorable and unfavorable attributes, such as improved sensitivity but reduced specificity. A good example of the use of decision analysis is the most recent US Preventive Services Task Force (USPSTF) recommendations for CRC screening [6], which used microsimulation modeling to help inform the recommendations. As noted by the authors “well-validated microsimulation models may be used to highlight the tradeoff between clinical benefit and resource utilization from different screening policies and inform decision making with standardized comparisons of net benefits and risks” [7]. As new tech-

nologies arise that offer trade-offs in performance, acceptability to patients and costs, we have to acknowledge that RCTs with CRC mortality as the primary outcome will not be feasible, and we will need to agree on what constitutes adequate evidence.

### **Colorectal cancer: an ideal target for prevention and early detection through screening**

Colorectal cancer is a common condition, with a pre-malignant lesion (the tubular adenoma) with a long dwell time, making it an ideal target for early detection and cancer prevention through screening. CRC is the second leading cause of cancer death in the USA and the third leading cause of cancer death among both men and women [8]. Over 148,000 people are diagnosed with colorectal cancer in the USA every year, and over 49,000 people die from it [8]. It is generally accepted that detection and removal of polyps at colonoscopy decreases colorectal cancer incidence. **B** The magnitude of that benefit is estimated to be between 76–90% [9]. There are data that show a gradual decline in CRC incidence in the USA since 1985 [10]. This incidence decline is greater for distal CRC than for proximal CRC. Possible explanations for this include: (1) earlier uptake of flexible sigmoidoscopy than colonoscopy for screening; (2) higher effectiveness of polypectomy for cancer prevention in the left than in the right colon due to colonoscopy technique or different polyp morphology; (3) biologic differences between distal and proximal cancers [11].

Screening for colorectal cancer is now widely recommended and screening programs are in place in many countries [12]. A number of randomized trials are also underway that evaluate flexible sigmoidoscopy compared with no screening [3, 13]. These data, coupled with evidence from the randomized trials of fecal occult blood testing [14–18], should provide ample evidence on the overall benefit of screening. As policy makers, clinicians and researchers launch their screening programs, they have to choose a test or strategy to implement, based on the trade-offs of operational demands, patient acceptance, capacity constraints and overall program cost. These decisions are often difficult and are often driven by political or economic issues.

### **Organized vs opportunistic screening**

The International Agency for Research on Cancer (IARC) defines an organized screening program as one that has the following features: (1) an explicit policy with specified age categories, method and interval for screening; (2) a defined target population; (3) a management team respon-

sible for implementation; (4) a health care team for decisions and care; (5) a quality assurance structure; and (6) a method for identifying cancer occurrence in the population [19]. In contrast, opportunistic screening is done outside of an organized screening program, often delivered through fee-for-service reimbursement of physicians. Compared with opportunistic screening, organized screening focuses much greater attention on the quality of the screening process including follow-up of participants [20]. Thus, a key advantage of organized screening is that it provides greater protection against the harms of screening, including over-screening, poor quality and complications of screening, and poor follow-up of those who test positive [20].

A critical appraisal has assessed the evidence for organized cancer screening programs by systematically evaluating the published literature from 1966 to 2002 [21]. The authors reported that although there is a substantial body of literature on organized cancer screening programs, most studies are descriptive, and of those that are evaluative, the focus is on components of the programs, rather than the organized screening programs as a whole. For the relatively few studies that evaluated the effectiveness of organized versus opportunistic screening, most are from the Scandinavian countries and focus on cervix cancer screening. The authors concluded that there is limited evidence to directly support the effectiveness of organized cervix cancer screening and somewhat weaker evidence for other cancers. The promise of organized cancer screening programs is that they achieve better accessibility, quality, accountability and outcomes. In this way, benefits are maximized and harms are reduced. We need further research that compares organized versus opportunistic CRC screening to determine whether organized screening delivers on this promise.

### **Fecal occult blood testing**

Fecal occult blood testing (FOBT) is the only colorectal cancer screening approach demonstrated to be effective in randomized controlled trials. Depending on whether the tests were done biennially or annually, and whether the tests were or were not rehydrated, fecal occult blood testing is associated with a 15–33% reduction in colorectal cancer mortality [14–16, 18], and a 17–20% reduction in colorectal cancer incidence [17]. The randomized trials that provided this evidence were all conducted with the originally available, standard guaiac FOBT (gFOBT), which is still widely used throughout the world. Fecal blood testing, offers the advantage of being non-invasive and convenient for patients. Tests can be sent through the mail directly to patients, samples are collected in the privacy of their homes and can be returned by mail to a central

processing laboratory. All of these are advantages for population screening.

Since the publication of those landmark studies, many newer tests for fecal blood have been approved for clinical use. There is evidence demonstrating that fecal immunochemical tests (FIT) are more sensitive than standard guaiac tests (GT), such as Hemoccult [22]. There is also evidence from a randomized trial that they are associated with improved adherence to screening, perhaps because they have improved collection devices, and require fewer samples and no dietary restrictions [23]. There is also mounting evidence that FITs have better sensitivity than high sensitivity GTs such as Hemoccult II SENSAs, with preserved specificity [24, 25]. Selected FITs offer the option of automated test reading, with resulting improved precision and reliability of the interpretation, and also the possibility to report a quantitative result, but with resultant trade-offs in sensitivity and specificity [26].

### Expected sensitivity of FITs

The standard hemoglobin concentration in most studies of FITs has been 100 ng of hemoglobin per ml of stool. At this concentration, results have varied somewhat between settings and depend on the number of samples and the gold standard used to determine the true prevalence of cancer. All studies have evaluated a single application of the FIT, leaving to modeling and speculation about the benefits of screening that accrue to patients who continue to screen in an annual or biennial program of screening. In a preventive health appraisal population from Kaiser Permanente, Allison used the three samples of the HemeSelect FIT and reported that the sensitivity for cancer was 68.8% and specificity for cancer was 94.4% [22]; this study used two-year follow-up for clinical cancer incidence as the gold standard for the presence of cancer. In a large screening colonoscopy cohort from Japan, Morikawa *et al.* reported a sensitivity of 65.8% and specificity of 95.5%, using a single application of the Magstream 1000 test [27]. The highest cancer sensitivity reported to date was 81.8%, with a specificity of 98.1%, using the three samples of the FlexSure OBT FIT and a definition of cancer that was based on a combination of flexible sigmoidoscopy evaluation for determination of the presence of left-sided colorectal cancers and two years of clinical follow-up for the presence of proximal colorectal cancers [24].

An explicit evaluation of varying the numbers of samples and the target concentration of hemoglobin was performed by Levi *et al.* in a high risk colonoscopy population [26]. Increasing the number of specimens increases the sensitivity for cancer detection from 64.7 to 82.4% to 88.2%, for one, two or three specimens. Specificity declines with the addition of each sample, from 94.3% to 91.9% to 89.7%. Lowering

the hemoglobin cutoff from 100 to 75, increases sensitivity by 0–6%, depending on the number of specimens and decreases specificity by 2% [26].

Studies that have directly compared the sensitive gFOBT (Hemoccult SENSAs) to a FIT, in a population large enough to obtain precise point estimates of sensitivity and specificity have been difficult to evaluate. Each study used a different reference standard and a different population. Since the same criterion was applied to both tests in each study, they do provide some evidence of relative sensitivity and specificity. In the one study in which a standard GT (Hemoccult II) was used, both the sensitive gFOBT and the FIT showed improved sensitivity (37.1% for Hemoccult II vs 68.8% for the FIT vs 79.4% for SENSAs). The major drawback with sensitive gFOBT has been its much lower specificity (94.4% for the FIT vs 86.7% for the gFOBT) [22].

At the current time, due to heterogeneity in the evidence, it is difficult to say that one FIT is clearly superior [28]. Sensitivity and specificity point estimates have varied across studies due to differences in populations and the criterion standard used to determine the true incidence of cancer. In most recent studies, however, the FIT has performed better than either standard GT or the increased sensitivity GT. In population screening practical considerations such as patient acceptance and reliability of results reporting, become nearly as important as pure test operating characteristics. This was recently demonstrated in Holland, where higher acceptance of FIT resulted in higher neoplasia detection [23]. In mass screening, the automated test processing available with the FIT offers an important advantage of improved test reliability and less risk of repetitive strain injury. The non-invasive, easily scaled option of the FIT is an important option for CRC screening applicable for most population screening programs.

### Stool DNA

Tests for deoxyribonucleic acid (DNA) mutations in stool were first described in 1992 [29]. There are two pathways providing targets for fecal screening. Genomic instability is caused by oncogene and tumor suppressor gene mutations, believed to occur in a specific sequence as colonic epithelium progresses through the adenoma–carcinoma sequence [30]. Microsatellite instability may be inherited as mutations in specific genes or acquired through epigenetic DNA methylation, providing an alternative pathway to tumorigenesis, and another target for fecal screening [31]. The initial approach to fecal DNA testing was in the form of a multi-target assay panel, combining detection of mutations in chromosomal instability markers k-ras, p53 and APC with BAT-26 (a marker of microsatellite instability). A DNA integrity assay (long DNA) was added as a generalized marker of escape from apoptosis. The initial report

demonstrated sensitivity of 93% for cancer and 87% for adenomas, with a specificity of 93% [32]. Other promising results were reported in several other small studies [33–36].

As evaluation of stool DNA moved from small, single center studies in high risk patients to large, multi-site clinical trials in average risk, asymptomatic screening subjects, sensitivity decreased. The sensitivity of the initial version of the stool DNA test, using 21 mutations in a range of markers (Version 1.0 or SDT-1) has been reported in larger studies to be between 25–52% for cancer and 18–20% for cancers plus advanced adenomas [37, 38]. This decrease in performance occurred for several reasons. The initially selected DNA mutations were not as commonly found among sporadic colorectal cancers and adenomas in a screening population compared to the high risk populations in the earlier studies. In addition, bacterial enzymes in stool digested the DNA during transport to a central testing site. The 21 marker panel is also very expensive to run, leading to a test that is too expensive to be clinically viable.

The testing panel has evolved to a more streamlined set of markers, primarily exploiting the hypermethylation of vimentin as a screening target, and a buffering system to preserve the long DNA marker during transport. In smaller, high risk patient populations, the newer assay (also known as Version 2.0) has demonstrated 86–88% sensitivity and 82–83% specificity for cancer [39, 40]. In the NCI funded screening study, the addition of a methylated vimentin based assay to a k-ras mutation assay combined with a scanning of cluster regions in APC, without the use of the buffer (SDT-2), was reported to be 58% sensitive for cancer alone, and 40% sensitive for cancer plus advanced adenomas [37]. Due to US FDA concerns, neither version 2.0 nor SDT-2 is available. A single marker test, based on hypermethylation of vimentin alone, is available from LabCorp. The performance of the current version of this test for screening patients is not known, and it has not been widely used.

## Flexible sigmoidoscopy

Flexible sigmoidoscopy is an endoscopic procedure that examines approximately the lower half of the colon. It may be performed with a variety of endoscopic instruments, including a 60 to 70 cm version of a standard colonoscope, an upper endoscope, a standard pediatric colonoscope or a short (70 cm) pediatric colonoscope. It is typically performed without sedation and a more limited bowel preparation than is used for standard colonoscopy. Since sedation is not required, it can be performed in office based settings and by diverse examiners, including specially trained nurses or physician assistants [41].

Flexible sigmoidoscopy use in the USA has been decreasing in the recent decade. Approximately 2.8 million flexible sigmoidoscopies and 14.2 million colonoscopies were estimated to have been performed in 2002 [42]. Low reimbursement and a shortage of adequately trained examiners are two barriers to flexible sigmoidoscopy availability [43, 44]. In settings where reimbursement has not been a concern, and where nurse endoscopists have been employed, high rates of flexible sigmoidoscopy utilization have been achieved and it continues to be performed [45, 46].

The use of flexible sigmoidoscopy for colorectal cancer screening is supported by high quality case-control and cohort studies. **B2, 3** In general, flexible sigmoidoscopy appears to be associated with a 60% reduction in colorectal cancer mortality for the area of the colon within its reach, and this protective effect appears to persist for 10 years or more [47]. A small randomized trial demonstrated decreased colorectal cancer incidence in the sigmoidoscopy screened group compared to a non-screened control group, but not an overall mortality benefit from screening [48]. There was higher all-cause mortality in the screening group, perhaps due to unbalanced distribution of cardiac risk factors in the two groups, or due to changes in lifestyle behavior after screening [49]. There are four randomized controlled trials ongoing in the USA and Europe [3, 50–52], and results should be reported soon.

The evidence for the diagnostic accuracy of flexible sigmoidoscopy is primarily derived from colonoscopy studies. Flexible sigmoidoscopy is 60–70% as sensitive as colonoscopy for detection of advanced adenomas and cancers in the colon [53, 54]. However, this figure varies according to age, since proximal neoplasia becomes more common after age 65 [55]. Flexible sigmoidoscopy may also be less sensitive in women than in men [56], but the overall prevalence of advanced colonic neoplasia is lower in women than in men [57].

The key limitation in the evidence is the lack of any longitudinal head-to-head comparison of flexible sigmoidoscopy screening with other screening techniques, such as colonoscopy or fecal blood testing. The key question for screening policy is the incremental benefit of colonoscopy over flexible sigmoidoscopy, given the higher direct medical and indirect (patient) costs of colonoscopy and the higher risk of complications with colonoscopy. There is also a lack of evidence on how race, ethnicity, gender or other cultural factors affect patients' perceptions of the optimal screening test.

Several lines of evidence support the idea that the incremental benefit of colonoscopy is less than simply the difference in sensitivity for advanced adenomas between colonoscopy and flexible sigmoidoscopy. A key issue is the rate at which these advanced adenomas progress to invasive and life-threatening colorectal cancers. Proximal and

distal colorectal cancers are, generally speaking, biologically different [11], and these biologic differences are known to affect the rate of progression through the adenoma–carcinoma sequence. Colonoscopy follow-up studies, including the National Polyp Study and the recent Manitoba Colonoscopy Study, have found that colorectal cancers that occur shortly after a colonoscopy with or without polypectomy are found disproportionately in the proximal colon [9, 58]. Therefore, published evidence suggests that most of the benefit of colonoscopy for cancer prevention through polyp detection and removal occurs in the distal colon, a region of the colon that is examined by flexible sigmoidoscopy. This feature decreases the risk-benefit advantage of colonoscopy over flexible sigmoidoscopy.

The chief advantage of flexible sigmoidoscopy is that it can be performed without sedation, by a variety of examiners in diverse settings. The absence of sedation is perceived by some patients as an advantage and by others as a disadvantage. The chief limitation of flexible sigmoidoscopy is that it does not examine the entire colon, but only the rectum, sigmoid and descending colon. The complications of flexible sigmoidoscopy include colonic perforation, even if no biopsy or polypectomy is performed, but this complication occurs in fewer than one in 20,000 examinations [3, 59].

The available published evidence supports performing flexible sigmoidoscopy screening at least every 10 years. More frequent examinations may be justified based on patient or provider preference, but there is no evidence to suggest that more frequent examinations will result in improved patient outcomes. Recent colorectal cancer screening guidelines have recommended a five-year interval between normal flexible sigmoidoscopies, while recommending a 10-year interval between colonoscopies [6, 60, 61]. The shorter interval is recommended for flexible sigmoidoscopy out of concern that it may be less sensitive than colonoscopy even in the area examined because of the differences in bowel preparation, the experience of the examiners performing the procedure and the effect that patient discomfort may have on depth of sigmoidoscope insertion and adequacy of mucosal inspection. **C5** The five-year interval also led to improved outcomes at acceptable cost in the USPSTF simulation modeling study [7]. In examinations where an experienced examiner feels comfortable that a well cleansed colon has been thoroughly examined, a 10-year interval between exams may be sufficient.

There may be considerable variation in adenoma detection at flexible sigmoidoscopy between different examiners [62, 63], and this variability may reduce the effectiveness of flexible sigmoidoscopy for colorectal cancer screening. Quality assurance is an important issue for flexible sigmoidoscopists, and has been reviewed in detail elsewhere [41]. Providers should be well trained, and should consider

exceeding the published ASGE standards for a minimum number of training examinations prior to performing sigmoidoscopy without supervision.

An incomplete flexible sigmoidoscopy, defined as a depth of insertion less than 40 cm, is associated with an increased risk for interval colorectal cancers in the time after a flexible sigmoidoscopy [55]. Incomplete examinations should be followed by alternative screening using a different method (annual fecal blood tests, double contrast barium enema or colonoscopy) if the examination was limited by angulation or patient discomfort, or if the colonic preparation was inadequate. **C5**

Ideally, providers performing flexible sigmoidoscopy should be skilled and comfortable taking biopsies, to allow the determination of whether small polyps are adenomas. The decision to follow up a flexible sigmoidoscopy with colonoscopy in patients with 1–2 adenomas smaller than 1 cm should be individualized based on provider and patient preferences, and concern about the risk of complications. In the absence of biopsies, referring all patients with polyps larger than 5 mm for colonoscopy is a reasonably effective management strategy [64]. **C5**

Flexible sigmoidoscopy is an effective, affordable and safe option for colorectal cancer screening. A shortage of adequately trained examiners and low reimbursement has limited its use. For providers who have been able to implement large-scale flexible sigmoidoscopy programs, it has been a feasible and safe test for screening. There are four randomized trials of this intervention currently ongoing, and we should learn significantly more about the performance of this test when the results of these are available.

---

## Radiologic screening

---

### Double contrast barium enema

Double contrast barium enema (DCBE) is endorsed for CRC screening in the current joint guideline from the American Cancer Society, the US Multi-Society Task Force on Colorectal Cancer and the American College of Radiology (ACS/USMSTF/ACR) [60, 61], but not in the current USPSTF guideline [6].

There are no RCTs with CRC mortality as the outcome that have evaluated DCBE for CRC screening. Few studies have compared DCBE with colonoscopy for the rate of detection of polyps in asymptomatic individuals. In the National Polyp Study (NPS), after prior adenoma removal 580 persons underwent 862 paired colonoscopy and DCBE examinations during surveillance. DCBE detected 48% of adenomas >1 cm [65]. Several studies have estimated the

sensitivity of DCBE for CRC detection. In a UK national audit of 5454 CRC patients, a sensitivity of 85.9% for CRC detection was reported [66]. In a US study of 485 CRC patients seen at 20 central Indiana hospitals a sensitivity of 85.2% for CRC detection was reported [67]. In a population-based Ontario study of 13,849 persons with CRC who had a prior DCBE, the sensitivity was 77.6% [68]. The range of reported values may be in part due to differences in study populations, study design and methods. However, taken together these findings indicate that the sensitivity of DCBE for the detection of large adenomas and CRC is lower than is the case for colonoscopy or CTC. Given the emergence of CT colonography (CTC) for CRC screening, the role of DCBE will likely continue to diminish.

### CT colonography (CTC) or virtual colonoscopy (VC)

CTC for CRC screening is endorsed by the ACS/USMSTF/ACR guideline [60, 61] but not the USPSTF [6]. The evidence to support CTC for CRC screening is indirect, as there are no RCTs that have evaluated the impact of CTC on CRC incidence or CRC mortality. The evidence for CTC is from cross-sectional studies that compare CTC and colonoscopy for the detection of colorectal neoplasia.

Two US studies have compared CTC with colonoscopy screening in asymptomatic adults. Pickhardt *et al.*, in a study of 1233 asymptomatic adults enrolled at three medical centers, reported 94% sensitivity and 96% specificity for detecting adenomas  $\geq 1$  cm [69]. The ACRIN study enrolled 2531 asymptomatic adults at 15 centers [70]. ACRIN reported 90% sensitivity and 86% specificity for detecting adenomas  $\geq 1$  cm and cancers. The sensitivity and specificity for smaller lesions was lower. In both studies barium and oral contrast tagging and 3D detectors were used. Whether the results of CTC detection for large adenomas can be generalized to community settings is unclear.

Several additional issues regarding CTC remain unresolved. First, the sensitivity and specificity of CTC for lesions  $< 6$  mm is low. Some have advocated a policy of not reporting these small lesions, although this is contentious. If these small lesions are reported when detected at CTC, the question is whether these individuals should be advised to undergo colonoscopy, or whether surveillance CTC is appropriate, and if so, at what interval [71]? Second, there is a risk of cancer associated with radiation exposure [72]. Third, there is lack of consensus regarding the reporting of extracolonic lesions detected at CTC and the management of these patients [73, 74]. Taken together, these issues, coupled with the lack of information of CTC performance in community settings, led the USPSTF to exclude CTC from its recommendations [6].

A US cost-effectiveness model that compared clinical and economic outcomes of CTC versus colonoscopy screening reported that even with similar performance, colonoscopy was preferred over CTC unless CTC were to cost significantly less than colonoscopy [75]. Similar findings were reported in a Canadian cost-effectiveness study [76].

Notwithstanding these unresolved issues, based on the endorsement of CTC by the ACS/USMSTF/ACR guideline, CTC screening is likely to increase in the USA and Canada. This is especially true if payers provide physician reimbursement for CTC screening.

A key operational issue with CTC is that if an abnormality is detected and colonoscopy is advised, the patient usually has to repeat the colon preparation and return for colonoscopy on a subsequent day. This will likely present a barrier to patient adherence. Optimizing CTC for CRC screening will likely mean integrating it with an expedited same-day colonoscopy service.

## Colonoscopy screening

### Evidence

Colonoscopy is endorsed for CRC screening by the ACS/USMSTF/ACR [60, 61] and the USPSTF [6]. The evidence to support this recommendation is indirect as there are no RCTs that have evaluated the impact of screening colonoscopy on CRC mortality. Nonetheless, the body of evidence to support screening colonoscopy is substantial [60, 61]. The evidence includes the role of colonoscopy in the three landmark RCTs that established the evidence for gFOBT screening, as well as the mortality reduction observed in case-control studies of flexible sigmoidoscopy [47]. An additional source of evidence is the National Polyp Study (NPS), a cohort study that demonstrated that patients with adenomas who underwent a baseline clearing colonoscopy had a 76 to 90% reduction in CRC incidence compared with the CRC incidence reported in three reference populations [9]. **B2** Subsequent studies have reported CRC incidence reductions that are smaller in magnitude than that observed in the NPS. For example, a study that combined data from three US adenoma chemoprevention trials, in which patients were followed after undergoing a clearing colonoscopy, reported a three-fold higher incidence of CRC compared with the NPS [77].

We lack evidence concerning the relative effectiveness and incremental benefit of colonoscopy compared with other less invasive screening tests, such as flexible sigmoidoscopy. Recent evidence indicates that in usual clinical practice, colonoscopy is less effective for lesions in the proximal colon. A population-based cohort study of 39,375 individuals of all ages from Manitoba demonstrated that negative colonoscopy was associated with a standardized

incidence ratio (SIR) for CRC of 0.28 (95% CI: 0.09–0.65) at 10 years. In that study, the proportion of incident CRCs in the proximal colon was higher in the negative colonoscopy cohort than in the Manitoba population, 47% vs 28%, respectively ( $p < 0.001$ ) [58]. In an Ontario study of 110,402 individuals with a negative complete colonoscopy, there was a sustained reduction in incident CRC overall and incident distal CRC for up to 14 years following the procedure. In the proximal colon, however, the reduction in incidence differed in magnitude and timing, and was observed in about half of the 14 follow-up years, and for the most part occurred after seven years of follow-up [78].

**B4** An Ontario case-control study reported that colonoscopy was associated with decreased CRC mortality, but this association was primarily due to lower mortality from left-sided cancers [79]. **B3** The estimates of the association of colonoscopy with lower mortality from left-sided CRC are similar to those case-control studies of sigmoidoscopy [47]. Two other studies showed that colonoscopy effectiveness differs for right and left-sided CRC [80, 81]. These case-control studies found that colonoscopy was associated with a much lower incidence of left-sided CRC relative to proximal cancers. **B3** Taken together, these studies provide consistent evidence that colonoscopy is less effective in the right colon.

There are several possible explanations for this finding. One possibility is the unique molecular characteristics that have been observed in proximal lesions. Proximal and distal lesions display differences in gene expression and tumor phenotype [11]. Another possibility is the different morphological characteristics of proximal lesions. For example, flat lesions, which may be more readily missed at colonoscopy, may be more common in the proximal colon [82]. Furthermore, the reduced effectiveness of colonoscopy in the proximal colon may be related to aspects of colonoscopy quality, such as inadequate bowel preparation or failed cecal intubation [83]. Future research should be directed at disentangling the relative contributions of tumor biology and colonoscopy quality in explaining these results. Regardless of their explanation, these results highlight an important limitation of colonoscopy in usual clinical practice.

## Quality

Recently, colonoscopy quality has received considerable attention [84–86]. Proposed intraprocedure quality indicators for screening colonoscopy and their targets include: cecal intubation rates  $>95\%$ ; adenoma detection rates  $>25\%$  for men and  $>15\%$  for women 50 years and older; mean colonoscopy withdrawal times  $>6$  minutes in normal colonoscopies. Standardized colonoscopy reporting systems [87] and public reporting by individual endoscopists have been proposed to facilitate quality improvement [88]. Evidence

to support these indicators includes reports of highly variable adenoma detection rates among endoscopists in practice and an association between higher detection rates and longer colonoscopy withdrawal times [89]. Clearly, withdrawal time is a proxy for careful technique. In one large institution, increasing withdrawal time alone had no effect on polyp detection [90]. The colonoscopy quality program in the UK focuses on adenoma detection rates rather than withdrawal time (personal communication: Roland Valori, September 2008).

Tandem colonoscopy studies [91] and studies of CTC followed by colonoscopy [92] report colonoscopy miss rates for adenomas  $>1$  cm of 6–12%. In addition, the colonoscopy miss rate for CRC is about 5%. Evidence to support this estimate includes a retrospective study at 20 Indiana hospitals that reported 47 (5%) of 941 CRC patients who had a colonoscopy within three years prior to their diagnosis of CRC had a reportedly normal colonoscopy [67]. An Ontario population-based cohort study of 12,487 persons with CRC reported a CRC miss rate of 2–6%, depending on cancer site, with right-sided CRC associated with higher (6%) miss rates [93].

A recent study of 1819 (largely) male veterans reported a 9.4% prevalence of non-polypoid (flat and depressed) colorectal neoplasia [94]. The investigators used indigo carmine dye to spray the mucosa to assist in the detection of these lesions at colonoscopy. The implications of this study for usual clinical practice are unclear. Whether this rather high prevalence is generalizable to other populations, whether missing such lesions contributes to missed CRCs, and whether advanced colonoscopy techniques will be required to detect these lesions remain unresolved.

The rates of colonoscopy-associated bleeding, perforation and death have been reported in two population-based studies that used information from administrative databases with validation using chart review. A US study evaluated 16,318 individuals 40 years of age and older who underwent outpatient colonoscopy at Kaiser Permanente of Northern California between January 1994 and July 2002. The rates of colonoscopy-related bleeding and perforation within 30 days following the procedure were 3.2/1000 and 0.9/1000 respectively, and the risk of death was 0.06/1000 or approximately 1/16,000 [95]. A Canadian study evaluated 97,091 persons 50 to 75 years of age who had an outpatient colonoscopy during 2002–2003 [96]. The rates of colonoscopy-related bleeding and perforation requiring hospital admission were 1.64/1000 and 0.85/1000 respectively, and the risk of death was 0.074/1000 or approximately 1/14,000. In both studies older age and having a polypectomy were associated with increased risk of bleeding or perforation. Given the central role of polypectomy in CRC prevention and its strong association with bleeding and perforation, best practice in terms of polypectomy technique needs to be defined [97]. Although colon-

oscopy-related bleeding and perforation have received the most attention, these do not account for all serious complications of colonoscopy. We currently lack estimates of the risks of other important complications of colonoscopy, such as cardiovascular events, in usual clinical practice.

## **Costs**

The direct cost per patient for a single episode of screening using colonoscopy exceeds the cost for FOBT. In addition, the indirect costs, including time off work for the screened subject and any accompanying caregiver, travel, and out of pocket expenses (e.g. for bowel preparation) are substantial and account for one-third of the total cost of the colonoscopy [98]. The burden of indirect costs may lead to reduced uptake of screening colonoscopy. In addition, the estimated additional cost in the USA of CRC care (screening, diagnosis, complications, treatment) with widespread screening colonoscopy at 75% compliance, was an additional \$3.8 billion per year [99].

## **Capacity**

A US simulation study evaluated capacity to provide CRC screening for the 41.8 million US adults who had not been screened in 2002 [100]. The results indicate that sufficient capacity for population screening exists only for FOBT. A screening colonoscopy program would require 10 years to screen the unscreened population because the demand would exceed supply [100]. This result has also been reported by others [101]. These findings provide a strong stimulus for screening approaches that focus constrained colonoscopy resources on those most likely to benefit.

## **Patient acceptance**

Screening colonoscopy requires a motivated patient, given the need for bowel preparation and conscious sedation, as well as the time involved, including time off work. Studies of patient preferences for CRC screening show no consistent preference among screening tests [102–104]. Not all patients will choose to undergo screening colonoscopy when provided with alternatives.

---

## **Implementing screening**

### **Cost effectiveness**

CRC screening is not only effective, but also cost-effective. In 2002, the USPSTF performed a systematic review of the cost-effectiveness of CRC screening (using gFOBT; FS; gFOBT and FS; DCBE; or colonoscopy) and reported that

compared with no screening, cost-effectiveness ratios for screening with any of these methods were between \$10,000 and \$25,000 per life-year saved [105]. No particular screening strategy was consistently found to have the best incremental cost-effectiveness ratio. A more recent cost-effectiveness study incorporated new information on costs and test performance of the stool-based CRC tests (gFOBT, FIT, fDNA) and compared these tests with colonoscopy [106]. All three stool-based tests were cost-effective, with gFOBT and FIT preferred if adherence to yearly testing is high, whereas FIT was preferred if adherence is poor. Importantly, the authors note that as the costs of care of patients with colorectal cancer increases because of the use of costly biologic agents, screening with inexpensive gFOBT and FIT may actually be cost saving. A recent decision analysis assessed life-years gained and colonoscopy requirements for several CRC screening strategies [7]. This analysis was done to inform the USPSTF recommendation. CRC screening with colonoscopy every 10 years, annual screening with a sensitive FOBT, or flexible sigmoidoscopy every five years with a midinterval FOBT, for persons age 50 to 75 years, provided similar gains in life-years assuming perfect adherence.

## **Practical considerations**

Although the cost per life-year saved for CRC screening compared with no screening is comparable to other interventions that are currently endorsed, such as breast cancer screening with mammography in women 50 years and older, this is only one aspect to consider in deciding whether to move forward with implementing population-based screening. In an organized screening program funding must be allocated to run the program. In addition, social marketing and health care provider campaigns are needed. Laboratory services and colonoscopy capacity must be in place, as well as treatment capacity. Clear referral pathways must be established. Finally, there must be quality assurance and monitoring and reporting systems [19].

In jurisdictions with publicly funded health care systems, a jurisdiction-wide policy must be in place that defines the target age group, the screening test to be implemented, and the testing interval. In Canada, Ontario was the first province to implement a population-based CRC screening program. In 1999, Cancer Care Ontario (CCO), the provincial agency responsible for cancer, convened an expert panel to develop recommendations for an organized CRC screening program in Ontario. The panel recommended a province-wide gFOBT-based CRC screening program for average-risk individuals 50 to 74 years of age (Ontario Expert Panel on Colorectal Cancer. Colorectal cancer screening: final report of the Ontario Expert Panel. Toronto, Ontario: CCO; 1999.) In 2002, this recommendation was

echoed at the national level by a committee convened by Health Canada (National Committee on Colorectal Cancer Screening, Recommendations for population-based colorectal cancer screening, Ottawa, Canada: Public Health Agency of Canada; 2002). A one-year pilot study to evaluate recruitment strategies for gFOBT screening was funded by the Ontario Ministry of Health and Long-Term Care (MOHLTC) in June 2003 (CCO: Ontario FOBT Project Steering Committee. Ontario FOBT project: final report (monograph on the Internet). Toronto, Ontario: CCO; 2006 Mar (cited 2007 Apr 05). Available from: <http://cancercare.on.ca/documents/OntarioFOBTProject-FinalReport.pdf>). In June 2005 CCO submitted a proposal to the MOHLTC for a provincial population-based CRC screening program. Based on the existing evidence for effectiveness and cost-effectiveness, coupled with the provincial and national consensus on CRC screening policy, and taking into account findings from the Ontario Pilot, the MOHLTC announced funding for the program in January 2007. Implementation began in April 2007. In March 2008 the MOHLTC and Cancer Care Ontario announced the public launch of the program, called ColonCancerCheck. ColonCancerCheck involves gFOBT for average risk individuals and colonoscopy for those at increased risk because of a family history of one or more first-degree relatives with CRC.

Operational challenges are multiple. Stakeholder engagement is crucial, particularly among physicians and their professional societies. This is especially the case when there is skepticism about the choice of screening test and program model. Laboratory professionals must be engaged and committed to quality assurance. In Ontario, CCO developed evidence-based FOBT standards to guide laboratory processing and kit performance [107]. CCO also developed colonoscopy standards [108] to set forth endoscopist, institution and performance standards for colonoscopy. For example, the standards state that endoscopists are required to perform at least 200 colonoscopies per year. Contracts with the laboratories set forth requirements for processing gFOBT kits, quality assurance and reporting to the Program. Funding was provided to 71 public hospitals to deliver additional colonoscopies to support the Program. The contracts with the public hospitals set forth requirements for monthly reporting to the Program of volumes, wait times and performance. The IM/IT system to support monitoring and reporting requirements, as well as letters of invitation to the target population and letters of recall for those with a negative gFOBT is under development.

In the USA, quality report cards for health plans, such as the Healthcare Effectiveness Data and Information Set (HEDIS), provide impetus for health insurers to compete on quality. Using published guidelines as a basis for setting specification, a hybrid of claims data and chart review is used to measure screening rates. Northern California

Kaiser Permanente reported that screening rates increased from 37% to 53% between 2005 and 2008, with a rate over 65% expected in 2009. The increase in screening rates has required an unprecedented investment in colonoscopy capacity and organized screening.

## Comparing guidelines

In 2008 two high profile, influential US organizations have published colorectal cancer screening guidelines: the American Cancer Society, US Multi-Society Task Force on Colorectal Cancer and American College of Radiology (ACS/USMSTF/ACR) [60, 61], and the US Preventive Services Task Force (USPSTF) (Table 18.1) [6]. The authors took somewhat different approaches, and this resulted in some differences in emphasis and recommendations [109]. The USPSTF undertook a formal, systematic, in-depth evidence review [28], and used simulation modeling when the evidence base was not sufficient to guide recommendations [7]. The ACS/MSTF/ACR process was more driven by expert opinion, when the evidence base was lacking. As a result, the USPSTF is more conservative in its recommendations, emphasizing the balance of risks and harms of screening. In the end, the guidelines are similar with several key differences.

Both guidelines, summarized in Table 18.1 emphasize a menu of options, recognizing that existing evidence and modeling studies do not support one clearly preferred

**Table 18.1** Comparison of guidelines for screening persons at average risk for colorectal cancer.

Screening method or variable	ACS-MSTF Recommendation	USPSTF Recommendation
Standard guaiac FOBT (gFOBT)	No	Annually
High sensitivity FOBT (gFOBT or FIT)	Annually	Annually
Flexible sigmoidoscopy alone	Every five years	Every five years
Double contrast barium enema	Every five years	Not recommended
CT colonography	Every five years	Not recommended
Colonoscopy	Every 10 years	Every 10 years
Stool DNA tests	Interval Uncertain	Not recommended
Age to begin screening	50	50
Age to end screening	Not stated	75

screening approach. Both guidelines recommend fecal occult blood testing, done annually in average risk patients. The ACS/MSTF/ACR makes a clear statement in favor of high sensitivity fecal blood tests, either gFOBT or FIT. Both guidelines recommend flexible sigmoidoscopy every five years, and the USPSTF model demonstrates an advantage of the five-year interval over the 10-year interval [7]. Both guidelines recommend colonoscopy every 10 years. The USPSTF explicitly rejects VC, citing inadequate information about the harms of radiation exposure and the problem of extracolonic findings as reasons to be cautious about VC. The ACS/MSTF/ACR included VC, as a screening option to be done every five years, citing the diagnostic accuracy studies demonstrating sensitivity approaching that of colonoscopy for larger polyps. Barium enema and stool DNA are both options on the ACS/MSTF/ACR guideline, but the USPSTF has excluded them due to a lack of evidence supporting their use.

Two other differences between the guidelines bear mentioning, and reflect the process differences between the two groups. The ACS/MSTF/ACR guideline came out with a strong statement in favor of tests that prevent cancer through the early detection and removal of adenomas, including flexible sigmoidoscopy, colonoscopy, virtual colonoscopy and double contrast barium enema [60, 61]. The USPSTF made no such distinction, taking a more firm evidence-based approach. The only evidence for the cancer prevention benefit of colonoscopy comes from the National Polyp Study [9]. A major limitation of that study was the lack of a concurrent control group [110]. In addition, the USPSTF made a firm statement about the age to begin and end screening for CRC screening, based on its simulation model, recommending discontinuing screening after age 75 in people who have had prior screening, or 85 for all patients [6]. Relying on the consensus of expert opinion, the ACS/MSTF/ACR guideline did not comment on a stopping age for screening.

How should the practicing physician handle the discrepancy between guidelines and the challenges with the implementation of a menu of screening options? The best approach is one that is organized, consistent and evidence-based. It is most effective for a group of physicians to decide together on an approach that will work for their setting, based on achievable capacity, patient acceptance, and the balance of risks and benefits. Once that approach has been agreed upon, efforts should be made to ensure that all eligible members of the target population receive the invitation to be screened, and that barriers to patient acceptance are removed, through the development of reminders, tracking systems and ease of appointments. It matters less which test is performed, since there is no clearly dominant strategy. The key issue is that patients receive regular screening at appropriate intervals and with adequate quality control.

## Prevention and treatment of travelers' diarrhea

*Herbert L DuPont*

Center for Infectious Disease, University of Texas Health Science Center at Houston, School of Public Health and Internal Medical Service, St. Luke's Episcopal Hospital, Department of Medicine, Baylor College of Medicine, Houston, USA

---

### Background

The first studies of travelers' diarrhea were carried out in the 1950s and 1960s by Kean and colleagues [1]. Kean's research team found that antibiotic drugs would successfully prevent TD during high-risk travel. Despite more than 50 years of research aimed at defining the cause and source of the causative agents we have seen no reduction in frequency of TD among persons venturing into tropical and semi-tropical areas from industrialized countries [1–3]. Following studies defining the importance of bacterial enteropathogens in TD, it was shown that antibacterial drugs could shorten the illness [4]. Recent studies have provided evidence that TD not only produces a full day of disability when it occurs but an important number of affected persons develop chronic functional bowel disease as a complication of TD.

This review looks at the available scientific evidence supporting the use of drugs and vaccines to prevent TD and therapies, new and old, aimed at shortening the duration of illness when it develops.

---

### Epidemiology of travelers' diarrhea

The world can be divided into three regions depending upon the rate of TD among visitors from industrialized countries (Figure 19.1). The high-risk regions of the world for TD are Latin America, Africa and Southern Asia, the moderate-risk regions are certain Caribbean islands (e.g. Jamaica), the Middle East, China, Thailand and Russia and the low-risk areas are the United States, Canada, north-

western Europe, Japan, New Zealand and Australia. The rate of diarrhea when people from low-risk areas visit the three regions are 40% [5, 6], 8–15% [6, 7] and ~4% [6], respectively. The 4% for groups moving from one low-risk area to another, is approximately the same as is seen when people from a high-risk area visits a low-risk region [8, 9]. Why diarrhea develops among people traveling to low-risk areas probably relates to multiple factors, including eating all meals at public restaurants with its increased risks of enteric infection compared with self-preparation of meals in homes [10], increased stress leading to autonomic intestinal motility alterations [11], and possibly excessive alcohol ingestion in a subset of travelers [12].

---

### Etiology of travelers' diarrhea

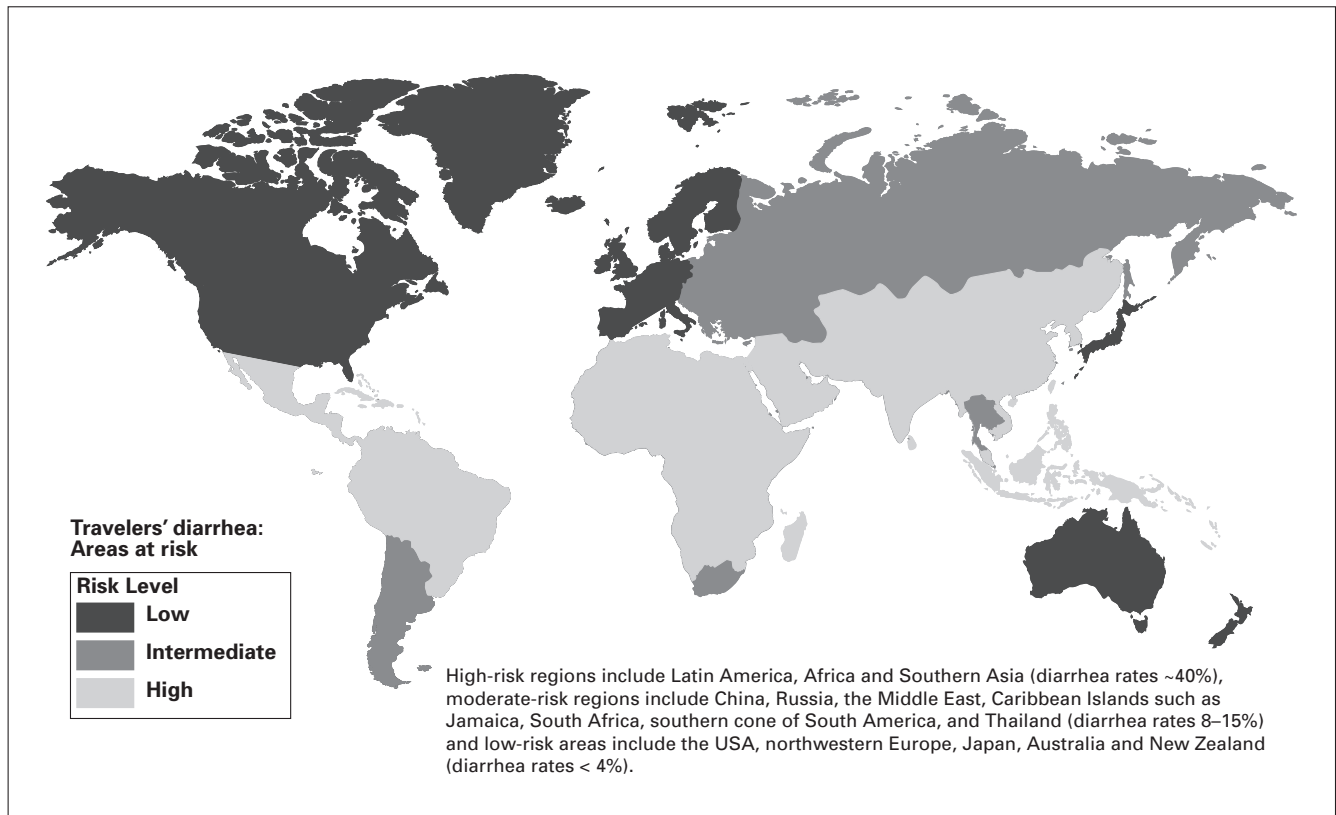

Studies in the 1970s identified enterotoxigenic *Escherichia coli* (ETEC) as the principal cause of TD [13–16]. In the last two decades enteroaggregative *E. coli* (EAEC) [17] and a variety of other bacteria [18] have been shown to be important causes of TD. The diarrheagenic *E. coli* (ETEC and EAEC) cause a majority of the diarrhea in Latin America [3, 18, 19] and Africa [20, 21]. While ETEC and EAEC are important causes of TD in Asia [18, 22, 23] other bacteria are important, including *Shigella*, *Campylobacter*, *Salmonella* and *Aeromonas* spp. [18, 22, 24–26]. The fact that invasive enteropathogens are relatively more important causes of TD in Asia influences recommendations on self-treatment for travel to these countries. Noroviruses explain between 10%–20% of cases of TD [27].

---

### Evidence-base evaluation

Guidelines used to establish the evidence base for evaluating evidence of efficacy of drugs and vaccines are outlined in Table 19.1.

**Figure 19.1** World map showing variation in risk of acquiring travelers' diarrhea among international visitors from low-risk regions. The figure is reprinted with permission from *Aliment Pharmacol Ther* [95].

**Table 19.1** Grading of clinical evidence in the chemoprevention and chemotherapy of travelers' diarrhea [80].

Category	Grade	Definition
Strength of evidence	A	Good evidence to support a recommendation for use
	B	Moderate evidence to support a recommendation for use
	C	Poor evidence to support a recommendation
	D	Moderate evidence to support a recommendation against use
	E	Good evidence to support a recommendation against use
Quality of evidence	I	Evidence from $\geq 1$ properly randomized, controlled trial
	II	Evidence from $\geq 1$ well-designed clinical trial without randomization, from case-controlled analysis of cohort study
	III	Consensus evidence, evidence from one authority or reports of expert committees

## Prevention of travelers' diarrhea

Given the high risk of acquiring TD and the importance of bacterial enteropathogens it is easy to see why there is such an active interest in preventing the illness through chemo or immune-prophylaxis.

## Historical considerations

The first evidence that bacterial enteropathogens were responsible for TD was provided by Kean and colleagues, showing the value of antibiotics in preventing the disease [1]. Prophylactic use of antibiotics during international travel in the 1950s was widely practiced. A study carried out in 1957 demonstrated that more than 35% of persons returning to the USA from Mexico were taking prophylactic antibiotics to prevent diarrhea during their trip [28]. During the 1968 Olympic Games in Mexico City, the British team credited taking multiple doses of oral sulfonamides and oral streptomycin for keeping them well during competition; the American and Australian teams had higher rates of diarrhea, probably because they relied upon a single daily dose of sulfonamide for protection [29].

Bradley and David Sack from Johns Hopkins then demonstrated the value of doxycycline in preventing TD [30, 31] until resistance to the drug prevented further evaluation [32]. In the 1980s studies were conducted showing the effectiveness of liquid [33] or tablet formulation [34] of bismuth subsalicylate (BSS) in preventing TD. BSS was safely given to the trial participants, with only darkening of stools and tongues from harmless bismuth sulfide, and mild tinnitus, presumably from the absorbed salicylate, as adverse effects. The drug was more effective when it was taken in a total dose of 2.1 g/d in four equally divided doses than when it was taken in a similar daily dose on a twice a day regimen, or in half of this dose four times a day [35].

Trimethoprim/sulfamethoxazole was shown to prevent TD in studies carried out in the 1980s [36]. Also, in the 1980s and 1990s, a number of trials established the value of the fluoroquinolones in preventing TD [37–40]. General use of antibiotics for chemoprophylaxis during travel was largely stopped by a Consensus Development Conference held at the National Institutes of Health in 1985 [41], because of concern about adverse effects, and the stimulation of resistance by widespread use of systemically absorbed antibiotics and also because of the difficulty in identifying appropriate recipients of preventive drugs.

The concept became of interest once more with the availability of non-absorbed (<0.4%) rifaximin. This antibacterial preparation had no obvious safety issues, as seen in the clinical trials, and the non-absorbed nature of the drug reduced the concerns about systemic side effects and development of resistance among extra-intestinal bacteria. Rifaximin was shown to be effective in preventing TD in two studies in Mexico, in 2003 [3] and 2005 [42]. A third trial was carried out in Thailand, but the frequency of TD was too low to permit evaluation of the efficacy of the drug (Steffen R, unpublished data).

## Immunoprophylaxis

After World War II it was found that rates of diarrhea in people became lower as they lived in high risk areas [43]. This immunity was shown to occur over several months in American students attending classes in Mexico [2]. The natural immunity that developed in these students was associated with reduced rates of ETEC diarrhea [14, 44]. Not surprisingly the first successful TD vaccine was directed toward prevention of ETEC. The first licensed vaccine, developed by the Swedish Biological Laboratories, consisted of a combination of whole cell *Vibrio cholerae* strains together with a recombinant form of the binding subunit of cholera toxin. The vaccine Dukoral provided short-term protection against ETEC [45] because of the similarity of the binding subunit of cholera toxin with the

binding subunit of heat labile enterotoxin (LT) of ETEC. This vaccine was shown to prevent TD [46] and is presently available commercially as an ETEC and cholera vaccine throughout Europe and Canada.

Following studies demonstrated the feasibility of developing a brisk IgG antibody response to transcutaneously administered ETEC LT [47] when a randomized, placebo-controlled trial was carried out in which the antigen or placebo was administered twice by skin patch to approximately 200 adults before travel to Mexico and Guatemala [48]. In this trial, the observed rates of moderate to severe diarrhea were: placebo 21%, LT patch, 5%,  $p = 0.007$ . A larger phase III study was planned for 2009.

---

## Effectiveness of chemoprophylaxis and immunoprophylaxis in the prevention of TD

In Table 19.2 the strength of evidence for the various preventive drugs and vaccines is provided. BSS, fluoroquinolones and rifaximin are labeled as A1 to indicate the existence of good evidence for efficacy in preventing TD, with at least one well designed randomized controlled clinical trial having been performed.

---

## Current practice and recommendations

In Figure 19.2, an algorithm is provided that outlines one approach to identifying persons who might be candidates for chemoprophylaxis during high-risk travel. If persons stay in better hotels, eat at hotel restaurants and exercise care on what foods and beverages are consumed, the need to use active prevention methods is lessened. Chemoprophylaxis is appropriate to offer to persons with underlying medical conditions that may be complicated by a diarrheal illness [5, 49], persons for whom an 8–10 hour illness could jeopardize the purpose of an important trip such as athletes during competition, politicians and business travelers with important meetings, musicians and certain tourists with a carefully planned itinerary [49], persons who have experienced a previous bout of TD, suggesting the presence of a genetic susceptibility [50–52], and other travelers who request a preventive medication [49]. The preferred drug is rifaximin used in a dose of one 200 mg tablet with the major daily meal(s). Taking two tablets a day with the two major meals is recommended to help deal with compliance concerns [3]. If only one dose a day is taken and it is missed, protection cannot be assured. In the second trial carried out in Mexico, a single dose of 600 mg/day was given with the first meal of the day [42]. BSS is a less convenient and slightly less effective alternative to rifaximin.

**Table 19.2** Evidence base of chemoprophylaxis in travelers' diarrhea (preventive drugs are given daily while in high-risk region).

Therapeutic agent (dose for preparations with good quality of evidence)	Strength of evidence	Quality of evidence	Comments (references)
Bismuth subsalicylate (BSS) (2–262 mg tablets chewed well with meals and at bedtime, eight tablets or 2.1 g/d)	A	I	Turns stools and tongue black (from bismuth sulfide salt which is harmless); can lead to important levels of serum salicylate [81]; must be taken 4 times/d; is inexpensive; should not be used in people with IBD or AIDS or for prolonged time periods as bismuth may be absorbed from an abnormal mucosa [82–84].
Doxycycline and TMP/SMX	D	III	Worldwide resistance to these drugs makes them ineffective currently.
Fluoroquinolone (ciprofloxacin 750 mg or levofloxacin 500 mg once a day)	A	I	Effective [37–40]; being absorbed will have side effects, for example insomnia, headache, <i>Candida</i> vaginitis [85]; may cause resistance among extra-intestinal bacteria [86] and <i>Clostridium difficile</i> colitis [73].
Rifaximin (200 mg once or twice a day with major meals, or 600 mg once a day with major meal)	A	I	Safest preparation available; provides high degree of protection [3, 42]; of uncertain value in preventing the broad range of invasive bacteria although active against <i>Shigella</i> [57]; lack of absorption (<0.4%) should prevent development of resistance among extra-intestinal flora.
Azithromycin	C	III	Optimal therapy for dysenteric illness, not recommended for chemoprophylaxis.
<i>Lactobacillus</i> GG (2 x 10 <sup>9</sup> bacteria/day in a single daily capsule)	B	I	Minimal level of protection provided (~ 40%) in one clinical trial [87].
<i>Saccharomyces boulardii</i> (500 mg twice a day)	C	I	Moderate level of protection in one study group, ineffective in others [88].
Whole cell ( <i>V. cholerae</i> ), binding subunit of cholera toxin ETEC vaccine (Dukoral) (two doses by mouth taken one week apart before travel)	B	I	Provides short-term protection against LT-ETEC [45] and possibly other forms of TD [46].
Transcutaneous heat labile enterotoxin (LT) ETEC vaccine (two skin patches are applied and left in place for six hours 2–3 weeks before travel)	B	I	Provides protection of uncertain duration against LT-ETEC and possibly other causes of TD [48].

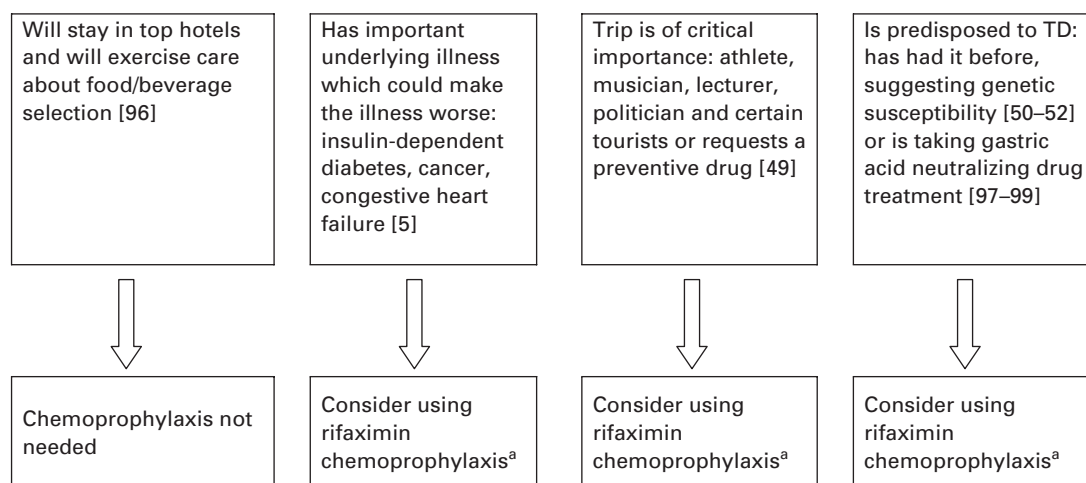

TMP/SMX: trimethoprim/sulfamethoxazole; IBD: inflammatory bowel disease; AIDS: acquired immune deficiency syndrome.

The primary objective of chemoprophylaxis is to prevent the disability associated with TD, which averages approximately 24 hours per illness [53, 54]. An unproven benefit of chemoprophylaxis is prevention of the chronic functional bowel syndromes, including IBS secondary to TD, which occur in approximately 10% of persons who experience diarrhea during international travel [55, 56].

### Future research in prevention of travelers' diarrhea

A fundamental question in the prevention of TD remains. Can careful attention to food and beverage intake, focusing

on consumption of only the safest items, lower the risk of TD? This is largely an unstudied area that needs innovative research approaches. A second question is: does rifaximin taken for chemoprophylaxis during high-risk travel prevent infection and diarrhea caused by invasive bacteria including *Campylobacter*, *Shigella* and *Salmonella*? Rifaximin prevented shigellosis and *Shigella* dysentery when adult volunteers were challenged with a virulent strain of *Shigella* [57]. Preventing invasive forms of TD should be a far easier task than treating an invasive enteric infection once the organisms have extensively penetrated the mucosa. The third question concerning prevention is whether chemoprophylaxis prevents the occurrence of post-infectious IBS. With the frequency of occurrence approaching 10% of TD

**Figure 19.2** Recommendations for chemoprophylaxis based on characteristics of future traveler.

<sup>a</sup>200 mg once or twice a day with major meals or 600 mg in a single dose with the first daily meal while out of town; alternative drug bismuth subsalicylate 2–262 mg tablets with meals and at bedtime (eight tablets/d or 2.1 g/d).

cases, prevention of IBS should be studied in future clinical trials.

## Treatment of travelers' diarrhea

### Symptomatic therapy

Drugs in this class are designed to reduce the number of unformed stools passed, allowing the traveler to better cope with illness symptoms. The drugs are not designed to cure this form of bacterial infection, and in many treated people the symptoms will continue, although improved, until antibacterial therapy is given. The first drug shown to have value in treatment of TD is bismuth subsalicylate (BSS) [58], which reduced the number of stools passed by 50% compared with placebo treatment. BSS exerts its anti-diarrheal effect through the drug's salicylate moiety [59]. Loperamide was more effective than BSS in a randomized controlled trial, reducing the number of stools passed in TD by 60% [60]. Loperamide decreases diarrhea by slowing the intraluminal column, giving more opportunity for the gut to absorb water and electrolytes [61]. The drug also has direct antisecretory effects [62].

### Antimicrobial therapy

Antimicrobial therapy is the mainstay of treatment of TD and is aimed at illness cure. Symptomatic treatments characteristically require rescue medication with antibacterial therapy to stop diarrhea [60, 63]. Trimethoprim/sulfamethoxazole was the first antibiotic shown to effectively reduce the duration of diarrhea. When TMP/SMX resist-

ance became widespread [64] other drugs were evaluated. The fluoroquinolones were found to be highly active in treating TD [23, 65–68]. Rifaximin, a poorly absorbed (<0.4%) antibacterial drug has been shown to be as effective as fluoroquinolones for overall TD [23, 69], while the drug is less effective against invasive pathogens as a group [23]. Azithromycin has been shown to effectively treat TD due to non-invasive [70] and invasive [26, 71] pathogens. The fluoroquinolones have adverse effects, including Achilles tendon rupture [72], for which a "black box warning" has been issued by the US FDA, and the occurrence of *Clostridium difficile* infection [73] due to near depletion of colonic flora caused by this class of drugs [37]. Azithromycin in the dose recommended commonly causes nausea [26]. The safest antibiotic treatment appears to be rifaximin, which has been as safe as the placebo control in each one of the clinical trials so far conducted.

### Combination therapy

Where loperamide has rapid onset of action and effectively controls the number of stools passed, antibiotics have slow onset of action but are employed to cure the infection and stop the diarrhea. The drugs can be given together, obtaining additive benefits [63, 74, 75].

## Evidence-based review of travelers' diarrhea treatment

All persons planning trips to developing regions should arm themselves with antidiarrheal drugs to employ if they develop diarrhea (see Table 19.3). The drugs for which

**Table 19.3** Evidence-base of chemotherapeutic agents in the travelers' diarrhea therapy.

Chemotherapeutic agent	Strength of evidence	Quality of evidence	Comments
Bismuth subsalicylate (BSS) (2–262 mg tablets chewed well or 30 ml of liquid preparation each 30 minutes for up to eight doses 2.1 g/d)	A	I	BSS is an effective treatment of TD leading to reduction in number of stools passes [58]. Turns stools and tongue black (from bismuth sulfide salt which is harmless); can lead to important levels of serum salicylate [81], taken four times a day, is inexpensive but should not be used in persons with advanced GI disease such as IBD or AIDS as bismuth may be absorbed from an abnormal mucosa [82–84].
Kaolin/pectin or attipulgite	C	I	Binds to water, making stools more formed without other apparent value [89].
Loperamide (4 mg initially followed by 2 mg after each unformed stools passed not to exceed 8 mg/d for ≤48 hours)	A	I	Most effective symptomatic drug in TD, can be used with antibiotics for maximum value, produces post-treatment constipation [60, 90].
Diphenoxylate hydrochloride with atropine (Lomotil) (2 tablets four times a day for ≤48 hours)	A	I	Effective, contains atropine which may produce cholinergic side effects without antidiarrheal properties [91], causes central opiate effects in with respiratory depression in children taking overdose [92].
TMP/SMX <sup>a</sup>	D	III	While earlier found to be safe and effective, current levels of resistance lower the drug's value [64].
Fluoroquinolones + (750 mg cipro or 500 mg levo once, can repeat next two mornings with incomplete response)	A	I	Effective in most cases, shortens diarrhea quickly, <i>Campylobacter</i> resistance strains [26, 93] and occurrence of post-treatment CDAD [73] remain problems; ciprofloxacin should have the lowest price as it has become a generic preparation in USA.
Rifaximin (200 mg three times a day for three days)	A	I	Safest drug, effective for therapy of non-invasive/inflammatory enteric pathogens due to diarrheagenic <i>E. coli</i> strains [23, 69, 94].
Azithromycin (1000 mg in single dose)	A	I	Effectively treats all bacterial causes of TD, treatment of choice for high fever and dysentery (passage of grossly bloody stools) [26, 70].

<sup>a</sup>trimethoprim/sulfamethoxazole; + ciprofloxacin (cipro), levofloxacin (levo); CDAD: *Clostridium difficile* associated diarrhea.

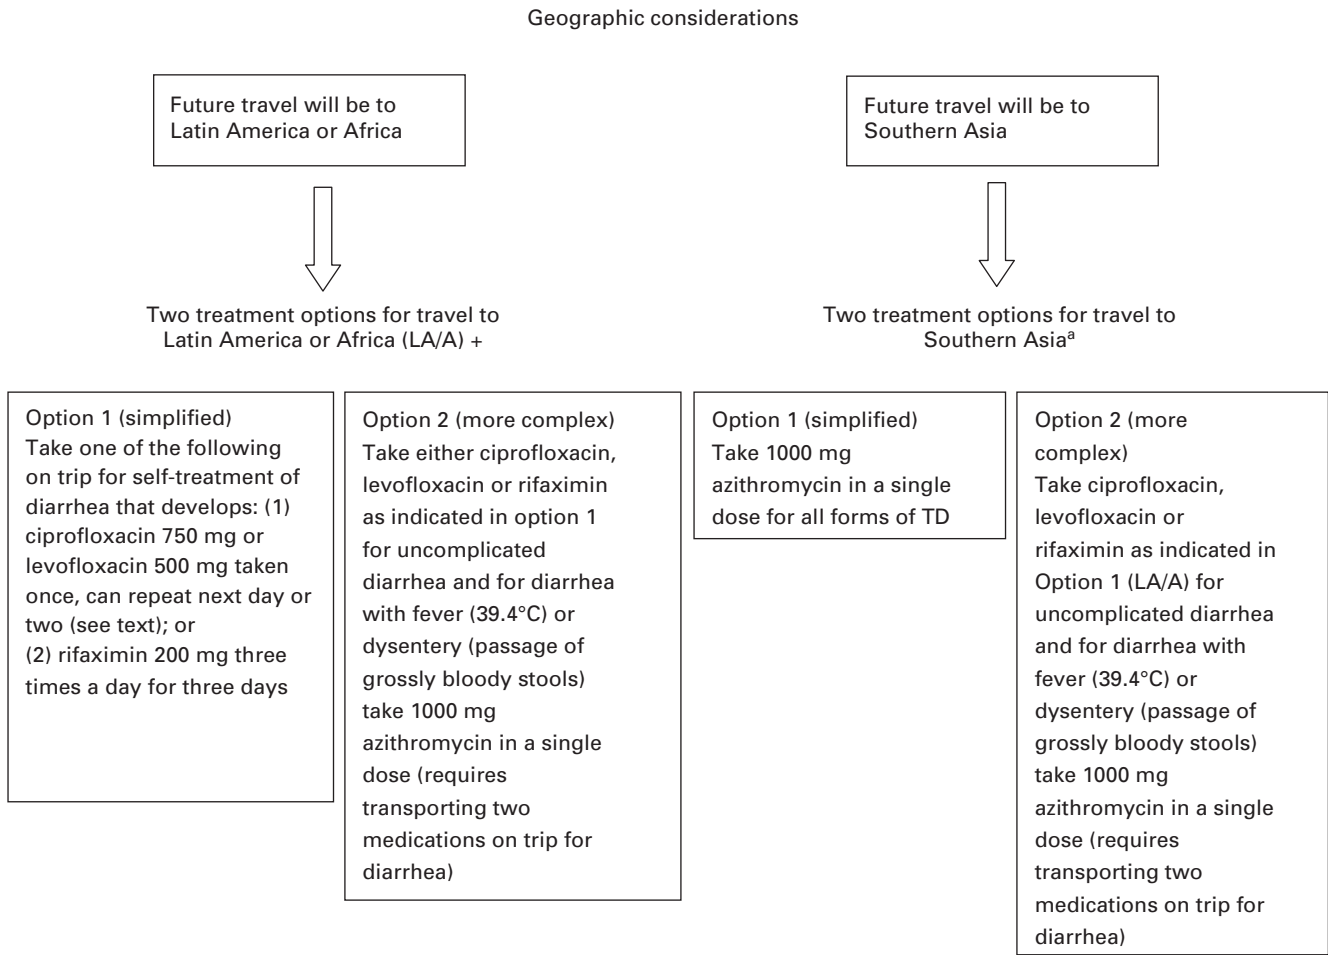

there is strong and quality evidence to support their use in the treatment of TD include BSS, loperamide, fluoroquinolones, rifaximin and azithromycin.

## Current practice and recommendations

In Figure 19.3 four treatment options are provided, along with a perspective on their specific usage. Option 1 is for travel medicine clinics to use as a routine, or for general travelers not likely to appreciate important clinical features of their illness. Option 2 is for the seasoned or insightful traveler who wants to tailor treatment to the specific syndrome experienced. For travel to Latin America or Africa where ETEC and EAEC are the principal pathogens, any one of the three principal TD antibiotics can be employed routinely, including fluoroquinolones, rifaximin or azithromycin. In the algorithm, option 2 requires that travelers make a distinction between their condition that is associ-

ated with passage of watery stools without fever versus a febrile and/or dysenteric illness. If fever (oral temperature >39.4°C) or if grossly bloody stools are passed the preferred drug is azithromycin in a single 1000 mg dose [26, 76]. This syndrome occurs in approximately 1–5% of TD cases developing in Latin America or Africa and at a slightly higher rate among travelers with diarrhea acquired in Southern Asia [20, 77, 78]. For travel to Southern Asia, where invasive pathogens are more common, the azithromycin option is relatively more important. Option 1 for travel to Southern Asia includes use of azithromycin for treatment of all cases of TD.

For the workhorse of TD treatment regardless of destination, rifaximin should be the standard drug for cases of watery diarrhea without fever or dysentery. This recommendation is based on the safety of the drug, which resembles the placebo controls in all studies so far conducted, and efficacy in the treatment of uncomplicated TD that is equivalent to that observed with the absorbed antibacterial

**Figure 19.3** Recommendations for self-therapy of travelers' diarrhea based on geographic considerations and clinical features of illness (Option 1 in the various regions lists the drugs in order of their development for TD therapy; Option 2 is for the more sophisticated traveler).

+ The major pathogens causing travelers' diarrhea in Latin America and Africa are the diarrheagenic *E. coli*: enterotoxigenic *E. coli* (ETEC) and enteroaggregative *E. coli* (EAEC). These organisms respond to all antibiotics listed in Options 1 and 2.

<sup>a</sup>While ETEC and EAEC remain the major pathogens for travel to Southern Asia, invasive pathogens are more important for travel to this region of the world, which are best treated by azithromycin (fluoroquinolone resistance among *Campylobacter* isolates is common and rifaximin shows reduced effectiveness in diarrhea caused by invasive pathogens).

drugs. The drug preserves colonic flora [3, 79] while fluoroquinolones deplete flora [37] and predispose to *C. difficile* diarrhea and colitis [73]. When rifaximin is used for chemoprophylaxis, azithromycin is recommended for breakthrough diarrhea [76]. The traveler can save unused drugs for future trips to high-risk areas if not needed during the current travels and before reaching the drug expiration date.

**Future research for treatment of travelers' diarrhea**

The most important question about therapeutic recommendations in TD relates to resistance patterns of the important

enteropathogens causing disease in the region being visited. Antimicrobial susceptibility patterns should be monitored for ciprofloxacin, levofloxacin, rifaximin, azithromycin and new antibiotics being developed for enteric bacterial infection. We also need to know more about safety of the available drugs. For example, will widespread use of the fluoroquinolones lead to important occurrence of fluoroquinolone resistance among extra-intestinal pathogens, including *Streptococcus pneumoniae*, and will this class of drugs encourage the overgrowth of *C. difficile* in a clinically important number of treated subjects?

Further research is needed to know the importance of TD to the development of PI-IBS and to the overall pool of IBS disease suffered by general populations. The natural history of PI-IBS needs further study to better understand

prognosis, pathogenesis and prevention. Randomized trials are needed to determine if very early antimicrobial therapy, initiated with the first symptom, including passage of the first unformed stool, significantly reduces the occurrence of PI-IB.

## Conclusions

For the foreseeable future, persons venturing into developing regions of Latin America, selected Caribbean islands, Africa and Southern Asia are at risk for TD. Education about the usually safe and often unsafe foods should be undertaken in all cases, although the value of dietary restrictions for prevention of enteric disease during high-risk travel is uncertain. To help determine whether chemoprophylaxis should be employed prior to travel, travelers should be screened for underlying illness, for the importance of the planned trip and for probable enhanced host susceptibility to diarrhea. The standard preventive drug for those falling into the recommended criteria is rifaximin. All travelers should be provided with curative treatment of TD that may develop. The mainstay of therapy is one of three antibacterial drugs: a fluoroquinolone, rifaximin or azithromycin. Azithromycin, while not recommended for all cases of TD, should be used preferentially for TD associated with fever or passage of grossly bloody stools. When rifaximin is used for chemoprophylaxis, azithromycin is the recommended backup drug for treatment of breakthrough diarrhea.

## Acknowledgments

Dr. DuPont has received honoraria for speaking for the following companies: Salix Pharmaceuticals; McNeil Consumer Healthcare; and IOMAI Corporation and has received grants through the University of Texas to support research from: Salix Pharmaceuticals; IOMAI Corporation and Optimer Pharmaceuticals.

### **Introduction**

The occurrence of large outbreaks of severe *Clostridium difficile* disease in Canada refocused attention on this interesting pathogen. The availability of newer techniques for strain typing and rapid diagnostic assays has increased the detection of emergent strains of “hypervirulent” types of *C. difficile*. The incidence of severe cases of *C. difficile* disease and the spread into populations once considered at low risk for *C. difficile* disease (peripartum women and non-health care associated cases) is described. Recently, a decreasing response rate to metronidazole therapy has increased the interest in investigational treatments. Evidence for effective treatment for initial episodes of *C. difficile* disease still favors metronidazole, but there is evidence that the more effective treatment for severe *C. difficile* disease is vancomycin. Investigational treatments for recurrent *C. difficile* disease have expanded to toxin absorbents, rifamycin-class antibiotics, probiotics and immunoglobulin preparations. Preventive strategies include *C. difficile* vaccines and enhanced infection control programs.

*Clostridium difficile*-associated disease (CDAD) has been studied since the first outbreaks of hospital-based CDAD cases were described in the early 1980s [1, 2]. Although formidable work has been accomplished on the epidemiology, clinical diagnosis and control of hospital outbreaks, CDAD continues to persist as a leading cause of nosocomial gastrointestinal illness [3–5]. Outbreaks of an emergent strain, BI/NAP1/027, caused large outbreaks of severe CDAD with high rates of mortality in Canada during 2003–2005 [6]. Other forms of CDAD that are now

recognized include recurrent CDAD, toxic megacolon and *C. difficile*-associated septicemia [7–11]. Little is known about these forms of CDAD (toxin megacolon, septicemia, brain empyema) other than that they occur sporadically and may cause significant clinical problems for patients and challenges for health care providers [12].

Vancomycin or metronidazole are typically used for the treatment of the first episode of CDAD. However, approximately 10–24% of patients with an episode of CDAD have at least one recurrence after the first antibiotic treatment is discontinued. Some of these patients develop a form of the disease known as recurrent CDAD that is characterized by recurrent episodes over several years despite treatment [13–16]. Since 2003, rates of metronidazole failure and recurrence rates have increased, casting doubts about the effectiveness of this antibiotic for CDAD [17]. In addition, vancomycin is now considered to be more effective in severe cases of CDAD [18].

The objective of this chapter is to describe the epidemiology, diagnosis and evidence-based treatment strategies for treatment and prevention of primary and recurrent CDAD.

### **Diagnosis**

Unlike most diseases, a simple laboratory assay is not definitive for the diagnosis of CDAD. The presence of *Clostridium difficile* (either a culture or positive toxin assay) must be accompanied by an appropriate clinical presentation (usually diarrhea), and other etiologies of diarrhea must be excluded [19]. The requirement for a combination of laboratory results and an appropriate clinical presentation is due to the occurrence of the asymptomatic carrier state in some patients who have a positive laboratory test for *C. difficile*, but no clinical symptoms. On the other hand, some patients with symptomatic disease may have negative laboratory tests for stool toxins.

The cell cytotoxin assay is considered to be the “gold standard” for diagnosis, but stool culture has the advan-

tage of detecting one-third more cases than cell cytotoxin assay. However, these two methods have lost favor in current practice [20, 21]. Currently, 79–95% of hospitals use rapid enzyme-immunoassays (EIA) to diagnose CDAD [22, 23]. These EIA kits have the advantages of rapid turnover (usually within one day) and high specificity (94–100%), but exhibit somewhat lower sensitivity (88–93%) [24, 25]. Newer types of tests using DNA probes for *C. difficile* toxin genes are promising. Direct stool PCR assays are rapid (<4 hours) and have better sensitivities than EIA. Peterson *et al.* tested 1368 stool samples and reported that PCR has 93.3% sensitivity and 97.4% specificity when compared to culture [19]. In an effort to combine rapid turn-around time and high sensitivities, a number of algorithms have been proposed. Most of these combine a screening step with rapid EIA for glutamate dehydrogenase (GDH), *C. difficile* antigen assay with a confirmatory assay for those who are GDH positive (either the cell cytotoxicity assay or an EIA for toxin A or B). A three-step algorithm consisting of (1) GDH screening, (2) a stool cytotoxin confirmation for positive GDH and (3) a toxigenic isolate assay from stool culture for all samples negative for stool cytotoxin was tested on 439 diarrheal stools. The sensitivity of this approach was 87%. The third step (stool culture and assaying isolates for toxin production) resulted in the detection of 33% more cases than were found using only the first two steps [20]. Balancing costs with the need for rapid diagnosis and high sensitivity for CDAD is paramount and continues to be challenging.

### Clinical presentation

Diarrhea due to CDAD has been defined as a change in bowel habits with at least three loose or watery bowel movements per day for at least two consecutive days or greater than eight loose or watery stools within 48 hours [26, 27]. The symptoms of CDAD can also include fever, nausea and abdominal cramping or pain [28].

The incubation period after acquisition of *Clostridium difficile* is usually one week or less, but can be up to as long as eight weeks after exposure to antibiotics [13, 29]. Asymptomatic carriers may also become symptomatic after exposure to antibiotics.

In 2005, a prospective observational study in 88 Quebec hospitals yielded 478 isolates of *C. difficile* with 61 different PFGE profiles. Severe disease was 2.3 times more frequent when both binary toxin genes and *tcdC* deletion were present. “Severe CDAD” was defined as being the cause or a contributing factor to 30-day mortality, or to the requirement for colectomy or admission to an intensive care unit [30].

Approximately 3–8% of CDAD patients develop “fulminant CDAD”, in which the clinical course is complicated by perforation, severe ileus with toxic megacolon, hypoten-

sion requiring vasopressors or refractory septicemia. A significant number of these patients require emergency colectomy [31].

### Complications

Complications of recurrent CDAD in one study included repeated hospitalizations for cases of severe recurrences (3 hospitalizations of 100 patients), development of toxic megacolon (0.5 of 100), septicemia (0.5 of 100) and *C. difficile*-associated arthritis (0.5 of 100) [14].

During the outbreaks in Canada, complicated cases of CDAD (elevated fever, leukocytosis, shock, ICU admission, requirement for colectomy) increased from 7% to 18%. It was postulated that the emergent BI/NAP10/27 strain was responsible [32]. Other strain types of CDAD are also associated with severe disease, but not with the hyperproduction of toxins.

### Costs

Studies of patients with CDAD have shown that the cost of medical care associated with CDAD cases may range from \$2000 to \$6000 per patient [28, 33, 34]. Recurrent CDAD has a higher impact on the medical care system. The impact is reflected in high costs of medical care, readmissions to hospital for severe recurrent episodes, and complications (toxic megacolon, septicemia, arthritis). In one study of 209 patients with recurrent CDAD, the total lifetime cost for direct medical expenses (including all prior episodes, enrollment episodes and subsequent recurrences) averaged \$10,970 per person [14]. The average cost of diagnosis and treatment for episodes other than the enrollment episode was \$3103 per patient. These costs do not include lost time from work, costs of complications, additional clinic visits or any indirect costs. In one prospective study, the average length of stay for a hospitalization due to a CDAD recurrence was  $8.8 \pm 8.6$  days (ranging from 3 to 26 days) [14]. Other studies have documented that CDAD extends hospital stays for hospitalized patients from 4 to 36 days [28, 34–36]. In a study of 1034 CDAD cases in Massachusetts during 2000, the average cost ranged from \$10,212–13,675/patient, projecting a national (US) cost of CDAD of \$3.2 billion/year [37].

---

## Epidemiology

### Incidence/prevalence

The prevalence of CDAD ranges from 0.15% to 10% in hospitalized patients during non-outbreak situations and may increase from 16% to 29% during hospital outbreaks of CDAD [4, 38–40]. The rates of CDAD have been increas-

ing globally over the years. In the USA, CDAD rates have doubled between 2001 and 2005 to 301,200 cases [41]. The prevalence of community acquired CDAD is typically much lower than health care associated CDAD but has increased from 7.7–12 per 100,000 person-years during the years from 1994 to 2000 [42, 43] to 22 per 100,000 in 2004 [44]. Community acquired cases may have a different clinical profile, because infection is not acquired at a health care setting and most (45–60%) are not associated with recent antibiotic use [21, 45, 46]. The rate of community acquired CDAD may be underestimated if patients with atypical risk factor profiles and no history of a recent health care admission are not assayed for *C. difficile*.

### Health care associated outbreaks

Documented outbreaks due to this organism are reported in hospitals and long-term care facilities around the world with increasing frequency [4, 47, 48].

A variety of patient populations has been shown to be susceptible to nosocomial CDAD. Outbreaks or nosocomial acquisition have occurred in patients in general medicine wards [4], surgical wards [49, 50], long-term care facilities [51], in elderly patients [52, 53], in pediatric patients [54, 55], patients who are immunocompromised either by HIV infection [48, 56], by cancer [57, 58], or by transplantation [59] and, less commonly, in new mothers [60, 61].

Strain typing techniques have been a valuable tool in tracking the routes of transmission during hospital outbreaks and in documenting those hospitals that may harbor both endemic strains and epidemic strains of *Clostridium difficile* [4, 62, 63]. Strain typing of isolates from hospitalized patients has also shown that half of clinical recurrences may be re-infections with a different strain of *Clostridium difficile*, adding support to the importance of nosocomial acquisition of new strains [15, 64].

The BI/NAP1/027 strain was associated with the Canadian outbreaks during 2003–2005. This strain is of toxinotype III (presence of binary toxin CDT) and contains dysfunctioning *tcdC* gene. A single nucleotide deletion at position 117 resulted in a stop codon for the *tcdC* gene, thus inactivating the down-regulation of *tcdA* and *tcdB* [65]. Strains with the *tcdC* deletion have been found to produce 16 times more Toxin A and 23 times more Toxin B than other *C. difficile* strains [66]. Another novel characteristic of this strain is that it is resistant to gatifloxacin and moxifloxacin. Older isolates (pre-2002) of BI/NAP1/027 were not resistant to fluoroquinolones [67]. As fluoroquinolones became commonly prescribed, the development of antibiotic resistance in health care associated strains of CDAD was a focus of clinical concern. Since the Canadian outbreaks, several outbreaks of the BI/NAP1/027 strain have been reported. Biller *et al.* reported that an outbreak in a hospital in Pennsylvania occurred after a formulary change

from levofloxacin to moxifloxacin and did not resolve after levofloxacin was reinstated. This outbreak was associated with the emergent strain [68]. A prospective study in Canada that collected *C. difficile* isolates from 88 hospitals in Quebec continued to find the persistence of the BI/NAP1/027 strain (57% were positive) after the outbreaks subsided [30]. In the USA, as of November 2007, 38 states have found BI/NAP1/027 in their hospital populations [69]. In contrast to studies reporting severe CDAD associated with BI/NAP1/027 isolates, a study at the Veterans' Administration (VA) Medical Center in Cleveland, Ohio, found 68 asymptomatic carriers of *C. difficile* and 13 (37%) were NAP1 isolates [70]. Tracking this emergent strain of *C. difficile* has documented how easily global transmission of this organism is achieved.

### Transmission

Transmission within the hospital has been shown to be largely due to horizontal transmission via environmental surface contamination, hand carriage by hospital personnel and infected roommates [4, 39, 62, 71]. In a cohort of 3500 patients, a multivariate analysis found that physical proximity to a patient with CDAD significantly increased the risk of CDAD (RR = 1.86; 95% CI: 1.06–3.28) [71]. New admissions who are *Clostridium difficile* positive have been shown to be a source of infection for susceptible patients [72]. In a prospective cohort study of 428 patients admitted to one general medicine ward, a multivariate model documented that the risk of nosocomial acquisition of *Clostridium difficile* was significantly higher after exposure to an infected roommate (RR 1.73; 95% CI: 1.15–2.55) [4]. Environmental surfaces are uniformly positive for *C. difficile* if a CDAD patient is in the room, compared to only 33% positivity if no CDAD patient is present (100%) [69].

### Risk factors

Risk factors for primary CDAD usually involve factors in one of three general areas: (1) factors that disrupt normal colonic flora, such as broad-spectrum antibiotics or surgery, (2) host factors, such as age, gender, diet, immune status, concurrent medical conditions or diseases, such as cancer, transplantation, other gastrointestinal conditions, or co-infection with other enteric pathogens and (3) exposure to the organism, usually through admission to a hospital with endemic *Clostridium difficile* or admission when an outbreak is occurring.

The normal colonic microflora has been shown to be protective of colonization by *Clostridium difficile* through a multifocal mechanism known as colonization resistance. This complex interaction of the intestinal microflora produces a wide variety of protective effects that may include spatial interference, attachment inhibition, production of

bacteriocins, production of toxin degrading proteases and stimulation of immunoglobulins that act as a barrier to the colonization of newly introduced pathogens [73]. Factors that disrupt this colonization resistance, such as exposure to antibiotics, surgery or medications, have been shown in epidemiologic studies to increase the risk of CDAD. Exposure to broad spectrum antibiotics has the highest risk associated with CDAD, but narrow spectrum antibiotics have also been implicated. Neither the dose nor the total duration of antibiotic therapy seems to be correlated with higher risk of developing CDAD in some studies [5, 28, 35, 48, 49, 51, 52, 53, 71]. Gastrointestinal surgery or manipulation, or nasogastric tube feeding have also been shown to be significant risk factors for CDAD in epidemiologic studies [35, 51, 74, 75].

Host factors that have been shown to be significant risk factors for CDAD include increasing age [14, 16, 28, 52], female gender [28, 49], serious underlying illness and the presence of other concurrent diseases [51, 52, 60]. Prolonged hospitalization has also been shown to increase the risk of *Clostridium difficile* acquisition [76].

Since many of these risk factors for CDAD are correlated, multivariate analysis is appropriate to provide an assessment of the independent risks associated with these factors. Most multivariate analyses have provided evidence that advanced age, antibiotic use, co-morbidities and longer hospital stays are independently predictive of CDAD [21, 77–79]. Using multivariate analysis of data from 37 hospitalized patients with cytotoxin positive CDAD and 37 hospital controls Brown reported that age greater than 65 yrs (OR 14.1; 95% CI: 1.4, 141), stay in an intensive care unit (OR 39.2; 95% CI: 2.2, 713), gastrointestinal procedures (OR 23.2; 95% CI: 2.1, 255) and over ten days of antibiotics (OR 16.1; 95% CI: 2.2, 117) were significant risk factors for CDAD [75]. Nelson *et al.* studied 33 hospitalized patients with CDAD and 32 controls and showed that the use of second or third-generation cephalosporin was a significant risk factor (OR 8.3; CI 95%: 1.4 to 48.9), as was the use of two or more antibiotics (OR 18.7; 95 % CI: 4.1–85.8) [80]. McFarland *et al.* studied 428 patients admitted to a general medicine ward and found five risk factors for CDAD using age and severity of co-morbidity-adjusted multivariate analysis severe underlying disease (RR = 5.18; 95% CI: 1.2, 22.2), cephalosporin use for at least one week (RR = 2.1; 95% CI: 1.1, 3.8), penicillin use for two weeks (RR = 3.4; 95% CI: 1.5, 7.9) and use of gastrointestinal stimulants (RR = 3.1; 95% CI: 1.7, 5.6), enemas (RR = 3.3; 95% CI 1: 5, 7.0) or stool softeners (RR = 1.7; 95% CI: 1.02, 3.0) [35]. Dubberke *et al.* studied 382 CDAD cases and 35,704 controls admitted to a St Louis Missouri hospital from January 2003 to December 2003. Multivariate analysis revealed the following risk factors: age over 45 years (adjusted odds ratio = 2.3), CDAD colonization pressure (adjusted odds ratio = 4.0) and antibiotic use (cephalosporins and fluoro-

quinolones) and third-generation cephalosporin use (over seven days' use) had an aOR = 9.2, 95% CI: 5.9–14.5) and over one week use of fluoroquinolones had an aOR = 2.5, 95% CI: 1.8–3.5) [81]. CDAD colonization pressure is an indicator of how long an affected patient was exposed to another patient infected with *C. difficile*.

## Recurrent disease

Prospective studies of risk factors for recurrent CDAD may help to define this subset of highly susceptible patients who have a tendency to develop the recurrent form of CDAD. The risk factors for recurrent CDAD have been reported to be slightly different from risk factors found for primary CDAD or risk factors for nosocomial CDAD [9, 26, 35, 75, 80, 82, 83]. In a prospective cohort study of 209 patients with recurrent CDAD, logistic regression revealed two significant independent risk factors for CDAD recurrence: increased age and a lower quality of health index at enrollment ( $X^2 = 9.03$ ,  $p = 0.01$ ) [14]. Patients who experienced recurrent disease were older ( $64.8 \pm 1.65$  years) than patients who did not ( $54.6 \pm 19.6$  years) and also exhibited a lower quality of health index ( $42.9 \pm 17.8$ ) compared to patients who did not experience recurrent disease ( $50.3 \pm 18.5$ ). The estimates of risk for CDAD recurrence were as follows: age (odds ratio (OR), 1.04; 95% CI: 1.01, 1.08) and a lower mean quality of health index (OR 0.96; 95% CI: 0.93, 0.99). There were no significant interactions observed in the analysis. No other risk factor was significant, including gender, number of prior episodes, type or dose of standard antibiotic, dose or duration of inciting antibiotic, days of follow-up, number of medications or prior surgeries, allergies, severity of enrollment episode, study center, or type of patient (inpatient or outpatient).

In another study comparing 34 patients with recurrent CDAD and 33 patients with non-recurrent CDAD, the risk factors for subsequent recurrences included a higher number of prior episodes (RR = 3.87, 95% CI: 1.12, 13.34), spring onset of initial episode (RR = 7.73; 95% CI: 1.07, 55.89) and the use of additional antibiotics (RR = 2.97; 95% CI: 1.11, 7.93) [9]. Do *et al.* analyzed 13 patients with recurrent CDAD and 46 patients with an initial episode of CDAD in a case-control study [84]. Risk factors for recurrent CDAD in this very small study included a history of chronic renal insufficiency and white blood cell count over  $15,000/\text{mm}^3$ .

Tal *et al.* performed a case-control study to compare 43 patients with recurrent CDAD to 38 patients with initial CDAD at a subacute geriatric department over a period of 18 months [82]. Risk factors for recurrent CDAD included fecal incontinence (OR = 2.75; 95% CI: 1.05, 7.54), longer duration of fever from admission until first episode of CDAD (OR = 1.11; 95% CI: 1.02, 1.25) and  $\text{H}_2$ -antagonist exposure (OR = 1.03; 95% CI: 1.14, 7.29). Given the small

numbers of patients studied and the rather low values for these observed odds ratios, these results provide only very limited evidence.

## Treatment for the initial episode

If possible, the inciting antibiotic should be discontinued. Fluid support (oral or intravenous) may be needed. Antiperistaltic or opiate drugs should be avoided on the basis of physiological considerations rather than clinical evidence. There is no proven role for treatment of asymptomatic carriers [85]. If the index of suspicion for CDAD is high, it is recommended that empiric therapy should be initiated, rather than waiting for confirmatory stool tests, although there is no good evidence on this point.

## Antibiotic treatments

Given the number and variety of clinical trials of antibiotics to treat CDAD, a 1997 meta-analysis proved to be valuable in assessing the efficacy of the various antibiotics. Of nine trials with suitable methodology to permit inclusion in the systematic review, only two were placebo controlled. Six other trials compared vancomycin to other antibiotics (fusidic acid, bacitracin and teicoplanin.). No single antibiotic was shown to be more effective than any other [86].

## Vancomycin

Several trials have demonstrated the efficacy of oral vancomycin for therapy of initial CDAD, given orally at doses of 500–1225 mg four times a day for 7–14 days (Table 20.1) [18, 27, 87–98]. Wenisch *et al.* performed a randomized, controlled trial of four antibiotic regimens [93]. One hundred and nineteen patients with *Clostridium difficile* toxin positive diarrhea were randomized to receive a 10-day course of one of the four antibiotic regimens: metronidazole (1.5 g/d), vancomycin (1.5 g/d), fusidic acid (1.5 g/d), or teicoplanin (800 mg/d) and followed for initial resolution of symptoms (“cure”) and for occurrence of a relapse within 30 days of antibiotic discontinuation (“relapse”). The four groups were comparable in terms of age, sex and previous antibiotic exposure. The initial cure rate was not significantly different among the treatment groups and ranged from 93–96%. The observed recurrence rates were: metronidazole 16%, vancomycin 16%, teicoplanin 7% and fusidic acid 28%. The difference between teicoplanin and fusidic acid groups was statistically significant ( $p = 0.04$ ). There were no reported adverse reactions to any of the four antibiotics. **A1c**

Several studies have shown equal efficacy for metronidazole and vancomycin [88, 93]. Teasley *et al.* [88] reported a randomized, controlled trial in which 94 patients with

CDAD were randomized to vancomycin (2 g/d for 10 days) or metronidazole 1 g/d for 10 days). The initial response rates (vancomycin 100%, metronidazole 95%) and recurrence rates (vancomycin 5%, metronidazole 11.5%) were not significantly different. **A1c** Olson *et al.* reported a case series of 908 patients in a 10-year surveillance study of *Clostridium difficile* at the Minneapolis VA Medical Center [99]. The initial response rates to metronidazole and vancomycin in a variety of dosage regimens were, respectively, 98 and 99%. **B4** When the relative odds of treatment failure or subsequent *Clostridium difficile* recurrence are used to evaluate the different antibiotics available to treat initial episodes of CDAD, vancomycin and metronidazole appear to have equal efficacies (Table 20.2).

In a randomized, controlled trial in which 46 patients were randomized to receive vancomycin at high dose (2 grams/day) or lower dose (500 mg/day) both groups responded with a mean of four days of diarrhea after initiation of therapy and nearly uniform resolution of diarrhea by a week of therapy [91]. Given the expense of vancomycin therapy, these data support the use of the lower dose regimen. **A1d**

As seen in Table 20.1, vancomycin cures rates are high, with failure rates ranging from 1–16%. Relapse rates after vancomycin have been fairly stable over the years. Vancomycin appears to be superior to metronidazole for cases of severe CDAD. If patients have severe CDAD (diarrhea with leukocytosis, fever  $>38.5^{\circ}\text{C}$ , PMC or toxic shock), and the intestines are functioning and not obstructed, vancomycin is more effective than metronidazole (97% vs 76%, respectively,  $p = 0.002$ ) [18]. **A1c** Vancomycin is also associated with more rapid recovery and less total cost of health care. A retrospective review of 32,325 cases of CDAD, revealed that patients treated with vancomycin exhibited shorter hospital stays (vancomycin 11.5 days, metronidazole 12.8 days,  $p < 0.001$ ), and the mortality rate was also lower (vancomycin 6.8%, metronidazole 7.9%,  $p = 0.02$ ). **B4** The estimated costs of hospital care were \$14,718 for vancomycin treated patients and \$16,953 for the metronidazole group ( $p < 0.001$ ) [100]. At a Cleveland Veterans' Administration hospital, in a small two-month observational study of 52 patients with CDAD, 18 patients were treated with vancomycin and 34 with metronidazole for at least six days [101]. Similar rates of treatment failure (persistent diarrhea at the end of treatment) were seen in patients treated with vancomycin: 1/18 (16%) and metronidazole: 4/34 (12%). Similar rates of CDAD recurrences were also observed: 2 (11%) patients receiving vancomycin and 4 (12%) receiving metronidazole. Although there was no significant difference between the treatments for cure rate and recurrence rate, it appeared that diarrhea resolved more rapidly and a greater proportion of patients' stools became negative for *C. difficile* on the fifth day of treatment in vancomycin treated patients. **B4**

Abbreviations: nr: not reported; ns: not significant; adjunct: in addition to standard antibiotics (vancomycin or metronidazole).

Ten metronidazole treated patients had their treatment changed to vancomycin due to lack of response, but only four completed an entire 10-day course of metronidazole, a factor that may bias these results.

While intravenous vancomycin has little efficacy, use of vancomycin enemas is an alternative when the oral route

is not feasible, e.g. in patients with paralytic ileus. However, there are no controlled trials demonstrating efficacy of this approach. Even the case series that suggest benefit are small. A recent series of nine hospitalized patients with severe *C. difficile* colitis showed response to adjunctive intracolonic therapy in eight (89%) [102]. Previously pub-

lished data suggested an overall efficacy of 83% (from 24 prior cases). There are insufficient data on which to make a recommendation for this form of therapy.

## Metronidazole

Oral metronidazole has been used for treatment of initial CDAD, and several clinical practice guidelines suggest that it should be first-line therapy. Recommended treatment is 250–500 mg orally four times a day for 7–14 days. Studies have shown a good response rate (>95%) [88, 93]. **A1c**

Metronidazole cure rates generally range between 76–90%, but the failure rate has increased from <16% pre-2003 to over 35% since 2004. In addition, the recurrence rate has also increased from ~20% pre-2003 to up to 47% since 2004. In 845 patients treated with metronidazole in Quebec during the 2003–2004 outbreaks, 26% failed initial treatment and 47.2% recurred within 60 days of treatment [17]. **B4** One proposed explanation of a higher rate of metronidazole treatment failure is that metronidazole resistance may have developed. However, metronidazole resistance is infrequent in *C. difficile* isolates. Of 415 *C. difficile* isolates

from patients in Spain, only 6% of isolates were resistant to metronidazole and 3% exhibited reduced susceptibility to vancomycin [103].

Another area of debate is the route of administration. Oral antibiotic treatment is preferred, but some patients have an ileus or toxic colon precluding the oral route. Observational evidence from case reports suggests that intravenous metronidazole is effective. In a series of 10 patients with *C. difficile* colitis given intravenous therapy a good response was observed in nine [104]. There are no controlled trials evaluating the efficacy of intravenous metronidazole.

### Investigational treatments

As shown in Table 20.1, due to the occurrence of treatment failures and of recurrent disease, new interventions are under investigation. Tinidazole has been tested and found to be safe in phase 2 trials, but phase 3 trials are needed to demonstrate efficacy [105].

### Absorbents

Another approach is the administration of an agent that may bind *C. difficile* toxins within the intestinal lumen. In a phase 2 randomized double-blind trial, tolevamer in doses of 3 or 6g/d) was compared to vancomycin (500mg/d) for 10 days in patients with initial or recurrent CDAD [96]. For patients with initial CDAD, the rates of recurrence were not significantly different by treatment group: 4/30 (13%) in the 3g tolevamer group, 5/39 (13%) in the 6g tolevamer group and 10/56 (18%) in the vancomycin group. **A1d** Phase 3 trials were recently completed, but the results have not yet been published.

### Bacitracin

Bacitracin is an orally administered non-absorbable antibiotic, that is characterized by an unpleasant taste and is relatively expensive. Two uncontrolled studies in 1980 showed response to therapy in small numbers of patients (two and four patients each) [106, 107]. More recently a double-blind randomized, controlled trial compared bacitracin (80,000 units daily) with vancomycin (500mg daily) in 42 patients. Clinical response (decreased diarrhea at four days) was similar in the two groups. **A1d** However, the bacitracin treated patient had higher rates of persistent *C. difficile* positive cultures in the stools [89]. The authors recommended bacitracin as a first-line alternative to vancomycin. A second randomized, controlled trial in 24 patients also showed similar efficacy of bacitracin and vancomycin, although vancomycin was more effective in clearing *C. difficile* and toxin from the stool [90]. A randomized trial com-

paring metronidazole and bacitracin would be important and has not been performed.

### Fusidic acid

Fusidic acid is considered to be an L-selectin blocker that inhibits leukocyte extravasation into inflamed sites [108]. In a small randomized trial in which 40 patients were randomized to one of four oral agents: fusidic acid, metronidazole, vancomycin and teicoplanin the response rates were similar for all four groups (93–96%). The authors recommend metronidazole because of its lower costs, reserving other drugs for patients who do not tolerate or respond to metronidazole [93]. A randomized, controlled trial in 131 patients with initial episodes of CDAD comparing fusidic acid (750mg/d) and metronidazole (1200mg/d) for seven days showed no statistically significant difference in clinical cure rate [97]. **A1d**

A phase 3 trial with patients randomized to fusidic acid (n = 59) or metronidazole (n = 55) for seven days found equivalent rates of cure and recurrences. **A1d** Resistance to fusidic acid was found in 1% of colonic isolates obtained from pre-treatment patients and from 11/20 (55%) of isolates in those patients who remained culture positive after treatment with fusidic acid [109].

### Probiotics

Probiotics are defined as live microorganisms that confer a health benefit on the host when administered in adequate amounts [110]. Probiotics have no proven role in treatment of initial CDAD. In a placebo controlled randomized trial of a probiotic mixture for the prevention of antibiotic-associated diarrhea, a secondary outcome was the prevention of CDAD [111]. Patients were randomized to receive either a probiotic mixture of *Lactobacillus casei*, *Lactobacillus bulgaricus* and *Streptococcus thermophilus* (Actimel drink) at a dose of  $2.2 \times 10^8$  cfu/day or a placebo drink for the duration of antibiotic therapy plus one additional week. Of the 113 subjects completing the trial, 0/56 (0%) developed CDAD in the probiotic group compared to 9/53 (17%) in the placebo group,  $p < 0.05$ . **A1c** The estimated cost of preventing one case of CDAD with probiotic was \$120.00. Currently, several probiotics are under development for CDAD including *Lactobacillus acidophilus*, *Saccharomyces boulardii* and a non-toxigenic strain of *Clostridium difficile*.

### Ramoplanin

This antibiotic targets bacterial DNA-dependent RNA polymerase and inhibits cell wall synthesis. In a phase 2 open-label trial of 86 CDAD patients were treated with 10 days of either ramoplanin (200mg bid or 400mg bid) or

vancomycin (125mg qid) [94]. The rates of cure were similar in all groups: 83% and 85% for patients receiving 200mg or 400mg of ramoplanin and 86% for patients receiving vancomycin. **A1d**

### Rifampin

In a phase 2 study of Rifampin 39 patients were randomized to receive either metronidazole 500mg tid or metronidazole plus rifampin 300mg bid for 10 days. The recurrence rates were similar by day 40 (38% and 42% respectively) [95]. **A1d**

### Teicoplanin

De Lalla *et al.* reported a randomized, controlled trial in which 46 patients with CDAD received either teicoplanin (200mg) or vancomycin 2g daily for 10 days [92]. The initial cure rates for teicoplanin and vancomycin were 96% and 100%, and the recurrence rates were 7.7% and 20%. These differences were not statistically significant. However, teicoplanin appeared to be significantly more protective against recurrent disease than fusidic acid (RR = 0.19; 95% CI: 0.04 to 0.99) (Table 20.1) [93]. **A1d**

### Tiacumicin B

Tiacumicin B (also known as OPT-80 and PAR-101) is a macrocyclic antiobiochemical that targets RNA polymerase. Early phase 1 studies showed it was well tolerated in healthy volunteers at doses up to 450mg/day [112]. In a phase 2 dose ranging study in 49 patients with mild to moderate CDAD [105] the cure rates were similar in patients receiving 100mg (86 %), 200mg (87%) or 400mg (100%). The recurrence rates for these treatments were also similar: 8%, 0% and 6%. Phase 3 trials are in progress.

---

## Treatment for recurrent CDAD

Most patients (76–98%) with their first episode of CDAD are cured after treatment with either vancomycin or metronidazole [9, 99]. However, a proportion of patients develop recurrent episodes of CDAD that may last for years, despite antibiotic treatment [9, 60]. Once a second episode of CDAD occurs, 60% of patients continue to experience subsequent episodes and are considered to have an especially difficult form of CDAD, designated “recurrent CDAD” [9, 60]. Treatment of recurrent CDAD has traditionally relied upon antibiotics (usually vancomycin or metronidazole), toxin binding resins, fecal enemas and the use of biotherapeutic agents [13, 26, 27, 113–115].

### Vancomycin or metronidazole treatments

There are a limited number of randomized trials comparing antibiotic treatments in patients with recurrent CDAD (in which patients with an initial episode have been specifically excluded) (Table 20.2) [27, 96, 98, 116–118]. Most trials have been in patients with initial disease, or have not specifically included or excluded patients with prior CDAD episodes. In a randomized, double-blind, placebo-controlled trial of an investigational probiotic treatment patients with recurrent CDAD were randomized to receive 10 days of either high dose vancomycin (2g/d), low dose vancomycin (500mg/d) or metronidazole (1g/d) plus either the probiotic or a placebo. In the three antibiotic treatment groups that received the probiotic placebo the observed recurrence rates were similar: high dose vancomycin 50%, low dose vancomycin 45% and metronidazole 50%. An earlier double-blind, placebo-controlled trial compared the efficacy of these antibiotics in various doses with a placebo in 102 patients. [27]. The observed recurrence rates of 43% for vancomycin-treated patients and 32% for metronidazole-treated patients were not significantly different. **A1a**

A series of 163 patients with recurrent CDAD who were followed prospectively documented the rate of CDAD recurrences over a two-month period in patients who were treated with a variety of strategies using either vancomycin or metronidazole [117]. Of the 125 patients treated with a variety of doses and durations of vancomycin, 46% subsequently developed recurrent CDAD. This recurrence rate was not significantly different from the rate of 42% in the 38 patients treated with metronidazole ( $p > 0.05$ ). **B4**

Similar rates of recurrence following therapy with vancomycin and metronidazole are seen despite the differences in the pharmacokinetics of these agents in the intestine. In the healthy intestine, metronidazole is rapidly absorbed from the feces, and the concentration within the lumen of the gut is low. Once an acute episode of CDAD occurs, high concentrations of metronidazole have been documented in the infected intestine [119]. Vancomycin is bacteriostatic on *Clostridium difficile* organisms, thus allowing the persistence of vegetative cells of *Clostridium difficile* and the rapid increase in *Clostridium difficile* after discontinuation [120]. The time required for spore germination, *C. difficile* overgrowth and acute toxigenic symptoms may be extremely short (usually 3–5 days) once the treatment antibiotics have been discontinued. In one long-term follow-up study 97% of recurrences were observed within four weeks of stopping antibiotics (median of seven days) [14]. The short time between the end of antibiotic therapy and the recurrence of symptoms was confirmed by two other studies of patients with recurrent CDAD [9, 99]. Delayed onsets of new episodes (four to eight weeks later) reported in some studies may be due to the exposure

to exogenous spores or germination of asymptomatic carriage of *Clostridium difficile* during the time when the normal colonic flora has not yet recovered. A previous study has shown that antibiotics may disrupt the normal flora for up to six weeks after discontinuation [121]. Continuation or restarting inciting antibiotics after successful treatments has been shown to increase the risk of recurrence [122].

Thus, the efficacy of treatment for recurrent CDAD may be influenced by the presence of residual *Clostridium difficile* spores in the intestinal tract and the interval over which the intestine is susceptible to *Clostridium difficile* overgrowth. Short duration antibiotic treatments may be effective in initially resolving the symptoms of diarrhea, but may be ineffective during the “window of susceptibility”, i.e. the interval during which the intestinal microflora needs to be re-established in order to resist the overgrowth of *Clostridium difficile* and recurrence of disease. Several strategies have been tested, including providing extended protection by tapering the dose or providing “pulsed” doses of antibiotics, use of biotherapeutic agents (“beneficial microbes”) or restoration of intestinal microflora using fecal infusions of bacteria or normal stool contents.

### Vancomycin taper/pulse

There have been two studies of patients with recurrent CDAD treated with either tapering or pulsed dosing of vancomycin. In an observational study of 163 patients with recurrent CDAD who were treated with a variety of strategies that included either vancomycin or metronidazole and followed for two months the overall recurrence rates for all patients receiving the two antibiotics were not significantly different [117]. **B4** Vancomycin tapering and vancomycin pulsed dosing were shown to be effective for reducing the frequency of recurrences. The recurrence rate for 14 patients treated with vancomycin in doses between 1 and 1.5 g/d for 10 days was 71% compared to a rate of 31% in 29 patients treated with a tapering dose of vancomycin (over a mean of 21 days), and there was only one recurrence in seven patients treated with a pulsed dosing of vancomycin (125–500 mg pulse every three days over a mean of 18 days). Although these patients were studied using standardized protocols this was not a randomized trial and the results are suggestive, but not definitive.

Tedesco *et al.* reported an uncontrolled study of 22 patients who had recurrent CDAD and were treated with a tapering dose of vancomycin for 21 days (500 mg/d for one week, 250 mg/d for the second week, 125 mg/d for the third week, and 125 mg on alternate days for a fourth week) and a pulse dose (125 mg every third day for 21 days). There were no recurrences, but the results of this uncontrolled study do not constitute definitive evidence [123]. **B4**

Adjunctive intracolonic vancomycin appeared to be beneficial in a case series of nine patients (three of whom had recurrent CDAD) but the results have not been confirmed in a randomized trial [102].

### Other investigational treatments

In contrast to patients with initial CDAD, no randomized, controlled trials of teicoplanin, bacitracin, or rifampin have been performed for patients with recurrent CDAD.

### Absorbents

Another approach that has been investigated in a phase 2 randomized double-blind trial is administration of an agent that may bind *C. difficile* toxins within the intestinal lumen. Tolevamer in doses of 3 or 6 g/d was compared to vancomycin 500 mg/d for 10 days in patients with initial or recurrent CDAD. In patients with recurrent CDAD, the rates of recurrence were: 4/11 in the 3 g tolevamer group, 0/12 in the 6 g tolevamer group and 4/15 in the vancomycin group [96]. These differences were not statistically significant, but this small study lacked power to demonstrate true differences in efficacy of these regimens, should they exist.

### Ion exchange resins

Although *in vivo* studies of two resins, cholestyramine and colestipol, demonstrated binding of cytotoxin (as well as some binding of vancomycin), and cholestyramine delayed death in the hamster model of clindamycin-induced cecitis [124] trials of ion exchange materials to bind toxins in humans have produced negative results. Colestipol was compared to placebo in a randomized, controlled trial in 38 patients with postoperative diarrhea. There was no difference in fecal excretion of *C. difficile* toxin, and treatment with ion exchange resins currently is not recommended [125]. **A1d** The study, however, lacks adequate power to show true differences between the treatment groups, should they exist.

### Probiotics

A meta-analysis of six randomized, controlled trials using probiotics combined with one of the two standard antibiotics to treat CDAD found that probiotics significantly reduced the risk of CDAD (combined RR = 0.59; 95% CI: 0.41, 0.85;  $p = 0.005$ ) [126]. **A1c** Although a variety of probiotic strains have been tested, most studies were not large randomized, controlled trials. It is important to note that the term “probiotic” covers a wide variety of bacterial and yeast strains, and clinical efficacy may be

linked to a specific strain. For example, not all *Lactobacilli* strains are equally effective probiotics for specific diseases. When considering efficacy of probiotics for any disease, it is important to link the clinical evidence with specific strains.

### *Saccharomyces boulardii*

There have been two double-blind randomized, controlled trials for the use of *Saccharomyces boulardii* and antibiotics for patients with recurrent CDAD (Table 20.2). In a trial in 168 patients with recurrent CDAD, standard antibiotics were combined with *Saccharomyces boulardii* or placebo [116]. Three antibiotic regimens were used for 10 days: vancomycin in doses of 2 g or 500 mg/d or metronidazole 1 g/d. At the end of the 10-day period either *Saccharomyces boulardii* or placebo (1 g/d for 28 days) were added to the antibiotic regimen. The patients were followed for two months for subsequent *Clostridium difficile* recurrences. A significant decrease in recurrences was observed only in patients treated with the high dose vancomycin and *Saccharomyces boulardii* treatment (16.7%) compared with patients who received high dose vancomycin and placebo (50%,  $p = 0.05$ ). **A1c** No significant reductions in recurrence rates in either the low dose vancomycin or metronidazole treatment groups, were observed in *Saccharomyces boulardii* treated patients, compared to placebo controls. No serious adverse effects were noted in any of these patients.

An earlier study had also indicated the efficacy of the combination treatment using a standard antibiotic (vancomycin or metronidazole) and *Saccharomyces boulardii* for patients with CDAD [27]. In this trial patients who received vancomycin or metronidazole in doses determined by the physician were randomized to receive either *Saccharomyces boulardii* (1 g/d) or placebo for 28 days. All patients were followed for two months for subsequent recurrences. Approximately half of the enrolled patients were experiencing their first episode and half had recurrent CDAD. In the 60 patients with recurrent CDAD the recurrence rate in patients who received *Saccharomyces boulardii* was 35% compared to 65% for patients in the placebo group ( $p = 0.04$ ). **A1d** In this small study vancomycin was not shown to be more effective than metronidazole, regardless of the dose or duration of treatment.

### *Lactobacillus rhamnosus* GG

*Lactobacillus* GG is another probiotic that has been reported to reduce CDAD recurrences in several case series and case reports [113, 127, 128]. A small randomized trial comparing *L. rhamnosus* GG ( $8 \times 10^{10}$  organisms/day) to placebo as an adjunctive to standard antibiotic therapy with vancomycin or metronidazole was terminated due to poor enrollment. The observed recurrence rates were 3/8 and 1/7 in the *Lactobacillus* and placebo groups [118].

## Fecal biotherapy

In an effort to replace the microflora disrupted by recurrent CDAD and antibiotic treatments, fecal enemas of normal stool contents have been administered to patients with recurrent CDAD [129–133]. However, no randomized, placebo-controlled trials have been performed. In the case reports describing the use of fecal enemas in a total of 87 patients with recurrent CDAD, 77 (89%) of the patients responded to fecal biotherapy [134]. **B4**

## Immunoglobulin

The use of immunoglobulin for patients with recurrent CDAD has been reported in the literature in small case series or case reports [135–137]. A phase 2 study of 79 patients who had toxin positive CDAD compared results in 18 patients given standard antibiotics and IV IgG treatment (200–300 mg/kg/d) with 61 controls who received standard antibiotics only. No significant differences in mortality (three died in each group) or colectomy (three in each group) were observed [138]. **B4**

Whey protein made from cows immunized with *C. difficile* is also being tested. In a phase 2 trial 77 CDAD patients were given anti-*C. difficile* whey protein concentrate in a dose of 5 g tid for 14 days after 10 days of treatment with vancomycin. No adverse effects were observed. Four of 63 (6.3%) patients experienced relapse within 46 days of completing this treatment [139]. Phase 3 trials are in progress. Another investigational approach is the use of a targeted immunoglobulin product specifically directed against *C. difficile* toxin. The safety and kinetics of neutralizing human monoclonal antibody against *C. difficile* toxin A is under study. In a phase 2 dose ranging study in 30 CDAD patients no serious adverse effects were noted [140]. Phase 3 trials are in progress.

## Treatment of asymptomatic carriers

Asymptomatic carriers of *Clostridium difficile* have been shown to be a source of new nosocomial cases of CDAD. In order to control the spread of *Clostridium difficile*, a policy of treating asymptomatic carriers has been tested by several investigators. However, treatment of asymptomatic carriers has not been found to reduce the incidence of CDAD and has not been shown to reduce the frequency of nosocomial outbreaks [141]. Bender *et al.* demonstrated that treatment of carriers with metronidazole was ineffective in reducing the incidence of new CDAD cases at a chronic care facility [142]. Delmee *et al.* were able to reduce the CDAD frequency in patients on a leukemia unit from 16.6% to 3.6% after all patients with *Clostridium difficile* were treated with vancomycin [143]. However, this study was not randomized and both symptomatic and asymptomatic

*Clostridium difficile* cases were treated. Johnson *et al.* treated 30 asymptomatic carriers of *Clostridium difficile* in a randomized, placebo-controlled trial with either vancomycin (1 g/d), metronidazole (1 g/d), or placebo [85]. Although vancomycin significantly reduced *Clostridium difficile* carriage at the end of the 10 days of treatment (10%) compared to either metronidazole (70%,  $p = 0.02$ ) or placebo (80%,  $p = 0.005$ ), the recurrence rate at the end of the two-month follow-up period was significantly higher (67%) in the vancomycin group compared to the placebo group (11%,  $p < 0.05$ ). **A1d** Although there are small randomized, placebo-controlled trials demonstrating the effectiveness of treating asymptomatic carriers, the overall evidence is not sufficiently strong to support a recommendation for the use of this intervention.

## Prevention

### Infection control

The importance of infection control practices for the prevention and control of nosocomial infections of CDAD and recurrent CDAD has been well documented [13, 26]. Studies documenting that 48–56% of clinical recurrences are new infections with a different strain of *Clostridium difficile* also add support to the importance of disrupting the nosocomial acquisition of new strains of *Clostridium difficile* in the hospital environment [15, 64, 144].

The most important intervention for prevention of CDAD is the interruption of the horizontal transmission of *Clostridium difficile*. Five aspects of infection control practices have been investigated: (1) environmental disinfection of contaminated surfaces or fomites, and medical equipment or use of disposable instruments, (2) reducing hand carriage by hospital care personnel, (3) isolation or cohorting of infected patients, (4) treatment of asymptomatic carriers and (5) multi-disciplinary approach using a combination of the above. None of these infection control practices has been evaluated in randomized, controlled trials, but most have been evaluated in the hospital environment using a defined intervention and have compared infection rates before and after the introduction of the intervention or have compared the results between a ward in which the intervention was introduced with those in a control ward in which the new intervention was not used.

Another strategy under investigation is vaccination of newly admitted patients at health care facilities using a vaccine against the toxins of *C. difficile*. One such vaccine, developed by Acambis, is currently under investigation in phase 3 trials. A small phase 2 study in 30 subjects showed that this vaccine was not associated with any serious adverse effects [145].

### Environmental disinfectants

Contamination of environmental surfaces by *Clostridium difficile* and its spores presents an extremely challenging problem for hospitals. The spores of *Clostridium difficile* can persist on surfaces or fomites for months and are not susceptible to normal room cleaning agents, and patients who are carriers of *Clostridium difficile* shed the spores onto a wide variety of hospital surfaces [4, 26, 146–148]. Several reviews have presented evidence that the use of environmental cleaning and an effective disinfectant has resulted in lower rates of health care associated CDAD [26, 149]. Mayfield *et al.* changed the type of room disinfectant used (to 1:10 hypochlorite solution) in rooms with 4252 bone marrow transplant patients and studied the incidence of CDAD [150]. The incidence of CDAD was 8.6 cases/1000 patient days before the intervention was introduced and decreased significantly to 3.3 cases/1000 patient days, (hazard ratio 0.37; 95% CI: 0.19–0.74). No similar decrease in the incidence of CDAD was noted for control wards where the new disinfectant was not tested. **B2** Struelens *et al.* found that the frequency of environmental positive isolation of *Clostridium difficile* fell significantly from 13% to 3% ( $p = 0.04$ ) after daily room disinfection was used (0.03% glutaraldehyde and 0.04% formaldehyde solution), along with a concurrent decrease in the incidence of CDAD cases [151]. Kaatz *et al.* used a phosphate buffered hypochlorite solution to disinfect hospital room surfaces during an outbreak of CDAD. The isolation rate for *Clostridium difficile* was 31.4% before and 0.6% after the hypochlorite disinfectant was introduced, and the outbreak ceased [152]. McMullen *et al.* compared room disinfection protocols in two intensive care units with high endemic rates of *C. difficile* [153]. The unit that followed a protocol using hypochlorite solution disinfection in all rooms within the unit (regardless of the location of a CDAD patient) exhibited a decline from 16.6/1000 to 2.8/1000 patient-days. However, the unit that only disinfected rooms with an infected CDAD patient also showed a significant decrease in CDAD rates from 10.4/1000 to 2.2/1000 patient days. The important conclusion is that hypochlorite disinfection appears to be effective, even when it is used only in rooms in which CDAD cases are located. **B2**

### Disinfection of medical equipment

Medical equipment that is used for patients infected with CDAD may become a source of new infections if not properly cleaned. Fiberoptic endoscopes have been shown to be a source of *Clostridium difficile*, but two studies found that exposure to 2% alkaline glutaraldehyde for five minutes resulted in 99% killing of *Clostridium difficile* on the surfaces [154, 155]. However, neither of these studies used a control group and they were not designed to document if the dis-

infection procedure resulted in fewer clinical cases of CDAD. Brooks *et al.* studied whether the replacement of electronic rectal thermometers, of which 21% had tested positive for *Clostridium difficile*, with single-use disposable thermometers resulted in lower rates of CDAD [156]. The incidence of *Clostridium difficile*-associated diarrhea decreased from 2.71/1000 patient days to 1.76/1000 patient days ( $p < 0.05$ ) after the introduction of disposable thermometers at the acute care hospital. A significant reduction of CDAD casea was also observed by Brooks *et al.* at a skilled nursing facility. Although this study was not a randomized trial, the pre and post-intervention measures were carried out using the same testing procedures and at the same institutions. **B4**

### Hand washing and disinfection

Nosocomial *Clostridium difficile* is frequently transmitted to other patients via the hands of hospital care personnel and visitors [4, 99]. Efforts to disrupt this method of transmission have included handwashing with disinfectants instead of non-disinfectant soaps, training programs on the importance of proper handwashing techniques, and the use of disposable gloves. In one prospective study, handwashing with 4% chlorhexidine gluconate resulted in a significantly lower isolation frequency of *Clostridium difficile* on the hand surfaces of tested hospital personnel (14%,  $p = 0.002$ ) compared to an isolation rate of 88% when non-disinfectant soap was used [4]. Currently, newer enteric precaution policies have included the use of vinyl disposable gloves. Three studies have documented that the use of gloves reduces the rate of *Clostridium difficile* isolation on the hands of health care personnel. In a study of 42 health care workers (doctors, nurses, physical therapists), the use of disposable gloves during the care of infected CDAD patients significantly reduced the rate of isolation of the hand carriage of *Clostridium difficile* from 58% prior to the use of gloves to 0% after the introduction of the requirement for wearing gloves ( $p = 0.04$ ) [4]. **B2** Johnson *et al.* tested the effectiveness of an educational program involving the use of disposable gloves on two wards assigned to the program and compared the results to two control wards [157]. The incidence of CDAD decreased from 7.7/1000 patient discharges before the program was started to 1.5/1000 during the six-month intervention ( $p = 0.01$ ). No significant decreases in CDAD were noted on the two control wards. **B2** Bettin *et al.* seeded 10 volunteers with *Clostridium difficile* and found that *Clostridium difficile* counts were significantly lower on gloved hands compared to bare hands, regardless of the type of handwashing agent used [158]. However, the effectiveness of limiting nosocomial spread of *Clostridium difficile* by handwashing or use of gloves as the sole control policy has not been tested in randomized, controlled trials.

Alcohol-based gels are effective for methicillin-resistant Staphylococcal elimination, but are not effective against spores of *C. difficile* [159, 160].

### Isolation or cohorting practices

Both asymptomatic and symptomatic infected patients increase the risk of nosocomial spread of *Clostridium difficile*. One control policy that has been investigated is the isolation of patients from the pool of susceptible uninfected patients in private rooms, or by “cohorting” patients who are infected with *Clostridium difficile* (or putting patients who are infected with *Clostridium difficile* in the same room). Boone *et al.* tested a new re-admission policy for patients who had been *Clostridium difficile* positive during a previous hospital stay [161]. These patients were screened for *Clostridium difficile* toxin shortly before or on admission and if positive, they were placed in isolation. The attack rate decreased from 13.3/1000 admissions before the policy was introduced to 8.7/1000. **B2** Another observational study of 428 patients admitted to a general medicine ward found that the *Clostridium difficile* acquisition rate tended to be higher in patients in double rooms (17/100) than in single rooms (7/100). **B4** However, it should be noted that these studies were not randomized, controlled trials. Most studies attempting to reduce the transmission of *Clostridium difficile* use the policy of private rooms or “cohorting”, but only as part of a multi-disciplinary approach rather than as an independent control policy.

### Antibiotic stewardship

Antibiotic stewardship programs are multi-disciplinary programs involving physicians, microbiologists, pharmacists and infection control practitioners, set protocols for prior authorization and concurrent review and feedback on antibiotic use. Health care systems, clinicians and patients need to be proactive in collaborative efforts. Valiquette *et al.* implemented an antimicrobial stewardship program during the Canadian outbreaks of 2005–2006 and decreased the use of target antibiotics by 54%, with a concurrent reduction in CDAD infection of 60% [162]. **B4** Increased infection control practices by themselves (2003–2004) did not appear to decrease CDAD rates.

Antibiotic restriction programs may also be effective in reducing CDAD rates. Three separate studies at Veterans' Affairs hospitals documented control of epidemics by restriction of clindamycin use. The first study from Tucson identified a five-fold increase in *C. difficile*, over half of which was associated with a single strain. Antibiotic use was analyzed and the introduction of a restriction on use of clindamycin was accompanied by a decrease in infection rates [38]. **B4** A second study at another VA medical center showed a prompt reduction in the frequency of CDAD

cases following introduction of a restricted clindamycin use policy. Although some more expensive antibiotics were used, net cost savings were realized, and isolates showed a return of clindamycin susceptibility [163]. A third study documented a decrease in CDAD following removal of several antibiotics from the hospital formulary [164]. **B4**

CDAD rates in an elderly care unit decreased following introduction of a restrictive antibiotic policy that specifically targeted cefuroxime use, substituting penicillin, trimethoprim and gentamycin for broad spectrum cephalosporins [165]. **B4**

Introduction of a restriction policy for injectable third-generation cephalosporins for elderly medical patients resulted in a significant reduction of CDAD cases from 4.5% of 2157 admissions before the policy to 2.2% of 2037 admissions during the antibiotic restriction policy [166]. **B2** No decrease in CDAD cases was observed in other wards used as controls.

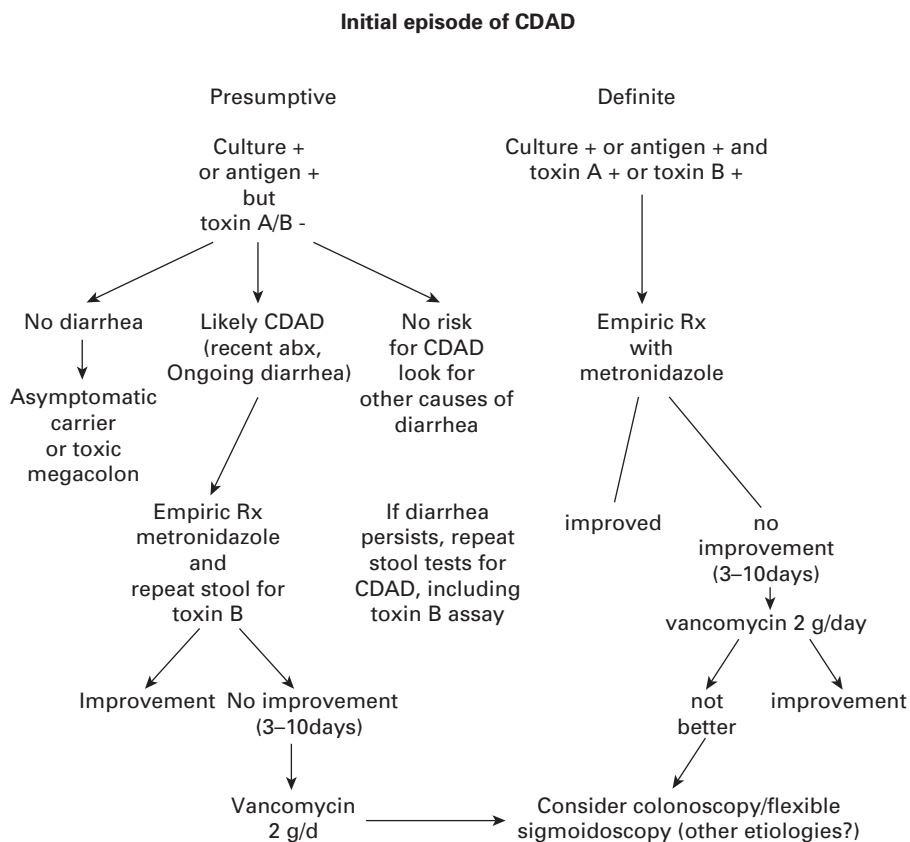

## Multi-disciplinary practices

Integrated, interdisciplinary infection control programs involving educational programs (handwashing, use of gloves, enteric precaution procedures), environmental disinfection and aggressive surveillance are effective in reduc-

ing CDAD rates. **B4** Struelens *et al.* demonstrated a significant reduction in new CDAD cases from 1.5 to 0.3 cases per 1000 discharges ( $p < 0.05$ ) after introduction of a control program consisting of intensive screening for *Clostridium difficile*, early enteric isolation precautions, rapid treatment of CDAD cases with vancomycin and room disinfection [151]. **B2** Brown *et al.* reported control practices including rapid patient isolation, treatment of CDAD cases and antibiotic restriction resulted in a decline of CDAD incidence from 2.2 % to 0.7% [75]. Bundled infection control programs (increased hand washing programs, environmental disinfection, antibiotic stewardship) have resulted in significant reductions of CDAD rates [159, 167–169], but randomized, controlled trials have not been published. Several reviews have presented evidence that the use of multi-disciplinary infection control programs have resulted in lower rates of nosocomial CDAD [26, 76, 149].

## Summary

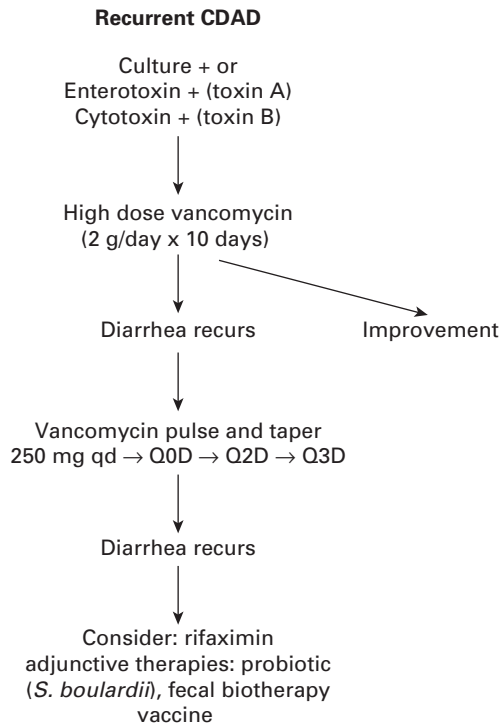

*Clostridium difficile*-associated diarrhea (CDAD) is an important cause of nosocomial outbreaks of gastrointestinal disease. Despite years of research regarding the pathogenesis and nosocomial transmission of this organism,

**Figure 20.1** Management of an initial episode of *Clostridium difficile*-associated diarrhea.

Abbreviations: CDAD: *Clostridium difficile* associated diarrhea; PMC: pseudomembranous colitis.

**Figure 20.2** Management of recurrent *Clostridium difficile*-associated disease.

Abbreviations: CDAD: *Clostridium difficile* associated diarrhea; QOD: every other day; Q2D: once every two days; Q3D: once every third day.

hospital outbreaks continue to occur. The management of patients with recurrent CDAD is appropriately focused more on efforts to clear the toxins of *Clostridium difficile* and restore the normal microbial flora. The treatment for this disease is complicated by the high frequency of asymptomatic carriers. Although these individuals contribute to spread of the disease, they should not be treated with antibiotics. Treatment strategies for the disease are dependent upon the individual patient's history of CDAD. Patients with an initial episode of CDAD may be treated equally well with either vancomycin 500 mg/day or metronidazole 1000–1500 mg/day (Figure 20.1), but the optimal management strategy has not been established in well-designed, randomized, controlled trials. Patients who develop the recurrent form of the disease may have a more difficult course, and the treatment choice is even less clear (Figure 20.2). Antibiotic treatment alone for recurrent CDAD may not be the optimal approach, since relapse remains a common problem, although prolonged vancomycin taper and pulsed doses demonstrate promise (Figure 20.2). There is evidence that combination therapy using vancomycin and a probiotic is also an effective treatment. More research is needed to investigate the value of other types of probiotics for recurrent CDAD and of other types of antibiotics for initial CDAD.

## Definition of irritable bowel syndrome

Irritable bowel syndrome (IBS) is a chronic functional disorder of the lower gastrointestinal (GI) tract characterized by abdominal pain or discomfort and disordered bowel habit [1]. Sufferers often report coexistent symptoms such as bloating, passage of mucus per rectum and a sensation of incomplete evacuation. In the last 30 years several symptom-based diagnostic criteria have been developed in an attempt to allow physicians to make a positive diagnosis of IBS without the need for recourse to invasive investigations of the GI tract to exclude organic disease. These include the Manning criteria, the Kruis scoring system, and the Rome criteria (Table 21.1).

The Manning criteria were first described in 1978 [2], when it was observed that individuals with an ultimate diagnosis of IBS following normal investigations of the lower GI tract were more likely to report certain individual symptom items than those who were found to have organic disease. These were lower abdominal pain relieved by defecation, a change in the frequency or form of stool associated with the onset of abdominal pain, patient-reported visible distension, the passage of mucus per rectum and a sensation of incomplete evacuation. The original authors did not recommend or validate a specific number of these criteria that should be used as a cutoff to diagnose IBS, but three or more are most often used in clinical practice.

The Kruis scoring system is a statistical model [3], and is used to predict the likelihood of a patient having IBS. It includes a combination of symptoms reported by the patient, signs recorded by the physician and laboratory tests (full blood count and erythrocyte sedimentation rate). A score of 44 or more is used as the cutoff to define the

presence of IBS. The model is complex and this may explain why it is little used, both in everyday clinical practice and in epidemiological surveys of the condition.

The Rome criteria were first proposed in 1990 [4]. These require the presence of abdominal pain or discomfort, which may or may not be relieved by defecation, in combination with either a change in the frequency or form of stool. The rationale for the development of these criteria was to allow a more reliable diagnosis of IBS to be reached, aid the development of specific therapies, reduce the ordering of unnecessary diagnostic tests, and help standardize the selection of patients for clinical trials of potential therapies for the condition [5]. From a research perspective, the Rome criteria have become increasingly important over the last 10 years, and have been revised in 1999 [6], and 2006 [1], to produce the Rome II and Rome III criteria. Whilst the process involved in developing and revising these criteria has been rigorous it has, for the most part, been based on literature review in order to allow a panel of experts to reach a consensus opinion, rather than on the results of well-designed prospective validation studies. The Rome criteria now allow the subclassification of individuals with IBS according to the predominant abnormality of stool pattern experienced: constipation; diarrhea; or those who have a mixed bowel pattern (previously termed alternating).

## Prevalence and incidence of irritable bowel syndrome

Irritable bowel syndrome is sufficiently common that between 3% and 22% of the general population report symptoms compatible with IBS in cross-sectional surveys [7–15]. The variability in reported prevalence is partly explained by the use of the various diagnostic criteria used to define IBS. Community based studies demonstrate a consistently higher prevalence when the Manning criteria are used than when the Rome criteria are utilized [7–9, 16].

**Table 21.1** Existing symptom-based diagnostic criteria and scoring systems for the diagnosis of irritable bowel syndrome.

Diagnostic criteria or model	Year described	Symptoms, signs, and laboratory investigations included in criteria or scoring system	Symptom duration required
Manning [2]	1978	Abdominal pain relieved by defecation Looser or more frequent stools with onset of pain Mucus per rectum Feeling of incomplete evacuation Patient-reported visible abdominal distension	No
Kruis [3]	1984	<b>Symptoms (reported by the patient):</b> Abdominal pain, flatulence, or bowel irregularity Description of abdominal pain as "burning, cutting, very strong, terrible, feeling of pressure, dull, boring, or 'not so bad' " Alternating constipation and diarrhea <b>Signs (recorded by the physician):</b> Abnormal physical findings and/or history pathognomonic for any diagnosis other than IBS Elevated erythrocyte sedimentation rate Elevated white cell count Anemia A history suggestive of blood in the stools	>2 years
Rome I [4]	1990	Abdominal pain or discomfort relieved with defecation, or associated with a change in stool frequency or consistency, <i>plus</i> two or more of the following on at least 25% of occasions or days: Altered stool frequency Altered stool form Altered stool passage Passage of mucus Bloating or distension	≥3 months
Rome II [6]	1999	Abdominal discomfort or pain that has two of three features: Relieved with defecation Onset associated with a change in frequency of stool Onset associated with a change in form of stool	≥12 weeks (need not be consecutive) in last one year
Rome III [1]	2006	Recurrent abdominal pain or discomfort ≥3 days per month in the last three months associated with two or more of: Improvement with defecation Onset associated with a change in frequency of stool Onset associated with a change in form of stool	Symptom onset ≥6 months prior to diagnosis

This difference may exist because the latter criteria are more restrictive and require minimum symptom duration of three months. The prevalence may also vary according to the demographics of the population under study. Irritable bowel syndrome is commoner in females [17, 18], and younger individuals [9, 19, 20] while the evidence for an effect of socioeconomic status on prevalence of IBS is conflicting [15, 21, 22]. The prevalence of IBS appears to be comparable among Western nations and those of the developing world and the Far East [9, 13, 23, 24], although there are fewer data available from the latter regions.

The prevalence of IBS is reported to remain relatively stable over short periods of time [11, 25, 26], with the reso-

lution of symptoms in some individuals matched by the onset of new symptoms in others. However, individuals readily change their subgroup, as defined by predominant stool pattern [27]. Over longer time-frames an increase in prevalence of IBS has been reported after 7 and 10 years of follow-up [28, 29]. The incidence of IBS is poorly reported. In a longitudinal study conducted in Sweden the three-month incidence was 0.2% [25]. A medical records review of a random sample of residents of Olmsted County, Minnesota, estimated that the incidence of clinically diagnosed IBS was 2 per 1000 adults per year [30]. Since many people with IBS do not seek health care, the true incidence may well be higher. In a more recent study, conducted in

almost 4000 individuals from a UK population based sample, the incidence was 1.5% per year during a 10-year period of follow-up [29].

### **Irritable bowel syndrome and health services**

Individuals with IBS are more likely to consume health care resources than those without GI symptoms [31]. Up to 80% of sufferers may consult their primary care physician as a result of symptoms [32, 33]. Factors that drive this choice are poorly understood, but symptom frequency and severity, fear of serious underlying illness, poor quality of life, and other coexisting functional GI diseases have all been shown to predict consultation behaviour [13–15, 32–35]. It has been estimated that IBS accounts for at least 3% of all consultations in primary care [35]. Of those who do consult a primary care physician, the majority are diagnosed and managed in primary care [36], but a significant proportion will be referred for a specialist opinion at some point [9, 10, 15, 33, 35].

The condition accounts for up to 25% of a gastroenterologist's time in the outpatient department [37], and medical treatment is considered to be unsatisfactory, with patients with IBS representing a significant financial burden to health services. Despite the recommendations made by various medical organisations for a diagnosis of IBS to be made on clinical grounds alone [38–41], rather than following attempts to exclude all possible organic pathology by exhaustive investigation, many patients with symptoms suggestive of IBS will undergo colonic investigation, performed presumably in an attempt to reassure both the patient and the physician due to the potential uncertainty that may surround the diagnosis [42], or incur other medical costs [31, 35]. The annual cost of drug therapy for IBS has been estimated at \$80 million in the USA [43]. In addition, patients with IBS are more likely to undergo unnecessary surgical procedures, with cholecystectomy, appendicectomy and hysterectomy rates two to three-fold higher than those observed in controls without IBS [44].

A recent systematic review of 18 studies from the UK and USA examined direct and indirect costs to the health service arising from IBS [45]. The authors estimated that IBS accounted for direct costs of between \$348 and \$8750 per patient per year, indirect costs of between \$355 and \$3344 per patient per year, and between 8.5 and 21.6 days of IBS-related sickness absence per patient per year.

### **Pathogenesis of irritable bowel syndrome**

There is no known structural, anatomical, or physiological abnormality that accounts for the symptoms that IBS suf-

ferers experience, and it seems unlikely that a single unifying mechanism explains them. It is more plausible that a combination of factors contributes to the abdominal pain and disturbance in bowel habit. Several proposed etiologies are discussed below.

### **Evidence for genetic susceptibility**

Irritable bowel syndrome aggregates within families. Relatives of a patient with IBS are almost three times more likely to report symptoms compatible with IBS than relatives of the patient's spouse [46]. Whether this is due to genetic susceptibility, shared childhood environment, or learned illness-behaviour is unclear. Twin studies demonstrate that there is a greater concordance of IBS in monozygotic versus dizygotic twins [47, 48]. However, having a parent with IBS was a stronger predictor than having a twin with IBS [48]. There is also evidence that children with a parent with IBS are more likely to report GI symptoms and have GI symptom-related absence from school [49]. There have been studies of various candidate genes [50, 51], but the results are conflicting, and their clinical significance is debatable.

### **Evidence for disturbed gastrointestinal motility**

Disturbances in GI motility are thought to play a role in IBS. Previous studies have demonstrated evidence of delayed gastric emptying [52], abnormalities in small bowel and colonic transit time [53], and an increase in colonic motility in response to meal ingestion in IBS [54]. However, these abnormalities are not always reproducible, cannot be used to aid diagnosis, and vary from patient to patient. Some of this variability may be related to the predominant stool pattern experienced by the patient, but as this pattern does not exhibit great stability during follow-up [27], it is conceivable that the disturbances themselves change with time.

### **Evidence for visceral hypersensitivity and abnormalities of central pain processing**

Abdominal pain in IBS is proposed to be related to visceral hypersensitivity, due to abnormal sensitisation of the peripheral and central nervous system. The cause of this sensitisation is unknown, but IBS sufferers report lower thresholds of pain during colonic, rectal and foregut stimulation [55, 56], with radiation to extra-abdominal sites. In addition, patients demonstrate enhanced activation of regions in the brain that are required for central pain processing in functional magnetic resonance imaging studies conducted during gut stimulation compared to controls [57, 58].

## Evidence for a post-infectious etiology and altered gut flora

There are numerous studies reporting an increase in symptoms that meet diagnostic criteria for IBS in individuals who have been exposed to an acute gastroenteritis of either bacterial or viral origin [59–61]. The development of post-infective IBS in one study was more likely to occur with younger age, female gender, and certain features of the initial acute illness, including bloody stools, abdominal pain and prolonged diarrhea [59]. Biopsies from the colon and terminal ileum of patients with post-infectious IBS demonstrate an increased inflammatory cell infiltrate [62], and when intestinal permeability is measured in these subjects it is increased compared to that of healthy individuals [63], which may allow luminal gut bacteria to activate an immune response in the GI mucosa, thereby leading to chronic low-grade inflammation in a subset [64].

The existence of post-infectious IBS has led to an increased interest in possible abnormalities in gut flora as a cause for the condition. Some investigators have reported altered gut flora in subjects with IBS compared to healthy controls [65], and others have reported a higher prevalence of small intestinal bacterial overgrowth in IBS patients than controls, as demonstrated by lactulose and glucose hydrogen breath testing [66, 67], as well as an improvement in symptoms after therapy with non-absorbable antibiotics [68].

## Making a diagnosis of irritable bowel syndrome

The assessment of a patient with suspected IBS should begin with a structured history to assess whether the individual's symptoms are compatible with the diagnosis. In a patient presenting with lower GI symptoms it is important to elicit the presence of alarm (red flag) symptoms such as weight loss, diarrhea and rectal bleeding as, if these are present, they are thought to predict colorectal cancer and therefore require urgent lower GI investigation, though their diagnostic utility in this situation is suboptimal [69]. Physical examination, including digital rectal examination, is unlikely to confirm the diagnosis of IBS, but should be conducted in order to exclude other organic causes of lower GI symptoms and, if normal, may reassure both the physician and patient.

## Utility of a physician's diagnosis

As all the current available symptom-based diagnostic criteria for IBS have been developed by gastroenterologists in secondary or tertiary care, their generalisability to patients presenting to a primary care physician is debatable. A con-

sensus panel reported that existing criteria were insufficiently broad for use in primary care [70], and a recent survey demonstrated that few physicians in primary care were familiar with these criteria, or used them to make a diagnosis of IBS, yet could still diagnose the condition with confidence using a pragmatic approach [71]. Guidelines for the management of IBS in primary care still advocate the use of diagnostic criteria [40, 72]. Unfortunately, there are no published studies reporting on the utility of a physician's opinion in making a diagnosis of IBS.

## Utility of individual lower gastrointestinal symptoms

The prevalence of symptoms such as lower abdominal pain, mucus per rectum, incomplete evacuation, looser or more frequent stools at the onset of abdominal pain, patient-reported visible distension and pain relieved by defecation has been reported in individuals with IBS compared to individuals without the syndrome [2–3, 73–76]. Unfortunately, nocturnal diarrhea, a symptom that is often used by physicians when taking a clinical history, as an indicator of organic disease, was not studied. Since none of the other lower GI symptoms has good sensitivity or specificity for making the diagnosis of IBS [77], combinations of symptoms, in the form of symptom based diagnostic criteria, have been recommended as a means of reaching a clinical diagnosis.

## Utility of symptom based diagnostic criteria

### Utility of the Manning criteria

The Manning criteria have been validated prospectively in three subsequent studies since their original description in 1978 [75, 76, 78]. Therefore in total they have been validated in over 500 patients. They performed best in the original validation study [2], but also performed well in a study conducted in secondary care in Turkey [78]. However, they performed poorly in the two other studies in India [76] and Korea [75]. A recent systematic review of pooled data from these four studies assessed the utility of the Manning criteria in predicting a diagnosis of IBS [77]. The presence of three or more of the Manning criteria appeared to increase the likelihood of IBS almost three-fold, while if only two or fewer criteria were present the likelihood of the diagnosis was reduced by over 70%.

### Utility of the Kruis scoring system

The utility of the Kruis scoring system has also been examined prospectively in three studies published since the original report in 1984 [73, 78, 79]. When data were pooled from all four studies [77], containing almost 1200 patients, a Kruis score of 44 or more increased the likelihood of IBS eight-fold, whilst a score less than 44 reduced the likeli-

hood of the diagnosis by 70%. Whilst the Kruis score appears to have good utility in confirming a diagnosis of IBS, it is probably too complex to be used in routine clinical practice. In addition, one of the items it collects, “a history pathognomonic for any diagnosis other than IBS”, and the fact that symptom duration is required to be in excess of two years, probably account for its higher utility than the Manning criteria, which do not require minimum symptom duration.

### Utility of the Rome criteria

Only one study has validated the Rome I criteria in a tertiary care setting in the UK [80]. The Rome I criteria had a sensitivity of 71%, a specificity of 85%, and their presence in a patient made a diagnosis of IBS four times more likely [77]. The Rome III criteria were validated in questionnaire form prior to their publication in two studies, using a group of patients with functional GI disorders as well as population controls, and were reported to have sensitivity of 71% and specificity of 88% for the diagnosis of IBS, as well as good test-retest reliability [81]. However, there have been no published studies that have validated either the Rome II or Rome III criteria prospectively, so their utility is relatively unknown. Given that the Rome I criteria were first described almost 20 years ago, and the Rome II criteria 10 years ago, the lack of validation is disappointing, particularly as these have become the gold standard, in research terms, for making a clinical diagnosis of IBS.

### Role of investigations in excluding organic disease in patients meeting diagnostic criteria for irritable bowel syndrome

Patients with IBS may have a degree of symptom overlap with individuals with organic diseases. Thyroid disease, celiac disease, inflammatory bowel disease, microscopic colitis, lactose intolerance, small intestinal bacterial overgrowth and even colorectal cancer, in the absence of alarm symptoms, may all present with similar symptoms. As we have discussed, current diagnostic criteria are not infallible, so there may be some value to performing a limited number of clinical investigations in individuals with suspected IBS in order to exclude organic diseases that may present in a similar manner. There have been numerous studies conducted in subjects meeting diagnostic criteria for IBS that have examined the role of applying various diagnostic tests, and which report the prevalence of organic disease in these individuals (Table 21.2). The available evidence is summarized below.

### Role of lower gastrointestinal investigations in irritable bowel syndrome

Five studies have reported findings following lower GI investigation in patients with IBS defined according to

various diagnostic criteria [79, 82–85]. Three of these utilized complete colonic investigation in over 600 patients, two with either full colonoscopy, or barium enema in combination with flexible sigmoidoscopy [83, 85], and one with either full colonoscopy or barium enema alone [79]. Only seven patients (1.1%) had an organic explanation for their symptoms, such as inflammatory bowel disease or colorectal cancer, after complete colonic investigation. One study used complete colonic investigation in patients aged over 50, and flexible sigmoidoscopy alone in the under 50s [84]. The study included 306 patients with IBS, according to the Rome I criteria, and only four (1.3%) had organic disease after investigation. Finally, one study used flexible sigmoidoscopy with routine rectal biopsy in 89 IBS patients [82]. None of these patients had organic disease diagnosed following this. This observation is in contrast to a series of patients diagnosed with microscopic colitis between 1985 and 2001 from Olmsted County, Minnesota, 40% to 55% of whom reported symptoms that met the Rome or Manning criteria, and one-third had been previously labeled as having IBS [86]. It appears, therefore, that colonic investigation has a very low yield in patients presenting with symptoms that are highly suggestive of IBS in the absence of alarm features.

### Role of celiac antibodies and distal duodenal biopsy in irritable bowel syndrome

Several case-control studies have examined the role of testing for celiac disease in patients meeting diagnostic criteria for IBS, but the results are conflicting. Studies from the UK and Iran have demonstrated an increased prevalence of positive celiac serology and biopsy-proven celiac disease in individuals with IBS [87–89], as defined using the Rome II criteria, compared to controls, but data from studies conducted in the USA and Turkey do not support this association [90–92]. Of the available current guidelines for the management of IBS, only those from the National Institute of Health and Clinical Excellence in the UK, which are written from a primary care perspective, recommend routinely screening for celiac disease, using serology, in patients with suspected IBS [40].

A recent systematic review and meta-analysis has examined this issue [93]. Pooled prevalence of positive IgA-class anti-gliadin antibodies was 4% in subjects meeting diagnostic criteria for IBS in seven studies. Six were case-control studies, and the odds of a positive test in cases was three-fold that of controls. Pooled prevalence of positive anti-endomysial antibodies or tissue transglutaminase was 1.6% in subjects meeting diagnostic criteria for IBS in 13 studies. Seven of these were case-control studies, with an odds ratio of almost 3 for a positive test in those meeting diagnostic criteria for IBS. The pooled prevalence of biopsy-proven celiac disease, following positive serology of any type, was 4% in seven studies. Five of these were case-

**Table 21.2** Yield of investigations in subjects meeting diagnostic criteria for irritable bowel syndrome.

Investigation used	Number of studies	Number of subjects meeting diagnostic criteria for IBS	Number with organic disease after investigation applied (%)
Complete colonic imaging	3	636	7 (1.1)
Complete colonic imaging for 50 years and over, flexible sigmoidoscopy for under 50s	1	306	4 (1.3)
Flexible sigmoidoscopy and rectal biopsy	1	89	0 (0)
IgA-class antigliadin antibodies	7	1104	36 (3.3)
Anti-endomysial or tissue transglutaminase antibodies	13	2021	41 (2.0)
Celiac serology of any type followed by distal duodenal biopsy if positive	7	1464	62 (4.2)
Lactose hydrogen breath testing	7	2149	756 (35)
Lactulose hydrogen breath testing	4	612	379 (62)
Glucose hydrogen breath testing	2	208	75 (36)
Jejunal aspirate and culture	1	162	7 (4.3)
Full blood count	2	496	1 (0.2)
C-reactive protein/erythrocyte sedimentation rate	1	300	3 (1)
Thyroid function tests	5	2160	91 (4.2)
Stool ova, cysts and parasites	2	1324	19 (1.4)
Barium meal and follow-through	1	114	1 (0.9)
Abdominal ultrasound scan	1	125	22 (18)

control studies, and the odds of biopsy-proven celiac disease in cases meeting diagnostic criteria for IBS was over four-fold that of controls. The odds of biopsy-proven celiac disease were not significantly different in those with constipation-predominant, diarrhea-predominant, or mixed bowel pattern, suggesting that screening for celiac disease should not be reserved for individuals with diarrhea-predominant IBS.

The pooled prevalence of biopsy-proven celiac disease in individuals meeting diagnostic criteria for IBS was estimated to be between 2% and 7% [93]. The true prevalence may be higher in these studies for several reasons. First, only individuals with positive serology were offered duodenal biopsy. Second, studies did not screen these individuals for IgA deficiency, which can lead to false negative serological tests. Third, a recent report has demonstrated that the sensitivity of serology is substantially lower in individuals who do not have total villous atrophy on duodenal biopsy [94]. Economic modelling studies suggest that if the prevalence of celiac disease in subjects meeting diagnostic criteria for IBS were between 5% and 8% then screen-

ing using serology, with duodenal biopsy for those testing positive, could be cost-effective depending on the willingness to pay, with a cost per quality adjusted life year gained of \$5000 [95, 96]. These data indicate that testing for celiac disease in patients with suspected IBS may be a worthwhile strategy.

### Role of testing for lactose intolerance in irritable bowel syndrome

Seven studies have screened IBS patients for lactose intolerance using lactose hydrogen breath testing [83, 84, 97–101]. Two studies conducted in Italy reported a prevalence of lactose intolerance in excess of 60% among those meeting diagnostic criteria for IBS [97, 100], but in the majority of studies the prevalence was around 25%, although in one study it was only 4% [101]. Of these seven studies, three were case-control studies [97, 98, 101], two of which used healthy controls from the general population [97, 101], and the third used healthy volunteers from among hospital staff [98]. Again results were conflicting, with one study suggesting a five-fold increase in lactose intolerance in IBS

subjects compared to controls, one study showing no difference in prevalence between the two, and the third a more modest increase in prevalence in cases with IBS. The data to support the role of lactose hydrogen breath testing in IBS are therefore conflicting, and at present no recommendation for the routine exclusion of lactose intolerance can be made.

### **Role of testing for small intestinal bacterial overgrowth in irritable bowel syndrome**

Small intestinal bacterial overgrowth has been proposed as a possible etiological factor in IBS. Lactulose and glucose hydrogen breath tests, and jejunal aspirate and culture, have been utilized in suspected IBS patients. Three studies have demonstrated a positive lactulose hydrogen breath test in 50–80% of patients with IBS defined according to the Rome I or II criteria [67, 102, 103], whilst the prevalence of a positive glucose hydrogen breath test has been reported to be between 30% and 40% in patients defined by Rome II criteria [66, 104]. These studies have caused considerable interest, and as a result of their findings antibiotics, such as rifaximin, have been used for the treatment of IBS [68]. However, a Swedish case-control study has reported that the prevalence of small intestinal bacterial overgrowth, following jejunal aspirate and culture, is no higher in subjects meeting the Rome II criteria for IBS than in healthy controls from the general population [105]. Only 7 (4%) of 162 IBS patients had a positive culture compared to 1 (4%) of 26 controls. These data are supported by a large case-control study conducted recently in the USA [106], in which the prevalence of a positive lactulose hydrogen breath test was equally high between IBS patients defined by Rome II criteria and healthy controls, suggesting that the high rates of positive breath testing may not be specific to individuals with IBS.

### **Role of blood tests in irritable bowel syndrome**

Several studies have reported on the yield of certain blood tests in suspected IBS patients [83, 84, 87, 107, 108]. Two of these reported on the utility of a full blood count [83, 87], but only one patient had an organic explanation for their symptoms, biopsy-proven celiac disease, after applying the test. Five studies have utilized thyroid function tests in IBS [83, 84, 87, 107, 108]. When data from these studies are combined, 91 (4.2%) of 1860 IBS patients had abnormal thyroid function. One study performed C-reactive protein and erythrocyte sedimentation rate in 300 IBS patients, only three of whom had organic disease after applying the tests [87]. A panel of blood tests, often performed when patients with IBS are first seen in the outpatient clinic, therefore has a low yield in detecting organic disease in this situation. However, it would appear that the routine checking of thyroid function in subjects meeting diagnostic criteria for IBS is a reasonable strategy.

### **Role of stool examination**

Two studies, which used the Rome I criteria and the International Congress definition of IBS [83, 84], tested stool for ova, cysts and parasites in over 1300 patients with suspected IBS. Of these, only 19 (1.4%) had a positive result. In one study none of the subjects meeting diagnostic criteria for IBS patients had a positive test.

### **Role of other abdominal investigations**

Only one study has reported on the utility of abdominal ultrasound scan in 125 individuals with Rome I IBS [109]. Of these subjects, 22 (18%) had abnormal ultrasound findings, 6 (5%) of whom had gallstones. However, the detection of gallstones did not lead to a revision of the diagnosis of IBS in any of the included patients. One study used barium meal and follow-through in 114 patients meeting Rome I criteria for IBS [107]. Only one patient was found to have Crohn's disease after investigation. These limited data do not support the routine use of either of these investigations in the diagnostic workup of patients with suspected IBS.

### **Summary**

There remains some uncertainty surrounding the diagnosis of IBS for both the patient and clinician. Despite the fact that many physicians, particularly those in primary care, are either unaware of or do not use current recommended diagnostic criteria for IBS, there is no evidence that IBS can be reliably diagnosed using a physician's opinion. Individual symptom items from the clinical history are unsatisfactory. Of the current symptom-based diagnostic criteria, the Manning criteria perform only modestly well overall, and less well in the two of the three prospective studies conducted since the original validation was performed. There are few data to support the use of the Rome I criteria, and no studies have validated the Rome II or III criteria, which is disappointing given that the latter are the current gold standard for the diagnosis of IBS. The best evidence appears to exist for the Kruis scoring system, although this system is probably too unwieldy for everyday use. Either further well-designed studies are required to validate current diagnostic criteria, or more accurate ways of diagnosing IBS without the need for investigation need to be developed.

In terms of investigating individuals with symptoms suggestive of IBS, there is limited evidence for a routine panel of blood tests, and more invasive investigations such as colonoscopy, breath testing, or barium studies appear to either have a very low yield, or have limited discriminatory value between IBS patients and normal individuals. In addition, the vast majority of studies have been conducted in secondary care settings, where the yield of organic disease is likely to be higher, and the findings should not

be extrapolated to patients presenting to a primary care physician with symptoms suggestive of IBS. Current evidence does suggest, however, that screening all individuals with suspected IBS for thyroid dysfunction and celiac disease, with distal duodenal biopsy in those with positive serology, is a worthwhile strategy.

## Treatment of irritable bowel syndrome

As IBS is a prevalent condition, with a chronic, relapsing and remitting course physicians need to have effective therapies available to them in order to drive down the costs of consultation and investigation in sufferers. Unfortunately, many of the traditional therapies, when studied in randomized controlled trials (RCTs), have shown variable efficacy in terms of their effect on resolution or cure of symptoms and follow-up in many cases has been limited to two or three months. In addition, newer agents such as the 5-hydroxytryptamine (5-HT) receptor agonists and antagonists, which showed initial promise, have been withdrawn due to concerns over their safety profile, though some of these are now available on a restricted use basis. Data from individual RCTs of various therapies are conflicting in many cases, and systematic reviews and meta-analyses do not always produce consistent evidence of benefit [110–117]. However, recently a number of systematic reviews and meta-analyses have been completed as part of the update of the American College of Gastroenterology's monograph on IBS [118], and have demonstrated some clinically useful results.

### Efficacy of fiber in irritable bowel syndrome

Traditionally, patients with IBS were told to increase the amount of fiber in their diet, due to potentially beneficial effects on intestinal transit time [119]. However, evidence for any benefit on global IBS symptoms from individual placebo-controlled trials has been conflicting [120–123], although many of these studies are small and may have lacked sufficient power to detect a significant benefit, should one exist. Previous systematic reviews have also disagreed on whether fiber has any therapeutic effect [110, 114, 117], and current guidelines for the management of IBS make varying recommendations concerning the role of fiber [38–41]. The use of insoluble fiber, such as bran, is generally discouraged due to concerns that it may exacerbate symptoms, particularly pain and bloating.

A recent systematic review and meta-analysis identified 12 placebo-controlled trials of fiber in IBS [124]. The main results of the meta analysis are shown in Figure 21.1. Overall, there appeared to be a modest benefit of fiber supplementation in IBS, with a number needed to treat (NNT) of 11. However, this effect was limited to ispaghula, a

soluble fiber, with a number needed to treat of 6. Insoluble fiber did not lead to any improvement in symptoms of IBS, though there was no convincing evidence that it worsened symptoms when data were pooled. Adverse events were very rare.

Unfortunately, the method of concealment of allocation was not reported in any of the trials, which may have led to an overestimation of the efficacy of fiber in IBS [125]. In addition, none of the trials adhered to the recommendations of the Rome committee for the design of trials of therapies for the functional GI disorders [126], most having been designed and conducted before these were published. Despite the methodological limitations of many of these RCTs, ispaghula is cheap and available over the counter, so it is probably a worthwhile first-line agent in patients with constipation-predominant IBS. **A1c**

### Efficacy of antispasmodics and peppermint oil in irritable bowel syndrome

The pain, discomfort and altered bowel habit that IBS sufferers report may result from a combination of altered GI motility, smooth muscle spasm, visceral hypersensitivity and abnormalities of central pain processing [54, 56, 127]. Smooth muscle relaxants could therefore ameliorate some of the symptoms of IBS. Numerous antispasmodic agents have been studied, but the existing RCTs have produced disparate results [128–131]. Peppermint oil may also have antispasmodic properties [132]. In contrast to antispasmodics, the available RCT evidence for peppermint oil shows definite benefit [133–136].

A systematic review and meta-analysis identified 22 placebo-controlled trials of various antispasmodics in IBS [124], and demonstrated an overall benefit with active therapy, with NNT = 5 (Figure 21.2). There were significantly more adverse events in participants randomized to antispasmodics, though the majority consisted of dry mouth, dizziness, and blurred vision, and none were serious. When subgroup analyses were conducted according to the type of antispasmodic used, it became apparent that many of the antispasmodics that are most commonly used in clinical practice, such as mebeverine, alverine and dicycloverine had little or no evidence of efficacy in IBS. The best evidence, in terms of the number of patients studied, appeared to exist for otilonium (435 patients) and hyoscine (426 patients), with NNT = 5 and 4 respectively. **A1a** When data were pooled for the four RCTs of peppermint oil in a systematic review, there was evidence of a clear benefit, NNT = 3 (Figure 21.3) [124]. **A1a** Adverse events with peppermint oil were very rare, and not more frequent than were observed with placebo.

Again, the majority of these studies predated the Rome recommendations for RCTs of therapies for IBS [126], and none reported the method of concealment of allocation, so

the number needed to treat may well be higher. The rationale for the efficacy of these drugs in IBS is speculative. Diarrhea-predominant IBS patients have a reduced colon diameter and accelerated small bowel transit on magnetic resonance imaging [137], so it may be that antispasmodics have their beneficial action via a combination of reduced colonic contraction and transit time, which may in turn lead to reduced pain and stool frequency. Peppermint oil has been shown to have antagonistic effects on the calcium channel [132], and may bring about smooth muscle relaxation, and therefore reduced contractility and pain.

As with ispaghula, antispasmodics and peppermint oil are cheap, and the latter is available over the counter. These therapies should probably be used as first-line interven-

tions for diarrhea-predominant IBS, although most of the trials predated the creation of these diagnostic subgroups, eliminating the possibility of analysis according to predominant stool pattern. **A1a** These agents may also benefit individuals whose predominant symptoms are either pain or bloating. Of the available antispasmodics, the strongest evidence base exists for hyoscine.

### Efficacy of antidepressants in irritable bowel syndrome

Patients with IBS demonstrate visceral hypersensitivity [56, 127], and exhibit lower pain thresholds to balloon distension of the rectum than normal individuals [56].

**Figure 21.3** Forest plot of randomized controlled trials of peppermint oil versus placebo in irritable bowel syndrome.

Antidepressants are often used to treat chronic pain, due to their modulatory effects on pain perception, and previous systematic reviews have demonstrated their efficacy in this situation [138, 139]. For these reasons, it has been postulated that tricyclic antidepressants (TCADs) or serotonin re-uptake inhibitors (SSRIs) may be beneficial in IBS, but existing data from both RCTs [140–143], and systematic reviews and meta-analyses are conflicting [113, 114, 117]. Therefore, recommendations made in IBS management guidelines are equivocal [38–41].

There has been a recent systematic review and meta-analysis identifying 13 RCTs of antidepressant therapy in IBS, reporting a number needed to treat with antidepressants of four [144]. It appeared that both TCADs and SSRIs were effective, with NNT = 4 (Figure 21.4). **A1a** Adverse events were commoner in those receiving active therapy, though this difference was not statistically significant, and none were serious.

Trials of antidepressant therapy were generally of higher quality than those of fiber, antispasmodics and peppermint oil. Imipramine has been shown to prolong orocecal transit time, whilst paroxetine reduces it [145]. It could be hypothesized, therefore, that TCADs will work better in diarrhea-predominant IBS and SSRIs in patients with the constipation-predominant pattern. **C5** Unfortunately, the majority of trials did not report data according to predominant stool pattern reported by the patient, so it was not possible to examine this issue in the systematic review. An alternative explanation for the beneficial effect of antidepressants in IBS is the treatment of coexistent depression. However, improvements in IBS symptoms did not correlate with depression scores in the included RCTs that reported these data, as is also the case for their effects in neuropathic pain [139].

As the RCTs identified in the systematic review used several different TCADs and SSRIs, it is difficult to know

if this is a true class effect, or whether the benefit is limited to specific drugs within these groups. Individual trials that demonstrated the greatest benefit of TCADs over placebo used amitriptyline, trimipramine and imipramine [142, 146, 147], whilst for SSRIs RCTs using fluoxetine, citalopram and paroxetine all demonstrated a greater efficacy than placebo [141, 143, 148]. It would therefore seem reasonable to use a TCAD, such as amitriptyline, in subjects with diarrhea-predominant IBS who do not respond to antispasmodics or peppermint oil, or an SSRI, such as citalopram, in constipation-predominant patients who have failed therapy with ispaghula. **C5**

### Efficacy of probiotics in irritable bowel syndrome

The role of altered gut flora in IBS is controversial [149], but there are studies that have demonstrated changes in intestinal microbiota in IBS patients compared to controls [65]. In addition, there have been many reports of new onset of symptoms compatible with IBS following acute bacterial and viral gastroenteritis [61]. Probiotics, which are live, or attenuated bacteria, or bacterial products that are beneficial to the host, have the potential to alter gut flora and have been shown to reduce the risk of antibiotic-associated diarrhea [150], and traveller's diarrhea [151], and to reduce the duration of acute illness in acute gastroenteritis [152]. They may have a beneficial effect on symptoms of IBS through a similar mechanism of action.

The effect of probiotics on IBS has been the subject of numerous RCTs, but results have been conflicting. A systematic review and meta-analysis identified 10 RCTs reporting dichotomous outcome data, and 15 RCTs reporting the effect of probiotics on overall IBS symptom scores [153]. The NNT for probiotics to improve or cure one patient's IBS symptoms was four, though there was statisti-

**Figure 21.4** Forest plot of randomized controlled trials of antidepressants versus placebo in irritable bowel syndrome. Ford AC, Talley NJ, Schoenfeld PS, *et al.* Efficacy of antidepressants and psychological therapies in irritable bowel syndrome: systematic review and meta-analysis. *Gut* 2009; **58**: 367–378.

cally significant heterogeneity, possibly associated with the clinical heterogeneity inherent in the use of many different probiotics in these studies. Global IBS symptom scores were also reduced by a significantly greater amount with probiotics than with placebo, symptom scores for abdominal pain were significantly reduced, and there was a trend towards a reduction in bloating scores. When subgroup analyses were conducted to examine the effect on symptom status according to the probiotic preparation used, there were no significant differences detected between *Lactobacillus*, *Bifidobacterium*, *Streptococcus* and combinations of probiotics. When effect on symptom scores was assessed, it appeared that combinations of probiotics had the greatest effect, followed by *Bifidobacterium*, with *Lactobacillus* having no effect.

How probiotics may exert their effects on patients with IBS is unclear, but animal models have demonstrated attenuation of post-infective intestinal dysmotility and improve-

ments in visceral hypersensitivity with probiotics [154–156]. Certain strains of probiotics have demonstrated the ability to induce the expression of cannabinoid and opioid receptors on intestinal cells [157], and to reduce circulating levels of cytokines [158]. These properties may explain possible benefits in IBS, by leading to a reduction in both visceral hypersensitivity and inflammation.

It would appear from the available evidence that probiotics are more effective than placebo in IBS. They may be of use as second-line interventions in individuals with particularly troublesome abdominal pain and bloating. **A1c**

**Efficacy of psychological therapies in irritable bowel syndrome**

Subjects with IBS are more likely to report a low quality of life [159–161], and have a higher prevalence of mood disorder, anxiety and neuroticism than patients with organic

disease or healthy controls [162]. Studies of IBS patients consulting in tertiary care settings have shown that a significant proportion have an underlying psychiatric illness [163, 164]. Even individuals who do not consult a physician with symptoms have higher levels of depression than normal subjects [165, 166]. Psychological interventions, such as cognitive behavioural therapy (CBT) [167, 168], relaxation therapy [169, 170], dynamic psychotherapy [171, 172] and multi-component psychological therapy [173, 174] have all been used in IBS. A previous systematic review identified 17 studies [175], 10 of which provided extractable dichotomous data, and reported an NNT of two for these interventions to improve or cure one patient's symptoms. However, there were less than 200 patients in total included in these ten studies, and nine of these were published by the same group of researchers, meaning that the validity of the findings of this review are questionable.

A more recent systematic review and meta-analysis published in 2008 identified 20 RCTs of psychological therapies in almost 1300 IBS patients [144]. The results are shown in Figure 21.5. When data from all studies were pooled the NNT was four, but there was significant heterogeneity between studies and evidence of publication bias, suggesting that this may be an overestimate of the treatment effect. In addition, there were nine studies emanating from the same centre, and when these were excluded from the analysis, the treatment effect was lower, but still statistically significant.

There appeared to be a beneficial effect of CBT, hypnotherapy, multi-component psychological therapy, and dynamic psychotherapy, but no effect was demonstrated for relaxation therapy or stress management. The largest number of trials studied CBT, and it may be that this modality has the greatest efficacy, but when the three RCTs originating from the same centre were excluded from the analysis the effect of CBT on IBS symptoms in the remaining four trials was no longer statistically significant. These interventions are time-consuming and expensive, and may not be cost-effective as an initial management strategy for IBS. As a result, they should be reserved for individuals who are unresponsive to, or intolerant of, more conventional therapies. **A1d**

### Efficacy of 5-HT<sub>3</sub> antagonists and 5-HT<sub>4</sub> agonists in irritable bowel syndrome

Abnormal levels of 5-hydroxytryptamine have been demonstrated in individuals with IBS, and this plays an important role in GI motility and sensation [176]. Pharmaceutical agents that act on this receptor have therefore been developed as a potential treatment for IBS. Alosetron, a 5-HT<sub>3</sub> antagonist, and tegaserod, a 5-HT<sub>4</sub> agonist, showed initial promise for the treatment of diarrhea and constipation-predominant IBS respectively, particularly in females [177–

180]. Unfortunately, both of these drugs demonstrated serious adverse effects during subsequent routine clinical use, with alosetron causing a number of cases of ischaemic colitis and severe constipation [181], and tegaserod being associated with an excess of cardiac and cerebrovascular ischaemic events [182]. As a result, both were withdrawn by the manufacturers, though alosetron is now available on a restricted use basis. Other agents that act on the 5-HT receptor that have been studied in IBS include cisapride, which is also only available on a restricted basis due to concerns about cardiovascular adverse effects.

Systematic reviews and meta-analyses conducted as part of the American College of Gastroenterology's monograph on IBS have studied the efficacy of all available 5-HT<sub>3</sub> antagonists and 5-HT<sub>4</sub> agonists [183]. Both alosetron and cilansetron were more effective than placebo in IBS, with numbers needed to treat of eight and six respectively [183]. Tegaserod was also more effective than placebo in 11 RCTs, with a number needed to treat of 10 [183]. Neither cisapride or renzapride appeared to have any benefit over placebo in IBS.

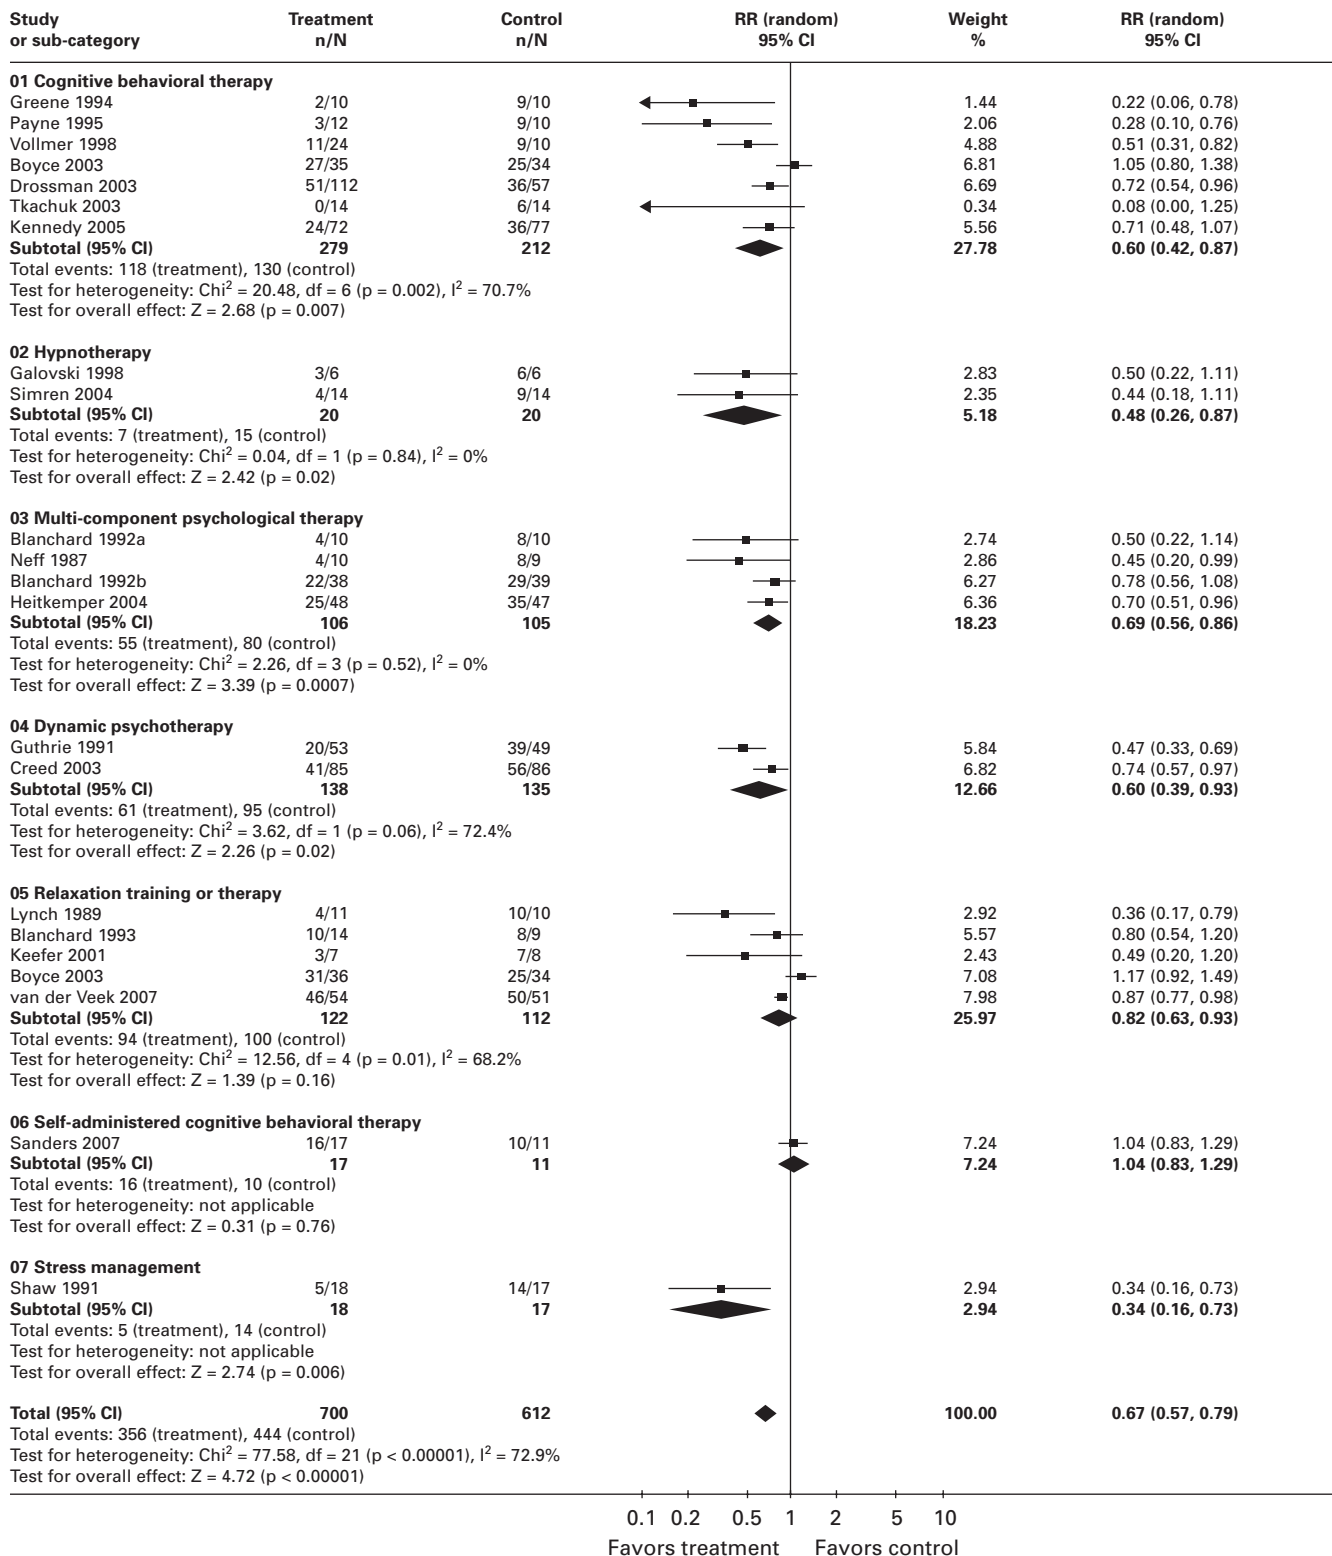

The NNTs for these agents are higher than those for ispaghula, antispasmodics, peppermint oil, antidepressants and psychological therapies. However, this may be due, in part, to the much higher quality of RCTs of 5-HT<sub>3</sub> antagonists and 5-HT<sub>4</sub> agonists [184], and adherence to the Rome committee recommendations for the design of treatment trials for functional GI disorders [126]. Due to their adverse safety profile, these drugs cannot be recommended as first-line therapies for the management of IBS and, where available, should probably be held in reserve for patients non-responsive to first-line therapies. **A1a**

### Efficacy of lubiprostone in irritable bowel syndrome

Lubiprostone is a prostaglandin E<sub>1</sub> derivative that activates a specific chloride channel in the GI tract, causing increased fluid secretion, and thereby improving GI transit. The drug has been used in chronic idiopathic constipation, and has been shown to be effective, leading to a significant improvement in patient-reported spontaneous bowel movements [185]. Recent trials have demonstrated both a statistically significant improvement in mean abdominal pain scores in patients with constipation-predominant IBS randomized to 12 weeks of lubiprostone compared with placebo [186]. A significant improvement in global symptoms [187], in terms of the responder rates, using an a priori definition based on the number of weeks during the trial that the treatment was deemed to be effective by the patient was also observed. Individual symptoms including abdominal pain or discomfort, stool consistency, straining and severity of constipation were all significantly improved with lubiprostone compared with placebo [187]. The only

 Comparison: 02 Psychological therapies  
 Outcome: 01 Global IBS symptoms or abdominal pain unimproved or persistent after therapy

**Figure 21.5** Forest plot of randomized controlled trials of psychological therapies versus control therapy or a physician's "usual management" in irritable bowel syndrome.

adverse events occurring more frequently in those receiving lubiprostone were diarrhea and nausea, particularly with higher doses [186, 187]. In an open-label extension of one of these trials, patients originally randomized to either lubiprostone or placebo were treated with the drug for a further 36 weeks [188]. Initial response rates were 15% with lubiprostone and 8% with placebo at 12 weeks, and these increased to 37% and 31% respectively at week 48. There were no serious adverse events in over 450 patients treated, suggesting that longer term treatment is both effective and safe. In another trial, patients receiving lubiprostone were randomized after 12 weeks of therapy to either a further four weeks of treatment, or four weeks of placebo [189]. The response rates at week 16 were 38% with lubiprostone compared to 40% with placebo, indicating a possible sustained effect of the initial 12 weeks of therapy on symptoms. The drug has recently been approved for the treatment of constipation-predominant IBS in women in some jurisdictions, but not in others. **A1a** Additional data from other RCTs may establish lubiprostone's true efficacy and place in the treatment of IBS.

### Efficacy of anti-diarrheals in irritable bowel syndrome

In individuals with diarrhea-predominant or alternating IBS there may be a role for anti-diarrheal agents, such as loperamide. These drugs are relatively safe, and are often available over the counter, but unfortunately there are few data to support their routine use in IBS patients. There have been only two placebo-controlled trials conducted in Scandinavia [190, 191], which when pooled contain fewer than 50 patients. Stool consistency and frequency improved in a greater proportion of individuals randomized to loperamide than placebo in both trials, but in terms of this translating into an improvement in other symptoms of IBS the results were conflicting. One study demonstrated a clear improvement in abdominal pain with loperamide after 13 weeks of therapy [191], but the second showed no beneficial effect on global IBS symptoms [190]. There are insufficient data to make any clear recommendations for the use of loperamide in IBS at the present time, but the drug class does improve diarrhea. **A1d**

### Efficacy of an exclusion diet in irritable bowel syndrome

Some individuals with IBS believe that they have food allergy or intolerance and therefore the exclusion of certain foods from the diet may have a beneficial effect in these individuals. In a UK study of over 100 subjects with IBS, IgG4 titres were significantly higher in IBS cases compared to controls for wheat, beef, lamb and pork [192], and symptoms improved significantly among sufferers following the

exclusion of some of these items [193]. Celiac disease may be more prevalent in patients with symptoms suggestive of IBS, and these individuals may respond to a gluten-free diet [88, 89]. There is now limited evidence that a gluten-free diet will alleviate symptoms in some IBS patients who do not have histological evidence of celiac disease [194]. As mentioned in the previous section, there is little convincing evidence that lactose intolerance is any commoner in IBS sufferers, though if an individual feels that their symptoms are made worse by dairy products a trial of withdrawal of these from the diet may be worthwhile. A systematic review of exclusion diets in individuals with IBS suggested that symptoms improved in a subset of patients [195], but the majority of these studies were non-randomized. As there are limited data from high quality studies to support a role for exclusion diets in the management of IBS these should not be used as a first-line therapy.

### Summary

Insoluble fiber such as wheat bran appears to have no benefit in IBS, but does not exacerbate symptoms, whilst soluble fiber in the form of ispaghula is beneficial and should be considered first line in constipation-predominant patients. Antispasmodics, particularly hyoscine, and peppermint oil are also effective in IBS, and should be used first line in diarrhea-predominant patients and those whose main complaints are pain and bloating. Anti-diarrheal agents, such as loperamide, improve stool form and frequency in IBS patients, but there is no clear evidence that this translates into a beneficial effect on either pain or global IBS symptoms. Antidepressants should be considered second line, in patients failing these therapies: TCADs for patients with the diarrhea-predominant pattern; and SSRIs for constipation-predominant IBS. Probiotics may also be considered second line in those with particularly troublesome pain and bloating. Psychological interventions, alosetron and lubiprostone should be considered for individuals who are non-responsive to first and second-line therapies, though psychological interventions are likely to be expensive and time-consuming to administer, alosetron has potentially serious side effects, and there are relatively few published data for lubiprostone. Exclusion diets do not have any high-quality evidence to support their use, but may still be helpful in a minority of challenging patients. A suggested treatment algorithm for patients with IBS, according to predominant symptom, is provided in Table 21.3.

### Prognosis of irritable bowel syndrome

Individuals with IBS suffer from a chronic relapsing and remitting medical disorder. Longitudinal studies have

**Table 21.3** Suggested order of medical therapies for irritable bowel syndrome according to predominant symptom.

Predominant symptom	First line	NNT	Strength of recommendation and quality of evidence	Second line	NNT	Strength of recommendation and quality of evidence	Third line	NNT	Strength of recommendation and quality of evidence
Pain and bloating	Antispasmodics (preferably hyoscine), peppermint oil	5 4 3	A1a A1a	Probiotics	4	A1c	Psychological therapies	4	A1d
Constipation	Ispaghula	6	A1c	SSRIs	4	A1c	Lubiprostone (where approved)	13	A1a
Diarrhea	Antispasmodics (preferably hyoscine), peppermint oil, loperamide (for diarrhea only)	5 4 3	A1a A1a A1a A1d	TCADs	4	A1a	Alosetron	8	A1a

examined the natural history of the condition. It appears that up to two-thirds of those reporting symptoms compatible with IBS in such surveys continue to experience symptoms over prolonged periods of follow-up [28, 29]. As these studies did not administer questionnaires to individuals at several points in time it is difficult to know whether symptoms were present continuously. This would seem unlikely, given that functional GI symptoms tend to fluctuate, with individuals developing symptoms compatible with other functional GI disorders, such as dyspepsia and reflux, during prolonged periods of follow-up [28, 196, 197]. Evidence of the degree of fluctuation in IBS is conflicting, however, with a seven-year follow-up study from Sweden suggesting that IBS was the most stable of all the functional GI disorders [28], whilst a study with 10 years of follow-up conducted in the UK demonstrated the opposite [197], with only 20% of individuals still meeting diagnostic criteria for IBS at 10 years. Even among those who do remain symptomatic, the predominant stool pattern experienced is reported to change in up to three-quarters of individuals [27]. Thus, individuals with IBS may need to be reassessed intermittently, and their current treatment reviewed.

Despite potential uncertainty surrounding the diagnosis of IBS it is unlikely to be revised during future follow-up. In a cohort of 112 IBS patients at the Mayo Clinic, less than 10% developed a subsequent organic GI disease, after a median length of follow-up of almost 30 years, and in almost all cases this was felt to be unrelated to their original presentation with symptoms that were compatible with IBS [198]. In another study from the USA, individuals meeting diagnostic criteria for IBS were followed up

between 10 and 13 years later [199]. Almost 50% had undergone a repeat structural evaluation of the lower GI tract in the intervening years, but this had not led to a diagnosis of organic disease in any of the subjects.

As there is no single pathophysiological abnormality that explains all the symptoms of IBS, there is no specific target for medical therapies. Treatment for the condition is largely directed toward relieving symptoms. This situation may be viewed as unsatisfactory, particularly from the patient's perspective, but there is now evidence from systematic reviews and meta-analyses of randomized controlled trials that many of the interventions that have been used traditionally in IBS are effective, despite earlier reports to the contrary, and newer agents continue to be developed.

**Introduction**

Acute colonic pseudo-obstruction (ACPO), also referred to as Ogilvie's syndrome [1], is a clinical condition with symptoms, signs and radiographic appearance of acute large bowel obstruction without a mechanical cause. ACPO occurs most often in hospitalized or institutionalized patients with serious underlying medical and surgical conditions. ACPO is an important cause of morbidity and mortality. The mortality rate is estimated at 40% when ischemia or perforation occurs [2]. Early detection and prompt appropriate management are critical to minimizing morbidity and mortality.

---

**Pathogenesis**

The pathogenesis of ACPO is not completely understood but likely results from an alteration in the autonomic regulation of colonic motor function [3]. Colonic pseudo-obstruction was first described in 1948 by Sir Heneage Ogilvie, who reported two patients with chronic colonic dilation associated with malignant infiltration of the celiac plexus [4]. Ogilvie attributed the syndrome to sympathetic deprivation. A better understanding of the autonomic nervous system in the gut has modified this hypothesis. The parasympathetic nervous system increases contractility, whereas the sympathetic nerves decrease motility [3]. An imbalance in autonomic innervation, produced by a variety of factors, leads to excessive parasympathetic suppression or sympathetic stimulation. The result is colonic atony and pseudo-obstruction.

Multiple predisposing factors or conditions have been associated with ACPO (Table 22.1). In a large retrospective series of 400 patients, the most common predisposing conditions were non-operative trauma (11.3%), infections (10%) and cardiac disease (10%) [2]. Cesarean section and hip surgery were the most common surgical procedures, with the onset of the syndrome occurring postoperatively at an average of 4.5 days. In another retrospective analysis of 48 patients, the spine or retroperitoneum had been traumatized or manipulated in 52% [4]. Over half the patients were receiving narcotics, and electrolyte abnormalities were present in approximately two-thirds. Thus, multiple metabolic, pharmacologic, or traumatic factors appear to alter the autonomic regulation of colonic function, resulting in pseudo-obstruction.

---

**Clinical features**

The exact incidence of ACPO is unknown. In the retrospective series of patients undergoing orthopedic procedures reported by Norwood and colleagues [5], the incidence of ACPO was 1.3%, 1.19%, and 0.65% following hip replacement, spinal operations and knee replacement respectively. ACPO most often affects those in late middle age (mean of 60 years of age), with a slight male predominance (60%) [2]. ACPO occurs almost exclusively in hospitalized or institutionalized patients with serious underlying medical and surgical conditions. Abdominal distention usually develops over three to seven days but can occur as rapidly as over a 24 to 48-hour period [2]. In surgical patients, symptoms and signs develop at a mean of five days postoperatively.

The clinical features of ACPO include abdominal distension, abdominal pain (80%), and nausea and/or vomiting (60%) [2]. Passage of flatus or stool is reported in up to 40% of patients. There is no significant difference in symptoms of patients with ischemic or perforated bowel, except for a

Abdominal/pelvic surgery	37	9.3
Neurologic	37	9.3
Orthopedic surgery	29	7.3
Miscellaneous medical conditions (metabolic, cancer, respiratory failure, renal failure)	128	32
Miscellaneous surgical conditions (urologic, thoracic, neurosurgery)	47	11.8

<sup>a</sup> Associated conditions in approximately 400 patients, reported by Vanek and Al-Salti [2]. Some patients had more than one associated condition.

higher incidence of fever [2]. On examination, the abdomen is tympanic and bowel sounds are typically present. Fever, marked abdominal tenderness and leukocytosis are more common in patients with ischemia or perforation but also occur in those who have not developed these complications [2].

The diagnosis of ACPO is confirmed by plain abdominal radiographs, which show varying degrees of colonic dilatation (Figure 22.1). Air fluid levels and dilatation can also be seen in the small bowel. Typically, the right colon and cecum show the most marked distension, and cutoffs at the splenic flexure are common. This distribution of colonic dilation may be caused by the different origins of the proximal and distal parasympathetic nerve supply to the colon [3]. A water soluble contrast enema or computed tomography (CT) scan should be obtained to exclude mechanical obstruction if gas and distension are not present throughout all colonic segments including the rectum and sigmoid colon.

Keys to management of ACPO include (1) early recognition and diagnosis, (2) evaluation to exclude mechanical obstruction or other causes of pseudo-obstruction (such as *Clostridium difficile* colitis [6], (3) assessment for signs of ischemia or perforation which would warrant urgent surgi-

**Figure 22.1** Abdominal radiographs of a patient with acute colonic pseudo-obstruction. The plain abdominal film shows marked dilatation, especially of the right colon. In addition, moderate small bowel dilatation is present.

#### BOX 22.1 Supportive therapy for acute colonic pseudo-obstruction

- Nil per os
- Correct fluid and electrolyte imbalances
- Nasogastric tube suction
- Rectal tube to gravity drainage
- Limit offending medications (especially narcotics)
- Frequent position changes, ambulate if possible

cal intervention, and (4) initiation of appropriate treatment measures.

## Management

Treatment options for ACPO include appropriate supportive measures, medical therapy, colonoscopic decompression, and surgery. Despite extensive literature documenting the clinical features of ACPO, there are very few randomized controlled clinical trials on the treatment of this condition, and most evidence for efficacy of treatments comes from uncontrolled studies.

### Supportive therapy

Supportive therapy (Box 22.1) should be instituted in all patients as it appears to be successful as the primary treatment in the majority of patients [7]. **B4** Patients are given nothing by mouth. Intravenous fluids are administered

and electrolyte imbalances are corrected. Nasogastric suction is provided to limit swallowed air from contributing further to colonic distension. A rectal tube should be inserted and attached to gravity drainage. Medications that can adversely affect colonic motility, such as opiates, anticholinergics and calcium channel antagonists are discontinued if possible. Ambulation and mobilization of patients are encouraged. The knee-chest position with hips held high has been advocated as aiding in evacuation of colonic gas [8]. None of these supportive measures has been studied in a randomized trial. **C5**

The reported success of supportive management is variable, with pooled rates from several retrospective series of approximately 85% [7, 9–13]. In these combined series, 111 patients were treated conservatively, of which 95 (86%) had resolution of the pseudo-obstruction. **B4** Sloyer *et al.* reported outcomes of 25 cancer patients with ACPO (mostly non-gastrointestinal malignancies) [7]. The mean cecal diameter was 11.7cm (range 9–18cm). Of the 24 patients treated conservatively, 23 (96%) improved by clinical and radiologic criteria with the median time to improvement of 1.6 days (mean 3 days). There were no perforations or ACPO-related deaths. The authors concluded that early endoscopic or surgical decompression is not necessary in patients with ACPO. **B4** In another recent retrospective series of 151 patients reported by Loftus *et al.*, 117 (77%) had spontaneous resolution of ACPO with conservative treatment [14]. **B4** These studies demonstrate that the initial management of ACPO should be directed towards eliminating or reducing the factors known to contribute to the problem.

### Patient outcome

The clinical dilemma facing the clinician caring for a patient with ACPO is whether to treat the patient with conservative measures and close observation versus proceeding with medical or endoscopic decompression of the dilated colon. The outcome of patients with ACPO is determined by multiple factors. The severity of the underlying illness appears to exert the greatest influence on patient outcome. ACPO often afflicts debilitated patients, which explains the significant morbidity and mortality even with successful treatment of the colonic dilatation. Other factors that appear to influence outcome are increasing age, maximal cecal diameter, delay in decompression and status of the bowel [2]. The risk of spontaneous colon perforation in ACPO is low but clearly exists. Rex reviewed all available reports in the literature and estimated the risk of spontaneous perforation to be approximately 3% [15]. The mortality rate in ACPO is approximately 40% when ischemia or perforation are present, compared with 15% in patients with viable bowel [2]. Retrospective analyses of patients with ACPO [2, 13] have attempted to identify clinical factors that

predict which patients are more likely to have complications such as ischemia or perforation. The risk of colonic perforation has been reported to increase with cecal diameter greater than 12cm and when distension has been present for more than six days [13]. In the large series reported by Vanek and Al-Salti, no cases of perforation were seen when the cecal diameter was less than 12cm [2]. However, at diameters greater than 12cm, there was no clear relationship between risk of ischemia or perforation and the size of the cecum. The duration and progression of colonic distension may be more important. Johnson and Rice reported a mean duration of distension of six days in patients who perforated compared with two days in those who did not [13]. A two-fold increase in mortality occurs when cecal diameter is greater than 14cm and a five-fold increase when delay in decompression is greater than seven days [2]. Thus, the decision to intervene with medical therapy, colonoscopy or surgery is dictated by the patient's clinical status. On the basis of the limited available evidence patients with marked cecal distension (>10cm) of significant duration (>3–4 days) and those not improving after 24–48 hours of supportive therapy are considered to be candidates for further intervention. **B4** In the absence of signs of ischemia or perforation, medical therapy with neostigmine should be considered the initial therapy of choice.

---

## Medical therapy

### Neostigmine

The only randomized controlled trial of an intervention for ACPO involves the use of neostigmine [16]. Neostigmine, a reversible acetylcholinesterase inhibitor, indirectly stimulates muscarinic receptors, thereby enhancing colonic motor activity, inducing colonic propulsion and accelerated transit [17]. The rationale for using neostigmine stems from the imbalance in autonomic regulation of colonic function that is proposed to occur in ACPO. Neostigmine was first used for manipulation of the autonomic innervation to the gastrointestinal tract by Neely and Catchpole over 30 years ago in studies on small bowel paralytic ileus [18]. Neostigmine, administered intravenously, has a rapid onset (1–20 minutes) and short duration (1–2 hours) of action [19]. The elimination half-life averages 80 minutes, but is more prolonged in patients with renal insufficiency [20].

A randomized double-blind, placebo-controlled trial evaluated neostigmine in patients with ACPO with a cecal diameter of >10cm and no response to 24 hours of conservative therapy [16]. Exclusion criteria were suspected ischemia or perforation, pregnancy, severe active bronchospasm, cardiac arrhythmias and renal failure. Patients

were randomized to receive neostigmine, 2 mg, or saline by intravenous infusion over 3–5 minutes. The primary endpoint was the clinical response to infusion, defined as a prompt reduction in abdominal distension by physical examination. Secondary endpoints included the change in measurements of colonic diameter on radiographs and abdominal girth. Patients not responding within three hours to initial infusion were eligible for open label neostigmine. A clinical response was observed in 10 of 11 patients (91%) randomized to receive neostigmine compared to 0 of 10 receiving placebo. **A1d** The median time to response was four minutes. Median reduction in cecal diameter (5 cm vs 2 cm) and abdominal girth (7 cm vs 1 cm) were significantly reduced in neostigmine-treated patients. Open-label neostigmine was administered to eight patients who failed to respond to the initial infusion (seven placebo, one neostigmine), and all had prompt decompression. Of the 18 patients who received neostigmine, either initially or during open-label treatment, 17 (94%) had a clinical response. The recurrence rate of colonic distension after neostigmine decompression was low (11%). The most common adverse effects observed with neostigmine were mild abdominal cramping and excessive salivation. Symptomatic bradycardia requiring atropine occurred in 2 of 19 patients.

Neostigmine was also evaluated in a double-blinded, placebo-controlled trial involving 24 critically ill, ventilated patients with ileus (defined as absence of stools for three

days) [21]. No details of the extent and duration of colonic distention were provided. Neostigmine was administered as a continuous infusion (0.4 mg/hour for 24 hours). Of the 13 patients receiving neostigmine, 11 passed stools, whereas none of the placebo treated patients passed stools ( $p < 0.001$ ). No acute serious adverse events occurred, but three patients had ischemic colonic complications 7 to 10 days after treatment.

There are also several uncontrolled observational studies supporting the use of neostigmine in this condition [14, 22–27]. Collectively, rapid decompression of colonic distension was observed in 88% of patients with a recurrence rate of 7% (Table 22.2). **B4** In the case series reported by Mehta and colleagues [28], a response to neostigmine was more likely in the postoperative setting (11 of 15 patients (73%) versus one of four patients (25%),  $p = 0.07$ ), and less likely in those with electrolyte imbalance or receiving anti-motility agents (3 of 15 (20%) versus 4 of 4,  $p = 0.003$ ). This study suggests that it may be important to correct electrolyte abnormalities and to limit potentially exacerbating medications.

Repeated infusions or more prolonged treatment with neostigmine have not been evaluated fully. There have been reports of patients with ACPO receiving repeated infusions and prolonged treatment with resolution [29]. This experience suggests that cautious repeated infusions can be successful and merits further study in patients with persistent or recurrent pseudo-obstruction.

**Table 22.2** Neostigmine for colonic decompression in patients with acute colonic pseudo-obstruction.

Study	No. of patients	Design	Dose	Decompression	Recurrence
Ponec <i>et al.</i> (1999) [16]	21 (neostigmine 11, placebo 10)	RCT; (OL in non-responders)	2.0 mg IV over 3–5 min	Neostigmine 10/11 in RCT; 17/18 total; placebo 0/10	2
Hutchinson and Griffiths (1992) [22]	11	OL	2.5 mg IV in one min.	8/11	0
Stephenson <i>et al.</i> (1995) [23]	12	OL	2.5 mg IV over 1–3 min.	12/12 (two patients required two doses)	1
Turegano-Fuentes <i>et al.</i> (1997) [24]	16	OL	2.5 mg IV over 60 min	12/16	0
Trevisani <i>et al.</i> (2000) [25]	28	OL	2.5 mg IV over 3 min	26/28	0
Paran <i>et al.</i> (2001) [26]	11	OL	2.5 mg IV over 60 min	10/11 (two patients required two doses)	0
Abeyta <i>et al.</i> (2001) [27]	8	Retrospective	2.0 mg IV	6/8 (two patients required two doses)	0
Loftus <i>et al.</i> (2002) [14]	18	Retrospective	2.0 mg IV	16/18	5

RCT: randomized controlled trial; OL: open-label trial; IV: intravenous.

The cost of neostigmine is minimal, with a 2 mg ampoule for parenteral use costing only US\$3 [16]. The cost to the patient after storage and handling fees are included is approximately US\$15.

Although neostigmine was associated with a favorable safety profile in the reported clinical trials, caution should be used when administering the medication. Neostigmine should be administered with the patient kept supine in bed with continuous electrocardiographic monitoring, physician assessment and measurement of vital signs for 15–30 minutes following administration [16]. Contraindications to its use include mechanical bowel obstruction, presence of ischemia or perforation, pregnancy, uncontrolled cardiac arrhythmias, severe active bronchospasm and renal insufficiency.

Thus, neostigmine appears to be an effective, safe and inexpensive method of colonic decompression in ACPO. The published data support its use as the initial therapy of choice for patients not responding to conservative therapy if there are no contraindications to its use. **A1d, B4** In patients with only a partial response or recurrence after an initial infusion, a repeated dose is reasonable and often successful. If the patient fails to respond after two doses, proceeding with colonoscopic decompression is advised.

### Other medications

Administration of polyethylene glycol electrolyte solution (PEG) in patients who have ACPO after initial resolution may decrease the recurrence rate of colonic dilation. Sgouros and colleagues [30] evaluated PEG in a randomized, controlled trial in ACPO patients who had initial resolution of colonic dilation. The study enrolled 30 patients with cecal diameter 10 cm or greater that had resolution of the colonic dilation with either neostigmine (22 patients) or endoscopic decompression (eight patients). Patients then were randomized to receive daily PEG 29.5 g or placebo. Recurrence was defined as a cecal diameter of 8 cm or greater with a concomitant 10% increase after the initial successful decompression. Five (33%) patients in the placebo group had recurrent cecal dilation compared with none in the PEG group ( $p = 0.04$ ). **A1d** Therapy with PEG resulted in a significant increase in stool and flatus output, decrease in colonic distention on radiographic measurements and improvement in abdominal girth [30].

There are few data on strategies to prevent the development of ACPO. A recent double-blind, randomized, placebo-controlled trial evaluated whether lactulose or PEG were effective in promoting defecation in critically ill patients, whether either of the two is superior, and whether the use of enteral laxatives is related to clinical outcome [31]. Three hundred and eight consecutive patients with multiple organ failure in whom defecation did not occur on the third day of admission to the ICU were included. Defecation occurred during the study period in a larger

proportion of patients receiving either laxative: (placebo 31%, PEG 74% and lactulose 69%,  $p = 0.001$ ). ACPO occurred in 4.1% of patients in the placebo group, 5.5% of patients in the lactulose group and 1.0% of patients in the polyethylene glycol group. Thus, it appears that the use of PEG in critically ill patients to promote defecation may prevent the development of ACPO, and that its use following a pseudo-obstruction episode decreases the recurrence rate. **A1c**

There are only anecdotal reports using other prokinetic agents in ACPO, and their use for the treatment of this condition cannot be recommended. Erythromycin, a motilin receptor agonist, has been reported to be successful in treating patients in a few case reports [32, 33]. Armstrong *et al.* reported decompression in two patients with ACPO with oral erythromycin (500 mg four times daily) for 10 days [32]. In another report, one patient had resolution of ACPO after three days of intravenous erythromycin therapy [33]. Cisapride, a partial 5-HT<sub>4</sub>-receptor agonist, has also been employed with some success in patients with ACPO [34]. However, this agent is no longer available for use in the USA and Canada due to class III arrhythmogenic properties. Lubiprostone, a novel chloride 2 channel activator approved for the treatment of constipation [35], has not been studied in pseudo-obstruction.

### Endoscopic decompression

Colonoscopic decompression may be required in patients with persistent, marked colonic dilatation that has failed to respond to supportive therapy and neostigmine, or when neostigmine is contraindicated. There is no well-defined standard of care regarding the use of colonoscopy in ACPO [8]. Colonoscopic decompression appears to be beneficial in ACPO, but it is associated with a greater risk of complications, is not completely effective and can be followed by recurrence [36]. **B4** Colonoscopy is done to prevent bowel ischemia and perforation. It should not be done if these complications have already developed.

Colonoscopy in ACPO is a technically difficult procedure and should be carried out by experts. Oral laxatives and bowel preparations should not be administered prior to colonoscopy [37]. Air insufflation should be minimized and the entire colon need not be examined. Prolonged attempts at cecal intubation are not necessary because reaching the hepatic flexure usually appears to be effective. Gas should be aspirated and the viability of the mucosa assessed during slow withdrawal of the endoscope. A tube for decompression should be placed in the right colon with the aid of a guidewire and fluoroscopic guidance. Commercially available, single use, over-the-wire colon decompression tubes are available. The guidewires for these kits are quite flexible (0.035 inches (0.89 mm)) and must be watched under fluoroscopy during advancement

**Table 22.3** Observational studies of colonoscopic decompression in acute colonic pseudo-obstruction.

Study	No. of patients	Successful initial decompression (%)	Overall colonoscopic success (%)	Complications
Nivatvongs <i>et al.</i> (1982) [38]	22	68	73	<1% (no perforations)
Strodel <i>et al.</i> (1983) [39]	44	61	73	2% (1 perforation)
Bode <i>et al.</i> (1984) [40]	22	68	77	4.5% (1 perforation)
Jetmore <i>et al.</i> (1992) [4]	45	84	36	<1% (no perforations)
Geller <i>et al.</i> (1996) [41]	41	95	88	2% (2 perforations)

and endoscopic withdrawal to minimize the formation of loops and ensure placement into the right colon.

The efficacy of colonoscopic decompression has not been established in randomized trials. Successful colonoscopic decompression has been reported in several case series that included hundreds of patients [4, 38–41]. **B4** Table 22.3 summarizes the larger reported series of colonoscopic decompression in ACPO. Rex reviewed the available literature of patients with ACPO treated with colonoscopy [36]. Successful initial decompression, determined by a reduction in radiographically measured cecal diameter was observed in 69% of 292 patients. Forty percent of patients treated without decompression tube placement had at least one recurrence, requiring an additional colonoscopy. Thus, an initial decompression colonoscopy without tube placement can be considered to be definitive therapy for less than 50% of patients [36]. To improve the therapeutic benefit, decompression tube placement at the time of colonoscopy is strongly recommended. The value of decompression tubes has not been evaluated in controlled trials, but anecdotal evidence suggests that they may lower the recurrence rate. In the series reported by Geller *et al.*, the overall clinical success of colonoscopic decompression was 88%. However, in procedures where a decompression tube was not placed the clinical success was poor (25%) [41].

### Surgical therapy

Surgical management is reserved for patients with signs of colonic ischemia or perforation, or for those who fail endoscopic and pharmacologic treatment. Surgical intervention is associated with significant morbidity and mortality, probably related to the severity of the underlying medical conditions in this group of patients. In the large retrospective series reported by Vanek and Al-Salti, 179 patients underwent surgery for ACPO with resulting morbidity and mortality rates of 30% and 6% respectively [2]. **B4** The type of surgery depends on the status of the bowel. Without perforated or ischemic bowel, cecostomy is the procedure of choice because the success rate is high, morbidity is relatively low and the procedure can be carried out under local

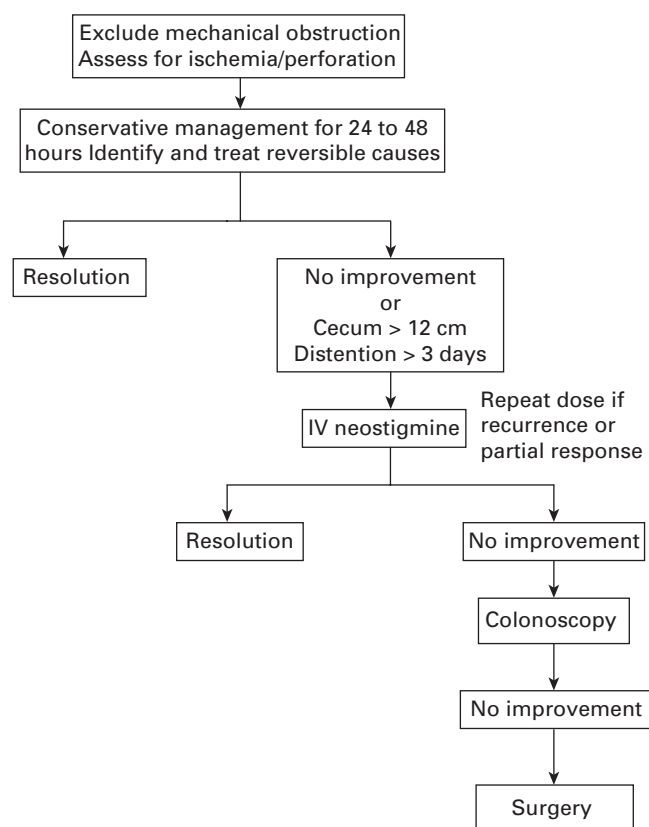

anesthesia [2]. Alternatively, percutaneous cecostomy through a combined endoscopic-radiologic approach can be considered in high surgical risk patients [42–44]. **C5** In cases of ischemic or perforated bowel, segmental or subtotal colonic resection is indicated, with either exteriorization or primary anastomosis.

### Clinical guidelines

An evidence-based guideline for the treatment of ACPO was recently published by the American Society for Gastrointestinal Endoscopy [8]. The guidelines recommend conservative therapy as the initial preferred management, based on observational studies only. Potentially contributory metabolic, infectious and pharmacologic factors should be identified and corrected. Active intervention is indicated for patients at risk of perforation and/or failing conservative therapy. Neostigmine is effective for the majority of patients. **A1a, B4** Colonic decompression is the initial invasive procedure of choice for patients who fail neostigmine therapy or for whom this drug is contraindicated. **B4** Surgical decompression should be reserved for patients with peritonitis or perforation and for those who fail endoscopic and medical therapy. **B4** A proposed algorithm for the management of ACPO is detailed in Figure 22.2.

### Summary

ACPO is a syndrome of massive dilatation of the colon without mechanical obstruction that results from an imbalance in the autonomic control of the colon. Evaluation involves exclusion of mechanical obstruction and assessing for signs of ischemia or perforation. Appropriate management includes supportive measures and selective use of neostigmine and colonoscopic decompression. Neostigmine is the only therapy for ACPO proved to be efficacious in a randomized controlled trial. Patient outcome is determined by the severity of the predisposing illness, patient age,

**Figure 22.2** Algorithm for suggested management for acute colonic pseudo-obstruction.  
IV: intravenous.

maximal cecal diameter, duration of colonic distension and viability of the bowel. Of these factors affecting outcome, the latter three are amenable to intervention. Thus, early recognition and management are critical to minimizing morbidity and mortality.

## Introduction

Surgical therapy for gallstones can be associated with morbidity and mortality, which has led to debate on its use, especially in asymptomatic and mildly symptomatic patients. Advancements in minimally invasive and endoscopic techniques make it imperative to understand the current evidence concerning the benefits and risks of surgical therapy for gallstone disease and its complications.

## Elective cholecystectomy

### Asymptomatic cholelithiasis in the general population

As abdominal ultrasound has become a routine investigation for abdominal symptoms, asymptomatic cholelithiasis is being diagnosed more frequently. Management of uncomplicated gallstones poses a dilemma as there are no controlled trials comparing prophylactic surgery with expectant management in asymptomatic patients with cholelithiasis. However, a number of cohort studies have been done to assess the probability of developing biliary pain and biliary complications in asymptomatic persons with gallstones.

Through the 1980s, a series of cohort studies were conducted by Gracie and Ransohoff [1], McSherry *et al.* [2], and Friedman *et al.* [3,4]. Gracie's study had complete follow-up on 123 people for 11–24 years. The cumulative probability of the development of biliary pain was 10% at five years, 15% at ten years, and 18% at twenty years. However, the fact that 89% of the study population were white American

males, and all were faculty members of the University of Michigan, limits the generalizability of this study. McSherry's study retrospectively identified 135 patients with asymptomatic cholelithiasis who were subscribers to the Health Insurance Plan of Greater New York, a mainly middle-income population of diverse ethnic origin. Over a mean follow-up of 46 months, 10.4% of patients developed symptoms, yielding a 2.7% annual rate of developing symptoms. Similarly, Friedman followed 123 ethnically diverse patients with asymptomatic gallstones in the Kaiser Permanente Medical Care Program (San Francisco) for 16–25 years. There was a 3–4% annual rate of biliary events in the initial ten years, and a 1–2% annual rate in the following ten years. At five years, 18% of patients had developed biliary symptoms. One death was attributable to cholangitis secondary to gallstones. A more detailed explanation of Gracie's data revealed that three patients eventually experienced biliary complications (2.4% of the population), but all of these had presented with pain before the complication. In McSherry's study, 10% of the population eventually developed symptoms and 71% of these patients had biliary colic as their only indication for elective cholecystectomy. Although the remaining patients had biliary complications prior to surgery (3% of the study population), it is unclear if they presented with pain first. Overall these studies yield an estimate of an annual rate of 1–2% of symptom development, and provide evidence that 90% of patients will present with pain prior to developing a biliary complication. Only 10% of patients will present with a biliary complication as the first manifestation of their biliary tract disease [4].

The Group for Epidemiology and Prevention of Cholelithiasis (GREPCO) in Italy prospectively followed 118 patients with asymptomatic cholelithiasis [5]. The cumulative probability of developing biliary colic was 12% at two years, 17% at four years and 26% at ten years. The cumulative probability of biliary complications was 3% at ten years. One patient died of gallbladder carcinoma. This represents a higher rate of symptoms, but not a higher rate

of complications than the studies from the 1980s. This study also showed that 74% of patients remained asymptomatic at ten years.

Ransohoff *et al.* performed a decision analysis on data first published by Gracie [1, 6, 7]. Using cholecystectomy mortality figures up to 1983, they found prophylactic cholecystectomy slightly decreased survival. The economic analysis did not favor prophylactic cholecystectomy. Although the models were constructed using data prior to laparoscopic cholecystectomies, the new approach is unlikely to alter the results.

Considering the current evidence, expectant management rather than prophylactic cholecystectomy is indicated for the typical patient with asymptomatic gallstones. However, certain populations who are more at risk for complications of gallstone disease should be considered separately.

### Asymptomatic cholelithiasis in diabetic patients

More liberal thresholds for elective cholecystectomy in asymptomatic diabetic patients have been suggested [8], based on early evidence suggesting a higher incidence of gallstone disease and biliary complications, and poorer outcomes for emergency surgery for biliary complications. Only Grade B evidence is available, which supports expectant management of asymptomatic cholelithiasis in this population rather than a more aggressive approach.

Chapman reviewed 308 diabetic patients and 318 non-diabetic controls [9]. The incidence of cholelithiasis was higher in the diabetic population (32.7% vs 20.8%,  $p < 0.001$ ). However, when the data were subjected to multivariate analysis, diabetes did not correlate strongly with the incidence of cholelithiasis, except in a subgroup of females with non-insulin dependent diabetes.

Del Favero prospectively studied the natural history of cholelithiasis in diabetes by following a cohort of 47 diabetic patients with asymptomatic cholelithiasis [10]. After five years, five patients presented with pain as their first symptom, one patient presented with cholecystitis and another patient presented with jaundice. The percentage of initially asymptomatic non-insulin dependent diabetic patients who went on to develop symptoms (14.9%) or complications (4.2%) compares favorably with the data available from studies of the general population.

Higher complication rates with emergency surgery for biliary complications in diabetic patients have been observed. Hickman *et al.* studied 72 diabetic patients who underwent cholecystectomy for cholecystitis and matched them for age, sex and date of operation with 72 non-diabetic patients [11]. Morbidity for the diabetic patients was 38.9% compared with 20.8% in the non-diabetic population. Mortality in the diabetic population was 4.2%, compared with zero in the control population and was

attributed to sepsis. The septic complication rate was higher in the diabetic (19.4%) than in the non-diabetic group (6.9%). This higher rate was maintained whether the diabetic patients had concurrent medical illness or not.

Landau *et al.* (1992) analyzed 566 cholecystectomies performed in the presence of acute cholecystitis [12]. Of these patients, 123 had diabetes mellitus and 433 did not have diabetes. The diabetic patients were found to have a higher rate of infected bile, gangrenous changes and perforation of the GB, in comparison with non-diabetic patients. Also, the morbidity rate of surgery for acute cholecystitis was significantly higher (21% vs 9%) in diabetic patients. Sandler used logistic regression when analyzing 126 diabetic patients and 855 non-diabetic patients with cholecystectomy and found diabetics have an increased morbidity primarily because they are older and have other medical problems [13]. Diabetes itself was not statistically significant for associated increased morbidity.

The natural history of asymptomatic cholelithiasis in diabetic patients appears to be similar to that in the general population. Asymptomatic cholelithiasis in diabetics should be managed expectantly and preventative surgery should not be recommended routinely. However, once symptoms develop early laparoscopic cholecystectomy is recommended to prevent complications.

### Asymptomatic cholelithiasis and the risk of cancer

Autopsy data have provided evidence that more than 80% of patients with gallbladder cancer have concomitant cholelithiasis. Maringhini *et al.* followed 2583 patients with known gallstones [14]. Only five patients (0.2%) developed gallbladder carcinoma. Ransohoff *et al.* reviewed 1000 patients with silent gallstones for a total of 7000 patient years and no patients developed gallbladder cancer [6]. The GREPCO in Italy followed up 118 patients with asymptomatic gallstones for ten years and only one patient developed and died of gallbladder cancer [5].

The incidence of gallbladder cancer varies widely in different populations, even in the presence of gallstone disease. Lowenfels *et al.* reported a case-control study of 131 patients with gallbladder carcinoma and 2399 patients without gallbladder carcinoma [15]. The 20-year cumulative risk for gallbladder cancer ranged from 0.13% in black males to 1.5% in native American females. The authors calculated that 769 cholecystectomies were required to prevent one gallbladder cancer in a low-risk population. However, only 67 cholecystectomies would be necessary to prevent one gallbladder malignancy in a high-risk population. **B3**

Hsing *et al.* conducted a population-based study from Shanghai of 627 patients with biliary tract cancers, 368 being gallbladder cancer [16]. Gallbladder cancer risk was

higher among subjects with both gallstones and self-reported cholecystitis, with an OR of 34.4. The OR associated with gallstones and gallbladder cancer was 23.8.

Patients with gallstones greater than 3 cm may be at risk for the development of gallbladder carcinoma. In 1983 Diehl reported this in a case-control study and the study by Lowenfels confirmed this observation in 1989 [17, 18]. These studies provided evidence for a nine to ten-fold increase in relative risk of developing gallbladder carcinoma for patients with stones greater than 3 cm in diameter compared to patients with stones less than 1 cm in diameter. Srikanth *et al.* found that one-half of gallbladders with a wall thickness >3 mm on US are likely to have xanthogranulomatous cholecystitis, and the risk of the patient having a gallbladder cancer is higher (3.3%) [19].

Grade B evidence supports the view that the risk of developing gallbladder cancer may be higher in patients with cholelithiasis. However, the increased risk appears to be insufficient to support a recommendation for prophylactic cholecystectomy. Although some subsets of the population (especially native American females) and patients with stones greater than 3 cm or gallbladder wall thickness >3 mm may be at sufficient risk to justify prophylactic cholecystectomy, further evidence would be needed to support a firm recommendation. **B3, B4**

### Porcelain gallbladder and risk of gallbladder cancer

Early case reports and small series initially indicated a correlation between porcelain gallbladder and carcinoma, which guided a recommendation for surgical therapy. However, more relevant information has only recently been published. A retrospective assessment by Towfigh *et al.* [20] examined 10,741 gallbladder specimens. Only 15 (0.14%) were porcelain gallbladders. All porcelain gallbladder specimens demonstrated chronic cholecystitis and partial calcification of the gallbladder wall and nine had cholelithiasis (60%). During this same period, 88 (0.82%) patients developed gallbladder cancer, none of whom showed calcification of the gallbladder wall. From these data, the authors challenged the link between porcelain gallbladder and gallbladder cancer. However, further insight may be gained from a study by Stephen and Berger [21]. This study reported data on 25,900 gallbladder specimens, of which 150 cases of gallbladder cancer and 44 cases of porcelain gallbladder (defined as the presence of wall calcifications) were identified. This study demonstrated that there are two types of wall calcification – diffuse intramural calcification and selective mucosal calcification. Gallbladder cancer was found in 7% of cases with selective mucosal calcification, but no case of gallbladder cancer was identified in the specimens with diffuse intramural calcification. Thus, conflicting data in the past may be attribut-

able to misclassification. However, in the preoperative setting, it may be difficult to distinguish these types of calcifications with standard imaging modalities. As a result, the authors still recommend cholecystectomy for patients with porcelain gallbladder, especially in those where there is incomplete calcification of the gallbladder wall. **CS**

### Symptomatic cholelithiasis

Grade B evidence supports the current approach to patients with symptomatic cholelithiasis. Patients with uncomplicated biliary colic should be offered surgery as an option to controlling symptoms. Patients with complications of cholelithiasis should have surgery to prevent further complications. The previously discussed natural history studies of McSherry *et al.* and Friedman *et al.* included a group of patients with symptomatic cholelithiasis [2, 3]. Additional data are also available from the National Cooperative Gallstone Study (NCGS) [22, 23]. McSherry followed 556 patients with symptomatic cholelithiasis [2]. During an average follow-up of 83 months, 169 (30%) patients reported worsening or continued severe symptoms, nine (1.6%) patients developed jaundice, and 47 (8.5%) patients developed cholecystitis. These data indicate a 4.3% annual rate of worsening or persistently severe symptoms and a 1.5% annual rate of biliary complications arising from symptomatic cholelithiasis. Friedman followed 298 patients with mild or non-specific symptoms and cholelithiasis for 16–25 years [3, 4]. The annual rate of developing cholecystitis or jaundice was 1%.

The NCGS was designed as a double-blind, randomized controlled trial of chenodiol [22, 23]. The group of patients who had received placebo provided another opportunity to study the natural history of symptomatic cholelithiasis. Seventy-seven patients presented with worsening symptoms of biliary colic or prolonged biliary pain during two years of follow-up. Seven patients “required cholecystectomy” during the follow-up, which represents a 34% annual incidence of “requiring a cholecystectomy”. The patients with symptomatic cholelithiasis in these studies did not suffer any greater mortality during the follow-up period than was experienced by patients in the asymptomatic population.

The rate of complications secondary to symptomatic cholelithiasis appears to be higher than that in patients with asymptomatic cholelithiasis. Recurrent or worsening symptoms may develop but there is no increased mortality from observation, at least in the short term. Therefore, “the subjective experience of the patient should be the principal determinant of whether and when the procedure should be performed”. Early surgical treatment is indicated once cholelithiasis is complicated by acute cholecystitis, choledocholithiasis, or cholangitis.

## Elective laparoscopic versus open cholecystectomy

Laparoscopic cholecystectomy is now considered standard of care for elective cholecystectomy. This approach has been “accepted” despite the lack of any evidence from a randomized controlled trial comparing standard open cholecystectomy and standard laparoscopic cholecystectomy. There is a lack of convincing evidence of decreases in length of stay, recovery time or economics (hospital or societal). However, the general acceptance of laparoscopic cholecystectomy as the standard of care, as well as public demand for minimally invasive surgery, will prevent a future randomized controlled trial that may definitively answer these questions. Nonetheless, laparoscopic cholecystectomy has had a significant impact on the management of gallstone disease, as evidenced by increasing rates

of elective cholecystectomy since its introduction in the 1980s [24, 25].

Evidence from five randomized controlled trials comparing elective laparoscopic cholecystectomy and minilaparotomy cholecystectomy is available [26–30] (Table 23.1). **Alc** There is no statistically significant difference in the incidence of biliary tract injuries, although in a study by McMahon *et al.* the only major biliary injury occurred in the laparoscopic group [27]. Quality of life data were obtained by both Barkun *et al.* and McMahon *et al.* [26, 27]. The laparoscopic group experienced a faster improvement in quality of life, but the two treatment groups were equal in this respect at three months. Similarly, there was better satisfaction with scarring in the laparoscopic group, but both groups were equally satisfied with their result at three months. The data from Majeed revealed no difference in time off work or time to return to full activity [29]. A cost minimization economic analysis was carried out by

**Table 23.1** Randomized controlled trials of laparoscopic cholecystectomy (LC) and mini-cholecystectomy (MC).

<sup>a</sup> Indicates differences reached statistical significance.

<sup>b</sup> This difference was statistically significant but did not include patients who were converted to standard cholecystectomy. If included, there was no statistically significant difference in length of hospital stay.

<sup>c</sup> Total complications.

<sup>d</sup> This included 1 (0.7%) major biliary injury in the LC group and no major biliary injuries in the MC group.

<sup>e</sup> Histology revealed a carcinoma of the gallbladder and ultrasound at three months showed multiple liver metastases and the patient died two months later.

McMahon [27]. Laparoscopic cholecystectomy was more costly after considering both perioperative and hospitalization costs (£1486 compared with £1090,  $p < 0.001$ ). Keus *et al.* found no significant difference in complications, but there was a significantly shorter operative time in the small-incision technique (mean 60.4 min.) compared to the laparoscopic cholecystectomy (mean 71.9 min.) [30].

Further data comparing laparoscopic to open cholecystectomy are available from the meta-analysis of Shea *et al.* of the outcomes of 78,747 patients undergoing laparoscopic cholecystectomy and 12,973 patients undergoing open cholecystectomy [31]. Mortality rates were lower for laparoscopic cholecystectomy than for open cholecystectomy, while common bile duct injury was higher for laparoscopic cholecystectomy than for open cholecystectomy. The data for common bile duct injury were re-analyzed by group-level logistic regressions to identify the differences in rates among the studies. A pattern of infrequent common duct injury in early studies, an increased incidence in studies initiated in early 1990, followed by a subsequent decrease in rate was revealed. However, the data were quite variable in terms of reporting of results and length of follow-up. The authors conceded, "there are still some considerable uncertainties that need to be addressed by better-designed studies and more complete reporting".

Considering the current evidence, in the elective setting, laparoscopic cholecystectomy appears to be as safe as open cholecystectomy and may provide short-term improvement in quality of life. **Ala, C** There is a lack of convincing evidence of decreases in length of stay, recovery time or economics (hospital or societal). However, the general acceptance of laparoscopic cholecystectomy as the standard of care as well as public demand for minimally invasive surgery will prevent a future randomized controlled trial that may definitively answer these questions.

### Further issues in elective laparoscopic cholecystectomy

With the advent of the laparoscopic cholecystectomy, there has been a move towards ambulatory surgery. Grade A evidence from two randomized trials which compared outpatient to inpatient laparoscopic cholecystectomy are available [32, 33]. Exclusion criteria included American Society of Anesthesiologists (ASA) III/IV, patients less than 18 and more than 70 years old, lack of a capable caregiver at home and complicated cholelithiasis (common bile duct stones or acute cholecystitis). The degree of pain, readmission and complication rates were the same in both groups. Late complications such as bile leaks became evident several days later and there was no benefit from 24-hour admission. Keulemans *et al.* found that 92% of the outpatients preferred outpatient care to clinical observa-

tion [33]. Of the 504 planned outpatient laparoscopic cholecystectomies, Bueno Lledo *et al.* found that 88.8% were discharged the same day [34]. Fifty-one patients required overnight stays (10.1%), most of them for "social" causes, and five patients required 1–2 day admission for intraoperative and postoperative complications. Six patients (1.1%) required readmission. In summary, outpatient laparoscopic cholecystectomy is a safe and feasible option for selected patients (defined by the exclusion criteria in the randomized trials). **Alc**

There are two randomized trials comparing three-port versus four-port laparoscopic cholecystectomy [35, 36]. In both studies there was no significant difference in operative time or complications. The main advantages of the three-port technique are that it causes less pain and leaves fewer scars. Again, this technique was carried out by expert hands and may not be generalized to all surgeons.

### Acute cholecystitis

Acute cholecystitis, inflammation secondary to obstruction of the cystic duct, is the most common complication of cholelithiasis. Laparoscopic cholecystectomy has become the treatment of choice for acute cholecystitis and there is now little controversy concerning the use of laparoscopic versus open cholecystectomy. Controversy remains over the timing of cholecystectomy.

In the pre-laparoscopic era, the question of early versus delayed cholecystectomy was heavily debated. Evidence from five randomized trials carried out in the 1970s and 1980s is available [37–41]. **Alc** These studies demonstrated that cholecystectomy could be carried out in the acute stage with shorter hospital stay, decreased mortality and fewer operative complications (Table 23.2).

The introduction of laparoscopic cholecystectomy caused a movement to return to delayed cholecystectomy for acute cholecystitis. This movement arose because laparoscopic cholecystectomy was considered to be associated with more complications and an increased risk of common bile duct injuries than interval laparoscopic cholecystectomy after the resolution of the acute episode. Grade A evidence from six randomized controlled trials on early versus delayed laparoscopic cholecystectomy is available (Table 23.3) [42–47]. Once again, the data show that early cholecystectomy, even if carried out with the laparoscopic approach, is safer and better for patients in terms of shorter illness and hospital stay, compared with delayed surgery.

Evidence regarding laparoscopic versus open cholecystectomy for acute cholecystitis is available from two randomized trials [48, 49]. **Alc** The results are summarized in Table 23.4. The laparoscopic approach did not increase mortality or morbidity compared with the open approach

**Table 23.2** Randomized controlled trials comparing early versus delayed open cholecystectomy for acute cholecystitis.

<sup>a</sup>Two out of four were retained common bile duct stones.

and offered the benefit of shorter hospital stay. Both studies found that the rate of conversion to the open procedure was slightly higher than the average observed in elective cholecystectomy series.

A retrospective study of 202 consecutive laparoscopic cholecystectomy patients compared complications and conversion rates when performed in the acute (<72hrs), intermediate (between 72hrs and 5 weeks) or delayed (>5 weeks) settings [50]. There was no significant difference in conversion rates (11–20%) or complication rates (7–16%) between the three groups and it was concluded that cholecystectomy can be performed safely during initial hospitalization regardless of symptom duration. Considering the current evidence, acute cholecystitis should be treated with early laparoscopic cholecystectomy (within the first 96 hours of symptoms).

## Cholecystectomy via NOTES

Natural orifice transluminal endoscopic surgery (NOTES) is a new technique that can be used to perform cholecystectomies through a transvaginal approach. The first human case was reported on 13 March 2007 by Zorron on a 43-year-old female with biliary colic [51]. Since then, Zornig reports 20 patients who have had transvaginal cholecystectomies with no intra- or postoperative compli-

cations [52]. Another three females of varying BMIs have successfully undergone cholecystectomy using the NOTES technique with no postoperative complications [53]. Also, there was a case report of a morbidly obese female with a BMI of 35.8 who had a cholecystectomy via transvaginal NOTES approach with no postoperative analgesic use and no postoperative complications [54]. Transvaginal endoscopic cholecystectomies may in the future provide a safe surgical technique for women of varying BMIs with less visible scars and less postoperative pain, but it is currently still under investigation and further research is required before its use is widely accepted.

## Gallstone pancreatitis

### Early endoscopic retrograde cholangiopancreatography

Evidence from three randomized controlled trials on early endoscopic retrograde cholangiopancreatography (ERCP) with stone extraction versus conservative therapy as a treatment for biliary pancreatitis is available [55–57]. **A1c** In patients with severe pancreatitis or with evidence of biliary obstruction or cholangitis, early ERCP within 72 hours of presentation probably decreases morbidity and mortality rates. In patients without these criteria, early ERCP has no benefit and may in fact increase morbidity and mortality. Therefore, patients must be carefully selected for early ERCP. (See Chapter 24 for further discussion.)

### Preoperative endoscopic retrograde cholangiopancreatography versus cholecystectomy with cholangiogram

Gallstone pancreatitis is considered to be an indication for imaging the biliary tree with either ERCP or intraoperative cholangiogram (IOC). In order to determine if ductal evaluation is always necessary before or during cholecystectomy for biliary pancreatitis, Ito *et al.* examined 148 patients undergoing cholecystectomy for biliary pancreatitis [58]. Only those patients at low risk for choledocholithiasis were included (normal or decreasing liver function tests and no ductal dilation on non-invasive preoperative imaging). The choice to perform IOC was based on the preference of the operating surgeon. Twenty-seven patients underwent IOC and 121 patients did not undergo IOC. There was no difference in recurrent pancreatitis, cholangitis and asymptomatic elevation of liver function tests three months after discharge. This study suggests that direct ductal evaluation can be omitted safely in patients with low risk of choledocholithiasis.

Seven observational studies, two with controls, have assessed the optimal approach to imaging the biliary tree

following an attack of gallstone pancreatitis [59–65]. Gallstone pancreatitis does not appear to be a strong predictor of CBD stones without evidence of a dilated CBD, persistently abnormal alkaline phosphatase or bilirubin, or evidence of cholangitis. Patients with these features may be considered for preoperative ERCP. **C5** In one retrospective study, the incidence of procedure-induced pancreatitis was 19% in the ERCP group and 6% in the surgical/IOC group [59]. The other retrospective study demonstrated similar results with pancreatic-biliary complications in 24% of the ERCP group and 6% of the surgical/IOC group [65]. The data suggest that preoperative ERCP may in fact increase overall morbidity compared with cholecystectomy with IOC, further supporting the approach of selective ERCP in this group of patients. **C5**

### Timing of surgery with gallstone pancreatitis

A number of studies have evaluated early versus delayed cholecystectomy in patients with gallstone pancreatitis. Burch *et al.* evaluated patients who underwent surgery after recovering from acute pancreatitis either during the same hospital admission or following discharge and scheduled elective surgery [66]. Although surgical complication rates were the same in both groups, total hospital stay was significantly longer in the delayed surgery group (14 vs 17 days,  $p = 0.01$ ). Furthermore, in the delayed group only 60% returned for surgery, and 29% of the original cohort required emergency treatment for recurrent pancreatitis or biliary disease before elective surgery. Kelly *et al.* randomized patients to early (less than 48 hours) and delayed (more than 48 hours) surgery [67]. With early surgery the morbidity and mortality rates were 30.1% and 15.1%, as compared with 5.1 and 2.4% in the delayed group ( $p < 0.005$ ). **A1c** When patients were stratified for disease severity based on Ranson's criteria, the differences in morbidity and mortality rates between early and delayed surgery were not statistically significant in patients with three or fewer Ranson's criteria. In patients with severe pancreatitis (more than three Ranson's criteria), the differences remained significant.

A retrospective review identified 164 patients with gallstone pancreatitis: 90 patients were discharged for readmission cholecystectomy and 74 patients had the cholecystectomy before discharge [68]. The patients in the discharged group waited on average  $40 \pm 69$  days versus  $8 \pm 10$  days in the group which remained in hospital (mean  $\pm$  SD). Of those patients who were discharged 20% (18 of 90) experienced an adverse event requiring readmission while awaiting their cholecystectomy: three had recurrent pancreatitis, ten had recurrent pain, and five developed acute cholecystitis.

Grade B/C evidence has recently been published examining the issue of whether cholecystectomy is even neces-

sary after successful ERCP with endoscopic sphincterotomy (ES) and clearance of bile duct stones [69, 70]. Kaw *et al.* followed patients prospectively to compare outcome after laparoscopic cholecystectomy and ERCP with ES or ERCP and ES alone for an average of 33 and 34 months respectively [69]. During follow-up, there was no significant difference in biliary complications or procedure-related complications. They concluded that laparoscopic cholecystectomy should only be attempted in patients with overt biliary symptoms and not for the prevention of gallstone pancreatitis. Kwon *et al.* found that only 4.8% of patients required a cholecystectomy for biliary complications at an average of 18.4 months following ERCP and ES [70]. This issue should be examined further by randomized controlled trials, but at this point there is no clear evidence that biliary complications can be completely avoided by ERCP and ES alone. In addition, these data conflict with Grade A evidence from studies looking at CBD stones (see below).

Based on these data, it is recommended that patients with acute severe gallstone pancreatitis undergo cholecystectomy following resolution of the acute episode but during the initial hospital stay. Patients with mild to moderate pancreatitis (three or fewer Ranson's criteria) can be considered for early laparoscopic cholecystectomy. **A1c, C5**

### Choledocholithiasis

Once CBD stones have been identified, the standard of care is to remove them, since stones left in the CBD may cause subsequent biliary complications including obstructive jaundice, pancreatitis and cholangitis.

See Chapter 24 for further discussion.

The surgical method for identifying CBD stones is operative cholangiography. However, the choice of routine versus selective cholangiography remains somewhat controversial [71–73]. Flum *et al.* performed a retrospective nationwide cohort analysis of 1,570,361 patients undergoing cholecystectomy from 1 January 1992, to 31 December 1999 [73]. There were 7911 common bile duct injuries (0.5%) with 2380 (0.39%) occurring in the 613,706 patients undergoing cholecystectomy with IOC and 5531 (0.58%) occurring in the 956,655 patients undergoing cholecystectomy without IOC (unadjusted relative risk, 1.49). After controlling for patient-level factors and surgeon-level factors, the risk of common bile duct injury was increased when IOC was not used (adjusted relative risk, 1.71). In a review of 2043 patients undergoing routine laparoscopic operative cholangiography, the incidence of unsuspected CBD stones was 2.8% [71]. Only 0.30% of patients not undergoing operative cholangiography ever became symptomatic. In order to better use resources, other studies have attempted to determine criteria for selective operative cholangiography. Borjeson *et al.* proposed criteria that included: normal liver

function tests, CBD diameter <10mm and no history of gallstone pancreatitis or jaundice [72]. One hundred and fifty-five patients who met these criteria were followed prospectively after laparoscopic cholecystectomy for a mean follow-up of 26 months. No patients had retained CBD stones during the follow-up period. Although none of these data provides Grade A evidence, the literature suggests that selective operative cholangiography is justified.

Once CBD stones are identified, there are three approaches to the management: open common bile duct exploration (OCBDE), ERCP and sphincterotomy, and laparoscopic common bile duct exploration (LCBDE).

Five randomized trials (Grade A) have compared OCBDE with ERCP in the management of CBD stones [74–78]. In the two smaller trials with 52 and 34 patients respectively, no differences in morbidity or mortality were seen [75, 76]. OCBDE was more successful at clearing stones than ERCP in one study (88% vs 65%) [75]. The two larger studies, with 228 and 120 patients respectively, demonstrated statistically significant increases in morbidity with ERCP, with the latter study also showing an increase in mortality with ERCP [74, 77]. **A1c** The fifth study (n = 83) also demonstrated a trend to increased morbidity with ERCP, but the difference was not statistically significant [78].
